LETTERS TO THE EDITOR		
An artificial neural network approach for predicting architectural speech security (L)	Jingfeng Xu, John S. Bradley, Bradford N. Gover	1709
Estimates of auditory filter phase response at and below characteristic frequency (L)	Andrew J. Oxenham, Stephan D. Ewert	1713
GENERAL LINEAR ACOUSTICS [20]		
Design and optimization of a noise reduction system for infrasonic measurements using elements with low acoustic impedance	Benoit Alcoverro, Alexis Le Pichon	1717
Analysis of the sound field in finite length infinite baffled cylindrical ducts with vibrating walls of finite impedance	Wei Shao, Chris K. Mechefske	1728
Acoustical measurement of the shear modulus for thin porous layers	Jean F. Allard, Michel Henry, Laurens Boeckx, Philippe Leclaire, Walter Lauriks	1737
Computation of scattering from clusters of spheres using the fast multipole method	Nail A. Gumerov, Ramani Duraiswami	1744
Modeling of phased array transducers	Rais Ahmad, Tribikram Kundu, Dominique Placko	1762
Lamb mode conversion at edges. A hybrid boundary element–finite-element solution	José M. Galán, Ramón Abascal	1777
Dispersion of waves in porous cylinders with patchy saturation: Formulation and torsional waves	James G. Berryman, Steven R. Pride	1785
A first-order statistical smoothing approximation for the coherent wave field in random porous random media	Tobias M. Müller, Boris Gurevich	1796

CONTENTS—Continued from preceding page

NONLINEAR ACOUSTICS [25]

Linear and nonlinear propagation of higher order modes in hard-walled circular ducts containing a real gas	Stefan Scheichl	1806
Simultaneous measurement of acoustic and streaming velocities in a standing wave using laser Doppler anemometry	Michael W. Thompson, Anthony A. Atchley	1828
Influences of a temperature gradient and fluid inertia on acoustic streaming in a standing wave	Michael W. Thompson, Anthony A. Atchley, Michael J. Maccarone	1839
On the interaction of counterpropagating acoustic waves in resonant rods composed of materials with hysteretic quadratic nonlinearity	Vitalyi Gusev	1850
On the stability of the effective apodization of the nonlinearly generated second harmonic with respect to range	Russell J. Fedewa, Kirk D. Wallace, Mark R. Holland, James R. Jago, Gary C. Ng, Brent S. Robinson, Matthew R. Rielly, James G. Miller	1858

AEROACOUSTICS, ATMOSPHERIC SOUND [28]

Acoustic pulse propagation through a fluctuating stably stratified atmospheric boundary layer	Igor Chunchuzov, Sergey Kulichkov, Alexander Otrezov, Vitaly Perepelkin	1868
The use of impedance matching capillaries for reducing resonance in rosette infrasonic spatial filters	Michael A. H. Hedlin, Benoit Alcoverro	1880
Simultaneous acoustic channel measurement via maximal-length-related sequences	Ning Xiang, John N. Daigle, Mendel Kleiner	1889

UNDERWATER SOUND [30]

Phase speed attenuation in bubbly liquids inferred from impedance measurements near the individual bubble resonance frequency	Preston S. Wilson, Ronald A. Roy, William M. Carey	1895
A phase-space Gaussian beam summation representation of rough surface scattering	Goren Gordon, Ehud Heyman, Reuven Mazar	1911
Phase-space beam summation analysis of rough surface waveguide	Goren Gordon, Ehud Heyman, Reuven Mazar	1922
Geoacoustic inversion in time domain using ship of opportunity noise recorded on a horizontal towed array	Cheolsoo Park, Woojae Seong, Peter Gerstoft	1933
Effects of environmental uncertainties on sonar detection performance prediction	Liewei Sha, Loren W. Nolte	1942
Bayesian sonar detection performance prediction in the presence of interference in uncertain environments	Liewei Sha, Loren W. Nolte	1954
Concurrent inversion of geo- and bio-acoustic parameters from transmission loss measurements in the Yellow Sea	Orest Diachok, Stephen Wales	1965
Long range acoustic imaging of the continental shelf environment: The Acoustic Clutter Reconnaissance Experiment 2001	Purnima Ratilal, Yisan Lai, Deanelle T. Symonds, Lilimar A. Ruhlmann, John R. Preston, Edward K. Scheer, Michael T. Garr, Charles W. Holland, John A. Goff, Nicholas C. Makris	1977
Time-reversal imaging for classification of submerged elastic targets via Gibbs sampling and the Relevance Vector Machine	Nilanjan Dasgupta, Lawrence Carin	1999
Protocols for calibrating multibeam sonar	Kenneth G. Foote, Dezhang Chu, Terence R. Hammar, Kenneth C. Baldwin, Larry A. Mayer, Lawrence C. Hufnagle, Jr., J. Michael Jech	2013

ULTRASONICS, QUANTUM ACOUSTICS, AND PHYSICAL EFFECTS OF SOUND [35]

- | | | |
|---|-----------------------------------|------|
| Multi-mode Lamb wave tomography with arrival time sorting | Kevin R. Leonard, Mark K. Hinders | 2028 |
|---|-----------------------------------|------|

STRUCTURAL ACOUSTICS AND VIBRATION [40]

- | | | |
|---|---|------|
| Regularization method for measurement of structural intensity using nearfield acoustical holography | Kenji Saijyou, Chiaki Okawara | 2039 |
| Smart panels with velocity feedback control systems using triangularly shaped strain actuators | Paolo Gardonio, Stephen J. Elliott | 2046 |
| Reconstruction of transient acoustic radiation from a sphere | Sean F. Wu, Huancai Lu, Manjit S. Bajwa | 2065 |

NOISE: ITS EFFECTS AND CONTROL [50]

- | | | |
|--|---|------|
| Analytical approach for sound attenuation in perforated dissipative silencers with inlet/outlet extensions | A. Selamet, M. B. Xu, I.-J. Lee, N. T. Huff | 2078 |
|--|---|------|

ARCHITECTURAL ACOUSTICS [55]

- | | | |
|--|--------------------------------|------|
| Absorptive properties of rigid porous media: Application to face centered cubic sphere packing | S. Gasser, F. Paun, Y. Bréchet | 2090 |
|--|--------------------------------|------|

ACOUSTIC SIGNAL PROCESSING [60]

- | | | |
|--|--|------|
| Theory and design of sound field reproduction in reverberant rooms | Terence Betlehem, Thushara D. Abhayapala | 2100 |
| Microphone array signal processing with application in three-dimensional spatial hearing | Mingsian R. Bai, Chenpang Lin | 2112 |
| The shift-invariant discrete wavelet transform and application to speech waveform analysis | Jörg Enders, Weihua Geng, Peijun Li, Michael W. Frazier, David J. Scholl | 2122 |
| Defect imaging with guided waves in a pipe | Takahiro Hayashi, Morimasa Murase | 2134 |

PHYSIOLOGICAL ACOUSTICS [64]

- | | | |
|--|---|------|
| Simplified nonlinear outer hair cell models | Niranjan Deo, Karl Grosh | 2141 |
| Modeling high-frequency electromotility of cochlear outer hair cell in microchamber experiment | Zhijie Liao, Aleksander S. Popel, William E. Brownell, Alexander A. Spector | 2147 |

PSYCHOLOGICAL ACOUSTICS [66]

- | | | |
|--|--|------|
| Modulation masking produced by second-order modulators | Christian Füllgrabe, Brian C. J. Moore, Laurent Demany, Stephan D. Ewert, Stanley Sheft, Christian Lorenzi | 2158 |
| The effect of spatial separation on informational masking of speech in normal-hearing and hearing-impaired listeners | Tanya L. Arbogast, Christine R. Mason, Gerald Kidd, Jr. | 2169 |

SPEECH PERCEPTION [71]

- | | | |
|---|---|------|
| A Speech Intelligibility Index-based approach to predict the speech reception threshold for sentences in fluctuating noise for normal-hearing listeners | Koenraad S. Rhebergen, Niek J. Versfeld | 2181 |
| Perception of pitch location within a speaker's F0 range | Douglas N. Honorof, D. H. Whalen | 2193 |
| Perception of aperiodicity in pathological voice | Jody Kreiman, Bruce R. Gerratt | 2201 |
| Consonant recognition and the articulation index | Jont B. Allen | 2212 |

ACOUSTICAL NEWS—USA

Elaine Moran

Acoustical Society of America, Suite 1N01, 2 Huntington Quadrangle, Melville, NY 11747-4502

Editor's Note: Readers of this Journal are encouraged to submit news items on awards, appointments, and other activities about themselves or their colleagues. Deadline dates for news items and notices are 2 months prior to publication.

The 148th meeting of the Acoustical Society of America held in San Diego, California

The 148th meeting of the Acoustical Society of America was held 15–19 November at the Town and Country Hotel in San Diego, California. This is the seventh time the Society has met in this city, the previous times being 1952, 1969, 1976, 1983, 1990, 1997.

The meeting drew a total of 1111 registrants, including 195 nonmembers and 230 students. Attesting to the international ties of our organization, 140 of the registrants, (that is, 13%) were from outside North America. There were 23 registrants from France, 22 from Japan, 19 from Germany, 17 from the United Kingdom, 10 from Korea, 6 from Italy, 4 each from Australia, Israel, Russia and Taiwan, 3 each from Denmark, New Zealand, People's Republic of China, and Portugal, 2 each from Brazil, Ireland, Norway and Sweden, and 1 each from Austria, Belgium, Finland, Malaysia, Spain, The Netherlands and Turkey. North American countries, the United States and Canada, accounted for 946 and 25 respectively.

A total of 770 papers, organized into 79 sessions, covered the areas of interest of all 13 Technical Committees. The meeting also included 7 meetings dealing with standards. The Monday evening tutorial lecture series was continued by Gerald D' Spain, Scripps Institution of Oceanography and Doug Wartok of Florida International University. Their tutorial, "Ocean Noise and Marine Mammals" was presented to an audience of about 135.

The Short Course on Acoustical Oceanography in Shallow Water was held on Sunday and Monday and the course instructors were George Frisk, Florida International University, Grand Deane, Scripps Institution of Oceanography, James Preisig, Woods Hole Oceanographic Institution and Dajun Tang, University of Washington. Fourteen registrants attended the short course.

The Society's thirteen Technical Committees held open meetings during the San Diego meeting where they made plans for special sessions at upcoming ASA meetings, discussed topics of interest to the attendees and held informal socials after the end of the official business. These meetings are working, collegial meetings and all people attending Society meetings are encouraged to attend and to participate in the discussions. More information about Technical Committees, including minutes of meetings, can be found on the ASA Website <<http://asa.aip.org/committees.html>>.

The equipment exhibit drew 13 exhibitors, including ACO Pacific, Inc., Bruel & Kjaer, Casella CEL USA, Eckel Industries, Acoustic Div., G.R.A.S. Sound and Vibration APS, Head Acoustics, Inc., MBI Productions Company, Inc., Navon Engineering Network, PCB Piezotronics/Larson Davis, Precision Filters Inc., Quest Technologies, Reson, and Springer Verlag New York. Exhibits included microphones, sound level alarms and monitoring systems, analyzers, sound absorbing materials and noise control enclosures, acoustic acquisition recorders, transducers, calibrators, baffles, software, accelerometers, sound level meters, dosimeters underwater acoustic transducers, and books on acoustics. An exhibit opening reception was held on Monday evening.

The ASA Student Council organized a Fellowship Workshop to provide information to help students and post-doctoral researchers obtain funding. Representatives from several government agencies attended including: National Science Foundation (NSF), Naval Research Laboratory (NRL), National Institutes of Health/National Institute of Deafness and Other Communication Disorders (NIH/NIDCD), the Office of Naval Research (ONR) and the Acoustical Society of America Prizes and Special Fellowships committee. The workshop drew over 70 attendees including undergraduates, graduate students, post-docs and faculty. After the workshop, the Council hosted a Student Reception with over 150 people in attendance. The Student Reception included the presentation of the inaugural Student Council Mentoring Award to David Blackstock (see Fig. 1).

FIG. 1. David Blackstock, recipient of the Student Council Mentoring Award.

Over 40 people participated in a technical tour and demonstration to visit two unique pipe organs in San Diego including the Spreckels Outdoor Pipe Organ in Balboa Park and a seven rank pipe organ at the First Methodist Church. Lyle Blackinton, Pipe Organ Builder, was the tour leader.

Social events included the two social hours held on Tuesday and Thursday, a reception for students, a Fellows Lounge and a Fellows Luncheon and the morning coffee breaks. A special program for students to meet one-on-one with members of the ASA over lunch, which is held at each meeting, was organized by the Committee on Education in Acoustics.

Walter Munk, ASA Honorary Fellow, of the Scripps Institution of Oceanography, was the speaker at the Fellows Luncheon which was attended by over 120 people.

These social events provided the settings for participants to meet in relaxed settings to encourage social exchange and informal discussions. The Women in Acoustics Luncheon was held on Wednesday afternoon and was attended by over 90 people.

The Acoustical Society Foundation sponsored a dinner on Wednesday evening. The theme of the dinner was "Honoring Women in Acoustics and

FIG. 3. ASA President William Kuperman congratulates Steven C. Thompson, recipient of the 2003 Science Writing Award in Acoustics for Professionals in Acoustics.

in particular the contributions of Robert and Evelyn Young to the Acoustical Society of America.” The speaker was Julie Shimer, CEO of Vocera Communications, who presented “Acoustic Challenges of the Next Generation Communicator.

The plenary session included a business meeting of the Society, announcements, acknowledgment of the members and other volunteers who organized the meeting and the presentation of awards and certificates to newly-elected Fellows.

The 2003 Science Writing Award in Acoustics for Journalists was presented to Ian Sample for his article “The Sound of Sunshine” published in the *Guardian* newspaper on July 24, 2003 (see Fig. 2). The Science Writing Award for Professionals in Acoustics was awarded to Stephen C. Thompson for his article “Tutorial on Microphone Technologies for Directional Hearing Aids,” published in *The Hearing Journal* (see Fig. 3).

The first Rossing Prize in Acoustics Education was presented to Allan D. Pierce of Boston University Afor

The Silver Medal in Acoustical Oceanography was presented to D. Vance Holliday of BAE Systems, “for contributions to the study of marine life, from plankton to whales.” (see Fig. 5). The Silver Medal in Biomedical Ultrasound/Bioresponse to Vibration was presented to James G. Miller of Washington University “for contributions to ultrasonic tissue characterization and quantitative echocardiography.” (see Fig. 6). The Silver Medal in Engineering Acoustics was presented to John V. Bouyoucos of Hydroacoustics, Inc., “for the invention and development of hydraulically powered acoustic amplifiers for underwater use.” (see Fig. 7). Honorary Fellowship was conferred upon Walter H. Munk of the Scripps Institution of Oceanography “for the invention of ocean acoustic tomography.” (see Fig. 8).

FIG. 4. Allan D. Pierce (r), recipient of the Rossing Prize in Acoustics Education receives congratulations from Thomas Rossing (l) and ASA President William Kuperman (c)

FIG. 5. ASA President William Kuperman presents Silver Medal in Acoustical Oceanography to D. Vance Holliday.

Election of 13 members to Fellow grade was announced and fellowship certificates were presented. New fellows are: Michael A. Ainslie, James J. Finneran, Klaus Genuit, Robert F. Gragg, K. Anthony Hoover, Patricia A. Keating, Volker Mellert, Robert E. Remez, Philippe Roux, Shihab Shamma, Yoiti Suzuki, Stephen C. Thompson and Manel E. Zakharia. (see Fig. 9)

ASA President William A. Kuperman expressed the Society’s thanks to the Local Committee for the excellent execution of the meeting, which clearly evidenced meticulous planning. Bill Kuperman also served as the Chair of the San Diego meeting (see Fig. 10) and he acknowledged the contributions of the members of his committee including: Michael J. Buckingham, Technical Program Chair, Patricia Jordan and Deborah Duckworth, Food Service/Social Events, Matthew A. Dzieciuch and Paul Baxley, Audio-Visual, Gail Smith, Accompanying Persons Program and Aaron Thode, Poster Sessions. He also expressed thanks to the members of the Technical Program Organizing Committee: Michael J. Buckingham, Technical Program Chair, Peter Gerstoft, Peter F. Worcester, Acoustical Oceanography; Ann E. Bowles, David A. Kastak, Animal Bioacoustics; Robin S. Glosemeyer, Architectural Acoustics; Francesco P. Curra, Biomedical Ultrasound/Bioresponse to Vibration; James P. Cottingham, Education in Acoustics and Musical Acoustics; Steven R. Baker, Engineering Acoustics; Alan H. Marsh, Noise; Robert M. Keolian, David L. Gardner, Physical Acoustics; Laura Dreisbach, Psychological and Physiological Acoustics; James V. Candy, Hassan H. Namarvar, Alireza A. Dibazar, Signal Processing in Acoustics; Dani Byrd, Jody Kreiman, Speech Communication; Courtney B. Burroughs, Structural Acoustics and Vibration; Stan E. Dosso, Kevin B. Smith, Underwater Acoustics; Melania Guerra, TPOM assistant.

The full technical program and award encomiums can be found in the

printed meeting program for readers who wish to obtain further information about the San Diego meeting. We hope that you will consider attending a future meeting of the Society to participate in the many interesting technical events and to meet with colleagues in both technical and social settings. Information on future meetings can be found in the *Journal* and on the ASA Home Page at <<http://asa.aip.org>>.

WILLIAM A. KUPERMAN
President 2004–2005

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

2005	
16–20 May	149th Meeting joint with the Canadian Acoustical Association, Vancouver, Canada [Acoustical Society of America, Suite 1N01, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; Email: asa@aip.org ; WWW: http://asa.aip.org].
16–19 May	Society of Automotive Engineering Noise & Vibration Conference, Traverse City, MI [Patti Kreh, SAE International, 755 W. Big Beaver Rd., Ste. 1600, Troy, MI 48084, Tel.: 248-273-2474; Email: pkreh@sae.org].
18–22 July	17th International Symposium on Nonlinear Acoustics,

FIG. 8. ASA President William Kuperman congratulates Walter H. Munk, who was named Honorary Fellow of the Society.

FIG. 9. New Fellows of the Acoustical Society of America receive certificates from ASA President and Vice President.

State College, PA [Anthony Atchley, The Pennsylvania State University, 217 Applied Research Lab Building, University Park PA 16802; Tel.: 814-865-6364E-mail: ISNA17@outreach.psu.edu; WWW: <http://www.outreach.psu.edu/c&i/isna17/>

17–21 October
150th Meeting joint with Noise-Con 2005, Minneapolis, Minnesota, [Acoustical Society of America, Suite 1N01, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; Email: asa@aip.org; WWW: <http://asa.aip.org>].

Cumulative Indexes to the Journal of the Acoustical Society of America

Ordering information: Orders must be paid by check or money order in U.S. funds drawn on a U.S. bank or by Mastercard, Visa, or American Express credit cards. Send orders to Circulation and Fulfillment Division, American Institute of Physics, Suite 1N01, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2270. Non-U.S. orders add \$11 per index.

Some indexes are out of print as noted below.

Volumes 1–10, 1929–1938: JASA, and Contemporary Literature, 1937–1939. Classified by subject and indexed by author. Pp. 131. Price: ASA members \$5; Nonmembers \$10

Volumes 36–44, 1964–1968: Contemporary Literature. Classified by subject and indexed by author. Pp. 1060. Out of Print

Volumes 45–54, 1969–1973: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 540. Price: \$20 (paperbound); ASA members \$25 (clothbound); Nonmembers \$60 (clothbound)

Volumes 55–64, 1974–1978: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 816. Price: \$20 (paperbound); ASA members \$25 (clothbound); Nonmembers \$60 (clothbound)

Volumes 65–74, 1979–1983: JASA and Patents. Classified by subject and

indexed by author and inventor. Pp. 624. Price: ASA members \$25 (paperbound); Nonmembers \$75 (clothbound)

Volumes 75–84, 1984–1988: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 625. Price: ASA members \$30 (paperbound); Nonmembers \$80 (clothbound)

Volumes 85–94, 1989–1993: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 736. Price: ASA members \$30 (paperbound); Nonmembers \$80 (clothbound)

Volumes 95–104, 1994–1998: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 632. Price: ASA members \$40 (paperbound); Nonmembers \$90 (clothbound)

Volumes 105–114, 1999–2003: JASA and Patents. Classified by subject and indexed by author and inventor. Pp.616 , Price: ASA members \$50; Nonmembers \$90 (paperbound)

ACOUSTICAL NEWS—INTERNATIONAL

Walter G. Mayer

Physics Department, Georgetown University, Washington, DC 20057

International Meetings Calendar

Below are announcements of meetings and conferences to be held abroad. Entries preceded by an * are new or updated listings.

April 2005

18–21 **International Conference on Emerging Technologies of Noise and Vibration Analysis and Control**, Saint Raphaël, France (Fax: +33 4 72 43 87 12; e-mail: goran.pavic@insa-lyon.fr)

May 2005

16–20 **149th Meeting of the Acoustical Society of America**, Vancouver, British Columbia, Canada (ASA, Suite 1N01, 2 Huntington Quadrangle, Melville, NY 11747-4502 USA; Fax: +1 516 576 2377; Web: asa.aip.org)

June 2005

1–3 ***1st International Symposium on Advanced Technology of Vibration and Sound**, Hiroshima, Japan (Web: dezima.ike.tottori-u.ac.jp/vstech2005)

20–23 **IEEE Oceans05 Europe**, Brest, France (ENST Bretagne—Technopôle Brest Iroise, 29238 Brest Cedex, France; Fax: +33 229 00 1098; Web: www.oceans05europe.org)

23–24 **2nd Congress of the Alps-Adria Acoustical Association (AAAA2005)**, Opatija, Croatia (Web: had.zea.fer.hr)

28–1 **International Conference on Underwater Acoustic Measurements: Technologies and Results**, Heraklion, Crete, Greece (Web: UAmesurements2005.iacm.forth.gr)

July 2005

4–8 **Turkish International Conference on Acoustics 2005: New Concepts for Harbor Protection, Littoral Security, and Underwater Acoustic Communications**, Istanbul, Turkey (Web: www.tica05.org/tica05)

11–14 ***12th International Congress on Sound and Vibration**, Lisbon, Portugal (Web: www.icsv12.ist.utl.pt)

August 2005

6–10 **Inter-Noise**, Rio de Janeiro, Brazil (Web: www.internoise2005.ufsc.br)

28–2 **EAA Forum Acusticum Budapest 2005**, Budapest, Hungary (I. Bába, OPAKFI, Fö u. 68, Budapest 1027, Hungary; Fax: +36 1 202 0452; Web: www.fa2005.org)

28–1 ***World Congress on Ultrasonics Merged with Ultrasonic International (WCU/UI'05)**, Beijing, China (Secretariat of WCU 2005, Institute of Acoustics, Chinese Academy of Sciences, P.O. Box 2712 Beijing, 100080 China; Fax: +86 10 62553898; Web: www.ioa.ac.cn/wcu-ui-05)

September 2005

4–8 **9th Eurospeech Conference (EUROSPEECH'2005)**, Lisbon, Portugal (Fax: +351 213145843; Web: www.interspeech2005.org)

5–9 **Boundary Influences in High Frequency, Shallow Water Acoustics**, Bath, UK (Web: acoustics2005.ac.uk)

18–21 ***IEEE International Ultrasonics Symposium**, Rotterdam, The Netherlands (Web: www.ieee-uffc.org)

20–22

***International Symposium on Environmental Vibrations**, Okayama, Japan (Web: isev2005.civil.okayama-u.ac.jp)

27–29

Autumn Meeting of the Acoustical Society of Japan, Sendai, Japan (Acoustical Society of Japan, Nakaura 5th-Bldg., 2-18-20 Sotokanda, Chiyoda-ku, Tokyo 101-0021, Japan; Fax: +81 3 5256 1022; Web: www.asj.gr.jp/index-en.html)

October 2005

12–14

***Acoustics Week in Canada**, London, Ontario, Canada (Web: caa-aca.ca)

19–21

36th Spanish Congress on Acoustics Joint with 2005 Iberian Meeting on Acoustics, Terrassa, Barcelona, Spain (Sociedad Española de Acústica, Serrano 114, 28006 Madrid, Spain; Fax: +34 914 117 651; Web: www.ia.csic.es/sea/index.html)

25–26

***Autumn Conference 2005 of the UK Institute of Acoustics**, Oxford, UK (Web: www.ioa.org.uk)

November 2005

4–5

***Reproduced Sound 21**, Oxford, UK (Web: www.ioa.org.uk)

June 2006

05–06

6th European Conference on Noise Control (EURONOISE2006), Tampere, Finland (Fax: +358 9 7206 4711; Web: www.acoustics.hut.fi/asf)

26–28

9th Western Pacific Acoustics Conference (WESPAC 9), Seoul, Korea (Web: www.wespac9.org)

July 2006

3–7

***13th International Congress on Sound and Vibration (ICSV13)**, Vienna, Austria (Web: info.tuwienac.at/icsv13)

September 2006

13–15

Vibrations of Shells and Plates, Third Edition

Werner Soedel

Marcel Dekker, Inc., New York, NY, 2004.

688 pp. Price \$185.00 (hardcover). ISBN 0-8247-5629-0

This is the third revised edition of the above book. It contains 21 chapters and covers aspects of theoretical development of the equations, free and forced vibration problems, methods of analysis, and complicating effects. The book is well written and rather comprehensive. It contains major revisions and/or additions to the second edition published more than 10 years earlier.

Chapter 1 covers an interesting introduction on the history of the development of shell and plate vibration problems. The fundamental equations of deep, thin shells are presented in the second chapter. Love's shell equations are derived. Treatment of shells with nonuniform thickness is also presented. This revised edition includes a new analytical treatment of finding the radii of curvature. The equations are specialized into specific shell geometries in Chap. 3. In particular, equations are developed for circular conical shells, circular cylindrical shells, and spherical shells. Chapter 4 offers a short, but important, treatment of curved beams and special cases of plate and shell vibrations.

Free vibration of shells and plates is the subject of Chap. 5. Problems that treat vibrations of simple beams, inplane as well as transverse vibrations of rectangular plates, and vibrations of circular plates and cylindrical shells are presented. Additional material found in this revised edition includes treatment of inplane vibration, which is important when piezoelectric materials are used, and solutions to the free vibration problem using power series methods.

Chapter 6 offers some of the simplified shell equations. Among the simplifications presented are those of the membrane shell theories, where bending moments are ignored, and the equations of Donnel and Mushtari, which are applicable to shallow shells. These simplified equations typically present a significantly reduced set of equations to treat special problems. They could be of importance to practicing engineers. The treatment of shallow shell structures including doubly curved rectangular panels is expanded greatly in Chap. 6.

Chapters 7 and 21 offer presentation of approximate solution techniques. These include the methods of Rayleigh, Ritz, finite difference, and finite elements as well as others. Expressions of strain energy which are quite important for many approximate techniques are also presented. These expressions are written for various types of shells in this revised edition.

Forced vibrations of shells by modal expansion are treated in Chap. 8. In addition to treatment of steady-state harmonic response, the chapter offers treatment of impact and impulsive loads. Treatments of some interesting initial value problems are included in this revised edition. The treatment of dynamic effects using Green's function is presented in Chap. 9.

Various complicating effects are presented in Chaps. 11–20. The effects of initial stresses on the shell vibrations are presented in Chap. 11. Treatment of shells having relatively high thickness is presented in Chap. 12. This treatment requires revising the fundamental assumption of Love leading to the derivation of new equations. Shear deformation and rotary inertia are to be included for such shells and/or plates. Chapter 13 addresses problems containing combinations of structures. These include structures with added mass as well as those made of more than one subsystem. Hys-

teresis damping is treated in Chap. 14, while composite structures are treated in Chap. 15. Treatment of sandwich structures is added to this chapter. Dealing with composite structures requires developing new equations for shells and/or plates. This was the subject of a new book by the reviewer.

Rotating structures are presented in Chap. 16. Of particular importance were rotating rings, rotating disks, and rotating circular cylindrical shells with the axis of rotation being the same as the axis of revolution. Some of these are additions found in the revised edition.

Thermal effects are discussed in Chap. 17. Treatment of shells on elastic foundation is presented in Chap. 18. This chapter is extensively revised in the third edition. Problems related to tire mechanics are addressed. In addition, problems addressing shells subjected to base excitation are also found in this revised edition. Interaction with gases and fluids is presented in Chap. 20. This addresses problems of submerged shell structures as well as fluid-filled ones.

Chapter 19 is an interesting discussion on the similitude and derivation of exact relations between scaled structures. This is of importance when tests are to be made on smaller scale structures for economic reasons. It is also important in building the rationale for nondimensionalization.

The book is an important reference to both researchers and practicing engineers who deal with the issue of vibration of shells and plates in their work. It is an excellent addition of knowledge to the engineering community and an important collection of specialized problems. This revised edition offers significant new material. One minor shortcoming of the book that should be stated is the drawings. They could have been improved in this revised edition to the high level of content reflected by the analytical treatment in the book.

Experimental Acoustics Inversion Methods for Exploration of the Shallow Water Environment

A. Caiti, J.-P. Hermand, S. M. Jesus, and M. B. Porter (Editors)

Kluwer Academic Publishers, Netherlands, 2000.
293 pp. Price: \$127.00 (hardcover), ISBN: 0792363051.

Shallow water acoustics, with the complexities caused by boundaries and variations in the water column, is a broad and fertile area for basic and applied research. The field has made exciting progress when theoretical work has met real data in shallow water environments. The greatest challenges may be inverse problems where the unknown and time-varying environments are estimated through acoustics signals as a means of remote sensing. Such inverse problems are, though complex, necessary because it is impossible to measure directly all relevant acoustic parameters in the vast spatial and temporal spaces of shallow waters. This title is truly welcome by anyone who has an interest in shallow water acoustics.

While shallow water acoustics inversion has been an area of active

research, the subject is so diverse that no single book has been published to give a coherent treatment of its various subjects. Alternatively, this title provides a compilation of several interrelated subjects in the area under a single hardcover. It is a result of a workshop attended by about 20 researchers in the field, each covering their individual efforts relevant to the book title. Readers will find that actual shallow water conditions provide the focus for this publication, because all the papers are based on real data from shallow water regions.

The contents can be divided loosely into four subjects. They deal, respectively, with the effects of internal tides, source localization, effects of bottom vegetation, and inversion of sediment parameters.

The three papers concerned with the investigation of internal tides are all based on the same data sets, dealing with different aspects of the problem. Rodriguez *et al.* observes that in the presence of internal wave packets, propagation signals can occasionally experience a gain, possibly due to resonating effects. Their modeling of a particular internal wave packet and sound traveling through a packet is consistent with their assumption. To experimentally investigate such propagation gain effects as well as loss effects over range and frequency, it seems necessary to measure snapshots of internal wave fields.

Stephenan *et al.* report that variations observed in acoustic signals can be associated with different environmental effects. Specifically, they show that the influence of the bottom on their sound propagation data is sufficiently different from that of the internal tides so that simple, separate signal processing methods can be applied to deal with both problems.

Porter *et al.* bridge the subjects of internal tides and source localization. A notable feature here is that broadband signals over an extended period of time are used to investigate source tracking. The authors show that while narrow-band signals would have demonstrated large variations in arrival structures, broadband signals show stable arrival structure even in strong range-dependent scenarios. Also of interest is that fairly simple modeling, without considering all the complicated environmental variations, is shown to yield good tracking results.

On the subject of source tracking and localization, the paper by Ianniello and Tattersall analyzes experimental performance of a sophisticated multiline horizontal array system. Using simultaneously towed arrays at different depths, the authors report that both source range and depth can be determined using range-independent modeling. To achieve their results, they relied on the availability of good environmental data. Clearly, the range of applicability and the performance of such tracking arrays merit further study.

Two papers in the book cover acoustic interactions with vegetation on the sea bottom. Bozzano discusses the development and testing of a high-frequency backscatter system operating in the mega-Hz range. It also provides ample background and references on the subject of sea grass detection using high-frequency sonar. An interesting paper by Hermand *et al.* uses a simple experimental design to study sound propagation over sea grass. The goal of the investigation is to use sound as a remote sensing tool to monitor oxygen synthesis by sea grass. Contemporaneous measurements of temperature, sunlight, and CTD, as well as sound propagation, enable the authors to relate the abrupt and marked change in sound attenuation to the onset of photosynthesis in the sea grass. Furthermore, the authors are able to conclude that bubble layers formed from the photosynthesis are responsible for the sound attenuation and dispersion. Their work is an encouraging step forward to realizing the goal of using sound to monitor bubble concentration on the sea grass, hence providing a method to study photosynthesis of bottom vegetation.

The greatest number of papers in this collection concerns the inversion of sea bottom properties and parameters. Among all the uncertainties of the shallow water environment, the bottom is the more complex compared to the sea surface and the water column because of its diverse composition and the various processes controlling its variability. Therefore, it is not surprising that controversy continues concerning the appropriate governing equation used to describe the bottom as an acoustic medium. The theoretical paper by Buckingham argues for a viscous-fluid wave equation based on measured data showing that the sediment attenuation coefficient expressed in decibels has a linear relation to frequency. More details of the theory can be found in papers in the *Journal of the Acoustical Society of America*. Chotiros, however, argues for a poro-elastic model of sandy sediments. He

discusses the sensitivity of reflection loss as a function of grazing angle and frequency to various Biot parameters within the poro-elastic model and concludes that there exists the possibility to invert for some of the Biot parameters, such as porosity and grain density, using measurements of reflection loss. The appropriate wave equation to describe the sea bottom is an area of intense interest; research continues and progress has been made on these questions since the publication of this book.

Several papers report the use of sound propagation in shallow water environments to invert for bottom parameters. The experimental techniques range from using a narrow band source combined with vertical line arrays, to broadband explosive sources, to drifting buoys. A common theme in all methods is to take advantage of the amplitude and phase information of the propagating field, combined with modeling of the forward field based on different approximations to the environment, to estimate certain bottom parameters. Chapman *et al.* use imploding light bulbs as sound sources and vertical line arrays to measure broadband propagation. Their inversion is based on matched field processing by applying ray tracing to short range data. It is encouraging to read that the researchers were able to use a relatively straightforward method to infer bottom properties.

Abawi *et al.* give a systematic comparison of several matched field processing methods based on a set of shallow water propagation data collected by a tilted line array from a towed narrow-band source. This investigation is timely and important in order to transition matched field research into applications.

Rogers *et al.* summarize many years of experimental study of the Yellow Sea. There have been several experiments in the same general area over a span of many years, representing a persistent effort to understand bottom properties in one particular shallow water environment. Of particular interest is the reported result on the nonlinear dependence of bottom attenuation coefficient expressed in decibels versus frequency. Clearly, in the frequency band below 1000 Hz, more investigation is needed on the frequency dependence of sediment sound speed and attenuation.

Hermand *et al.* report research on geoacoustic inversion with drifting buoys. Several types of drifting buoys are tested over different sediments. A controlled source is used to transmit to these buoys. The abilities of these buoys with large dynamic ranges are articulated. This reviewer wishes there were more space devoted to the details of their inversion methods and a discussion of the success or failure of the inversion.

The paper by Caiti and Bergem is an ambitious effort to invert for a large number of bottom parameters from normal incidence backscatter data using a parametric source. The inverted parameters include not only the mean properties of the bottom such as mean sound speed and density, but also parameters controlling interface roughness and subbottom heterogeneity. Normal incidence data are attractive because they can be obtained over long tracks. If reliable inversions can be obtained using normal incident data, towed systems, such as the reported parametric sonar or chirp sonar, will be able to provide a practical method to collect bottom parameters over long tracks or large areas. However, this paper can only be considered an initial effort toward that goal because it does not offer a convincing case for the validity of the inversion results. To demonstrate the validity of the inversion, it is important to (1) establish the soundness of the forward model for the environment concerned, (2) independently measure with adequate resolution environmental parameters, and (3) assess the accuracy and associated error analysis of the inversion technique. The authors have yet to achieve these goals. It should be emphasized that their work is in an important area where increased effort ought to be placed.

While this book is not an introductory text for students, it is a useful reference for scientists and engineers working in the field of shallow water acoustics; through it an appreciation of several important areas of active research is gained. Readers should be aware that because of the limited number of papers, the subjects covered are by no means exhaustive for the area of acoustic inversion methods in shallow water environments.

OBITUARIES

Søren Buus • 1951–2004

Søren Buus, a Fellow of the Society and a prominent researcher in speech and hearing science, died on 29 April 2004, after a nine-month illness. At the time of his death, he was Professor in the Department of Electrical and Computer Engineering and Director of the Communications and Digital Signal Processing Center at Northeastern University in Boston.

Professor Buus was born in Denmark on 29 January 1951 and developed an early interest in music and electronics. This led to an M.S. degree in 1976 from the Technical University of Denmark in Electrical Engineering and Acoustics. Soon thereafter, he came to Northeastern University in the United States, where he received his Ph.D. with Bertram Scharf in 1980 in experimental psychology. Early professional appointments were as a Senior Scientist at Northeastern, as a researcher designing Fender musical instruments at CBS, and as a Research Associate at Harvard with David Green. In 1986, he accepted a faculty position at Northeastern University, where he subsequently established the Hearing Research Laboratory of that University, and commenced a long-term collaboration with Mary Florentine, who directed the neighboring Communication Research Laboratory. The two laboratories jointly fostered interdisciplinary research with participation including students and faculty from engineering, audiology, speech, linguistics, and psychology.

Buus' research interests were in hearing and in speech perception, including the application of digital signal processing and microcomputer hardware and software for hearing rehabilitation, and he collaborated extensively with many well-known researchers in these fields. Among the scientists who worked with Buus at Northeastern were Robert Carlyon, Andrew Oxenham, Andrzej Miskiewicz, Hannes Müsch, and Tilmann Zwicker. Other activities included stints as guest researcher with Georges Canévet and Bertram Scharf at the Laboratory of Mechanics and Acoustics, CNRS Marseille, with Zwicker and Klump at the Technical University of Munich, with Namba and Kuwano at Osaka University, and with Poulsen at the Technical University of Denmark. Buus was a Fellow of the Acoustical Society of America and served on the ASA's Technical Committee on Psychological and Physiological Acoustics. He was also on the Editorial Board of *Hearing Research*.

Over the years, Buus has supervised, collaborated in, and participated in a wide variety of significant research projects. One recent project concerned the relation between the ability to discriminate differences among simple and complex sounds and the ability to understand speech in difficult listening situations, as when the speech is degraded by noise, reverberation, and/or limited bandwidth. Another project focused on temporal, spectral,

and across-ear integration of loudness and on how the loudness of moderate-level sounds is affected by preceding higher-level sounds. The long-term goal of this research has been the development of a general, quantitative model of the perception of tones, noise, and speech in both normal and impaired hearing.

Buus published many articles during his life, a good number of which can be found in this journal. One major theme, initiated with the paper "Release from masking caused by envelope functions" (*JASA*, December 1985) was the theoretical explanation of comodulation masking release, which is the improvement in the detection of a tone buried in a fluctuating noise seen when the noise level is increased by adding noise bands with similar envelopes at other spectral locations. According to Buus' theory, detection improves because the additional bands serve as cues that allow the listener to vary the weight assigned to the signal band over time and to listen primarily when the short-term masker energy is low; in other words, the cues promote "listening in the valleys."

Subsequent research at several different laboratories supports the hypothesis that listening in the valleys can probably explain most instances of comodulation masking release. Another research thrust, initiated by the paper "An excitation-pattern model for intensity discrimination" (*JASA*, December 1981, coauthored with Florentine), combined the notion of excitation patterns with signal-detection theory to model intensity discrimination and to show that discrimination must be performed by integration of information across all stimulated frequency-selective channels. The model permitted Buus, together with Klump, Gleich, and Langemann (*JASA*, July 1995) to develop and test the first quantitative model of auditory perception in a nonhuman species (the starling), tying together a wide variety of physiological and behavioral data for that species. The integration of information across independent frequency bands embodied in both models has been used by other authors in the development of physiologically based models of perception.

One may also note the recent work with Müsch (his doctoral student) on the use of statistical decision theory to predict speech intelligibility, with a sequence of papers published in *JASA*, starting with June 2001.

At Northeastern, Buus was a popular and effective teacher, who loved to explain things and to help others to understand. An accomplished musician, he was a recognized authority on the technical and perceptual aspects of guitars and guitar amplifiers. Many members of the Society, for example, may remember the invited presentation he gave with Tilmann Zwicker in June 1998 at the ASA/ICA meeting, on distortion as an artistic tool for guitar playing (*JASA*, Vol. 103, p. 2797).

Buus leaves his mother, three siblings, and their families, his wife (Mary Florentine, Matthews Distinguished Professor of Audiology at Northeastern), and their daughter (Julia Buus Florentine, a student at Herlufsholm High School in Denmark).

43.25.Lj LOUDSPEAKER AND METHOD OF DRIVING THE SAME AS WELL AS AUDIO SIGNAL TRANSMITTING/RECEIVING APPARATUS

Toru Sasaki *et al.*, assignors to Sony Corporation
 19 October 2004 (Class 381/111); filed in Japan 9 January 1998

During the past few years there has been considerable experimentation with loudspeakers that utilize an ultrasonic beam to create audible sound from empty air. None of this work is referenced in the patent at hand, but a thorough theoretical analysis of the disclosed scheme is included. Two

frequency-modulated signals are combined electronically or acoustically. The first is modulated by an audio signal and the second is modulated by an inverted version of the same audio signal. Corrective filtering is said to be greatly simplified, requiring no trigonometric functions. With a suitable array of piezoelectric transducers, a highly directional beam can be produced, with side lobes attenuated by more than 20 dB. The patent suggests that such

an arrangement can be used as a practical, low-cost source of "secret sound" for teleconferencing, museum exhibits, theme park rides, and private listening.—GLA

6,796,079

43.30.Nb SOLUBLE, MOVING, SOUND PRODUCING BAIT APPARATUS AND METHOD

J. Scott McCain, Minden, Louisiana
 28 September 2004 (Class 43/42); filed 15 November 2002

The patent author asserts that until his previous invention, "the lake, river, and ocean beds of the world were destined to become covered with an impervious layer of non-biodegradable plastic worm fishing lures." The author then argues that the use of bubbles will eliminate this waste. So, he proposes a mixture of citric acid and bicarbonate of soda, together with other attractants. When hydrated, CO₂ bubbles are generated, leading fish to the hook and the dinner table.—MK

6,804,167

43.30.Tg BI-DIRECTIONAL TEMPORAL CORRELATION SONAR

Anthony L. Scoca *et al.*, assignors to Lockheed Martin Corporation
 12 October 2004 (Class 367/89); filed 19 May 2003

A temporal correlation sonar is described that can continuously calculate the vector velocity of a surface ship. First and second pulses are radiated from the ship towards the ocean bottom. A planar array of hydrophones equally spaced around the perimeter of a square, i.e., a tetrad array, receives the echoes. Correlograms of the first pulse received at any hydrophone versus the second pulses received at the others are generated. Combining the known hydrophone separations and the times corresponding to the peak

amplitudes of these correlograms yields the velocity data. Using the data from a pair of hydrophones spaced along the ship's axis yields the forward velocity; similarly, athwart-ship velocity can be calculated. Since the velocity data stream generated is continuous, a simple time integration should produce ship-position information.—WT

6,813,220

43.30.Vh ACOUSTIC FENCE

Gary W. Hicks and Larry R. McDonald, assignors to Science Applications International Corporation
2 November 2004 (Class 367/136); filed 17 January 2003

An acoustic fence is realized by spacing a series of sonar modules, each with omni-directional radiation patterns, along some desired protective boundary. The modules may be spaced in relation to one another such that there is overlap in their coverage patterns. Each module collects range information on encroaching targets as a function of time. These data are relayed to a central processing unit via a telemetry link which then estimates the paths of these targets and makes threat level estimates relative to whatever the fence is supposed to be protecting.—WT

6,798,715

43.30.Wi BIOMIMETIC SONAR SYSTEM AND METHOD

John B. Harmon *et al.*, assignors to Neptune Technologies, Incorporated
28 September 2004 (Class 367/99); filed 9 July 2001

A portable sonar unit, capable of being carried by a diver or mounted on a small underwater vehicle, ensonifies submerged objects, digitizes the echo returns, and classifies and stores these digitized signals using an electronic processing procedure that is believed to emulate the process used by the bottlenose dolphin. Hence the name Biomimetic Sonar. The system then provides a probable identification of the object based on comparison with a library of similarly processed acoustic images.—WT

6,798,122

43.30.Yj LIGHTWEIGHT UNDERWATER ACOUSTIC PROJECTOR

Thomas R. Howarth *et al.*, assignors to The United States of America as represented by the Secretary of the Navy
28 September 2004 (Class 310/344); filed 5 November 2002

A planar grid array is realized by mounting a number of standard cylindrical "cymbal"-type flexensional piezoceramic driver elements within holes in a stiff mounting board. To mechanically isolate the drivers from the board, they are each surrounded at their outer rim by a soft rubber grommet. The elements can be electrically connected in various patterns for input impedance and directivity considerations.—WT

6,798,888

43.30.Yj MOUNT FOR UNDERWATER ACOUSTIC PROJECTOR

Thomas R. Howarth *et al.*, assignors to The United States of America as represented by the Secretary of the Navy
28 September 2004 (Class 381/162); filed 5 November 2002

In a variation of United States Patent 6,798,122, reviewed above, rather than each "cymbal"-type driver element having an individual isolation grommet and in turn being mounted in a common rigid support plate, here the driver elements are mounted in holes in a single rubber sheet which is then sandwiched between a pair of rigid acoustically transparent sheets of

plastic such as Plexiglas™ with holes corresponding to the driver element positions.—WT

6,814,180

43.30.Yj MONOPOLE-DRIVEN UNDERWATER SOUND SOURCE

Hans Thomas Rosby and James H. Miller, assignors to The Board of Governors for Higher Education, State of Rhode Island and Providence Plantations
9 November 2004 (Class 181/120); filed 22 January 2002

An underwater sound source consists of a spherical piezoceramic monopole driver 30 supported at the center of a free-flooded metal or plastic tube 12 via an appropriate structure 100 and 104. The length of the tube, approximately 2 m, is chosen such that the source is resonant, in water, at

about 260 Hz. Harnesses 90 and 92 support mooring line 110 and weight line 112 respectively. Module 40, centered about the displacement node of the tube, houses the requisite electronics. Radiation into the surrounding medium is from the ends of the tube 20 and 22.—WT

6,796,195

43.35.Yb APPARATUS FOR DETERMINING PARTICLE SIZE

Malcolm J. W. Povey *et al.*, assignors to Baker Hughes, Incorporated
28 September 2004 (Class 73/865.5); filed 24 April 2003

This is an updated version of United States Patent 6,481,268 [reviewed in *J. Acoust. Soc. Am.* **113**(6), 2955 (2003)]. Measuring the size and concentration of small particles in fluids is an important consideration in many industrial processes, and several methods have been devised using ultrasonic imaging for this purpose. Some of these derive useful information from speckle, a characteristic that is usually regarded as a nuisance. The method described here introduces an ultrasonic signal into a fluid. A sensing transducer picks up the signal after it has been scattered by the particles and

feeds the resulting electrical signal to a computer. The computer is programmed to perform a Fourier transform, identify the speckle signal in the frequency domain, and relate certain characteristics of the speckle signal to particle size and distribution. The patent describes suitable algorithms in considerable detail and also includes a good summary of prior art, albeit with the proviso that "Applicants reserve the right to challenge the accuracy and pertinence of the cited references."—GLA

6,806,623

43.35.Yb TRANSMIT AND RECEIVE ISOLATION FOR ULTRASOUND SCANNING AND METHODS OF USE

David A. Petersen *et al.*, assignors to Siemens Medical Solutions USA, Incorporated
19 October 2004 (Class 310/334); filed 27 June 2002

Ultrasound imaging for echocardiography applications necessitates transducers with high volume-per-second rates for scanning. For real time imaging of moving structures, 20 or more two- or three-dimensional representations need to be generated each second. Large amounts of information are communicated from an ultrasound probe to an ultrasound base unit. The preferred embodiments described in this patent include methods and systems for isolating transmit and receive circuitry at an ultrasound transducer element. Separate electrodes or electrodes on opposite sides of a transducer element are connected to the separate transmit and receive paths or channels. Instead of high-voltage transmit and receive switching, the transducer element isolates the transmit channel from the receive channel. The transmit channel includes circuitry for limiting the voltage at one electrode during

receive processing, such as a switch enable connecting the electrode to ground. The receive channel includes circuitry for limiting the voltage at an electrode during transmit processing, such as a diode clamp preventing voltage swings greater than diode voltage at the electrode. Limiting the voltage provides virtual grounding or a direct current for either the transmitting or receiving operation. A unipolar pulse may be generated on a transmit channel starting at one voltage and ending at a different voltage. For example, a pulse may start at zero voltage and end on a positive voltage, with a subsequent pulse starting at the positive voltage and ending at zero voltage. These mirrored unipolar transmit waveforms may be used for phase inversion imaging, such as adding responsive received signals for isolating harmonic information.—DRR

6,810,742

43.35.Zc METHOD OF AND AN APPARATUS FOR DETERMINING THE SPEED OF SOUND IN A MATERIAL

Martin Sauerland, assignor to SMS Meer GmbH
2 November 2004 (Class 73/597); filed in Germany 29 May 2002

The patent first explains how known techniques can monitor the wall thickness of pipe or tubing during production if the speed of sound through the material at the temperature of fabrication can be specified. Interpolating from standardized tables may not be accurate enough. The arrangement shown provides a simple, practical test technique. Sample 1 is a solid rod made from the material to be tested. Notches 3 and 4 are milled into the rod

to act as reflectors. The notched end of the rod is placed inside furnace 7 and heated to the desired temperature, which may be greater than 600 °C. The opposite end of the rod is cooled by immersion in tank 11. Ultrasonic test head 10 generates a pulse and then receives reflections from the two notches. Since the distance between the notches is known, the time interval between the two reflections can be used to calculate sound speed.—GLA

6,813,528

43.38.Ar APPARATUS AND METHOD FOR OUTPUTTING AUDIO SIGNAL OF LAPTOP COMPUTER COUPLED WITH DOCKING STATION

Sung-dong Yang, assignor to Samsung Electronics Company, Limited
2 November 2004 (Class 700/94); filed in the Republic of Korea 9 March 1998

The patent deals with some of the challenges and opportunities of enhancing the audio performance of a laptop computer when it is coupled to a larger system via a so-called docking station. While retaining the small

stereo loudspeakers built into the basic laptop, the docking station supplies its own audio enhancements through the use of additional loudspeakers, primarily to extend the low-frequency response.—JME

6,812,617

43.38.Bs MEMS DEVICE HAVING A FLEXURE WITH INTEGRAL ELECTROSTATIC ACTUATOR

Thomas Wayne Ives, assignor to Hewlett-Packard Development Company, L.P.

2 November 2004 (Class 310/309); filed 18 April 2002

The patent describes a clever electrostatically actuated, micromechani-

cal "spine." The device looks neat, but no force or displacement capabilities are given. Probably just a sketchbook curiosity.—JAH

6,812,814

43.38.Bs MICROELECTROMECHANICAL (MEMS) SWITCHING APPARATUS

Qing Ma *et al.*, assignors to Intel Corporation

2 November 2004 (Class 333/262); filed 7 October 2003

This patent describes the layout of a tiny electrostatically actuated switch suitable for rf switching. Several embodiments and fabrication methods are described, with typical connections being made by a $5 \times 5 \times 20 \mu\text{m}$ gold bar, which should result in reasonable contact resistances. The focus of the inventors is on the geometry of the switch—no performance figures are given.—JAH

6,798,654

43.38.Dv WOOFER MODULE OF A PORTABLE COMPUTER

Hung-Yue Chang *et al.*, assignors to Wistron Corporation

28 September 2004 (Class 361/686); filed in Taiwan, Province of China 26 September 2002

The quality of sound produced by, even so-called, multimedia portable computers is in many cases a joke. Despite the inherent problems with trying to move lots of air to produce better quality sound from these devices (due to the minuscule space to place loudspeakers), the need by the manufacturer to use the cheapest transducers known to man in order to be cost

competitive, and the need for the user to suspend disbelief, many inventors still are toiling in the manner of Sisyphus. This patent describes a small ported enclosure that can attach to one of the computer's expansion ports or slots. One assumes that the stiffness of the enclosure is sufficient for the need and that the transducer is up to the task.—NAS

6,804,370

43.38.Dv SPEAKER CAPABLE TO PLAYBACK IN WIDE FREQUENCY RANGE

Hideaki Sugiura, assignor to Pioneer Corporation; Tohoku Pioneer Corporation

12 October 2004 (Class 381/424); filed in Japan 29 March 2002

Cone-type electrodynamic loudspeakers are known to have resonances. One of the notable resonances is that of the cone. The patent uses two diaphragms **10a** and **10b** that have different radii of curvature and that also have the benefit of different resonant frequencies. Somehow, by "equal-

izing areas" of the inner diaphragm, S1 for 10a, and of the outer diaphragm, S2 for 10b, the sound pressure levels are equalized with each other. The patent states that this compound cone, with the equalized area diaphragms, results in a smoother high-frequency response.—NAS

6,812,607

43.38.Dv AUXILIARY COUPLING DISK FOR MINIATURE VIBRATION VOICE-COIL MOTORS

Chien-Chung Sun, assignor to Risun Expanse Corporation
2 November 2004 (Class 310/81); filed 5 August 2003

This patent discloses a method for increasing the vibration output from an electric motor of limited size, through the use of a magnetic, eccentric rotor. The inventor's concept of small is "less than 20 mm diameter."—JAH

6,811,385

43.38.Fx ACOUSTIC MICRO-PUMP

Daniel R. Blakley, assignor to Hewlett-Packard Development Company, L.P.
2 November 2004 (Class 417/413.2); filed 31 October 2002

This patent describes a peristaltic fluid pump having an inner diameter of tens of microns created by a sequence of piezoelectric rings surrounding a tubular passage. There is a good deal of discussion of the preferred positions of the piezoelectric rings but next to nothing on the physics of what is going on in the channel. There is also no discussion of the amplitude dependence of what would apparently be a nonlinear effect, leading one to suspect that the device has not actually been studied.—JAH

6,812,618

43.38.Fx CONTROL APPARATUS FOR VIBRATION TYPE ACTUATOR

Tadashi Hayashi, assignor to Canon Kabushiki Kaisha
2 November 2004 (Class 310/316.01); filed in Japan
28 December 2000

This patent describes several control circuits for piezoelectric traveling-wave-type actuators. As such it belongs in the field of electronics. No mention is made of the application of the circuits to MEMS actuators, though it most certainly could be done.—JAH

6,801,631

43.38.Hz SPEAKER SYSTEM WITH MULTIPLE TRANSDUCERS POSITIONED IN A PLANE FOR OPTIMUM ACOUSTIC RADIATION PATTERN

Donald J. North, Los Angeles, California
5 October 2004 (Class 381/336); filed 24 May 2000

Loudspeakers are usually used in rectangular rooms. It follows that first-order reflections from a loudspeaker to a listener must be influenced by the horizontal and vertical directional characteristics of the loudspeaker. Therefore, if a simple square array is rotated slightly as shown, then the

effective center-to-center spacing is reduced in the horizontal and vertical planes, attenuating off-axis lobes up to a higher Nyquist frequency. In theory, it all makes sense.—GLA

6,809,465

43.38.Hz ARTICLE COMPRISING MEMS-BASED TWO-DIMENSIONAL E-BEAM SOURCES AND METHOD FOR MAKING THE SAME

Sungho Jin, assignor to Samsung Electronics Company, Limited
26 October 2004 (Class 313/310); filed 24 January 2003

This is a description of a MEMS device that allows you to make and steer a large number of electron beams for use in a plasma panel or an x-ray source. The approach is to make an array of tips that can be steered electrically. There is no mention of how the device would be constructed or whether the various materials are process compatible.—JAH

6,792,120

43.38.Ja AUDIO SIGNAL ENHANCEMENT AND AMPLIFICATION SYSTEM

Jonathan M. Szenics, Flemington, New Jersey
14 September 2004 (Class 381/120); filed 23 February 2000

Motional feedback has been known for almost 50 years. According to the inventor, "tube amplifiers are still the gold standard by which any new amplification/signal processing device is judged." His solution is to epoxy a piezoelectric sensor to a speaker cone. That signal is then amplified with a

coil rubs against one of the pole pieces. Moreover, the inner flange of the suspension can be conveniently tuned to supply additional energy at very high frequencies.—GLA

6,807,284

43.38.Ja SPEAKER AND SPEAKER DEVICE

Takeshi Nakamura, assignor to Murata Manufacturing Company, Limited
19 October 2004 (Class 381/423); filed in Japan 28 September 1998

The patent describes a device that is said to emit nondirectional, low-frequency waves. This is done by having a loudspeaker 16 mounted in a case 12 such that the volume of air enclosed is airtight. "By storing the speaker unit inside of a very small case, the resonant frequency of the speaker is significantly increased, enabling the fidelity of the speaker to be improved by generating sound at frequencies below the resonant frequency.

10

By providing the speaker unit on a floor side of the case, it is possible to cut off sound emitted by the speaker unit to the outside thereof, so that only sound generated by the expansion and contraction of the case is emitted." Which, in the least, doesn't sound very efficient.—NAS

6,810,988

43.38.Ja SPEAKER'S DAMPER WITH LEAD WIRE AND GUIDE SLEEVE

Yen-Chen Chan, Taipei Hsien, Taiwan, Province of China
2 November 2004 (Class 181/171); filed 2 December 2002

Centering spider 1 is a conventional corrugated, woven design. Lead

wires are threaded through little loops, like basting, to keep them separated and restrain unwanted vibrations.—GLA

6,810,125

43.38.Kb MICROPHONE EMULATION

Doran Oster et al., assignors to Sabine, Incorporated
26 October 2004 (Class 381/111); filed 4 February 2002

For musicians who are into digital production techniques the notion of a microphone simulator is not new. Just as the impulse response of classic equalizers and other effects generators of past years can be measured and

used to simulate the original devices, so likewise can the response of classic microphones be duplicated for similar purposes. There is absolutely nothing new in this basic premise, but one of the claims of the patent describes its application in the context of a standard wireless microphone channel. Why? Perhaps to establish some kind of primacy in the field of live music entertainment, in which wireless microphones are widely used by vocalists on the move.—JME

6,801,628

43.38.Lc SYSTEM AND METHOD FOR ADJUSTING FREQUENCY RESPONSE CHARACTERISTICS OF A SPEAKER BASED UPON PLACEMENT NEAR A WALL OR OTHER ACOUSTICALLY-REFLECTIVE SURFACE

James Thiel, assignor to Thiel Audio Products
5 October 2004 (Class 381/56); filed 14 May 2001

There are several, if not more, systems commercially available today that take into account what is called the "room acoustics." This patent describes a device 150 that is inserted into the signal chain before a power amplifier 130 to adjust the signal 310 from signal source device 120. The distance from the wall is the main input parameter to 152, which is obtained

via manual entry or by automatic means from 154. The object is to reduce the peak in response that one can find at the low end due to the wall reflection. The equations used vary as a function of distance, with the coefficients changing at a distance of approximately 2.7 m. An example of an implementation, with design equations, is provided.—NAS

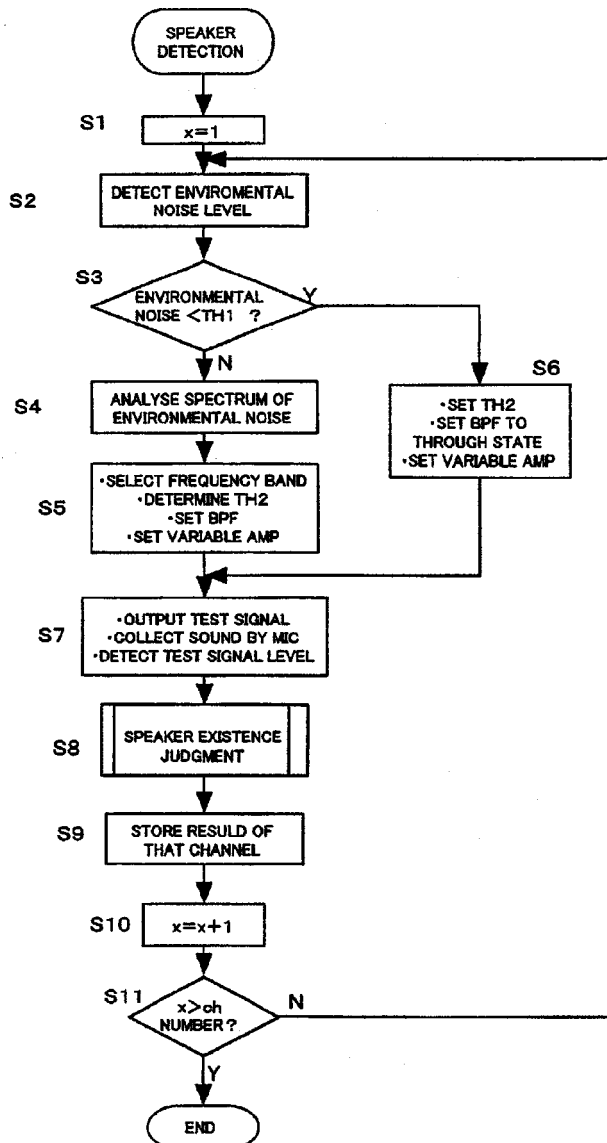

6,813,577

43.38.Lc SPEAKER DETECTING DEVICE

Hajime Yoshino and Kazuya Tsukada, assignors to Pioneer Corporation

2 November 2004 (Class 702/111); filed in Japan 27 April 2001

Many surround sound systems include a test mode in which pink noise is sequentially fed to all six loudspeaker channels. The flow chart shows how a computer program can augment this simple procedure to automati-

cally check whether each speaker is operational—not for relative level, polarity, or delay—just whether it is alive or dead. If there is any memory left over, another program might be added to let the user know if the equipment is actually turned on when the pilot light is lit.—GLA

6,801,815

43.38.Md SOUND AND IMAGE PRODUCING SYSTEM

Andrew S. Filo and David G. Capper, assignors to Hasbro, Incorporated

5 October 2004 (Class 700/94); filed 28 July 2000

In the cut-throat toy business, the recording and playback of sounds for toys and similar entertainment devices is often the one important component in the device that generates the sale of same. The present invention appears to be an outgrowth and enhancement of the assignee's Hit Clips product line, albeit one that could have better sound quality (this information comes from the reviewer's resident expert on such devices). Player 12, which, in the several embodiments described appears to be compact in size, appears to

be a "dumb" device in that it has little or no personality or audio functionality until cartridge 10 is plugged in. In other embodiments, device 10 can be connected to other equipment to download new sounds and personality. The patent describes in minute detail the construction of the cartridges and some of the forms that the players can take. Further, it states that "users may purchase and collect cartridges; users may also trade cartridges amongst themselves; high school students may clip players to a zipper on their backpacks." The expert consulted is not quite that old.—NAS

6,810,987

43.38.Si EARBUD HEADSET

Frederick P. DeKalb, assignor to Plantronics, Incorporated

2 November 2004 (Class 181/129); filed 6 December 2002

The earbud shown is intended to provide enhanced sound quality and positional stability in ears of various sizes. Novel features include a thin

edge portion 20, which is said to allow acoustic coupling to deeper areas of the user's ear, and positioning member 22, which contacts an upper concha of the ear.—GLA

6,801,633

43.38.Tj SUBWOOFER ASSEMBLY

Dennis A. Tracy, Culver City, California
 5 October 2004 (Class 381/389); filed 25 January 2001

Any passenger on a commercial aircraft who has listened to the audio system via headphones realizes that the low-frequency reproduction is even poorer than that of the mid frequencies (the high frequencies being virtually nonexistent due to the ambient noise in the cabin). In fact, high-quality sound to accompany the in-flight entertainment is not only not available, today it is an oxymoron. "A need, therefore, exists for a speaker assembly providing high-quality sound, while also meeting the size and weight requirements of an aircraft." This patent sets out to provide some improve-

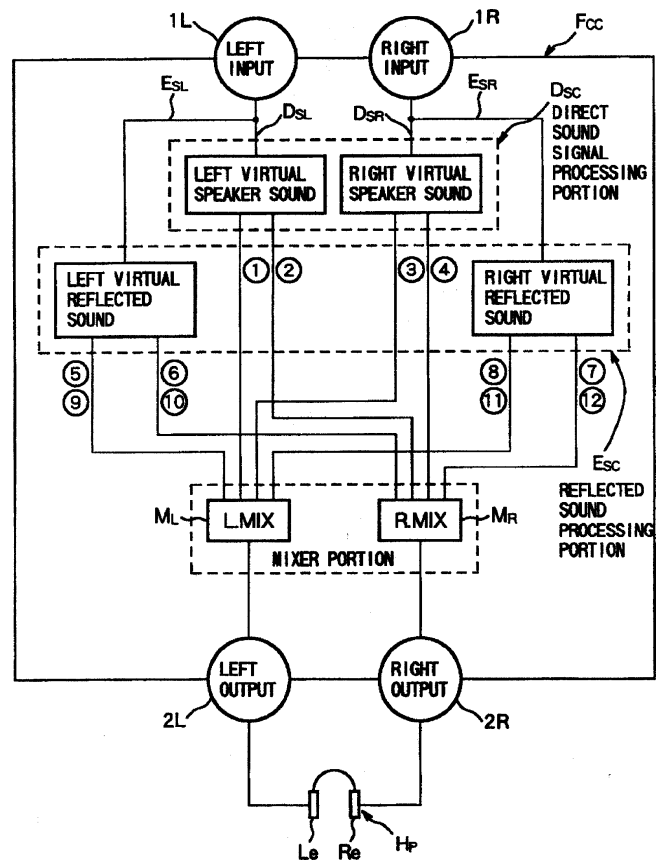

ment at subwoofer frequencies. By using a subwoofer enclosure 22 mounted below the aisle 16 in the aircraft fuselage 12, the low frequencies produced by this device within the passenger compartment are said to be improved. One supposes the improvement here is that of the sound level. Great, so you will soon not only have the pleasure of listening to the multiple cell phone conversations around you, but they will be accompanied by the subwoofer component of the video that you are not watching.—NAS

6,801,627

43.38.Vk METHOD FOR LOCALIZATION OF AN ACOUSTIC IMAGE OUT OF MAN'S HEAD IN HEARING A REPRODUCED SOUND VIA A HEADPHONE

Wataru Kobayashi, assignor to OpenHeart, Limited; Research Network, a Limited Responsibility Company
 5 October 2004 (Class 381/17); filed in Japan 30 September 1998

This patent describes a method for making headphones sound like loudspeakers by simulating both direct sound and first-order reflections. The

inventors maintain that an audio signal above a certain critical frequency can be positioned at any virtual location through a combination of delay and comb-filtering.—GLA

6,804,361

43.38.Vk SOUND SIGNAL PLAYBACK MACHINE AND METHOD THEREOF

Shintaro Hosoi and Hiroyuki Hamada, assignors to Pioneer Corporation
 12 October 2004 (Class 381/99); filed in Japan 12 June 2001

Most conventional frequency-dividing networks produce substantial delay distortion in their summed response. A number of alternative constant-voltage circuits have been proposed, but are largely unused because of unwanted side effects. However, in 1985 Vanderkooy and Lipshitz disclosed a clever method of realizing linear phase response by introducing time offset into the high-frequency channel, and this approach is also used in the circuit shown. In this case, the inventors are concerned with the crossover between multiple surround sound speakers and a common subwoofer. To at least one

reader, the problem of synchronizing all five speakers with an off-center subwoofer is not dealt with convincingly.—GLA

6,799,465

43.38.Yn SHOCK WAVE VIBRATION GENERATOR FOR MEASURING OR TESTING OR IMAGING PURPOSES

Stephen Bruce Berman, Austin, Texas
5 October 2004 (Class 73/590); filed 16 July 2002

Those familiar with shock wave testing may find this patent informative. However, this reviewer finally gave up trying to make sense of sentences like, "In one embodiment of the present invention, a method utilizes one or more shock wave vibratory forces produced by one or more cavitating spaces within one or more fluid substances within one or more housings which is therefore an improvement of the art of methods for producing vibrator devices that are particularly adapted for producing and applying non-shock wave vibratory forces, for example, any testing purposes or any measuring purposes."—GLA

6,813,218

43.38.Zp BUOYANT DEVICE FOR BI-DIRECTIONAL ACOUSTO-OPTIC SIGNAL TRANSFER ACROSS THE AIR-WATER INTERFACE

Lynn T. Antonelli and Fletcher Blackmon, assignors to The United States of America as represented by the Secretary of the Navy
2 November 2004 (Class 367/3); filed 6 October 2003

A floating buoy consists of a hollow shell having a set of underwater acoustic transducers mounted against its lower portion while the upper portion features a dome-shaped retro-reflective coating that can be vibrated in accordance with received acoustic signals to retro-reflect impinging in-air

laser signals back to a remote receiver. Alternatively, the upper portion will vibrate in response to an incident in-air laser control signal. Consequently, the buoy functions as a system for either translating in-air optical signals to underwater acoustic signals or translating underwater acoustic signals to in-air optical signals.—WT

6,805,805

43.40.Ey SYSTEM AND METHOD FOR RECEPTACLE WALL VIBRATION IN A CENTRIFUGE

Curtis Kirker and Berkeley F. Fuller, assignors to Phase Incorporated
19 October 2004 (Class 210/781); filed 13 August 2002

In a centrifuge, the centrifugal force achieved by spinning drives the heavier materials outwards from the center of the centrifuge. The heavier materials contact the sloped and converging walls of collecting receptacles leading to exit outlets or nozzles. Because such heavier materials tend to adhere to the sloped walls, their outward movement tends to be restricted.

Vibrating the centrifuge's receptacle tends to loosen these materials from the walls and thus to promote their egress from the centrifuge. A means is provided here to vibrate the centrifuge receptacle through the use of a vibratory device communicating with the receptacle wall.—DRR

6,796,618

43.40.Kd METHOD FOR DESIGNING LOW VIBRATION OMNI-DIRECTIONAL WHEELS

Donald Barnett Harris, Arlington, Virginia
28 September 2004 (Class 301/501); filed 18 October 2002

Most omni-directional vehicles use wheels that feature rollers positioned about the periphery of the wheel, with the roller axes at some angle relative to the wheel's primary plane and axis. As the wheel turns, the area contacting the ground shifts across the surface of each roller and the portion of the roller that supports the vehicle's weight changes. With conventional

roller designs, the compliance that contacts the ground changes, resulting in changing vertical deflection of the vehicle and thus in vibration. The present patent proposes roller designs that avoid this problem by maintaining constant ground-contacting compliance.—EEU

6,789,025

43.40.Le CYCLIC TIME AVERAGING FOR MACHINE MONITORING

Johannes I. Boerhout, assignor to SKF Condition Monitoring, Incorporated
7 September 2004 (Class 702/56); filed 4 December 2002

A common means of monitoring the condition of a machine uses vibration sensors attached to the machine, processing of the signals from the vibration transducer, and computer-based analysis of these signals to determine the contribution of bearing wear, shaft irregularities, etc., before the catastrophic failure of the machine. Here, a set of N vibration amplitude values is accumulated from which a set of n averaged amplitude values, separated by period M , is obtained, with $n < N$. A novel feature is that some of the n values do not correspond to any of the N values. A very novel part of the patent is that the final two figures referenced in the patent text do not appear in the patent. Figure 4 in this patent is identical to Figure 1 in United States Patent 6,792,360, seen with the review of that patent below.—NAS

6,789,422

43.40.Le METHOD AND SYSTEM FOR BALANCING A ROTATING MACHINERY OPERATING AT RESONANCE

Talmadge D. Ward, Jr., assignor to United States Enrichment Corporation
14 September 2004 (Class 73/462); filed 21 December 2001

This patent describes a method to speed the balancing of multishaft rotating equipment where the shafts are not necessarily aligned along a common axis of rotation. The patent presents a clear and useful tutorial on the various methods of shaft balancing, vibration analysis of machines, rotor dynamics, and the rotor influence coefficient test. An example of the method for a specific piece of machinery, specific transducers, and data collection

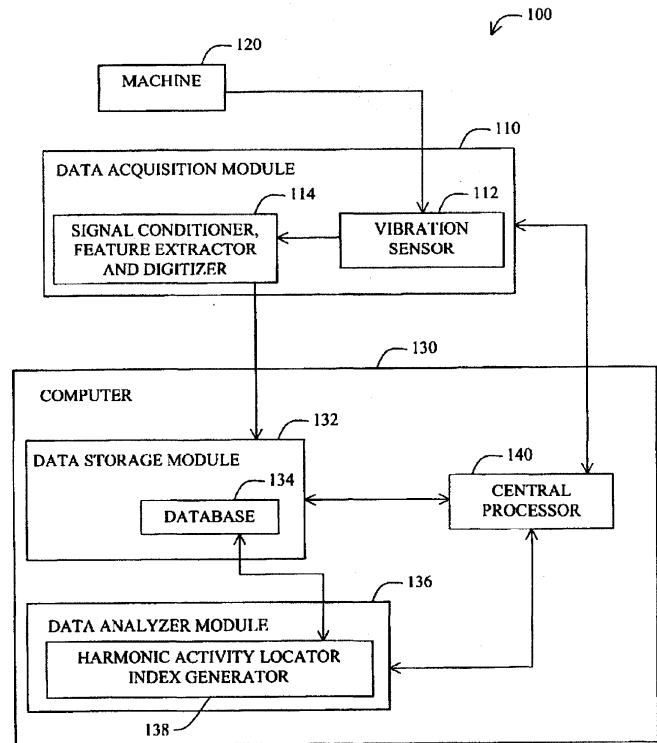

and analysis equipment is presented. The method uses a proximity transducer 408 on one shaft to provide rotational velocity data and a pair of vibration transducers 410 mounted perpendicular to one another. A detailed procedure is presented that purports to decrease the time to balance and, one would assume, the accuracy of the balancing.—NAS

6,792,360

43.40.Le HARMONIC ACTIVITY LOCATOR

Adrianus J. Smulders *et al.*, assignors to SKF Condition Monitoring, Incorporated
14 September 2004 (Class 702/35); filed 4 December 2002

This patent describes a computer-based method of processing vibration data in the frequency domain that uses a harmonic activity index based on frequency spectrum information and that of, one supposes, a known-defects harmonic series. It is written in classic "patenesque," stating in the claims that estimated values K and R are indicative of the total energy in the spectrum,

that a derived value I_{HAL} is based in part on K and R , and that using I_{HAL} and the fundamental frequency of the component defect it may be determined whether the vibrations of the machine are caused by the defect. There are 33 other claims, too.—NAS

6,801,864

43.40.Le SYSTEM AND METHOD FOR ANALYZING VIBRATION SIGNALS

Niel Miller, assignor to AB SKF
5 October 2004 (Class 702/56); filed 15 November 2001

Identification of defects or damage in rolling element bearings is accomplished by filtering vibration data in bands that are determined in part on the basis of the shaft's rotation speed. The bands are arranged to encompass signals that correspond to defects in the rotating inner ring, the rotating outer ring, and the rotating elements. User-defined alarm levels are determined by comparing the signals to a noise floor.—EEU

6,807,866

43.40.Le TRANSDUCER OF THE VIBRATION TYPE, SUCH AS AN ELECTROMECHANICAL TRANSDUCER OF THE CORIOLLIS TYPE

Wolfgang Drahm and Alfred Rieder, assignors to
Endress+Hauser Flowtec AG
26 October 2004 (Class 73/761.355); filed 22 February 2002

Coriolis mass flow meters are well known. Such a flow meter basically consists of a curved tube, which is made to vibrate at a resonance in its plane. Coriolis forces, which depend on the mass flow rate, then cause out-of-plane vibrations and these are sensed to obtain a measure of the flow rate. The present patent describes a particular configuration of the curved tube that results in minimal vibration transmission to its end supports.—EEU

6,811,630

43.40.Sk ULTRASONIC VIBRATION METHOD AND ULTRASONIC VIBRATION APPARATUS

Morio Tominaga and Shinji Iwahashi, assignors to Sony
Corporation
2 November 2004 (Class 156/73.1); filed in Japan
20 November 2000

This is a method for exciting a composite ultrasonic vibration in a structure. Two coupled, intersecting ultrasonic horns 11, 12 are driven in their respective longitudinal dimensions to excite a respective transverse

vibration in the other horn. The point at which the horns are joined is thus driven in a composite vibration, which can be transmitted to another member (not shown in the figure) or used to perform an operation such as ultrasonic welding.—IMH

6,811,631

43.40.Sk DEVICE AND METHOD FOR WELDING THIN-WALLED WORK PIECES USING ULTRASOUND

Hartmut Möglich, assignor to Herrmann Ultraschalltechnik
GmbH & Company KG
2 November 2004 (Class 156/73.1); filed in Germany
30 March 2002

This is an ultrasonic welding tool that secures a portion of thin work

pieces 54, 56 within a mating projection 41 and recess 46.—IMH

6,813,950

43.40.Sk PHASED ARRAY ULTRASONIC NDT SYSTEM FOR TUBES AND PIPES

David Glascock *et al.*, assignors to R/D Tech Incorporated
9 November 2004 (Class 73/633); filed 25 July 2002

This is a system for nondestructive testing of solid tubes. The system includes a phased ultrasonic array 2 having a curved face to match tube 4

being tested. Defects in 3-D (longitudinal, transverse, oblique) are detected by refraction of incident waves in a transmit/receive configuration of the array.—IMH

6,607,359

43.40.Tm APPARATUS FOR PASSIVE DAMPING OF FLEXURAL BLADE VIBRATION IN TURBO-MACHINERY

Andreas H. von Flotow, assignor to Hood Technology Corporation
19 August 2003 (Class 416/229 R); filed 31 January 2002

A scheme to reduce high-order mode vibration in turbine blades consists of a pocket machined into the blade near the tip. A metal insert in this pocket forms the aerodynamic surface of the blade. In response to blade vibration, frictional losses induced by relative motion of the metal insert provide damping.—KPS

6,796,408

43.40.Tm METHOD FOR VIBRATION DAMPING USING SUPERELASTIC ALLOYS

Yang Sherwin and Donald G. Ulmer, assignors to The Boeing Company
28 September 2004 (Class 188/378); filed 13 September 2002

Superelastic, or shape memory alloys, can be deformed repeatedly at high strain levels and still return to their original shapes without accumulating classical fatigue damage. As the load on such an alloy is reversed, considerable energy dissipation occurs as the result of the fully reversible martensitic phase transformation in the alloy. The present patent addresses the use of shape memory alloys for damping of vibrations of such components as turbine blades. Structural dynamic analyses are to be carried out in order to identify areas of high vibratory stress and thermal analyses are to be performed in order to determine the approximate maximum operating temperatures in these areas. The idea is then to dispose a suitably selected alloy in these areas.—EEU

6,799,642

43.40.Tm VIBRATION DAMPER BETWEEN TWO COMPONENTS

Gunter Wolf *et al.*, assignors to Andreas Stihl AG & Company
5 October 2004 (Class 173/162.2); filed in Germany
7 February 2001

This patent pertains to a spring-type isolation system to be placed between the housing of a motor-driven chain saw and a handle thereof. In order to permit the saw to be guided by its operator in the event that the spring breaks, a restraint device is provided in mechanical parallel with the spring, but arranged so that it normally does not short-circuit the spring.—EEU

6,802,405

43.40.Tm FRICTION VIBRATION DAMPER

Carl L. Barcock and Geoffrey R. Tomlinson, assignors to Rolls-Royce plc
12 October 2004 (Class 188/268); filed in the United Kingdom
3 March 2001

This damper is intended to be attached to an engine or machining tool whose vibrations in the vicinity of 10 Hz are to be suppressed. The damper consists of one or more chambers whose volumes are about 95% filled with small particles, which may be spherical with diameters of at least two discrete sizes in the range of 0.1 to 5.0 mm, or elongated, or disc shaped. The chambers are shaped or provided with baffles so that the particles are prevented from moving in convection like flow patterns.—EEU

6,805,053

43.40.Tm METHOD AND DEVICE FOR SUPPRESSING VIBRATIONS IN A PRINTING PRESS

Christopher Berti *et al.*, assignors to Heidelberger Druckmaschinen AG
19 October 2004 (Class 101/480); filed in Germany
20 November 2001

This patent in essence describes single-degree-of-freedom dynamic absorbers whose natural frequencies are automatically tuned to the rotational speeds of selected rollers. A typical torsional absorber consists of a disc mounted at the end of a cantilevered shaft, whose effective length is varied by means of an actuator. The actuator is activated via a controller signal, determined on the basis of the measured printing press rotational speed.—EEU

6,807,863

43.40.Tm VIBRATION PICKUP COMPRISING A PRESSURE SLEEVE

Hartmut Brammer, assignor to Robert Bosch GmbH
26 October 2004 (Class 73/702); filed in Germany
15 December 1999

This patent describes a configuration of an engine knock sensor that can be mounted so as to make secure contact with the vibrating engine. The sensor elements are essentially ring shaped and disposed around a central tubular sleeve, through which a mounting bolt can be placed. The sensor's surface that is to be in contact with the engine has a concave shape to ensure good contact with the engine surface.—EEU

6,814,548

43.40.Tm MULTIPLE PISTON ENGINE WITH VIBRATION REDUCING PROPERTIES

Michel Sagnet, assignor to Peugeot Citroen Automobiles S.A.
9 November 2004 (Class 417/273); filed in France
17 December 1999

This patent relates not to engines and not primarily to vibration reduction, but generally to multipiston pumps and compressors and to their noise reduction. Whereas prior designs achieve noise reduction by arranging the cylinders with angular offsets between their operating cycles, the present patent describes cylinder arrangements that result in different fundamental frequencies for the different cylinders, thus spreading the spectrum of the total generated noise. Different cylinder natural frequencies are achieved by arranging the different pistons to displace different volumes.—EEU

6,806,667

43.40.Vn CONTROL UNIT AND CONTROL METHOD FOR CONTROLLING VIBRATION OF AN ELECTRIC VEHICLE

Shoichi Sasaki and Yoshiaki Ito, assignors to Toyota Jidosha Kabushiki Kaisha
19 October 2004 (Class 318/432); filed 23 May 2003

This patent is asserted to be applicable to hybrid vehicles that are driven by a combination of an internal combustion engine and an electric motor. The speed of the electric motor and the speeds of the drive wheel are sensed and the corresponding signals are fed to a controller. The latter provides a torque compensation signal to the electric motor. Several control algorithms are presented, said to require a relatively small amount of computation.—EEU

6,591,939

43.50.Gf MARINE ENGINE SILENCER

Joseph I. Smullin and Matthew E. Denis, assignors to Smullin Corporation
15 July 2003 (Class 181/260); filed 27 April 2001

A muffler for a marine engine includes a chamber that separates the exhaust gas from the cooling water with which it has been mixed. The

gas/water mixture enters through pipe 189 and flows upwards through tubes 175 which swirl the mixture within the separation chamber. The water mixture exits through 109 and the gas through 107.—KPS

6,595,319

43.50.Gf MUFFLER

Ronald G. Huff, Westlake, Ohio
22 July 2003 (Class 181/250); filed 30 October 2001

An automobile muffler is described which consists of straight pipe 67 and a side branch resonator. The half-wavelength resonator is open at both

ends. In order to achieve a compact arrangement, the side branch length is folded back on itself. Several alternative geometrical arrangements are described.—KPS

6,619,276

43.50.Gf POSITIVE CRANKCASE VENTILATION ORIFICE MUFFLER

Alan S. Miller and David Thomas Hanner, assignors to General Motors Corporation
16 September 2003 (Class 123/572); filed 28 August 2002

Reduction of noise generated by flow through a positive crankcase ventilation system (PCV) of an automobile is described. The design consists of a cylindrical body 24 with a single output orifice 30 and two inlet orifices

32 and 34. The two inlet orifices have slightly different diameters designed to create "destructive wave interferences" resulting in a 10-dB reduction in sound level at high frequencies.—KPS

6,622,482

43.50.Gf COMBINED CATALYTIC MUFFLER

Glenn Knight and Nils Rodeblad, assignors to Environmental Control Corporation
23 September 2003 (Class 60/299); filed 27 June 2001

A muffler intended for small engines such as those found in lawnmow

ers incorporates a catalytic converter. Arrangements based on cylindrical (see figure) and rectangular geometries are described.—KPS

6,644,061

43.50.Gf SOUND MUFFLING DEVICE FOR AN AIR CONDITIONING UNIT

Joseph W. Woolfson, Brooklyn, New York
11 November 2003 (Class 62/296); filed 2 August 2002

A device for reducing the sound of water droplets falling onto the upper surface of a window or wall-mounted air conditioning unit consists of several screens mounted parallel to one another and located just above the

upper surface of the unit. The first, upper, screen has a coarse mesh, the one below it has finer mesh, and the last one is finer still. Materials such as plastic, metal wire, and nylon screen are recommended and various mounting arrangements are described.—KPS

6,644,437

43.50.Gf VEHICLE EXHAUST WITH LENGTH-EQUALIZING MUFFLER

Alan William Hayman, assignor to General Motors Corporation
11 November 2003 (Class 181/268); filed 2 August 2002

Transverse mounted V-6 and V-8 engines may have exhaust systems with dual exhaust pipes leading from front and rear cylinder banks of the engine to a single muffler. The resultant unequal lengths of pipe lead to a "raspy" exhaust sound quality. A muffler is designed such that it has two internal inlet pipes that have lengths differing by an amount equal to the length difference between the exhaust pipes from the engine, thus achieving approximately overall equal lengths. An additional feature of this muffler design is a valve that is activated by the exhaust pressure, thus achieving dual flow paths and raising the back pressure at low exhaust flow rates.—KPS

6,648,628

43.50.Gf GAS FLOW MUFFLING DEVICE

Scott F. Eiklor, Paoli, Indiana
18 November 2003 (Class 431/114); filed 5 March 2001

Sound generated by burning gas in appliances such as gas logs is reduced by inserting device **10** into the inlet of pipe **18** into which the gas flows. This insert consists of a braided metallic element made from bronze surrounded by a braided fibrous element made of fiberglass. The gas flows

through small orifices formed by the braided insert before flowing through the larger orifices **34** where the gas is burned. It is speculated that the reduction in sound is brought about through a change from laminar to turbulent flow induced by the smaller, upstream orifices.—KPS

6,804,513

43.50.Jh NOISE MONITORING SYSTEM

Tsunehiro Okuya *et al.*, assignors to Honda Giken Kogyo Kabushiki Kaisha
12 October 2004 (Class 455/423); filed in Japan 20 December 2000

The inventors want to monitor vehicle noise and transmit it via radio when it exceeds a threshold. The whole concept is obvious "to those skilled in the art."—MK

6,626,216

43.50.Lj PNEUMATIC TIRE HAVING HOLLOW PARTICLES IN BASE RUBBER

Akira Minagoshi, assignor to Nokia Corporation
30 September 2003 (Class 152/209.4); filed in Japan 29 June 2000

A method to reduce noise inside a vehicle due to tire-road interaction is described. A tire consists of cap rubber **2A**, which contacts the road surface, attached to a layer of base rubber **2B**. Hollow particles, of diameter

40–200 μm , are mixed in the base rubber and have a volume fraction of 5% to 20%. Details regarding the effects of material selection, particle diameter, and volume fraction on road handling ability and road noise are provided.—KPS

6,600,408

43.50.Lj SOUND TRANSMISSION DEVICE FOR A MOTOR VEHICLE

Norbert Walter *et al.*, assignors to Mahle Filtersysteme GmbH; Bayerische Motorenwerke Aktiengesellschaft
29 July 2003 (Class 340/384.1); filed in Germany 14 May 1999

A device that is designed to introduce engine noise into the passenger compartment of a car is composed of tube **18** connected to air intake **1** and to chamber **26**, thus forming a Helmholtz resonator. A flexible diaphragm **27**

forms an airtight seal. Appropriate choices of geometrical sizes, as well as damping provided by foam 30, enable suitably high sound levels to be transmitted through the engine firewall with no need for penetrations.—KPS

6,612,106

43.50.Nm SEGMENTED MIXING DEVICE HAVING CHEVRONS FOR EXHAUST NOISE REDUCTION IN JET ENGINES

Ronald L. Balzer, assignor to The Boeing Company
2 September 2003 (Class 60/204); filed 30 March 2001

Jet noise from commercial aircraft may be reduced by means of serrated trailing edges on the exhaust nozzles of both the combustor and bypass ducts. In contrast to other designs, this one utilizes rounded rather than sharp serrations. This is said to minimize the generation of unwanted high-frequency noise while improving the desired low-frequency attenuation.—KPS

6,615,576

43.50.Nm TORTUOUS PATH QUIET EXHAUST EDUCTOR SYSTEM

Yogendra Y. Sheoran *et al.*, assignors to Honeywell International Incorporated
9 September 2003 (Class 60/39.5); filed 21 January 2002

Reduction of noise radiated from auxiliary power units commonly found on commercial jet aircraft is achieved via several means. Line-of-

sight from the combustor is blocked, eductor mixing duct 230 and exhaust duct 232 are acoustically treated in the baffled sidewall, and a multi-lobed suppressor is provided at the exhaust exit.—KPS

6,805,633

43.55.Pe GAMING MACHINE WITH AUTOMATIC SOUND LEVEL ADJUSTMENT AND METHOD THEREFOR

Marvin Arthur Hein, Jr. *et al.*, assignors to Bally Gaming, Incorporated
19 October 2004 (Class 463/35); filed 7 August 2002

A system and method are described for automatically adjusting the sound volume of a gaming machine to an appropriate level based on the ambient noise level. The gaming machine may implement an open-loop control algorithm when the machine's sound output is inactive as determined, e.g., by software, or by analyzing samples from a soundboard. A closed-loop control algorithm may be implemented while the gaming machine is active. Alternatively, the machine may implement only an open-loop algorithm that provides volume adjustment only when the machine's sound output is inactive, in which case the adjusted volume is maintained through an active period, then adjusted again during the next inactive period. A saturation back-off feature prevents the sound level of the gaming machine from escalating to a maximum, saturation level.—DRR

6,815,044

43.55.Ti MULTILAYER PANEL WITH AN IMPROVED NOISE DAMPING

Klaus Boock, assignor to Airbus Deutschland GmbH
9 November 2004 (Class 428/172); filed in Germany 15 July 2002

The slots in the core section of this multilayer panel are cut in a curved layout, rather than in typical parallel rows. Also, the depth of the slots varies along their length. In this manner, the panel, which might be used as a cabin divider for a vehicle, has improved transmission loss properties.—CJR

6,796,671

43.58.Wc CONTACT ACTIVATED SOUND AND LIGHT GENERATING NOVELTY FOOD CONTAINERS

Elliot A. Rudell *et al.*, assignors to Rudell Design
28 September 2004 (Class 362/101); filed 21 May 2003

Starting from the fundamental concept of using two electrodes and a conducting comestible, the inventors propose all numbers of different containers that generate light and/or sound.—MK

6,809,634

43.58.Wc BUZZER-DRIVING APPARATUS

Hideaki Uemura and Kenji Wakana, assignors to Sumitomo Wiring Systems, Limited
26 October 2004 (Class 340/384.73); filed in Japan 25 April 2001

It is well known that any electromechanical device, including buzzers, can be connected to the output of a microcomputer. So, it is not surprising that a single-bit output can control the pitch of a buzzer through its duty cycle, is it? Apparently the authors disagree.—MK

6,798,369

43.58.Wc PRECISION, WIDE BAND PULSE WIDTH MODULATOR FOR DIGITAL TO ANALOG CONVERSION

Charles F. Weber, assignor to Visteon Global Technologies, Incorporated
28 September 2004 (Class 341/144); filed 8 August 2003

Designed for the automotive electronics market, the sound conversion circuit has pulse width modulators 23–26 (internal to microprocessor 19).

These are summed at node 32 and simply filtered as shown. Simple, crude, but effective.—MK

6,813,363

43.66.Ts PROCEDURE FOR SETTING A HEARING AID, AND HEARING AID

Andi Vonlanthen, assignor to Phonak AG
2 November 2004 (Class 381/313); filed in the World IPO
14 October 1999

Each microphone of a two-microphone directional system used in a hearing aid is normally designated to be a front or rear microphone. The outputs of the microphones connecting to the signal processor in the directional system must be configured to have the axis of directionality pointing forward whether the hearing aid is worn in the left or right ear. A switching

network is implemented under fitting software control to adjust the effective position of the microphones for use in either left or right hearing aids, thus enabling a single universal microphone configuration to be manufactured.—DAP

6,813,364

43.66.Ts ELECTRIC/ACOUSTIC TRANSDUCER MODULE, IN-EAR HEARING AID AND METHOD FOR MANUFACTURING AN IN-EAR HEARING AID

Andi Vonlanthen, assignor to Phonak AG
2 November 2004 (Class 381/322); filed in the World IPO
16 June 1999

A resilient transducer isolator system is described for keeping the loudspeaker floating, preventing it from touching the hearing aid housing. Low-frequency response is enhanced by additional ports to the isolator gap from behind the diaphragm of the loudspeaker. The system permits automatic

insertion of the transducer module into the hearing aid housing. An acoustically transparent membrane prevents debris from obstructing the hearing aid output and also helps to acoustically seal the transducer output from the rest of the hearing aid.—DAP

6,815,434

43.66.Vt METHODS FOR TREATING HEARING LOSS

Jonathan Kil and Eric D. Lynch, assignors to Sound Pharmaceuticals Incorporated
9 November 2004 (Class 514/58); filed 3 January 2003

Each of the methods described in the patent document consists of the step of administering to a subject an amount of an otoprotectant composition reportedly able to ameliorate hearing loss. In some embodiments, the otoprotective composition consists of a pharmaceutically effective amount of at least one glutathione peroxidase mimic (i.e., a composition comprising enselen). In some embodiments, among others, the otoprotective composition consists of a supposedly pharmaceutically effective amount of (a) at least one glutathione peroxidase mimic and (b) at least one glutathione or glutathione precursor (e.g., a composition comprising allopurinol and N-acetyl-cysteine).—DRR

6,768,803

43.72.Ew METHOD AND APPARATUS FOR SELECTIVE ACOUSTIC SIGNAL FILTERING

Gilles Duhamel, assignor to Sonomax Hearing Healthcare Incorporated
27 July 2004 (Class 381/372); filed 20 March 2000

Diaphragm 112 is excited by sound entering enclosure 100 through port 102 from sound source 124. Magnet 114 is attached to diaphragm 112.

Passive and/or active components in load **110** and connected through electrical port **106** can shape the response of induction coil **116** which in turn couples to **112** through **114**. Thus, the sound emanating from acoustic port **104** can be further modified from that of the original. Since items **100**, **102**, **104**, and **116** are present in many hearing aids, the patent describes an additional measure of frequency response modification that can be added to the aid.—NAS

6,813,490

43.72.Ew MOBILE STATION WITH AUDIO SIGNAL ADAPTATION TO HEARING CHARACTERISTICS OF THE USER

Heikki Lang *et al.*, assignors to Nokia Corporation
2 November 2004 (Class 455/414.1); filed 17 December 1999

The real novelty proposed in this patent is a system that is promised to custom enhance a speech signal for the benefit of a user whose audiometric profile (or some set of parameters specifying individual hearing ability) is known. The authors propose to make speech more intelligible by transposing the spectrum of sounds to a frequency range that can be heard by the user, while keeping the essential frequency relations among formants intact. To those well-versed in the art, such a proposal is recognizable as a likely pipe dream and, as is typical of such, the patent fails to provide any implementable (or even meaningful) indication of just how such a miraculous speech frequency transposition is to be accomplished. The patent spends a great deal of space detailing how such a system could be integrated into a mobile user station, relegating the all-important modification of the speech signal to a black box in the diagrams. The best that can be said here is that certainly the goal of the patented novelty is a laudable one. It is surprising that an unattained goal has been patented.—SAF

6,810,378

43.72.Ja METHOD AND APPARATUS FOR CONTROLLING A SPEECH SYNTHESIS SYSTEM TO PROVIDE MULTIPLE STYLES OF SPEECH

Gregory P. Kochanski and Chi-Lin Shih, assignors to Lucent Technologies Incorporated
26 October 2004 (Class 704/258); filed 24 September 2001

Explicitly based on the methods employed by human mimics of the speech of other humans, this patent describes a system using a database of templates controlling patterns of fundamental frequency, amplitude characteristics, etc. The method selects templates matching the characteristics of a particular speaker and uses these templates to generate synthesized speech mimicking the speaker. Some of the relevant information is incorporated into the patent by reference to another patent application, which at present does not appear in patent databases.—HRJ

6,813,604

43.72.Ja METHODS AND APPARATUS FOR SPEAKER SPECIFIC DURATIONAL ADAPTATION

Chi-Lin Shih and Jan Pieter Hendrik van Santen, assignors to Lucent Technologies Incorporated
2 November 2004 (Class 704/260); filed 13 November 2000

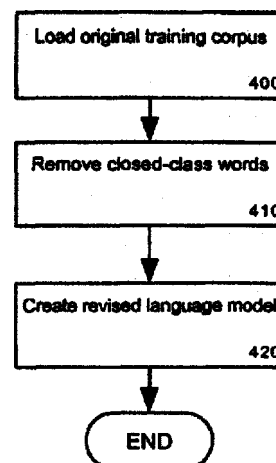

The durational patterns of different people's speech can vary in non-uniform ways—different speakers will have different durations for different speech sounds, and vary these durations to a different extent depending on speech rate, sentence structure, etc. This patent describes a method for determining an individual's durational characteristics for different sounds, modeling those characteristics, and adapting a text-to-speech system's durational patterns to follow an individual speaker's model.—HRJ

6,772,116

43.72.Ne METHOD OF DECODING TELEGRAPHIC SPEECH

James R. Lewis, assignor to International Business Machines Corporation
3 August 2004 (Class 704/231); filed 27 March 2001

Decoding telegraphic speech such as newspaper headlines requires different speech recognition techniques than conventional methods used to recognize speech that contains closed class words such as "a" or "the."

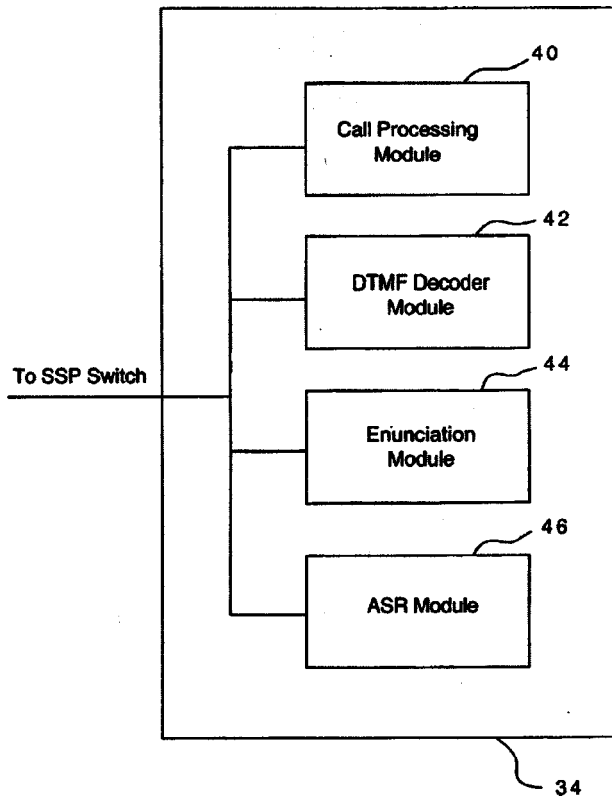

Described is a method for selectively applying telegraphic language models to user-spoken utterances in order to improve decoding accuracy.—DAP

6,778,640

43.72.Ne NETWORK AND METHOD FOR PROVIDING A USER INTERFACE FOR A SIMULTANEOUS RING TELECOMMUNICATIONS SERVICE WITH AUTOMATIC SPEECH RECOGNITION CAPABILITY

Zeeman Zhang and Joseph Knoerle, assignors to BellSouth Intellectual Property Corporation
17 August 2004 (Class 379/88.01); filed 9 August 2000

A speech recognition system allows telecommunications users to utilize advanced calling features by speaking predetermined voice commands over either landline or wireless telephones rather than having to dial numerical codes. A switch detects triggering events and routes the communications

to an intelligent resource server that contains speech recognition capability and an enunciation module that produces audible prompts and responses.—DAP

6,778,641

43.72.Ne TELEPHONE INDEPENDENT PROVISION OF SPEECH RECOGNITION DURING DIAL TONE AND SUBSEQUENT CALL PROGRESS STATES

Paul Andrew Erb, assignor to Mitel Knowledge Corporation
17 August 2004 (Class 379/88.01); filed in the United Kingdom
13 September 2000

A speech recognition engine resource is allocated automatically during calls from telephone device users with no additional intervention by the user.—DAP

6,785,654

43.72.Ne DISTRIBUTED SPEECH RECOGNITION SYSTEM WITH SPEECH RECOGNITION ENGINES OFFERING MULTIPLE FUNCTIONALITIES

James Cyr *et al.*, assignors to Dictaphone Corporation
31 August 2004 (Class 704/270.1); filed 30 November 2001

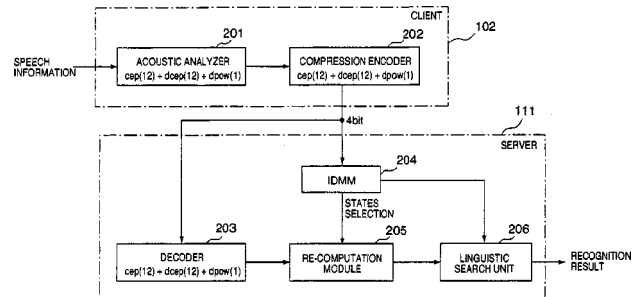

Processed speech inputs are stored until they are forwarded to one of several speech recognition engines. There are several servers performing different functions in each speech recognition engine, each of which can be activated when needed or deactivated when not in use. As more users are added, the distributed system is said to provide more optimal performance as the load increases as compared to a central processing facility.—DAP

6,813,606

43.72.Ne CLIENT-SERVER SPEECH PROCESSING SYSTEM, APPARATUS, METHOD, AND STORAGE MEDIUM

Teruhiko Ueyama *et al.*, assignors to Canon Kabushiki Kaisha
2 November 2004 (Class 704/270.1); filed in Japan 24 May 2000

To minimize the amount of data transfer between a client and a server, speech parameters are compression-encoded before transfer to the server.

After 25-dimensional speech parameters are produced by an acoustic analysis, they are quantized and encoded into compressed parameters at four bits per dimension per frame.—DAP

6,435,933

43.75.Ef GAME CALL APPARATUS

Robert E. Browne, Sharon, Tennessee
20 August 2002 (Class 446/207); filed 20 November 2001

This well written disclosure illustrates how a capped reed (ala Krumhorn) can be used as a duck or goose call. Standard modern woodworking

construction is used throughout: o-rings, acrylic bodies, and plastic reeds.—MK

6,791,022

43.75.Gh STRINGED MUSICAL INSTRUMENT

Philip Shepard Green, Palo Alto, California
14 September 2004 (Class 84/731); filed 25 February 2002

Travelling with a guitar can be inconvenient. This invention is a portable, decomposable electric guitar. As shown in the figure, note how the body is shaped like an acoustic body. The support arm 20 allows the sides 10 and 15 to be connected. The connecting rod 30 is not connected to a

piston but adds stiffness. The fretboard and string tensioners are affixed via 280. Lacking a body resonance, the sound must be electronically processed.—MK

6,800,797

43.75.Gh METHOD AND APPARATUS FOR PRODUCING ACOUSTICAL GUITAR SOUNDS USING AN ELECTRIC GUITAR

Henry Martin Steiger III, Phoenix, Arizona
5 October 2004 (Class 84/267); filed 15 February 2002

Once again, we see an electric guitar trying to masquerade as an acoustic guitar. The inventor wants to use the hollow body to supply body

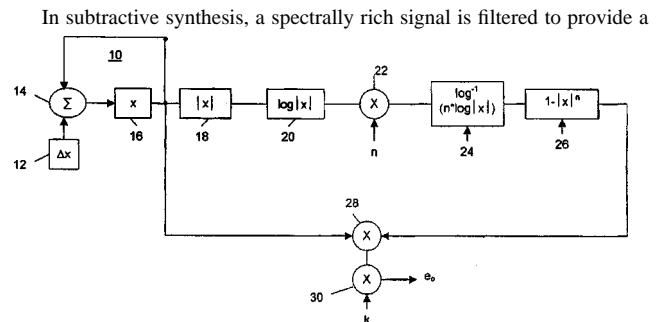

resonance but it's filled with the mechanical strummer 18 and loudspeakers 40. Note the use of a keyboard 31 rather than frets.—MK

6,806,413

43.75.Wx OSCILLATOR PROVIDING WAVEFORM HAVING DYNAMICALLY CONTINUOUSLY VARIABLE WAVESHAPE

Robert Chidlaw and Ralph Muha, assignors to Young Chang Akki Company, Limited
19 October 2004 (Class 84/660); filed 31 July 2002

palette of interesting timbres. The proposed generator is $y = x \times (1 - x^n)$. As shown in the figure, this can be done via table lookup.—MK

6,809,673

43.75.Yy MULTI-CHANNEL CIRCUIT WITH CURRENT STEERING DIGITAL TO ANALOGUE CONVERTERS WITH MINIMIZED CROSSTALK

Anthony Scanlan and John Patrick Purcell, assignors to Analog Devices, Incorporated
26 October 2004 (Class 341/144); filed 10 October 2002

To isolate the current switches in a digital-to-analog converter, it is "standard operating procedure" to provide external pins for decoupling capacitors (providing on-chip capacitors would be prohibitively expensive). The inventors present an alternative—the use of cascode switches connected to the power rails. The gate capacitance will provide some feedthrough but this is not analyzed or discussed.—MK

6,796,943

43.80.Qf ULTRASONIC MEDICAL SYSTEM

Takashi Mochizuki, assignor to Aloka Company, Limited
28 September 2004 (Class 600/437); filed in Japan 27 March 2002

The intent of this ultrasonic system is to locate tumors so that they can be treated by radiation in an accurate fashion. The ultrasonic diagnostic apparatus 12 sends echo data to a host controller 20. In the host controller, a probe coordinate operation unit computes the coordinates of 3-D probe 10

using x-ray source 18 as a reference position. A tissue coordinate operation unit computes the coordinates of tumor 30 using the probe as a reference origin. The tumor coordinates are relayed to the x-ray irradiation unit 78, so that the tumor is targeted and irradiated.—DRR

6,802,813

43.80.Qf METHODS AND APPARATUS FOR MONITORING AND QUANTIFYING THE MOVEMENT OF FLUID

Ernest G. Schutt, San Diego, California
12 October 2004 (Class 600/454); filed 23 May 2003

A methodology is ostensibly to be provided for monitoring and quantifying the movement of fluid in a target region. Generally, an imaging agent is introduced into a target region through fluid flow. The imaging agent in the target region is then disrupted using appropriate methods, such as the application of ultrasonic energy. As fluid flow brings undisrupted imaging agent into the target region, the rate of accumulation is monitored and quantified, thereby providing the exchange rate and flow rate of the fluid in the target region. This method is said to be useful for medical applications such as determining the flow rate of blood in an organ or tissue.—DRR

43.80.Sh APPARATUS FOR MEASURING HEMODYNAMIC PARAMETERS

Richard T. Redano, assignor to Neutrino Development Corporation
9 November 2004 (Class 600/454); filed 27 April 2002

Apparently intended as an alternative to Viagra, this device is aimed at treating vasculogenic erectile dysfunction that results from inadequate blood flow into the penis. The first step of the method is coupling an ultrasound source to the target. The ultrasound source is coupled to a lesion-free region of the penile outer surface. The second step of the method is transmitting ultrasound energy into the corpora cavernosum at a sufficient frequency and intensity to increase hemodynamic flow. The frequency applied is a function of the depth of desired penetration into the corpora cavernosum.—DRR

43.80.Vj ULTRASOUND IMAGING WITH CONTRAST AGENT TARGETED TO MICROVASCULATURE AND A VASODILATOR DRUG

Morten Eriksen *et al.*, assignors to Amersham Health AS
2 November 2004 (Class 424/9.52); filed in the United Kingdom
21 October 1997

A combination of an ultrasound contrast agent and a vasodilator drug is used. The contrast agent accumulates in concentrations related to the regional rate of tissue perfusion. The vasodilator drug enhances the difference between normally perfused and underperfused tissue.—RCW

6,814,701

43.80.Vj METHOD AND APPARATUS FOR ULTRASOUND DIAGNOSTIC IMAGING

Tadashi Tamura, assignor to Aloka Company, Limited
9 November 2004 (Class 600/443); filed 16 April 2003

Speckle noise in ultrasound images is reduced by forming overlapping sector images from different apexes and combining the images to produce a compound image.—RCW

LETTERS TO THE EDITOR

This Letters section is for publishing (a) brief acoustical research or applied acoustical reports, (b) comments on articles or letters previously published in this Journal, and (c) a reply by the article author to criticism by the Letter author in (b). Extensive reports should be submitted as articles, not in a letter series. Letters are peer-reviewed on the same basis as articles, but usually require less review time before acceptance. Letters cannot exceed four printed pages (approximately 3000–4000 words) including figures, tables, references, and a required abstract of about 100 words.

An artificial neural network approach for predicting architectural speech security (L)

(Received 26 August 2004; revised 6 January 2005; accepted 6 January 2005)

Signal-to-noise type measures have been developed for predicting architectural speech privacy and speech security, which is required to accurately rate the probability of a listener outside a room being able to overhear conversations from within the room. However, these measures may not be ideal for speech security situations. In the present work, an approach that uses the artificial neural networks to directly represent the functional relationship between the octave band (250 Hz–8 kHz) S/N ratios and the speech intelligibility score and security thresholds has been investigated. The artificial neural network approach provides a direct and accurate method for predicting the speech intelligibility score and security thresholds. © 2005 Acoustical Society of America.

Pages: 1709–1712

I. INTRODUCTION

Speech security can be described on three different levels. The first level would be when only a very small percentage or none of the overheard words is intelligible. The second level is when no words are intelligible and it is often still possible to recognize the cadence or rhythm of the speech. Finally, the highest level of speech security would be when all speech sounds from the adjacent space are completely inaudible.¹ Speech privacy and speech security have been related to signal-to-noise (S/N) type measures, where the signal is the speech from the adjacent space. The simplest measure is the difference of A-weighted speech and noise levels. More sophisticated measures such as the Articulation Index (AI) (Ref. 2) and its more recent replacement, the Speech Intelligibility Index (SII),³ are known to be better related to speech intelligibility within rooms. However, Gover and Bradley¹ have shown that SII and AI cannot be used to describe conditions for high levels of speech security which would correspond to acoustical conditions below $SII=0$, where SII is not defined. The difference in A-weighted levels is not limited in this way but it is much less accurately related to intelligibility scores. A more successful measure is the SII-weighted S/N ratio, which is a weighted sum of one-third-octave-band S/N ratios using the same frequency weightings as the SII measure. Although the SII-weighted

S/N ratio predicts the intelligibility score and threshold reasonably well, the S/N loudness ratio provides a more accurate estimation of the thresholds of cadence and audibility.¹

In the present work, an approach that uses the artificial neural networks (ANNs) to directly represent the functional relationship between the octave band (250 Hz–8 kHz) S/N ratios and the speech intelligibility score and security thresholds has been investigated. The objectives of the ANNs are to predict (a) the speech intelligibility score, namely the percentage of words correctly identified by each individual; (b) the intelligibility threshold, namely the percentage of listeners able to correctly identify at least one word; (c) the ca-

TABLE I. Ranges of input variables.

Input variables	Range of input variables for predicting the intelligibility scores and the intelligibility threshold		Range of input variables for predicting the cadence threshold and the audibility threshold	
	Minimum dB	Maximum dB	Minimum dB	Maximum dB
S/N Ratio at 250 Hz	-34.8	6.2	-34.8	-8.3
S/N Ratio at 500 Hz	-30.2	13.1	-30.2	-2.3
S/N Ratio at 1 kHz	-32.7	1.3	-32.7	-15.7
S/N Ratio at 2 kHz	-28.2	7.1	-28.2	-1.8
S/N Ratio at 4 kHz	-27.4	10.0	-21.8	0.5
S/N Ratio at 8 kHz	-23.2	8.7	-16.6	-6.3

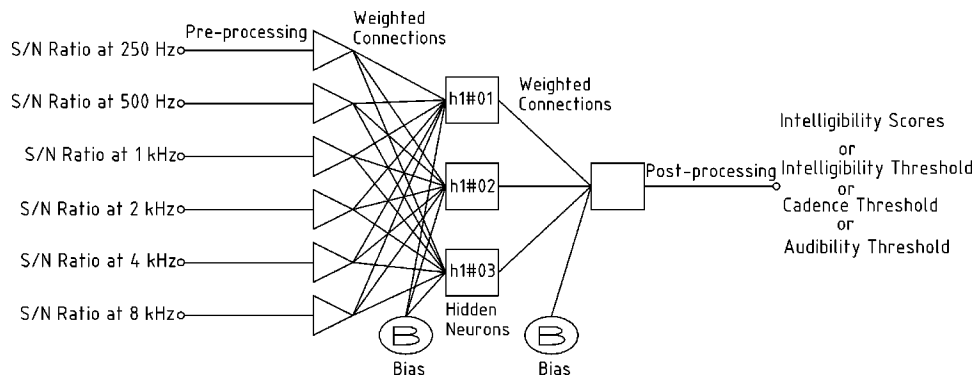

FIG. 1. Illustration of a three-layer feed-forward artificial neural network.

dence threshold, namely the percentage of listeners able to detect the cadence of the speech; and (d) the audibility threshold, namely the percentage of listeners able to hear the presence of the speech.

The ANN approach provides a direct and accurate method for predicting the speech intelligibility score and security thresholds. ANNs are inherently capable of representing nonlinear systems. They learn from historical data and model input–output functional relationships. The history and theory of ANNs, their advantages and shortcomings in applications, and their future utility have been presented elsewhere^{4–6} and will not be presented here. A brief overview of how ANNs operate is presented by Nannariello *et al.*⁷ and Li *et al.*⁸

II. DATABASE FOR ANN MODELS

Two speech intelligibility and security experiments were carried out by Gover and Bradley¹ at the Institute for Research in Construction (IRC), National Research Council Canada (CNRC). In the first intelligibility experiment (intelligibility scores and the intelligibility threshold), 36 subjects each listened to 340 test sentences. Subjects were then divided into two groups, 19 “better” subjects and 17 “worse” subjects, in accordance with their mean intelligibility scores across all 340 sentences. A follow-up experiment intended to determine not only the intelligibility score and the intelligibility threshold but also the thresholds of cadence of the speech and audibility of any speech sounds. In this second experiment the 19 better subjects from the first experiment each listened to 160 sentences. Details of these two experiments are presented by Gover and Bradley.¹

The results of 19 better subjects in the above two experiments constitute the database for the ANN models in the present work. The 9500 [19×(340+160)] individual intelligibility score test cases were used as the database for predicting the intelligibility score. Of the 9500 cases, 7600 were used for training, 950 for verification, and 950 for testing. All the sentences in the first and second experiments, *viz.*, 500 (340+160) sentences (cases), were used as the database for predicting the intelligibility threshold. Of the 500 cases, 310 were used for training, 95 for verification, and 95 for testing. For predicting the cadence threshold and the audibility threshold, the 160 sentences (cases) in the second experiment were used as the database. Of the 160 cases, 128 were used for training, 16 for verification, and 16 for testing.

III. INPUTS AND OUTPUTS OF ANN MODELS

The inputs of the ANN models for all four prediction situations are the octave band (250 Hz–8 kHz) S/N ratios, that is to say, the difference in the transmitted speech level and the background noise level at each octave frequency band from 250 Hz to 8 kHz. The range of the input variables for predicting the intelligibility score and the intelligibility threshold when considering both experiments is different from that for predicting the audibility and the cadence thresholds when accounting for only the second experiment. Table I provides the range of each input variable of the four ANN models. The outputs of the ANN models are the intelligibility score, the intelligibility threshold, the cadence threshold, and the audibility threshold, and are within the range of 0%–100%.

IV. ARCHITECTURE OF ANN MODELS AND PROCEDURES OF ANN ANALYSIS

Figure 1 illustrates the three-layer feed-forward ANN architecture applied in the present work. One hidden neuron layer, with three hidden neurons, was used. The ANN analysis was undertaken using STATISTICA Neural Networks.⁹ The weights, which were initialized to uniformly distributed random values using the “uniform method,” were adjusted by using “back propagation” and “conjugate gradient” algorithms to minimize the prediction error during the training. Conditions were set within the STATISTICA Neural Networks program by altering the model’s parameters. “Early stopping” and “Weigend weight regularization” techniques were used to control overfitting. Training of ANNs was stopped when the rms error of the verification set could no longer be improved. The test set was used to independently check the performance of the network when an entire network design procedure was completed.

V. MODUS OPERANDI OF ANN MODELS

For the present work, the preprocessing of the inputs involves scaling input values to an appropriate range suitable for use in the ANN. Input values are multiplied by a scale factor, followed by the addition of a shift factor. Table II provides the shift and scale factors to input variables of each ANN model. These factors are automatically generated by the scaling algorithm of the STATISTICA Neural Networks.⁹

Each preprocessed neuron is multiplied by a scalar weight connecting the first-layer neurons to the hidden-layer neurons. At each neuron within the hidden layer, the weighted inputs are summed and bias value is subtracted

from the summed weighted inputs. The resulting value is passed through a nonlinear activation function, in this work, sigmoidal logistic function ($1/(1+e^{-x})$, where x is the resulting value). Table III provides the weights and biases linked to hidden neurons of each ANN model attained by training.

The output value of each hidden neuron is multiplied by the scalar weights for each connection between the hidden layer and the output neuron. The weighted outputs are summed and a bias value is subtracted from the sum to produce a single output value. Table IV provides the weights and biases linked to the output neuron of each ANN model attained by training.

The output is postprocessed by subtracting the shift factor, followed by division by the scale factor. In the present work, the shift factor and scale factor are 0 and 1, respectively, in all four situations as the range of outputs has already been normalized between 0 and 1 in the original database.

Work carried out by Nannariello *et al.*¹⁰ and Xu *et al.*¹¹ presented a method of how to embed an ANN model into a standard spreadsheet. The same procedure can be adopted with those details provided in Table II–Table IV.

VI. RESULTS OF ANN ANALYSIS

Table V presents the statistical analysis results based on the ANN models specified in the above section. In a regression problem, the standard deviations (S.D.) of both the prediction error and original output data are important and they can be related by the S.D. ratio. The S.D. ratio in a regression problem is the ratio of the S.D. of the prediction error to

TABLE IV. Weights and biases to the output neuron of each ANN model.

that of the original output data (an S.D. ratio of 0.1 is considered an excellent fit of the data, and an S.D. ratio of 1.0 is a poor fit).⁹ The correlation coefficients R^2 (the “coefficient of determination”) of the ANN predictions over the entire data sets for the intelligibility scores, intelligibility threshold, cadence threshold, and audibility threshold were 0.773, 0.929, 0.967, and 0.942, respectively. For comparison, in the work of Gover and Bradley,¹ the SII-weighted S/N measure has an R^2 of 0.762 for predicting the intelligibility scores and an R^2 of 0.919 for predicting the intelligibility threshold, and the S/N loudness ratio has an R^2 of 0.956 for predicting the cadence threshold and an R^2 of 0.899 for predicting the audibility threshold.

VII. DISCUSSIONS AND CONCLUSIONS

The present work indicates that the ANN approach provides a direct and accurate method for predicting speech intelligibility scores and security thresholds. The current method for predicting the speech intelligibility and privacy is first to develop a certain index and then relate the index to the subjective scores using a transfer function.^{1–3} The ANN approach can use the S/N ratio information to directly predict the subjective speech intelligibility score and security thresholds. Compared with the previous work¹ that used one-third-octave-band S/N ratios, the ANN approach produced comparable, or better in terms of the audibility threshold, prediction results using only the “octave band” S/N ratios.

Specifics of the ANN models for predicting the speech security and intelligibility scores are also provided in the present work. With this information, ANN models can be embedded into standard spreadsheet applications, thus allowing predictions to be made in a transparent and direct fashion.

Similar investigations that use one-third-octave-band (160 Hz–8 kHz) S/N ratios have also been conducted in the present work. However, the results of the one-third-octave-band analysis were only slightly better than those of the octave-band analysis. This may be due to the information in adjacent one-third-octave bands being highly correlated and therefore not contributing any significant new information to the ANN.

The present work only takes into account the S/N ratios in predicting the architectural speech intelligibility score and security thresholds. Other factors, such as talker gender and voice characteristics, speech material, room characteristics, and so on could be included in the ANN models to investigate the possibility of further improving the prediction accuracy.

(Received 2 August 2004; revised 2 January 2005; accepted 7 January 2005)

Animal studies in basal cochlear regions have shown that basilar-membrane phase curvature (or rate of change of group delay with frequency) is negative around characteristic frequency (CF), but near zero well below CF. This study examined whether psychophysical masking experiments in humans show the same difference between on- and off-CF phase curvature. Masked thresholds were measured for a 2-kHz signal in the presence of harmonic tone complex maskers with a fundamental frequency of 100 Hz, band-limited between 200 and 1400 Hz (off-frequency masker) or between 1400 and 2600 Hz (on-frequency masker). The results from four normal-hearing listeners are consistent with predictions from animal physiological data: negative phase curvature is found for the on-frequency masker, whereas the phase curvature for the off-frequency masker is near zero. The method and results provide a strong test for the temporal response of computational models of human cochlear filtering. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1863012]

I. INTRODUCTION

The amount of masking produced by a harmonic tone complex depends strongly on the phase relationships between the individual masker components (Smith *et al.*, 1986; Kohlrausch and Sander, 1995). The most commonly used stimuli in such experiments have been Schroeder-phase complexes (Schroeder, 1970), which have a group delay that changes linearly with frequency, producing a constant phase curvature and a time waveform that can be described as a repeating linear frequency glide. A modification of the original Schroeder equation, provided by Lentz and Leek (2001), which describes the phase of each component, is given by

$$\theta_n = C \pi n(n-1)/N, \quad (1)$$

where n is the component number, N is the total number of components, and C is a multiplicative constant. Positive (m_+) and negative (m_-) Schroeder-phase stimuli correspond to $C=1$ and $C=-1$, respectively, and a sine-phase (or cosine-phase) complex can be generated using $C=0$. Positive and negative Schroeder-phase complexes have very similar time waveforms,¹ but can produce differences in masked threshold that exceed 20 dB. The current explanation is that the positive phase curvature of the m_+ waveform interacts with the negative curvature of the basilar-membrane filter to produce a waveform with near-zero phase curvature, such as a sine-phase complex. The resulting highly modulated temporal envelope allows for signal detection at points in time with low signal-to-masker ratios. In contrast, the

negative phase curvature of the m_- waveform interacts with the basilar membrane to produce a waveform that still has a relatively flat temporal envelope, resulting in higher signal-to-masker ratios at threshold [Kohlrausch and Sander (1995); see also Oxenham and Dau (2001a), for the possible role of peripheral compression in determining thresholds in simultaneous masking]. The phase curvature of the complex is given by

$$\frac{d^2\theta}{df^2} = C \frac{2\pi}{Nf_0^2}, \quad (2)$$

where N is the total number of components in the complex, and f_0 is the fundamental frequency (Kohlrausch and Sander, 1995).

Using these complexes, it has been possible to derive estimates of the phase curvature of cochlear filtering at characteristic frequencies (CFs) between 125 and 8000 Hz (Oxenham and Dau, 2001b). The reasoning is that the masker phase curvature producing the lowest signal threshold is the one that produces the most highly modulated temporal envelope after cochlear filtering (Kohlrausch and Sander, 1995), which tends to occur when the filtered waveform has a phase curvature of zero. Thus, minimum threshold will be reached when the phase curvature of the masker is equal and opposite to the phase curvature of the cochlear filter at the CF corresponding to the signal frequency (Oxenham and Dau, 2001b). Physiological studies of basilar-membrane responses to Schroeder-phase stimuli have confirmed the basic pattern of expected effects, such as more modulated responses for stimuli with positive phase curvature (Recio and Rhode, 2000; Summers *et al.*, 2003).

Studies so far have used harmonic complexes with constant phase curvature (Smith *et al.*, 1986; Kohlrausch and

^{a)}Electronic mail: oxenham@mit.edu

^{b)}Present address: Center for Applied Hearing Research, Acoustic Technology, Ørsted-DTU, Technical University of Denmark, DK-2800 Lyngby, Denmark.

Sander, 1995; Carlyon and Datta, 1997; Summers and Leek, 1998; Oxenham and Dau, 2001a, b). By deriving the phase curvature of cochlear filtering from such maskers it is assumed that cochlear filtering can also be approximated as having constant phase curvature. As discussed by Oxenham and Dau (2001b), this assumption is supported by physiological data for frequencies around CF (Shera, 2001). However, at frequencies well below CF, phase curvature tends to zero. In fact the physiological data from animals using CFs of 1 kHz and above suggest that the phase response can be roughly divided into two regions, with negative curvature around CF and zero curvature for frequencies half an octave or more below CF (Shera, 2001). The situation appears to be different in apical regions of the cochlea (at CFs lower than about 1000 Hz), where the phase curvature at CF tends to zero (Oxenham and Dau, 2001b), or possibly even becomes positive (Carney *et al.*, 1999).

The change in phase curvature with frequency observed at high CFs provides an opportunity to further test the hypothesis that changes in masked threshold as a function of masker phase curvature reflect the phase response of cochlear filtering. Specifically, a masker with components around the signal frequency should produce minimum masking when the masker phase curvature is positive and “cancels out” the negative phase curvature of the on-frequency cochlear phase response. In contrast, a masker with components only well below the signal frequency should produce minimum masking when the masker phase curvature is zero, reflecting the fact that the off-frequency cochlear phase curvature is thought to be near zero. This prediction forms the basis of the experiment reported here.

II. METHODS

A. Stimuli

Masked thresholds of a 2-kHz sinusoid were measured in the presence of a harmonic tone complex masker with a fundamental frequency (F_0) of 100 Hz. The masker bandwidth extended from 1400 to 2600 Hz for the on-frequency condition, and from 200 to 1400 Hz for the off-frequency condition. Thus, the masker had the same bandwidth (1200 Hz) and the same total number of sinusoidal components (13) in both conditions. In the on-frequency condition, all masker components had equal amplitudes and the overall (rms) masker level was 73 dB SPL. In the off-frequency condition, the masker spectrum was shaped with a -6 dB/oct slope, such that each component was attenuated relative to the adjacent lower component, to reduce the influence of possible edge effects produced by the highest-frequency masker component (Kohlrausch and Houtsma, 1992). The overall (rms) off-frequency masker level of 88 dB SPL was 15 dB higher than in the on-frequency condition, so as to produce similar signal thresholds in both conditions. The signal had a total duration of 260 ms, including 30-ms raised-cosine onset and offset ramps, and was temporally centered within the masker, which had a total duration of 320 ms, including 10-ms raised-cosine onset and offset ramps. The starting phase of the signal was randomized from trial to trial. The starting phases of the masker components

were selected according to the modification of Schroeder's (1970) equation, as shown in Eq. (1) (Lentz and Leek, 2001), with C values ranging from -1 to 1 in steps of 0.25 .

The stimuli (masker and signal) were presented to the left ear of each subject. A contralateral Gaussian noise, band-pass filtered between 1400 and 2800 Hz, was gated synchronously with each masker and presented to the right ear at a spectrum level of 20 dB SPL/Hz. This was to prevent the detection of the signal by the right ear via acoustic or electric crosstalk. In the on-frequency conditions, a pink noise, band-pass filtered between 25 and 1000 Hz, was presented to the left (signal) ear at a level of 44 dB SPL per $\frac{1}{3}$ octave band. This level was chosen to be 25 dB below the level of the masker within the $\frac{1}{3}$ octave around the signal frequency. The purpose of the pink noise was to mask possible distortion products generated by the signal and masker.

Stimuli were generated digitally and played out via a RME DIGI96/8 PAD soundcard and an external SEKD ADSP 2496 PRO digital-to-analog converter at 24-bit resolution and a sampling rate of 32 kHz. The stimuli were then passed through a Behringer HA4600 headphone buffer and presented over Sennheiser HD 580 headphones to listeners seated in a double-walled sound-attenuating booth.

B. Procedure

An adaptive three-interval three-alternative forced-choice procedure was used in conjunction with a two-down one-up tracking rule to estimate the 70.7% correct point on the psychometric function (Levitt, 1971). The masker was presented on each interval and the signal was presented randomly in one of the three intervals with equal probability. Each interval in a trial was separated by an interstimulus interval (ISI) of 500 ms. The intervals were marked on a computer monitor and feedback was provided after each trial. Listeners responded via the computer keyboard or mouse. The initial step size was 8 dB, which was reduced to 4 dB after the first two reversals and then to 2 dB after the next two reversals. Threshold was defined as the mean of the remaining six reversals. At least four threshold estimates were made for each condition. In the very rare case that standard deviation across the four runs was greater than 4 dB, another two estimates were made and the mean of all six was recorded. The conditions were run using a randomized blocked design, with all conditions being presented once before embarking on a repetition of the conditions. The order of presentation of the conditions was selected randomly for each listener and each repetition. Measurements were made in 2-h sessions, including many short breaks. No more than one session per listener was completed in any one day.

C. Listeners

Four listeners (three male, one female—ML) participated. Two were the authors; the other two were students at the University of Oldenburg. The ages of the subjects ranged from 23 to 32 years. All had audiometric thresholds of 15 dB HL or lower at octave frequencies between 250 and 8000 Hz. Subjects AO, SE, and KB had considerable experience in psychoacoustic detection tasks and were familiarized with

FIG. 1. Individual signal thresholds in the presence of the on-frequency (left panel) and off-frequency (right panel) maskers. Error bars denote ± 1 standard deviation across the individual repetitions. In line with predictions, masking minima are reached for a positive phase curvature for on-frequency masker, but are closer to zero for the off-frequency masker.

the present experiment before data were collected. Subject ML had no previous experience in psychoacoustic experiments and received about 2 h of training before data collection started. Subjects KB and ML were compensated for their services on an hourly basis.

III. RESULTS AND DISCUSSION

The individual results are shown in Fig. 1. The left panel shows results with the on-frequency masker; the right panel shows results with the off-frequency masker. Different symbols represent thresholds from different subjects, as shown in the legend, and error bars denote ± 1 standard deviation of the individual estimates. Despite differences in individual thresholds of 10 dB or more, the patterns of results are generally similar across the four subjects. In particular, all four subjects show a minimum masked threshold at a positive C value for the on-frequency masker: AO, KB, and SE show a minimum at around $C=0.5$, while ML shows similar thresholds at $C=0$ and $C=0.25$, with a slightly lower value at 0.25. All four subjects show a minimum at a lower C value for the off-frequency masker: individual minima are either at $C=0$ or $C=-0.25$.

The differences between the on- and off-frequency conditions are seen clearly in a direct comparison of the mean results (Fig. 2). The two curves are fitted sinusoidal functions, as described in Oxenham and Dau (2001b). The minima of the fitted functions were 0.42 and -0.05 for the on- and off-frequency conditions, respectively. The masker curvature at these minima in rad/Hz^2 [as calculated from Eq. (2)] can be normalized into dimensionless units by multiplying by $f_s^2/2\pi$, where f_s is the signal frequency (Oxenham and Dau, 2001b; Shera, 2001). The normalized masker curvature at the minimum of the masking function for the present on-frequency data is 12.9, implying a normalized cochlear filter phase curvature of -12.9 , which is in good agreement with previous estimates at 2000 Hz, using different subjects and different masker F0s and bandwidths, which range between -8 and -16 (Lentz and Leek, 2001; Oxenham and Dau, 2001b). The novel condition tested here involves the off-frequency masker. Here, the estimated curva-

ture using the same signal frequency is close to zero, in clear contradiction to an assumption that curvature remains constant with frequency at a given CF.

Overall, the data support the hypothesis outlined in the introduction:

- (1) Masking patterns for the off-frequency masker produce a minimum at around zero phase curvature, suggesting no phase curvature in the cochlear filter response to stimuli well below CF.
- (2) Masking patterns for the on-frequency masker produce a minimum at a positive masker phase curvature, presumably counteracting the negative phase curvature of cochlear filtering around CF.

A phase versus frequency plot of these data (not shown) is consistent with physiological data of basilar-membrane motion at the basal end of the cochlear, in showing a nearly straight-line section for frequencies half-an-octave or more below CF and a more curved negative-going section for frequencies around CF (de Boer and Nuttall, 1997; Ruggero *et al.*, 1997; Rhode and Recio, 2000; Shera, 2001). The situ-

FIG. 2. Mean signal thresholds, along with fitted sinusoidal functions. Open symbols represent thresholds from the on-frequency condition; filled symbols represent thresholds from the off-frequency condition. Error bars denote ± 1 standard error of the mean across the four subjects. Minima of the fitted functions are reached for C values of 0.42 and -0.05 for the on- and off-frequency conditions, respectively.

ation at signal frequencies well below the one tested here (2000 Hz) is likely to be different, in that the phase curvature tends to zero even in the on-frequency case (Oxenham and Dau, 2001b).

One assumption of our technique is that the masker phase curvature that produces the most modulated temporal envelope is independent of the relative component amplitudes. This assumption is important because component amplitudes can be varied by experimental manipulations as well as by outer-, middle-, and inner-ear filtering. Numerical simulations have confirmed this assumption in all conditions tested so far when the Hilbert envelope is used. However, the assumption does not always hold when measures such as the crest factor (Strickland and Viemeister, 1996) are used directly on the stimulus waveform, rather than the envelope. Although it is universally assumed that signal detection in these situations is based on envelope, rather than raw waveform, properties, we cannot completely rule out some influence of temporal factors not represented in the Hilbert envelope. Empirical tests are required to settle this question, although informal testing has not yet yielded any situations where the phase curvature producing minimum threshold is affected by the relative amplitudes of the masker components.

One potential limitation of the present technique is that it does not allow a detailed view of how the curvature changes with frequency; we have only shown the estimated curvature for two fairly broad sample frequency regions. By using maskers with nonconstant phase curvature, it may be possible to map out changes in curvature with frequency in more detail. However, it may be that inherent measurement errors would swamp more fine-grained effects than those found here. A method for using envelope modulation in the auditory nerve to map out cochlear phase responses has been proposed recently (van der Heijden and Joris, 2003). By using the modulation at the beat frequencies between unequally spaced sinusoids, it was possible to derive a much more detailed phase response even in cochlear regions where the auditory nerve fibers no longer phase-lock to the temporal fine structure. While our technique and that of van der Heijden and Joris (2003) both use aspects of envelope modulation, theirs has the advantage of providing a much more detailed function of phase versus frequency. Unfortunately, there does not seem to be any obvious way of translating their technique into a task suitable for behavioral experiments.

In summary, masked thresholds for a sinusoidal signal in a harmonic tone complex vary with masker phase curvature and masker frequency region as would be predicted from animal physiological studies of basal cochlear mechanics: on-frequency maskers indicate negative phase curvature, while maskers well below the signal frequency indicate near-zero phase curvature. The results suggest that it is possible—to a limited extent—to map out changes in human cochlear phase response with frequency. Such results should provide important tests for computational models of human cochlear filtering.

This work was supported primarily by the National Institutes of Health (Grant No. R01 DC 03909). It was begun while the second author was a visiting scientist at MIT's Research Laboratory of Electronics, and was completed while the first author was a fellow at the Hanse Institute for Advanced Study, Delmenhorst, Germany. We thank Torsten Dau, Van Summers, and an anonymous reviewer for helpful comments on previous versions of this manuscript.

¹If cosines are used as the basis functions, the negative sign in the equation leads to a simple time reversal of the overall waveform. If sines are used as the basis functions (as was done in this study), the negative sign leads to a time-reversal and inverting of the overall waveform. This is because the sine and cosine functions are dot-symmetric and symmetric about zero, respectively.

Design and optimization of a noise reduction system for infrasonic measurements using elements with low acoustic impedance

Benoit Alcoverro^{a)} and Alexis Le Pichon^{b)}

CEA/DASE-LDG, BP12, 91680 Bruyères-le-Châtel, France

(Received 22 July 2002; revised 17 March 2004; accepted 29 March 2004)

The implementation of the infrasound network of the International Monitoring System (IMS) for the enforcement of the Comprehensive Nuclear-Test-Ban Treaty (CTBT) increases the effort in the design of suitable noise reducer systems. In this paper we present a new design consisting of low impedance elements. The dimensioning and the optimization of this discrete mechanical system are based on numerical simulations, including a complete electroacoustical modeling and a realistic wind-noise model. The frequency response and the noise reduction obtained for a given wind speed are compared to statistical noise measurements in the [0.02–4] Hz frequency band. The effects of the constructive parameters—the length of the pipes, inner diameters, summing volume, and number of air inlets—are investigated through a parametric study. The studied system consists of 32 air inlets distributed along an overall diameter of 16 m. Its frequency response is flat up to 4 Hz. For a 2 m/s wind speed, the maximal noise reduction obtained is 15 dB between 0.5 and 4 Hz. At lower frequencies, the noise reduction is improved by the use of a system of larger diameter. The main drawback is the high-frequency limitation introduced by acoustical resonances inside the pipes.

I. INTRODUCTION

A renewed interest in the detection of infrasonic energy in the atmosphere appeared with the CTBT Organization. Associated with seismic, hydroacoustic, and radionuclide monitoring, the infrasound detection systems are dedicated to the monitoring of atmospheric tests. Ever since their progressive installation, these systems have also shown their importance in the monitoring of the environment, through the study of low-frequency acoustic signals of both natural and human origin.

The main problem in the detection of infrasonic waves is the reduction of acoustic background noise related to atmospheric turbulence. One way of attenuating the noise consists of connecting the pressure sensor to spatial acoustic filters. These filters make use of the incoherent structure of the background noise compared with the infrasonic pressure wave (McDonald and Herrin, 1975; Bedard, 1977). The turbulent movement of air close to the ground is complex. In a general way, atmospheric turbulence at a point consists of eddies moved by the wind that set the mass of air in rotation. The largest diameter (D) of the eddy is linked to the frequency of the pressure fluctuations (f) and the wind speed (V) by the well-know relation $f=V/D$. In the case of coherent acoustic waves, the ratio between the propagation velocity of the wind-related noise and the propagation speed of the infrasonic signal is much lower than unity. For a given frequency, this implies that several wavelengths of atmospheric noise exist in the same space occupied by only one wavelength of the acoustic signal. Assuming the wavelength of

the pressure to be measured is large compared with the dimensions of the filtering system, the summation of pressure—comprising both acoustic signal and atmospheric noise—from a spatial array of air inlets leads to a noticeable improvement in the signal-to-noise ratio. In the case of random noise with normal distribution amplitude, the differences of phase between the various points of measurement reduce the amplitude of the noise by a factor equal to the square root of the number of measurement points (Daniels, 1959). In reality, the performance of the filtering system is limited by attenuation and distortion during propagation of the signal in the pipes. In particular, the natural resonance of the system becomes a major disadvantage with increasing dimension of the system.

The majority of existing systems are based on pipes proposed by Daniels (Daniels, 1959). This system is made up of a succession of rigid pipes of increasing diameter, forming a linear array, to which is connected capillary air inlets. A satisfactory signal-to-noise ratio is attained for frequencies lower than 1 Hz. However, linear systems (i.e., with constant attenuation of sound propagation per unit length) exhibit a nonisotropic noise reduction and sensitivity (Noel and Whitaker, 1991). A circular system with a more omnidirectional response is better adapted, such as that proposed by Burridge (1971) and Grover (1971).

A qualitative analysis of measurements from different systems underlines the fact that long linear systems can be replaced by circular systems of a smaller size (Noel and Whitaker, 1991; Grover, 1971). With a diameter of 100 m and for frequencies lower than 0.5 Hz, these systems display performances comparable with the linear system of Daniels. Circular systems have the advantage of showing isotropic noise reduction when the impedance of the air inlets is suf-

^{a)}Electronic mail: benoit.alcoverro@antigone.cea.fr

^{b)}Electronic mail: alexis.le-pichon@cea.fr

ficiently large to allow perfect acoustic summation over the entire circumference of the circle (Burrige, 1971). However, in addition to the problems of maintenance related to the large size of these systems, with particular care to avoid obstructing the air inlets, a major disadvantage is the difference in response between each air inlet for frequencies of the order of 1 Hz as well as the possible resonances induced in the [0.02–4] Hz band.

Other noise reduction systems are based on the use of microporous pipes arranged radially in a circle centered on the microbarometer (Noel and Whitaker, 1991). The performances of a 16-m diameter ring fitted with 96 capillary air inlets and a system with porous pipes arranged in a 25-m cross are comparable. The porous pipe solution is inexpensive and provides a significant improvement of the signal-to-noise ratio in the [0.1–10] Hz frequency band (Haak and de Wilde, 1996). However, the performances of these systems deteriorate rather quickly with time under severe meteorological conditions. The major drawback of the porous pipes and the capillaries are the variability of the physical properties with time under standard weather conditions (prolonged exposure to bad weather and dust). Although this solution is attractive as well as efficient, it is not sufficiently robust to be used under the operational conditions of the CTBT detection networks.

Our aim in this paper is the dimensioning and optimization of a discrete acoustical-mechanical system using elements with low acoustic impedance by using numerical simulations (Alcoverro, 1998). This system presents roughly the same performances obtained with porous pipes. A precise electroacoustic modeling of the system takes into account the frequency response of the acoustical circuits and the sensor coupling effects. A synthetic input pressure is generated by a wind model based on the analysis of the spatial coherence of the background noise as a function of wind speed. These numerical simulations, validated by a limited number of experimental measurements, provide an optimum diameter and number of air inlets in the [0.02–4] Hz frequency band under different wind conditions.

II. ACOUSTIC MODELING OF A DISCRETE MECHANICAL SYSTEM

A. Description of the parameters and dimensioning

This system consists of nonporous pipes and low-impedance air inlets that are directly connected to the microbarometer. The air inlets are composed of open pipes protected by a fine mesh to avoid an obstruction. To maintain isotropic noise reduction, the distribution of the air inlets is made as circular as possible. Such geometry ensures an identical transfer function between each air inlet and the microbarometer (Fig. 1). In order to reduce the complexity of the system, each air inlet is connected to the sensor by two pipes of length L_1 and L_2 and also by means of four primary summation cavities. The measured and calculated improvement in the signal-to-noise ratio is of the order of 15 dB in the [0.1–10] Hz band (Alcoverro, 1998). The diameter of the system depends on the noise reduction expected at low frequency for a given wind speed, as well as on the upper limit

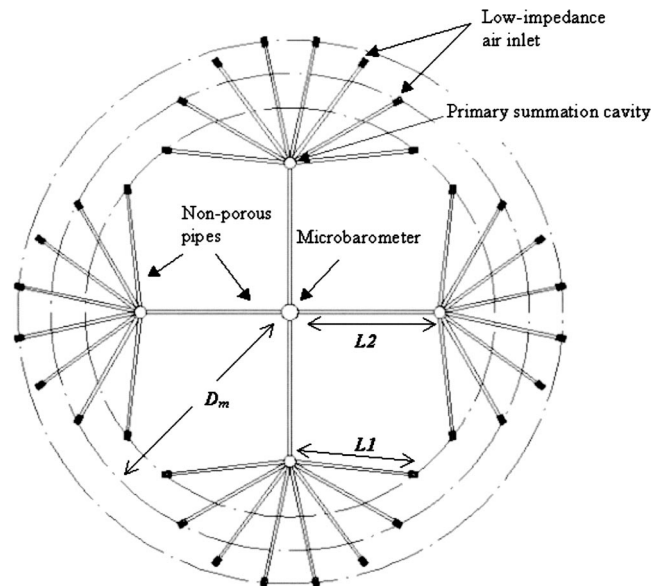

FIG. 1. Discrete mechanical noise reduction system, composed of 32 low-impedance air inlets, arranged in a circle of 16 m mean diameter (D_m) with $L_1=4$ m and $L_2=5$ m. The proposed geometry makes it possible to obtain an identical travel time between each air inlet and the sensor. The distance between the air inlets is always the same. Beyond 1 Hz, the maximum noise reduction is of the order of 15 dB for wind speeds lower than 2 m/s. The first resonance frequency is at 12 Hz.

imposed by the first resonance frequency of the pipes (Sec. IV). A diameter ranging between 10 and 20 m yields a first resonance frequency around 10 Hz, which ensures a flat response in amplitude up to 4 Hz.

For the simulation, we first construct an electroacoustic model from a given geometry (mean diameter and number of air inlets) and the constructive parameters (air entries, pipes, summation cavities, and the model of the microbarometer used). The transfer functions $H_i(\omega)$ linking each air inlet with the pressure measured by the sensor is calculated. The principle of superposition is used to calculate the total response of the system by temporal summation, considering the other air inlets as open. Then, the influences on the amplitude response of the length and diameters of the pipes, the cavity volumes, and the number of air inlets are determined. The noise reduction of a system subjected to a given wind speed is obtained by convolution of the pulse response $h_i(t)$ of all the transfer functions $H_i(\omega)$ with the synthetic wind-noise pressure at each air inlet $w_i(t)$ (Sec. III B). To incorporate the concept of spatial filtering into the model, $h_i(t)$ takes account of the propagation delay (from the air inlet i to a reference point) introduced by the propagation speed of eddies (controlled by the wind speed). The noise reduction is obtained by calculating the spectra ratio of $\sum_i \{h_i(t) * w_i(t)\}$ and the synthetic wind-noise $w_i(t)$ (Sec. IV A).

B. Electroacoustic modeling

The frequency response of the system in amplitude and phase is obtained by calculating the transfer functions $H_i(\omega)$. Figure 2 presents an acoustic analog model of the noise reducer shown in Fig. 1. The elements constituting this model are given in Appendix A, including the air inlet, the

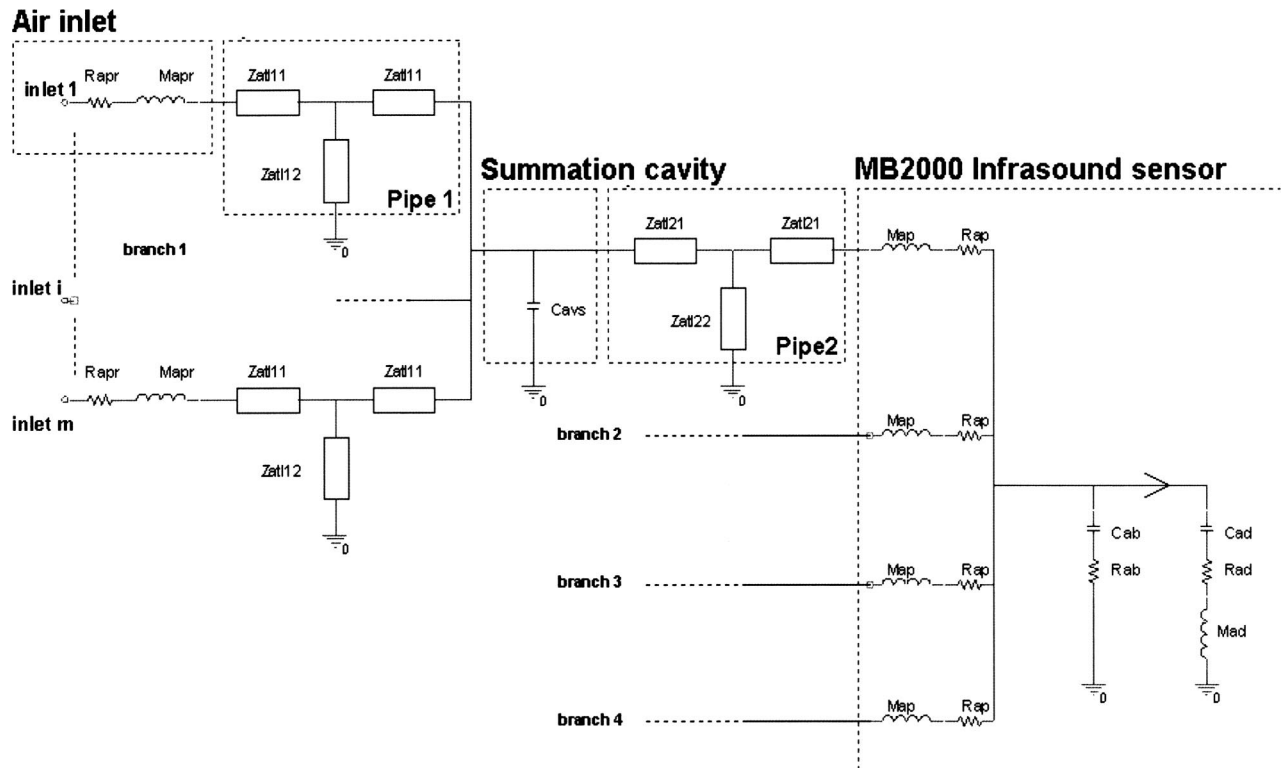

FIG. 2. Electroacoustic model of a noise reducer with 32 air inlets and 4 branches.

pipes, the summation cavity, and the microbarometer used. The method of calculation of the transfer functions is given in Appendix B.

C. Optimization of the constructive parameters

In this section, the frequency response of the noise reduction system is analyzed through a parametric study. Figure 3 summarizes the main effects induced by a change of the following parameters: average diameter $D_m = 2(L_1 + L_2)$ and internal diameter of the pipes $2r_p$, number of air inlets and volume of the summation cavities V_s (the 0 dB reference is the level of excitation provided by the signal applied to each air inlet).

The main results are as follows.

- (i) Figure 3(a) shows several resonances above 1 Hz. These resonances are mainly due to the length of the pipes terminated by a low impedance (pipes are open or emerge into a cavity). The frequency peaks corresponds to the fundamentals and odd harmonics resonances in each elementary pipe. If the impedance at the end of each pipe had a value close to the characteristic impedance of an infinite pipe, namely $\rho c/S$, these resonances could be reduced. With an internal diameter of 15 mm, the value of the characteristic impedance is $2.3 \times 10^6 \Omega \text{A}$ and could be obtained by using a 50-mm length capillary with 2 mm internal diameter. The frequency f_0 of the first resonance is inversely proportional to the average diameter D_m of the system and depends on the sound speed c . f_0 has

been evaluated as

$$f_0 \sim 0.7 \frac{c}{D_m}. \quad (1)$$

- (ii) As shown by Fig. 3(b), any increase in the internal diameter tends to decrease the viscothermic losses, which also amplifies the resonances. On the other hand, there is little change in the resonant frequency (because of the decreasing acoustic mass of the pipe). Using a small diameter increases the risk of obstruction by foreign bodies or condensation. The choice of an internal diameter around 15 mm seems reasonable. This value is very close to the diameter of the air entries on the sensor, allowing a correct acoustic impedance match at the entry to the sensor.
- (iii) Figure 3(c) shows that the frequency of the resonances is unaffected by the number of air inlets. Only the gain of the transfer function is reduced as a function of the number of inlets (about -33 dB for 48 air inlets). After summation of all the measurement points, a signal at 4 Hz is not attenuated (Sec. IV E).
- (iv) Figure 3(d) confirms that the volume of the summation cavities should not exceed 1 l. If this volume is higher, the equivalent capacity of the cavity increases, which tends to decrease the cutoff frequency of the low pass circuit formed by the acoustic mass of the pipes combined with this capacity.

Figure 4 presents the transfer function of the 16-m noise reducer. The amplitude response is uniform up to 5.5 Hz (± 3 dB), while the phase does not vary by more than 10° below

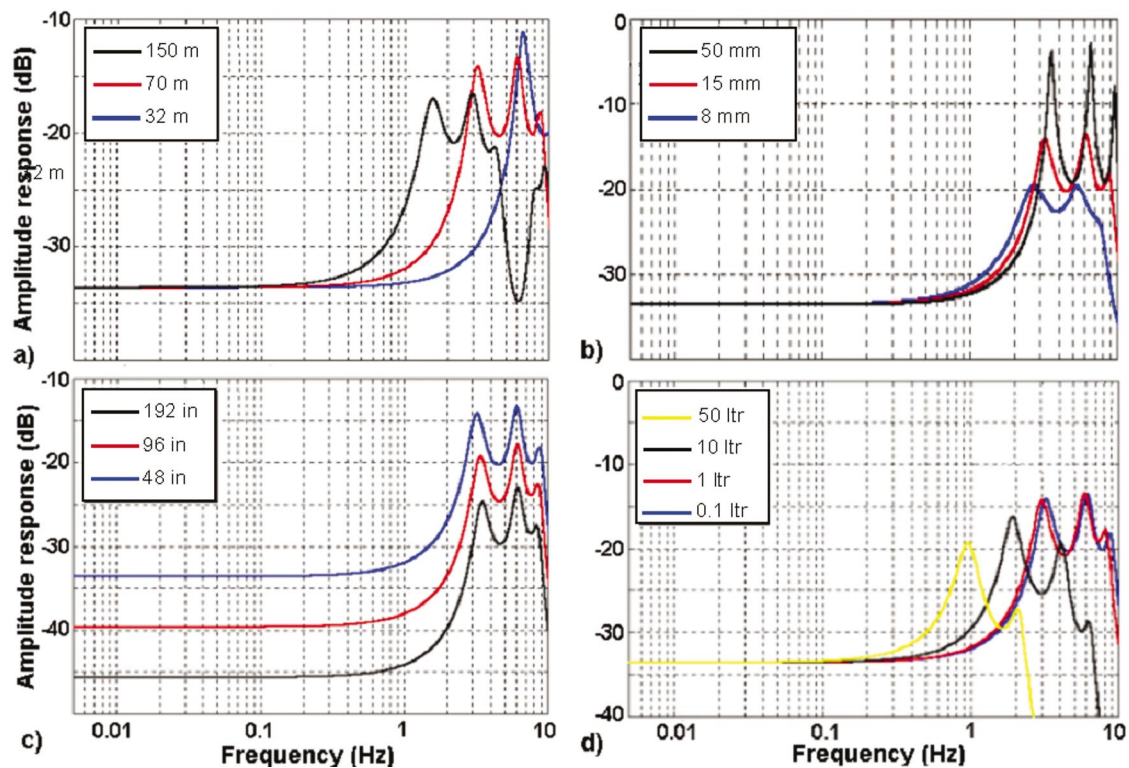

FIG. 3. Effects of the constructive parameters on frequency response. (a) Influence of the pipe length l : system with 48 air inlets and pipes of 15 mm internal diameter. (b) Influence of the internal diameter: 48 air inlets and 70 m length. (c) Influence of the number of air inlets: pipes of 15 mm diameter and 70 m length. (d) Influence of the volume of the summation cavities: 0.1 to 50 l for 48 air inlets and 70 m length.

4 Hz. The performance of such a system is limited to low wind speeds (Sec. IV E).

III. ESTABLISHMENT OF A WIND MODEL

The simulation of the noise reduction requires the establishment of a model representative of the wind-noise pres-

sure. This model is derived from observations of the coherence criterion for atmospheric pressure fluctuations measured at several points.

A. Measurements of coherence

It has been shown that, for periods ranging between and 0.2 s and 1 week, the atmospheric pressure spectrum is

FIG. 4. Transfer function of the 16 m system.

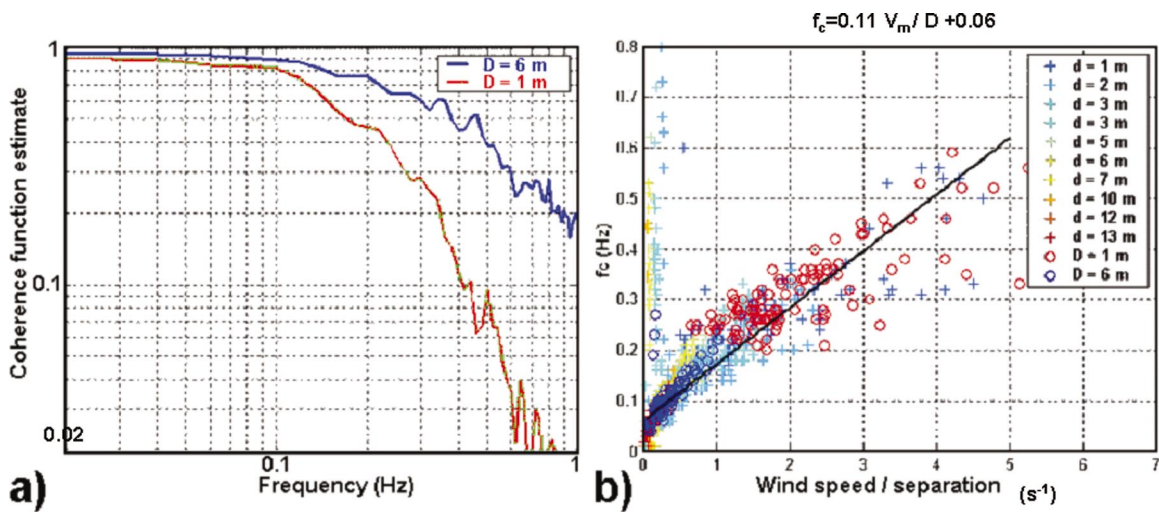

FIG. 5. Coherence as a function of frequency and wind speed. (a) Coherence plotted as a function of frequency for wind speed of 5 m/s and distances of 1 and 6 m. (b) Frequency of decorrelation plotted as a function of intersensor distance and wind speed.

strongly dependent on gravity waves as well as convective effects in the boundary layer of the atmosphere (Gossard and Munk, 1954; Canavero and Einaudi, 1987; Einaudi *et al.*, 1989). The amplitude of the wind-generated noise is strongly correlated with wind speed at the surface for periods shorter than 300 s, with most of the energy concentrated below 60 s (Kimball and Lemon, 1970; Grover, 1971; Wilczak *et al.*, 1992). In particular, hydrostatic and dynamic effects have been identified as the principal physical phenomena producing the pressure fluctuations (Bedard *et al.*, 1992). The pressure spectrum is proportional to a power of the frequency, with the exponent ranging between $-5/3$ and $-7/3$ (Eliot, 1972; Canavero and Einaudi, 1987; Wilczak *et al.*, 1992).

Experiments were carried out to refine the coverage of the parameters controlling the spatial correlation of the pressure variations at low wavelengths (1–10 m). The decrease of coherence with increasing distance between two microbarometers is more marked in the direction of the prevailing winds than in the transverse direction (McDonald *et al.*, 1971). In order to reduce the wind direction effect on the coherence measurements, the pressure variations were measured on cleared ground (covered with close-cropped grass) by five microbarometers set up in two configurations:

- (i) sensors aligned in the direction of the prevailing winds;
- (ii) sensors laid out in two overlapping equilateral triangles, with sides of 1 and 6 m, having one of the apices in common. The anemometer is fixed at a height of 1.5 m in the center of the larger triangle.

For eight days, the pressure, wind speed, and direction were continuously recorded using a 24 bits DASE digitizer at a 20 Hz sample rate.

The decorrelation of the background noise has been evaluated using the standard procedure for coherence estimation (Priestley, 1966; Mack and Flinn, 1971; McDonald and Herrin, 1975; Einaudi *et al.*, 1989). The dependence of the background noise coherence has been studied as a function of the distance separating the sensors for wind speeds rang-

ing from 0 to 7 m/s. The frequency above which the coherence is lower than 0.5, named decorrelation frequency f_c , has been extracted from measurement data on 500 s time windows. Figure 5(a) gives an example of the variation of coherence for two different distances. These measurements show that convected turbulence is normally dispersive. When measurements are taken by sensors separated by some fraction of the eddy diameters, coherence decreases with increasing distance between sensors. Figure 5(b) shows that, to a first approximation, f_c increases as a function of the V_m/D ratio, where V_m is the average wind speed and D is the distance separating the measurement points. A first-order curve fitting yields

$$f_c \approx 0.11 \frac{V_m}{D} + 0.06. \quad (2)$$

(In a future work, more exact fitting using polynomial fittings and a larger wind speed data recording will give more precise results). In addition to the wind speed, atmospheric turbulence also depends on the properties of the boundary layer, the nature of the surface hydrostatic effects, and the presence of atmospheric waves (Mack and Flinn, 1971; McDonald and Herrin, 1975; Einaudi *et al.*, 1989). The measured bias and the scattering of measurements may be ex-

FIG. 6. Definition of the coherence area.

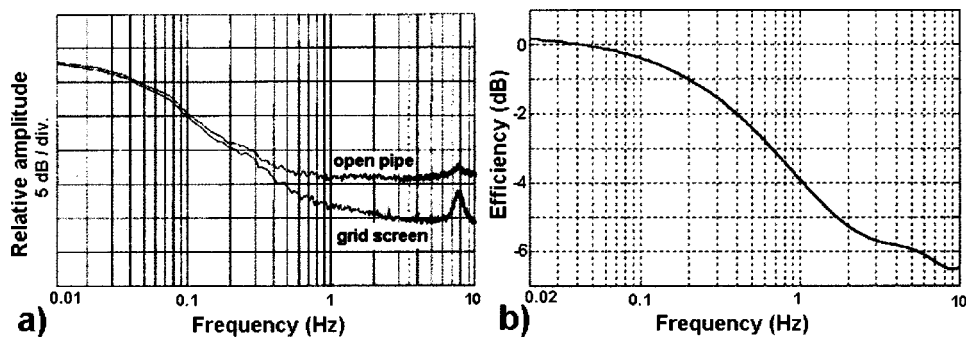

FIG. 7. Effect of grid screens on noise reduction. (a) Comparative spectra of the noise generated in a wind tunnel operated at 2 m/s, measured with and without grid screens (the rotational frequency of the blades is 8 Hz). (b) Curve of the $P(f)$ polynomial modeling the noise reduction obtained with grid screens.

plained by the complex structure of atmospheric turbulence phenomena. A greater dispersion of the points is noted for wind speeds lower than 1 m/s. This is attributed to a marked stable peak with a period between 4 and 7 s, originating from oceanic swell (Donn, 1967). The strong correlation of these signals from one sensor to another partly explains the increase of the decorrelation frequency between 0.2 and 0.5 Hz at low wind speeds.

B. Wind model

If n measurement points p_i are considered, $n-1$ points p_k are at a distance of $d_{i,k}$ from point p_i . Between points p_k and p_i , the wind-noise pressure exhibits a coherence function whose cut-off frequency is given by Eq. (2). Correlation area Z_{ni} attached to points p_i is shown in Fig. 6. These zones of coherence Z_{ni} are defined like circular areas centered on p_i with a radius equal to an entire multiple of the smallest $d_{i,k}$. Several points p_k can be present within the zones of coherence. To satisfy Eq. (2), a normal random temporal sequence $\{n_i\}$ is applied to point p_i . The distance $d_{i,k}$ is calculated for each point p_k and the sequence $\{n_{i,k}\}$ is applied to points p_k . The $\{n_{i,k}\}$ sequences are derived from the $\{n_i\}$ sequences by using a first-order low-pass filter with a cut-off frequency of

$$fc_{i,k} = 0.2 \frac{V_m}{d_{i,k}}. \quad (3)$$

For each point p_i , the signal representative of the wind is generated by

$$\{w_i(t)\} = \sum_{k=1 \dots n} \{n_{i,k}(t)\}. \quad (4)$$

The procedure is repeated for all points p_i with $i=[1,n]$. The spectrum of the wind-noise pressure thus generated presents a slope close to -1.3 , which is reasonably close to the experimental values.

IV. SIMULATION OF NOISE REDUCTION AND EXPERIMENTS

The impulse responses $h_i(t)$ are derived from the transfer function $H_i(\omega)$ established in Sec. II. These responses $h_i(t)$ are convolved with the synthetic wind noise $w_i(t)$. The response of the system to a wind excitation is given by the sum of the convolution:

$$y(t) = \sum_i \{h_i(t) * w_i(t)\}. \quad (5)$$

FIG. 8. Simulations and measurements of noise reduction for the 16 m system, for wind speeds of 2 and 4 m/s.

The comparison is performed between the spectra amplitudes of $y(t)$ and one $w_i(t)$.

A. Effect of the air inlets

With a diameter of 15 mm, the air inlets are essentially open. The inlets are covered by a protective 1 mm mesh wire-screen shield to prevent the entry of foreign bodies likely to block the pipes. Moreover, comparative noise measurements with and without grid screens show a significant wind-noise reduction above 5 Hz [Fig. 7(a)]. To take into account the screen effect, the noise spectrum is weighted using the following approximation function derived from measurements [Fig. 7(b)]:

$$P(f) = 0.9661 + 0.8443 \cdot f - 0.2861 \cdot f^2 + 0.0470 \cdot f^3 - 0.0036 \cdot f^4 + 0.0001 \cdot f^5. \quad (6)$$

The noise reduction simulated as a function of frequency is given by

$$E(f) = \frac{P(f) \cdot |Y(f)|}{|W(f)|}, \quad (7)$$

where $Y(f)$ and $W(f)$ are the Fourier transform of $y(t)$ and $w_i(t)$, respectively.

B. Validation experiments

The validation of the acoustic modeling of the complete system is carried out in our facilities located near Paris. The following experimental protocol is applied.

- (i) The experiment is located on a clear ground. To ensure the same noise level conditions (boundary layer effects), the air entries to the open sensor are located at the same height as the air inlets of the noise reduction system (<0.2 m). Accordingly, the sensors must be subjected to the same wind conditions (a distance of separation lower than 10 m).
- (ii) A microbarometer is connected to the noise reducer.
- (iii) An open microbarometer is used as a pressure reference.
- (iv) An anemometer is used for the measurement of wind speed (height of ~ 2 m).
- (v) All measurements channels are recorded by a 24 bits DASE digitizer at a 20 Hz sample rate and transmitted to Paris in real time via satellite link.

FIG. 9. Variant of the system for wind speeds higher than 5 m/s, with an average diameter of 70 m, 48 air inlets. The length of each pipe is 12.5 m.

C. Noise reduction simulated for a 16-m system

This system is optimized for wind speeds lower than 5 m/s, with: $D_m = 16$ m ($L_1 = 4$ m, $L_2 = 5$ m), 32 air inlets placed 0.2 m off the ground and 4 summation cavities (Fig. 1). Figure 8 reports the results of the noise reduction simulations compared with measurements. With a difference between simulation and measurements less than 4 dB, simulations are consistent with the measurements. The maximum noise reduction obtained is about 15 dB. The main results are the following.

- (i) For frequencies lower than 0.02 Hz, there is no noise reduction.
- (ii) A maximum noise reduction of about 15 dB is obtained at 1 Hz.
- (iii) At higher frequencies, the noise level is amplified by the first resonant frequency (Fig. 4).
- (iv) With increasing wind speed, the noise reduction pattern is shifted toward higher frequencies.

D. Noise reduction simulated for a 70 m system

When the wind speed becomes higher than 5 m/s, a 16 m system is no longer appropriate. To obtain a comparable

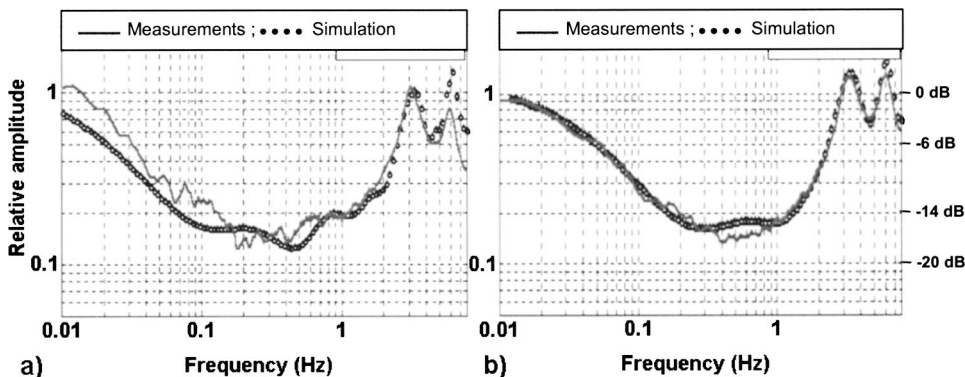

FIG. 10. Simulation and measurement of the 70 m system for wind speeds of 2 and 5 m/s. (a) Wind speed of 2 m/s. (b) Wind speed of 5 m/s.

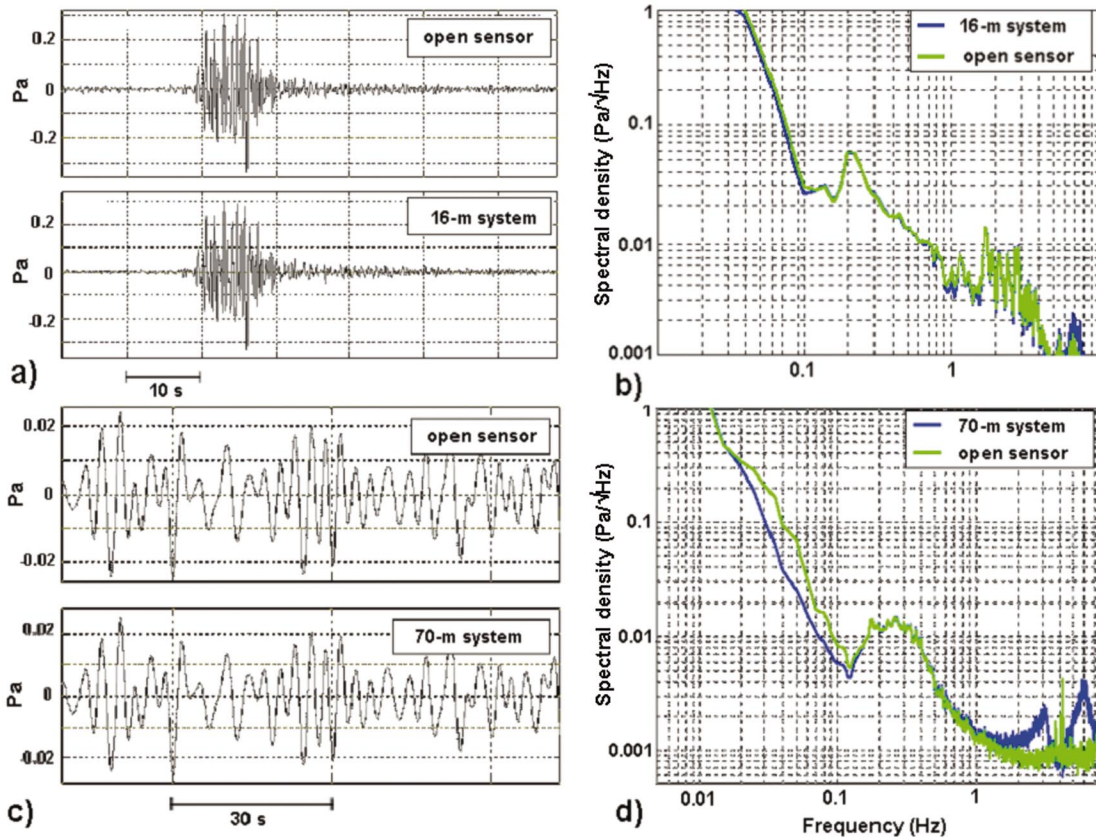

FIG. 11. Nondistortion of waveform and spectra amplitude of infrasound signals without wind. (a)–(b) Concorde signal recorded with and without the 16 m system and corresponding spectrum. (c)–(d) Microbaroms recorded with and without the 70 m system (signals filtered between 0.1 and 1 Hz) and the corresponding spectrum.

noise reduction in the frequency band [0.02–4] Hz, the diameter should be increased. Such a system is presented in Fig. 9. With an average diameter of 70 m, this arrangement comprises 48 air inlets and 12 summation cavities. Its electroacoustic model can be derived from a similar scheme presented in Fig. 2. Figure 10 shows the results of simulations of this system compared with measurements for winds of 2 and 5 m/s. The main results are the following.

- (i) For frequencies lower than 0.02 Hz, in contrast to the 16 m system (Fig. 8), the noise reduction is weak but not negligible (up to 6 dB).
- (ii) The maximum noise reduction (15 dB) is obtained between 0.1 and 1 Hz for wind speeds lower than 6 m/s. This maximal noise reduction is lower than the theoretical noise reduction provided by 48 air inlets (17 dB) (Daniels, 1959).
- (iii) The amplitude and the frequency of the resonances are well predicted. The first resonant peak is introduced by the longer elementary pipe (Hedlin *et al.*, 2003). This tends to limit the frequency band of large-sized systems to frequencies lower than 1 Hz (Grover, 1971; Noel and Whitaker, 1991).
- (iv) Compared with the 16-m system, the noise reduction pattern is shifted toward the low frequencies for the same wind speeds.

E. Effect on the signal

Figures 11(a) and 11(b) represent a signal generated by

the Concorde sonic boom recorded with and without the 16-m system without wind. These signals, consistently recorded by an array of microbarographs in France, are associated with the daily supersonic Concorde flights between North America and Europe (Le Pichon, 2002). The measured signal amplitudes with and without the noise reducer are identical (~ 0.6 Pa peak-to-peak). Figures 11(c) and 11(d) represent the signal of microbaroms from the Atlantic Ocean

FIG. 12. Dimensioning diagram for a wind noise reducer as a function of the effective band and the average wind speed.

recorded with and without the 70-m system. These two signals have an identical time sequence and spectra amplitude. Since the level of noise is significantly reduced by these systems, an increase in the signal-to-noise ratio for infrasound measurements is expected.

F. Discussion

Following the simulations, it appears that, for a circular repartition of a finite number of inlets, we have the following.

- (i) The minimal frequency f_1 at which the noise reduction starts depends both on the wind speed V and the size of the system D_m (Figs. 8 and 10) and can be approximated by the relation $f_1 = 0.14 V/D_m$. The frequency band of noise reduction is shifted toward higher frequencies with a decreasing size of the system or increasing wind speed.
- (ii) The frequency band is limited by resonance whose frequency f_0 depends only on the size of the system [Eq. (1)].
- (iii) Because of resonance, the theoretical noise reduction provided by a large number of air inlets cannot be attained. This is particularly noticeable in the case of strong winds, where the maximal noise reduction below the resonance is lower than the theoretical noise reduction.
- (iv) The optimal number of air inlets and the size of the system can be established as a function of the average wind speed and the effective frequency band.
- (v) By removing resonances and using a large number of inlets, the noise reduction could be improved in high frequencies.

Items (i) and (ii) give the effective frequency band of noise reduction, according to the average wind speed and the outer diameter. The diagram presented by Fig. 12 dimensions the noise reduction system. Inclined lines are plotted for various wind speeds, and the figure gives the frequency of onset of noise reduction f_1 according to the array size. The appearance of acoustic resonant peaks is represented as a zone on the top right-hand corner. For a given wind speed, the minimal size of the system is given by the intersection between the minimal frequency f_1 and the lines of equal

values of wind speed. For example, for a system subjected to a wind of 10 m/s, a diameter of 70 m provides an onset of noise reduction at 0.02 Hz. The horizontal projection towards the right gives the upper frequency of the effective band (1.1 Hz). A 16-m diameter system is efficient from 0.02 to 4 Hz, for wind speeds lower than 2.5 m/s. For higher wind speeds, the noise reduction is limited to the high-frequency band (for a wind speed of 10 m/s, the effective band is [0.08–4] Hz).

V. CONCLUSION

The development of infrasound equipment in the framework of the CTBT requires the study of robust and effective systems for the reduction of acoustic noise generated by the wind. The design of a system using low-impedance acoustic elements has been investigated. The optimization of these systems has been carried out by numerical simulations based on electroacoustic modeling and the use of an appropriate wind-noise model. The noise reduction has been first simulated and then validated by experiments. The results obtained allowed us to optimize a system efficient in the [0.02–4] Hz band. The diameter of the system, as well as the maximum noise reduction attainable for a given frequency band and wind speed, have been determined. It has been shown that the low onset frequency of noise reduction depends only on the size of the system and increases with wind speed. The resonances inside the pipes limit the effective bandwidth in both frequency response and noise reduction. The noise reduction obtained with an infinite number of air inlets cannot theoretically exceed 25 dB for low wind speed and decreases with increasing wind speed. A maximum noise reduction of the order of 20 dB is obtained with about 100 air inlets. In order to enhance the performances of these systems, the resonances need to be reduced or shifted. One way would be to use purely acoustic systems based on impedance matching by means of capillaries (Christie, 2001; Hedlin, 2001).

ACKNOWLEDGMENTS

The authors gratefully acknowledge Dr. M. Hedlin for his interest in this field and for the many helpful discussions we had during the completion of this work.

APPENDIX A: ELEMENTS OF ELECTROACOUSTIC MODEL (Fig. 2)

Elements	Model	Values
Air inlet: <i>Radiation impedance</i>	From the radiation impedances (Beranek, 1986): $Z_{ar} = R_{apr} + j\omega \cdot M_{apr}$	$a < 10$ mm, $f = 10$ Hz $\rho = 1.225$ kg/m ³ $ Z_c > 1300$ k Ω A ^a $R_{apr} = 52E - 6$ Ω A ^a $M_{apr} = 0.26$ kg/m ⁴
a : radius of measurement port ρ : air density k : acoustic wave number c : sound speed in air	$R_{apr} = Z_c \frac{(ka)^2}{1 + (ka)^2}$ $M_{apr} = Z_c \frac{ka}{1 + (ka)^2}$ with: $Z_c = \frac{\rho c}{\pi a^2}$, $k = \frac{2\pi f}{c}$	$\Rightarrow R_{apr} \ll Z_c $
Pipes 1 and 2: <i>Dissipative transmission line</i>	$Z_{at11} = Z_c \cdot \tanh\left(\frac{\Gamma \cdot l}{2}\right)$	$\eta = 18.6 \times 10^{-6}$ (Pa s) at 20 °C.

APPENDIX A: (continued)

Elements	Model	Values
<i>l</i> : length of pipes η : viscosity coefficient of air <i>S</i> : cross section of the pipe	$Z_{\text{atli2}} = \frac{Z_c}{\Gamma \cdot l}$ $Z_c = R_0 \cdot [(1 + 0.369 \cdot r_v^{-1}) - j \cdot 0.369 \cdot r_v^{-1}]$ $\Gamma = \mathbf{k} \cdot [1.045 \cdot r_v^{-1} + j \cdot (1 + 1.045 \cdot r_v^{-1})]$ <p>with $R_0 = \frac{\rho \cdot c}{S}$, $r_v = \sqrt{\frac{2 \cdot \rho \cdot l \cdot S}{\eta}} \geq 1$</p>	These broad tube approximations (Keefe, 1984) are close to exact wave parameters (Benade, 1968).
Summation cavity: Acoustic compliance V_s : cavity volume	$C_{\text{avs}} = \frac{V_s}{\rho \cdot c^2}$	$V_s = 0.3 \times 10^{-3} \text{ m}^3$
Microbarometer		MB2000 type
Inlet pipes: Mass + losses l_p : length of inlets r_p : radius of inlets	$R_{\text{ap}} = \frac{8 \cdot \eta \cdot l_p}{\pi \cdot r_p^4}, \quad M_{\text{ap}} = \frac{\rho \cdot l_p}{\pi \cdot r_p^2}$	$l_p = 30 \text{ mm}, r_p = 5 \text{ mm}$
Inner volume: Acoustic compliance V_{ab} : volume of cavity and losses R_{ab}	$C_{ab} = \frac{V_{ab}}{\rho \cdot c^2}, \quad R_{ab}$	$V_{ab} = 0.6 \times 10^{-3} \text{ m}^3$ $C_{ab} = 4.33 \times 10^{-6} \text{ m}^3 \text{ Pa}$ $R_{ab} = 500 \Omega^{\text{a}}$

^a Ω A denotes an MKS acoustic ohm in Pa s/m³.

APPENDIX B: CALCULATION OF TRANSFER FUNCTIONS BY THE MATRIX METHOD

The diagram for a node *k* is shown by Fig. 13(a). The acoustic flow rate between node *k* and node *j* is written as

$$qv_{(j,k)} = \frac{N_j - N_k}{Z_{(j,k)}}, \tag{B1}$$

with $\sum_j qv_{(j,k)} = 0$ at node *k*, it follows that

$$\sum_j \frac{N_j}{Z_{(j,k)}} - N_k \cdot \sum_j \frac{1}{Z_{(j,k)}} = 0. \tag{B2}$$

If an air inlet is connected to node *k* by a pipe, the impedance is modeled by Ze_k (formed by M_{apr} , R_{apr} , and Z_{atli1} . Figure 13(b) presents the corresponding diagram. From Eq. (B2), we can write

$$\sum_j \frac{N_j}{Z_{(j,k)}} - N_k \cdot \left(\frac{1}{Ze_k} + \sum_j \frac{1}{Z_{(j,k)}} \right) = e_k \cdot - \frac{1}{Ze_k}. \tag{B3}$$

In order to simplify the establishment of transfer functions and perform the calculations, a matrix resolution method is used with the following:

- (i) the impedance matrix [*Z*] representing the impedances defined by Eqs. (B2) and (B3);
- (ii) the vector {*N*} representing the pressures at the nodes;
- (iii) the vector {1/*Ze*} representing the inlet admittances;
- (iv) the vector {*e*} representing the pressure applied to the air inlets.

We obtain

FIG. 13. Calculation of transfer functions. (a) Diagram for a node *k*. $qv_{(i,k)}$ is the volume flow rate between nodes *i* and *k*, N_j is the pressure potential at node *j* and $Z_{(i,k)}$ is the acoustic impedance between nodes *i* and *k*. (b) The calculation of impedance Ze_k .

$$\begin{bmatrix} \ddots & & \vdots & & & & \\ \cdots & & -\sum_j \frac{1}{Z_{(j,m)}} & & & & \\ & & \vdots & & \ddots & & \\ \cdots & & \frac{1}{Z_{(m,k)}} & & \cdots & -\sum_j \frac{1}{Z_{(j,k)}} & \cdots & \frac{1}{Z_{(n,k)}} & \cdots \\ & & \vdots & & \ddots & & & \vdots & \\ & & & & & & & -\sum_j \frac{1}{Z_{(j,n)}} & \cdots \\ & & & & & & & \vdots & \ddots \end{bmatrix} \cdot \begin{bmatrix} \vdots \\ N_m \\ \vdots \\ N_k \\ \vdots \\ N_m \\ \vdots \end{bmatrix} = \begin{bmatrix} \vdots \\ -\frac{1}{Ze_m} \\ \vdots \\ -\frac{1}{Ze_k} \\ \vdots \\ -\frac{1}{Ze_n} \\ \vdots \end{bmatrix} \cdot \begin{bmatrix} \vdots \\ e_m \\ \vdots \\ e_k \\ \vdots \\ e_n \\ \vdots \end{bmatrix}$$

which has the form

$$[Z] \cdot \{N\} = - \left\{ \frac{1}{Ze} \right\} \cdot \{e\}. \quad (\text{B4})$$

The vector $\{N\}$ is then calculated at the node representing the pressure potential in the summation cavity of the microbarometer. The resolution is performed for each frequency as follows:

$$\{N(\omega)\} = [Z(\omega)]^{-1} \cdot \left\{ -\frac{e(\omega)}{Ze(\omega)} \right\}. \quad (\text{B5})$$

The transfer function linking the pressure in the sensor cavity N_p to the excitation present at air inlet e_j is obtained using a vector $\{e\}$. All the components e_k of this vector are null, except for the component corresponding to air inlet j ($e_j \neq 0$):

$$\begin{Bmatrix} \vdots \\ N_j(\omega) \\ \vdots \\ N_p(\omega) \end{Bmatrix} = [Z(\omega)]^{-1} \cdot \begin{Bmatrix} 0 \\ \vdots \\ -\frac{e_j(\omega)}{Ze_j(\omega)} \\ \vdots \\ 0 \end{Bmatrix}. \quad (\text{B6})$$

Finally, the transfer function $H_j(\omega)$ is given by

$$H_j(\omega) = \frac{N_p(\omega)}{e_j(\omega)}. \quad (\text{B7})$$

(Received 26 April 2004; revised 13 January 2005; accepted 14 January 2005)

This paper describes an analytical model of finite cylindrical ducts with infinite flanges. This model is used to investigate the sound radiation characteristics of the gradient coil system of a magnetic resonance imaging (MRI) scanner. The sound field in the duct satisfies both the boundary conditions at the wall and at the open ends. The vibrating cylindrical wall of the duct is assumed to be the only sound source. Different acoustic conditions for the wall (rigid and absorptive) are used in the simulations. The wave reflection phenomenon at the open ends of the finite duct is described by general radiation impedance. The analytical model is validated by the comparison with its counterpart in a commercial code based on the boundary element method (BEM). The analytical model shows significant advantages over the BEM model with better numerical efficiency and a direct relation between the design parameters and the sound field inside the duct. © 2005 Acoustical Society of America. I. INTRODUCTION

Magnetic resonance imaging (MRI) scanners are popular medical diagnostic devices providing useful information about a patient's internal organs in a noninvasive manner. However, a disadvantage of MRI is the high level of acoustic noise generated during scanning. This noise is caused by the Lorentz forces acting on the gradient coils bound within an epoxy resin cylinder. As the gradient current switches direction the gradient windings vibrate, leading to the generation of sound waves.¹

Recently measures have been taken to control the acoustic noise generated by MRI scanners. The technique of active noise control (ANC) for the reduction of MRI noise has been studied.^{2–4} ANC was found to be effective only at relatively low frequencies. Mansfield *et al.*⁵ proposed a technique called active acoustic screening for quiet gradient coil design. While reducing the acoustic noise inside MRIs, this type of screening inevitably reduces the gradient strength as well. Yoshida *et al.*⁶ used “independent suspension” of the coil to dampen vibrations, while a “vacuum vessel enclosure” of the coil shields transmission of sound waves through the air. These methods are not suitable for all kinds of new MRI scanners and are impossible to retrofit to existing machines.

Optimizing the design of the gradient coil system could attenuate the root cause of acoustic noise. A clear understanding on the characteristics of structural vibration and acoustic radiation of the gradient coil system is necessary for the design of quiet MRI scanners. Kessels⁷ has developed a mathematical model of gradient coil structural vibrations due to the Lorentz forces acting on the windings. An acoustical model has been studied by Kuijpers.⁸ He used a baffled finite cylindrical duct with vibrating walls to describe the sound radiation of a gradient coil cylinder by assuming that only the cylinder could vibrate and thus radiate acoustic energy. This model can only be applied to the duct walls with zero acoustic admittance (or infinite acoustic impedance). It may

not always be reasonable to regard the walls as acoustically rigid. This limitation also restricts the application of this method to a gradient coil covered by sound absorption materials.

Studies on the acoustic radiation in cylindrical ducts have been reported,^{9–15} but they mainly discuss situations with simple sources (point source) or sound propagations inside ducts without vibrating walls. Models dealing with more complicated vibration conditions have also been reported.^{16,17} These models only investigate the sound field in closed cylindrical ducts (chambers).

A schematic cross section of a gradient coil system of a typical MRI scanner is shown in Fig. 1 and can be described as an axisymmetric cylinder, that is, a finite cylindrical duct with infinite baffles at the two open ends. The isocenter is the coordinate origin for the model.

Due to wave reflection at the openings of a duct, the acoustic radiation impedances at the open ends should be considered as a boundary condition for the analytical model. The radiation impedances at the open end of a finite cylindrical duct with an infinite flange were studied by Zorumski.¹¹ His results showed that the acoustical conditions of the duct wall have a significant influence on the radiation impedances.

In this paper, the radiation impedances are calculated for a finite cylindrical duct with rigid and absorptive walls. Based on these results, the inside sound field generated by the vibrating wall is simulated. The variations of the pressure levels caused by applying different acoustic admittances to the wall are also shown and discussed. The results obtained from the analytical models are compared with the data calculated using the commercial software SYSNOISE, which is based on the boundary element method (BEM). Compared with the BEM, the most important feature of analytical methods is that they can generally show the dominant parameters for the modeled problems more directly and, therefore, yield

FIG. 1. Schematic cross-sectional view of an MRI scanner.

more physical insight into the problem. In addition, they are much more computationally efficient.

II. THEORY

An analytical model for the sound field generated by the structural vibration of the wall of a finite cylindrical duct with finite acoustic impedance will be derived in this section. First, the fundamental theory of duct acoustics will be reviewed briefly. Then, the boundary problem will be solved by making the acoustical model satisfy both boundary conditions at the duct wall (vibrating and with a finite acoustic impedance) and the two open ends (radiation impedances).

A. Sound field of a infinite cylindrical duct

The sound field inside an infinite cylindrical duct can be expressed as a sum of modal solutions (a time factor $e^{i\omega t}$ is understood throughout this paper),

$$p(r, \theta, x) = \sum_{m=-\infty}^{\infty} \sum_{n=1}^{\infty} J_m(\alpha_r^{mn} r) e^{-im\theta} [A_{mn} e^{-i\alpha_x^{mn} x} + B_{mn} e^{i\alpha_x^{mn} x}], \quad (1)$$

where x is the coordinate in the axial direction of the duct, r is in the radial direction, and θ is in the circumferential direction (see Fig. 2). $J_m(\alpha_r^{mn} r)$ are the Bessel functions of the first kind with circumferential order m . Here n is the radial mode number. The parameters α_x and α_r are the wave num-

FIG. 2. Cylindrical polar coordinates.

bers in the axial and the radial direction, respectively. A and B are the modal coefficients of the forward- and backward-propagating acoustic wave modes, respectively. For the rigid wall case, the boundary condition can be expressed as

$$J'_m(\alpha_r^{mn} a) = 0. \quad (2)$$

For the wall with a finite acoustic impedance, the boundary condition should satisfy the following equation:¹⁸

$$\alpha_r^{mn} J'_m(\alpha_r^{mn} a) = i\beta k J_m(\alpha_r^{mn} a), \quad (3)$$

where J'_m is the derivative of J_m with respect to its argument; a is the radius of the duct and β is a specific acoustic admittance defined as $\beta = \xi - i\sigma = \rho c/Z$. It should be noted that $Z = p/u_n$, where Z is the acoustic impedance, p is the pressure on the surface, and u_n is the normal surface velocity. The parameters ρ and c are the density and speed of sound in the media, respectively, and k is the free field wave number.

The velocity distribution of the vibrating wall can be written in the form of a Fourier series,

$$\begin{aligned} u_r(a, \theta, x) &= U(\theta, x) \\ &= \frac{1}{2\pi} \sum_{m=-\infty}^{\infty} e^{im\theta} U_m(x) \\ &= \frac{1}{4\pi^2} \sum_{m=-\infty}^{\infty} e^{-im\theta} \int_{-\infty}^{\infty} \tilde{U}_m e^{-i\alpha_x x} d\alpha_x. \end{aligned} \quad (4)$$

Assuming the length of the vibrating wall is $2L$, the Fourier coefficients, \tilde{U}_m , are defined by

$$\tilde{U}_m = \int_0^{2\pi} e^{im\theta} d\theta \int_{-L}^L U(\theta, x) e^{i\alpha_x x} dx. \quad (5)$$

By considering the acoustic impedance of the wall, the sound pressure should satisfy the combined boundary condition at the wall,

$$\begin{aligned} \left. \frac{\partial p}{\partial r} \right|_{r=a} &= i\rho\omega u_r(a, \theta, x) + ik\beta p \\ &= \frac{i\rho ck}{4\pi^2} \sum_{m=-\infty}^{\infty} e^{-im\theta} \int_{-\infty}^{\infty} \tilde{U}_m e^{-i\alpha_x x} d\alpha_x + ik\beta p. \end{aligned} \quad (6)$$

In Eq. (6) the first term indicates the effect of the surface velocity distribution; the second term is the influence of the finite impedance.

The sound pressure can also be expressed by the spatial Fourier transformation in the axial direction and the Fourier series in the circumferential azimuth, θ , of the pressure mode. Therefore, a solution for the sound field is

$$p(r, \theta, x) = \sum_{m=-\infty}^{\infty} e^{-im\theta} \int_{-\infty}^{\infty} A_m J_m(\alpha_r r) e^{-i\alpha_x x} d\alpha_x, \quad (7)$$

where $\alpha_r^2 = k^2 - \alpha_x^2$, and A_m are the coefficients. At a particular frequency and for a certain acoustic mode, the axial wave number $\alpha_x^{mn} = \sqrt{k^2 - \alpha_r^{mn}} = 0$. This is called the cutoff frequency below which the particular modes cannot propagate

FIG. 3. The residue integration contour.

freely in the duct. Those axial modes above the cutoff frequency are called cut-on modes.

Bringing the above equation into Eq. (6) to solve for the boundary condition, the following expression can be obtained:

$$\alpha_r A_m J'_m(\alpha_r r) = \frac{i\rho ck}{4\pi^2} \tilde{U}_m + ik\beta A_m J_m(\alpha_r r). \quad (8)$$

The sound pressure can now be represented by replacing A_m in Eq. (7),

$$p(r, \theta, x) = \frac{i\rho ck}{4\pi^2} \sum_{m=-\infty}^{\infty} e^{-im\theta} \int_{-\infty}^{\infty} \frac{\tilde{U}_m}{\alpha_r J'_m(\alpha_r a) - ik\beta J_m(\alpha_r a)} \times J_m(\alpha_r r) e^{-i\alpha_x x} d\alpha_x. \quad (9)$$

This equation can be solved by the residue integration method. An integration contour is chosen to enclose the lower half-plane when $x \geq 0$ and enclose the upper half-plane, where $x < 0$, as shown in Fig. 3. The poles, α_x^{mn} , inside the contour can be calculated from

$$\alpha_x^{mn} = \pm \sqrt{k - \alpha_r^{mn}}, \quad (10)$$

where α_r^{mn} are solved by rewriting Eq. (3) as $\alpha_r J'_m(\alpha_r r) - ik\beta J_m(\alpha_r r) = 0$. When $x \geq 0$, only the poles α_x^{mn}

FIG. 4. Boundary conditions for the finite cylinder. (The sound field should satisfy both the impedance and velocity boundary conditions at the duct wall and the radiation impedance boundary condition at the open ends.)

$= -\sqrt{k - \alpha_r^{mn}}$ are inside the contour. Conversely, the poles $\alpha_x^{mn} = \sqrt{k - \alpha_r^{mn}}$ are inside the integration contour for $x < 0$. Thus the integral in Eq. (9) can be calculated by the sum of the residues at these poles (see Appendix A) and it can be rewritten as

$$p(r, \theta, x) = \frac{\rho ck}{2\pi} \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} \frac{(\alpha_r^{mn})^2}{\alpha_x^{mn}} \times \frac{J_m(\alpha_r^{mn} r)}{(\alpha_r^{mn})^2 a J'_m(\alpha_r^{mn} a) + ik\beta J_m(\alpha_r^{mn} a)(1 - ika\beta)} \times \int_{-L}^L U_m(x') e^{-i\alpha_x^{mn}|x-x'|} dx' \dots, \quad (11)$$

where $\text{Re}(\alpha_x^{mn})$ and $\text{Im}(\alpha_x^{mn}) \geq 0$ for $x < 0$; $\text{Re}(\alpha_x^{mn})$ and $\text{Im}(\alpha_x^{mn}) < 0$ for $x \geq 0$.

B. Sound field of a finite cylindrical duct

The expression of the sound pressure level, $P(r, \theta, x)$, for a finite duct must satisfy the boundary at the wall caused by the structural vibration and finite acoustic impedance. The expression also needs to agree with radiation impedances at the duct open ends (see Fig. 4). Therefore, the reflection at the open ends should be taken into consideration and the total pressure needs to be expressed as a sum of the above solution satisfying the boundary condition at the wall and a general solution. The total solution that satisfies the boundary conditions at both the wall and the open ends can be represented as

$$p(r, \theta, x) = p'(r, \theta, x) + p''(r, \theta, x), \quad (12)$$

where

$$p'(r, \theta, x) = \frac{\rho ck}{2\pi} \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} \frac{(\alpha_r^{mn})^2}{\alpha_x^{mn}} \frac{J_m(\alpha_r^{mn} r)}{(\alpha_r^{mn})^2 a J'_m(\alpha_r^{mn} a) + ik\beta J_m(\alpha_r^{mn} a)(1 - ika\beta)} \int_{-L}^L U_m(x') e^{-i\alpha_x^{mn}|x-x'|} dx', \quad (13)$$

$$p''(r, \theta, x) = \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} B_{mn} J_m(\alpha_r^{mn} r) (e^{-i\alpha_x^{mn} x} + e^{i\alpha_x^{mn} x}). \quad (14)$$

In these expressions, B_{mn} are the coefficients for the general solution and it is assumed that they are the same for the forward-propagating ($e^{-i\alpha_x^{mn}x}$) and backward-propagating ($e^{i\alpha_x^{mn}x}$) acoustic wave modes because the duct is symmetric about the center plane A (see Fig. 4). In fact, the velocity distribution of the duct wall is also symmetric about the center plane due to the symmetry of the gradient coil windings. Therefore, the total solution for the sound field satisfies the boundary condition:

$$\frac{\partial p}{\partial r} = \frac{\partial p'}{\partial r} + \frac{\partial p''}{\partial r} = i\rho\omega u_r(a, \theta, x) + ik\beta p. \quad (15)$$

The expression for the total pressure can be rearranged as

$$p(r, \theta, x) = \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} J_m(\alpha_r^{mn}r) [(G'_{mn}(x) + B_{mn}) \times e^{-i\alpha_x^{mn}x} + (G''_{mn}(x) + B_{mn})e^{i\alpha_x^{mn}x}] \quad (16)$$

with

$$G'_{mn}(x) = \frac{\rho ck}{2\pi} \frac{(\alpha_r^{mn})^2}{\alpha_x^{mn}[(\alpha_r^{mn})^2 a J_m''(\alpha_r^{mn}a) + ik\beta J_m(\alpha_r^{mn}a)(1 - ik\alpha\beta)]} \int_{-L}^x U_m(x') e^{i\alpha_x^{mn}x'} dx', \quad (17)$$

$$G''_{mn}(x) = \frac{\rho ck}{2\pi} \frac{(\alpha_r^{mn})^2}{\alpha_x^{mn}[(\alpha_r^{mn})^2 a J_m''(\alpha_r^{mn}a) + ik\beta J_m(\alpha_r^{mn}a)(1 - ik\alpha\beta)]} \int_{-x}^L U_m(x') e^{i\alpha_x^{mn}x'} dx', \quad (18)$$

The pressure at an open end (suppose the right side, $x=L$) is

$$p(r, \theta, L) = \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} [(G_{mn} + B_{mn})e^{-i\alpha_x^{mn}L} + B_{mn}e^{i\alpha_x^{mn}L}] J_m(\alpha_r^{mn}r). \quad (19)$$

with

$$G_{mn}(x) = \frac{\rho ck}{2\pi} \frac{(\alpha_r^{mn})^2}{\alpha_x^{mn}[(\alpha_r^{mn})^2 a J_m''(\alpha_r^{mn}a) + ik\beta J_m(\alpha_r^{mn}a)(1 - ik\alpha\beta)]} \int_{-L}^L U_m(x') e^{i\alpha_x^{mn}x'} dx'. \quad (20)$$

The corresponding axial velocity is

$$u_x(r, \theta, L) = \frac{1}{\rho c} \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} \frac{\alpha_x^{mn}}{k} [B_{mn}e^{i\alpha_x^{mn}L} - (G_{mn} + B_{mn})e^{-i\alpha_x^{mn}L}] J_m(\alpha_r^{mn}r). \quad (21)$$

The acoustic pressure and velocity amplitudes at the open ends of the duct can be expressed in terms of the acoustic modes in radial r and circumferential θ directions as¹¹

$$p(r, \theta, x) = \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} P_{mn} J_m(\alpha_r^{mn}r), \quad (22)$$

$$u_x(r, \theta, x) = \frac{1}{\rho c} \sum_{m=-\infty}^{\infty} e^{-im\theta} \sum_{n=1}^{\infty} V_{mn} J_m(\alpha_r^{mn}r), \quad (23)$$

where P_{mn} and V_{mn} are the modal coefficients for the pressure and velocity, respectively.

Comparing Eqs. (22) and (23) to Eqs. (19) and (21), respectively, the amplitudes of modal pressure P_{mn} and velocity V_{mv} are

$$P_{mn} = (G_{mn} + B_{mn})e^{-i\alpha_x^{mn}L} + B_{mn}e^{i\alpha_x^{mn}L} = B_{mn}(e^{i\alpha_x^{mn}L} + e^{-i\alpha_x^{mn}L}) + G_{mn}e^{-i\alpha_x^{mn}L}, \quad (24)$$

$$V_{mv} = \frac{\alpha_x^{mn}}{k} [B_{mn}e^{i\alpha_x^{mn}L} - (G_{mn} + B_{mn})e^{-i\alpha_x^{mn}L}] = \frac{\alpha_x^{mn}}{k} [B_{mn}(e^{i\alpha_x^{mn}L} - e^{-i\alpha_x^{mn}L}) - G_{mn}e^{-i\alpha_x^{mn}L}]. \quad (25)$$

The relationship between the modal pressure and velocity amplitudes can be expressed by the radiation impedance, Z , at the open end with an infinite flange,

$$P_{mn} = \sum_{l=1}^{\infty} Z_{mnl} V_{ml}, \quad (26)$$

where l and n are the orders of radial incident and reflected modes, respectively. Referring to Appendix B, the radiation impedance, Z , can be calculated using

$$Z_{mnl} = \frac{1}{W} \int_0^{\pi/2} \frac{\sin^3 \phi J_m'^2(ka \sin \phi) - 2i\beta \sin^2 \phi J_m(ka \sin \phi) J_m'(ka \sin \phi) - \beta^2 \sin \phi J_m^2(ka \sin \phi)}{(\sin^2 \phi - (\alpha_r^{mn})^2/k^2)(\sin^2 \phi - (\alpha_r^{ml})^2/k^2)} d\phi$$

$$+ \frac{i}{W} \int_0^\infty \frac{\cosh^3 \xi J_m'^2(ka \cosh \xi) - 2i\beta \cosh^2 \xi J_m(ka \cosh \xi) J_m'(ka \cosh \xi) - \beta^2 \cosh \xi J_m^2(ka \cosh \xi)}{(\cosh^2 \phi - (\alpha_r^{mn})/k^2)(\cosh^2 \phi - (\alpha_r^{ml})^2/k^2)} d\xi. \quad (27)$$

Bringing the above two equations for P_{mn} and V_{mv} into Eq. (26) gives

$$B_{mn}(e^{i\alpha_x^{mn}L} + e^{-i\alpha_x^{mn}L}) + G_{mn}e^{-i\alpha_x^{mn}L}$$

$$= \sum_{v=1}^{\infty} Z_{mnv} \frac{\alpha_x^{mn}}{k} [B_{mn}(e^{i\alpha_{xm}^n L} - e^{-i\alpha_x^{mn}L}) - G_{mn}e^{-i\alpha_x^{mn}L}]. \quad (28)$$

For a fixed order, m , the above equation can be expressed in matrix form as

$$\mathbf{g}_m \mathbf{E}_m + \mathbf{E}_m' \mathbf{b}_m = \mathbf{Z}_m (\mathbf{K}_m \mathbf{E}_m'' \mathbf{b}_m - \mathbf{K}_m \mathbf{g}_m)$$

for $m=0, \pm 1, \pm 2, \dots$. (29)

The detailed expressions of the matrices in Eq. (29) are presented in Appendix C. The coefficient matrix \mathbf{b}_m can be solved using the following equation,

$$[\mathbf{E}_m + \mathbf{Z}_m \mathbf{K}_m] \mathbf{g}_m = [\mathbf{Z}_m \mathbf{K}_m \mathbf{E}_m'' - \mathbf{E}_m'] \mathbf{b}_m. \quad (30)$$

Once \mathbf{b}_m is known, these values can be brought into Eq. (16) and the sound field pressure, p , can be calculated.

III. NUMERICAL RESULTS AND DISCUSSION

To verify the validity of the above mathematical model, the sound pressures at various points within the sound field inside a finite cylindrical duct were calculated. The radii of the gradient coils of MRI scanners are normally about 0.3 m. The radius of the gradient coils for the 4 Tesla, Varian/Siemens, Unity INOVA whole-body MRI system, used in previously reported experimental studies,⁴ is 0.34 m (1.2 m in length). Therefore, a cylindrical duct with 0.3-m radius and 1.2-m length was used for the simulations and different wall acoustic impedances (rigid, $\beta=0.1$ and $\beta=0.3$) were applied. The analytical results are compared with the data calculated using the commercial code LMS SYSNOISE, which is based on the boundary element method (BEM).

FIG. 5. The sound pressure level, L_p , at the isocenter calculated with different truncated orders, $n=5, 7$ and 9 (the wall admittance $\beta=0.1$).

The velocity distribution on the duct wall can normally be expressed by a sum of trigonometric functions in the circumferential and axial directions, such as

$$U = \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} U_A \cos(m\theta) \cos(n\pi x/2L). \quad (31)$$

The amplitude, $U_A=0.001$ m/s, is arbitrarily chosen. The parameter L is the length of the duct; $m=0$ and $n=2$, and $m=1$ and $n=3$, are used in the calculations. Thus the velocity distribution can be written as

$$U = 0.001 [\cos(2\pi x/1.2) + \cos(\theta) \cos(3\pi x/1.2)]. \quad (32)$$

Equation (13) is used for calculating the pressure. It is apparent, because of the Bessel functions [see Eq. (33)], that just the first term, $0.001 \cos(2\pi x/1.2)$ ($m=0$), of the duct vibration velocity contributes to the sound pressure at the center line ($r=0$):

$$J_m(\alpha_r^{mn} r)|_{r=0} = 1 \quad \text{when } m=0,$$

$$J_m(\alpha_r^{mn} r)|_{r=0} = 0 \quad \text{when } m \neq 0. \quad (33)$$

The infinite matrices for the analytical model of finite ducts are truncated. The sound pressure level, L_p (dB) (with a reference of $20 \mu\text{Pa}$), from 100 to 3000 Hz at the isocenter and the point $r=0, x=0.3$ m for the duct wall with the admittance $\beta=0.1$ calculated with different truncated orders, $n=5, 7$ and 9 , are shown in Figs. 5 and 6, respectively. It is obvious that there is a significant difference between the results calculated by order $n=5$ and the other two situations (orders $n=7$ and $n=9$) at the higher frequencies (>2400 Hz). The reason is that higher duct modes contribute little to the sound pressure below their cutoff frequency. For the analysis frequency up to 3000 Hz, there are harmonic orders from $n=1$ to $n=6$ ($m=0$) with their corresponding cutoff frequencies below 3000 Hz. (see Table I). This also holds for the order $m=1$. This suggests that infinite matrices truncated at the order $n=5$ are not accurate enough at high frequencies (>2400 Hz). However, using truncated orders $n=7$ or n

FIG. 6. The sound pressure level, L_p , at the point $r=0, x=0.3$ m calculated with different truncated orders $n=5, 7$ and 9 (the wall admittance $\beta=0.1$).

TABLE I. Cutoff frequencies, α_{cutoff} , in Hz corresponding to radial acoustic modes, α_r^{mn} . (For the rigid wall, $m=0$ and $m=1$.)

n	1	2	3	4	5	6
$m=0$	0	691	1266	1834	2402	2970
$m=1$	332	961	1540	2113	2681	3259

=9 will be acceptable for analysis of frequencies up to 3000 Hz.

It is impossible to build a duct with infinite baffles with the SYSNOISE software. However, the size of the baffles can be defined as relatively large in the BEM model for comparison to the analytical model for the finite duct with infinite flanges. For most MRI scanners, the gradient coils are actually baffled by the casing (1–1.5 m in radius) of the static magnet. Therefore, for assessing the influence of the baffle radius to acoustic response of the BEM model, the L_p at the isocenter and a particular point on the center line ($r=0, x=0.3$ m) for different baffles with radius R of 1.5, 3, and 5 m (rigid wall) are calculated and shown in Figs. 7 and 8, respectively. These results are quite close (except for a little difference at the lower frequencies) especially for the baffles of 3 and 5 m in radius. These results indicate that the BEM model with baffle 3 or 5 m validates the analytical model. The results are applicable to simulate the acoustic response of a real MRI scanner. For an analysis frequency up to 3000 Hz, at least 7400 elements are used for the BEM model to satisfy the minimum accuracy requirement.

The sound pressure level, L_p , at the isocenter for different duct wall conditions (rigid, $\beta=0.1$ and $\beta=0.3$) calculated by the BEM model (SYSNOISE) and the analytical model are shown in Fig. 9. This figure shows that the sound pressure level at the isocenter calculated by both of the methods reaches a good agreement. The pressure peaks appear around 700, 1300, 1850, 2400, and 3000 Hz (around cutoff frequencies for $m=0$, referring to Table I). This indicates that the sound energy at the isocenter of the finite cylindrical duct is concentrated around the duct cutoff frequencies. This is due to the fact that the wave reflections at the open ends reach their maximum value at the cutoff frequencies, causing acoustic resonance inside the duct. The cutoff frequencies are dependent on the geometrical dimension (radius) of the duct.

Compared with the results calculated by the analytical model for the duct with acoustic rigid wall, reductions of the sound pressure level L_p at the isocenter around cutoff frequencies are shown in Table II when absorptive boundary conditions for the duct wall are applied. The noise reduction is obvious especially at the first peak at 700 Hz and the fifth

FIG. 7. The sound pressure level, L_p , at the isocenter with different baffle radii: 1.5, 3, and 5 m (rigid wall).

FIG. 8. The sound pressure level, L_p , at the point $r=0, x=0.3$ m with different baffle radii: 1.5, 3, and 5 m (rigid wall).

peak at 3000 Hz. These results also reveal that more noise attenuation takes place as the value of the admittance, β , increases.

Since the sound field inside the duct is symmetrical to the isocenter, the acoustical pressure distributions for half the duct ($r=0-0.2$ m, $x=0-0.6$ m) with the wall admittance of $\beta=0.1$ were calculated by the analytical model. The results from the analytical method and the differences between the analytical model and the BEM model are shown in Figs. 10–13 for the frequencies 700, 1300, 1850, and 2400 Hz, respectively. The results show that the sound fields obtained by both methods are similar except for some differences close to the open end.

IV. CONCLUSIONS

An analytical model for the acoustic radiation inside finite cylindrical ducts with infinite flanges has been presented. This model has been validated for a duct wall with acoustically rigid boundary conditions and absorptive boundary conditions. The acoustic response of the analytical model

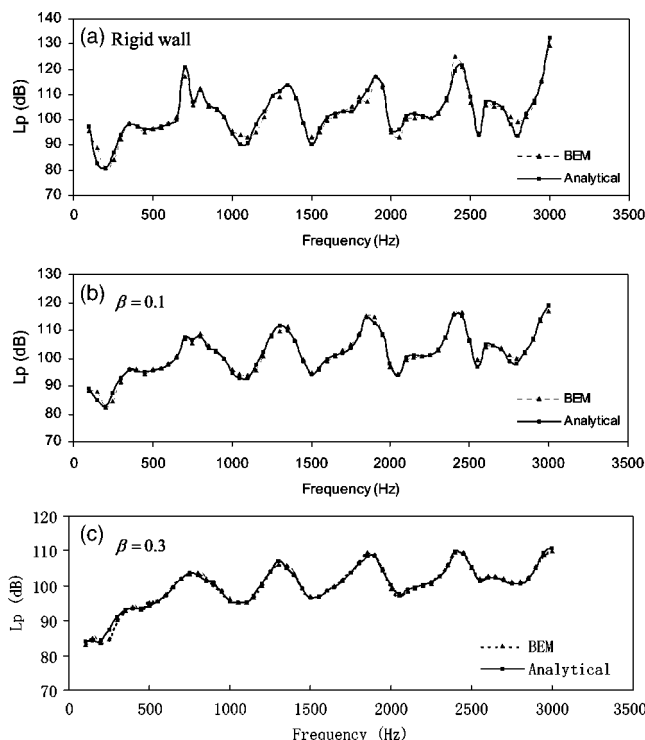

FIG. 9. The sound pressure level, L_p , at the isocenter calculated by the BEM and the analytical method for different wall conditions: (a) rigid, (b) $\beta=0.1$, and (c) $\beta=0.3$.

TABLE II. The sound pressure level, L_p (dB), reduction around the cutoff frequencies when absorptive boundary conditions are applied.

Frequency (Hz)	700	1300	1850	2400	3000
$\beta=0.1$	13	1.9	2.3	4	13.1
$\beta=0.3$	16	6.5	8	9.5	21.3

was found to be in a good agreement with the results obtained by the BEM model with LMS SYSNOISE.

When compared with the BEM model, the analytical model more directly shows the relationship of the sound field to the geometrical parameters and boundary conditions of the cylindrical duct. The observation of acoustic energy concentration around the cutoff frequencies can make it possible for MRI scanner designers to avoid designing inherently noisy gradient coils. The simulation results also show that using absorptive materials to cover the duct wall may be an effective way to reduce the noise without changing the design of the scanner. The other important benefit of using the analytical model is that reduced computer resources are required and it runs much faster than the BEM model, especially for the ducts with absorptive walls and a wide range of analysis

frequencies. As an example, it normally took more than 2 weeks for calculating a model with absorptive walls from 100 to 3000 Hz (with a frequency resolution of 50 Hz) using SYSNOISE on a computer with an Intel P4 1.7G Hz CPU and 1.5 GB memory. The same calculation required only about 2 h for the analytical model on the same computer.

APPENDIX A: RESIDUE INTEGRATION

From the Eq. (9), the integration

$$\int_{-\infty}^{\infty} \frac{J_m(a_r r)}{\alpha_r J'_m(a_r a) - ik\beta J_m(a_r a)} e^{-i\alpha_x x} d\alpha_x$$

could be solved by the residue integration method,¹⁸

$$\int_{-\infty}^{\infty} F(\alpha_x) e^{-i\alpha_x x} d\alpha_x = \begin{cases} -2\pi i \sum \text{Re}^-(\alpha_x^{mn}), & x \geq 0, \\ 2\pi i \sum \text{Re}^+(\alpha_x^{mn}), & x < 0, \end{cases} \quad (\text{A1})$$

where $F(\alpha_x) = J_m(a_r r) / [\alpha_r J'_m(a_r a) - ik\beta J_m(a_r a)]$, $\sum \text{Re}^-(\alpha_x^{mn})$ is the sum of the residues of $F(\alpha_x) e^{-i\alpha_x x}$ at all its poles on and below the real axis, and $\sum \text{Re}^+(\alpha_x^{mn})$ is the sum of the residues of $F(\alpha_x) e^{-i\alpha_x x}$ at all its poles above the real axis.

The residue can be calculated by

FIG. 12. The sound field (L_p) at 1850 Hz ($\beta=0.1$). (a) Calculated by the analytical model. (b) The difference of results between the analytical model and the BEM model.

FIG. 13. The sound field (L_p) at 2400 Hz ($\beta=0.1$). (a) Calculated by the analytical model. (b) The difference of results between the analytical model and the BEM model.

$$\operatorname{Re}(\alpha_x^{mn}) = \frac{J_m(\alpha_r r)}{(d/d\alpha_x)(\alpha_r J'_m(\alpha_r a) - ik\beta J_m(\alpha_r a))|_{\alpha_x^{mn}}} = \frac{(\alpha_r^{mn})^2}{\alpha_x^{mn}} \frac{J_m(\alpha_r^{mn} r)}{(\alpha_r^{mn})^2 a J''_m(\alpha_r^{mn} a) + ik\beta J_m(\alpha_r^{mn} a)(1 - ika\beta)}. \quad (\text{A2})$$

APPENDIX B: CALCULATION OF RADIATION IMPEDANCES

The generalized radiation impedance can be written as

$$Z_{mnl} = \frac{-i}{N_{mn}N_{ml}} \int_0^\infty \frac{\tau}{\sqrt{\tau^2 - 1}} D_{mn}(\tau) D_{ml}(\tau) d\tau, \quad (\text{B1})$$

$$N_{mn} = ka \left[\frac{1}{2} \frac{((\alpha_r^{mn} a)^2 - m^2) J_m^2(\alpha_r^{mn} a)}{(\alpha_r^{mn} a)^2} + J_m'^2(\alpha_r^{mn} a) \right]^{1/2}, \quad (\text{B2})$$

$$D_{mn}(\tau) = \frac{k^2 a}{(\alpha_r^{mn})^2 - \tau^2 k^2} [k\tau J_m(\alpha_r^{mn} a) J'_m(\tau ka) - k_r^{mn} J'_m(\alpha_r^{mn} a) J_m(\tau ka)]. \quad (\text{B3})$$

Equation (B1) shows the incident modes can be coupled with other reflection modes. Equation (B1) can be simplified as

$$Z_{mnl} = \frac{1}{W} \int_0^\infty \frac{\tau^3 J_m'^2(\tau ka) - 2i\beta\tau^2 J_m(\tau ka) J'_m(\tau ka) - \beta^2 \tau J_m^2(\tau ka)}{\sqrt{1 - \tau^2} (\tau^2 - (\alpha_r^{mn})^2/k^2) (\tau^2 - (\alpha_r^{ml})^2/k^2)} d\tau \quad (\text{B4})$$

with

$$W = \frac{1}{2} \left[\left(1 - \left(\frac{\beta k}{\alpha_r^{mn}} \right)^2 - \frac{m^2}{(\alpha_r^{mn} a)^2} \right)^{1/2} \left[1 - \left(\frac{\beta k}{\alpha_r^{ml}} \right)^2 - \frac{m^2}{(\alpha_r^{ml} a)^2} \right]^{1/2} \right]. \quad (\text{B5})$$

The integral can be split into two parts over the range (0,1), and (1, ∞) and with the changes of variable, $\tau = \sin \phi$ and $\tau = \cos \xi$, in those respective ranges, the impedance equation becomes

$$Z_{mn\nu} = \frac{1}{W} \int_0^{\pi/2} \frac{\sin^3 \phi J_m'^2(ka \sin \phi) - 2i\beta \sin^2 \phi J_m(ka \sin \phi) J_m'(ka \sin \phi) - \beta^2 \sin \phi J_m^2(ka \sin \phi)}{(\sin^2 \phi - (\alpha_r^{mn})^2/k^2)(\sin^2 \phi - (\alpha_r^{m\nu})^2/k^2)} d\phi \\ + \frac{i}{W} \int_0^\infty \frac{\cosh^3 \xi J_m'^2(ka \cosh \xi) - 2i\beta \cosh^2 \xi J_m(ka \cosh \xi) J_m'(ka \cosh \xi) - \beta^2 \cosh \xi J_m^2(ka \cosh \xi)}{(\cosh^2 \phi - (\alpha_r^{mn})^2/k^2)(\cosh^2 \phi - (\alpha_r^{m\nu})^2/k^2)} d\xi. \quad (\text{B6})$$

APPENDIX C: THE MATRIX REPRESENTATION FOR EQ. (28)

For a fixed order, m , Eq. (28) can be expressed by matrices as

$$\mathbf{g}_m \mathbf{E}_m + \mathbf{E}_m' \mathbf{b}_m = \mathbf{Z}_m (\mathbf{K}_m \mathbf{E}_m'' \mathbf{b}_m - \mathbf{K}_m \mathbf{g}_m) \quad \text{for } m=0, \pm 1, \\ \pm 2, \dots, \quad (\text{C1})$$

where

$$\mathbf{g}_m = [G_{m1} \quad G_{m2} \quad G_{m\nu}]^T, \quad (\text{C2})$$

$$\mathbf{b}_m = [B_{m1} \quad B_{m2} \quad B_{m\nu}]^T. \quad (\text{C3})$$

\mathbf{E}_m , \mathbf{E}_m' , and \mathbf{E}_m'' are diagonal matrices,

$$\mathbf{E}_m = \begin{bmatrix} e^{-ia_x^{m1}L} & 0 & 0 \\ 0 & e^{-ia_x^{m2}L} & 0 \\ 0 & 0 & e^{-ia_x^{m\nu}L} \end{bmatrix}, \quad (\text{C4})$$

\mathbf{E}_m'

$$= \begin{bmatrix} e^{-ia_x^{m1}L} + e^{ia_x^{m1}L} & 0 & 0 \\ 0 & e^{-ia_x^{m2}L} + e^{ia_x^{m2}L} & 0 \\ 0 & 0 & e^{-ia_x^{m\nu}L} + e^{ia_x^{m\nu}L} \end{bmatrix}, \quad (\text{C5})$$

\mathbf{E}_m''

$$= \begin{bmatrix} e^{ia_x^{m1}L} - e^{-ia_x^{m1}L} & 0 & 0 \\ 0 & e^{ia_x^{m2}L} - e^{-ia_x^{m2}L} & 0 \\ 0 & 0 & e^{ia_x^{m\nu}L} - e^{-ia_x^{m\nu}L} \end{bmatrix}. \quad (\text{C6})$$

The general impedance matrix is given by

$$\mathbf{Z}_m = \begin{bmatrix} Z_{m11} & Z_{m12} & Z_{m1\nu} \\ Z_{m21} & Z_{m22} & Z_{m2\nu} \\ Z_{m\mu 1} & Z_{m\mu 2} & Z_{m\mu\nu} \end{bmatrix}. \quad (\text{C7})$$

\mathbf{K}_m is a diagonal matrix, which is composed of the ratio of the axial wave number of the acoustic modes to the wave number in the free field. It can be written as

$$\mathbf{K}_m = \begin{bmatrix} \alpha_x^{m1}/k & 0 & 0 \\ 0 & \alpha_x^{m2}/k & 0 \\ 0 & 0 & \alpha_x^{m\nu}/k \end{bmatrix}. \quad (\text{C8})$$

(Received 20 July 2004; revised 18 January 2005; accepted 20 January 2005)

Simulations performed with the Biot theory show that for thin porous layers, a shear mode of the structure can be induced by a point-source in air located close to the layer. The simulations show that this mode is present around frequencies where the quarter wavelength of the shear Biot wave is equal to the thickness of the samples and show that it can be acoustically detected from the fast variations with frequency of the location of a pole of the reflection coefficient close to grazing incidence. The mode has been detected with this method for two reticulated plastic foams. For one of the foams studied, the velocity and the damping of the Rayleigh wave have been measured on a thicker layer of the same medium at higher frequencies, giving a real part of the shear modulus close to the one obtained from the measured location of the pole. The strong coupling of the shear mode with the acoustic field in air allows the measurement of the shear modulus without mechanical excitation. © 2005 Acoustical Society of America. I. INTRODUCTION

Acoustical excitations from a sound source in air generally do not create noticeable displacements of the porous frame for usual sound-absorbing materials. As a consequence, the measurement of the rigidity coefficients of the porous frames is performed with mechanical excitations.^{1–7} A contact surface with a static stress is generally present and the material, often strongly nonlinearly reacting, can be modified by the experimental procedure. This drawback is avoided when the Rayleigh wave velocity is measured,⁸ but this measurement can only be performed on sufficiently thick layers; the penetration of the Rayleigh wave inside the material is of several shear wavelengths. Free field measurements of the surface impedance can be used, with the Biot theory,^{9,10} to evaluate the velocity of the frame-borne compressional wave.¹¹ At normal incidence, a mode related to this wave can be excited. This mode is with a good approximation the quarter wavelength resonance of the compressional wave in the frame, and is present at frequencies where the wavelength is close to four times the thickness l of the layer. The surface impedance at normal incidence for a layer glued to a rigid impervious backing presents around these frequencies fast variations if the loss angle of the frame is sufficiently small, but this is not the case for most of the porous sound absorbing media. The excitation of shear modes related to the Biot shear wave would need less energy at equal loss angles because the shear modulus is smaller than the modulus related to frame compressional waves. These modes cannot be excited by plane waves at normal

incidence but at large angles of incidence θ . At $\theta = \pi/2$, the surface impedance $Z_s(\pi/2)$ can be measured with the Tamura method,¹² but areas as large as 10 m² are needed, over which the porous layer must be carefully glued to a rigid impervious backing, and the experimental procedure is complicated. It has been shown recently that for thin porous layers with a motionless frame (the thickness l of a thin layer verifies $|\delta|l \ll 1$, where δ is the wave number in the air saturating the frame), a pole of the reflection coefficient exists at a complex angle of incidence θ_p close to $\pi/2$, and θ_p can be evaluated easily from measurements of the monopole pressure field close to grazing incidence.^{13–15} More precisely, the reflection coefficient V is given by

$$V(\cos \theta) = \frac{Z_s(\cos \theta) - Z/\cos \theta}{Z_s(\cos \theta) + Z/\cos \theta}, \quad (1)$$

and the angle θ_p is a solution of the following equation,

$$\cos \theta_p = -\frac{Z}{Z_s(\cos \theta_p)}, \quad (2)$$

where Z is the characteristic impedance of air, and the surface impedance Z_s is given by

$$Z_s(\theta) = \frac{iZ_1}{\phi \cos \theta_1} \cot(\delta l \cos \theta_1). \quad (3)$$

In this equation, Z_1 is the characteristic impedance in the fluid equivalent to the air saturating the porous medium, ϕ is the porosity, and θ_1 is the refraction angle given by $\sin \theta_1 = (\sin \theta)k/\delta$, k being the wave number in the free air. For thin layers θ_p is close to $\pi/2$ because $Z/|Z_s(\theta_p)| \ll 1$, and $\cos \theta_p$ is close to $-Z/Z_s(\pi/2)$. In Fig. 1, a sketch of the experimental set for the measurement method is presented. The monopole

FIG. 1. Symbolic sketch of the experiment, the monopole source S, and the receiver at M above the porous layer.

source S and the receiver at M are located at small distances, respectively h_1 and h_2 , from the porous layer. The distance R_2 from the source to the receiver, R_1 from the image of the source to the receiver, and the radial distance r are much larger than $h_1 + h_2$, and the angle of specular incidence θ_0 is close to $\pi/2$. (The symbols θ_0 and θ are used for the angle of specular incidence and for the angle of incidence of plane waves, respectively.) The method is based on the use of the following approximation for the monopole reflected field p_r over thin porous layers with a motionless frame, valid under the condition θ_0 and θ_p close to $\pi/2$:

$$p_r = \frac{\exp(ikR_1)}{R_1} \left[1 - \sqrt{2\pi k R_1} \exp\left(\frac{3\pi i}{4}\right) \times \cos \theta_p \exp(-w^2) \operatorname{erfc}(-iw) \right], \quad (4)$$

$$w = \sqrt{2kR_1} \exp\left(\frac{\pi i}{4}\right) \sin \frac{\theta_p - \theta_0}{2}. \quad (5)$$

Under the condition θ_0 and θ_p close to $\pi/2$, w can be rewritten

$$w = \sqrt{\frac{1}{2}kR_1} \frac{\pi i}{4} \exp(\cos \theta_0 - \cos \theta_p). \quad (6)$$

The possible variations of $Z_s(\theta_p)$ around frequencies where the shear mode is excited are much easier to measure with the new method than $Z_s(\pi/2)$ with the Tamura method. The Biot theory is used in Sec. II to describe the shear mode and to predict the surface impedance and $\cos \theta_p$. The validity of Eqs. (4)–(6) in the context of the Biot theory is discussed in Sec. III. Measurements of $\cos \theta_p$ leading to an evaluation of the shear modulus for two porous foams are presented in Sec. IV.

II. DESCRIPTION OF THE SHEAR MODE

The Biot theory, with the formalism developed in Ref. 16, has been used to predict the surface impedance with the model by Johnson *et al.*¹⁷ for the viscous and inertial interaction, and the model by Lafarge¹⁸ for the incompressibility of air. The stress-strain relations in the Biot theory are

$$\sigma_{ij}^s = [(P - 2N)\theta^s + Q\theta^f] \delta_{ij} + 2Ne_{ij}^s, \quad (7)$$

$$\sigma_{ij}^f = Q\theta^s + R\theta^f, \quad (8)$$

where θ^f and θ^s are the dilatation of the air and of the frame, respectively, e_{ij}^s are the strain components of the frame, and σ_{ij}^f and σ_{ij}^s are the stress components of the air and of the frame, respectively. The stress components are related to forces per unit area of porous medium; then $\sigma_{ij}^f = -\phi p \delta_{ij}$, where p is the pressure in the air that saturates the porous medium. The Biot elasticity coefficients P , Q , and R , with the simplifications suggested in Ref. 16 (see Eqs. 6.21–6.28 of Ref. 16), are given by

$$P = \frac{4}{3}N + K_b + \frac{(1-\phi)^2}{\phi} K_f, \quad (9)$$

$$Q = K_f(1-\phi), \quad (10)$$

$$R = \phi K_f, \quad (11)$$

$$K_b = \frac{2}{3}N(1+\nu)/(1-2\nu), \quad (12)$$

where K_b is the bulk modulus of the frame, N is the shear modulus, and ν is the Poisson ratio. The incompressibility K_f of the air saturating the porous frame is given in the present work by

$$K_f = \frac{K_a}{\beta}, \quad (13)$$

where K_a is the adiabatic incompressibility of air and β is given by Eq. (30) of Ref. 18:

$$\beta = \gamma - (\gamma - 1) \left[1 + \frac{1}{-i\tilde{\omega}'} \left(1 - \frac{M'}{2} i\tilde{\omega}' \right)^{1/2} \right]^{-1}, \quad (14)$$

$$\tilde{\omega}' = \frac{\rho_0 \operatorname{Pr} \omega k_0'}{\eta \phi}, \quad (15)$$

$$M' = \frac{8k_0'}{\phi \Lambda'^2}. \quad (16)$$

In these equations, η is the viscosity, ρ_0 is the density of air, γ is the ratio of the specific heats, Pr is the Prandtl number, k_0' is the thermal permeability, and Λ' is the thermal characteristic dimension of the porous frame.

The equations of motion governing the displacement \mathbf{u}^s of the frame and \mathbf{u}^f of the saturating fluid are

$$-\omega^2(\tilde{\rho}_{11}\mathbf{u}^s + \tilde{\rho}_{12}\mathbf{u}^f) = (P - N)\nabla\nabla\cdot\mathbf{u}^s + N\nabla^2\mathbf{u}^s + Q\nabla\nabla\cdot\mathbf{u}^f, \quad (17)$$

$$-\omega^2(\tilde{\rho}_{22}\mathbf{u}^f + \tilde{\rho}_{12}\mathbf{u}^s) = R\nabla\nabla\cdot\mathbf{u}^f + Q\nabla\nabla\cdot\mathbf{u}^s. \quad (18)$$

The renormalized densities $\tilde{\rho}_{11}$, $\tilde{\rho}_{22}$, and $\tilde{\rho}_{12}$ are given by (see Eqs. 6.58 of Ref. 16)

$$\tilde{\rho}_{11} = \rho_1 + \rho_a - ib, \quad (19)$$

$$\tilde{\rho}_{12} = -\rho_a + ib, \quad (20)$$

$$\tilde{\rho}_{22} = \phi\rho_0 + \rho_a - ib. \quad (21)$$

The coefficient b related to the viscous and the inertial interaction is given in the present work by

$$b = -\frac{\sigma}{\omega} \phi^2 G_j(\omega), \quad (22)$$

$$G_j(\omega) = \left(1 - \frac{4i\alpha_\infty^2 \eta \rho_0 \omega}{\sigma^2 \Lambda^2 \phi^2} \right)^{1/2} \quad (23)$$

(see Eq. 5–64 of Ref. 16 with a complex conjugation due to the opposite time dependence), where α_∞ is the tortuosity, σ is the flow resistivity, and Λ is the characteristic viscous dimension. The added density ρ_a is given by

$$\rho_a = \rho_0 \phi (\alpha_\infty - 1). \quad (24)$$

The wave numbers k_1 and k_2 for both Biot compressional waves, and k_3 for the Biot shear wave, are given by

$$k_{1,2}^2 = \frac{\omega^2}{2(PR - Q^2)} [P\tilde{\rho}_{22} + R\tilde{\rho}_{11} - 2Q\tilde{\rho}_{12} \pm \sqrt{\Delta}], \quad (25)$$

$$k_3^2 = \frac{\omega^2}{N} \left[\frac{\tilde{\rho}_{11}\tilde{\rho}_{22} - \tilde{\rho}_{12}^2}{\tilde{\rho}_{22}} \right], \quad (26)$$

$$\Delta = (P\tilde{\rho}_{22} + R\tilde{\rho}_{11} - 2Q\tilde{\rho}_{12})^2 - 4(PR - Q^2)(\tilde{\rho}_{11}\tilde{\rho}_{22} - \tilde{\rho}_{12}^2). \quad (27)$$

Both compressional waves can be related to a velocity potential φ for the frame and $\varphi_f = \mu \varphi$ for the saturating fluid. The related displacements \mathbf{u}^s and \mathbf{u}^f are given by

$$\mathbf{u}^s = \frac{i}{\omega} \nabla \varphi, \quad (28)$$

$$\mathbf{u}^f = \frac{i\mu}{\omega} \nabla \varphi. \quad (29)$$

The coefficients μ are given by

$$\mu_{1,2} = \frac{Pk_{1,2}^2 - \omega^2 \tilde{\rho}_{11}}{\omega^2 \tilde{\rho}_{12} - Qk_{1,2}^2}. \quad (30)$$

The shear wave is related to a vector velocity potential for the frame Ψ , and a vector velocity potential for air $\Psi_a = \mu_3 \Psi$.

The related displacements are given by

$$\mathbf{u}^s = \frac{i}{\omega} \nabla \wedge \Psi, \quad (31)$$

$$\mathbf{u}^f = \frac{i}{\omega} \mu_3 \nabla \wedge \Psi, \quad (32)$$

and μ_3 is given by

$$\mu_3 = -\tilde{\rho}_{12}/\tilde{\rho}_{22}. \quad (33)$$

A plane wave in air impinging upon the porous layer with an angle of incidence θ is represented in Fig. 2. The incidence plane is xoz , the axis x is parallel to the air-porous medium interface. The incident field creates in the porous layer a field which can be described by six potentials with the same horizontal wave number vector component $\xi = k \sin \theta$, φ_1^+ , φ_1^- for the first compressional wave with opposite z wave number vector components $\alpha_1 = (k_1^2 - \xi^2)^{1/2}$ and $-\alpha_1$, respectively. Similarly, two potentials φ_2^+ and φ_2^- are defined for the second compressional wave, related to the z wave number vector components $\alpha_2 = (k_2^2 - \xi^2)^{1/2}$ and $-\alpha_2$, and two potentials $\Psi^+ = \mathbf{n}\varphi_3^+$, $\Psi^- = \mathbf{n}\varphi_3^-$, related to $\alpha_3 = (k_3^2$

FIG. 2. A plane wave in air, incident on a porous layer. The angle of incidence is θ , the incidence plane is oxz .

$-\xi^2)^{1/2}$ and $-\alpha_3$, \mathbf{n} being the unit vector on the y axis. The scalar functions φ_j^\pm can be written

$$\varphi_j^\pm = a_j^\pm \exp(\pm i\alpha_j z + i\xi x), \quad (34)$$

where the six constant coefficients a_j^\pm can be predicted from the boundary conditions.

The porous layer is glued to the rigid impervious backing. At the contact surface with the rigid impervious backing the boundary conditions are $u_z^s = u_x^s = u_z^f = 0$, which can be rewritten

$$\begin{aligned} \alpha_1 [a_1^+ \exp(i\alpha_1 l) - a_1^- \exp(-i\alpha_1 l)] + \alpha_2 [a_2^+ \exp(i\alpha_2 l) \\ - a_2^- \exp(-i\alpha_2 l)] + \xi [a_3^+ \exp(i\xi l) + a_3^- \exp(-i\xi l)] \\ = 0, \end{aligned} \quad (35)$$

$$\begin{aligned} \xi [a_1^+ \exp(i\alpha_1 l) + a_1^- \exp(-i\alpha_1 l)] + \xi [a_2^+ \exp(i\alpha_2 l) \\ + a_2^- \exp(-i\alpha_2 l)] - \alpha_3 [a_3^+ \exp(i\xi l) - a_3^- \exp(-i\xi l)] \\ = 0, \end{aligned} \quad (36)$$

$$\begin{aligned} \alpha_1 \mu_1 [a_1^+ \exp(i\alpha_1 l) - a_1^- \exp(-i\alpha_1 l)] \\ + \alpha_2 \mu_2 [a_2^+ \exp(i\alpha_2 l) - a_2^- \exp(-i\alpha_2 l)] \\ + \xi \mu_3 [a_3^+ \exp(i\xi l) + a_3^- \exp(-i\xi l)] = 0. \end{aligned} \quad (37)$$

Let p and U_z be the pressure and the z component of the air velocity in the free air at the contact surface with the porous layer. At this interface, the boundary conditions can be written¹⁹

$$\phi u_z^f + (1 - \phi) u_z^s = U_z, \quad (38)$$

$$\sigma_{zz}^f = -\phi p, \quad (39)$$

$$\sigma_{zz}^s = -(1 - \phi)p, \quad (40)$$

$$\sigma_{xz}^s = 0. \quad (41)$$

A preliminary use of Eqs. (35)–(37) provides the reflection coefficients at a rigid and impervious boundary for the three Biot waves and first information concerning the shear modes. For $a_1^+ = 1$, $a_2^+ = a_3^+ = 0$, i.e., a compressional wave φ_1^+ of amplitude unity at the air-porous layer boundary, the expressions for the a_i^- , $i = 1, 3$, solutions of Eqs. (35)–(37) and denoted as $r_{1,i}$ are given in the first line of Table I. In the same way, the second line gives the expressions $r_{2,i}$, $i = 1, 3$, of the a_i^- related to $a_2^+ = 1$, $a_1^+ = a_3^+ = 0$, and the third line gives the expressions $r_{3,i}$, $i = 1, 3$, of the a_i^- related to a_3^+

TABLE I. The coefficients $r_{i,j}$ expressed with $A = \alpha_1 \alpha_2 (\mu_1 - \mu_2)$, $B = \alpha_1 \xi (\mu_1 - \mu_3)$, $C = \alpha_2 \xi (\mu_2 - \mu_3)$, $D = \alpha_3 A + \xi (B - C)$, and $T_{i,j} = \exp(-i(\alpha_i + \alpha_j)l)$.

$r_{1,1}DT_{1,1}$ $\alpha_3 A + \xi(B + C)$	$r_{1,2}DT_{1,2}$ $-2\xi B$	$r_{1,3}DT_{1,3}$ $-2\xi A$
$r_{2,1}DT_{2,1}$ $2\xi C$	$r_{2,2}DT_{2,2}$ $\alpha_3 A - \xi(B + C)$	$r_{2,3}DT_{2,3}$ $-2\xi A$
$r_{3,1}DT_{3,1}$ $-2\alpha_3 C$	$r_{3,2}DT_{3,2}$ $2\alpha_3 B$	$r_{3,3}DT_{3,3}$ $\alpha_3 A - \xi(B - C)$

$= 1$, $a_1^+ = a_2^+ = 0$. The factor $\exp(i\xi x)$ has been removed from the different amplitudes. At the air-porous layer interface, each incident wave in the layer will be associated with its reflected field, so that Eqs. (35)–(37) will be automatically satisfied. Equations (38)–(41) can be rewritten

$$i\alpha_1(\phi\mu_1 + (1 - \phi))[a_1^+(1 - r_{1,1}) - a_2^+r_{2,1} - a_3^+r_{3,1}] + i\alpha_2(\phi\mu_2 + (1 - \phi))[-a_1^+r_{1,2} + a_2^+(1 - r_{2,2}) - a_3^+r_{3,2}] + i\xi(\phi\mu_3 + (1 - \phi))[a_1^+r_{1,3} + a_2^+r_{2,3} + a_3^+(1 + r_{3,3})] = -i\omega U_z, \quad (42)$$

$$\frac{-i}{\omega}\{(Q + R\mu_1)k_1^2[a_1^+(1 + r_{1,1}) + a_2^+r_{2,1} + a_3^+r_{3,1}] + (Q + R\mu_2)k_2^2[a_1^+r_{1,2} + a_2^+(1 + r_{2,2}) + a_3^+r_{3,2}]\} = -\phi p, \quad (43)$$

$$\frac{-i}{\omega}\{(P + Q\mu_1)k_1^2 - 2N\xi^2[a_1^+(1 + r_{1,1}) + a_2^+r_{2,1} + a_3^+r_{3,1}] + [(P + Q\mu_2)k_2^2 - 2N\xi^2][a_1^+r_{1,2} + a_2^+(1 + r_{2,2}) + a_3^+r_{3,2}] + 2N\xi\alpha_3[-a_1^+r_{1,3} - a_2^+r_{2,3} + a_3^+(1 - r_{3,3})]\} = -(1 - \phi)p, \quad (44)$$

$$2\xi\alpha_1[a_1^+(1 - r_{1,1}) - a_2^+r_{2,1} - a_3^+r_{3,1}] + 2\xi\alpha_2[-a_1^+r_{1,2} + a_2^+(1 - r_{2,2}) - a_3^+r_{3,2}] + (\xi^2 - \alpha_3^2) \times [a_1^+r_{1,3} + a_2^+r_{2,3} + a_3^+(1 + r_{3,3})] = 0. \quad (45)$$

The three Eqs. (43)–(45) provide the ratios a_1^+/p , a_2^+/p , and a_3^+/p . Reporting these ratios in Eq. (42) provides the surface impedance $Z_s(\theta) = p/U_z$. The predicted $\cos\theta_p$ is obtained from the series $(\cos\theta_p)_i$ defined by the following iterative equation

$$(\cos\theta_p)_{i+1} = 0.8(\cos\theta_p)_i - 0.2 \frac{Z}{Z_s((\theta_p)_i)}, \quad (46)$$

with $(\theta_p)_1 = \pi/2$. A general description of the shear mode with Eqs. (42)–(45) is beyond the aim of the present work. The main properties of the mode are shown in the context of a simulation with a porous foam.

The porous material used for the simulations is a typical foam with a thickness $l = 1$ cm. The parameters that describe the foam are given in Table II (yellow foam), except the imaginary part of the shear modulus N , and the thickness l . The layer is set on a rigid impervious backing and the frame

FIG. 3. The surface impedance at normal incidence. Same parameters as in the second column of Table I (yellow foam) except thickness $l = 1$ cm and $\text{Im } N = -6.2$ kPa: —, $\text{Im } N = -1.55$ kPa: ---.

is motionless at the contact surface. The surface impedances at normal incidence $Z_s(0)$ and $\cos(\theta_p)$ are represented in Figs. 3 and 4 for two loss angles, 0.1 and 0.025, respectively. The Poisson ratio ν is real, because previous measurements^{7,20} give $\text{Im } \nu = 0$, and $\text{Re } \nu = 0.3$. This choice for $\text{Re } \nu$ is arbitrary; coefficients ν previously measured for different foams range from 0.1 to 0.5, but it has no significant effect on the shear mode. There is only a small shift, around 10 Hz, of the location of the peak related to the shear mode in Fig. 4 when ν varies from 0 to 0.5. The shear mode is located around 813 Hz, where the quarter shear Biot wavelength is equal to the thickness of the layer, and the compressional mode is located around 1500 Hz. At normal incidence, $\xi = 0$, and $r_{3,1} = r_{3,2} = r_{1,3} = r_{2,3} = 0$, $r_{3,3} = 1$. Then Eq. (45) gives $a_3^+ = 0$ and the Biot shear wave is not present. Let ξ_p be the horizontal wave number component related to the pole, $\xi_p = k \sin\theta_p$. When $\cos\theta_p$ is small, $\sin\theta_p$ is close to 1, and ξ_p is close to k . All the coefficients $r_{i,j}$ are different from 0, and the shear wave is present and gives a contribution to U_z and p via u_z^s , u_z^f , σ_{zz}^s , and σ_{zz}^f . This contribution and a_3^+ reach a maximum when the coefficient $T_{3,3} = \exp(-2i\alpha_3 l)$ of

FIG. 4. Predicted $\cos\theta_p$ as a function of frequency for the same material as in Fig. 3. $\text{Im } N = -6.2$ kPa: —, $\text{Im } N = -1.55$ kPa: ---.

Table I is close to -1 , for $\text{Re } \alpha_3 l$ close to $\pi/2$. The shear mode does not exist if the shear wave is faster than the sound in air, because in this case $\alpha_3 = (k_3^2 - k^2)^{1/2}$ is, in a first approximation, an imaginary quantity. In the simulation (and for the usual plastic open-cell foams), the speed of the shear waves in the foam is much smaller than the sound speed in the free air, and α_3 is close to k_3 . For a loss angle equal to 0.1 ($\text{Im } N = -6200 \text{ Pa}$), the influence of the compressional mode is negligible on the impedance but the shear mode is detectable on the behavior of $\cos \theta_p$. For a loss angle equal to 0.025 ($\text{Im } N = -1550 \text{ Pa}$), the presence of the shear mode is much more obvious than the presence of the compressional mode on the pole location. The shear mode appears in a small range of frequencies where it is related to a horizontal wave number component close to k , which allows a strong coupling with the pressure field in the free air at grazing incidence. An opposite case is the one of the Rayleigh wave, which can propagate at the same frequencies on samples of larger thickness. The order of magnitude of the Rayleigh wave velocity is around 50 m/s, which corresponds to a horizontal wave number component seven times as large as k . The coupling with the field in air at grazing incidence is weak, with no noticeable effect on $\cos \theta_p$.

III. VALIDITY OF THE APPROXIMATION FOR p_r IN THE CONTEXT OF THE BIOT THEORY

The method used to measure $\cos \theta_p$ for thin porous layers with a motionless frame is based on the use of Eqs. (4)–(6). These expressions have been obtained with the reference integral method described by Brekhovskikh and Godin²¹ from the Sommerfeld representation of the reflected monopole field

$$p_r = i \int_0^\infty \frac{k \xi d\xi}{\lambda} V(\lambda) J_0(\xi k r) \exp[ik\lambda(h_1 + h_2)], \quad (47)$$

which can be rewritten

$$p_r = \frac{i}{2} \int_{-\infty}^\infty \frac{k \xi d\xi}{\lambda} V(\lambda) H_0^{(1)}(\xi k r) \exp[ik\lambda(h_1 + h_2)], \quad (48)$$

$$\lambda = (1 - \xi^2)^{1/2}, \quad \text{Im}(\lambda) \geq 0,$$

where $H_0^{(1)}$ is the Hankel function of zeroth order. A complex angle θ can be defined by $\sin \theta = \xi$, $\cos \theta = \lambda$. Using the asymptotic development of the Hankel function, $H_0^{(1)}(u) = (2/\pi u)^{1/2} \exp(iu - i\pi/4)$, Eq. (48) can be rewritten

$$p_r = \left(\frac{k}{2\pi r}\right)^{1/2} \exp\left(\frac{i\pi}{4}\right) \int_{-\infty}^\infty F(\xi) \exp[\rho f(\lambda)] d\xi, \quad (49)$$

$$F(\xi) = \sqrt{\frac{\xi}{1 - \xi^2}} V(\lambda), \quad (50)$$

$$f(\lambda) = i \cos(\theta - \theta_0), \quad (51)$$

$$\rho = kR_1. \quad (52)$$

Using the reference integral method with the notations of Ref. 21, $q = \sin \theta$, $q_p = \sin \theta_p$, and $q_0 = \sin \theta_0$, p_r can be rewritten

$$p_r = \left(\frac{k}{2\pi r}\right)^{1/2} \exp(i\pi/4) \exp[\rho f(q_0)] \times \left[a \mathcal{F}_1(1, \rho, s_p) + \left(\frac{\pi}{\rho}\right)^{1/2} \Phi_1^0(0) \right], \quad (53)$$

$$a = 1 / \left(\frac{dF^{-1}(q)}{dq} \right)_{q=q_p}, \quad (54)$$

$$\mathcal{F}_1(1, \rho, s_p) = i\pi \exp(-\rho s_p^2) \text{erfc}(-i\sqrt{\rho} s_p), \quad (55)$$

$$\Phi_1^0(0) = F(q_0) (-2/f_{q_2}''(q_0))^{1/2} + \frac{a}{s_p}, \quad (56)$$

$$s_p = \exp(i\pi/4) \sqrt{2} \sin \frac{\theta_p - \theta_0}{2}. \quad (57)$$

With $f_{q_2}''(q_0) = -i/\cos^2(\theta_0)$, the term $F(q_0) (-2/f_{q_2}''(q_0))^{1/2}$ gives a contribution p_{r1} to p_r given by

$$p_{r1} = V(\cos \theta_0) \exp(ikR_1) / R_1, \quad (58)$$

independently on the expression which defines V . The two terms with the factor a give the contribution p_{r2} given by

$$p_{r2} = a \exp(ikR_1 + i3\pi/4) (k/2r)^{1/2} (-i + w\sqrt{\pi} \exp(-w^2) \times \text{erfc}(-iw)) / w, \quad (59)$$

where w is given by Eq. (5), and the coefficient a is given by

$$a = \frac{-2 \cos \theta_p}{\sqrt{\sin \theta_p}} [1 + (\cos \theta_p / Z_s(\cos \theta_p))] \times (dZ_s/d \cos \theta)_{\theta=\theta_p}^{-1}. \quad (60)$$

The reflected pressure can be written

$$p_r = V(\cos \theta_0) \exp(ikR_1) / R_1 - \frac{\cos \theta_p}{w} \sqrt{\frac{2k}{r \sin \theta_p}} \times \frac{\exp(ikR_1 + i3\pi/4) [-i + w\sqrt{\pi} \exp(-w^2) \text{erfc}(-iw)]}{[1 + (\cos \theta_p / Z_s(\cos \theta_p)) (dZ_s/d \cos \theta)_{\theta=\theta_p}]}. \quad (61)$$

If Z_s does not depend on θ_p , this equation is identical to Eq. 1-4-10 of Ref. 21 for locally reacting surfaces

$$p_r = V(\cos \theta_0) \exp(ikR_1) / R_1 - \frac{\cos \theta_p}{w} \sqrt{\frac{2k}{r \sin \theta_p}} \exp(ikR_1 + i3\pi/4) [-i + w\sqrt{\pi} \exp(-w^2) \text{erfc}(-iw)]. \quad (62)$$

If θ_p and θ_0 are sufficiently close to $\pi/2$, ($\sin \theta_p$)^{1/2} can be removed and Eqs. (5) and (62) can be replaced by Eqs. (6) and (4). These equations can be used also for thin layers with a motionless frame or in the context of the Biot theory if

$$|(\cos \theta_p / Z_s(\cos \theta_p)) (dZ_s/d \cos \theta)_{\theta=\theta_p}| \ll 1. \quad (63)$$

An evaluation of the left side of this equation is not very simple. If the structural damping of the frame is small, the shear mode induces fast variations of Z_s with frequency, Eq. (63) is not satisfied, and Eqs. (4)–(6) cannot be used, but the loss angle for usual open-cell foams is large. Comparisons

FIG. 5. $\cos \theta_p$ as a function of frequency, yellow foam; measurement \blacksquare - \blacksquare - \blacksquare , prediction —.

between estimations of the reflected pressure over thin porous layers, obtained with Eq. (47) and with Eqs. (4)–(6), have been performed around frequencies where the shear mode is present, showing that for loss angles of the frame larger than $\frac{1}{100}$, Eqs. (4) and (6) provide a good approximation for the reflected pressure for thin layers. The loss angle for usual open-cell foams is much larger than $\frac{1}{100}$.

IV. EXPERIMENTAL EVALUATION OF THE SHEAR MODULUS

In Fig. 1 a symbolic sketch of the experimental set up is presented. The monopole source S is a pipe fed by a compression driver. The receiver at M is an electret microphone. The distances z_1 from the porous layer to the source and z_2 from the layer to the microphone are $z_1 = z_2 = 3$ mm. The distance r from the source to the receiver is $r = 23$ cm. The angle of specular reflection is θ_0 verifying $\cot \theta_0 = (z_1 + z_2)/r$. The porous layers are glued to a rigid impervious backing, the area of the layers is close to 1 m^2 . The evaluation of $\cos \theta_p$ with Eq. (4) is performed from a measurement of the ratio $p_r / (\exp(ikR_1)/R_1)$ where $\exp(ikR_1)/R_1$ is the direct field at a distance R_1 from the source. The measurement of the ratio is obtained from a measurement of the pressure p_h related to the direct field, the porous surface being replaced by a rigid, impervious surface and a second measurement over the porous surface of the pressure p_t . Both measurements are performed with the same geometry, close to grazing incidence so that R_1 and R_2 are equal in a first approximation. The ratio in Eq. (4) can be evaluated from

$$p_r / (\exp(ikR_1)/R_1) = \frac{p_t - p_h/2}{p_h/2}, \quad (64)$$

and $\cos \theta_p$ is given by

$$2 \frac{p_h - p_t}{p_h} = \cos \theta_p \exp\left(\frac{3\pi i}{4}\right) \left[\sqrt{2\pi k R_1} \exp(-w^2) \times \text{erfc}(-iw) \right]. \quad (65)$$

An iterative procedure¹⁴ is used to evaluate $\cos \theta_p$ from Eq. (65). For thin layers with a source-receiver

FIG. 6. $\cos \theta_p$ as a function of frequency, black foam; measurement \blacksquare - \blacksquare - \blacksquare , prediction —.

distance smaller than 1 m, w is small and the first value for $\cos \theta_p$ is obtained with $w = 0$, giving $\cos \theta_p = 2(1 - p_t/p_h) / \exp(3\pi i/4) \sqrt{2\pi k R_1}$. The derivative of $g(w) = \exp(-w^2) \text{erfc}(-iw)$ is $g'_w(w) = -2wg(w) + 2i/\sqrt{\pi}$ (see Ref. 22, Chap. 7), and the derivative $dw/d \cos \theta_p$ of $w = (1/2ikR_1)^{1/2} (\cos \theta_0 - \cos \theta_p)$ is $dw/d \cos \theta_p = -(1/2ikR_1)^{1/2}$. These two relations are used to minimize the left- and right-hand side difference of Eq. (65).

Measurements have been performed on two foams, a yellow foam of thickness $l = 0.5$ cm and a black foam (S616D) manufactured by Recticel (Plejadenaan, 15, B-1200 Brussels) of thickness $l = 1$ cm. Measurements on the yellow foam are presented in Fig. 5 and on the black foam in Fig. 6. Fast variations of $\cos \theta_p$ similar to the ones of Fig. 4 are present for both foams. A set of parameters given in Table II has been used to predict $\cos \theta_p$ in Figs. 4 and 5. The flow resistivities and the densities in Table II are measured and the shear moduli have been chosen to set the fast predicted variations at the same frequencies as the measured ones. The other parameters have been set to reasonable values. The frequencies where the fast variations occur are mainly related to densities and shear moduli; the other parameters have a very small influence on the localization of the fast variations. For the black foam, measurements of the Rayleigh wave velocity have been performed on a sample of thickness $l = 6$ cm with the method described in Ref. 8: a Rayleigh-like wave is excited with a conventional shaker in

TABLE II. Parameters for the porous materials.

Parameters	Yellow foam	Black foam
porosity ϕ	0.99	0.99
flow resistivity σ ($\text{Nm}^{-4} \text{s}$)	40 000.0	130 000.0
thermal permeability k'_0 (m^2)	10^{-9}	5×10^{-10}
viscous dimension Λ (μm)	100	60
thermal dimension Λ' (μm)	300	180
tortuosity α_∞	1.05	1.1
density ρ_s (kg/m^3)	58	59
shear modulus N (kPa)	62.0 - i 1.55	125.0 - i 6.0
Poisson ratio (ν)	0.3	0.3
thickness l (cm)	0.5	1.0

FIG. 7. Arrival time and attenuation as a function of position at 2 kHz, 25 °C. The phase velocity and attenuation are determined from a linear regression and an exponential regression on the data, respectively.

contact with the surface of the sample and the vertical displacement is measured at several distances from the source using a Polytec vibrometer. A line source has been used as an excitation and the signal was a narrow-band Gaussian burst centered around the measuring frequency. The shear modulus was extracted from the phase velocity of the Rayleigh wave and the attenuation was measured from the decay of the amplitude as a function of position. Figures 7(a) and (b) show typical results as a function of position at a center frequency of 2 kHz and ambient temperature 25 °C. Table III summarizes the results at 2 and 4 kHz under the hypothesis of a Poisson ratio $\nu=0.3$. The yellow foam is much less rigid at very low frequencies than the black foam, but it has not been possible to measure the Rayleigh wave velocity (samples of sufficient thickness were not available). The effect of the shear mode is a peak limited over a small range of frequencies. The precision of the measurement of $\text{Re } N$ is limited by the broadness of the peak. For the materials studied, the precision is about $\frac{10}{100}$ for $\text{Re } N$ and $\frac{50}{100}$ for $\text{Im } N$. The fast increase of $\text{Im } N$ with frequency can explain the difference between the measured $\text{Im } N$ around 1.2 kHz with the point source method and around 2 kHz with the Rayleigh wave. The measurements of $\text{Re } N$ by both methods give similar results.

V. CONCLUSION

The acoustic field created by a point-source close to thin layers of open-cell foams can be strongly coupled with a shear mode around frequencies where the quarter shear wavelength is equal to the thickness of the layer. The strong coupling is due to the fact that the horizontal wave-number

TABLE III. Measured wave number of the Rayleigh wave and shear modulus.

Frequency (kHz)	$\text{Re } k_R$ (m^{-1})	$\text{Im } k_R$ (m^{-1})	N (kPa)
2	283.0	12.0	135.0 - i 11.0
4	576.0	65.0	126.0 - i 29.0

component of the mode is close to the wave number in the free air. The amplitude of the mode is sufficiently large for the mode to be detected acoustically from the fast variations with frequency of the location of a pole of the reflection coefficient. The description with the Biot theory of the interaction between the shear mode and the acoustic field in air is in good agreement with the experiment. This is a new example of the adequacy of the Biot theory for the description of the acoustical properties of sound-absorbing media. This work also shows the interest of the method of localizing a pole of the reflection coefficient from short range pressure measurements close to grazing incidence.

(Received 23 June 2004; revised 5 November 2004; accepted for publication 1 December 2004)

A T-matrix based method of solution of the multiple scattering problem was presented by the authors [J. Acoust. Soc. Am. **112**, 2688–2701 (2002)]. This method can be applied to the computation of relatively small problems, since the number of operations required grows with the number of spheres N as $O(N^3)$, and with the sixth power of the wave number. The use of iterative techniques accelerated using the fast multipole method (FMM) can accelerate this solution, as presented by Koc and Chew [J. Acoust. Soc. Am. **103**, 721–734 (1998)] originally. In this study we present a method that combines preconditioned Krylov subspace iterative techniques, FMM accelerated matrix vector products, a novel FMM-based preconditioner, and fast translation techniques that enable us to achieve an overall algorithm in which the cost of the matrix-vector multiplication grows with N as $O(N \log N)$ and with the third power of the wave number. We discuss the convergence of the iterative techniques, selection of the truncation number, errors in the solution, and other issues. The results of the solution of test problems obtained with the method for $N \sim 10^2 - 10^4$ for different wave numbers are presented. © 2005 Acoustical Society of America. I. INTRODUCTION

Problems of acoustic and electromagnetic wave propagation through a medium consisting of the carrier fluid or solid and inclusions in the form of solid particles, droplets, and bubbles are of great practical and theoretical interest, and there are several approaches for the modeling of these. One approach is based on the development of continuum theories that treat a large system as a single complex medium with special properties that are obtained on the basis of spatial or other types of averaging (e.g., see Nigmatulin, 1990; Cafilisch *et al.*, 1985). This approach is validated against experiments and has many strengths, such as a relative simplicity of the description, a clear relation to the physics, and the operation with quantities that can be measured. However, as with any theory, the continuum theories have some limits and restrictions that follow from basic assumptions. For example, the models normally are based on assumptions that the medium is acoustically homogeneous (Gumerov *et al.*, 1988; Duraiswami and Prosperetti, 1995). This means that the wavelengths should be much larger than the characteristic size a and distance d between the particles ($ka \ll 1$, $kd \ll 1$, where k is the wave number). While some assumptions can be relaxed, an accurate averaging procedure should take into account many real effects, and unavoidably introduces assumptions that permit one to link the description of the processes at the “microlevel” with the behavior of quantities at the “macrolevel.”

Another approach is based on the direct computation of the acoustic field in the system at the level of particle sizes, based on fundamental governing equations applicable at the “microlevel.” While valid and free of many limitations of the continuum theory, this approach is computationally challenging. It is more or less obvious that there should be substantial efforts toward some theories that combine direct

computations, stochastic and continuum medium approach to extend their limits, and, in fact, this is not a purpose of this paper. Here we are interested with a solution of some “intermediate” class of problems, when, on the one hand, the number of particles is large enough to make conclusions of a statistical nature, and, on the other hand, may be small compared to real systems.

The problems, which are out of the range of continuum theories, are related to the acoustic wavelengths, which are comparable with the size of the particles. This may include both ultrasound propagation in dispersed systems, or lower-frequency sound propagation in some environment with larger objects (e.g., fish). In this case the number of scatterers in the system can be, say, several thousands. Since in the present paper we are solving the problem for the three-dimensional (3D) Helmholtz equation, which also appears in electromagnetics, the method may also be applicable to the solution of problems in diffraction optics, x-ray scattering, and so on. In many situations the scatterers can be assumed to be spherical, and the boundary conditions on the scatterer have a strong influence on the results.

There exist several approaches to the solution of the multiple scattering problems, and the T-matrix method and its modifications are among these approaches (Waterman and Truell, 1961; Peterson and Strom, 1974; Varadan and Varadan, 1980; Wang and Chew, 1993; Mischenko *et al.*, 1996; Koc and Chew, 1998) and recently in our paper [Gumerov and Duraiswami, 2002; which in the sequel we will refer to as (GD02)]. A solution of the problem for spherical scatterers based on a multipole re-expansion technique was presented in (GD02). This solution is based on a representation of the scattered field for each sphere by a series of multipoles, the coefficients of which can be determined by applying the impedance boundary conditions cor-

responding to each sphere. This was achieved using re-expansion matrices, which enable one to find the expansion coefficients in a basis conveniently located at the center of an arbitrary scatterer. Since the series are infinite, we used truncation to keep only p^2 terms in the series, where p is a quantity termed the truncation number.

In (GD02) the computational complexity for solution of this problem for N scatterers is $O(p^6 N^3)$. While we found that this method is reliable and fast for relatively small N and p , the solution of problems for a larger number of scatterers ($N \geq 10^3$) or higher frequencies (since for convergence $p > ka$) with this method is computationally intractable.

Such computations are also known as “brute-force” method, and there exist several papers in electromagnetics and acoustics that present algorithms of lower complexity. For example, Wang and Chew (1993), present a generalized recursive aggregate T-matrix algorithm (RATMA), with complexity $O(p^2 P^4 N)$ (in our notation), where P^2 is the number of harmonics to expand the field of the aggregated scatterers. The latter quantity is related to the size of the computational domain, D_0 , and $P \sim kD_0$. If we assume that the volume fraction of scatterers is constant, and so $D_0 \sim N^{1/3} a$, and since the truncation numbers can be estimated as $p \sim ka$, we can see that actually the RATMA scales as $O(p^6 N^{7/3})$. The RATMA does not improve the sixth power in the complexity dependence on p . That is why the computations with this algorithm can be performed only for low p (i.e., low ka). For example, Wang and Chew (1993) presented computations of electromagnetic scattering problem for large enough $N = 6859$, but for relatively low $kD_0 < 10$ (truncation numbers in these computations $p \leq 3$). In this context we should note that the accuracy of computations depends not only on the size of the domain or the size of scatterers (kD_0 and ka), but also on the interparticle distances, d/a . Even for $ka < 1$, truncation numbers can be, say $p \sim 15$, for the relatively low accuracy of computations of 1%, in the case that the scatterers are nearly touching (see the discussion on truncation numbers later in this paper).

Another, rather obvious, idea to improve the “brute-force” method is to use iterative methods for a solution of the linear system. If N_{iter} is the number of iterations to achieve a required accuracy and each iteration requires one matrix-vector multiplication, which can be performed directly for $O(p^4 N^2)$ operations, the total complexity of the algorithm will be $O(p^4 N^2 N_{\text{iter}})$. Comparing with the RATMA, we can see that for $N_{\text{iter}} \ll p^2 N^{1/3}$, an iterative technique is faster.

A further improvement of the algorithm complexity comes from the acceleration of the matrix-vector multiplication. Currently two major techniques are known to reduce the complexity of solution from $O(N^2)$ to $O(N \log N)$ or $O(N)$ (if we assume that the truncation number does not depend on N): the Fast Fourier Transform (FFT) and the Fast Multipole Method (FMM).

The FFT cannot be applied if the scatterers are not located in a regular grid. However, this can be fixed by using translations from the scatterer locations to the regular grid, which is an idea of the FMMFFT (Koc and Chew, 1998). As originally introduced, the FMMFFT utilizes the diagonal

forms of the translation operators and has complexity $O(p^4 N + p^2 N \log N)$. Recently some modifications of the FMMFFT, such as the FFTM (Ong *et al.*, 2004) appeared in the literature, which utilize different translation methods (recursively computed translation matrices) and have complexity $O(p^4 N \log N)$.

The FMM was introduced in Greengard and Rokhlin (1987) for solution of the Laplace equation in two and three dimensions. Later, this method was intensively studied and extended to a solution of many other problems. Sangani and Mo (1996) applied it to multiparticle systems using the analog of the T-matrix idea for the case of Laplace and Stokes interactions of multiple particles via the FMM.

In the original work, functions were represented via a set of expansion coefficients over a local or multipole basis. The translation operators in this case appeared to be dense matrices converting one set of the expansion coefficients to the other. If the number of expansion coefficients is p^2 , this results in $O(p^4)$ translation complexity and in $O(p^4 N)$ overall complexity of the algorithm if p is the same for all the levels of hierarchical space subdivision. In the case of the Laplace equation, this results in a fast enough algorithm. However, for the Helmholtz equation for a given accuracy, the number of terms needed in the expansion grows with the largest length scale in the problem. Consequently, if we want to use the method as is, then for the Helmholtz equation instead of p^2 we should use P^2 , which is the number of terms needed to represent the function at the coarsest level. For a uniform volume distribution of the scatterers with a constant volume fraction, we have $P \sim kD_0 \sim ka N^{1/3} \sim p N^{1/3}$, which results in $O(p^4 N^{7/3})$ complexity. This is slower than $O(p^4 N^2)$ required for direct matrix-vector multiplication, and so the FMM in its original form is not applicable to the scattering problem.

To reduce the cost of the FMM, an alternative function representation, via samples of the so-called “signature function” (also called the Herglotz wave function), was introduced by Rokhlin (1993). This representation gives rise to the diagonal forms of the translation operators. The number of samples is proportional to the number of harmonics in spectral representation, and here we can treat this quantity as p^2 . The diagonal forms provide $O(p^2)$ translation complexity. If the original FMM using the diagonal forms is employed for a solution of the Helmholtz equations, we should use P^2 instead of p^2 that results in $O(P^2 N) = O(p^2 N^{5/3})$ complexity of the matrix-vector multiplication. As was suggested by Rokhlin, the way to overcome these large complexities in the FMM is to vary the size of the vectors representing functions from level to level.

The algorithm of this type based on the diagonal forms of the translation operators with interpolation/interpolation procedures (MLFMA) is presented in Chew *et al.* (2001) and used for the acoustic scattering problems by Koc and Chew (1998). If the interpolation/interpolation procedures are performed with complexity $O(M)$ for $O(M)$ samples of the signature function with the required accuracy, then a solution of the Helmholtz equation can be obtained for $O(p^2 N)$ operations. The algorithm of Koc and Chew (1998), however, formally has complexity $O(p^4 N)$, since it requires a conver-

sion of the function representation from the set of multipole expansion coefficients to samples of the signature function, and further accounting for near interactions is also estimated (by us) as $O(p^3N)$. Our computations show that for dense systems a computation of the near interactions can be several times more expensive than a computation of the farfield interactions.

In fact, the $O(p^4N)$ conversion is not a necessary step for the algorithm if it operates with the expansion coefficients and uses matrix translation operators. The complexity of such nondiagonalized operations can be reduced to $O(p^3)$ for p^2 expansion coefficients using rotational-coaxial translation decomposition, and this is sufficient to achieve $O(p^3N \log N)$ overall complexity of the matrix-vector multiplication for the volume distribution of scatterers. While this fact is simple and we provide its proof in this paper, it seems to have been overlooked in the previous publications, where one can find statements that only the diagonal forms of the translation operators provide algorithms scaled as $O(N)$ or $O(N \log N)$ for the Helmholtz equation. The benefits of operating in the space of expansion coefficients also include stability of the translations, which does not require interpolation/interpolation or spherical filtering procedures that are necessary for the methods using diagonal forms and is an expensive part of it (Darve, 2000a; Chew *et al.*, 2001). Another benefit is the stability of computations for the cases of low ka and relatively large p .

While the paper of Koc and Chew (1998) presumably is the first that uses a combination of the T-matrix method and iterative techniques accelerated by the FMM and/or FFT for solution of acoustic scattering problems, several important issues still remain to be worked out. First, the iterative techniques presented in that paper are relatively standard, and their rate of convergence can be slow. As we found from our numerical experiments for systems of densely packed scatterers, N_{iter} at sufficiently large N may even grow as $O(N)$, which brings the total complexity of the FMM accelerated methods to $O(N^2)$ or $O(N^2 \log N)$. One of the ways to treat this problem is to use properly designed preconditioners. In this paper we introduce for the first time the flexible generalized minimal residual method (FGMRES) with a right dense preconditioner, which can also be computed with the FMM/GMRES. Our results show that this can substantially speed up the algorithm, and experimental data on the complexity fit complexities $O(N^{1+\beta})$ with low β . Second, we establish both *a priori* error bounds and used an *a posteriori* error check of the solution to see how the error depends on the relative scatterer locations and the truncation numbers used. Third, as it was presented, the T-matrix could be arbitrary, but at the same time the application of the method to real problems of interest in computational acoustics was limited. In the present paper we apply the solution to problems that have been studied extensively in acoustics, of multiple scattering from spheres. To solve this problem, we exploited the multipole solution for the boundary value problem for spheres presented in (GD02) and used the explicit T matrices, which depend on the scatterer sizes, impedances, etc. This allows one to model and investigate various parametric dependencies, and, move the method to the solution of gen-

eral practical acoustical problems. Finally, we used a variant of the FMM operating with expansion coefficients only, where the rectangularly truncated translation operators were computed using fast recursive algorithms and decompositions (Gumerov and Duraiswami, 2003). Numerical experiments show the performance and efficiency of our algorithm and support, that the matrix-vector multiplication is performed with $O(N)$ or $O(N \log N)$ complexity.

II. STATEMENT OF THE PROBLEM

The problem considered is that in (GD02), and is repeated here to establish the notation. Consider sound scattering by N spheres with radii a_1, \dots, a_N situated in \mathbb{R}^3 . The coordinates of the centers of the spheres are denoted as $\mathbf{r}'_q = (x'_q, y'_q, z'_q)$, $q = 1, \dots, N$. The scattering problem in the frequency domain is reduced to the solution of the Helmholtz equation for complex potential $\psi(\mathbf{r})$,

$$\nabla^2 \psi + k^2 \psi = 0, \quad (1)$$

with the following general impedance boundary conditions on the surface S_q of the q th sphere:

$$\left(\frac{\partial \psi}{\partial n} + i \sigma_q \psi \right) \Big|_{S_q} = 0, \quad q = 1, \dots, N, \quad (2)$$

where k is the wave number and σ_q are complex admittances, and $i = \sqrt{-1}$. In the particular case of sound-hard surfaces ($\sigma_q = 0$) we have the Neumann boundary conditions,

$$\partial \psi / \partial n \Big|_{S_q} = 0, \quad (3)$$

and in the case of sound soft surfaces ($\sigma_q = \infty$) we have the Dirichlet boundary conditions,

$$\psi \Big|_{S_q} = 0. \quad (4)$$

Usually the potential is represented in the form

$$\psi(\mathbf{r}) = \psi_{\text{in}}(\mathbf{r}) + \psi_{\text{scat}}(\mathbf{r}), \quad (5)$$

where $\psi_{\text{scat}}(\mathbf{r})$ is the potential of the scattered field. Far from the region occupied by spheres, the scattered field should satisfy the Sommerfeld radiation condition:

$$\lim_{r \rightarrow \infty} r \left(\frac{\partial \psi_{\text{scat}}}{\partial r} - ik \psi_{\text{scat}} \right) = 0. \quad (6)$$

We must determine $\psi(\mathbf{r})$ or $\psi_{\text{scat}}(\mathbf{r})$ at any \mathbf{r} on the surface of the spheres or outside them.

III. SOLUTION USING THE MULTIPOLE RE-EXPANSION METHOD

A. T matrix for a single scatterer

We first solve the scattering problem (1)–(6) for a single scatterer ($N = 1$) in an arbitrary incident field. We assume that the incident field has no singularities in the domain inside the scatterer or on its boundary, and since it satisfies the Helmholtz equation it can be expanded near the center of this scatterer, \mathbf{r}'_q ($q = 1$), in the form

$$\psi_{\text{in}}(\mathbf{r}) = \sum_{n=0}^{\infty} \sum_{m=-n}^n E_n^{(q)m} R_n^m(\mathbf{r}_q) = \mathbf{E}^{(q)} \cdot \mathbf{R}(\mathbf{r}_q),$$

$$\mathbf{r}_q = \mathbf{r} - \mathbf{r}'_q. \quad (7)$$

Here $E_n^{(q)m}$ are the expansion coefficients of the potential over the basis of the regular solutions $R_n^m(\mathbf{r} - \mathbf{r}'_q)$ of the Helmholtz equation in the spherical coordinates $\mathbf{r}_q = (r_q, \theta_q, \varphi_q)$ connected with the center of the sphere:

$$R_n^m(\mathbf{r}_q) = j_n(kr_q) Y_n^m(\theta_q, \varphi_q),$$

$$\mathbf{r}_q = r_q (\sin \theta_q \cos \varphi_q, \sin \theta_q \sin \varphi_q, \cos \theta_q),$$

$$n = 0, 1, \dots, \quad m = -n, \dots, n, \quad (8)$$

where $j_n(kr)$ are the spherical Bessel functions of the first kind and $Y_n^m(\theta, \varphi)$ are the orthonormal spherical harmonics:

$$Y_n^m(\theta, \varphi) = (-1)^m \sqrt{\frac{2n+1}{4\pi} \frac{(n-|m|)!}{(n+|m|)!}} P_n^{|m|}(\cos \theta) e^{im\varphi},$$

$$n = 0, 1, \dots, \quad m = -n, \dots, n, \quad (9)$$

where $P_n^m(\mu)$ are the associated Legendre functions. Further, for compactness of notation, we use the following abbreviation to denote the sum represented by the product of two vectors: $\mathbf{A} = \{A_n^m\}$ and $\mathbf{B} = \{B_n^m\}$:

$$\mathbf{A} \cdot \mathbf{B} = \sum_{n=0}^{\infty} \sum_{m=-n}^n A_n^m B_n^m, \quad \mathbf{A} = \{A_n^m\}, \quad \mathbf{B} = \{B_n^m\}. \quad (10)$$

The scattered field $\psi^{(q)}(\mathbf{r}) = \psi_{\text{scat}}(\mathbf{r})$ can be represented in the form

$$\psi^{(q)}(\mathbf{r}) = \sum_{n=0}^{\infty} \sum_{m=-n}^n A_n^{(q)m} S_n^m(\mathbf{r}_q) = \mathbf{A}^{(q)} \cdot \mathbf{S}(\mathbf{r}_q). \quad (11)$$

Here $A_n^{(q)m}$ are the expansion coefficients of the potential over the basis of the singular at $\mathbf{r} = \mathbf{r}'_q$ radiating solutions $S_n^m(\mathbf{r} - \mathbf{r}'_q)$ of the Helmholtz equation:

$$S_n^m(\mathbf{r}_q) = h_n(kr_q) Y_n^m(\theta_q, \varphi_q),$$

$$n = 0, 1, \dots, \quad m = -n, \dots, n, \quad (12)$$

where $h_n(kr)$ are the spherical Hankel functions of the first kind.

By ‘‘T matrix for scatterer q ’’ we mean the matrix $\mathbf{T}^{(q)}$ with elements $T_{nn'}^{(q)mm'}$ that relates the expansion coefficients of the incident and scattered fields:

$$\mathbf{A}^{(q)} = \mathbf{T}^{(q)} \mathbf{E}^{(q)},$$

$$\left(A_n^{(q)m} = \sum_{n'=0}^{\infty} \sum_{m'=-n'}^{n'} T_{nn'}^{(q)mm'} E_{n'}^{(q)m'}, \right.$$

$$\left. n = 0, 1, \dots, \quad m = -n, \dots, n \right). \quad (13)$$

In general, the T matrix can be determined for a scatterer of an arbitrary shape by a solution of the corresponding boundary value problem (1)–(6). For the case of spheres, this solution can be obtained analytically, as shown in (GD02).

Based on this solution, the T matrix for a spherical scatterer of radius a_q and complex admittance σ_q is a diagonal matrix with elements

$$T_{nn'}^{(q)mm'} = - \frac{j_n'(ka_q) + (\sigma_q/k) j_n(ka_q)}{h_n'(ka_q) + (\sigma_q/k) h_n(ka_q)} \delta_{nn'} \delta_{mm'}, \quad (14)$$

where $n, n' = 0, 1, \dots$; $m = -n, \dots, n$; and $m' = -n', \dots, n'$.

B. Decomposition of the scattered field

Due to the linearity of the problem, the scattered field can be represented in the form

$$\psi_{\text{scat}}(\mathbf{r}) = \sum_{q=1}^N \psi^{(q)}(\mathbf{r}), \quad (15)$$

where $\psi^{(q)}(\mathbf{r})$ can loosely be thought of as the part of the scattered field introduced by the q th sphere, though, of course, it contains the influence of all the spheres. Each potential $\psi_q(\mathbf{r})$ is regular outside the q th sphere and satisfies the Sommerfeld radiation condition, so that it can be represented as prescribed by Eq. (11). In the vicinity of the q th scatterer we can write Eq. (15) as

$$\psi_{\text{scat}}(\mathbf{r}) = \psi^{(q)}(\mathbf{r}) + \phi^{(q)}(\mathbf{r}),$$

$$\phi^{(q)}(\mathbf{r}) = \sum_{q' \neq q} \psi^{(q')}(\mathbf{r}), \quad q, q' = 1, \dots, N. \quad (16)$$

The latter sum represents the function $\phi^{(q)}(\mathbf{r})$ that is regular in the part of the domain occupied by the q th scatterer and so can be represented as

$$\phi^{(q)}(\mathbf{r}) = \mathbf{B}^{(q)} \cdot \mathbf{R}(\mathbf{r}_q), \quad (17)$$

where $\mathbf{B}^{(q)} = \{B_n^{(q)m}\}$ is a vector of expansion coefficients over the basis of regular spherical functions (8). These coefficients can be expressed via the coefficients $\mathbf{A}^{(q')}$, $q' = 1, \dots, N$, $q' \neq q$ for all the scatterers, except of the q th scatterer, as

$$\mathbf{B}^{(q)} = \sum_{q' \neq q} (\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q'}, \mathbf{r}'_q) \mathbf{A}^{(q')},$$

$$\mathbf{r}'_{q'} = \mathbf{r}'_q - \mathbf{r}'_{q'}, \quad q, q' = 1, \dots, N, \quad (18)$$

where $(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q'}, \mathbf{r}'_q)$ is the re-expansion matrix with elements $(S|R)_{nn'}^{mm'}(\mathbf{r}'_{q'}, \mathbf{r}'_q)$ defined as the coefficients of expansion of the singular basis functions centered at $\mathbf{r}'_{q'}$ over the regular basis functions centered at \mathbf{r}'_q (see Gumerov and Duraiswami, 2003),

$$S_{nn'}^{m'}(\mathbf{r}'_{q'}) = \sum_{n=0}^{\infty} \sum_{m=-n}^n (S|R)_{nn'}^{mm'}(\mathbf{r}'_{q'}, \mathbf{r}'_q) R_n^m(\mathbf{r}_q),$$

$$q, q' = 1, \dots, N, \quad q' \neq q. \quad (19)$$

Now, using Eqs. (5), (7), (16), (11), and (17), we can represent the total field near the q th scatterer in the form

$$\psi(\mathbf{r}) = \mathbf{E}_{\text{eff}}^{(q)} \cdot \mathbf{R}(\mathbf{r}_q) + \mathbf{A}^{(q)} \cdot \mathbf{S}(\mathbf{r}_q), \quad \mathbf{E}_{\text{eff}}^{(q)} = \mathbf{E}^{(q)} + \mathbf{B}^{(q)}, \quad (20)$$

where we introduced the notation $\mathbf{E}_{\text{eff}}^{(q)}$ for the expansion coefficients of the “effective” incident field near the q th scatterer. Indeed, the first equation (20) shows that the multiple scattering problem is equivalent to a single scattering problem for the q th scatterer placed in the field, which is a superposition of the actual incident field and the fields scattered by the other scatterers. In this case the solution of the boundary value problem (1)–(6) for the q th scatterer is given by the \mathbf{T} matrix, which relates the expansion coefficients $\mathbf{A}^{(q)}$ and $\mathbf{E}_{\text{eff}}^{(q)}$ as prescribed by Eq. (13). So we have

$$\mathbf{A}^{(q)} = \mathbf{T}^{(q)}(\mathbf{E}^{(q)} + \mathbf{B}^{(q)}), \quad q = 1, \dots, N. \quad (21)$$

Now we can see that the system of equations (18) and (21) with respect to $\mathbf{A}^{(q)}$ and $\mathbf{B}^{(q)}$ is closed, as $\mathbf{T}^{(q)}$ and $\mathbf{E}^{(q)}$ are known (given). The coefficients $\mathbf{B}^{(q)}$ can be excluded to reduce the size of the system:

$$(\mathbf{T}^{(q)})^{-1} \mathbf{A}^{(q)} - \sum_{q' \neq q} (\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q',q}) \mathbf{A}^{(q')} = \mathbf{E}^{(q)}, \quad q = 1, \dots, N. \quad (22)$$

This system also can be represented as a single equation,

$$\mathbf{L}\mathbf{A} = \mathbf{E}, \quad (23)$$

where the vectors and matrices are stacked as

$$\mathbf{L} = \begin{pmatrix} (\mathbf{T}^{(1)})^{-1} & -(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{21}) & \cdots & -(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{N1}) \\ -(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{12}) & (\mathbf{T}^{(2)})^{-1} & \cdots & -(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{N2}) \\ \cdots & \cdots & \cdots & \cdots \\ -(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{1N}) & -(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{2N}) & \cdots & (\mathbf{T}^{(N)})^{-1} \end{pmatrix}, \quad (24)$$

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}^{(1)} \\ \mathbf{A}^{(2)} \\ \cdots \\ \mathbf{A}^{(N)} \end{pmatrix}, \quad \mathbf{E} = \begin{pmatrix} \mathbf{E}^{(1)} \\ \mathbf{E}^{(2)} \\ \cdots \\ \mathbf{E}^{(N)} \end{pmatrix}.$$

This system can be solved by appropriately truncating the infinite vectors to p^2 coefficients ($\mathbf{A}^{(q)} = \{A_n^{(q)m}\}$, $n = 0, \dots, p-1$, $m = -n, \dots, n$). The final linear system with Np^2 unknowns is the same as in (GD02) [where Eq. (22) was multiplied by matrix $\mathbf{T}^{(q)}$ for each q]. Therefore $O(N^3 p^6)$ operations are required for a direct solution of this system. Using Eqs. (15) and (11) knowing all $\mathbf{A}^{(q)}$ enables the determination of $\psi_{\text{scat}}(\mathbf{r})$ everywhere in space. For the surface values of the potential and its normal derivatives simpler expressions can be used [see (GD02)].

IV. ITERATIVE METHODS

The first substantial reduction in complexity can be achieved by using iterative methods for solving the linear system. Assuming that each iteration involves one large dense matrix-vector multiplication of complexity $O(N^2 p^4)$ and that the iterative process converges to the required accuracy in N_{iter} steps, we immediately obtain a computational complexity $O(N_{\text{iter}} N^2 p^4)$ instead of $O(N^3 p^6)$. For example, if $N \sim 100$, $p \sim 10$, and $N_{\text{iter}} \sim 10$, the savings could be of order 10^3 times. Of course convergence may be slow, but as long as $N_{\text{iter}} \ll Np^2$, the iterative procedure brings substantial savings. We note in this context that there exist methods

(e.g., based on Krylov subspaces) that guarantee that an exact solution will be achieved in $N_{\text{iter}} \leq Np^2$ in exact arithmetics, while in practice the goal is to achieve this at much smaller N_{iter} .

Treating the multiple scattering problem as the solution of a dense linear system, we can employ different iterative methods starting from simple iterations to various versions of conjugate gradient, and Krylov subspace methods (see, e.g., Saad, 2003). Convergence of these methods can be improved by using well-designed preconditioners, block decompositions, etc.

The description and analysis of the entire area of iterative techniques is beyond the scope of this paper, and we refer the interested reader to the textbooks (Kelly, 1995; Saad, 2003). The use of a preconditioning matrix plays an important role, and the most efficient iterative schemes we used were based on the Flexible GMRES (FGMRES), which uses as the right preconditioner an approximate (GMRES) inverse of a matrix that approximates the system matrix \mathbf{L} (24). We describe details of this iterative technique in the next section since it is related closely to the FMM-based matrix-vector product.

Any iteration method builds a sequence of approximations to the solution

$$\mathbf{A}_0^{(q)}, \mathbf{A}_1^{(q)}, \dots; \quad \lim_{j \rightarrow \infty} \mathbf{A}_j^{(q)} = \mathbf{A}^{(q)}, \quad q = 1, \dots, N, \quad (25)$$

where $\mathbf{A}_0^{(q)}$ is some initial guess, e.g.,

$$\mathbf{A}_0^{(q)} = \mathbf{T}^{(q)} \mathbf{E}^{(q)}, \quad q = 1, \dots, N, \quad (26)$$

and stops when the convergence criterion is achieved. The convergence condition can be, e.g.,

$$\max_q \|\mathbf{A}_{j+1}^{(q)} - \mathbf{A}_j^{(q)}\| < \epsilon, \quad (27)$$

where $\|\cdot\|$ is some norm to measure the distance between two vectors (e.g., $\|\mathbf{A}\| = \max_{n,m} |A_n^m|$). Also, for each iteration it involves a computation of matrix vector product $\mathbf{L}\mathbf{A}_j$ for a given input vector \mathbf{A}_j . Thus, the speed of an iterative method can be improved by reducing the number of iterations and speeding up the embedded matrix vector products.

If we turn to the equation to be solved (23), we can see from Eq. (24) that the matrix \mathbf{L} can be decomposed as

$$\mathbf{L} = \mathbf{T}^{-1} - (\mathbf{S}|\mathbf{R}), \quad (28)$$

where \mathbf{T}^{-1} is a diagonal matrix for spherical scatterers and block-diagonal otherwise, and $(\mathbf{S}|\mathbf{R})$ is the matrix consisting of the $(\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q,q'})$ blocks. Assuming that the product $\mathbf{T}^{-1}\mathbf{A}$ can be computed rapidly, we use the FMM to accelerate the computation of $\mathbf{B} = (\mathbf{S}|\mathbf{R})\mathbf{A}$, or

$$\mathbf{B}_j^{(q)} = \sum_{q' \neq q} (\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q',q}) \mathbf{A}_j^{(q')}, \quad q = 1, \dots, N, \quad j = 0, 1, \dots \quad (29)$$

V. FAST MULTIPOLE METHOD

The second substantial speed up of the solution can be obtained by accelerating the matrix-vector product (23) in the iterative methods via the multilevel Fast Multipole

Method (FMM). We refer the reader to details of the method in Greengard (1988) and for particulars of the method we used (Gumerov *et al.*, 2003). Below we describe the method used for the multiple scattering problems.

A. Data structures

The FMM operates with the spatial data organized in octrees. This means that the computational domain is the cube, or box, of size $D_0 \times D_0 \times D_0$ that encloses all the scatterers. We assign level 0 to this cube. Further, the computational domain is subdivided into eight smaller boxes $D_1 \times D_1 \times D_1$, each of size $D_1 = 0.5D_0$. This is referred to as level 1. Level 2 is obtained by the subdivision of boxes in level 1 by 8, and so on until some level l_{\max} , where there are $8^{l_{\max}}$ boxes of size $D_{l_{\max}} = 2^{-l_{\max}}D_0$. To each box we assign some index (n, l) , $n = 0, \dots, 8^l - 1$, $l = 0, \dots, l_{\max}$. Such a space partitioning generates a hierarchical data structure with “parent–children” relationships, where any box of level $l = 0, \dots, l_{\max} - 1$ can be considered as a “parent,” with 8 children boxes obtained by its subdivision. Neighbors of a box B are boxes at the same level, that share at least one boundary point with box B . Boxes that are not adjacent to the boundaries of the computational domain have 26 neighbors, which together with the box itself form the “neighborhood” of the box.

In the multiple scattering problem we say that scatterer q belongs to box (n, l) if the center \mathbf{r}'_q of the smallest sphere enclosing the scatterer is located inside that box (for spherical scatterers this sphere is simply its surface). Any box may intersect a scatterer, which does not belong to it (see Fig. 1). However, we require that the size of the smallest box (at the maximum level of space partitioning) is determined as below to ensure both the correctness of the FMM procedure and ensure the validity of the multipole re-expansions on the surfaces of neighboring scatterers. If the scatterers q and q' belong to two different boxes at the finest level with indices (n_q, l_{\max}) and $(n_{q'}, l_{\max})$, which are not neighbors, then the field scattered by q' can be described by the local expansion of type (17) centered at the center of box (n_q, l_{\max}) in the domain occupied by the sphere surrounding the scatterer q . The maximum distance from the center of box $(n_{q'}, l_{\max})$ to a point on the surface of scatterer q' is $D_{l_{\max}}\sqrt{3}/2 + a_{\max}$, where a_{\max} is the maximum possible size of the scatterer, $a_{\max} = \max(a_1, \dots, a_N)$. The minimum possible distance from the center of the box $(n_{q'}, l_{\max})$ to a point on the surface of the q th scatterer is then $3D_{l_{\max}}/2 - a_{\max}$. The requirement on the validity of expansions will be satisfied if $3D_{l_{\max}}/2 - a_{\max} > D_{l_{\max}}\sqrt{3}/2 + a_{\max}$, which yields the following condition:

$$D_{l_{\max}} > \frac{4}{3 - \sqrt{3}} a_{\max} \approx 3.15 a_{\max},$$

$$l_{\max} < \log_2 \left(\frac{3 - \sqrt{3}}{4} \frac{D_0}{a_{\max}} \right). \quad (30)$$

Note that this condition also ensures that the farfield re-expansion about the center of the box (n_q, l_{\max}) of the field

FIG. 1. Illustration of space partitioning and data structure for multiple scattering problem. The minimal spheres enclosing each scatterer are shown (so an actual scatterer of arbitrary shape is located inside the sphere). The white sphere belongs to the black box. The gray spheres are its neighbors. These are spheres which belong (in terms of their centers) to the E_2 neighborhood of the black box. The black spheres are the far spheres, they belong to the E_3 neighborhood of the black box (the centers are located outside the E_2 neighborhood). For a description of different neighborhoods see also Fig. 2.

scattered by scatterer q is valid at any point on the surface of the scatterer q' .

A stronger limitation on l_{\max} follows from formal requirements of the translation theory. Again, we can consider two closest boxes $(n_{q'}, l_{\max})$ and (n_q, l_{\max}) , which are not neighbors, and try to evaluate the effect of scatterer q' on q . The multipole series representing the potential of the scatterer q' , whose center in the worst case is located at distance $D_{l_{\max}}\sqrt{3}/2$ from the center of the box $(n_{q'}, l_{\max})$ should be translated first to the center of this box, then to the center of the box (n_q, l_{\max}) , and finally to the center of scatterer q with a guarantee that the final local expansion is valid within the sphere of radius a_{\max} . This can be provided if $2D_{l_{\max}} > D_{l_{\max}}\sqrt{3}/2 + D_{l_{\max}}\sqrt{3}/2 + a_{\max}$, which is a condition that spheres of radii $D_{l_{\max}}\sqrt{3}/2$ and $D_{l_{\max}}\sqrt{3}/2 + a_{\max}$ circumscribing the boxes $(n_{q'}, l_{\max})$ and (n_q, l_{\max}) , respectively, do not intersect ($2D_{l_{\max}}$ is the distance between the box centers). This condition can also be rewritten as

$$D_{l_{\max}} > \frac{1}{2 - \sqrt{3}} a_{\max} \approx 3.73 a_{\max},$$

$$l_{\max} < \log_2 \left[(2 - \sqrt{3}) \frac{D_0}{a_{\max}} \right]. \quad (31)$$

A further limitation on l_{\max} should be imposed, since we use truncated expansions. The truncation error is a function of the truncation number, which in turn depends on the distance between the center of the domain of local expansion and the closest point on the sphere surrounding the box containing the multipole, $b_{l_{\max}} = 2D_{l_{\max}} - D_{l_{\max}}\sqrt{3}/2$. The dimensionless parameter,

$$\delta_{\min} = b_{l_{\max}} / (D_{l_{\max}}\sqrt{3}/2 + a_{\max}) > 1, \quad (32)$$

then plays an important role for a selection of the truncation number (see the section below) ($p \rightarrow \infty$ for $\delta_{\min} \rightarrow 1$). If this parameter is specified, then we have the following modification for condition (31):

$$D_{l_{\max}} \geq \frac{2\delta_{\min}}{4 - (1 + \delta_{\min})\sqrt{3}} a_{\max},$$

$$l_{\max} \leq \log_2 \left[\frac{4 - (1 + \delta_{\min})\sqrt{3}}{2\delta_{\min}} \frac{D_0}{a_{\max}} \right], \quad \delta_{\min} > 1. \quad (33)$$

It can be seen that in any case $\delta_{\min} < 4/\sqrt{3} - 1 \approx 1.31$. Note that in some test cases we found numerically that the algorithm may continue to perform satisfactorily when l_{\max} exceeds the value prescribed by conditions (30)–(33).

B. Field decomposition

The field $\phi^{(q)}(\mathbf{r})$ [see Eq. (17)] due to the potentials centered at spheres other than the q th sphere can be decomposed into two parts:

$$\phi^{(q)}(\mathbf{r}) = \phi_{\text{near}}^{(q)}(\mathbf{r}) + \phi_{\text{far}}^{(q)}(\mathbf{r}), \quad \mathbf{B}^{(q)} = \mathbf{B}_{\text{near}}^{(q)} + \mathbf{B}_{\text{far}}^{(q)},$$

$$\phi_{\text{near}}^{(q)}(\mathbf{r}) = \mathbf{B}_{\text{near}}^{(q)} \cdot \mathbf{R}(\mathbf{r}_q), \quad \phi_{\text{far}}^{(q)}(\mathbf{r}) = \mathbf{B}_{\text{far}}^{(q)} \cdot \mathbf{R}(\mathbf{r}_q), \quad (34)$$

where $\phi_{\text{near}}^{(q)}(\mathbf{r})$ is the field potential centered at the spheres that belong to the neighborhood $\Omega^{(q)}$ of the box containing the q th sphere at level l_{\max} , $\phi_{\text{far}}^{(q)}(\mathbf{r})$ is the field scattered by the other spheres, and $\mathbf{B}_{\text{near}}^{(q)}$ and $\mathbf{B}_{\text{far}}^{(q)}$ are the respective expansion coefficients in the basis $\mathbf{R}(\mathbf{r}_q)$. According to Eq. (18), these coefficients can be written in the form

$$\mathbf{B}_{\text{near}}^{(q)} = \sum_{\mathbf{r}_{q'} \in \Omega^{(q)}, q' \neq q} (\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q'}) \mathbf{A}^{(q')},$$

$$\mathbf{B}_{\text{far}}^{(q)} = \sum_{\mathbf{r}_{q'} \notin \Omega^{(q)}} (\mathbf{S}|\mathbf{R})(\mathbf{r}'_{q'}) \mathbf{A}^{(q')}. \quad (35)$$

In the iterative algorithm, the coefficients $\mathbf{A}^{(q)}$ are known from the previous iteration step, and the purpose is to determine $\mathbf{B}^{(q)}$ for the next iteration step [see Eq. (29)]. As there are not many scatterers in the neighborhood of the q th sphere, the coefficients $\mathbf{B}_{\text{near}}^{(q)}$ can be computed directly using the first equation in (35). The major computational expense comes from the second sum. To compute $\mathbf{B}_{\text{far}}^{(q)}$ we use the FMM, as described in the next section. Based on a given set of coefficients $\{\mathbf{A}^{(q)}\}$, the FMM provides coefficients $\mathbf{D}^{(q)}$ of the farfield expansion near the center of the box at the finest level, containing the q th scatterer, $\mathbf{r}_*^{(q)}$:

$$\phi_{\text{far}}^{(q)}(\mathbf{r}) = \mathbf{D}^{(q)} \cdot \mathbf{R}(\mathbf{r} - \mathbf{r}_*^{(q)}), \quad q = 1, \dots, N. \quad (36)$$

To get $\mathbf{B}_{\text{far}}^{(q)}$, which are the coefficients for expansion about the center of the q th sphere we need to translate this expansion to the proper center. This can be done by using the local-to-local translation operator, or by applying the $(\mathbf{R}|\mathbf{R})$ re-expansion matrix to coefficients $\mathbf{D}^{(q)}$:

$$\mathbf{B}_{\text{far}}^{(q)} = (\mathbf{R}|\mathbf{R})(\mathbf{r}'_q - \mathbf{r}_*^{(q)}) \mathbf{D}^{(q)}, \quad q = 1, \dots, N. \quad (37)$$

Here the $(\mathbf{R}|\mathbf{R})$ re-expansion matrix has entries $(R|R)_{nn'}^{mm'}$ that are the expansion coefficients of the regular basis func-

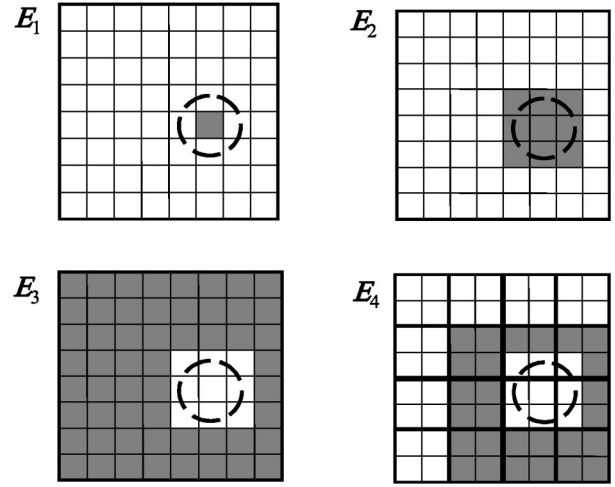

FIG. 2. The domains used for the construction of a hierarchical re-expansion procedure in FMM (shown in projection to a plane). A circle separates the box for which domains are drawn.

tion over the same type of basis, whose center is shifted:

$$R_{n'}^{m'}(\mathbf{r} - \mathbf{r}_*^{(q)}) = \sum_{n=0}^{\infty} \sum_{m=-n}^n (R|R)_{nn'}^{mm'}(\mathbf{r}'_q - \mathbf{r}_*^{(q)}) R_n^m(\mathbf{r}_q),$$

$$q = 1, \dots, N, \quad n' = 0, 1, \dots, \quad m' = -n', \dots, n'. \quad (38)$$

C. Details of the fast multipole method

In the FMM we introduce the following hierarchical domains, associated with each level of space subdivision: $E_1(n, l)$, the set of points located inside box (n, l) ; $E_2(n, l)$, the set of points located inside the neighborhood of box (n, l) ; $E_3(n, l)$, the set of points located in the computational domain, which are outside the neighborhood of box (n, l) [this domain is complementary to $E_2(n, l)$], and $E_4(n, l)$, the set of points located in domain $E_2(\text{Parent}(n), l-1)$, but outside domain $E_2(n, l)$. For boxes, whose parents are not adjacent to the boundaries of the computational domain, $E_4(n, l)$, consists of 189 boxes of level l . These domains are shown in Fig. 2. We associate fields $\psi_j^{(n, l)}(\mathbf{r})$ with every domain $E_j(n, l)$, $j = 1, \dots, 4$. These are fields scattered by all the spheres, which belong to the respective domains. We also associate truncation numbers $p_2, \dots, p_{l_{\max}}$ with each level of subdivision $l = 2, \dots, l_{\max}$. The selection of these truncation numbers is based on the error analysis and is discussed later. The algorithm consists of two major parts. In the first part we set up the hierarchical data structure, based on the location and sizes of the scatterers. This step need be performed only once for a given scatterer configuration, and is not repeated during the iterative process. The second part consists of the upward pass and the downward pass, followed by the final summation step, which is described by Eqs. (35) and (37), leads to a determination of the expansion coefficients $\mathbf{B}^{(q)}$, $q = 1, \dots, N$.

1. Upward pass

The purpose of the upward pass is to determine coefficients $\mathbf{C}^{(n,l)}$ of expansion for all functions $\psi_1^{(n,l)}(\mathbf{r})$ over the bases of the S functions centered at the box centers $\mathbf{r}_*^{(n,l)}$:

$$\begin{aligned} \psi_1^{(n,l)}(\mathbf{r}) &= \mathbf{C}^{(n,l)} \cdot \mathbf{S}(\mathbf{r} - \mathbf{r}_*^{(n,l)}), \quad l=2, \dots, l_{\max}, \\ \forall n, \quad \mathbf{r}'_q &\in E_1(n,l), \quad q=1, \dots, N. \end{aligned} \quad (39)$$

Here the length of the truncated coefficient vectors $\mathbf{C}^{(n,l)}$ and, respectively, the basis functions $\mathbf{S}(\mathbf{r} - \mathbf{r}_*^{(n,l)})$ depends on the level l and is of length p_l^2 . To build the coefficients we apply the multipole-to-multipole, or the $(\mathbf{S}|\mathbf{S})$ translation operator, which can be thought of as a rectangularly truncated matrix with entries $(S|S)_{nn'}^{mm'}$, defined as re-expansion coefficients for the S functions:

$$\begin{aligned} S_{n'}^{m'}(\mathbf{r} + \mathbf{t}) &= \sum_{n=0}^{\infty} \sum_{m=-n}^n (S|S)_{nn'}^{mm'}(\mathbf{t}) S_n^m(\mathbf{r}), \\ n' &= 0, 1, \dots, \quad m' = -n', \dots, n', \end{aligned} \quad (40)$$

where \mathbf{t} is the translation vector determined by the location of the expansion centers. Note that for the Helmholtz equation we have $(\mathbf{S}|\mathbf{S})(\mathbf{t}) = (\mathbf{R}|\mathbf{R})(\mathbf{t})$.

- Step 1. For each scatterer determine the coefficients of the S expansion centered at the center of the box $\mathbf{r}_*^{(q)} = \mathbf{r}_*^{(n, l_{\max})}$ at the finest level, (n, l_{\max}) , to which this scatterer belongs using the multipole-to-multipole $S|S$ translation of the coefficients $\mathbf{A}^{(q)}$ to the center of this box:

$$\begin{aligned} \tilde{\mathbf{C}}^{(q)} &= (\mathbf{S}|\mathbf{S})(\mathbf{r}_*^{(q)} - \mathbf{r}'_q) \mathbf{A}^{(q)}, \quad q=1, \dots, N, \\ \mathbf{r}'_q, \mathbf{r}_*^{(q)} &\in E_1(n, l_{\max}). \end{aligned} \quad (41)$$

This step of the algorithm provides a representation of the scattered field for the q th scatterer (11) about the center of the box to which it belongs:

$$\psi^{(q)}(\mathbf{r}) = \mathbf{A}^{(q)} \cdot \mathbf{S}(\mathbf{r}_q) = \tilde{\mathbf{C}}^{(q)} \cdot \mathbf{S}(\mathbf{r} - \mathbf{r}_*^{(q)}). \quad (42)$$

Note that the length of truncated vectors $\mathbf{A}^{(q)}$ is p^2 , while the length of the truncated vectors $\tilde{\mathbf{C}}^{(q)}$ is $p_{l_{\max}}^2$. These lengths can be the same or different. We discuss this issue later.

Step 2. Consolidate all the expansions at the finest level, to obtain the expansion coefficients $\mathbf{C}^{(n, l_{\max})}$ of functions $\psi_1^{(n, l_{\max})}(\mathbf{r})$ over the S basis:

$$\mathbf{C}^{(n, l_{\max})} = \sum_{\mathbf{r}_*^{(q)} \in E_1(n, l_{\max})} \tilde{\mathbf{C}}^{(q)}, \quad \mathbf{r}_*^{(n, l_{\max})} = \mathbf{r}_*^{(q)}. \quad (43)$$

Step 3. For $l = l_{\max} - 1, \dots, 2$, recursively obtain expansion coefficients $\mathbf{C}^{(n,l)}$ for all other functions $\psi_1^{(n,l)}(\mathbf{r})$ over the S basis using the multipole-to-multipole translation operators from the centers of children boxes containing the scatterers, $\mathbf{r}_*^{(n', l+1)}$, to the center of their parent box, $\mathbf{r}_*^{(n,l)}$, and the consolidation of the coefficients:

$$\mathbf{C}^{(n,l)} = \sum_{n' \in \text{Children}(n,l)} (\mathbf{S}|\mathbf{S})(\mathbf{r}_*^{(n,l)} - \mathbf{r}_*^{(n', l+1)}) \mathbf{C}^{(n', l+1)}. \quad (44)$$

Here $\text{Children}(n,l)$ denotes the set of children boxes for box (n,l) . These boxes are of a smaller size than (n,l) and located at the level $l+1$.

2. Downward pass

The purpose of the downward pass is to determine coefficients $\mathbf{D}^{(n,l)}$ of expansion for all functions $\psi_3^{(n,l)}(\mathbf{r})$ over the bases of the R functions centered at $\mathbf{r}_*^{(n,l)}$:

$$\begin{aligned} \psi_3^{(n,l)}(\mathbf{r}) &= \mathbf{D}^{(n,l)} \cdot \mathbf{R}(\mathbf{r} - \mathbf{r}_*^{(n,l)}), \quad l=2, \dots, l_{\max}, \\ \forall n, \quad \mathbf{r}'_q &\in E_1(n,l), \quad q=1, \dots, N. \end{aligned} \quad (45)$$

Here the length of truncated coefficient vectors $\mathbf{D}^{(n,l)}$ and, respectively, the basis $\mathbf{R}(\mathbf{r} - \mathbf{r}_*^{(n,l)})$ depends on the level l and is p_l^2 . To build them we apply the multipole-to-local and local-to-local, or the $(\mathbf{S}|\mathbf{R})$ and $(\mathbf{R}|\mathbf{R})$ translation operators, which can be thought of as square and rectangularly truncated matrices, respectively, since the $(\mathbf{S}|\mathbf{R})$ translation is applied for boxes at the same level, while the $(\mathbf{R}|\mathbf{R})$ translation is used to translate coefficients from a lower level to a higher level. In the process we also determine coefficients $\tilde{\mathbf{D}}^{(n,l)}$ of expansion for potential $\psi_4^{(n,l)}(\mathbf{r})$ over the local bases:

$$\begin{aligned} \psi_4^{(n,l)}(\mathbf{r}) &= \tilde{\mathbf{D}}^{(n,l)} \cdot \mathbf{R}(\mathbf{r} - \mathbf{r}_*^{(n,l)}), \quad l=2, \dots, l_{\max}, \\ \forall n, \quad \mathbf{r}'_q &\in E_1(n,l), \quad q=1, \dots, N. \end{aligned} \quad (46)$$

We need to do this in terms of organization of the hierarchical procedure, which is based on the following property of the domains $E_3(n,l)$ and $E_4(n,l)$ (see Fig. 2):

$$E_3(n,l) = E_3(n', l-1) \cup E_4(n,l), \quad n' = \text{Parent}(n). \quad (47)$$

This results in

$$\psi_3^{(n,l)}(\mathbf{r}) = \psi_3^{(n', l-1)}(\mathbf{r}) + \psi_4^{(n,l)}(\mathbf{r}), \quad n' = \text{Parent}(n), \quad (48)$$

and enables recursion with respect to the levels of the octree.

- Step 1. (This step and step 2 of the downward pass are performed recursively for $l=2, \dots, l_{\max}$.) Obtain coefficients $\tilde{\mathbf{D}}^{(n,l)}$ for all boxes containing the scatterers. We obtain these coefficients by the multipole-to-local translations of respective coefficients $\mathbf{C}^{(n', l)}$, followed by the consolidation of the expansions:

$$\begin{aligned} \tilde{\mathbf{D}}^{(n,l)} &= \sum_{\mathbf{r}_*^{(n', l)} \in E_4(n,l)} (\mathbf{S}|\mathbf{R})(\mathbf{r}_*^{(n,l)} - \mathbf{r}_*^{(n', l)}) \mathbf{C}^{(n', l)}, \\ \forall n, n', \quad \mathbf{r}'_q &\in E_1(n,l), \quad \mathbf{r}'_{q'} \in E_1(n', l), \quad q, q' = 1, \dots, N. \end{aligned} \quad (49)$$

Step 2. At level $l=2$ we have $E_3(n,2) = E_4(n,2)$, which results in $\mathbf{D}^{(n,2)} = \tilde{\mathbf{D}}^{(n,2)}$. For levels $l=3, \dots, l_{\max}$ we have, from Eq. (48),

$$\mathbf{D}^{(n,l)} = (\mathbf{R}|\mathbf{R})(\mathbf{r}_*^{(n,l)} - \mathbf{r}_*^{(n', l-1)}) \mathbf{D}^{(n', l-1)} + \tilde{\mathbf{D}}^{(n,l)}, \quad (50)$$

$$n' = \text{Parent}(n), \quad l = 2, \dots, l_{\max}, \quad \forall n, \quad \mathbf{r}'_q \in E_1(n, l),$$

$$q = 1, \dots, N.$$

3. Final summation

The final summation step results in a determination of the scattered field at the current iteration, since the domains $E_3(n, l)$ and $E_2(n, l)$ are complementary. This step of the usual FMM procedure is skipped here, since all we need are the expansion coefficients at the finest level $\mathbf{D}^{(q)} = \mathbf{D}^{(n, l_{\max})}$, $\mathbf{r}'_q \in E_1(n, l_{\max})$, $q = 1, \dots, N$. Equation (37) then provides coefficients $\mathbf{B}_{\text{far}}^{(q)}$.

D. Truncation numbers

To apply the algorithm we need to specify the truncation numbers p for the coefficients $\{\mathbf{A}^{(q)}\}$ and truncation numbers $p_2, \dots, p_{l_{\max}}$. Their selection depends on the acceptable error of computations, which is determined by the rate of convergence of the series being truncated. Consider first the selection of p .

The series under consideration converge absolutely and uniformly only for $p \geq ka$. For relatively low ka ($ka \leq 10$), one can select p as

$$p = [ka] + p_0(ka, \epsilon, \delta), \quad p_0 \geq 1, \quad \delta = b/a \geq 1, \quad \epsilon > 0, \quad (51)$$

where p_0 depends on the prescribed accuracy ϵ and the distance b between the center of the scatterer and the closest point on the surface of the closest scatterer. While there are some theories for the expansion errors (e.g., Koc *et al.*, 1999; Darve, 2000b), they usually deal with the error of expansion of a single source. We suggest the evaluation of p_0 based on error maps (or their approximations) obtained as a solution of the scattering problem for two spheres placed in the field of the plane incident wave, $\psi_{\text{in}}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}}$. This problem can be solved very rapidly based on direct matrix inversion for coaxial spheres (GD02), where the parameters p_0 , ka , and δ can be varied within the range under consideration, while the error of the solution ϵ can be determined *a posteriori*, as the error in boundary conditions.

Indeed, we note that since any radiating basis function satisfies the Helmholtz equation, the expansion truncated with an arbitrary p will satisfy the Helmholtz equation and radiation condition (6). So the only equation that is not satisfied exactly by the approximate solution is the boundary condition (2). Once an approximate solution is computed, i.e., the expansion coefficients $\{\mathbf{A}^{(q)}\}$ are found, we can compute the normal derivative on the surface for any scatterer using the differentiation theorem for the spherical basis functions in an arbitrary direction specified by the unit vector $\mathbf{n} = (n_x, n_y, n_z)$ (Gumerov and Duraiswami, 2003):

$$\begin{aligned} \frac{1}{k} \mathbf{n} \cdot \nabla S_n^m(\mathbf{r}) &= \frac{1}{2} (n_x - i n_y) [b_{n+1}^{-m-1} S_{n+1}^{m+1}(\mathbf{r}) - b_n^m S_{n-1}^{m+1}(\mathbf{r})] \\ &+ \frac{1}{2} (n_x + i n_y) [b_{n+1}^{m-1} S_{n+1}^{m-1}(\mathbf{r}) - b_n^{-m} S_{n-1}^{m-1}(\mathbf{r})] \\ &+ n_z [a_{n-1}^m S_{n-1}^m(\mathbf{r}) - a_n^m S_{n+1}^m(\mathbf{r})], \end{aligned} \quad (52)$$

FIG. 3. Dependences of the shift in the truncation number, p_0 , defined by Eq. (51) on the dimensionless wave number ka for two sound-hard spheres of equal size. The curves are computed to provide the error $\epsilon^{(bc)}$ in boundary conditions shown near the curves. Two sets of curves marked by the filled and empty symbols correspond to different distances between the spheres ($\delta=1.5$ and $\delta=2$, respectively).

where the coefficients a_n and b_n are specified by Eqs. (62) and (63). Therefore, as the truncated solution is computed, the left-hand side of Eq. (2) can be determined, and there are no additional errors for derivative computation or approximation. If we sample the surface with M points, we can then compute the following errors in boundary conditions:

$$\epsilon_m^{(bc)} = \frac{M |\Delta_{bc}(\mathbf{y}_m)|}{[\sum_m |\psi|_{S_q}(\mathbf{y}_m)|^2]^{1/2}}, \quad \epsilon^{(bc)} = \max_m \epsilon_m^{(bc)}, \quad (53)$$

$$\Delta_{bc}(\mathbf{y}_m) = a_q \left(\frac{\partial \psi}{\partial n}(\mathbf{y}_m) + i \sigma_q \psi(\mathbf{y}_m) \right) \Big|_{S_q}, \quad m = 1, \dots, M.$$

Figure 3 illustrates dependencies $p_0(ka, \epsilon^{(bc)}, \delta)$ for two fixed values of δ and a range of ka . The spheres are sound-hard, $\sigma_q = 0$, $q = 1, 2$. Here for each curve $\epsilon^{(bc)}$ is fixed (p_0 is not an integer due to interpolation). $\epsilon^{(bc)}$ was computed according to Eq. (53), where each sphere was sampled with 181 equispaced points with respect to the spherical polar angle θ . For the low-frequency region, $ka \leq 1$ and $\epsilon^{(bc)} \geq 10^{-4}$, we have $p_0 \sim p_{00}(\epsilon, \delta) + \log(ka)$, which in the semi-logarithmic coordinates is a linear dependence. For higher frequencies, $ka \geq 1$, we have $p_0 \sim (ka)^\nu$, where theoretically $\nu = 1/3$ and that is pretty close to our computations. The dependence on δ in this range is rather weak (when δ is not very close to unity), while for lower frequencies the truncation number substantially depends on this parameter. Figure 4 illustrates dependencies $p_0(ka, \epsilon^{(bc)}, \delta)$ for fixed $ka = 1$ and varying δ . It is seen that if the spheres are very close to each other ($\delta \sim 1$), the truncation number should be high to provide small errors. However, if it is sufficient to compute a solution with, say, $\sim 1\%$ of relative error, these computations can be achieved with $p_0 \sim 10$, even when the spheres touch each other.

FIG. 4. Dependences of the shift in the truncation number, p_0 , defined by Eq. (51) on the dimensionless parameter δ characterizing the distance between the spheres for two sound-hard spheres of equal size. The curves are computed to provide the error $\epsilon^{(bc)}$ in boundary conditions shown near the curves.

For larger ka the truncation number can be selected based on the high-frequency asymptotics of the spherical Bessel functions (e.g., see Chew *et al.*, 2001):

$$p = P(ka, \epsilon) = ka + \frac{1}{2} \left(3 \ln \frac{1}{\epsilon} \right)^{2/3} (ka)^{1/3}. \quad (54)$$

In this equation the truncation number does not depend on δ , while such a dependence can be introduced. Equation (54) is qualitatively consistent with the behavior of the error observed in computations where δ is not very close to 1. To relate it to the actual error observed for a solution of the two sphere scattering problem one should relate ϵ to $\epsilon^{(bc)}$, and we found that for the range plotted in Fig. 3 one can set $\epsilon \sim 10^{-2} \epsilon^{(bc)}$ to fit results for $ka > 1$.

Similar formulas can be applied for a computation of the truncation numbers used in the FMM, in which case we need to specify what we mean by a and δ here. The parameter a can be selected as the radius of the smallest sphere that encloses the box of level l plus a_{\max} and δ formally is limited by the value $\delta < 1.31$ (see the discussion on l_{\max} previously, while a more accurate analysis is required here, since the “worst case” analysis usually substantially overestimates actual errors). Since the size of this box is $D_l = 2^{-l} D_0$, one can set

$$a_l = 2^{-l-1} 3^{1/2} D_0 + a_{\max}, \quad p_l = P(ka_l, \epsilon). \quad (55)$$

In computations we used this formula for automatically setting the level-dependent truncation numbers with function $P(ka, \epsilon)$ specified by Eq. (54), where ϵ was some prescribed error. In computations we also performed an *a posteriori* actual error check using Eq. (53), which is valid for an arbitrary number of spheres.

We note also that for the present problem, when the number of scatterers can be large, and so for fixed ka and the volume fraction of scatterers we have $D_0 \sim N^{1/3} a$, truncation numbers p_l used in the FMM can be substantially larger than p . In other words, if the wavelength is comparable with the

size of the scatterer, then the size of the computational domain is much larger than the wavelength for large N .

We can note that in the case when the spheres are close or may touch each other, p can be larger than p_l to provide the required accuracy. To avoid unnecessary computations in this case, translations for the farfield expansions at the finest level can be made to obtain only $p_{l_{\max}}^2$ terms, since terms of degree n corresponding to $p_{l_{\max}} \leq n < p$ are due to the influence of close neighbors. Moreover, in computations of the near field, we can subdivide the set of neighbor spheres into two sets: those that are closer than some prescribed b_* (or δ_*), for which the interaction should be computed using all p^2 terms, and the other neighbors, whose interactions with the given sphere can be efficiently computed using only $p_{l_{\max}}^2$ terms. We found numerically that these tricks may bring substantial savings in computational time, while almost not affecting the accuracy of the procedure.

E. Complexity estimates

In the FMM, translations occur between two subsequent levels l and $l+1$ (for the local-to-local or multipole-to-multipole translations) or on the same level l (for the multipole-to-local translations). Since the number of coefficients representing the potential for each box at level l is p_l^2 and $p_{l+1}^2 \sim p_l^2$, we can estimate the complexity of a single translation associated with level l as $O(p_l^{2\nu})$, where $\nu \geq 1$ is some parameter, that we call the “translation exponent.” For example, if the translation is performed by multiplication of the translation matrix by the vector of coefficients, the complexity of the translation will be $O(p_l^4)$, in which case $\nu = 2$.

To evaluate the number of operations required for all translations, we assume that the scatterers are distributed more or less evenly in space, and so all 8^l boxes at level l contain some scatterers. The maximum number of translations associated with any box at level l is finite (8 multipole-to-multipole translations in the upward pass, 8 local-to-local translations in the downward pass, and 189 multipole-to-local translations in the downward pass). This shows that the translation cost associated with each box at level l is $O(p_l^{2\nu})$ (with a large asymptotic constant). Therefore the total number of translations can be evaluated as

$$N_{\text{trans}} = O \left(\sum_{l=2}^{l_{\max}} p_l^{2\nu} 8^l \right). \quad (56)$$

From Eqs. (54) and (55) we can majorate the dependence of p_l on l with function $p_l = \beta k D_0 2^{-l}$, where β is some constant. Substituting this into Eq. (56), we obtain

$$N_{\text{trans}} = (k D_0)^{2\nu} O \left(\sum_{l=2}^{l_{\max}} 2^{(3-2\nu)l} \right). \quad (57)$$

Three qualitatively different cases can be identified now. The first case, $\nu < 1.5$, corresponds to “fast translations.” In this case we have $N_{\text{trans}} \sim (k D_0)^{2\nu} 2^{(3-2\nu)l_{\max}}$. Assuming that $D_0 \sim N^{1/3} a$, so $k D_0 \sim N^{1/3} ka \sim N^{1/3} p$ and $2^{3l_{\max}} \sim N$, we can see that $N_{\text{trans}} \sim p^{2\nu} N$. So the algorithm scales as $O(p^{2\nu} N)$, with p taken for the truncation of coefficients $\{\mathbf{A}^{(q)}\}$ [see Eqs. (51) and (54)]. The second case, $\nu = 1.5$, corresponds to

the “critically fast translations,” and this value of ν can be called a “critical translation exponent.” We have then, using the same assumptions as for the first case, $N_{\text{trans}} \sim (kD_0)^3 I_{\text{max}} \sim p^3 N \log N$, or complexity $O(p^3 N \log N)$. Finally, we have the case of “slow translations,” $\nu > 1.5$. Here $N_{\text{trans}} \sim (kD_0)^{2\nu} \sim p^{2\nu} N^{2\nu/3}$. So the FMM in this case scales as $O(p^{2\nu} N^{2\nu/3})$, or superlinearly with N , $2\nu/3 > 1$. It is interesting to note that in the first case the major number of translation operations are performed at the finest level of space partitioning l_{max} , in the second case the number of operations for each level is approximately the same, while in the third case the major complexity comes from operations at the coarsest level $l=2$. So two competing effects, the reduction of the number of boxes, and an increase of the truncation numbers compensate each other in the “critical” case. To provide an algorithm that scales as $O(N \log N)$, one should use at least an $O(p^3)$ translation method.

Note that the theoretically minimum translation exponent is $\nu=1$ (one operation per one expansion coefficient). This value is also “critical” for two-dimensional problems, and for three-dimensional problems, where the scatterers are distributed over some surface. The later case also applies to the boundary element methods. For these cases to have an $O(N \log N)$ complexity FMM algorithm with a variable truncation number, one should employ the theoretically fastest translation methods.

Finally, we note that the total complexity of the method consists of the complexity of translations plus complexity of generation of function representations for each box at the finest level, the complexity of evaluation of function representations, and the final summation. In the present paper all procedures have complexity $O(p^3)$. Taking into account that such operations should be performed for each point, the total complexity of the present algorithm will be $N_{\text{oper}} = O(p^3 N) + O(p^3 N \log N) = O(p^3 N \log N)$.

In the paper of Koc and Chew (1998), the diagonal forms of the translation operators obtained by Rokhlin (1993) are used. Formally, the complexity of these translation methods can be evaluated as $O(p^2)$, while their implementation requires additional procedures, such as interpolation and antinterpolation (e.g., see Darve, 2000a; Chew *et al.*, 2001), or the filtering of spherical harmonics. These procedures can be much more expensive than the translation itself [e.g., K -point Lagrange interpolation, the complexity can be evaluated as Kp^2 , and for $K \sim p$ this results in $O(p^3)$ complexity], while they can be efficient for higher frequencies. In any case, if we assume that the complexity of the translation method is $O(p^2)$ ($\nu=1$) we obtain $N_{\text{trans}} \sim O(p^2 N)$. However, higher complexity comes from the initial and final steps of the algorithm. To use the diagonal forms we need to convert the representation based on expansion coefficients to that based on samples of the signature function over the sphere. A bandlimited function with p^2 coefficients can be represented by $O(p^2)$ samples, and the conversion of one representation to the other using a direct integral evaluation (as did Koc and Chew) requires $O(p^4)$ operations. The same relates to the final evaluation step, where we should convert the function representation from the samples of the signature function to the expansion coefficients. So the total complex-

ity of the Koc and Chew algorithm can be evaluated as $O(p^4 N) + O(p^2 N) = O(p^4 N)$. There may be some possibilities to improve the complexity of the Koc and Chew algorithm, e.g., if a fast Legendre transform were available (an item of current research). We note that formally the complexities of the Koc and Chew method and the present method are the same for $p \sim \log N$, while, in practice, the quality of implementation, which influences the asymptotic constants, can reduce the execution time of the algorithm several times and factors of type $\log N$ in the range of N considered in this paper are unimportant, except from a theoretical point of view.

F. Translation method

For the present class of problems $O(p^3)$ -translation methods based on the use of the re-expansion matrices can be employed, as they provide a transparent link to the coefficients of the expansions.

The translation method based on a direct computation of the re-expansion matrices $(\mathbf{E}|\mathbf{F})(\mathbf{t})$, where $(\mathbf{E}|\mathbf{F})$ can be any combination of letters \mathbf{S} and \mathbf{R} , followed by their multiplication by the vectors of expansion coefficients has complexity $O(p^4)$. This is the lowest complexity that one can expect, even using recursive procedures for the computation of matrix elements, since the matrix is dense. To achieve $O(p^3)$ complexity, we used a translation method based on the rotation-coaxial translation decomposition of an arbitrary translation operators:

$$(\mathbf{E}|\mathbf{F})(\mathbf{t}) = \mathbf{Rot}^{-1}\left(\frac{\mathbf{t}}{t}\right) (\underline{\mathbf{E}|\mathbf{F}})(t) \mathbf{Rot}\left(\frac{\mathbf{t}}{t}\right),$$

$$t = |\mathbf{t}|, \quad \mathbf{E}, \mathbf{F} = \mathbf{S}, \mathbf{R}, \quad (58)$$

where $\mathbf{Rot}(\mathbf{t}/t)$ is the rotation transform matrix, which enables one to obtain the expansion coefficients in the reference frame rotated by such way that the z axis of the new reference frame is directed as the unit vector \mathbf{t}/t , $(\mathbf{E}|\mathbf{F})(t)$ denotes the coaxial translation matrix that performs $\overline{\text{translation}}$ along the z axis for distance t and $\mathbf{Rot}^{-1}(\mathbf{t}/t)$ is the backward rotation, which brings the reference frame to its initial orientation. Each of these operations can be performed with complexity $O(p^3)$ using a recursive computation of the matrix elements (Gumerov and Duraiswami, 2003). So, e.g., for the $(\mathbf{S}|\mathbf{R})$ translation of some vector \mathbf{C} , we first produce $\tilde{\mathbf{C}} = \mathbf{Rot}(\mathbf{t}/t)\mathbf{C}$, then $\mathbf{C}' = (\mathbf{S}|\mathbf{R})(t)\tilde{\mathbf{C}}$, and finally $\hat{\mathbf{C}} = \mathbf{Rot}^{-1}(\mathbf{t}/t)\mathbf{C}'$ for the expense of $O(p^3)$ operations, opposed to $O(p^4)$ operations if we use straightforward multiplication $\hat{\mathbf{C}} = (\mathbf{S}|\mathbf{R})(\mathbf{t})\mathbf{C}$.

1. Rotation transform

In general, an arbitrary rotation transform can be specified by three angles of rotation, e.g., the Euler angles, α_E , β_E , γ_E , or angles α , β , γ related to the Euler angles as $\alpha = \pi - \alpha_E$, $\beta = \beta_E$, and $\gamma = \gamma_E$, which are more convenient, since they are related to the spherical angles (θ_i, φ_i) of the unit vector $\mathbf{t}/t = (\sin \theta_i \cos \varphi_i, \sin \theta_i \sin \varphi_i, \cos \theta_i)$ as $\beta = \theta_i$ and $\alpha = \varphi_i$ (see Fig. 5). The rotation transform of the expansion coefficients is a function of the rotation matrix $Q(\alpha, \beta, \gamma)$. The inverse rotation transform is the same func-

FIG. 5. An illustration of rotation specified by angles α , β , and γ . Angles β and α are the spherical polar angles of the translation vector \mathbf{t} .

tion from the inverse rotation matrix $Q^{-1}(\alpha, \beta, \gamma) = Q^T(\alpha, \beta, \gamma) = Q(\gamma, \beta, \alpha)$, so we can describe only the forward rotation, since the inverse rotation can be obtained simply by exchanging angles α and γ .

Rotation of the truncated vector \mathbf{C} with components $\{C_n^{m'}\}$ can be performed according to the following formula:

$$\tilde{C}_n^{m'} = e^{-im'\gamma} \sum_{m=-n}^n H_n^{m'm}(\beta) e^{im\alpha} C_n^m, \quad n=0,1,\dots,p-1, \quad m' = -n, \dots, n. \quad (59)$$

Here $H_n^{m'm}(\beta)$ are the entries of a real dense matrix that can be computed recursively (Gumerov and Duraiswami, 2003):

$$H_{n-1}^{m',m+1} = \frac{1}{b_n^m} \left\{ \frac{1}{2} [b_n^{-m'-1} (1 - \cos \beta) H_n^{m'+1,m} - b_n^{m'-1} (1 + \cos \beta) H_n^{m'-1,m}] - a_{n-1}^{m'} \sin \beta H_n^{m'm} \right\}, \quad n=2,3,\dots, \quad m' = -n+1, \dots, n-1, \quad m=0, \dots, n-2, \quad (60)$$

starting with the initial values

$$H_n^{m'0}(\beta) = (-1)^{m'} \sqrt{\frac{(n-|m'|)!}{(n+|m'|)!}} P_n^{|m'|}(\cos \beta), \quad n=0,1,\dots, \quad m' = -n, \dots, n. \quad (61)$$

The coefficients a_n^m and b_n^m of the recurrence relation (60) are

$$a_n^m = \begin{cases} \sqrt{\frac{(n+1+|m|)(n+1-|m|)}{(2n+1)(2n+3)}}, & n \geq |m|, \\ 0, & |m| > n, \end{cases} \quad (62)$$

$$b_n^m = \begin{cases} \sqrt{\frac{(n-m-1)(n-m)}{(2n-1)(2n+1)}}, & 0 \leq m \leq n, \\ -\sqrt{\frac{(n-m-1)(n-m)}{(2n-1)(2n+1)}}, & -n \leq m < 0, \\ 0, & |m| > n. \end{cases} \quad (63)$$

The amount of the recursive computations can be reduced using the symmetry relations:

$$H_n^{mm'}(\beta) = H_n^{m'm}(\beta) = H_n^{-m',-m}(\beta), \quad n=0,1,\dots, \quad m', m = -n, \dots, n. \quad (64)$$

So computations of the general rotation can be organized as follows. First we compute all rotation coefficients $H_n^{m'm}(\beta)$. This requires $O(p^3)$ operations. Then we perform the multiplication $D_n^m = e^{im\alpha} C_n^m$, $n=0,1,\dots,p-1$, $m=-n,\dots,n$. This can be treated as multiplication of vector \mathbf{C} by a diagonal matrix and requires $O(p^2)$ operations. Then for each subspace of degree n we perform multiplication of the dense $(2n+1) \times (2n+1)$ matrix with the entries $H_n^{m'm}(\beta)$ by vector \mathbf{D} , and this totals in $O(p^3)$ operations for all subspaces and produces the vector \mathbf{G} . The last step is multiplication of this vector by the diagonal matrix, to produce the final result: $\tilde{C}_n^{m'} = e^{-im'\gamma} G_n^{m'}$, $n=0,1,\dots,p-1$, $m' = -n, \dots, n$. This takes $O(p^2)$ operations.

We note that the decomposition can be simplified by setting $\gamma=0$, since the rotations with angles α and β align the new z axis with direction \mathbf{t}/t , while the latter rotation does not change this direction (see Fig. 5). So the forward transform can be performed with the rotation matrix $Q(\varphi_t, \theta_t, 0)$ ($\alpha = \varphi_t$, $\beta = \theta_t$, $\gamma = 0$) and the inverse with $Q(0, \theta_t, \varphi_t)$.

2. Coaxial translation

Coaxial translations, or translations along the z axis, can also be performed with lower complexity than the general translation, since each subspace of order m is invariant with respect to this type of translation. So if $\hat{\mathbf{C}} = (\mathbf{E}|\mathbf{F})(t)\mathbf{C}$, we have

$$\hat{C}_n^m = \sum_{n'=|m|}^{p-1} (E|F)_{n'n}^m(t) C_n^m, \quad m=0, \pm 1, \dots, \pm(\min(p, p')-1), \quad n'=0, 1, \dots, p'-1, \quad E, F = S, R. \quad (65)$$

Here $(E|F)_{n'n}^m$ are the entries of matrix $(\mathbf{E}|\mathbf{F})(t)$, which is truncated rectangularly, since it applies to vector \mathbf{C} of total length p^2 and produces a vector $\hat{\mathbf{C}}$ of total length $(p')^2$. This is due to the algorithm, where the truncation number must change from level to level. Since the truncation numbers p' and p are of the same order, the total complexity of the matrix-vector multiplication (65) is $O(p^3)$ for a given translation matrix. All entries of this matrix can be computed recursively for an expense of $O(p^3)$ operations using the following recursions (Gumerov and Duraiswami, 2003):

$$\begin{aligned} \text{To advance with respect to the order } n \text{ at fixed } m \geq 0: \\ a_n^m (E|F)_{n',n+1}^m = a_{n-1}^m (E|F)_{n',n-1}^m - a_{n-1}^{m'} (E|F)_{n'+1,n}^m \\ + a_{n-1}^{m'-1} (E|F)_{n'-1,n}^m, \end{aligned} \quad (66)$$

with the a 's given by Eq. (62). For advancement with respect to m :

$$\begin{aligned} b_{m+1}^{-m-1} (E|F)_{n',m+1}^m = b_n^{-m-1} (E|F)_{n'-1,m}^m \\ - b_{n+1}^m (E|F)_{n'+1,m}^m, \end{aligned} \quad (67)$$

$$n' = m + 1, m + 2, \dots, \quad E, F = S, R,$$

with the b 's given by Eq. (63). The recursive procedure starts with the initial values

$$\begin{aligned} (S|R)_{n'0}^0(t) &= (-1)^{n'} \sqrt{2n'+1} h_{n'}(kt), \\ (R|R)_{n'0}^0(t) &= (-1)^{n'} \sqrt{2n'+1} j_{n'}(kt). \end{aligned} \quad (68)$$

For the Helmholtz equation we have $(S|S)_{n'n}^m(t) = (R|R)_{n'n}^m(t)$, and so only the latter coefficients need be computed. We also note that computational savings can be achieved using the following symmetries of the coaxial translation coefficients:

$$\begin{aligned} (E|F)_{n'n}^m &= (E|F)_{n'n}^{-m} = (E|F)_{n'n}^{|m|} = (-1)^{n+n'} (E|F)_{nn'}^m, \\ E, F &= S, R. \end{aligned} \quad (69)$$

G. Use of the FMM for preconditioning in the GMRES

Our computations show that the plain (without preconditioning) GMRES slows down substantially at larger N and for relatively high volume fractions of the spheres (in this case the number of iterations increases proportionally to N). If $N_{\text{iter}} = O(N)$ then a method that requires $O(N \log N)$ per matrix-vector multiplication will require $O(N^2 \log N)$ operations to solve the problem. We found that this drawback can be fixed in many cases by the use of properly designed preconditioners. The GMRES with the right preconditioner \mathbf{M}^{-1} solves the problem

$$\mathbf{L}\mathbf{M}^{-1}(\mathbf{M}\mathbf{A}) = \mathbf{E}, \quad (70)$$

which is formally equivalent to the original problem (23) for arbitrary invertible matrix \mathbf{M} . If solution of the system $\mathbf{M}\mathbf{A} = \mathbf{F}$ for an arbitrary input \mathbf{F} can be obtained faster than solution of the original system $\mathbf{L}\mathbf{A} = \mathbf{F}$, and \mathbf{M} is a good approximation of \mathbf{L} ($\mathbf{M} \approx \mathbf{L}$), then one can expect a substantial reduction in the number of iterations.

The FMM provides a good tool for building a preconditioner (for the discussion of preconditioning see Kelly, 1995; Saad, 2003). The preconditioners that can be constructed are based on decompositions of the dense $(S|R)$ matrix in Eq. (28):

$$\begin{aligned} (S|R) &= (S|R)_{\text{near}} + (S|R)_{\text{far}}, \quad \mathbf{M}_{\text{sparse}} = \mathbf{T}^{-1} - (S|R)_{\text{near}}, \\ \mathbf{M}_{\text{dense}} &= \mathbf{T}^{-1} - (S|R)_{\text{far}}, \end{aligned} \quad (71)$$

where $(S|R)_{\text{near}}$ is a sparse matrix, which includes only interactions between the scatterers located in the same neighborhood (say at the maximum level of space subdivision), and $(S|R)_{\text{far}}$ is the matrix, which includes farfield interactions. This decomposition, in fact, is decomposition (35) in terms of the resulting vector \mathbf{B} . The matrix-vector products $\mathbf{M}_{\text{sparse}}\mathbf{A}$ or $\mathbf{M}_{\text{dense}}\mathbf{A}$ involving preconditioners $\mathbf{M}_{\text{sparse}}$ and $\mathbf{M}_{\text{dense}}$ then can be computed faster than $\mathbf{L}\mathbf{A}$, since only part of the FMM operations are needed to perform the computations. At first look, it seems that it is more reasonable to use $\mathbf{M}_{\text{sparse}}$ as the preconditioner, since presumably matrix-vector multiplication in this case should be cheaper. However, there are two reasons, both working in the same direction, why the use of $\mathbf{M}_{\text{dense}}$ may make more sense.

The first reason is based on the efficiency of the preconditioner in terms of the process convergence. Despite the fact that the distance between the neighbor scatterers is smaller and the interaction between any pair of neighbors is stronger than between the remote particles, the number of neighbors is also substantially smaller. Since this interaction decays as r^{-1} , while the number of particles in the farfield increases as r^3 (for a uniform distribution) the effect of the farfield on the given scatterer dominates for larger domain sizes and a larger number of scatterers. Most computational work then is to iterate the solution for a proper determination of the farfield, and that is what the unpreconditioned method does.

The second reason is a feature of the FMM that appears to have been used for the first time here. It is based on the efficiency of the preconditioner in terms of the speed of matrix-vector multiplication. It may seem paradoxical but in the FMM as described above the computation of $(S|R)_{\text{far}}\mathbf{A}$ can be much faster than the computation of $(S|R)_{\text{near}}\mathbf{A}$. This happens due to limitations of type (31) on the maximum level of space subdivision and takes place for a relatively high volume fraction of scatterers [for low volume fractions $(S|R)_{\text{near}}\mathbf{A}$ can be computed faster]. Indeed if l_{max} is small enough, then the most computational work is spent for direct computations of matrix-vector products $\mathbf{B}_{\text{near}} = (S|R)_{\text{near}}\mathbf{A}$ [for $l_{\text{max}} = 1$ we have $(S|R)_{\text{near}} = (S|R)$ and need to multiply the matrix by vector directly for cost $O(N^2)$]. An increase of l_{max} reduces the number of direct matrix-vector products, while increasing the total number of translations. There exist some optimum $l_{\text{max}}^{\text{opt}}$, where the costs of translations and direct computations is balanced. It appears that for high volume fractions of scatterers $l_{\text{max}}^{\text{opt}} > l_{\text{max}}$, where l_{max} is limited by condition (31) (we checked this numerically for some spatially uniform random distributions of the scatterers), and so the use of $\mathbf{M}_{\text{dense}}$ is preferable.

Finally, we note that we computed the matrix-vector product $\mathbf{A} = \mathbf{M}^{-1}\mathbf{F}$ by solving $\mathbf{M}\mathbf{A} = \mathbf{F}$ using the unpreconditioned GMRES, which introduced an internal iteration loop. As a convergence criterion for this internal process we imposed the error of iteration much larger than the error for an external loop (this is possible, since the preconditioner can be computed roughly). This type of iterative scheme produces poor results if a regular GMRES is used, due to the nonlinear dependence of \mathbf{A} on \mathbf{F} in this process. It is also well known that this drawback can be fixed by the use of flexible GMRES, which we do. For details refer to Saad (1993).

VI. NUMERICAL RESULTS AND DISCUSSION

A. Test problems computed

The multiple scattering problem even with spherical scatterers is a multiparametric problem with many degrees of freedom. In the tests we selected a few typical types of spatial distributions: uniformly random, periodic (spheres in a grid), randomly periodic, where some random pattern is repeated several times in a cubic mesh, and uniformly random with some limitations on the interparticle distances (e.g., that the ratio of the minimum distance between the sphere centers to the sphere radius, d_{min}/a , is some prescribed number). The

FIG. 6. Examples of distributions of N spheres used in computations: periodic, randomly periodic, and random.

latter type of distribution enables computations with high accuracy (which depends on d_{\min}/a , as discussed above). We also performed computations for monodisperse (all spheres of the same size) and polydisperse systems (see Fig. 6). In the latter case the radii of the spheres were distributed between some a_{\min} and a_{\max} (we used uniformly random distributions, while other situations are possible, depending on a particular physical problem). The number of spheres was varied in range $N=[10,10000]$. This also depends on ka , which was varied in range $0.1 < ka < 5$, and the volume fraction of the spheres in the computational domain, α :

$$\alpha = \frac{4\pi Na^3}{3D_0^3}, \quad a^3 = \sum_{q=1}^N a_q^3. \quad (72)$$

For larger ka and smaller α we used smaller number N to stay within the range $kD_0 < 100$, according to the equation

$$kD_0 = \left(\frac{4\pi N}{3\alpha}\right)^{1/3} ka. \quad (73)$$

Potentially larger kD_0 's are possible; however, some loss of precision was observed at larger kD_0 , which may be related to the number of bits representing float numbers and the growth of the cut-off errors.

We also varied the boundary admittances σ_q of the scatterers. Despite the fact that the procedure allows computations with different σ_q 's for each scatterer, we did not conduct systematic tests of this case and in all computations we assumed that all admittances are the same $\sigma_q = \sigma$, $q = 1, \dots, N$.

B. Field visualization

Once computations of the expansion coefficients $\{\mathbf{A}^{(q)}\}$ are performed, the problem is how to determine the surface and spatial distributions of the potential and the surface distributions of its normal derivative. A computation of the surface distributions is a relatively easy task, since we have (GD02),

$$\psi|_{S_q} = \frac{1}{ika_q^2} \sum_{n=0}^{p-1} \sum_{m=-n}^n \frac{A_n^{(q)m} Y_n^m(\theta_q, \varphi_q)}{kj'_n(ka_q) + i\sigma_q j_n(ka_q)}, \quad (74)$$

$$\begin{aligned} \frac{\partial \psi}{\partial n}|_{S_q} &= -\frac{\sigma_q}{ka_q^2} \sum_{n=0}^{p-1} \sum_{m=-n}^n \frac{A_n^{(q)m} Y_n^m(\theta_q, \varphi_q)}{kj'_n(ka_q) + i\sigma_q j_n(ka_q)} \\ &= -i\sigma_q \psi|_{S_q}. \end{aligned} \quad (75)$$

FIG. 7. Examples of the computation of the surface potential for 100 spheres exposed to a plane wave directed as shown by the arrows.

An example of surface potential visualization for the case of 100 spheres is shown in Fig. 7.

A computation of the potential at M spatial locations \mathbf{y}_m , $m=1, \dots, M$ can be a computationally more expensive task than the solution of the problem itself, if this is performed in a straightforward way. The spatial visualization, however, can be performed as fast as the solution and with the same accuracy, if the FMM is applied to this task. Two major modifications of the algorithm are needed in this case. First, we separate the set of N scatterer centers from the set of M evaluation points. The octree-based space partitioning is applied to the new data structure. As soon as the expansion coefficients $\mathbf{A}^{(q)}$, $q=1, \dots, N$ are known, the upward pass then is the same as for solution of the scattering problem, while in the downward pass the process goes over the hierarchy of the evaluation points [see the separation of data hierarchies discussed in Gumerov *et al.*, (2003)]. At the end of the downward pass we obtain the expansion coefficients $\mathbf{D}^{(n, l_{\max})}$ for each target box (the box containing the evaluation points). Then, as the final summation step, we compute the potential for all evaluation points as

$$\begin{aligned} \psi(\mathbf{y}_m) &= \psi_{\text{in}}(\mathbf{y}_m) + \mathbf{D}^{(n, l_{\max})} \cdot \mathbf{R}(\mathbf{y}_m - \mathbf{r}_*^{(n, l_{\max})}) \\ &\quad + \sum_{\mathbf{r}'_q \in E_2(n, l_{\max})} \mathbf{A}^{(q)} \cdot \mathbf{S}(\mathbf{y}_m - \mathbf{r}'_q), \\ \forall \mathbf{y}_m \in E_1(n, l_{\max}), \quad m &= 1, \dots, M. \end{aligned} \quad (76)$$

Here the first term on the right-hand side is the known potential of the incident field at the receiver locations, the second term is the potential of the field scattered by the scatterers located outside the neighborhood of the target box, and the third term is a field scattered by the scatterers located in the neighborhood of the receiver and found by direct evaluation. The complexity of this procedure for the $O(p^3)$ translation method is of type $O((N+M)\log N)$ if the same l_{\max} is used for the space imaging method as for the solution of the problem. If there are many imaging points in a target box, finer space partitioning can be used to reduce the complexity, and the optimum number of levels can be found experimentally or based on some theory applicable for the FMM (Gumerov *et al.*, 2003).

Figure 8 illustrates the “speckle patterns” on the image plane shown in Fig. 7 by blue dots. The solution is obtained using the FMM both for an accelerated iterative solution of

FIG. 8. Speckle patterns on the imaging plane computed using the FMM for scattering of plane waves of different wavelengths from 100 scatterers (the geometry and the imaging plane are shown in Fig. 7).

the linear system and for imaging of the field as described. The images are computed for monochromatic fields of different frequencies. These pictures are frames of a movie that animates the wave propagation in time, by plotting $\text{Re}\{\psi(\mathbf{r})e^{-i\omega t}\}$ for different t . A similar figure (Fig. 9) illustrates the “speckle patterns” for the case of 10 000 equal spheres ($a=1$) with centers that are randomly distributed inside a cube $80 \times 80 \times 80$ ($d_{\min}=2.5$).

C. A posteriori error evaluation

For these tests we used Eq. (51) to obtain the truncation number where we varied p_0 , and Eqs. (54) and (55) for the FMM procedure, where ϵ was specified to be the same as for the convergence of the iterative process. After the iterative process (GMRES) was terminated, we computed the potential at M sampling points according to Eq. (74) and the relative errors in boundary conditions using (53). The spheres were distributed randomly inside a cubic box with the restriction that the distance between the sphere centers exceeds some prescribed d_{\min} . Test were made for the incident wave $\psi_{\text{in}}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}}$.

An example of the computed surface error is shown in Fig. 10. This figure illustrates the behavior of $|\psi|_{S_q}(\mathbf{y}_m)$ and $\Delta_{bc}(\mathbf{y}_m)$ for $M=3200$ sampling points allocated on the surfaces of 100 equal size sound-hard spheres for $p=11$ ($ka=1$, $kD_0 \approx 30$, $\sigma=0$, $\alpha=0.042$, $d_{\min}/a=3$, $l_{\max}=3$, $\epsilon=10^{-10}$). It is seen that the maximum absolute error of computations in this case is less than 10^{-4} , while the average error of computations is of the order of 10^{-6} .

The parameter d_{\min}/a has a substantial effect on the accuracy. Figure 11 illustrates this effect for the same settings as for 10, where the truncation number and d_{\min}/a were varied. The relative error $\epsilon^{(bc)}$ defined by Eq. (53), that also can

FIG. 9. Speckle patterns on the imaging plane computed using the FMM for scattering of plane waves of different wavelength from 10 000 spheres of size $a=1$ randomly distributed inside a cube $80 \times 80 \times 80$. The image plane is located at $z=82$ (assuming that the computational domain is between $z=-1$ and $z=81$ and the plane wave propagates in the positive direction).

FIG. 10. The modulus of the potential and the absolute error in boundary conditions obtained *a posteriori* as functions on the surface node index. The surface of each of 100 spheres was sampled by 32 points.

be assigned as the relative error in the “infinity” norm L_∞ , is much larger (about one order of magnitude) than the average, or L_2 -norm error, $\epsilon_2^{(bc)}$, defined as

$$\epsilon_2^{(bc)} = \frac{1}{M} \left\{ \sum_{m=1}^M [\epsilon_m^{(bc)}]^2 \right\}^{1/2}, \quad (77)$$

with $\epsilon_m^{(bc)}$ specified in Eq. (53). It is seen that even for the case when the spheres may touch ($d_{\min}/a=2$), computations can be performed with relatively small truncation numbers if an accuracy $\epsilon^{(bc)}$ of the order of a few percent is acceptable (that might be sufficient for comparisons with experiments, field imaging, etc.). For computations with high precision, the truncation numbers should be increased, which may substantially slow down the computation process. One of the methods to treat this drawback is to introduce truncation numbers p_q for each scatterer, $q=1, \dots, N$, which should depend on the distance from the q th sphere to its closest neighbor sphere. In the present study, however, we did not perform

FIG. 11. Dependencies of the relative errors in the infinite (solid lines) and quadratic (dashed lines) norms on the truncation number p for the same parameters as shown in Fig. 10. The errors are computed for random distributions with different ratios d_{\min}/a shown near the curves.

FIG. 12. Convergence of the unpreconditioned GMRES at different dimensionless wave numbers ka shown near the curves.

modifications, since our goal was to develop and test the base algorithm.

D. Convergence

Several factors may affect the rate of convergence of the iterative method and more or less a complete study involves the investigation of the multiparametric space. In the present tests we usually fixed all parameters for the case and varied one or two parameters to see their effect on the convergence rate and accuracy of computations. Figure 12 shows the effect of the frequency on the convergence of unpreconditioned GMRES. For the case illustrated, 200 equal size sound-hard spheres with random distribution of their centers were generated as described above ($d_{\min}/a=2.3$). The truncation numbers were selected according to Eq. (51) with a constant $p_0=10$ for all cases, while the FMM truncation numbers were determined according to Eq. (54) with $\epsilon=10^{-4}$. It is seen that in this case the number of iterations to achieve specified accuracy increases with ka . An *a posteriori* error check for the boundary conditions at 6400 points shows that for this case the error $\epsilon^{(bc)}$ defined by Eq. (53) does not exceed 5×10^{-3} for all cases, while $\epsilon_2^{(bc)}$ defined by Eq. (77) is about 1 order of magnitude smaller. We found that the iteration process for higher frequencies ($ka \geq 5$, $kD_0 \geq 100$) diverges, and special methods for treatment of higher frequencies are required. Several methods can be tried in this case, such as using preconditioners based on high-frequency asymptotic expansions of the system matrix, and some relaxation methods, where, e.g., the impedance of the spheres, σ , can be gradually adjusted during the iteration process. Indeed, we did some preliminary computations with fixed $ka=4$ and varying σ and found that, say for $\sigma/k \sim 0.1$, the number of iterations to achieve the same accuracy drops by a factor of 2.

Properly designed preconditioners can substantially reduce the computation time to obtain a solution of specified accuracy. Some results of the use of GMRES and FGMRES with the right dense preconditioner $\mathbf{M}_{\text{dense}}$ [see Eq. (71)] is shown in Table I. This table shows computational results for

TABLE I. Performance of the FMM accelerated GMRES/FGMRES. $N=10\,000$. Number of complex unknowns= 2.25×10^6 .

Preconditioner	No. external iterations	No. internal iterations	CPU time (s)
No preconditioner	58	0	8340
Right dense, $\epsilon_{\text{pre}}=0.1$	11	87	3460
Right dense, $\epsilon_{\text{pre}}=0.01$	10	165	4525

10 000 sound hard spheres of equal size with a randomly periodic distribution (blocks of 80 spheres with random distribution of centers, $d_{\min}/a=2$, $\alpha=0.2$, were repeated 125 times to occupy a larger cube). Here $D_0/a=60$ and $ka=0.5$, $l_{\max}=4$, $\epsilon=10^{-4}$, $p=7$, and the CPU time was measured for 3.2 MHz dual Intel Xeon processor (3.5 GB RAM, 25% CPU resource allocation for a task). The table shows that the number of iterations for the external loop can be drastically reduced due to the use of a preconditioner. The price to pay for this is the internal iterative loop, which uses also GMRES to obtain a solution of the equation $\mathbf{M}_{\text{dense}}\mathbf{A}=\mathbf{F}$. However, for the present case matrix-vector multiplication $\mathbf{M}_{\text{dense}}\mathbf{A}$ was seven times faster than performing multiplication $\mathbf{L}\mathbf{A}$ (both using the FMM). This resulted in a decrease of the overall computational time. A solution of equation $\mathbf{M}_{\text{dense}}\mathbf{A}=\mathbf{F}$ can be performed with much less accuracy, ϵ_{pre} (shown in the first column of the table), than the accuracy required for the external iterative process. This can be a subject for optimization, since the increase of the accuracy for internal iterations reduces the number of external iterations and increases the number of the internal iterations. We also need to mention that the efficiency of preconditioners depend on several other parameters, including wave number, number of scatterers, surface admittance, volume fraction, etc. (See Table I)

E. Performance study

To determine the dependence of the CPU time required for a solution of the problem, and to check the consistency of the actual results with the theoretical predictions, we conducted a performance study. All computations were made in double precision complex arithmetic on a desktop PC (3.2 MHz dual Intel Xeon processor, 3.5 GB RAM, 25% CPU resource allocated for a task). As a test distribution we used randomly periodic distributions of equal size sound hard spheres (blocks of 80 spheres with random distribution of centers, $d_{\min}/a=2$, were repeated m^3 times to occupy a larger cube, $m=1, \dots, 5$; an example for $m=2$, $N=640$ is shown in Fig. 6). Since the volume fraction and the wave number in the tests were fixed ($\alpha=0.2$, $ka=0.5$) the increase in the number of spheres also means the increase of the size of the computational domain [see Eq. (73)].

We found that to reduce the CPU time for the present case, one should select the computational domain size larger than the size of the box, which encloses all the spheres. The size of the computational domain can be determined based on l_{\max} according Eq. (33) as

FIG. 13. Dependences of the CPU time (Intel Xeon 3.2 GHz, 3.5 Gb RAM) on the number of scatterers ($ka=0.5$, $p=15$, $\epsilon=10^{-4}$) for randomly-periodic distribution of sound-hard spheres of equal size (see Fig. 6). The triangles and squares show the CPU time required for matrix-vector multiplication using the FMM for the preconditioner and full matrix, respectively. The disks show the total CPU time for the execution of the algorithm. The lines show the interpolation of data.

$$D_0 = \frac{2\delta_{\min}}{4 - (1 + \delta_{\min})\sqrt{3}} 2^{l_{\max}} a_{\max}. \quad (78)$$

Setting here $l_{\max}=2,3,\dots$, we can determine a discrete set of D_0 . For computations we selected the minimum of D_0 from this set, which encloses all the spheres. Although δ_{\min} here should be larger than 1, we found with the *a posteriori* error check that $\delta_{\min}=1$ provides stable and accurate results in this case. Note that for performance tests we accepted relative errors $\epsilon^{(bc)}$ of about 2% (the errors $\epsilon_2^{(bc)}$ were one order of magnitude smaller). To provide this order of errors we set $\epsilon=10^{-4}$ for the global iteration convergence, while the error for the preconditioner was set to $\epsilon_{\text{pre}}=0.2$. In all computations we used a truncation number of $p=15$. This substantially exceeds $p_{l_{\max}} \sim 8$, and the choice of p was dictated by a desire to compute accurately the case of touching spheres. Since the excessive value $p=15$ is due only to the influence of the neighbor spheres, for each sphere we took the contribution of the neighbors with $d/a < 1.3$ into harmonics of degree $n=8,\dots,15$, while we neglected the effect of other scatterers on these harmonics (see the discussion at the end of Sec. V D). An *a posteriori* error check showed that the relative errors specified above were achieved.

Figure 13 shows the measurements of the CPU time for various operations of the algorithm based on the FGMRES with a right preconditioner. It is seen that the computation time scales almost linearly for a single matrix-vector multiplication in the internal or external loop using the FMM. This agrees well with the theoretical predictions of complexity $O(N \log N)$. Due to the growth of the number of iterations both in the internal and external loops with N , the total CPU time scales as $O(N^{1.25})$. This shows that some average number of internal-external iterations, N_{iter} , is proportional in the present case to $N^{0.25}$ or so. As it was discussed previously, an optimum can be sought by varying ϵ_{pre} , and pos-

sibly, ϵ , to perform better, while we kept these parameters for the illustration case fixed. Note that for large N and unpreconditioned GMRES we found that the number of iterations N_{iter} grows proportionally to N for $N \geq 2000$, which substantially reduces the efficiency of the algorithm.

It is also noteworthy that even for $N=80$ the size of the complex system matrix \mathbf{L} is $Np^2 \times Np^2 = 18\,000 \times 18\,000$, which would require several hours to solve the problem directly, while the present method requires only 10 s for this operation. We also found that a solution of this problem using GMRES without preconditioners and the FMM for matrix-vector multiplication takes about 75 s of CPU time for the same machine. Cases with larger N were not even computable due to memory limitations.

VII. CONCLUSIONS

We have developed and tested a procedure for a solution of the acoustic scattering problems for the case of clusters consisting of a relatively large number of spherical scatterers of various radii and impedances arbitrarily located in three-dimensional space. This procedure uses a multipole re-expansion technique, the fast multipole method, and iteration algorithms, such as GMRES with possible preconditioners and is accelerated utilizing the FMM. We developed and tested a technique for *a posteriori* error control, investigated convergence, and performance of the method in a certain range of parameters and found that this technique can be an efficient, accurate, and powerful tool for solution of such multiple scattering problems.

While the method is developed and tested for spherical scatterers, it can be naturally extended for the computation of scattering from objects of an arbitrary shape, as soon as the T matrices for the single scatterers are known analytically or precomputed numerically. Several research issues for further improvement of the method remain open, e.g., the problem of computations for very high frequencies or large domain sizes, $kD_0 \geq 100$.

Phased array transducers are multi-element transducers, where different elements are activated with different time delays. The advantage of these transducers is that no mechanical movement of the transducer is needed to scan an object. Focusing and beam steering is obtained simply by adjusting the time delay. In this paper the DPSM (distributed point source method) is used to model the ultrasonic field generated by a phased array transducer and to study the interaction effect when two phased array transducers are placed in a homogeneous fluid. Earlier investigations modeled the acoustic field for conventional transducers where all transducer points are excited simultaneously. In this research, combining the concepts of delayed firing and the DPSM, the phased array transducers are modeled semi-analytically. In addition to the single transducer modeling the ultrasonic fields from two phased array transducers placed face to face in a fluid medium is also modeled to study the interaction effect. The importance of considering the interaction effect in multiple transducer modeling is discussed, pointing out that neighboring transducers not only act as ultrasonic wave generators but also as scatterers. © 2005 Acoustical Society of America.

I. INTRODUCTION

A phased array transducer is composed of many elements arranged in a certain pattern that emit acoustic energy at different times. The elements can be pulsed in certain sequence to control the beam angle, also known as the steering angle. During conventional ultrasonic nondestructive testing (NDT) experiments, one transducer mechanically moving from one point to the next or several transducers working simultaneously inspect an object. Mechanical movement of one transducer is a time-consuming operation and the use of multiple transducers is an expensive operation. On the other hand, one phased array transducer can scan an object relatively quickly because it can inspect a wide range by emitting acoustic energy in controlled directions. Thus efficient scanning is possible by phased-array transducers. Wooh and Shi (1999) and Azar and Wooh (1999a, b) experimentally studied the steering and focusing behavior of phased array transducers in concrete structures. In the present paper phased array transducers are semi-analytically modeled by the distributed point source method (DPSM). The DPSM is a semi-analytical technique used to model ultrasonic (or eddy current) transducers for computing pressure and velocity fields (or magnetic fields) generated by the transducers. Placko and Kundu (2001, 2003) first developed the method for ultrasonic transducer modeling. This technique has been used to model ultrasonic fields in homogeneous and nonhomogeneous fluids, and scattered fields generated by a solid scatterer of finite dimension placed in the fluid (Placko *et al.*, 2001, 2002, 2003). Inhomogeneous media composed of fluid

and solid materials with a fluid–solid interface have also been modeled by this technique (Lee *et al.*; 2002). Use of the DPSM for solving problems other than ultrasonic problems is discussed in Placko *et al.*, (2001). In the DPSM technique, the active part of the transducer surface is discretized into a finite number of small hemispherical surface areas. Point sources are placed at the centers of these hemispheres. Each point source acts as an active source of energy. For each point source, an analytical solution for the generated field can be obtained. The total ultrasonic field is computed by superimposing the solutions of all point sources.

In this research work, a phased array transducer is modeled using the DPSM to obtain the ultrasonic field in a homogeneous medium. For this purpose the transducer face is discretized and point sources are placed in every elemental area. The point sources are excited with a certain phase difference (or time lag) to enhance the dynamic focusing. Later, interaction between two phased array transducers placed in a homogeneous medium is studied. The results presented here compare the phased array transducer and conventional planar transducer generated ultrasonic beams in different directions. The results also show the importance of considering the interaction effect between two phased array transducers when the total field is computed. For computing a mathematically correct ultrasonic field, it should be kept in mind that a transducer not only acts as a generator of the ultrasonic energy but also as a scatterer of the energy generated by the other transducer. However, the scattering effect is found to be small in many cases considered in this paper.

II. THEORY

The distributed point source method can be used to compute the pressure field generated by an ultrasonic transducer

^{a)} Author to whom correspondence should be addressed. Electronic mail: tkundu@email.arizona.edu

FIG. 1. Four point sources distributed over a finite surface of an ultrasonic transducer.

of finite dimension, placed in a homogeneous or nonhomogeneous fluid (or fluid–solid) media, or in a fluid with a scatterer of finite dimension. The theory associated with this formulation is briefly described in the following. For more detailed description the readers are referred to Placko and Kundu (2003) and Ahmad *et al.* (2004).

A. Planar transducer modeling by the distributed of point source method (DPSM)

The basic principle of the DPSM for modeling of magnetic and ultrasonic sensors has been described in a number of earlier publications (Placko and Kundu, 2003). The active surface of the transducer is discretized into an array of point sources. Sources on the transducer surface are shown in Fig. 1. Each point source transmits a signal. The total signal is the superposition of the signals transmitted by all point sources. The pressure field generated by a plane source of finite dimension can be assumed to be the summation of the pressure fields generated by a number of point sources distributed over the surface of the finite source as shown in Fig. 1. The finite plane source can be, for example, the front face of a transducer as shown in the figure. The combined effect of a large number of point sources distributed on a plane surface is the vibration of the particles in the direction normal to the plane surface. Non-normal components of motion at a point on the surface, generated by neighboring source points, cancel each other.

B. Computation of an ultrasonic field in a homogeneous fluid using the distributed point source method

For a flat surface transducer, where all point sources are excited at the same time, the pressure field generated at a point \mathbf{x} (see Fig. 2) by the transducer can be obtained by integrating the spherical waves, as done in the conventional surface integral technique (Schmerr, 1998; Placko and Kundu, 2003),

$$p(\mathbf{x}) = \int_S B \frac{\exp(ik_f r)}{4\pi r} dS, \quad (1)$$

where B relates the source velocity and pressure and, thus, proportional to the source velocity amplitude, k_f is the wave number and r is the distance between the observation point \mathbf{x} and the source points distributed over the transducer face.

For a phased array transducer, the point sources are excited at different times. Let the strength of the m th point

FIG. 2. Velocity v_m at point \mathbf{x} due to the m th point source.

source be A_m , and it is excited at a time t_m . Then the pressure at a distance r_m from the point source is given by

$$p_m(r) = A_m \frac{\exp(ik_f r_m - i\omega t_m)}{r_m}, \quad (2)$$

where ω is the angular frequency. For the phased array transducer, the point sources on the surface are assumed to be excited after different time intervals Δt_m ; in Eq. (2) the term t_m can be expressed in terms of a time lag from a reference time t ,

$$t_m = t - \Delta t_m. \quad (3)$$

If there are N point sources distributed over the transducer surface, as shown in Fig. 2, then the total pressure at point \mathbf{x} is given by

$$\begin{aligned} p(\mathbf{x}) &= \sum_{m=1}^N p_m(r_m) \\ &= \sum_{m=1}^N A_m \frac{\exp(ik_f r_m - i\omega(t - \Delta t_m))}{r_m}, \end{aligned} \quad (4)$$

where r_m is the distance of the m th point source from point \mathbf{x} .

It should be noted here that Eq. (1) can be written in discrete summation form in the following manner:

$$p(\mathbf{x}) = \sum_{m=1}^N B_m \frac{\exp(ik_f r_m)}{4\pi r_m} \Delta S_m. \quad (5)$$

In Eq. (5) the time dependence $e^{-i\omega t}$ is implied. If Eq. (4) is specialized for the conventional or static transducer case where all elements are excited at the same phase, then Eq. (4) is simplified to

$$p(\mathbf{x}) = \sum_{m=1}^N A_m \frac{\exp(ik_f r_m)}{r_m}. \quad (6)$$

In Eq. (6) the time dependence $e^{-i\omega t}$ is implied. Comparing Eqs. (5) and (6) the relation between A_m and B_m can be obtained,

$$A_m = \frac{B_m \Delta S_m}{4\pi}. \quad (7)$$

The particle velocity in the radial direction, generated by the m th point source at a distance r , is given by

$$v_m(r) = \frac{A_m}{i\omega\rho} \frac{\partial}{\partial r} \left(\frac{\exp(ik_f r - i\omega(t - \Delta t_m))}{r} \right)$$

$$= \frac{A_m}{i\omega\rho} \left(\frac{ik_f \exp(ik_f r)}{r} - \frac{\exp(ik_f r)}{r^2} \right)$$

$$\times \exp(-i\omega(t - \Delta t_m)),$$

or

$$v_m(r) = \frac{A_m}{i\omega\rho} \frac{\exp(ik_f r)}{r} \left(ik_f - \frac{1}{r} \right)$$

$$\times \exp(-i\omega(t - \Delta t_m)). \quad (8)$$

After contributions of all N sources are added, the velocity components in the three orthogonal directions x_1 , x_2 , and x_3 (see Fig. 2) are obtained,

$$v_1(\mathbf{x}) = \sum_{m=1}^N v_{1m}(r_m) = \sum_{m=1}^N \frac{A_m}{i\omega\rho} \frac{x_{1m} \exp(ik_f r_m)}{r_m^2}$$

$$\times \left(ik_f - \frac{1}{r_m} \right) \exp(-i\omega(t - \Delta t_m)),$$

$$v_2(\mathbf{x}) = \sum_{m=1}^N v_{2m}(r_m) = \sum_{m=1}^N \frac{A_m}{i\omega\rho} \frac{x_{2m} \exp(ik_f r_m)}{r_m^2}$$

$$\times \left(ik_f - \frac{1}{r_m} \right) \exp(-i\omega(t - \Delta t_m)), \quad (9)$$

$$v_3(\mathbf{x}) = \sum_{m=1}^N v_{3m}(r_m) = \sum_{m=1}^N \frac{A_m}{i\omega\rho} \frac{x_{3m} \exp(ik_f r_m)}{r_m^2}$$

$$\times \left(ik_f - \frac{1}{r_m} \right) \exp(-i\omega(t - \Delta t_m)).$$

On the transducer surface $v_1=0$ and $v_2=0$ because the transducer surface vibrates with a nonzero velocity in the x_3 direction only. Note that for conventional transducers $v_3=v_0$ (the time dependence $e^{-i\omega t}$ is implied) and for phased array transducers $v_3=v_0 \exp\{-i\omega(t - \Delta t_m)\}$. If the observation point \mathbf{x} is placed on the transducer surface, then the three expressions of Eq. (9) should be equal to 0, 0, and v_0 (or $v_0 \exp\{-i\omega(t - \Delta t_m)\}$), respectively. Thus, from N points on the transducer surface, $3N$ equations are obtained. However, we have only N unknowns (A_1, A_2, \dots, A_N) in the above equation set. To obtain the same number of unknowns as equations the number of unknowns can be increased from N to $3N$ by replacing each point source by a triplet. In triplet modeling the single source of every sphere is replaced by three sources. Three point sources of each triplet are located at three vertices of an equilateral triangle and these triangles are oriented randomly on a plane at $x_3 = -r_s$. Random orientations of triplet sources are necessary to preserve the iso-

tropic material properties and prevent any preferential orientation. It should be noted that the triplet source modeling is not needed if only the v_3 component of displacement is equated to v_0 .

For viscous fluid and solid interface modeling all three velocity components should be matched across an interface, but that is not necessary for ideal or perfect fluid modeling. In this paper ideal fluids are considered and only the v_3 component of velocity is matched at the transducer–fluid interface. However, it was observed that the ultrasonic field computed by matching only the v_3 component of velocity was very close to the one obtained by matching all three velocity components, if the number of point sources considered in the triplet modeling and simple (or single) source modeling were kept same. In other words, N triplet sources (consisting of $3N$ point sources) generate an ultrasonic field that is very close to the one produced by $3N$ simple point sources. Since the total number of point sources used in the DPSM modeling controls the computation time, both triplet and simple point source modeling takes almost the same amount of computer time for a similar degree of accuracy in computation.

The point sources are placed at $x_3 = -r_s$ to guarantee a nonvanishing denominator in Eq. (9). Note that if the point sources are placed on the transducer surface, then for some observation points on the transducer surface the distance (r_m) between the m th source and the observation point may vanish, giving rise to the numerical error (division by zero) while computing the velocity components using Eq. (9). For this reason point sources are placed at $x_3 = -r_s$, slightly behind the transducer face at $x_3 = 0$. The length r_s is obtained by equating the total hemi-spherical surface area ($2\pi N r_s^2$) of N hemispheres of radius r_s to the front surface area (A) of the transducer. Note that N is the number of point sources used to model the transducer face.

After solving the system of $3N$ linear equations (for triplet sources) or a system of N linear equations (for simple point sources obtained by equating only v_3 to v_0 or $v_0 \exp\{-i\omega(t - \Delta t_m)\}$) the source strengths A_m associated with all point sources are obtained. After evaluating A_m , the pressure $p(\mathbf{x})$ can be calculated at any point (on the transducer surface or away) from Eq. (4).

C. Matrix formulation

Equation (9) can be written in the form of a matrix equation,

$$\mathbf{V}_S = \mathbf{M}_{SS} \mathbf{A}_S, \quad (10)$$

where \mathbf{V}_S is the $(3N \times 1)$ vector of the velocity components at N number of surface points and \mathbf{A}_S is the $(3N \times 1)$ vector containing the strengths of $3N$ point sources. \mathbf{M}_{SS} is the $(3N \times 3N)$ matrix relating the two vectors \mathbf{V}_S and \mathbf{A}_S , where

$$\{\mathbf{V}_S\}^T = [v_1^1 \quad v_2^1 \quad v_3^1 \quad v_1^2 \quad v_2^2 \quad v_3^2 \quad \cdots \quad v_1^N \quad v_2^N \quad v_3^N], \quad (11)$$

$$\{\mathbf{A}_S\}^T = [A_1 \quad A_2 \quad A_3 \quad A_4 \quad A_5 \quad A_6 \quad \cdots \quad A_{3N-2} \quad A_{3N-1} \quad A_{3N}], \quad (12)$$

and

$$\mathbf{M}_{SS} = \begin{bmatrix} f(x_{11}^1, r_1^1) & f(x_{12}^1, r_2^1) & f(x_{13}^1, r_3^1) & \dots & \dots & f(x_{1(3N-1)}^1, r_{3N-1}^1) & f(x_{1(3N)}^1, r_{3N}^1) \\ f(x_{21}^1, r_1^1) & f(x_{22}^1, r_2^1) & f(x_{23}^1, r_3^1) & \dots & \dots & f(x_{2(3N-1)}^1, r_{3N-1}^1) & f(x_{2(3N)}^1, r_{3N}^1) \\ f(x_{31}^1, r_1^1) & f(x_{32}^1, r_2^1) & f(x_{33}^1, r_3^1) & \dots & \dots & f(x_{3(3N-1)}^1, r_{3N-1}^1) & f(x_{3(3N)}^1, r_{3N}^1) \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ f(x_{31}^N, r_1^N) & f(x_{32}^N, r_2^N) & f(x_{33}^N, r_3^N) & \dots & \dots & f(x_{3(3N-1)}^N, r_{3N-1}^N) & f(x_{3(3N)}^N, r_{3N}^N) \end{bmatrix}_{3N \times 3N}, \quad (13)$$

where

$$f(x_{jm}^n, r_m^n) = \frac{x_{jm}^n \exp(ik_f r_m^n)}{i\omega\rho(r_m^n)^2} \left(ik_f - \frac{1}{r_m^n} \right) \times \exp(-i\omega(t - \Delta t_m^n)). \quad (14)$$

In Eq. (14), the first subscript j of x can take value 1, 2, or 3 and indicate whether x is measured in the x_1 , x_2 , or x_3 direction. The subscript m of x and r can take values from 1 to $3N$ depending on which point source is considered and the superscript n can take any value between 1 and N corresponding to the point on the transducer surface where the velocity component is computed. In this formulation for $3N$ point sources, three boundary conditions on the velocity are satisfied at every point of the N boundary points.

Source strength vectors can be obtained as

$$\mathbf{A}_S = [\mathbf{M}_{SS}]^{-1} \mathbf{V}_S = \mathbf{N}_{SS} \mathbf{V}_S. \quad (15)$$

The pressure \mathbf{P}_T and velocity vector \mathbf{V}_T at any given number (M) of points $\{\mathbf{x}\}$ on a target surface can be simultaneously obtained by

$$\begin{aligned} \mathbf{P}_T &= \mathbf{Q}_{TS} \mathbf{A}_S, \\ \mathbf{V}_T &= \mathbf{M}_{TS} \mathbf{A}_S. \end{aligned} \quad (16)$$

Matrix \mathbf{M}_{TS} is same as \mathbf{M}_{SS} of Eq. (13) when the target points or reference points are identical to the transducer surface points where the velocity components are matched to obtain the point source strength vector \mathbf{A}_S in Eq. (15). Matrix \mathbf{Q}_{TS} is obtained as

$$\mathbf{Q}_{TS} = \begin{bmatrix} \frac{\exp(ik_f r_1^1 - i\omega(t - \Delta t_1^1))}{r_1^1} & \frac{\exp(ik_f r_2^1 - i\omega(t - \Delta t_2^1))}{r_2^1} & \dots & \dots & \frac{\exp(ik_f r_{3N}^1 - i\omega(t - \Delta t_{3N}^1))}{r_{3N}^1} \\ \frac{\exp(ik_f r_1^2 - i\omega(t - \Delta t_1^2))}{r_1^2} & \frac{\exp(ik_f r_2^2 - i\omega(t - \Delta t_2^2))}{r_2^2} & \dots & \dots & \frac{\exp(ik_f r_{3N}^2 - i\omega(t - \Delta t_{3N}^2))}{r_{3N}^2} \\ \frac{\exp(ik_f r_1^3 - i\omega(t - \Delta t_1^3))}{r_1^3} & \frac{\exp(ik_f r_2^3 - i\omega(t - \Delta t_2^3))}{r_2^3} & \dots & \dots & \frac{\exp(ik_f r_{3N}^3 - i\omega(t - \Delta t_{3N}^3))}{r_{3N}^3} \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \frac{\exp(ik_f r_1^{N_T} - i\omega(t - \Delta t_1^{N_T}))}{r_1^{N_T}} & \frac{\exp(ik_f r_2^{N_T} - i\omega(t - \Delta t_2^{N_T}))}{r_2^{N_T}} & \dots & \dots & \frac{\exp(ik_f r_{3N}^{N_T} - i\omega(t - \Delta t_{3N}^{N_T}))}{r_{3N}^{N_T}} \end{bmatrix}_{M \times 3N}. \quad (17)$$

Replacing \mathbf{A}_S by $[\mathbf{M}_{SS}]^{-1} \mathbf{V}_S$ in Eq. (16) we get

$$\begin{aligned} \mathbf{P}_T &= \mathbf{Q}_{TS} [\mathbf{M}_{SS}]^{-1} \mathbf{V}_S, \\ \mathbf{V}_T &= \mathbf{M}_{TS} [\mathbf{M}_{SS}]^{-1} \mathbf{V}_S. \end{aligned} \quad (18)$$

D. Pressure field in a homogeneous fluid

Following the DPSM technique described above, the ultrasonic field in a homogeneous fluid (water) generated by a flat circular transducer is computed. For such simple problem geometry the expression of the near field zone length and the divergence angle of the emitted beam can be calculated in closed form (Kundu, 2000). Numerically computed values of

these two parameters are compared with the closed form analytical values to check the accuracy of the numerical results.

From Kundu 2000,

$$N_F = \frac{D^2 - \lambda^2}{4\lambda} \approx \frac{D^2}{4\lambda} \quad \text{for } \lambda \ll D \quad (19a)$$

and

$$\phi = 2 \sin^{-1} \left(1.2 \frac{\lambda}{D} \right), \quad (19b)$$

where N_F is the near field length the distance between the transducer face and the last peak of the pressure field along

FIG. 3. Acoustic pressure variation along the central axis (Z -axis) of a circular transducer. Coordinate Z is measured from the transducer face. The transducer diameter (D)=2.528 mm, signal frequency (f)=5 MHz. Solid and dashed lines are generated by the DPSM technique and the analytical formula [Eq. (20)], respectively. Near field zone (N_F) predicted by Eq. (19a) matches with the last peak of the curve.

the x_3 (or Z) axis. D is the transducer diameter; λ is the wavelength of the ultrasonic signal, and ϕ is the divergence angle.

The analytical expression of the pressure in a homogeneous fluid along the central axis of a circular transducer is (Placko and Kundu, 2003)

$$p(x_3) = \rho c_f v_0 [\exp(ik_f x_3) - \exp(ik_f \sqrt{x_3^2 + a^2})] \quad (20)$$

Figure 3 shows acoustic pressure variations along the central axis (Z axis) of a circular transducer computed by the DPSM technique described above (solid curve) and the analytical expression [Eq. (20), dashed curve]. Coordinate Z is measured from the transducer face. The transducer area is 2.24 mm², its diameter (D)=2.528 mm, and signal frequency (f)=5 MHz. For the DPSM modeling 128 sources

FIG. 4. Ultrasonic field generated by a 6-mm-diam circular transducer excited at 2.2 MHz frequency, following DPSM technique (from Nasser, 2004).

FIG. 5. Focal point P for a phased array transducer. V_p and H_p denote the position of point P relative to the transducer surface.

are placed at $x_3 = -r_s$, while the transducer face is at $x_3 = 0$. For this problem geometry

$$r_s = \sqrt{\frac{\pi D^2}{4 \times 2 \pi N}} = \frac{D}{\sqrt{8N}} = \frac{2.528}{\sqrt{8 \times 128}} = 0.08 \text{ mm.}$$

Since the wave speed in the surrounding fluid (water) is 1.49 km/s, wavelength λ is equal to 0.298 mm for the 5-MHz signal. From Eq. (19a) N_F is found to be 5.3 mm. This theoretical value of N_F matched very well with the last peak. The matching between the DPSM computed curve and the analytical solution in Fig. 3 is also excellent.

Figure 4 shows acoustic pressure in front of a transducer with diameter $D=6$ mm and $f=2.2$ MHz, obtained by the DPSM technique with $N=200$. The theoretical divergence angle ϕ for this transducer is 15.6°, calculated from Eq. (19b). The divergence angle in Fig. 4 is measured and found to be about 15°, very close to the theoretical prediction. These two checks—Figs. 3 and 4—validate the DPSM computed results.

The only restriction of this technique for guaranteeing accurate computation is that the distance between the neighboring point sources should be less than the wavelength of the ultrasonic signal (Placko and Kundu, 2003).

FIG. 6. Point P can receive two rays, direct ray 1 and reflected ray 2, from a single point source y_m .

E. Dynamic focusing and time lag determination

The main purpose of the phased array transducer is to be able to steer the beam and focus it at any point of interest by accurately controlling the time delay of excitation of the point sources. Figure 5 shows how the time delay can be determined for a desired direction of the transmitted beam.

The time lag Δt_n can be obtained from the following equation, so that all signals arrive at point P at the same time:

$$\Delta t_n = \frac{\Delta p}{c} = \frac{P_n - P_{n-1}}{c}, \quad (21)$$

where c is the velocity of the pressure wave in the medium, and P_n and P_{n-1} are the distances of the n th and $(n-1)$ th point sources, respectively, from point P . If the distance between two consecutive point sources is dx , then P_n and P_{n-1} can be expressed as

$$\begin{aligned} P_n &= \sqrt{V_p^2 + [H_p + (n-1)dx]^2} \quad \text{and} \\ P_{n-1} &= \sqrt{V_p^2 + [H_p + (n-2)dx]^2}, \end{aligned} \quad (22)$$

where V_p and H_p are vertical and horizontal distances, respectively, of point P from one edge of the transducer face as shown in Fig. 5.

Note that the selection of the focal point automatically determines the steering direction; thus both the focal point and the steering direction are determined in this manner.

F. Modeling of the ultrasonic field in a homogeneous fluid in the presence of a solid scatterer

When a solid scatterer is placed in front of a transducer in a homogeneous fluid, the ultrasonic field can be computed using the DPSM, by placing point sources both along the transducer surface and along the fluid–solid interface of the solid scatterer. The acoustic field in the fluid is computed by superimposing the contributions of two layers of point sources distributed over the transducer face and the scatterer face as shown in Fig. 6. Two layers of sources are located at a small distance, r_s , away from the transducer face and interface, respectively, such that the apex of every sphere (of radius r_s) touches the transducer face or the fluid–solid interface, as shown in the figure.

Strength of the point sources distributed along the transducer surface can be obtained from Eq. (15) and from the specified boundary conditions at the fluid–solid interface.

For finding the strength of the point sources attached to the interface, velocity components at the interface due to the reflected waves at the interface are to be matched, as described below.

Velocity components at M interface points due to ray 1 only (ignoring reflection) can be easily obtained from the N triplet sources in the following manner [Eq. (16)]:

$$\mathbf{V}_T^i = \mathbf{M}_{TS}^i \mathbf{A}_S, \quad (23)$$

where \mathbf{V}_T^i is the velocity vector at the interface points (\mathbf{x}_n) due to the incident beam only, \mathbf{A}_S is the vector of the point source strengths on the transducer surface. \mathbf{M}_{TS}^i is the matrix that relates the two vectors \mathbf{V}_T^i and \mathbf{A}_S , and the components of \mathbf{M}_{TS}^i are similar to the components of \mathbf{M}_{SS} , the only difference is in the dimensions of the two matrices when the number of point sources at the transducer surface and the interface are different.

For computing the source strength at the interface, the velocity due to the reflected field at the interface (generated by the point sources at the transducer face) and the velocity due to the direct incident field produced by the point sources at the interface are equated. Note that

$$\mathbf{V}_T^r = \mathbf{M}_{TS}^r \mathbf{A}_S \quad (24)$$

is the velocity due to the reflected beam only (ray 2 of Fig. 6). \mathbf{M}_{TS}^r is the $(M \times N)$ [or $(3M \times 3N)$ if all three velocity components are matched] matrix that relates the two vectors \mathbf{V}_T^r and \mathbf{A}_S of Eq. (24). Note that components of \mathbf{M}_{TS}^r can be obtained by multiplying \mathbf{M}_{TS}^i by the appropriate reflection coefficient (Placko and Kundu, 2003).

The velocity field at the same point generated by the interface point sources is obtained from the following equation,

$$\mathbf{V}_T^r = \mathbf{M}_{TI}^i \mathbf{A}_I, \quad (25)$$

where \mathbf{V}_T^r is the $(M \times 1)$ or $[(3M \times 1)]$ vector, same as that in Eq. (24). \mathbf{A}_I is the $(M \times 1)$ or $[(3M \times 1)]$ vector of the strength of interface sources; this vector is unknown. \mathbf{M}_{TI}^i is the $(M \times M)$ or $[(3M \times 3M)]$ matrix that relates the two vectors \mathbf{V}_T^r and \mathbf{A}_I . Components of \mathbf{M}_{TI}^i are computed using similar mathematical formulation as those for \mathbf{M}_{SS} in Eq. (13). However, there are some differences between \mathbf{M}_{SS} and \mathbf{M}_{TI}^i —their dimensions are different and the time delay factor is absent in \mathbf{M}_{TI}^i ,

$$\mathbf{M}_{TI}^i = \begin{bmatrix} f(x_{11}^1, r_1^1) & f(x_{12}^1, r_2^1) & f(x_{13}^1, r_3^1) & \cdots & \cdots & f(x_{1(L-1)}^1, r_{L-1}^1) & f(x_{1L}^1, r_L^1) \\ f(x_{21}^1, r_1^1) & f(x_{22}^1, r_2^1) & f(x_{23}^1, r_3^1) & \cdots & \cdots & f(x_{2(L-1)}^1, r_{L-1}^1) & f(x_{2L}^1, r_L^1) \\ f(x_{31}^1, r_1^1) & f(x_{32}^1, r_2^1) & f(x_{33}^1, r_3^1) & \cdots & \cdots & f(x_{3(L-1)}^1, r_{L-1}^1) & f(x_{3L}^1, r_L^1) \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ f(x_{31}^M, r_1^M) & f(x_{32}^M, r_2^M) & f(x_{33}^M, r_3^M) & \cdots & \cdots & f(x_{3(L-1)}^M, r_{L-1}^M) & f(x_{3L}^M, r_L^M) \end{bmatrix}_{L \times L}, \quad (26)$$

FIG. 7. Modeling of multiple transducers placed in a homogeneous fluid.

where $L=M$ (or $3M$) for matching only one component (or three components) of velocity across the interface,

$$f(x_{jm}^n, r_m^n) = \frac{x_{jm}^n \exp(ik_f r_m^n)}{i\omega\rho(r_m^n)^2} \left(ik_f - \frac{1}{r_m^n} \right). \quad (27)$$

Since \mathbf{A}_I of Eq. (25) is unknown, \mathbf{A}_I is solved in the following manner:

$$\mathbf{A}_I = [\mathbf{M}_{TI}^i]^{-1} \mathbf{V}_T^r = ([\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r) \mathbf{A}_S. \quad (28)$$

The above equation gives the source strength vector at the interface in terms of the source strengths at the transducer face.

The velocity vector on the transducer surface, generated only by the point sources distributed over the transducer face, can be obtained from Eq. (23):

$$\mathbf{V}_S^i = \mathbf{M}_{SS}^i \mathbf{A}_S. \quad (29)$$

FIG. 8. (a) A phased array transducer with a steering angle θ and (b) a regular transducer rotated at an angle θ .

\mathbf{V}_S^i is the $(N \times 1)$ [or $(3N \times 1)$] vector of the velocity components at the transducer surface. At this step, \mathbf{A}_S is the unknown $(N \times 1)$ [or $(3N \times 1)$] vector of the point source strengths distributed over the transducer face and \mathbf{M}_{SS}^i is the $(N \times N)$ [or $(3N \times 3N)$] matrix, identical to the matrix \mathbf{M}_{SS} , defined in Eq. (13).

In the same manner, velocity components on the transducer surface, only due to the interface sources are obtained,

$$\mathbf{V}_S^r = \mathbf{M}_{SI}^i \mathbf{A}_I. \quad (30)$$

The above equation is derived from Eq. (25), after placing the target points on the transducer surface. Here, \mathbf{V}_S^r is a $(N \times 1)$ [or $(3N \times 1)$] vector of the velocity components at N points on the transducer surface, \mathbf{A}_I is the unknown $(M \times 1)$ [or $(3M \times 1)$] vector of the interface source strengths and \mathbf{M}_{SI}^i is the $(N \times M)$ [or $(3N \times 3M)$] matrix, similar to the one given in Eq. (13).

Adding Eqs. (29) and (30), the total velocity at the transducer surface is obtained:

$$\mathbf{V}_S = \mathbf{V}_S^i + \mathbf{V}_S^r = \mathbf{M}_{SS}^i \mathbf{A}_S + \mathbf{M}_{SI}^i \mathbf{A}_I. \quad (31)$$

Substituting Eqs. (24) and (25) into Eq. (31):

$$\begin{aligned} \mathbf{V}_S &= \mathbf{M}_{SS}^i \mathbf{A}_S + \mathbf{M}_{SI}^i \mathbf{A}_I \\ &= \mathbf{M}_{SS}^i \mathbf{A}_S + \mathbf{M}_{SI}^i [\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r \mathbf{A}_S \Rightarrow \mathbf{V}_S \\ &= [\mathbf{M}_{SS}^i + \mathbf{M}_{SI}^i [\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r] \mathbf{A}_S, \end{aligned} \quad (32)$$

or,

FIG. 9. Ultrasonic pressure fields for a phased array transducer for steering angles equal to (a) 0°, (b) 10°, (c) 30° and (d) 45°.

$$\mathbf{A}_S = [\mathbf{M}_{SS}^i + \mathbf{M}_{SI}^i [\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r]^{-1} \mathbf{V}_S, \quad (33)$$

where

$$\mathbf{V}_S = [0 \ 0 \ v_0 \ 0 \ 0 \ v_0 \ 0 \ 0 \ v_0]^T. \quad (34)$$

Note that v_0 is the value of v_3 (x_3 component of velocity) on the transducer surface. This choice for \mathbf{V}_S reflects the fact that the vibration produced by a piezoelectric transducer has only normal velocity components on its active surface.

After obtaining \mathbf{A}_S , the pressure field at any point between the transducer and the scatterer can be computed in the following manner:

$$\begin{aligned} \mathbf{P}_T &= \mathbf{P}_S^i + \mathbf{P}_I^i, \\ \mathbf{P}_S^i &= \mathbf{Q}_{TS}^i \mathbf{A}_S = \mathbf{Q}_{TS}^i [\mathbf{M}_{SS}^i + \mathbf{M}_{SI}^i [\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r]^{-1} \mathbf{V}_S, \end{aligned} \quad (35)$$

TABLE I. Water and steel properties.

Material and properties	P-wave speed (km/s)	S-wave speed (km/s)	Density (gm/cc)
Steel	5.96	3.26	7.932
Water	1.49	...	1

$$\begin{aligned} \mathbf{P}_I^i &= \mathbf{Q}_{TI}^i \mathbf{A}_I = \mathbf{Q}_{TI}^i [[\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r] \mathbf{A}_S \\ &= \mathbf{Q}_{TI}^i [[\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r] [\mathbf{M}_{SS}^i + \mathbf{M}_{SI}^i [\mathbf{M}_{TI}^i]^{-1} \mathbf{M}_{TS}^r]^{-1} \mathbf{V}_S. \end{aligned}$$

G. Interaction between two transducers in a homogeneous fluid

When two transducers are placed in a homogeneous fluid, the ultrasonic field can be modeled by superimposing two simpler problems as shown in Fig. 7. Fields due to these two simpler problems can be added to obtain the total ultrasonic field at any point x_n . Note that each transducer face will act as the source of energy as well as a reflecting surface. For simplicity we will call one of the transducers as the left side transducer and the second one as the right side transducer (see Fig. 7).

As shown in Fig. 7, the original problem is decomposed into two problems—in one problem, the right transducer is replaced by an imaginary scatterer and, in the second problem, the left transducer is replaced by the imaginary scattering surface (see the bottom two figures of Fig. 7). For the first problem (the left figure), the ultrasonic field at a point \mathbf{x}_n is the combined effect of the ultrasonic rays coming from the left side transducer face and the imaginary scatterer on the right side. For the second problem (the right figure) the

FIG. 10. Ultrasonic pressure fields for a conventional planar transducer for rotation angles equal to (a) 0° , (b) 10° , (c) 30° and (d) 45° .

acoustic field at point \mathbf{x}_n is the combined effect of the right side transducer and the imaginary scatterer on the left side.

For both problems the transducer and the scatterer surfaces are modeled as distributed point sources. The total ultrasonic field at point \mathbf{x}_n generated by the two transducers is then obtained by superimposing the two solutions. In mathematical notations, the modeling steps described above can be written as

$$\begin{aligned}
 \mathbf{P}_{left} &= \mathbf{P}_{S(left)}^i + \mathbf{P}_{I(right\ scatterer)}^i, \\
 \mathbf{P}_{right} &= \mathbf{P}_{S(right)}^i + \mathbf{P}_{I(left\ scatterer)}^i, \\
 \mathbf{P}_{Total} &= \mathbf{P}_{left} + \mathbf{P}_{right},
 \end{aligned} \tag{36}$$

where \mathbf{P}_{left} and \mathbf{P}_{right} are the pressure fields generated by problems 1 and 2, respectively. \mathbf{P}_S^i and \mathbf{P}_I^i are obtained from Eq. (35). \mathbf{P}_{Total} is the combined effect for the two transducers. Note that \mathbf{P}_I^i takes into account the interaction effect. If the ultrasonic fields generated by the two transducers are simply added without taking into account the interaction (or scattering) effect of one transducer on the other, then \mathbf{P}_I^i will not appear in the formulation.

III. NUMERICAL RESULTS AND DISCUSSION

The main objective of this paper is to model a phased array transducer with dynamic focusing using the distributed point source method (DPSM). The first part of this research work involves the modeling of the time-dependent excitation of point sources in a phased array transducer. The second part focuses on studying the interaction effect when two phased array transducers are placed, face to face, in a homogeneous fluid (water) medium. Phased array transducers provide dynamic capabilities compared to the conventional static transducers. For conventional transducers the transducer surfaces are rotated to achieve the desired steering angle (see Fig. 8). In a phased array transducer, the transducer surface does not have to be rotated or translated (moved). For a phased array transducer, different segments of the transducer are activated at different time intervals. In the DPSM modeling technique individual point sources are excited at a predetermined time interval. MATLAB codes, based on the DPSM, have been developed to introduce the time-dependent excitation of the point sources.

A. Dynamic steering and focusing

As mentioned earlier, in a phased array transducer, dynamic steering and focusing can be achieved by suitably se-

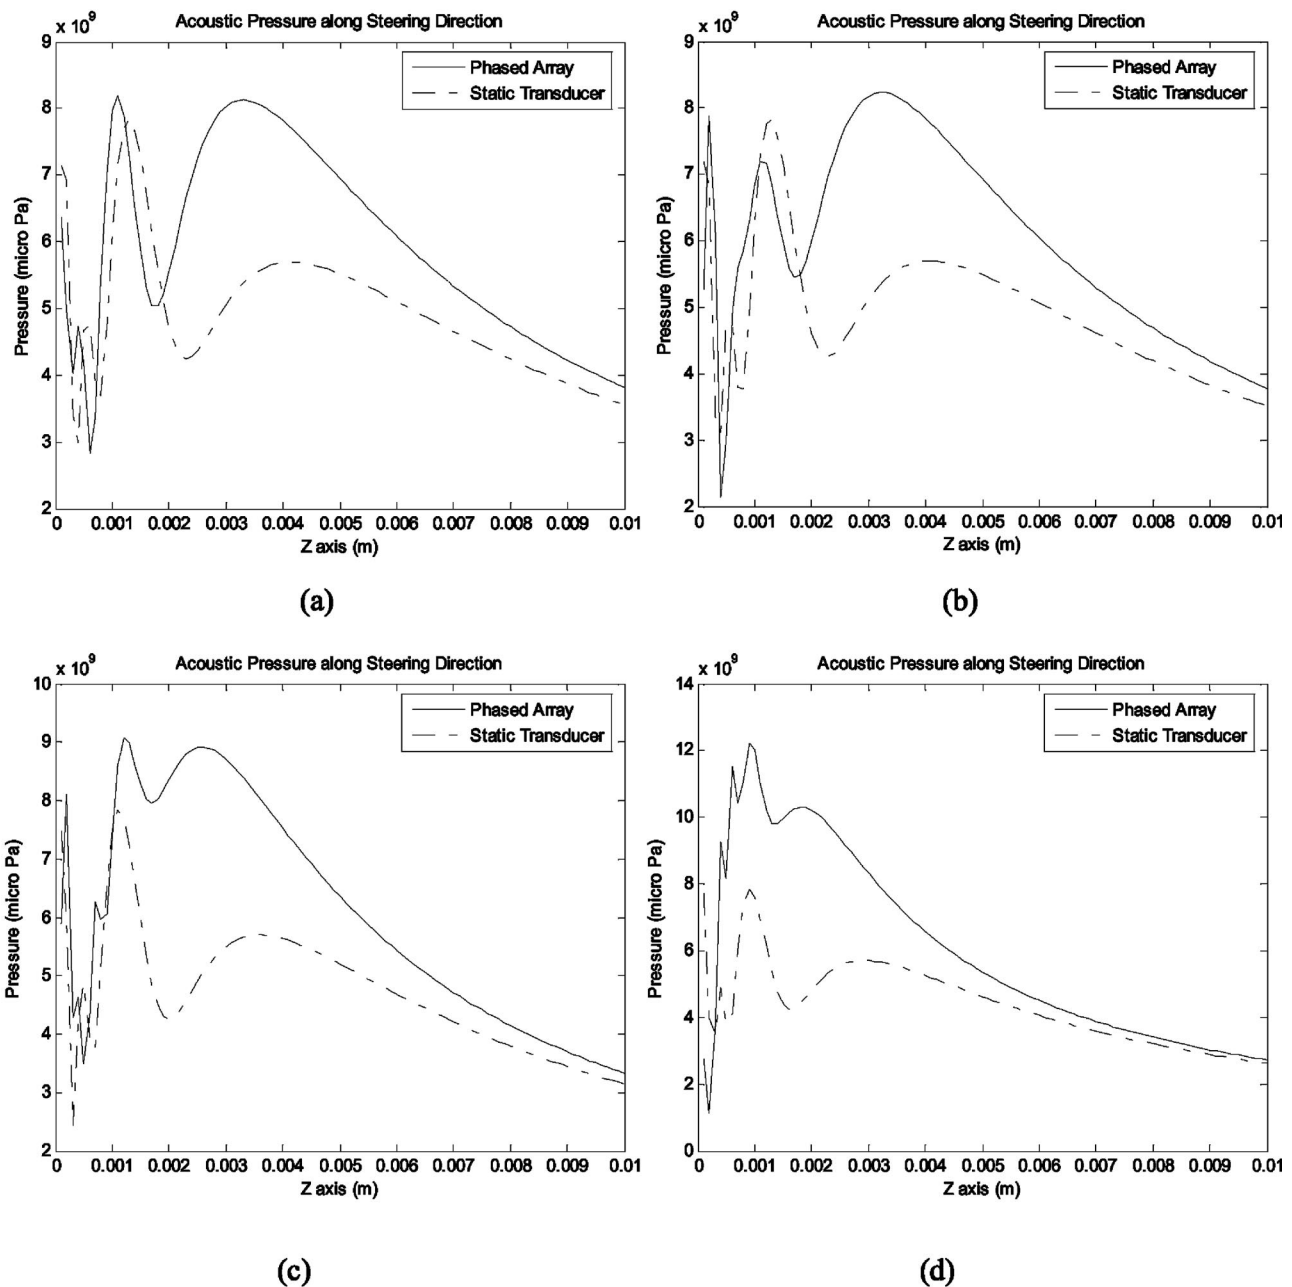

FIG. 11. Comparison of acoustic pressures along the steering directions generated by the phased array transducer and the conventional static transducer for steering angles equal to (a) 0° , (b) 10° , (c) 30° and (d) 45° . The pressure values are proportional to the transducer surface velocity amplitude v_0 and can be easily changed by simply altering v_0 . For this reason the absolute values of the plotted pressure are not very important; however, the variation of the pressure, which is independent of the transducer surface velocity amplitude, is important.

lecting the time phase and point of focus as described in Sec. II E. In the first investigation, we modeled a phased array transducer that produces ultrasonic beams at angles $\sim 0^\circ$, 10° , 30° and 45° . Figure 9 shows the pressure fields generated by a rectangular phased array transducer in a homogeneous fluid (water). The area of the transducer surface is 2.5 mm^2 and its length to width ratio is 2:1. The outermost layer of the transducer is taken as steel. The acoustic properties of steel and water are given in Table I. We will use the term “steering angle” for the angle that the ultrasonic beam makes with the normal direction to the transducer face. The excitation frequency is 5 MHz.

The purpose of this investigation is to compare the ultrasonic fields generated by phased array transducers and

conventional planar transducers rotated at different steering angles. Figures 9(a)–(d), show the acoustic pressure fields generated by a phased array transducer for steering angles equal to $\sim 0^\circ$, 10° , 30° and 45° , respectively. Note that the scales in x and y directions are different. Figures 10(a)–(d), show the acoustic pressures generated by a conventional planar transducer when the axis of the transducer surface is rotated by 0° , 10° , 30° and 45° angles, respectively. In this paper phased array and conventional transducers are also called as dynamic and static transducers, respectively. For both these transducers, the surface area is equal to 2.5 mm^2 and the number of point sources is equal to 98. Fourteen rows of elements are distributed along the x direction representing 14 physical elements of the phased array transducer.

Each physical element is discretized into 7 point sources distributed along the y direction, giving rise to a total of 98 point sources. Note that the spacing between two neighboring point sources is smaller than the wavelength. Such small spacing is needed for right convergence of the solution (Placko and Kundu, 2003).

In Fig. 9, the normal distance of the focal point from the transducer face is set at 10 mm in the Z direction. The steering angles of 0° , 10° , 30° and 45° are achieved by changing the horizontal distance of the focus point, keeping the normal distance fixed at 10 mm. Figures 9(a) and 10(a) are pressure fields generated by the phased array and conventional static transducers for a steering angle of 0° . From these figures, it can be seen that the maximum pressure intensities are 8.2×10^9 and 7.6×10^9 units for phased array and static transducers, respectively. In the figures, it is also observed that the pressure beam produced by the phased array transducer is narrower or more collimated than that produced by the conventional static transducer. Similar conclusions are drawn from Figs. 9(b) and 10(b) for 10° steering angle, Figs. 9(c) and 10(c) for 30° steering angle and Figs. 9(d) with 10(d) for 45° steering angle. Such observation is expected because the phased array transducer is focused at a finite distance while the conventional planar transducer is focused at infinity.

Figures 11(a)–(d), plot the pressure fields along the steering directions for both phased array and conventional transducers for 0° , 10° , 30° and 45° inclination angles, respectively. These figures show that near the transducer face, the pressure intensity for the two cases are somewhat close, but beyond this near field region the pressure difference between these two types of transducers is much greater. The phased array transducer produces stronger pressure beams than the static transducer in the region between the focal point ($Z = 10$ mm) and the near field distance N_F .

B. Interaction between two phased array transducers placed face to face

In the second investigation, the interaction effect between two phased array transducers placed in a homogeneous medium is studied. The transducer faces are placed parallel to each other as shown in Fig. 12. The central axes of the transducers are collinear. The surrounding medium is water. The direct field generated by the first transducer as well as the scattered field from the second transducer is calculated. Note that each transducer surface is modeled as the energy-generating surface as well as the scattering surface or the reflecting surface for the ultrasonic field generated by the other transducer.

The steering angle for the phased array transducer is varied to study the interaction effect as a function of the steering angle. We studied the interaction of the transducers for three different steering angles. For the first case, the steering angle is very small ($\theta \approx 0^\circ$). For the second and third cases the steering angle is increased to 10° and 30° , respectively. The reason for the incident angle to be close to 0° but not exactly equal to 0° is that during the discretization process of the transducer face the point source placements have some randomness. Thus for the 0° case all point sources are not necessarily placed in perfect symmetry with

FIG. 12. Steering direction for two transducers.

respect to the transducer axis going through the focal point. Therefore, the field generated for the 0° case is not necessarily perfectly symmetric about the central axis of the transducer. Three different steering angles (θ) are analyzed because when θ is small (close to 0°), the bulk of the incident pressure beam hits the surface of the second transducer face. For 10° steering angle, a part of the beam hits the opposite transducer and, for 30° steering angle, the bulk of the incident beam travels through the fluid medium without hitting the second transducer. We compared the acoustic pressure fields generated by the phased array transducers when the interaction or the scattering effect of the second transducer is ignored and when it is included. Figures 13(a) and (b) show the pressure fields generated by the phased array transducers for a small steering angle ($\theta \approx 0^\circ$) when the interaction effect is ignored. Figures 14(a) and (b) plot the acoustic pressures generated by the same transducers when the interaction effect is included. Let us state here again what we mean by the interaction effect being ignored and included. The acoustic pressure field in Fig. 13(a) is generated by the bottom transducer when the top transducer is absent. In other words, in Fig. 13(a) the ultrasonic waves generated by the bottom transducer propagate freely without being interrupted or scattered by the top transducer. The top transducer generates a similar beam that is simply a mirror image of the bottom transducer generated beam and is not shown here. Figure 13(b) is the superposition of uninterrupted fields generated by the bottom transducer [Fig. 13(a)] and the top transducer (not shown).

On the other hand, Figs. 14(a) and (b) show the pressure fields obtained after considering the interaction effect. Figure 14(a) shows the pressure field generated by the bottom transducer when the top transducer, placed at a distance of 10 mm, acts as a scatterer, in this case mostly as a reflector. The pressure beam generated by the bottom transducer is partly

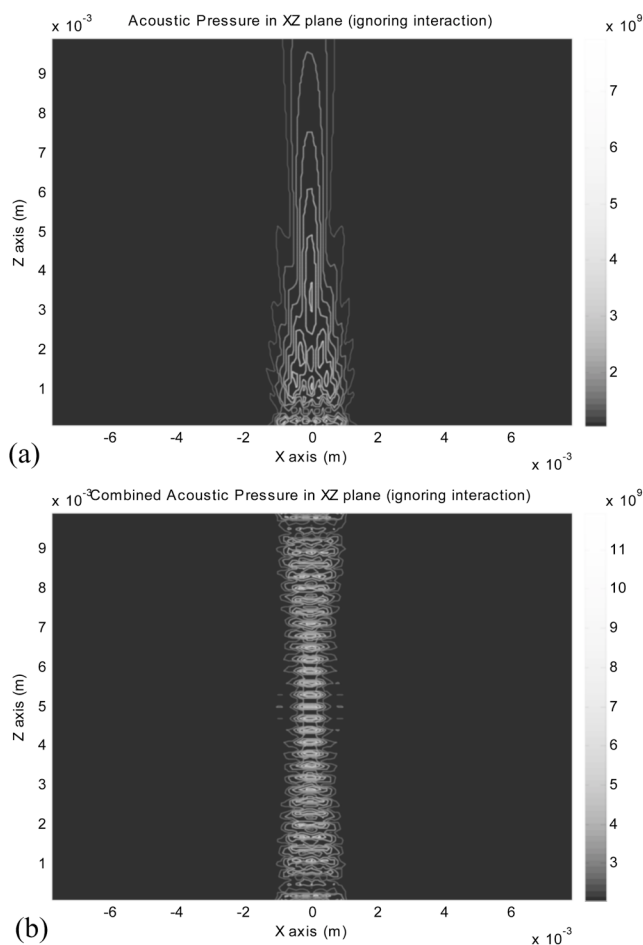

FIG. 13. Acoustic pressure in the XZ (or x_1x_3) plane for phased array transducers when the interaction effect is ignored. Transducers are placed at a distance of 10 mm. (a) shows pressure fields generated by the bottom transducer in the absence of the top transducer when the steering angle is 0° . (b) shows the total field, obtained by adding two fields generated by the bottom transducer [shown in (a)] and the top transducer [a mirror image of (a)].

reflected or scattered by the top transducer and thus affects the total pressure field in the homogeneous medium. It should be mentioned here that for Fig. 14(a) the top transducer surface acts only as a scatterer and not as a wave generator. The top transducer generates a similar beam that is simply a mirror image of the bottom transducer generated beam and is not shown here. Figure 14(b) is the superposition of the field shown in Fig. 14(a) and a similar field (simply a mirror image) generated by the top transducer. The steering angle is $\sim 0^\circ$ for both Figs. 13 and 14.

In Fig. 14(a), the interaction effect (due to the reflection at the top transducer surface) can be clearly seen. In this figure the interference between the direct incident ultrasonic beam from the bottom transducer and the reflected beam from the top transducer causes alternate peaks and dips in the pressure field whereas, in Fig. 13(a), no such peaks and dips are observed. The difference between Figs. 13(b) and 14(b) is comparatively less prominent; however, one can see from these two figures that in the central region, near $z = 5$ mm, the beam in Fig. 14(b) is slightly wider than that in Fig. 13(b).

FIG. 14. Acoustic pressure in the XZ (or x_1x_3) plane for phased array transducers when the interaction effect is considered. Transducers are placed at a distance of 10 mm. (a) shows pressure fields generated by the bottom transducer when the top transducer acts as a scatterer or reflector, for 0° steering angle. (b) shows the total field, obtained by adding two fields generated by the bottom transducer [shown in (a)] and the top transducer [a mirror image of (a)].

In Fig. 15(a) the pressure variations along the steering direction are plotted for both cases, i.e., when the interaction effect is considered and when it is ignored. In Fig. 15(a), the two lines almost coincide. When the difference between the two pressure fields is plotted one can see in Fig. 15(b) that the difference is more prominent near the transducer faces. Figure 15(c) shows the pressure difference as a percentage of the total pressure plotted as a function of the distance from the transducer surface. Note that the maximum difference between the two pressure fields is about 4% within 1 mm of the transducer face and it is less than 0.5% when the distance from the transducer face is greater than 2.5 mm. The reason for the pressure difference being higher near the transducer face is that the reflected pressure produced by the second transducer is relatively stronger near the reflecting surface and it becomes weaker as the distance from the reflecting surface increases.

Figure 16 shows the pressure field when the steering angle is 10° and the interaction effect is considered. Figure 16(a) plots the pressure field generated by the bottom transducer and then scattered by the top transducer. Small scattering effect can be noticed in the top part of the beam for z

FIG. 15. Acoustic pressures generated by two phased array transducers, placed face to face with steering angle = 0° , when the interaction effect is considered and when it is ignored. (a) shows the two pressure fields that almost coincide along the central axis of the transducers. (b) shows the difference between the two pressure fields. (c) shows the percentage difference between the two fields. Because of symmetry the percentage difference is plotted from the transducer face to the central plane only.

between 9 and 10 mm. Figure 16(b) shows the total effect when both top and bottom transducers are excited. The pressure fields generated after ignoring the interaction effect are very similar to the figures shown in Fig. 16 although not identical, and not shown separately here. The difference between these two pressure fields is plotted in Fig. 17. Figure 17(a) shows the difference between the total pressure fields along the steering line when the interaction effect is consid-

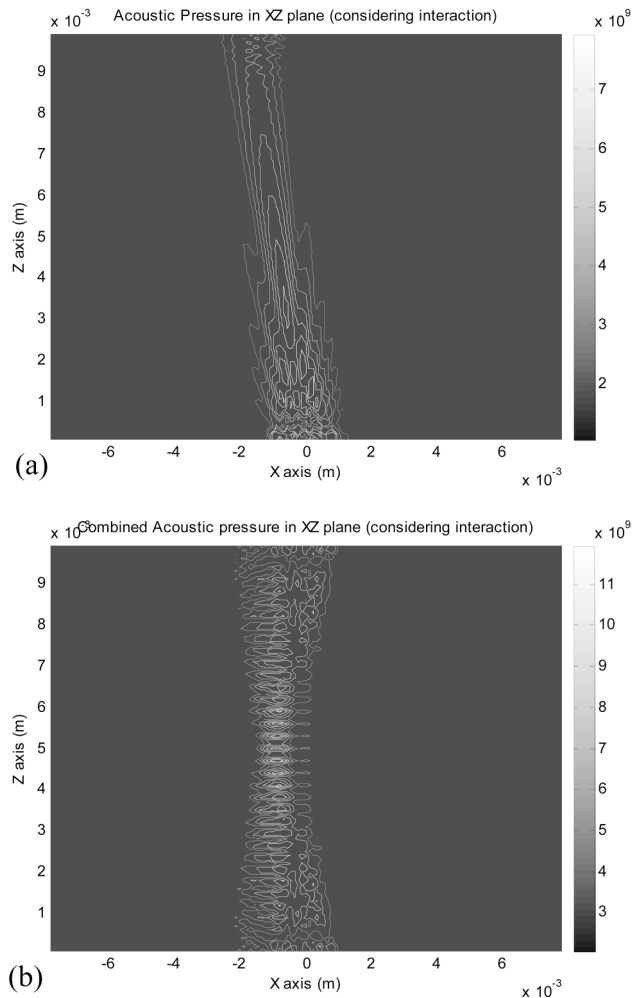

FIG. 16. Acoustic pressure in the XZ (or x_1x_3) plane for phased array transducers when the interaction effect is considered. Transducers are placed at a distance of 10 mm. (a) shows pressure fields generated by the bottom transducer when the top transducer acts as a scatterer or reflector, for 10° steering angle. (b) shows the total field, obtained by adding two fields generated by the bottom transducer [shown in (a)] and the top transducer [a mirror image of (a)].

ered [Fig. 16(b)] and when it is ignored (corresponding figure is not shown); Fig. 17(b) shows the percentage difference between the two pressure fields along the steering line. Because of symmetry the percentage difference is plotted from the transducer face to the central plane only. Note that the maximum difference between the two pressure fields is about 17.5% within 1.4 mm of the transducer face and it is less than 0.2% when the distance from the transducer face is greater than 2.8 mm. From Figs. 16 and 17, it is clear that the interaction from the second transducer surface has some effect on the total pressure distribution. It is interesting to note that although for the inclined beam comparatively less energy is being reflected by the second transducer the difference between the two pressure fields is greater near the transducer face in Fig. 17(b) in comparison to that in Fig. 15(c). For $\sim 0^\circ$ steering angle probably some destructive interference between the two reflected beams reduces the interaction effect to some extent. However, in the central region Fig. 15(c) shows a higher value in comparison to that in Fig. 17(b).

(a)

(b)

FIG. 17. Pressure difference for 10° steering angle. (a) Difference between the total pressure fields along the steering line when the interaction effect is considered [Fig. 16(b)] and when it is ignored (not shown); (b) shows the percentage difference between the two pressure fields along the steering line. Because of symmetry the percentage difference is plotted from the transducer face to the central plane only.

Figure 18 shows the pressure field for 30° steering angle when the interaction effect is considered. These plots are similar to Fig. 16, the only difference is that the steering angle for Fig. 18 is 30° and for Fig. 16 it was 10° . Figure 18(a) plots the pressure field generated by the bottom transducer and scattered by the top transducer. Hardly any scattering effect can be observed in this figure because the pressure beam almost completely misses the second transducer. Figure 18(b) shows the total effect when both top and bottom transducers are excited. Pressure fields generated by ignoring the interaction effect looks almost identical to the figures shown in Fig. 18 and not shown separately here. Although to the naked eye they look almost identical, there is some difference between these two pressure fields. This difference is plotted in Fig. 19. Figure 19(a) shows the difference between the total pressure fields along the steering line when the interaction effect is considered [Fig. 18(b)] and when it is ignored (corresponding figure is not shown); Fig. 19(b) shows the percentage difference between the two pressure fields along the steering line. Because of symmetry the percentage difference is plotted from the transducer face to the central

(b)

FIG. 18. Acoustic pressure in the XZ (or x_1x_3) plane for phased array transducers when the interaction effect is considered. Transducers are placed at a distance of 10 mm. (a) shows pressure fields generated by the bottom transducer when the top transducer acts as a scatterer or reflector, for 30° steering angle. (b) shows the total field, obtained by adding two fields generated by the bottom transducer [shown in (a)] and the top transducer [a mirror image of (a)].

plane only. Note that the maximum difference between the two pressure fields is about 14% within 1 mm of the transducer face and it is less than 0.1% when the distance from the transducer face is greater than 1.2 mm. In the central zone, the pressure difference is negligible. Therefore, even when the ultrasonic beam from one transducer apparently misses the other transducer, there is some significant scattering effect near the transducer face and it should not be ignored while computing the total field.

IV. CONCLUSION

The advantage of using a phased array transducer is its faster scanning capability that is achieved by removing the mechanical movement of the transducer and combining the electronic focusing with the beam steering. In this research, the distributed point source method (DPSM) is used to model phased array transducers. Different point sources placed on the transducer face are excited with varying time delays. The delay in excitation time is changed to produce acoustic beams with various steering angles. Comparison between the pressure fields produced by phased array transducers and conventional transducers for different steering angles shows that the focusing effect in the phased array transducers helps

FIG. 19. Pressure difference for 30° steering angle. (a) Difference between the total pressure fields along the steering line when the interaction effect is considered [Fig. 18(b)] and when it is ignored (not shown); (b) shows the percentage difference between the two pressure fields along the steering line. Because of symmetry the percentage difference is plotted from the transducer face to the central plane only.

us in producing stronger and better collimated beams than the conventional planar transducers. Pressure fields are modeled for single transducers as well as for pairs of phased array transducers placed face to face, to study the interaction effect for different steering angles. As expected, relatively stronger interaction effect is observed near the transducer face because the scattered field is relatively stronger there. Interestingly, even when the steering angle is large and the beam generated by one transducer apparently misses the other transducer, the field near the transducer face produced by the simple superposition of two generated beams significantly differs from the total field that includes the interaction effect. However, in the central region, away from the transducer face, the interaction or scattering effect is very small. Therefore, simple superposition of two ultrasonic fields generated by two individual phased array transducers working independently, in absence of the second transducer, is sufficient to model the combined ultrasonic field in this region.

Lamb mode conversion at edges. A hybrid boundary element–finite-element solution

José M. Galán^{a)} and Ramón Abascal^{b)}

Escuela Superior de Ingenieros, Camino de los Descubrimientos s/n, E-41092, Sevilla, Spain

(Received 1 October 2000; revised 1 July 2002; accepted 3 December 2004)

Two general and flexible numerical techniques based on the finite-element and boundary element methods developed by the authors in a previous paper are applied to study Lamb wave propagation in multilayered plates and Lamb mode conversion at free edges for frequencies beyond the first cutoff frequency. Both techniques are supported by a meshing criterion which guarantees the accuracy of the results when a condition is fulfilled. A finite-element formulation is directly applicable to study Lamb wave propagation and reflection by simple obstacles such as a flat edge. In order to tackle Lamb wave diffraction problems by defects with more complex geometries, a hybrid boundary element–finite-element formulation is used. This technique provides a major improvement with respect to the only previous boundary element application on Lamb waves: the connecting boundary might be placed as close to the reflector as desired, reducing greatly the requirement on mesh size. Two main application problems on practical metallic plates are studied and compared with reported numerical, theoretical, and experimental results: (1) Lamb wave propagation in degraded titanium diffusion bonds, and (2) Lamb mode conversion at inclined or perpendicular free edges of steel plates for frequencies beyond the first cutoff frequency. © 2005 Acoustical Society of America. I. INTRODUCTION

The use of elastic guided waves for nondestructive testing (NDT) purposes is developing rapidly.¹ Their long propagation distance and their ability to travel along the structures are advantages with respect to bulk wave ultrasonic techniques. Some successful applications have already been reported.^{2,3} This paper focuses on Lamb waves, which are guided waves in plates. A thorough theoretical analysis of these waves can be found in the literature.^{4–6}

A further development of Lamb wave NDT techniques requires understanding the interaction with defects and geometrical features. Lamb wave scattering is more complex than bulk wave scattering because the whole set of propagating modes is generated in the scattered field. This behavior restrains an analytical solution to very simple cases, and a numerical approach is therefore required.

The reflection at the edge of a semi-infinite plate is the simplest case of Lamb wave scattering, but it provides insight into its essential features. The first studies were aimed to explain the edge resonance phenomena.^{7–12} Later, the mode conversion for frequencies above the first cutoff frequency was studied theoretically,^{11,8} numerically,¹³ and experimentally.¹⁴ Lamb wave scattering by more general and realistic obstacles and defects (such as cracks, delaminations, or corrosion) has also been studied by other authors. Some theoretical approaches^{15–18} are available which express the field in the plate as an analytical normal mode expansion, but they are valid for very particular geometries. In the numerical studies, the finite-element (FE) method is the most

widely used technique. Two different implementations are considered: (1) Frequency-domain analysis, where a normal mode expansion of the far field is connected to a FE discretization of the defect neighborhood,^{19–23} (2) Time-domain analysis, where the scattering of ultrasonic pulses of finite duration is considered.^{24–26} Alleyne and Cawley²⁴ perform a postprocessing of the results to extract the modal content of the signals through a 2D-FFT. Verdict *et al.*²⁵ and Zgonc and Achenbach²⁶ use the time records directly to train neural networks for defect detection and characterization.

The boundary element (BE) method has not been used in guided wave scattering problems until very recently.^{13,27} The pioneering works by Cho and Rose combine the 2D frequency-domain BE method with a truncated analytical normal mode expansion including propagating modes only. This hybrid method was applied to study the reflection at free edges of semi-infinite steel plates,¹³ and the scattering by elliptical and rectangular surface defects on steel and aluminum plates.²⁷

The authors presented in a previous paper²⁸ two numerical techniques for the study of Lamb waves in plates which simplify the calculation of dispersion curves and diffraction by defects. The first technique is an FE formulation^{29–31} with two important features: (a) dispersion curves can be approximated easily and accurately up to the maximum frequency of interest by solving a quadratic eigensystem; (b) the FE dynamic stiffness matrix of the semi-infinite plate is an accurate approximation of an absorbing boundary condition for Lamb waves, which automatically takes into account the radiation of energy towards infinity in the form of propagating modes and includes the near-field effect of the evanescent modes. The second technique is a hybrid BE–FE formulation which uses the FE dynamic stiffness matrix of the semi-

FIG. 1. FE discretization of a multilayered plate.

infinite plate as an absorbing boundary condition on a BE region modeling the vicinity of a defect. The coupling between the FE and BE regions might be placed as close to the defect as desired. Both formulations are complemented by a meshing criterion which assures the accuracy of the results.

Additional results on Lamb wave propagation and scattering in metallic materials are presented in this paper. A multilayered plate which models a degraded titanium diffusion bond is studied to check the performance and applicability of the FE technique to nonhomogeneous plates. The reflection of high Lamb modes at the edge of a semi-infinite steel plate is analyzed. Reflection of Lamb waves at inclined edges is solved by the hybrid BE–FE technique.

II. AN FE FORMULATION FOR LAMB WAVES

A. Dynamic stiffness matrix of an infinite plate

Let us consider an infinite multilayered plate of thickness $2h$ under plane strain as shown in Fig. 1. Displacements corresponding to plane harmonic waves propagating in the x direction are considered. The plate cross section is discretized with n elements and N nodes, and shape functions are used to interpolate the variables. One-dimensional isoparametric (linear or quadratic) finite elements are used. Each element must be homogeneous, although the mesh may have elements of different materials.

The global stiffness and mass matrices for the infinite plate can be obtained and assembled into the global system of equations, rendering²⁸

$$(k^2\mathbf{A} + ik\mathbf{B} + \mathbf{G} - \omega^2\mathbf{M})\mathbf{d} = \mathbf{f}, \quad (1)$$

where the matrices \mathbf{A} , \mathbf{G} , and \mathbf{M} are symmetric and \mathbf{B} is antisymmetric, and \mathbf{d} and \mathbf{f} are vectors containing the nodal values of the displacements and consistent forces, respectively. The homogeneous problem with $\mathbf{f} = \mathbf{0}$ is used to obtain the Lamb wave modes and wave numbers.

B. Dynamic stiffness matrix of a semi-infinite plate

A semi-infinite plate of thickness $2h$ extending over the range $x \in (-\infty, x_0]$ is considered (see Fig. 2). The elastodynamic field can be expressed as a superposition of Lamb modes (normal mode expansion^{7,11}) where only modes satis-

FIG. 2. Geometry of a semi-infinite plate.

fying the radiation condition are included. These are nonevanescent modes propagating towards $x = -\infty$ or evanescent modes with decaying amplitude for $x \rightarrow -\infty$. Taking into account that the dependence with x and t is $\exp[i(kx + \omega t)]$, the former modes have a real, positive wave number (except for backward waves) and the latter have a complex wave number with negative imaginary part.

For a certain frequency ω , the FE formulation approximates the Lamb modes with the solutions of the quadratic eigensystem in Eq. (1). A mesh of N nodes produces $4N$ eigenvalues for 2D problems, from which only $2N$ satisfy the radiation condition. These $2N$ approximated modes, which include propagating and evanescent modes, are used in a normal mode expansion of the reflected field at the edge, providing a relationship between displacements and consistent nodal forces at section $x = x_0$:²⁸ $\mathbf{F}^{\text{refl}} = \mathbf{S}\mathbf{u}^{\text{refl}}$, where \mathbf{S} is the FE dynamic stiffness matrix of the semi-infinite plate which is independent of x_0 .

1. Incident wave

Some excitation at $x < x_0$ not included in the previous model can generate a Lamb wave which will propagate through the plate towards the edge, $x = x_0$. Superposition can be applied by expressing the total field as the sum of an incident and a reflected wave: $\mathbf{u} = \mathbf{u}^{\text{I}} + \mathbf{u}^{\text{refl}}$ and $\mathbf{F} = \mathbf{F}^{\text{I}} + \mathbf{F}^{\text{refl}}$, where the incident field is known. A relationship between displacements and consistent forces in the total field can be written: $\mathbf{F} - \mathbf{F}^{\text{I}} = \mathbf{S}(\mathbf{u} - \mathbf{u}^{\text{I}})$.

The excitation source can generate all the possible modes (propagating and evanescent) at that frequency. If the source is sufficiently far from the edge, the evanescent modes have zero amplitude at section $x = x_0$ because their amplitude decays exponentially with distance. Only propagating modes will reach the edge. In this paper, incident plane harmonic Lamb waves containing a single propagating mode are considered. By taking into account the boundary condition at $x = x_0$, participation factors of modes in the reflected field are calculated.

2. Partition of energy flux. Conservation of energy

The total reflected energy flux is computed from the FE results as follows:

$$E_{\text{ref}} = \sum_{\text{propagating } m} |\alpha^{(m)}|^2 E^{(m)}, \quad (2)$$

where $\alpha^{(m)}$ is the participation coefficient of mode m and $E^{(m)}$ is the energy flux averaged over a period carried by the propagating mode m . The summation is extended over the propagating modes only, since the evanescent modes do not carry any net energy flux when averaged over a period.

The principle of conservation of energy applied to a semi-infinite plate states that the energy flux transported by the incident wave E_{inc} must be equal to the energy flux transported by the reflected wave E_{ref} through any cross section of the plate. In this work two main sources of approximation are considered: an FE discretization is used and only a finite number of modes is retained in the normal mode expansion. They both introduce an error in the solution which causes the

violation of the energy-flux conservation principle. A first estimation of the accuracy of the results is that the energy-flux conservation is satisfied within a small margin, which is a necessary but not sufficient condition to validate the numerical results. All the numerical results for Lamb wave scattering in semi-infinite plates presented subsequently in this paper satisfy energy-flux conservation within a 1% margin, which is a very tight limit in comparison to previous published work^{20,13} where even a 10% error is allowed.

C. Meshing criterion

An analysis of the error when the FE stiffness matrix is used instead of the exact stiffness matrix for a thin, homogeneous plate was carried out by the authors in a previous paper,²⁸ from which a meshing criterion was proposed that can be applied to calculate dispersion curves and to solve Lamb wave scattering problems. In order to obtain accurate results, the meshing criterion requires the fulfillment of the following condition:²⁸

$$\frac{\lambda_T}{L} > \beta, \quad (3)$$

where L is the element size, $\lambda_T = 2\pi c_T/\omega$ is the wavelength of transverse waves at frequency ω , $\beta=20$ for linear elements, and $\beta=4$ for quadratic elements. This criterion has a clear physical interpretation: in order to get accurate results with an FE mesh, the number of elements per transverse wavelength must be greater than β . It agrees with the usual rule-of-thumb of FE in dynamics. From the viewpoint of a practical application, the following two solutions are provided by the meshing criterion:

- (i) Determination of element size L to get accurate results up to a given maximum frequency ω_{\max} , which yields $L < 2\pi c_T/\beta\omega_{\max}$;
- (ii) Determination of the maximum frequency that a given mesh of element size L can solve accurately: $\omega < 2\pi c_T/\beta L$.

III. SOME FE RESULTS

A. Numerical calculation of dispersion curves

The FE formulation is able to produce dispersion curves for Lamb waves in a simple manner by solving the eigenproblem in Eq. (1). In this paper, dispersion curves are calculated by means of a wave number sweep using IMSL eigenroutines.³²

1. Homogeneous isotropic plate

The dispersion curves for Lamb waves in homogeneous plates were calculated by Mindlin and other authors in the 50's,⁴⁻⁶ by numerically tracking the roots of the Rayleigh-Lamb frequency equations. Although the dimensionless dispersion curves only depend on Poisson's ratio,⁵ the numerical calculation requires complete definition of the material and dimensions of the plate. A plate of thickness $2h = 2$ mm with Poisson's ratio $\nu=0.25$ and bulk wave velocities $c_L = 1$ km/s and $c_T = 1/\sqrt{3}$ km/s is considered.

FIG. 3. Dispersion curves with 24 linear elements and 12 quadratic elements.

The dimensionless FE results obtained are plotted and compared with exact dispersion curves in Fig. 3. Exact branches corresponding to symmetric modes are plotted with a thin continuous line, exact branches corresponding to anti-symmetric modes with a thin dotted line, FE results with linear elements with \circ dots and numerical results with quadratic elements with \times crosses. The meshes of linear and quadratic elements used have the same number of d.o.f. The agreement is excellent up to the limit defined by the meshing criterion. The thick black line encloses an area where the error in the linear element stiffness matrices is below 5%.

2. Titanium diffusion bond

Diffusion-bonded members are used in aerospace structures. The quality of the bond is an aspect which must be assessed by some NDT technique, among which Lamb waves have been considered.¹ The thin diffusion bond interface can be modeled as a thin layer having distinct properties from the titanium (Ti). Bond quality can be represented in this manner by assigning degraded properties to the bond layer. In this paper the FE formulation is applied to calculate dispersion curves for a titanium diffusion bond under two different bonding conditions: (1) perfect bonding, where the bond layer has the same properties as Ti and therefore a homogeneous Ti plate is considered; (2) poor-quality bonding, where the bond layer has degraded properties compared to Ti. A nonuniform mesh of 27 quadratic elements is used, which is guaranteed by the meshing criterion to provide accurate results for frequencies up to $\omega h/(c_T)_{Ti} < 15.8$. The geometry is perfectly symmetrical with respect to the plate midplane, and the dimensions are total thickness $2h = 2.01$ mm, bond layer thickness 0.01 mm. The material properties used in the calculations are for titanium $\rho = 4.46$ kg/dm³, $c_L = 6.06$ km/s, $c_T = 3.23$ km/s and for the poor-quality bond layer $\rho = 2.2$ kg/dm³, $c_L = 1.35$ km/s, $c_T = 0.55$ km/s. Numerical results are plotted in Fig. 4, where they are compared with the exact results for the homogeneous Ti plate. One observes a shift to the right in the $k-\omega$ dispersion curves of the degraded bond with respect to the perfect bond case, which agrees with experimental observations and previous numerical calculations.¹

FIG. 4. Dispersion curves for titanium diffusion bond.

Dispersion curves for the imperfect bond are compared in Fig. 5 with those obtained with DISPERSE,³³ a commercial software to generate dispersion curves which makes use of the global matrix method. A complete agreement between both results is observed.

B. Reflection of an S0 mode by a free end

The reflection of an S0 mode by a free edge of a semi-infinite homogeneous plate was solved by Gazis and Mindlin⁷ for frequencies below the first cutoff frequency, by Torvik¹¹ for frequencies below the third cutoff frequency, and by Gregory and Gladwell⁸ for even higher frequencies.

A semi-infinite homogeneous plate of thickness $2h$ with a free end at $x=0$ is considered. The material is linear, elastic, and isotropic, with a Poisson's ratio $\nu=0.25$. For numerical calculations, a plate thickness $2h=2$ mm, and bulk wave velocities $c_L=1$ km/s and $c_T=1/\sqrt{3}$ km/s are considered.

Since the reflector (free end) is symmetric, there cannot be any mode conversion between symmetric and antisymmetric modes. The numerical results reproduce this effect exactly. The minimum number of elements required by the meshing criterion in order to accurately reproduce Fig. 4 from Ref. 8 is $n_{\min}=11$. Numerical results with 11, 22, and 44 quadratic elements are represented and compared with those of Gregory and Gladwell in Fig. 6, showing excellent agreement.

Shaw,¹⁰ while studying experimentally the axisymmetric resonant vibrations of thick barium titanate disks ($\nu=0.31$),

FIG. 5. Dispersion curves for imperfect diffusion bond. Comparison with DISPERSE.

FIG. 6. Reflection of mode S0 by a free end. Results with quadratic elements.

observed the existence of an edge resonance below the first cutoff frequency which he could not explain theoretically. A theoretical explanation was first given by Gazis and Mindlin,⁷ who showed that it is produced by a pair of evanescent modes corresponding to complex conjugate roots of the frequency equation when the S0 mode impinges on the edge. A similar edge resonance was found at the free edges of semi-infinite plates. Later, Torvik,¹¹ Tsao and Auld,¹² and Gregory and Gladwell⁸ confirmed those conclusions by means of more refined calculations. Using the FE formulation, a resonance in the second and third symmetric modes was found at a frequency $(\omega h/c_L)^2=1.493$, where they are evanescent, which agrees with the results reported by those authors.

C. Reflection of higher Lamb modes by a free end

The reflection of higher Lamb modes by a free edge of a semi-infinite homogeneous plate was studied experimentally using photoelasticity by Zhang *et al.*,¹⁴ and numerically by Cho and Rose,¹³ using a combination of a normal mode expansion technique and BEM with piecewise constant elements. The approach of the latter paper is based on expanding the scattered field as a superposition of Lamb modes (normal mode expansion) and keeping only propagating modes. The dispersion curves are obtained by numerically finding the roots of the exact Rayleigh–Lamb frequency

FIG. 7. Reflection of S0 mode at a flat free edge.

FIG. 8. Reflection of $S1$ mode at a flat free edge.

equation for the plate. The analytical expressions for displacements and stresses are used in order to obtain a non-reflecting boundary condition. Since only propagating modes are included in the modal superposition, the absorbing boundary must be placed far enough from the edge (at a distance longer than one wavelength of the incident mode) in order to avoid the near-field effect of evanescent modes. This approximation is satisfactory except in the neighborhood of the cutoff frequencies, where evanescent modes with wave numbers having very small imaginary part and therefore with a very weak exponential decay are found.

The FE formulation is used to study the reflection of higher modes at free flat edges. In order to compare with Cho and Rose's results, a semi-infinite homogeneous plate of thickness $d=2h=1$ mm with a free end at $x=0$ is considered. The material is common steel, with density $\rho=7.8$ kg/dm³ and bulk wave velocities $c_L=5.94$ km/s and $c_T=3.2$ km/s. Since the reflector (free edge) is symmetric, no mode conversion between symmetric and antisymmetric modes can occur. The numerical results reproduce this effect exactly.

The maximum frequency considered in Cho and Rose's paper¹³ is $f=6$ MHz. The minimum number of quadratic elements required by the meshing criterion for frequencies up to that value is $n_{\min}=8$. A uniform FE mesh of 8 quadratic elements was used to get the numerical results which are plotted in Figs. 7-11. Using a uniform mesh of 16 elements does not change the results practically. The agreement with Cho and Rose, who used more than 200 constant elements, is

FIG. 9. Reflection of $S2$ mode at a flat free edge.

FIG. 10. Reflection of $A0$ mode at a flat free edge.

good. Moreover, since the formulation used in this work retains the evanescent modes in the far-field expansion, the results are also accurate in the neighborhood of the cutoff frequencies. Cho and Rose reported some values of the reflected amplitudes above 1 (see Fig. 11), which clearly violates the energy-conservation principle, but never beyond the $\pm 10\%$ bound allowed in their calculations.

The FE results presented satisfy the energy-flux reciprocity principle, i.e., when a p mode is incident on to the edge, the fraction of energy which is transformed into an n mode is precisely the same as that transformed into a p mode upon incidence of an n mode onto the edge.

IV. THE BE METHOD

The BE method (BEM) is a numerical method that has been widely and successfully used to solve elastodynamic problems.^{34,35} Some of its advantages with respect to other domain-type methods, such as FE and finite difference methods, are (1) reduction of the dimension of the problem, since only the surface of the domain has to be discretized; (2) better performance in the analysis of high-stress gradient problems, such as cracks. In this section the formulation of BEM is briefly described.

The reciprocal theorem for two time-harmonic elastodynamic states of the same frequency ω on a body Ω with surface Γ can be written as³⁴

FIG. 11. Reflection of $A1$ mode at a flat free edge.

FIG. 12. Hybrid BE–FE model for the inclined edge.

$$\int_{\Gamma} t_i u_i^* d\Gamma + \int_{\Omega} \rho b_i u_i^* d\Omega = \int_{\Gamma} t_i^* u_i d\Gamma + \int_{\Omega} \rho b_i^* u_i d\Omega, \quad (4)$$

where the field variables u_i , t_i , b_i , u_i^* , t_i^* , and b_i^* are the components of the displacements, tractions, and body forces, respectively, that depend on position \mathbf{x} and frequency ω and might be real or complex-valued.

The elastodynamic fundamental solution corresponds to the displacements and stresses produced by a time-dependent point load in an unbounded medium. It was first presented by Stokes.⁵ Assuming that the second state in Eq. (4) (the one denoted by*) is the fundamental solution for a unit time-harmonic load of frequency ω applied along the l direction at a point $\mathbf{x}=\xi \in \Omega$, taking the collocation point ξ to the boundary by a limiting process, and extracting the singularity at $r=0$ due to the fundamental solution, renders

$$c_{lk}(\xi) u_k(\xi, \omega) + \int_{\Gamma} t_{lk}^*(\mathbf{x}, \xi, \omega) u_k(\mathbf{x}, \omega) d\Gamma(\mathbf{x}) = \int_{\Gamma} u_{lk}^*(\mathbf{x}, \xi, \omega) t_k(\mathbf{x}, \omega) d\Gamma(\mathbf{x}), \quad (5)$$

where the integrals are Cauchy principal value integrals, u_k and p_k are the boundary displacements and tractions, and the matrix $c_{lk}(\xi)$ only depends on the smoothness and the local geometry of the boundary at the collocation point ξ .

The numerical solution of Eq. (5) requires the discretization of the boundary Γ into elements $\Gamma = \sum_{j=1}^n \Gamma_j$, where n is the number of elements and Γ_j the boundary of element j . Over each element, geometry, displacements, and tractions are interpolated in terms of their nodal values by means of shape functions. In BEM, displacements and tractions are interpolated independently, in contrast with FEM where stresses (and tractions) are obtained as derivatives of the interpolated displacements. Substituting the element discretization into Eq. (5) yields two equations relating the displacement of the collocation point with the nodal displacements and tractions of all boundary nodes. A system of equations in terms of the nodal values as the only unknowns can be obtained by writing that equation at all boundary nodes, which after taking the boundary conditions into account provides the solution on the boundary.

V. HYBRID BE–FE FORMULATION

The problem of Lamb wave interaction with complex obstacles and defects is tackled by dividing the geometry in two regions, as shown in Fig. 12: (1) neighborhood of the defect and (2) far field. The former region is modeled with BE, which is proven very accurate and successful in the study of harmonic problems and can reproduce accurately

many kinds of obstacles, such as inclusions, voids, delaminations, and cracks. The latter region is modeled with FE by means of a truncated normal modal expansion which gives rise to the dynamic stiffness matrix of the semi-infinite plate \mathbf{S} . This matrix represents a nonreflecting boundary condition for Lamb waves with a very high accuracy up to a frequency limit defined by the meshing criterion [Eq. (3)]. It reproduces in a precise manner the energy flux towards infinity through a semi-infinite plate in the form of propagating Lamb modes. The near-field effect of evanescent modes is also taken into account.

This modeling strategy is similar to that followed by Cho and Rose,^{13,27} but our approach introduces three main improvements.

- (1) Not only propagating but also evanescent modes are used in the far-field expansion. Therefore, the response in the neighborhood of the cutoff frequencies is reproduced better;
- (2) The dispersion curves and modes are obtained numerically by the FE method, which greatly simplifies the calculation of the wave numbers and permits the extension to sandwich plates without any additional effort; and
- (3) Quadratic boundary elements are used instead of constant elements.

This hybrid BE–FE formulation requires a coupling between the BE and FE regions. Several techniques can be found in the literature.^{36,37} In our approach, compatibility and equilibrium are enforced variationally and at an element level.²⁸

It was shown²⁸ that the fictitious absorbing boundary can be placed as close to the reflector as desired without any decrease in accuracy. This is in clear contrast with Ref. 13, where the coupling between normal mode expansion and BE region had to be done at a distance d_f longer than an incident wavelength. This distance becomes large for high frequencies and consequently demands a large number of elements. The explanation for this behavior is that Ref. 13 does not include evanescent modes in the normal mode expansion, which are essential in the vicinity of reflectors. The number of elements required to solve the problem with the proposed hybrid formulation is therefore greatly reduced.

FIG. 13. Reflection of S0 mode at a 45 deg inclined free edge.

FIG. 14. Reflection of A0 mode at a 45 deg inclined free edge.

FIG. 16. Reflection of A0 mode at a 60 deg inclined free edge.

VI. SOME HYBRID BE-FE RESULTS

A. Reflection of S0 and A0 modes by inclined free edges

Let us consider a semi-infinite homogeneous plate of thickness $2h = 1$ mm with an inclined free edge with an inclination angle θ with respect to the vertical axis. A Lamb mode (S0 or A0) is incident from $x = -\infty$. The material is common steel, with density $\rho = 7.8$ kg/dm³ and bulk wave velocities $c_L = 5.94$ km/s and $c_T = 3.2$ km/s. Because of the geometry this problem cannot be solved using only the FE formulation of Sec. II B. The hybrid BE-FE model for this problem is shown in Fig. 12. The fictitious boundary is placed as close to the edge as possible in order to reduce the number of elements in the BE region. Quadratic elements of size $L = 0.125$ mm are used to mesh both regions. According to the meshing criterion, this element size gives accurate results up to 6 MHz.

This problem is solved for two different angles $\theta = 60$ deg and 45 deg using meshes of 38 and 28 quadratic elements, respectively. The results of the partition of energy flux are shown in Figs. 13-16. Since the reflector is not symmetric, a mode conversion between symmetric and antisymmetric modes occurs and can be observed in the figures. The numerical results satisfy the energy-flux reciprocity principle, as shown in Fig. 17.

FIG. 15. Reflection of S0 mode at a 60 deg inclined free edge.

VII. CONCLUSIONS

Two numerical techniques based on the finite-element- and boundary element methods developed by the authors in a previous paper are applied to practical cases of Lamb waves in metallic plates with excellent results.

Dispersion curves for degraded titanium diffusion bonds, modeled as nonhomogeneous three-layer plates, have been calculated and compared with previously reported experimental and numerical results. A shift of the degraded curves with respect to the perfect bond curves is observed, in complete agreement with previous work.

Reflection of high Lamb modes at the free edge of a semi-infinite steel plate are studied and compared with previous work by Cho and Rose. The agreement is good, with a much smaller mesh and computational effort. Reflection at an inclined edge of a semi-infinite steel plate is studied using the hybrid BE-FE technique for two different angles, $\theta = 60$ deg and 45 deg.

The meshing criterion proposed by the authors has been used in all the examples and is shown to provide meshes whose results are accurate up to the desired frequency. The accuracy of the scattering results is such that energy-flux conservation and reciprocity are satisfied within a 1% margin.

The hybrid technique developed by the authors contains

FIG. 17. Check of the reciprocity principle for Lamb mode reflection at inclined free edges.

two main improvements as compared to previous BE techniques for Lamb wave problems.

- (1) The fictitious boundary might be placed as close to the reflector as desired, since evanescent modes are included in the normal mode expansion. Hence, the mesh size requirement is greatly reduced.
- (2) The accuracy of the numerical results is under control by the proposed meshing criterion.

In conclusion, the two numerical techniques presented by the authors for the study of Lamb waves in homogeneous or sandwich plates greatly simplify the calculation of dispersion curves and diffraction by defects. They provide a flexible and general tool to solve Lamb wave scattering problems that can be readily extended to study defects of more complex geometry in semi-infinite and infinite plates.

(Received 9 September 2004; revised 23 December 2004; accepted 31 December 2004)

Laboratory experiments on wave propagation through saturated and partially saturated porous media have often been conducted on porous cylinders that were initially fully saturated and then allowed to dry while continuing to acquire data on the wave behavior. Since it is known that drying typically progresses from outside to inside, a sensible physical model of this process is concentric cylinders having different saturation levels—the simplest example being a fully dry outer cylindrical shell together with a fully wet inner cylinder. We use this model to formulate the equations for wave dispersion in porous cylinders for patchy saturation (i.e., drainage) conditions. In addition to multiple modes of propagation obtained numerically from these dispersion relations, we find two distinct analytical expressions for torsional wave modes. We solve the resulting torsional wave dispersion relation for two examples: Massillon sandstone and Sierra White granite. One essential fact that comes to light during the analysis is that the effective shear moduli of the gas- and liquid-saturated regions must differ, otherwise it is impossible to account for the laboratory torsional wave data. Furthermore, the drainage analysis appears to give improved qualitative and quantitative agreement with the data for both of the materials considered. © 2005 Acoustical Society of America. I. INTRODUCTION

The most successful and also most common method of remote sensing used in oil and gas exploration is reflection seismology.¹ The goals motivating use of such acoustic/seismic methods are first to delineate geologic traps for fluids and then to determine (to whatever extent possible) the nature and spatial distribution of the fluids in those traps. These problems are challenging from viewpoints of both engineering practice and fundamental science of acoustics. The present work addresses one unresolved fundamental issue concerning effects that nonuniform spatial distributions of pore fluids have on sound speeds in laboratory ultrasound experiments.

The classic work of Pochhammer² and Chree³ gave exact solutions for wave propagation in elastic rods. When the rod is instead a porous cylinder with fluid-filled pores, the equations of linear elasticity do not describe all possible motions of the fluid/porous-solid mixture. Biot's theory of fluid-saturated porous media^{4,5} provides a continuum theory, permitting the fluid and solid components to move independently and accounts approximately for the attenuation of waves due to viscous friction. Gardner^{6,7} used Biot's theory^{4,5} to study long-wavelength extensional waves in circular cylinders. Gardner considered only the low-frequency regime where the second bulk compressional mode predicted

by Biot's theory is diffusive in character. Gardner also limited consideration to the case of open-pore surface boundary conditions.

The present work is based in part on another paper by Berryman,⁸ in which both open- and closed-pore surface boundary conditions for the fluid-saturated porous cylinder were studied. Here we consider only the open-pore surface, but we allow patchy (nonuniform) saturation^{9–16} inside the cylinder. In particular, it is quite common to study partial saturation in the laboratory under drainage or drying conditions wherein an initially fully saturated porous cylinder is allowed to dry (from the outside in) while the experimenter continues to acquire data on the cylinder's modes of oscillation. We want to model this behavior explicitly, as we anticipate the results to differ significantly from those for homogeneous partial saturation. The simplest model of patchy saturation due to drainage from laboratory samples is surely concentric cylinders with a fully dry (air saturated) outer cylindrical shell enclosing a fully liquid-saturated inner cylinder.

No doubt a more realistic model would involve many shells with various degrees of partial saturation between the dry outer shell and the saturated inner cylinder at the core, but such complications will not be treated here. We find that studies of the two-layer case have all the important physical complications expected in this problem, while still having enough simplicity that some of the analysis can be done semi-analytically—thereby providing some of the sought after insight into the problem.

^{a)}Electronic mail: berryman1@llnl.gov

^{b)}Electronic mail: spride@lbl.gov

One somewhat unusual aspect of the presentation is that we allow the possibility that the shear modulus of a liquid-filled porous medium can be larger than that of the same medium filled with gas.¹⁷⁻¹⁹ Although this concept disagrees with Gassmann's quasi-static result for isotropic materials, it is now well understood that fluid dependence of shear is possible for heterogeneous, unrelaxed, and/or high-frequency experiments. In fact the laboratory data we are attempting to model and ultimately explain demand that this possibility be considered.

We present the equations of poroelasticity, and then show the forms of the equations needed for cylindrical geometry. Appropriate boundary conditions for our problem are discussed. Equations are subsequently formulated to determine both the extensional and torsional modes of concentric poroelastic cylinders under conditions of partial saturation. Solutions of these equations are computed and discussed here for torsional waves, while the harder problem of extensional waves will be treated fully in a second installment to be presented at a later date.

II. EQUATIONS OF POROELASTICITY

For long-wavelength disturbances (i.e., wavelength $\lambda \gg h$, where h is a typical pore size) propagating through a porous medium, we define average values of the (local) displacements in the solid and also in the saturating fluid. The average displacement vector for the solid frame is \mathbf{u} while that for the pore fluid is \mathbf{u}_f . The average displacement of the fluid relative to the frame is $\mathbf{w} = \phi(\mathbf{u}_f - \mathbf{u})$, where ϕ is porosity. For small strains, the frame dilatation is

$$e = e_x + e_y + e_z = \nabla \cdot \mathbf{u}, \quad (1)$$

where e_x, e_y, e_z are the Cartesian strain components. Similarly, the average fluid dilatation is

$$e_f = \nabla \cdot \mathbf{u}_f \quad (2)$$

(e_f also includes flow terms as well as dilatation) and the increment of fluid content is defined by

$$\zeta = -\nabla \cdot \mathbf{w} = \phi(e - e_f). \quad (3)$$

With these definitions, Biot²⁰ obtains the stress-strain relations in the form

$$\delta\tau_{xx} = He - 2\mu(e_y + e_z) - C\zeta, \quad (4)$$

and similarly (with permutations) for the other compressional components $\delta\tau_{yy}, \delta\tau_{zz}$, while

$$\delta\tau_{zx} = \mu \left(\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x} \right), \quad (5)$$

and again for $\delta\tau_{yz}, \delta\tau_{xy}$ for the other shear components. Finally, for the fluid pressure,

$$\delta p_f = M\zeta - Ce. \quad (6)$$

The $\delta\tau_{ij}$ (for $i, j = x, y, z$) are deviations from equilibrium of average Cartesian stresses in the saturated porous material and δp_f is similarly the isotropic pressure deviation in the pore fluid.

With time dependence of the form $\exp(-i\omega t)$, the coupled wave equations that incorporate (4)–(6) take the form

$$\begin{aligned} \omega^2(\rho\mathbf{u} + \rho_f\mathbf{w}) &= C\nabla\zeta - (H - \mu)\nabla e - \mu\nabla^2\mathbf{u}, \\ \omega^2(\rho_f\mathbf{u} + q\mathbf{w}) &= M\nabla\zeta - C\nabla e, \end{aligned} \quad (7)$$

where $\rho = \phi\rho_f + (1 - \phi)\rho_m$ is the bulk-density of the material and $q = \rho_f[\alpha/\phi + iF(\xi)\eta/\kappa\omega]$ is the effective density of the fluid in relative motion. The kinematic viscosity of the liquid is η , the permeability of the porous frame is κ ; the dynamic viscosity factor is given, for our choice of sign for the frequency dependence, by $F(\xi) = \frac{1}{4}\{\xi T(\xi)/[1 + 2T(\xi)/i\xi]\}$, where $T(\xi) = [\text{ber}'(\xi) - i\text{bei}'(\xi)]/[\text{ber}'(\xi) - i\text{bei}'(\xi)]$ and $\xi = (\omega h^2/\eta)^{1/2}$. The functions $\text{ber}(\xi)$ and $\text{bei}(\xi)$ are the real and imaginary parts of the Kelvin function. The dynamic parameter h is a characteristic length generally associated with and comparable in magnitude to the steady-flow hydraulic radius. The tortuosity $\alpha \geq 1$ (a pure number related to the average grain shapes and/or the pore topology) has been measured by Johnson *et al.*²¹ and has also been estimated theoretically by Berryman.²² It is also related to the electrical formation factor F by $\alpha = \phi F$.

The poroelastic moduli H , C , and M are given²³⁻²⁷ by

$$H = K + \frac{4}{3}\mu + (K_m - K)^2/(D - K), \quad (8)$$

$$C = K_m(K_m - K)/(D - K), \quad (9)$$

and

$$M = K_m^2/(D - K), \quad (10)$$

where

$$D = K_m[1 + \phi(K_m/K_f - 1)] \quad (11)$$

with K_m being the solid grain bulk modulus, K_f being the pore fluid bulk modulus, and ϕ being the porosity. Equations (8)–(11) are correct as long as the porous material can be considered homogeneous on the microscopic scale as well as the macroscopic scale, which we assume to hold for the present application.

To decouple the wave equations (7) into Helmholtz equations for the three modes of propagation for isotropic systems [fast longitudinal, slow longitudinal, and transverse (or shear)], we note that the displacements \mathbf{u} and \mathbf{w} can be decomposed as

$$\mathbf{u} = \nabla Y + \nabla \times \boldsymbol{\beta}, \quad \mathbf{w} = \nabla \psi + \nabla \times \boldsymbol{\chi}, \quad (12)$$

where Y, ψ are scalar potentials and $\boldsymbol{\beta}, \boldsymbol{\chi}$ are vector potentials. Substituting (12) into (7), we find (7) is satisfied if the following two pairs of equations hold:

$$(\nabla^2 + k_s^2)\boldsymbol{\beta} = 0, \quad \boldsymbol{\chi} = -\rho_f\boldsymbol{\beta}/q \quad (13)$$

and

$$(\nabla^2 + k_{\pm}^2)A_{\pm} = 0, \quad (14)$$

where k_s is the shear (or transverse) wave number, k_+ is the fast-longitudinal wave number, and k_- is the slow-longitudinal wave number. These wave numbers are defined by

$$k_s^2 = \omega^2(\rho - \rho_f^2/q)/\mu \quad (15)$$

and

$$k_{\pm}^2 = \frac{1}{2}\{b + f \mp [(b-f)^2 + 4cd]^{1/2}\}, \quad (16)$$

$$b = \omega^2(\rho M - \rho_f C)/\Delta, \quad c = \omega^2(\rho_f M - qC)/\Delta, \\ d = \omega^2(\rho_f H - \rho C)/\Delta, \quad f = \omega^2(qH - \rho_f C)/\Delta, \quad (17)$$

with $\Delta = MH - C^2$. This linear combination of scalar potentials has been chosen to be $A_{\pm} = \Gamma_{\pm} Y + \psi$, where

$$\Gamma_{\pm} = d/(k_{\pm}^2 - b) = (k_{\pm}^2 - f)/c. \quad (18)$$

With the identification (18) of the coefficients Γ_{\pm} , the mode decoupling is complete.

Equations (13) and (14) are valid for any choice of coordinate system. They may therefore be applied to boundary value problems with arbitrary symmetry. Biot's theory can therefore be applied to porous elastic cylinders in the next section.

III. EQUATIONS FOR POROUS CYLINDER

To work most easily in cylindrical geometry, we rewrite the stress-strain relations (4)–(6) in cylindrical coordinates. If z is the coordinate along the cylinder axis while r and θ are the radial and azimuthal coordinates, it is not difficult to show that

$$\delta\tau_{rr} = He - 2\mu(e_{\theta} + e_z) - C\zeta, \quad (19)$$

$$\delta\tau_{r\theta} = \mu\left(\frac{\partial u_{\theta}}{\partial r} - \frac{u_{\theta}}{r} + \frac{1}{r}\frac{\partial u_r}{\partial \theta}\right), \quad (20)$$

$$\delta\tau_{rz} = \mu\left(\frac{\partial u_r}{\partial z} + \frac{\partial u_z}{\partial r}\right), \quad (21)$$

and (6) for δp_f remains unchanged. The stress increments $\delta\tau_{zz}$, $\delta\tau_{\theta\theta}$, and $\delta\tau_{\theta z}$ are not of direct interest in the present application. The dilatations are given by

$$e = e_r + e_{\theta} + e_z, \quad (22)$$

where

$$e_r = \frac{\partial u_r}{\partial r}, \quad e_{\theta} = \frac{u_r}{r} + \frac{1}{r}\frac{\partial u_{\theta}}{\partial \theta}, \quad e_z = \frac{\partial u_z}{\partial z}. \quad (23)$$

We redefine the vector potential β in terms of two scalar potentials according to

$$\beta = \hat{z}\beta_1 + \nabla \times (\hat{z}\beta_2), \quad (24)$$

where \hat{z} is a unit vector in the z direction and both β_i 's satisfy

$$(\nabla^2 + k_s^2)\beta_i = 0 \quad \text{for } i=1,2. \quad (25)$$

For the problem of interest here, there are two distinct regions: The first region is a circular cylinder centered at the origin, within which solutions of (14) and (25) must be finite at the origin. Solutions of these Helmholtz equations take the form

$$A_{\pm} = \alpha_{\pm} J_0(j_{\pm}) \exp[i(k_z z - \omega t)], \quad (26)$$

$$\beta_1 = \gamma_s J_0(j_s) \exp[i(k_z z - \omega t)], \quad (27)$$

$$\beta_2 = (\alpha_s / ik_z) J_0(j_s) \exp[i(k_z z - \omega t)], \quad (28)$$

where

$$j_{\pm} = k_{\pm} r, \quad j_s = k_s r, \quad (29)$$

and

$$k_{\pm r}^2 = k_{\pm}^2 - k_z^2, \quad k_{sr}^2 = k_s^2 - k_z^2. \quad (30)$$

J_0 is the zeroth order Bessel function of the first kind. The coefficients α_{\pm} , α_s , γ_s , are constants to be determined from the boundary conditions. (Note that the coefficients α_{\pm} and α_s should not be confused with the tortuosity symbol α introduced earlier.)

The second region is a cylindrical shell surrounding the first region. In this region, the factors k_{\pm} and k_s can take different values from those in the central region, indicated by k_{\pm}^* and k_s^* (where $*$ means air-filled, and does *not* ever mean complex conjugate in this paper). Furthermore, two linearly independent solutions of the equations are allowed, i.e., both J_0 and Y_0 (the Bessel function of the second kind, sometimes known as the Neumann function). In the outer shell, we therefore have four coefficients apiece for J_0 and Y_0 , all of which must also be determined by the boundary conditions.

First note that

$$Y = (A_+ - A_-)/(\Gamma_+ - \Gamma_-), \\ \psi = (A_+ \Gamma_- - A_- \Gamma_+)/(\Gamma_- - \Gamma_+) \quad (31)$$

from the definitions of A_{\pm} . Then, substituting (26)–(28) and (31) into (12), and the result into (6) and (19)–(21), we learn how the stress distribution in the cylinder is related to the unknown potential amplitudes α_{\pm} , α_s , and γ_s :

$$\delta\tau_{r\theta} = m_{11}\gamma_s \equiv -\mu k_{sr}^2 J_2(j_s) \gamma_s, \quad (32)$$

$$\delta\tau_{rr} = a_{11}\alpha_+ + a_{12}\alpha_- + a_{13}\alpha_s, \quad (33)$$

$$-\delta p_f = a_{21}\alpha_+ + a_{22}\alpha_- + a_{23}\alpha_s, \quad (34)$$

$$\delta\tau_{rz} = a_{31}\alpha_+ + a_{32}\alpha_- + a_{33}\alpha_s. \quad (35)$$

Here the a_{ij} coefficients are defined in terms of known quantities—while using the definition $\Xi \equiv 1/(\Gamma_+ - \Gamma_-)$ —by

$$a_{11} = \Xi[(C\Gamma_- - H)k_+^2 + 2\mu k_z^2] J_0(j_+) \\ + 2\Xi \mu k_{+r} J_1(j_+)/r, \quad (36)$$

$$a_{12} = -2\Xi \mu k_{-r} J_1(j_-)/j_- \\ + \Xi[(H - C\Gamma_+)k_-^2 - 2\mu k_z^2] J_0(j_-), \quad (37)$$

$$a_{13} = 2\mu k_{sr}^2 J_2(j_s), \quad (38)$$

$$a_{21} = \Xi(M\Gamma_- - C)k_+^2 J_0(j_+), \quad (39)$$

$$a_{22} = \Xi(C - M\Gamma_+)k_-^2 J_0(j_-), \quad (40)$$

$$a_{31} = -2i\Xi \mu k_z k_{+r} J_1(j_+), \quad (41)$$

$$a_{32} = 2i\Xi \mu k_z k_{-r} J_1(j_-), \quad (42)$$

$$a_{33} = -\mu(k_s^2 - 2k_z^2)k_{sr} J_1(j_s)/ik_z, \quad (43)$$

and $a_{23}=0$. There is an implicit factor of $\exp[i(k_z z - \omega t)]$ on the right-hand side of (32)–(35).

Berryman⁸ has shown that a_{11} , a_{13} , a_{31} , and a_{33} reduce in the limit $\phi \rightarrow 0$ to the corresponding results for isotropic elastic cylinders by Pochhammer,² Chree,^{3,28} Love,²⁹ and Bancroft,³⁰ as they should.

IV. BOUNDARY CONDITIONS

Appropriate boundary conditions for use with Biot's equations have been considered by Deresiewicz and Skalak,³¹ Berryman and Thigpen,³² and Pride and Haartsen,³³ so we make use of these results here.

At the external surface $r=R_2$ where the outer porous material contacts the surrounding air, it is most appropriate for the drainage experiments to be analyzed while using free surface conditions

$$-\delta p_f = 0, \quad \delta \tau_{rr} = 0, \quad \delta \tau_{r\theta} = 0, \quad \delta \tau_{rz} = 0 \quad (44)$$

for the deviations from static equilibrium. (If instead the cylinder is sealed on $r=R_2$, then the first of these needs to be replaced by $w_r=0$. While of theoretical interest, this condition is not one appropriate for the conditions of the actual laboratory experiments we will analyze.)

The internal interface condition at $r=R_1$ needs more precise definition. We assume that all the meniscii that are separating the inner fluid (liquid) from the outer fluid (gas) are contained within a thin layer (shell) of thickness δh (a few grain sizes in width) straddling the surface $r=R_1$. The porous-continuum boundary conditions used at the $r=R_1$ interface are to be understood in the limit where $\delta h/R_1 \rightarrow 0$.

All fluid that enters this interface layer goes into stretching the meniscii since as Pride and Flekkoy³⁴ have shown, it is reasonable to assume that the contact lines of the meniscii remain pinned under linear seismic stressing (strains $\leq 10^{-6}$). The locally incompressible flow conserves fluid volume so that the rate at which the inner fluid enters the interface layer is equal to the rate at which the outer fluid leaves the layer. With the assumed $e^{-i\omega t}$ time dependence, this becomes the fluid displacement condition

$$w_r(r=R_1 + \delta h/2) = w_r^*(r=R_1 - \delta h/2). \quad (45)$$

Another boundary condition defines the incremental change in the fluid-pressure difference across the interface layer as being the surface tension times the average incremental change in the curvature of the meniscii. In terms of porous-continuum variables, Nagy and Blaho³⁵ and Nagy and Nayfeh³⁶ have defined this interface condition as

$$\delta p_f - \delta p_f^* = W w_r, \quad (46)$$

where W is called the membrane stiffness. Nagy and Nayfeh³⁶ have shown that $W = \sigma/\kappa$ (where σ is surface tensions and κ is permeability) for pore models in which the pores are straight cylinders. Pride *et al.*³⁷ have shown that when the dimensionless inequality $\sigma R_2^2/(\kappa K R_1) < 1$ is satisfied, finite stiffness of the meniscii may be neglected so that

$$\delta p_f = \delta p_f^* \quad (47)$$

everywhere along the interface $r=R_1$ (recall that R_2 is the sample radius). With $\kappa = 100$ mDarcy, $K = 10$ GPa, and σ

$= 10^{-2}$ Pa m (typical values for a sandstone and an air/water interface), we find that R_2^2/R_1 should be less than 10 cm in order for Eq. (47) to apply. Since most laboratory samples are smaller than 10 cm in radius, Eq. (47) is therefore valid at all saturation levels for the types of materials of interest here, so no further reference to the surface tension (or membrane stiffness) needs to be made.

We also have the standard porous-continuum results that

$$\tau_{rr} = \tau_{rr}^*, \quad \tau_{r\theta} = \tau_{r\theta}^*, \quad \tau_{rz} = \tau_{rz}^*, \quad (48)$$

which express momentum conservation at the interface, and the time derivatives of the displacement components satisfy

$$\dot{u}_r = \dot{u}_r^*, \quad \dot{u}_\theta = \dot{u}_\theta^*, \quad \dot{u}_z = \dot{u}_z^*, \quad (49)$$

which express the fact that the grains remain in (welded) contact at the interface.

To apply the boundary conditions (45) and (47), we need in addition to (34) the result

$$w_r = a_{41}\alpha_+ + a_{42}\alpha_- + a_{43}\alpha_s, \quad (50)$$

where [again using $\Xi \equiv 1/(\Gamma_+ - \Gamma_-)$]

$$a_{41} = \Xi k_{+r} J_1(j_+) \Gamma_-, \quad (51)$$

$$a_{42} = -\Xi k_{-r} J_1(j_-) \Gamma_+, \quad (52)$$

$$a_{43} = k_{sr} J_1(j_s) \rho_f / q. \quad (53)$$

The remaining stress conditions (48) are determined by (33) and (35).

To apply the boundary conditions (49), we need the explicit expressions for the displacement which follow from (12). The results are of the form

$$u_r = a_{51}\alpha_+ + a_{52}\alpha_- + a_{53}\alpha_s, \quad (54)$$

where

$$(\Gamma_+ - \Gamma_-) a_{51} = -k_{+r} J_1(j_+), \quad (55)$$

$$(\Gamma_+ - \Gamma_-) a_{52} = k_{-r} J_1(j_-), \quad (56)$$

$$a_{53} = k_{sr} J_1(j_s), \quad (57)$$

and

$$u_z = a_{61}\alpha_+ + a_{62}\alpha_- + a_{63}\alpha_s, \quad (58)$$

where $a_{61} = a_{62} = 0$ and

$$a_{63} = k_{sr}^2 J_0(j_s) / i k_z. \quad (59)$$

Both (54) and (58) are needed for extensional waves, while the remaining component,

$$u_\theta = m_{21} \gamma_s \equiv k_{sr} J_1(j_s) \gamma_s, \quad (60)$$

is needed only for torsional waves. As before, there is an implicit factor of $\exp i(k_z z - \omega t)$ on the right-hand side of (51)–(53), (55)–(57), and (59).

It follows from (32)–(35), (50), and (60) that γ_s (for the inner cylinder) and the corresponding coefficients for the cylindrical shell are all completely independent of the other mode coefficients and, therefore, relevant to the study of torsional waves, but not for extensional waves. Pertinent equations for the torsional wave dispersion relation are continuity

FIG. 1. Cross-section of a circular cylinder, where $R_1 = S^{1/2}R_2$ is determined by the liquid saturation level S .

of the angular displacement, u_θ , and stress, $\tau_{r\theta}$, at the internal interface, and vanishing of the stress, $\tau_{r\theta}$, at the external surface.

The final set of equations for the extensional wave dispersion relation involves nine equations with nine unknowns. The nine unknowns are α_+ , α_- , α_s (coefficients of J_0 in the central cylinder), plus three α^* 's (coefficients of J_0) and three η^* 's (coefficients of Y_0) for region of the cylindrical shell. The nine equations are the continuity of radial and one tangential stress as well as radial and one tangential displacement at the interfacial boundary (totaling four conditions), continuity of fluid pressure and normal fluid increments across the same boundary (two conditions), and finally the vanishing of the external fluid pressure, and radial and one tangential stress at the free surface (three conditions). The extensional wave dispersion relation is then determined as in Berryman⁸ by those conditions on the wave number k_z that result in vanishing of the determinant of the coefficients of this 9×9 complex matrix.

V. ELEMENTARY TORSIONAL MODES

The torsional mode of cylinder oscillation (which is trivial for a simple cylinder, porous or not) is determined here by a 3×3 system, of which eight elements are in general nonzero. This system is therefore similar in size and difficulty to the cases studied earlier by Berryman⁸ for extensional waves in a simple fully saturated poroelastic cylinder. On the other hand, for extensional waves, the matrix determining the extensional wave dispersion relation for patchy saturation has 81 elements, of which 69 will in general be nonzero. This problem requires sufficiently different treatment from that for the torsional case that we set it aside to be studied fully in a separate presentation (Part II).

We assume that the cylinder has liquid saturation level $S = (R_1/R_2)^2$, where R_2 is the radius of the cylinder and $r = R_1$ is the location of the liquid–gas interface (see Sec. IV and Fig. 1). The dispersion relation for torsional waves is then given by

$$\begin{vmatrix} m_{11}^*(R_2) & n_{11}^*(R_2) & 0 \\ -m_{11}^*(R_1) & -n_{11}^*(R_1) & m_{11}(R_1) \\ -m_{21}^*(R_1) & -n_{21}^*(R_1) & m_{21}(R_1) \end{vmatrix} = 0, \quad (61)$$

where m_{11} and m_{21} are given by (32) and (60). The coefficients m_{11}^* and m_{21}^* have the same functional forms as m_{11}

and m_{21} , but the constants are those for the shell, rather than the inner cylinder. Similarly, n_{11}^* and n_{21}^* are just the same as m_{11}^* and m_{21}^* except that J_0 and J_1 are replaced everywhere by Y_0 and Y_1 , respectively.

Analysis proceeds by noticing immediately that there could be two elementary solutions of (61), one with $m_{11}^*(R_2) = n_{11}^*(R_2) = 0$ (exterior condition) and another with $m_{11}(R_1) = m_{21}(R_1) = 0$ (interior condition). First, the interior condition is satisfied, for example, when $k_{sr} = 0$ or, equivalently, when $k_z^2 = k_s^2$. This corresponds to a torsional mode of propagation having wave speed and attenuation determined exactly by the bulk shear wave number in the saturated interior region, but this interior region is not moving since $k_{sr} = 0$ also implies that $u_\theta = 0$ from (60). Thus, the interior condition results in the drained outer shell twisting back and forth around a stationary inner liquid-saturated cylinder. Second, the exterior condition is similarly satisfied when $k_{sr}^* = 0$ or, equivalently, when $k_z^2 = (k_s^*)^2$. This condition looks at first glance as if it might be spurious because $k_{sr}^* = 0$ suggests that u_θ at the exterior boundary might vanish identically, and then this would correspond to a trivial solution of the equations. However, looking closer, this is not the case, because at the external boundary

$$u_\theta = k_{sr}^* [J_1(j_s^*) \gamma_s^* + Y_1(j_s^*) \epsilon_s^*], \quad (62)$$

so as $k_{sr}^* \rightarrow 0$, the first term on the right-hand side of (62) does vanish, both because $k_{sr}^* \rightarrow 0$ and also because $J_1(j_s^*) \rightarrow 0$. But the second term does not vanish in this limit because $|Y_1(j_s^*)| \rightarrow 2/\pi k_{sr}^* R_2 \rightarrow \infty$ as $k_{sr}^* \rightarrow 0$, and the product gives the finite result: $2/\pi R_2$. So this condition is not spurious and corresponds to a torsional wave propagating with the speed and attenuation of the bulk shear wave number in the outer, drained shell material.

Can both of these elementary modes be excited? If we assume for the moment that Gassmann's equations²³ (also see Berryman³⁸) apply to the sample, then $\mu^* = \mu$, and the only changes in shear wave velocity in the two regions are those induced by the changes in mass. In this situation, the wave speed in the air/gas-saturated region will be faster than that in the water/liquid-saturated region, since liquid is more dense than gas. Thus, the real part of k_s^* is smaller than that of k_s , and while the condition $(k_{sr}^*)^2 = 0$ implies that the real part of k_{sr}^* is positive, the condition $k_z^2 = 0$ implies that the real part of $(k_{sr}^*)^2$ is negative. Therefore, assuming (as we generally do here) that the attenuation in the system is relatively small, the condition $k_z = k_s^*$ leads to a propagating wave, while $k_z = k_s$ leads to a strongly evanescent wave. Thus, for Gassmann conditions on shear, only one of these possible modes actually propagates.

Note that, if/when Gassmann's results do not apply to the system (say at ultrasonic frequencies^{17–19,39}), then the results of the preceding paragraph must necessarily be reconsidered. In particular, if the shear modulus changes rapidly with the introduction of liquid saturant, it is possible that the shear wave speed for a liquid-saturated porous material may be higher than that for the gas saturated case. In this situation, all the inequalities of the preceding paragraph would be reversed, and then the condition $k_z = k_s$ leads to a propagating wave, while $k_z = k_s^*$ leads to a strongly evanescent wave.

TABLE I. The zeroes $j_{2,n}$ of $J_2(z)$ as a function of the order n of appearance along the real axis.

Order n	$j_{2,n}$
0	0.000 000 000 000 00
1	5.135 622 301 840 68
2	8.417 244 140 399 87
3	11.619 841 172 149 06

Our conclusion then is that both modes can indeed be excited, but probably not simultaneously in the same system and/or in the same frequency band. In a highly dispersive porous system and with broadband acoustic signal input, it could happen that both modes are propagating simultaneously in time, but in distinct/disjoint frequency bands.

VI. HIGHER ORDER TORSIONAL MODES

For fully saturated porous cylinders, the factor that determines the torsional modes of propagation is $m_{11}(r)$ in (32). The critical factor here is the Bessel function $J_2(j_s)$ and, specifically, the whereabouts of its zeroes. One source of this information, to five figure accuracy, is the reference of Abramowitz and Stegun,⁴⁰ which provides not only the location of the zeroes $j_{2,n}$, but also the values of the corresponding derivatives $J_2'(j_{2,n})$. Having these derivatives is useful for improving the accuracy of the zeroes with a Newton–Raphson iterative method, based on $j_{2,n} = j_{2,n}^{old} - J_2(j_{2,n}^{old})/J_2'(j_{2,n}^{old})$. This approach gives a very rapid improvement to the values of the $j_{2,n}$'s within two to three iterations. The results to order $n=3$ are shown in Table I.

Having already understood the zeroth-order contributions to the dispersion relation (61) due to zeroes of k_{sr} and k_{sr}^* , we are now free to consider that neither of these factors vanishes for the higher-order modes. This assumption permits us to factor these wave numbers in or out of the determinant whenever it is convenient to do so. In particular, we note that the first two columns of (61) would have a common factor of $\mu^*(k_{sr}^*)^2$ (which could then be safely eliminated) if we first multiply the bottom row by a factor of $\mu^*k_{sr}^*$. Having made these simplifications, we find

$$\begin{vmatrix} J_2(k_{sr}^*R_2) & Y_2(k_{sr}^*R_2) & 0 \\ J_2(k_{sr}^*R_1) & Y_2(k_{sr}^*R_1) & \mu k_{sr} J_2(k_{sr}R_1) \\ J_1(k_{sr}^*R_1) & Y_1(k_{sr}^*R_1) & \mu^*k_{sr}^*J_1(k_{sr}R_1) \end{vmatrix} = 0, \quad (63)$$

after also eliminating a common factor of -1 from the top row, and $-k_{sr}$ from the third column.

Expanding the determinant along the third column, we have

$$0 = \mu^*k_{sr}^*J_1(k_{sr}R_1) \begin{vmatrix} J_2(k_{sr}^*R_2) & Y_2(k_{sr}^*R_2) \\ J_2(k_{sr}^*R_1) & Y_2(k_{sr}^*R_1) \end{vmatrix} - \mu k_{sr} J_2(k_{sr}R_1) \begin{vmatrix} J_2(k_{sr}^*R_2) & Y_2(k_{sr}^*R_2) \\ J_1(k_{sr}^*R_1) & Y_1(k_{sr}^*R_1) \end{vmatrix}. \quad (64)$$

Some elementary consequences of this equation are the following. (a) As $R_1 \rightarrow 0$ so there is no liquid left in the system,

$J_1(k_{sr}R_1)$ and $J_2(k_{sr}R_1) \rightarrow 0$ like R_1 , while $Y_1(k_{sr}^*R_1)$ and $Y_2(k_{sr}^*R_1) \rightarrow \infty$ like $1/R_1$. So the dispersion relation is always satisfied in the limit when $J_2(k_{sr}^*R_2) = 0$, which is exactly the condition for the fully dry cylinder as expected. (b) If $R_1 \rightarrow R_2$, then the first determinant vanishes identically. The second determinant does not vanish in general since it approaches the Wronskian $J_2Y_1 - J_1Y_2 = 2/\pi k_{sr}^*R_2$, so the condition becomes $k_{sr}J_2(k_{sr}R_1) = 0$, again as expected. (c) The special case of $k_{sr} \rightarrow 0$ does not affect these conclusions, as both $J_1(k_{sr}R_1)$ and $J_2(k_{sr}R_1) \rightarrow 0$ in this limit, as they should. (d) The only case that is missing from (64) is the one for $k_{sr}^* \rightarrow 0$. But this multiple zero of the original dispersion relation (61) was eliminated when we removed two factors of $(k_{sr}^*)^2$ from the first and second column in the first step of our simplification of the dispersion relation – a step which is always legitimate *except* when $k_{sr}^* = 0$.

We conclude that, with the one trivial exception just noted, these simplifications have kept the basic nature of the dispersion relation intact.

A. Lower frequency results

At lower frequencies in the range $f < 1$ kHz, we may typically expect^{18,41,42} that Gassmann's results hold for the poroelastic medium, where $\mu^* \equiv \mu$. Also, to a very good approximation $k_s^* \simeq k_s$, where the only deviations from equality are those due to the differences in the densities of liquid and gas constituents. So deviations from this approximation are most substantial when the porosity is high. From (63), we see that if the products μk_{sr} and $\mu^*k_{sr}^*$ are equal, then these factors can be removed from the third column of the determinant. Then, the resulting third column can be subtracted from the first column, and the result can be expanded along the first column to give

$$\frac{2J_2(k_{sr}R_2)}{\pi k_{sr}R_1} \simeq 0, \quad (65)$$

having again used the fact that $J_2(z)Y_1(z) - J_1(z)Y_2(z) = 2/\pi z$. So the important zeroes in this case are again those of J_2 , some of which are already displayed in Table I.

Ignoring the imaginary part of k , which is usually quite small in this limit, we have the analytical result that

$$v_z^{(n)} = \frac{v_s}{[1 - (j_{2,n}v_s/\omega R_2)^2]^{1/2}}. \quad (66)$$

Thus, at the higher frequencies, this velocity approaches that of the shear wave as expected. When the lower frequencies are approached, there is an obvious cutoff frequency, $f_c^n = j_{2,n}v_s/2\pi R_2$, below which these torsional modes do not propagate for $n \geq 1$. Since this low-frequency cutoff may often be inconsistent with the assumption under consideration here (i.e., that frequencies are low enough so Gassmann's equation is satisfied), we expect generally that very few of the higher-order modes can be excited in this limit. The main result is therefore that $v_z = v_z^0 = v_s$ is the velocity that will normally be observed in laboratory experiments in this frequency domain, with only very rare exceptions. Recent experimental findings of Wisse *et al.*,⁴³ although for a somewhat different physical problem, nevertheless seem to be consistent with these results.

FIG. 2. Shear wave velocities as a function of water saturation for drainage experiments by Murphy.^{44,45}

We will not consider this rather special case any further in this paper.

B. Higher-frequency results

The more interesting case is that for higher frequencies, in which case it is now understood^{18,41,42} that the simple Biot–Gassmann theory is actually inadequate because there can be dependence of μ on liquid saturant properties at higher frequencies, in the range $f > 1$ kHz. The precise frequency at which this becomes important is material dependent and, therefore, the value 1 kHz is merely a convenient rule of thumb, but it is generally observed that for ultrasonic frequencies $f > 20$ kHz some deviations from Biot–Gassmann predictions are normally found. So it is in this regime that the distinctions between air- and water-filled pores become important for the torsional motion of a cylinder.

1. Case: $\mu^* = \mu$

Even if there is no difference between μ^* and μ , there can still be significant differences between k_s^* and k_s due to the differences in the fluid viscosities and densities of liquid and gas constituents. So we discuss this case now. For Massillon sandstone, Murphy^{44,45} measured extensional and shear wave velocities at $f = 560$ Hz and at $f = 200$ kHz over a range of partial saturations produced using the drainage method (Fig. 2). Relevant properties of this sandstone are listed in Table II. Data for the lower-frequency (560 Hz) experiment appear to satisfy the condition $\mu^* = \mu$, as has often been observed about this data set.

TABLE II. Properties of Massillon sandstone used in Murphy’s experiments¹¹ and Spirit River sandstone in Knight and Nolen-Hoeksema’s experiments.¹³

Property	Massillon	Spirit River
Porosity (%)	23.0	5.2
Permeability (mD)	7.37×10^2	1.0×10^{-3}
Grain size (μm)	150–200	125–150

FIG. 3. Shear wave velocities as a function of water saturation for drainage experiments by Murphy⁴⁴ in Sierra White granite.

2. Case: $\mu^* \leq \mu$

The presence of liquid in the pores may alter the mechanical behavior of rocks under shear deformations in at least two quite distinct ways: (a) It is often observed that a very small amount of some liquids can cause chemical interactions that tend to soften the binding material present among the grains of such a system. When this happens, the shear modulus is usually observed to decrease. (See, for example, Fig. 3 for Sierra White granite.⁴⁴) So this situation implies that $\mu^* \geq \mu$, contrary to both Gassmann’s results and the stiffening effect that might be expected due to having liquid in the pores. Although this situation is well known in practice, we will ignore it in our modeling efforts. Our justification for this will be that the medium we are calling “dry” should in fact be termed “drained” (but with the bulk of the liquid actually removed from the pores) in the sense that it has been wetted previously and therefore has these chemical softening effects already factored into the modulus μ^* . In any case, our goal here is not so much to fit data for specific rocks, but rather to understand general trends. (b) The other situation that can also occur in practice—particularly at higher frequencies—is that the liquid saturating the porous material can have a non-negligible mechanical effect^{17–19,42,46} that tends to strengthen the medium under shear loading so that $\mu \geq \mu^*$. If this strengthening effect is great enough [and there are experimental results (see Fig. 4) that confirm this does happen in practice¹⁸], then it is possible the density effect is more than counterbalanced by the enhanced shear modulus effect with the result that the speed of shear wave propagation in the liquid-saturated medium is greater than that in the air-saturated case. Depending on details of the liquid distribution in the pores, either of these cases can be included in the analysis.

For Massillon sandstone, Murphy^{44,45} also measured extensional and shear wave velocities at $f = 200$ kHz over a range of partial saturations produced using the drainage method. Relevant properties of this sandstone were listed before in Table II.

VII. SOLVING THE DISPERSION RELATION

We will now show results for two cases (both from Murphy’s thesis⁴⁴): first the Massillon sandstone (at 560 Hz) and

FIG. 4. Shear wave velocities as a function of water saturation for drainage experiments of Knight and Nolen-Hoeksema¹³ in Spirit River sandstone.

then the Sierra White granite (at about 200 kHz). We might expect based just on the experimental frequencies that the sandstone behavior would be close to that predicted by Gassmann, while that of the granite may differ from Gassmann.

An important observation concerning how to proceed with the analysis follows from the fact that we are seeking a curve in the complex plane, points along the curve depending on the level of saturation S . We know (at least in principle) the locations of the end points of this curve since they are exactly the points for full liquid saturation and full gas saturation. If we assume that the attenuation is relatively small so the wave numbers k_s and k_s^* have small imaginary parts, then to a reasonable approximation it must be the case that the curve of interest lies close to the real axis in the complex k_z^2 plane. If the imaginary parts exactly vanish, the curve reduces to a straight line on the real axis in this plane. These observations suggest that it might be helpful to trace rays in the complex plane radiating out from the origin, and in particular a ray (i.e., a straight line) passing through the origin and also through the point corresponding to whichever point, k_s^2 or $(k_s^*)^2$, happens to lie closest to the origin should provide a good starting point for the analysis. Another alternative is to consider the straight line that connects these two points directly, even though it would not in general also be a ray through the origin (unless there is no attenuation). Both of these alternatives have been tried.

The first alternative, considering a complex ray through the origin and then passing through the closest point k_s^2 or $(k_s^*)^2$, has the very important characteristic that the values of the dispersion function become purely imaginary in the shadow (i.e., in the contiguous region leading away from the origin) of the starting point of the curve. This fact provides a great simplification because we need the dispersion function to vanish identically—both in real and imaginary parts, and this shadow region has the nice characteristic that the real part is automatically zero. So the only remaining issue is to check where the imaginary part vanishes. This procedure is much easier to implement and to understand intuitively than trying to find the complex zeroes using something like a Newton method, which could also be implemented for this problem.

FIG. 5. Showing how the imaginary parts of the dispersion relation for Massillon sandstone change in the complex k_z^2 plane as k_z varies from k_{sa} to k_{sw} . The real part of the dispersion relation is either zero or very close to zero along this line and therefore the desired points are those where the imaginary part crosses the zero line.

The second alternative is not as rigorous as the first, but for the case of small attenuation gives very similar results and is especially easy to implement. In this case we need only consider the line connecting the two points k_s^2 and $(k_s^*)^2$ in the complex plane. It turns out that in the two cases considered here, the real part of the dispersion function is again either zero or very small, so that it makes sense to treat this approach as an approximation to the first one in that we need only seek the points where the imaginary part vanishes. This procedure is very intuitive and examples are shown in Figs. 5–8.

A. Massillon sandstone

For Massillon, we have the Gassmann-like situation in which the shear wave speed for the drained case is smaller

FIG. 6. Comparison between the points that solve the dispersion relation for the patchy cylinder, plotted as $\rho/\mu = 1/v_s^2$ versus water saturation S , for Massillon sandstone at 560 Hz. Data are from Murphy.^{44,45} The Gassmann curve is computed assuming that the shear modulus μ is constant and that the only quantity changing is therefore the density ρ .

FIG. 7. Showing how the imaginary parts of the dispersion relation for Sierra white granite change in the complex k_z^2 plane as k_z varies from k_{sd} to k_{sw} . The real part of the dispersion relation is either zero or very close to zero along this line and therefore the desired points are those where the imaginary part crosses the zero line.

than that for the fully saturated case and therefore $\text{Re}(k_s^*) < \text{Re}(k_s)$. Figure 5 shows how the imaginary parts of the dispersion function change in this case as the real part of k_z^2 varies from $\text{Re}[(k_s^*)^2]$ to $\text{Re}(k_s^2)$ (i.e., from air saturated to water saturated). Figure 5 shows four of these curves ($S = 0.2$ to 0.8). Figure 6 was generated by completing the procedure for 19 equally spaced points in saturation S . Figure 6 shows, furthermore, that the curve obtained actually fits the data for Massillon better than does Gassmann (i.e., represented by the straight line between the end points). This result was a bit of a surprise as virtually everyone (including

FIG. 8. Comparison between the points that solve the dispersion relation for the patchy cylinder, plotted as $\rho/\mu = 1/v_s^2$ versus water saturation S , for Sierra White granite at 200 kHz. Data are from Murphy.^{44,45} For Sierra White, Gassmann's equation clearly does not apply since the shear modulus μ must have increased with water saturation. Data and patchy calculation results are therefore compared to the saturation weighted average of $1/v_s^2$ in analogy to the Gassmann result.

the present authors) has often considered these data to be the best known proof of the accuracy of Gassmann's equations for partial saturation problems.

In fact, we could have chosen to fit the data better in the region close to full saturation. This choice would have moved the two theoretical curves down somewhat, but nevertheless this would not change our general conclusions that the data do not fall on a straight line, and that the trend in the data is more closely approximated by the patchy saturation curve. The slope of the Gassmann straight line depends only on the solid and fluid densities, and (except for a fixed scale factor) not on the shear modulus of the porous solid.

B. Sierra White granite

For Sierra White (data from Murphy⁴⁴), we have the non-Gassmann-like situation in which the shear wave speed for the drained case is larger than that for the fully saturated case and therefore $\text{Re}(k_s^*) > \text{Re}(k_s)$. Figure 7 shows how the imaginary parts of the dispersion function change in this case as the real part of k_z^2 varies from $\text{Re}(k_s^2)$ to $\text{Re}[(k_s^*)^2]$ (i.e., from water saturated to air saturated). Figure 7 shows four of these curves ($S = 0.2$ to 0.8). Figure 8 was generated by completing the procedure for 19 equally spaced points in saturation S . Figure 8 shows, furthermore, that both data and the curve obtained here differ substantially from the simple straightline average that might have been anticipated. Furthermore, the dispersion curve does in fact move in the right direction to agree with the data. What to expect in this situation was certainly not known by the authors at the outset since the common understanding of poroelasticity does not extend to this rather difficult set of partial saturation problems. But, it is gratifying to see this relatively simple theory clearly picks the right trends and agrees reasonably well with these data.

C. General behavior of the curves

Since the curves obtained in Figs. 6 and 8 are very well behaved, it seems appropriate to check for simple dependencies on the saturation parameter S . Both curves look like they might be linear in S with a small amplitude quadratic correction. This hypothesis is tested in Figs. 9 and 10. We find that the quadratic dependence is essentially exact to graphical accuracy for Massillon sandstone, and it is close but not exact for the Sierra White granite. This result is intriguing, but we have not yet tried to analyze this behavior and therefore will not attempt an explanation of it at this time.

VIII. SUMMARY

Biot fast- and slow-wave effects in layered materials have been studied previously by Pride *et al.*⁴⁷ and by many others found in their references. The present work is motivated by the desire to understand how fluids interacting with common poroelastic systems may result in observed wave speeds and viscous attenuation in partially saturated (and especially in patchy saturated) cylinders. These effects can then be observed in the speeds and attenuations of extensional and torsional waves. There are large quantities of such data al-

FIG. 9. Comparison between the points that solve the dispersion relation in the complex k_z^2 plane and a simple quadratic fit in water saturation S , for the Massillon sandstone measured by Murphy.^{44,45} The fit is nearly perfect for this case.

ready available, and one thrust of our future work will be to reanalyze these data in light of the methods developed here. We have concentrated on analysis of the shear and torsional wave speeds here, as this is clearly the first essential step in the overall analysis of these problems. The next step will be the more complicated solution of the extensional wave problem for these same systems.

ACKNOWLEDGMENTS

We thank Bill Murphy and Rosemarie Knight for providing access to their unpublished data files. We thank Brad Artman for helpful comments on the manuscript. The work of JGB was performed under the auspices of the U.S. Department of Energy under contract No. W-7405-ENG-48 and supported specifically by the Geosciences Research Program of the DOE Office of Basic Energy Sciences, Division of Chemical Sciences, Geosciences and Biosciences. The work of SRP was supported by the Director, Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy under Contract No. DE-AC03-76F00098.

FIG. 10. Comparison between the points that solve the dispersion relation in the complex k_z^2 plane and a simple quadratic fit in water saturation S , for the Sierra White granite measured by Murphy.^{44,45} The fit is also good for this case, but not as good as it was for Massillon sandstone.

A first-order statistical smoothing approximation for the coherent wave field in random porous media

Tobias M. Müller^{a)} and Boris Gurevich^{b)}

Department of Exploration Geophysics, Curtin University^{c)} GPO Box U1987, Perth,
Western Australia 6845, Australia

(Received 6 October 2004; revised 24 November 2004; accepted 26 January 2005)

An important dissipation mechanism for waves in randomly inhomogeneous poroelastic media is the effect of wave-induced fluid flow. In the framework of Biot's theory of poroelasticity, this mechanism can be understood as scattering from fast into slow compressional waves. To describe this conversion scattering effect in poroelastic random media, the dynamic characteristics of the coherent wavefield using the theory of statistical wave propagation are analyzed. In particular, the method of statistical smoothing is applied to Biot's equations of poroelasticity. Within the accuracy of the first-order statistical smoothing an effective wave number of the coherent field, which accounts for the effect of wave-induced flow, is derived. This wave number is complex and involves an integral over the correlation function of the medium's fluctuations. It is shown that the known one-dimensional (1-D) result can be obtained as a special case of the present 3-D theory. The expression for the effective wave number allows to derive a model for elastic attenuation and dispersion due to wave-induced fluid flow. These wavefield attributes are analyzed in a companion paper. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1871754]

I. INTRODUCTION

Understanding elastic wave attenuation and dispersion in porous fluid-saturated materials is important in such diverse applications as architectural acoustics, soil and rock mechanics, and exploration seismology. One major cause of elastic wave attenuation is viscous dissipation due to the flow of the pore fluid induced by the passing wave. Wave-induced fluid flow occurs as a passing wave creates local pressure gradients within the fluid phase and the resulting fluid flow is accompanied with internal friction until the pore pressure is equilibrated. The fluid flow can take place on various length scales: for example, from compliant fractures into the equant pores (so-called squirt flow^{1–3}), or between mesoscopic heterogeneities like fluid patches in partially saturated rocks.^{4–7}

Theoretical studies of the elastic wave attenuation due to wave-induced flow go back to the 1970s. In such studies wave propagation in an inhomogeneous porous medium is usually analyzed using Biot's equations of poroelasticity with spatially varying coefficients.⁸ The first models of attenuation due to wave-induced flow considered flow caused by a regular assemblage of inhomogeneities of ideal shape such as two concentric spheres or flat slabs.^{9–11} A general theory of wave propagation in heterogeneous porous media using the double-porosity approach was recently developed by Pride and Berryman¹² and Pride *et al.*¹³ In the case of patchy saturation, the results of this theory coincide with those obtained earlier by Johnson¹⁴ using a slightly different method. Although mathematical formulations in the theories Pride and Berryman¹² and Johnson¹⁴ allow for arbitrary geometry of the inhomogeneities, closed-form expressions for

attenuation and phase velocity can only be obtained for a regular system of simple geometrical shapes such as concentric spheres.

In real rocks heterogeneities are more likely to be spatially distributed in a random fashion. Therefore, it is desirable, as suggested by Lopatnikov and Gurevich,¹⁵ to model wave-induced flow using the theory of waves in random media.¹⁶ For one-dimensional (1-D) porous media, Gurevich and Lopatnikov¹⁷ showed that elastic wave attenuation in a randomly layered porous medium differs significantly from attenuation in periodically layered porous media.^{10,18} This suggests that the effects of three-dimensional inhomogeneities on elastic wave wave attenuation and dispersion in porous media may also be different for random and periodic spatial configurations. One approach to this problem is to consider a homogeneous porous medium with randomly distributed discrete, regularly shaped 3-D inclusions. However, so far only the attenuation due to conversion scattering at spherical inclusions from fast P waves into Biot's slow P wave is known.¹⁹

Our purpose in this paper is to analyze the effect of wave-induced fluid flow on the dynamic characteristics of coherent elastic waves propagating in a porous medium whose properties are continuous random functions of position. Our approach is based on the statistical wave theory, as applied to Biot's equations of poroelasticity.⁸ We restrict our analysis to the case of mesoscopic inhomogeneities, that is, inhomogeneities whose characteristic size a is much larger than the typical size of pores or grains a_{pore} but, at the same time, much smaller than the wavelength of the propagating elastic wave, λ :

$$a_{\text{pore}} \ll a \ll \lambda. \quad (1)$$

In other words, we ignore pore-scale heterogeneities, which

FIG. 1. Sketch of a heterogeneous porous medium where only the bulk modulus of the drained-framework-of-grains fluctuates. The homogeneous background medium is characterized by the bulk modulus K_d^B . There are inhomogeneities with higher bulk moduli, that is $K_d^{(1)} > K_d^B$, and other inhomogeneities with lower bulk modulus, $K_d^{(2)} < K_d^B$. The inhomogeneities have a length scale of a that is much larger than the typical pore scale a_{pore} . During the compression cycle of a wave there will be fluid flow from inhomogeneities with $K_d^{(2)}$ into the background and flow from the background into inhomogeneities with $K_d^{(1)}$. During the extension cycle of the wave the fluid flow becomes reversed.

allows the application of Biot's equations for a poroelastic continuum.⁸ We model wave propagation in the inhomogeneous porous medium using Biot's equations of poroelasticity with randomly varying coefficients (see Fig. 1). By using a Green's function approach, these partial differential equations transform into a system of integral equations. This latter system is solved by means of the method of statistical smoothing which is widely used in problems of electromagnetic, acoustic, and elastic wave propagation.^{20–22} More precisely, we employ a first-order statistical smoothing approximation that sometimes is referred to as a Bourret approximation.^{16,23} For poroelastic media, this method was earlier employed to compute P -wave attenuation and dispersion due to conversion scattering from fast P waves into Biot's slow waves in a randomly layered porous medium.¹⁷ We follow this strategy and analyze the conversion scattering from fast P waves into Biot's slow wave in 3-D randomly inhomogeneous porous media. Biot's slow wave is a highly dissipative wave mode. Therefore, the use of the first-order statistical smoothing approximation to the conversion scattering problem in Biot's equations of poroelasticity quantifies the dissipation of wave field energy due to energy transfer from the coherent component of the fast P wave into the dissipative slow P -wave mode. This is different from the usual application of the method of smoothing to energy conserving wave systems, where an apparent dissipation (so-called scattering attenuation) results from the energy transfer from the coherent component of the wave field into the incoherent component.

In light of previous results for randomly layered porous media, it is useful to introduce some simplifications from the outset. First of all, we restrict our analysis to low frequencies. Specifically, we assume that frequency ω is much

smaller than the critical Biot frequency $\omega_B = \phi \eta / \kappa_0 \rho_f$:

$$\omega \ll \omega_B, \quad (2)$$

where ϕ and κ_0 denote the porosity and permeability of the composite material, while ρ_f and η are the density and viscosity of the pore fluid. Condition (2) implies that the standard Biot's visco-inertial attenuation and dispersion (the so-called Biot's global flow mechanism) is neglected and the P wave number k_p is real. Furthermore, at low frequencies the slow wave is much slower than the fast P wave and therefore the ratio of k_p to slow P wave number k_{ps} is a small parameter:

$$\frac{|k_p|}{|k_{ps}|} \ll 1. \quad (3)$$

Wherever applicable we make use of relation (3), being aware of the underlying low-frequency assumption.

The strategy of this paper is as follows. First, we apply the method of Green's functions to Biot's equations of poroelasticity in order to represent the wavefield due to point source excitation (Sec. II). Next, we derive an integral wavefield representation for the case when the coefficients in Biot's equations exhibit a randomly fluctuating component. This wavefield representation (also called the scattering equation) is then converted into an integral equation for Green's function for the inhomogeneous medium. In Sec. III we apply a perturbation method to compute an approximation for the mean of the Green's function. From this Green's function we derive and analyze an explicit expression for the effective, complex P wave number that accounts for the conversion scattering from P into slow P waves. The range of applicability of our theory is analyzed in Sec. IV. Finally, in Sec. V we show how the results of the aforementioned 1-D theory can be recovered as a limiting case of the more general 3-D theory. A detailed analysis of attenuation and dispersion as functions of frequency and the potential applicability of these wavefield signatures to interpret the effect of wave-induced flow in real rocks is presented in a companion paper.²⁴

II. FORMULATION OF THE POROELASTIC SCATTERING PROBLEM

A. Green's function approach for Biot's equations of poroelasticity

In order to study dynamic effects of elastic wave propagation in porous media, we base our analysis on Biot's equation of poroelasticity.⁸ Using index notation—summation over repeated indices is assumed and partial derivatives are denoted as $_{,i}$ or ∂_i —we can write the equations of motion in the frequency domain (the time-harmonic dependency $\exp(-i\omega t)$ is omitted),

$$\rho \omega^2 u_i + \rho_f \omega^2 w_i + \tau_{ij,j} = 0, \quad (4)$$

$$\rho_f \omega^2 u_i + q \omega^2 w_i - p_{,i} = 0, \quad (5)$$

where τ_{ij} is the total stress tensor, p the fluid pressure, while u_i and w_i are the components of the solid and relative fluid displacement vectors, respectively. The relative fluid displacement is defined as $w_i = \phi(U_i - u_i)$, where is U_i the

fluid displacement. The densities of the solid and fluid phase are denoted by ρ_g and ρ_f so that the bulk density is given by $\rho = \phi\rho_f + (1 - \phi)\rho_g$, where ϕ is porosity. The parameter q is defined as $q = i\eta/(\omega\kappa_0)$, where η is viscosity and κ_0 permeability. We note that this definition of q is a consequence of the low-frequency assumption (2).

In order to obtain a closed system of wave equations in the displacements u_i and w_i , we complement the equations of motion with the stress-strain relations for an isotropic poroelastic medium,⁸

$$\tau_{ij} = G[u_{i,j} + u_{j,i} - 2\delta_{ij}u_{j,j}] + \delta_{ij}[Hu_{j,j} + Cw_{j,j}], \quad (6)$$

$$p = -Cu_{j,j} - Mw_{j,j}. \quad (7)$$

Here G is the porous-material shear modulus, and H is the undrained, low-frequency P -wave modulus given by Gassmann's equation:

$$H = P_d + \alpha^2 M, \quad (8)$$

where

$$M = [(\alpha - \phi)/K_g + \phi/K_f]^{-1}. \quad (9)$$

In Eqs. (8)–(9), $P_d = K_d + 4/3G$ is the P -wave modulus of the drained frame, $\alpha = 1 - K_d/K_g$ is the Biot–Willis coefficient, $C = \alpha M$, and K_g , K_d , and K_f denote the bulk moduli of the solid phase, the drained frame, and the fluid phase, respectively. Symbol δ_{ij} is Kronecker's delta (the identity tensor).

It is expedient to write the above system of coupled wave equations in matrix form:

$$\begin{bmatrix} L_{ik}^{(1)} & L_{ik}^{(2)} \\ L_{ik}^{(3)} & L_{ik}^{(4)} \end{bmatrix} \cdot \begin{bmatrix} u_k \\ w_k \end{bmatrix} = \mathbf{0}, \quad (10)$$

where we defined the linear differential operators as follows:

$$L_{ik}^{(1)} = \rho\omega^2\delta_{ik} + \partial_j G[\delta_{jk}\partial_i + \delta_{ik}\partial_j - 2\delta_{ij}\partial_k] + \partial_i H\partial_k, \quad (11)$$

$$L_{ik}^{(2)} = \rho_f\omega^2\delta_{ik} + \partial_i C\partial_k, \quad (12)$$

$$L_{ik}^{(3)} = L_{ik}^{(2)}, \quad (13)$$

$$L_{ik}^{(4)} = q\omega^2\delta_{ik} + \partial_i M\partial_k. \quad (14)$$

Note that in inhomogeneous media all the poroelastic parameters are functions of position. In the presence of point sources, the right-hand side of Eq. (10) can be written as

$$-\begin{bmatrix} F_i^0 \delta(r_i - r'_i) \\ f_i^0 \delta(r_i - r'_i) \end{bmatrix}, \quad (15)$$

where F_k^0 and f_k^0 represent constant forces applied to the bulk and fluid phase, respectively, and $\delta(r_i - r'_i)$ denotes the Dirac delta function. The response of system (10) to point sources of the form (15) can be formulated as²⁵

$$\begin{bmatrix} u_i \\ w_i \end{bmatrix} = \begin{bmatrix} G_{ik}^F & G_{ik}^f \\ G_{ik}^f & G_{ik}^w \end{bmatrix} \cdot \begin{bmatrix} F_k^0 \\ f_k^0 \end{bmatrix}, \quad (16)$$

where G_{ik}^F , G_{ik}^f , and G_{ik}^w denote the Green's tensors. Thus, the point source response of system (10) in an isotropic unbounded medium is described by three Green's tensors. Explicit expressions for the G_{ik} 's for a homogeneous medium

are given by Pride and Haartsen²⁵ and reproduced in Appendix A. The wavefields observed at position \mathbf{r} due to arbitrary point sources F_i and f_i , applied at position \mathbf{r}' , can be expressed by a convolution equation of the form

$$\begin{bmatrix} u_i(\mathbf{r}) \\ w_i(\mathbf{r}) \end{bmatrix} = \int_{V'} d^3\mathbf{r}' \begin{bmatrix} G_{ik}^F(\mathbf{r} - \mathbf{r}') & G_{ik}^f(\mathbf{r} - \mathbf{r}') \\ G_{ik}^f(\mathbf{r} - \mathbf{r}') & G_{ik}^w(\mathbf{r} - \mathbf{r}') \end{bmatrix} \cdot \begin{bmatrix} F_k(\mathbf{r}') \\ f_k(\mathbf{r}') \end{bmatrix}. \quad (17)$$

On the basis of Eq. (17), we now derive a wavefield representation in a randomly inhomogeneous medium.

B. The basic scattering equation

In randomly inhomogeneous porous media, all poroelastic parameters can be presented as random fields $X(\mathbf{r})$. To be more specific, we assume that each of these poroelastic parameters is the sum of a constant background value, \bar{X} , and a fluctuating part, $\tilde{X}(\mathbf{r})$, so that

$$X = \bar{X} + \tilde{X} = \bar{X}(1 + \varepsilon_X), \quad (18)$$

where $\varepsilon_X = \tilde{X}/\bar{X}$ denotes the relative fluctuations. The average over the ensemble of the realizations (denoted by $\langle \cdot \rangle$) of ε_X is assumed to be zero: $\langle \varepsilon_X \rangle = 0$. The spatial correlation function of two random fields is defined as

$$B_{XX}(\delta\mathbf{r}) = \langle \varepsilon_X(\mathbf{r} + \delta\mathbf{r})\varepsilon_X(\mathbf{r}) \rangle, \quad (19)$$

where the dependence of B on the difference vector $\delta\mathbf{r}$ only is a consequence of the assumption of statistically homogeneous random fields,¹⁶ which we use throughout this paper. The variance of the random process ε_X will be denoted as $B_{XX}(0) = \langle \varepsilon_X^2 \rangle = \sigma_{XX}^2$. Using (18), the differential operators L_{ik} can be also decomposed as²¹

$$L_{ik} = \bar{L}_{ik} + \tilde{L}_{ik}, \quad (20)$$

where the perturbing operator \tilde{L}_{ik} satisfies $\langle \tilde{L}_{ik} \rangle = 0$. As is typical for statistical wave problems, in the following we assume that the constant part \bar{X} and statistical properties of the fluctuations ε_X are known. Therefore, rather than seeking the solution of Eq. (17) for a given realization ε_X , we seek statistical moments of the solution for given statistical properties of fluctuations.

The substitution of (20) into matrix equation (10) yields

$$\begin{bmatrix} \bar{L}_{ik}^{(1)} & \bar{L}_{ik}^{(2)} \\ \bar{L}_{ik}^{(2)} & \bar{L}_{ik}^{(4)} \end{bmatrix} \cdot \begin{bmatrix} u_k \\ w_k \end{bmatrix} = - \begin{bmatrix} \tilde{L}_{ik}^{(1)} & \tilde{L}_{ik}^{(2)} \\ \tilde{L}_{ik}^{(2)} & \tilde{L}_{ik}^{(4)} \end{bmatrix} \cdot \begin{bmatrix} u_k \\ w_k \end{bmatrix}, \quad (21)$$

In the most general case, the perturbing operators \tilde{L}_{ik} contain fluctuations of all poroelastic moduli and densities. The right-hand side of (21) can be thought of as a source term in the homogeneous system (10) due to the presence of inhomogeneities (so-called secondary sources). Thus, Eq. (21) can be understood as an inhomogeneous equation with constant coefficients, whose formal solution can be written by substituting the source term into Eq. (17):

$$\begin{bmatrix} u_i \\ w_i \end{bmatrix} = \begin{bmatrix} u_i^0 \\ w_i^0 \end{bmatrix} + \int_V dV \begin{bmatrix} G_{ij}^F & G_{ij}^f \\ G_{ij}^f & G_{ij}^w \end{bmatrix} \cdot \begin{bmatrix} \tilde{L}_{jk}^{(1)} & \tilde{L}_{jk}^{(2)} \\ \tilde{L}_{jk}^{(2)} & \tilde{L}_{jk}^{(4)} \end{bmatrix} \cdot \begin{bmatrix} u_k \\ w_k \end{bmatrix}. \quad (22)$$

Equation (22) is the basic poroelastic scattering equation. The total wavefields u_i and w_i are composed of wavefields propagating in the homogeneous background medium, u_i^0 and w_i^0 , and scattered wavefields (the second term). By definition, u_i^0 and w_i^0 satisfy the homogeneous equation (10). The scattered wavefields are represented by volume integrals whose kernels involve the Green's tensors and the secondary sources. The scattered wavefields vanish if there are no fluctuations in the medium parameters. The integration volume encompasses the inhomogeneous part of the medium, which in our case is the whole 3-D space. We note that Eq. (22) is closely related to the representation integral of the scattered field in an unbounded medium (for the poroelastic formulation of this theorem we refer to Norris²⁶ and Pride and Haartsen²⁵). According to Eq. (17), the wavefields can be represented as a convolution of Green's tensors with the source function. Let us denote Green's tensors for the homogeneous background medium by ${}^0G_{ik}^{F,f,w}$ and for the inhomogeneous medium by $G_{ik}^{F,f,w}$. Substituting these wavefield representations into Eq. (22), we obtain an equation for the Green's tensors of the inhomogeneous medium,

$$\begin{bmatrix} G_{im}^F & G_{im}^f \\ G_{im}^f & G_{im}^w \end{bmatrix} = \begin{bmatrix} {}^0G_{im}^F & {}^0G_{im}^f \\ {}^0G_{im}^f & {}^0G_{im}^w \end{bmatrix} + \int_V dV \begin{bmatrix} {}^0G_{ij}^F & {}^0G_{ij}^f \\ {}^0G_{ij}^f & {}^0G_{ij}^w \end{bmatrix} \cdot \begin{bmatrix} \tilde{L}_{jk}^{(1)} & \tilde{L}_{jk}^{(2)} \\ \tilde{L}_{jk}^{(2)} & \tilde{L}_{jk}^{(4)} \end{bmatrix} \cdot \begin{bmatrix} G_{km}^F & G_{km}^f \\ G_{km}^f & G_{km}^w \end{bmatrix}. \quad (23)$$

In order to simplify the equations that follow, we introduce a shorthand notation. The latter equation can be symbolically rewritten as

$$\mathbf{G} = \mathbf{G}^0 + \int \mathbf{G}^0 \tilde{\mathbf{L}} \mathbf{G}, \quad (24)$$

where \mathbf{G} , \mathbf{G}^0 , and $\tilde{\mathbf{L}}$ represent matrices, whose elements are tensors of rank two, and matrix multiplication rules apply. In (24) we also omitted the integration volume for brevity.

III. FIRST-ORDER STATISTICAL SMOOTHING OF BIOT'S EQUATIONS OF POROELASTICITY

A. Mean Green's tensor

We will now analyze Eq. (24) using a statistical approach. Since the matrix of perturbing operators $\tilde{\mathbf{L}}$ in Eq. (24) contains fluctuating medium parameters, the resulting matrix of Green's tensors also contains randomly fluctuating elements. Because individual realizations of the random wavefields are never known, it is natural to analyze the statistical moments of \mathbf{G} . Solving Eq. (24) by iteration we obtain the scattering series

$$\mathbf{G} = \mathbf{G}^0 + \int \mathbf{G}^0 \tilde{\mathbf{L}} \mathbf{G}^0 + \int \int \mathbf{G}^0 \tilde{\mathbf{L}} \mathbf{G}^0 \tilde{\mathbf{L}} \mathbf{G}^0 + \int \int \int \dots \quad (25)$$

Averaging this equation by the ensemble of realizations and regrouping the scattering terms yields

$$\bar{\mathbf{G}} = \mathbf{G}^0 + \int \int \mathbf{G}^0 \mathbf{Q} \bar{\mathbf{G}}, \quad (26)$$

where $\bar{\mathbf{G}} = \langle \mathbf{G} \rangle$ is the matrix of mean Green's tensors, and \mathbf{Q} is the matrix operator defined as

$$\mathbf{Q} = \begin{bmatrix} Q_{ik}^{(1)} & Q_{ik}^{(2)} \\ Q_{ik}^{(3)} & Q_{ik}^{(4)} \end{bmatrix} = \left\langle \tilde{\mathbf{L}} \mathbf{G}^0 \tilde{\mathbf{L}} + \int \tilde{\mathbf{L}} \mathbf{G}^0 \tilde{\mathbf{L}} \mathbf{G}^0 \tilde{\mathbf{L}} + \int \dots \right\rangle. \quad (27)$$

Operator \mathbf{Q} given by Eq. (27) corresponds to the kernel-of-mass operator in the acoustic formulation.¹⁶ The linear integral equation in $\bar{\mathbf{G}}$ [Eq. (26)] is the poroelastic analog of the Dyson equation (see also Gurevich and Lopatnikov,²⁷ where an analogous equation for the mean field is derived). It is not possible to obtain an exact solution of Eq. (26). A first-order statistical smoothing consists in the first-order truncation of the infinite series expression for the operator \mathbf{Q} . Then, we obtain the following approximation for the mean Green's tensor:

$$\bar{\mathbf{G}} = \mathbf{G}^0 + \int \int \mathbf{G}^0 \langle \tilde{\mathbf{L}} \mathbf{G}^0 \tilde{\mathbf{L}} \rangle \bar{\mathbf{G}} \quad (28)$$

$$= \mathbf{G}^0 + \int \int \mathbf{G}^0 \mathbf{Q}^B \bar{\mathbf{G}}. \quad (29)$$

The truncation of the series (27) implies that the first-order statistical smoothing is valid when $|\varepsilon_X| \ll 1$, i.e., when the absolute value of the relative fluctuations of X is a small parameter. Note also that the elements of matrix operator \mathbf{Q}^B only contain terms involving the second statistical moment of the fluctuating parts of the \tilde{L}_{ik} 's, that is, they are of the order $O(\varepsilon^2)$. Higher-order correlations are neglected within the accuracy of the first-order statistical smoothing approximation.

Since Eq. (29) contains a double volume convolution, it is expedient to work with its spatial Fourier transform:

$$\bar{\mathbf{g}} = \mathbf{g}^0 + (8\pi^3)^2 \mathbf{g}^0 \mathbf{q} \bar{\mathbf{g}}, \quad (30)$$

where $\bar{\mathbf{g}}$, \mathbf{g}^0 , and \mathbf{q} denote the spatial Fourier transforms of $\bar{\mathbf{G}}$, \mathbf{G}^0 , and \mathbf{Q}^B , respectively (see Appendix A for a definition of the Fourier transform pair). Equation (30) is of the same form as the equation for the mean Green's function in acoustic random media. However, in contrast to the acoustic case, Eq. (30) is not a simple algebraic equation for the mean Green's tensors, but a system of four tensorial equations for the three unknown mean Green's tensors. Formally, we can express the solution of (30) in the form $\bar{\mathbf{g}} = \mathbf{W}^{-1} \mathbf{g}^0$, where \mathbf{W}^{-1} is the inverse of the matrix $\mathbf{W} = \mathbf{I} - (8\pi^3)^2 \mathbf{g}^0 \mathbf{q}$ with the identity tensor \mathbf{I} . However, the computation of \mathbf{W}^{-1} is cumbersome. Instead, we are looking for a more feasible way to compute some elements of $\bar{\mathbf{g}}$. Carrying out the necessary matrix multiplications in (30), we find that this system splits up into two pairs of coupled equations. Since we are only interested in the characteristics of the fast P wave, which are exclusively contained in the Green's tensor \bar{g}^F [see also Eqs. (16) and (A1)], we analyze only those two equations that involve \bar{g}_{ik}^F . We obtain

$$\begin{aligned} \bar{g}^F = g^F + (8\pi^3)^2 [g^F q^{(1)} \bar{g}^F + g^F q^{(2)} \bar{g}^f + g^f q^{(3)} \bar{g}^F \\ + g^f q^{(4)} \bar{g}^f], \end{aligned} \quad (31)$$

$$\begin{aligned} \bar{g}^f = g^f + (8\pi^3)^2 [g^f q^{(1)} \bar{g}^F + g^f q^{(2)} \bar{g}^f + g^w q^{(3)} \bar{g}^F \\ + g^w q^{(4)} \bar{g}^f], \end{aligned} \quad (32)$$

where we omitted subscripts for brevity. The quantities g without an upper bar denote the background space Green's tensors. Since all quantities $q^{(i)}$ ($i=1, \dots, 4$) are of the order $O(\varepsilon^2)$, \bar{g}^f is also of the order $O(\varepsilon^2)$. Inserting the expression for \bar{g}^f [Eq. (32)] into Eq. (31) and neglecting terms of higher order than $O(\varepsilon^2)$, we obtain

$$\begin{aligned} \bar{g}^F = g^F + (8\pi^3)^2 [q^F q^{(1)} \bar{g}^F + g^F q^{(2)} g^f + g^f q^{(3)} \bar{g}^F \\ + g^f q^{(4)} g^f]. \end{aligned} \quad (33)$$

Equation (33) is an implicit equation for the mean Green's tensor \bar{g}^F . Because of its tensorial character, an explicit solution for \bar{g}^F is still difficult to construct. Note, however, that we are not interested in the mean Green's tensor itself but only in a mean P wave number contained in \bar{g}^F .

B. Effective wave number of the fast P -wave

In order to extract an effective wave number from Eq. (33) we have to introduce further simplifications. Because of the assumption of small fluctuations in the medium parameters ($\varepsilon \ll 1$), we can expect that the fluctuations of the wavefield are also small if the wavelengths are much larger than the size of the inhomogeneities. Then, we can assume that mean Green's tensor $\bar{g}_{ik}^F(\mathbf{K})$ is of the same functional form as a background Green's tensor $g_{ik}^F(\mathbf{K})$ given by Eq. (A8), however, involving some effective P -wave number (and also effective bulk density).

Let us construct a simple case, where most of the Green's tensor components vanish. This can be achieved using the following procedure: We consider an incoming, plane P wave propagating in the x_3 direction (i.e., only the displacement component u_3 is nonzero). The resulting coherent P wave in the inhomogeneous medium will also propagate in the x_3 direction. Therefore, only the tensor components $i=j=3$ of g_{ij}^F need to be analyzed. Noting that in this case the Green's tensor $g_{ik}^F(\mathbf{K})$ yields the largest contribution for the spatial wave number $K=k_p$, we can approximate the full Green's tensor (A8) by

$$g_{33}^F \approx \frac{-1}{8\pi^3 \rho \omega^2} \left(1 + \frac{K^2}{k_p^2 - K^2} \right). \quad (34)$$

We assume that the mean Green's tensor component is given by

$$\bar{g}_{33}^F \approx \frac{-1}{8\pi^3 \bar{\rho} \omega^2} \left(1 + \frac{K^2}{\bar{k}_p^2 - K^2} \right), \quad (35)$$

where \bar{k}_p is the searched-for effective P wave number. Substituting Eq. (34) for g^F and Eq. (35) for \bar{g}^F into Eq. (33) we obtain, after algebraic manipulations,

$$\bar{k}_p \approx k_p \left(1 + \frac{4\pi^3}{\rho \omega^2} q_{33}^{(1)} \right). \quad (36)$$

Here we neglected terms that contain combinations of the tensor components $q_{33}^{(i)}$. This introduces no additional inac-

curacy because higher-order correlations are neglected within the accuracy of the first-order statistical smoothing $O(\varepsilon^2)$.

The remaining problem is the evaluation of $q_{33}^{(1)}$ in (36), or equivalently, of $Q_{33}^{(1)}$ in space domain. In explicit form, from the first term in the expansion of \mathbf{Q} as given by Eq. (27), we obtain

$$\begin{aligned} Q_{ik}^{(1)}(\mathbf{r}' - \mathbf{r}'') = & \langle \tilde{L}_{ij}^{(1)}(\mathbf{r}') G_{jl}^F(\mathbf{r}' - \mathbf{r}'') \tilde{L}_{lk}^{(1)}(\mathbf{r}'') \\ & + 2\tilde{L}_{ij}^{(1)}(\mathbf{r}') G_{jl}^f(\mathbf{r}' - \mathbf{r}'') \tilde{L}_{lk}^{(2)}(\mathbf{r}'') \\ & + \tilde{L}_{ij}^{(2)}(\mathbf{r}') G_{jl}^w(\mathbf{r}' - \mathbf{r}'') \tilde{L}_{lk}^{(2)}(\mathbf{r}'') \rangle, \end{aligned} \quad (37)$$

where for statistically homogeneous random media both Q_{ik} and G_{ik} depend only on the difference vector $\mathbf{r}' - \mathbf{r}''$. It is interesting to note that in the elastic limit, only the first term of $Q_{ik}^{(1)}$ is nonzero. In the poroelastic case we have to analyze all three terms. Expression (37) involves the perturbing operators $\tilde{L}_{ij}^{(1)}$ and $\tilde{L}_{ij}^{(2)}$ (but not $\tilde{L}_{ij}^{(4)}$). Let us now specify the perturbing operators resulting from (11) and (12),

$$\tilde{L}_{ik}^{(1)} = \tilde{\rho} \omega^2 \delta_{ik} + \partial_j \tilde{G} [\delta_{jk} \partial_i + \delta_{ik} \partial_j - 2\delta_{ij} \partial_k] + \partial_i \tilde{H} \partial_k, \quad (38)$$

$$\tilde{L}_{ik}^{(2)} = \tilde{\rho}_f \omega^2 \delta_{ik} + \partial_i \tilde{C} \partial_k, \quad (39)$$

for a particular situation in which we can find an explicit analytical expression for the right-hand side of Eq. (37). In the following, we neglect fluctuations of the densities ρ and ρ_f . This is possible because of the restriction to low frequencies. It can be shown that incorporation of density fluctuations yields a correction to the background P wave number [the second term in Eq. (36)], which scales with ω^3 , whereas the other fluctuations result in a ω^2 dependence, as shown below. This simplification is also in accordance with the 1-D result,¹⁷ where the density fluctuations do not appear in the final expression for the effective P wave number though these fluctuations were not neglected *a priori*. These simplifications yield

$$\tilde{L}_{ik}^{(1)} = \partial_k \tilde{G} \partial_i + \partial_j \delta_{ik} \tilde{G} \partial_j - 2\partial_i \tilde{G} \partial_k + \partial_i \tilde{H} \partial_k, \quad (40)$$

$$\tilde{L}_{ik}^{(2)} = \partial_i \tilde{C} \partial_k. \quad (41)$$

A detailed computation of the three $Q_{ik}^{(1)}$ terms in Eq. (37) using the perturbing operators (40) and (41) is provided in Appendix B. The result in the wave number domain can be represented as

$$q_{33}^{(1)} = q^{HH} + q^{HG} + q^{HC} + q^{GG} + q^{GC} + q^{CC}, \quad (42)$$

where

$$\begin{aligned} q^{HH} = & \frac{1}{8\pi^3} k_p^2 \left(\frac{H^2}{P_d} B_{HH}(0) \right. \\ & \left. + \frac{C^2}{N} k_{ps}^2 \int_0^\infty r B_{HH}(r) \exp[ik_{ps} r] dr \right), \end{aligned} \quad (43)$$

$$q^{HG} = -\frac{1}{3\pi^3} k_p^2 \left(\frac{GH}{P_d} B_{HG}(0) + \frac{\alpha^2 MG}{P_d} k_{ps}^2 \int_0^\infty r B_{PM}(r) \exp[ik_{ps}r] dr \right), \quad (44)$$

$$q^{HC} = -\frac{1}{4\pi^3} \frac{C^2}{N} k_p^2 \left(B_{HC}(0) + k_{ps}^2 \int_0^\infty r B_{HC}(r) \exp[ik_{ps}r] dr \right), \quad (45)$$

$$q^{GG} = \frac{1}{15\pi^3} \frac{G}{NH^2} k_p^2 \left([4C^2G + 4NHG + NH^2] B_{GG}(0) + 4C^2G k_{ps}^2 \int_0^\infty r B_{GG}(r) \exp[ik_{ps}r] dr \right) \quad (46)$$

$$q^{GC} = \frac{1}{3\pi^3} \frac{\alpha^2 MG}{P_d} k_p^2 \left(B_{GC}(0) + k_{ps}^2 \int_0^\infty r B_{GC}(r) \exp[ik_{ps}r] dr \right), \quad (47)$$

$$q^{CC} = +\frac{1}{8\pi^3} \frac{C^2}{N} k_p^2 \left(B_{CC}(0) + k_{ps}^2 \int_0^\infty r B_{CC}(r) \exp[ik_{ps}r] dr \right). \quad (48)$$

Here, B_{HH} , B_{HC} , B_{HG} , B_{GG} , B_{GC} , B_{CC} denote the (cross-) correlation functions of the random fields \tilde{H} , \tilde{G} , and \tilde{C} defined by Eq. (19). In the derivation of the $Q_{ik}^{(1)}$ terms we assumed that the random media realizations are statistically isotropic and therefore the correlation functions depend only on r . The upper bar denoting the background properties is omitted. It is important to note that Eqs. (43)–(48) will provide a correction term to the background P wave number [see Eq. (36)], which exclusively accounts for conversion scattering into Biot's slow wave. The separation of terms in the operator $Q_{ik}^{(1)}$ that describe the scattering process from fast into Biot's slow P wave and all other scattering processes is possible because of the low-frequency assumption [Eq. (3)]. In other words, because of the large separation between the two characteristic frequencies for ordinary elastic scattering and conversion scattering into Biot's slow wave, we can distinguish between the different scattering processes, using the frequency dependency of the corresponding terms in the scattering equation (see also Appendix B).

We will now assume that all correlation functions are of the same functional form and only differ by their variances, i.e., $B_{XY} = \sigma_{XY}^2 B(r)$ with $B(0) = 1$ and $B(\infty) = 0$. Substituting then expressions (43)–(48) into Eq. (36) we obtain the final result for the effective P wave number,

$$\bar{k}_p = k_p \left(1 + \Delta_2 + \Delta_1 k_{ps}^2 \int_0^\infty r B(r) \exp[ik_{ps}r] dr \right), \quad (49)$$

with the dimensionless coefficients

$$\Delta_1 = \frac{\alpha^2 M}{2P_d} \left(\sigma_{HH}^2 - 2\sigma_{HC}^2 + \sigma_{CC}^2 + \frac{32}{15} \frac{G^2}{H^2} \sigma_{GG}^2 - \frac{8}{3} \frac{G^2}{H} \sigma_{HG}^2 + \frac{8}{3} \frac{G}{H} \sigma_{GC}^2 \right), \quad (50)$$

$$= \frac{\alpha^2 M}{2P_d} \left(\left(\left(\varepsilon_H - \frac{4}{3} \frac{G}{H} \varepsilon_G - \varepsilon_C \right)^2 \right) + \frac{16}{45} \frac{G^2}{H^2} \sigma_{GG}^2 \right), \quad (51)$$

$$\Delta_2 = \Delta_1 + \frac{1}{2} \sigma_{HH}^2 - \frac{4}{3} \frac{G}{H} \sigma_{HG}^2 + \left(\frac{4G}{H} + 1 \right) \frac{4}{15} \frac{G}{H} \sigma_{GC}^2. \quad (52)$$

The structure of the effective P wave number can be explained as follows: Due to the presence of random inhomogeneities, there are two terms added to the background wave number k_p . The first term, Δ_2 , is frequency independent and consists in a weighted sum of the variances of the random fields \tilde{H} , \tilde{G} , and \tilde{C} . The second term is frequency dependent and contains an integral over the correlation function multiplied by a weighted sum of the variances, Δ_1 . It is important to note that the expression for \bar{k}_p describes only the process of conversion scattering from fast into slow P waves. The contribution of purely elastic scattering is left out. The corresponding result would include additional terms involving the correlation functions B_{HH} , B_{GG} , and B_{HG} that describe the elastic scattering (P to P and S waves) and produces the typical Rayleigh frequency dependence for attenuation.²³ In other words, the second and third terms of the effective P wave number (49) correspond to the mechanism of wave-induced fluid flow only. Therefore, an analysis of the properties of \bar{k}_p gives insight into the relationship between the properties of elastic waves and wave-induced flow. By definition, the real part of \bar{k}_p is related to the phase velocity v through $v(\omega) = \omega / \Re\{\bar{k}_p\}$, whereas the imaginary part yields the attenuation coefficient γ : $\gamma(\omega) = \Im\{\bar{k}_p\}$. From the structure of Eq. (49), it can be seen that the phase velocity of the coherent wave in an equivalent medium is smaller than in the background medium. By inspection we find that $\gamma > 0$, that is, the coherent wave is exponentially damped. A detailed analysis of attenuation and velocity dispersion in an equivalent medium is presented in a companion paper.

IV. RANGE OF APPLICABILITY

The derivation of the dispersion relation (49) and the associated results on attenuation and phase velocity dispersion are based on several assumptions that restrict their range of applicability. The main restriction on our results is due to the use of the first-order statistical smoothing approximation. In the acoustic case the applicability condition of this approximation can be written as¹⁶

$$\sigma_n^2 (ka)^2 \ll 1, \quad (53)$$

where σ_n^2 denotes the variance of the velocity fluctuations, k is the wave number of a wave propagating in the homogeneous background, and a is a characteristic length scale associated with the size of the inhomogeneities. Condition (53) ensures that the correction terms to the background wave

number [similar to those in Eq. (49)] are small. More precisely, this condition was obtained by analyzing the next term in the equation for the kernel-of-mass operator \mathcal{Q} and requiring that the difference between the correction terms from the first-order statistical smoothing and that of the next, higher-order approximation is small. It is natural to assume that a similar condition must hold in the poroelastic case.

Using the first-order statistical smoothing the kernel-of-mass operator \mathbf{Q} can be approximated by $\mathbf{Q}^B \approx \langle \tilde{\mathbf{L}} \mathbf{G}^0 \tilde{\mathbf{L}} \rangle$ [Eq. (29)]. The next term in the infinite series for \mathbf{Q} reads as

$$\mathbf{Q}^{(2)} = \langle \tilde{\mathbf{L}} \mathbf{G} \tilde{\mathbf{L}} \rangle, \quad (54)$$

where $\tilde{\mathbf{G}}$ is the matrix of the mean Green's tensors found from the first-order statistical smoothing. To compute $\mathbf{Q}^{(2)}$, we assume that there is no multiple scatter of slow P waves into slow P waves and, therefore, the mean Green's tensor component \tilde{g}_{33}^F is still of the form (35). Then we can derive from Eq. (33) an equation for the effective P wave number similar to (36), but now involving $q_{33}^{(1)}$ determined from (54). The computation of $q_{33}^{(1)}$ according to (54) is analogous to that shown in the previous section and results in an effective P wave number \bar{k}_{p2} :

$$\bar{k}_{p2} \approx k_p + \Delta_2 k_p + \Delta_1 \bar{k}_p k_{ps}^2 \int_0^\infty r B(r) \exp[ik_{ps} r] dr, \quad (55)$$

with \bar{k}_p given by (49). Let us compare this result with the result for the effective wave number using first-order statistical smoothing [Eq. (49)]. Assuming that \bar{k}_p can be represented as a sum of background wave number k_p and a correction term Δk , the difference between (55) and (49) becomes

$$\bar{k}_{p2} - \bar{k}_p = \Delta k \Delta_1 k_{ps}^2 \int_0^\infty r B(r) \exp[ik_{ps} r] dr. \quad (56)$$

A necessary condition for the significance of the correction term using the first-order statistical smoothing Δk is the smallness of the difference (56) compared to Δk :

$$\left| \frac{\bar{k}_{p2} - \bar{k}_p}{\Delta k} \right| \ll 1. \quad (57)$$

Using for instance the correlation function $B(r) = \exp(-|r|/a)$, we obtain, from (56) and (57),

$$\max\{\Delta_1 (|k_{ps}|a)^2, \Delta_2\} \ll 1. \quad (58)$$

Relation (58) gives an estimate of the applicability of the first-order statistical smoothing approximation. That is, our results can be used in the case of weak-contrast media and weak wavefield fluctuations.

Physically, the existence of slow P waves is associated with the equilibration of pore pressure that at low frequencies is controlled by the diffusion equation with diffusion length¹⁸ $\lambda_D = \sqrt{\kappa_0 N / \omega \eta}$. Therefore, the interplay between λ_D and the correlation length a defines two different regimes. If $\lambda_D > a$ then the wave-induced pressure disturbance is equilibrated. This relation holds for low frequencies and thus defines the low-frequency or relaxed regime. Conversely, if $\lambda_D < a$ then there is not enough time for the pore

pressure to relax. This unrelaxed case occurs at high frequencies. A characteristic frequency that separates these low- and high-frequency regimes can be written as

$$\omega_c = \frac{\kappa_0 N}{a^2 \eta}. \quad (59)$$

Note that this characteristic frequency is identical to the frequency where maximal attenuation occurs.²⁴ The existence of both regimes within our wavefield approximation, which is based on the low-frequency approximation of Biot's equations, is only possible if

$$\omega_c \ll \omega_B, \quad (60)$$

which imposes the additional condition for the average size of the mesoscopic inhomogeneities,

$$a^2 \gg \frac{\kappa_0 N}{\eta \omega_B}. \quad (61)$$

Conditions (58) and (61) define the range of applicability of our results. Whereas condition (60) is a necessary condition for the validity of our results, there exists another condition for the observability of wave-induced flow. Only if ω_c is sufficiently different from the characteristic frequency, where elastic scattering of the fast wave modes dominates (i.e., $P \rightarrow P$ and $P \rightarrow S$), it is possible to distinguish between the two processes. Elastic scattering will dominate at frequency $\omega_S = c/a$, where c is the phase velocity of the fast P -wave mode. Therefore, the observability condition $\omega_S \gg \omega_c$ imposes $a^2 \gg \kappa_0^2 N \rho / (\eta^2 H)$.

V. REDUCTION TO THE 1-D CASE

In order to further substantiate our results, we analyze their connection with the known 1-D result. For a system of randomly layered porous media an effective, complex P wave number was obtained earlier by Gurevich and Lopatnikov;¹⁷ see their equation (56). This 1-D result is also based on the method of (first-order) statistical smoothing. If only the parameter M fluctuates, the 1-D result can be rewritten as

$$\bar{k}_p^{1D} = k_p^* \left[1 + \frac{1}{2} i \frac{\alpha^2 M}{P_d} k_{ps}^* \int_0^\infty dz B_{MM}(z) \exp[ik_{ps}^* z] \right], \quad (62)$$

where k_p^* and k_{ps}^* denote effective wave numbers that involve effective parameters H^* , N^* , and effective densities ρ^* , q^* . These effective parameters can be computed according to the so-called poroelastic Backus averaging.^{17,18,28} By neglecting terms higher than $O(\epsilon^2)$ —which is the overall precision of the weak-fluctuation approximation—we can replace k_{ps}^* with k_{ps} . The effective parameter H^* is computed according to

$$H^* = P_d + \alpha^2 M^* = P_d + \alpha^2 \left\langle \frac{1}{M} \right\rangle^{-1} \approx H \left[1 - \frac{\alpha^2 M}{H} B_{MM}(0) \right]. \quad (63)$$

Then the effective P wave number k_p^* can be expressed as

$$k_p^* = \omega \sqrt{\frac{\rho^*}{H^*}} \approx k_p \left[1 + \frac{1}{2} \frac{\alpha^2 M}{H} B_{MM}(0) \right]. \quad (64)$$

Using (64) Eq. (62) can be written in the form

$$\begin{aligned} \bar{k}_p^{1D} = k_p & \left[1 + \frac{\alpha^2 M}{2H} B_{MM}(0) \right. \\ & \left. + \frac{1}{2} i \frac{\alpha^2 M}{P_d} k_{ps} \int_0^\infty dz B_{MM}(z) \exp[ik_{ps}z] \right]. \quad (65) \end{aligned}$$

We will now show that the 1-D result (65) can be recovered from the 3-D result. To do so, we analyze the expression for the Q_{ik} tensor component in the wave number domain q_{33} that is of the form [cf. Eq. (B5)]

$$q_{33} \propto \int d^3 \mathbf{r} B(\mathbf{r}) \frac{\exp[ik_{ps}R]}{R} \exp[-i\mathbf{K} \cdot \mathbf{r}], \quad (66)$$

where we used only the poroelastic part of $G_{ij,ij}^F$ and $R = |\mathbf{r}|$. Note that in order to obtain Eq. (66) it is not necessary to assume statistical isotropy. We are now considering the following limiting situation.

(a) To degenerate the 3-D random medium into a 1-D random medium we stretch the correlation lengths perpendicular to the direction of wave propagation, a_\perp , to infinity so that the correlation function becomes only a function of z with parameter a_\parallel , i.e., the correlation length parallel to the direction of wave propagation. Obviously, if the wave propagates mainly in the z direction we can also write the spatial wave vector as $\mathbf{K} \approx (0, 0, k_p)^T$.

(b) Since in such a 1-D random medium there are only two directions of wave propagation ($\pm z$), we can use the small-angle approximation¹⁶ (or Fresnel approximation) of the propagator-like term $\exp[ik_{ps}R]/R$:

$$\frac{\exp[ik_{ps}R]}{R} \approx \frac{\exp[ik_{ps}z]}{z} \exp\left[\frac{ik_{ps}r_t^2}{2z}\right], \quad (67)$$

where r_t denotes the absolute value of the transverse coordinate vector $\mathbf{r}_t = (x, y)^T$. Introducing the simplifications proposed in (a) and (b) into Eq. (66) and using cylindrical coordinates $d^3 \mathbf{r} = dz dr_t d\phi r_t$, we obtain

$$\begin{aligned} q_{33} \propto 4\pi \int_0^\infty dz B(z) \frac{\exp[ik_{ps}z]}{z} \exp[-ik_p z] \\ \times \int_0^\infty dr_t r_t \exp\left[\frac{ik_{ps}r_t^2}{2z}\right]. \quad (68) \end{aligned}$$

The low-frequency condition $k_p/k_{ps} \ll 1$ means that we can replace the exponential $\exp[-ik_p z]$ by 1. The integral with respect to r always converges because k_{ps} is complex and produces an exponential decreasing multiplier. After performing the integration and substituting the result into Eq. (36), we obtain

$$\begin{aligned} \bar{k}_p = k_p & \left[1 + \frac{\alpha^2 M}{2H} B_{MM}(0) \right. \\ & \left. + \frac{1}{2} i \frac{\alpha^2 M}{P_d} k_{ps} \int_0^\infty dz B_{MM}(z) \exp[ik_{ps}z] \right], \quad (69) \end{aligned}$$

which is identical to Eq. (65).

In conclusion, the 1-D effective P wave number can be exactly obtained from the 3-D result. We note that we have only considered the particular case of M fluctuations. However, the approach can be also applied in the case of other parametrizations.

VI. CONCLUSIONS

In the framework of the theory of wave propagation in random media we analyzed the properties of the coherent wave propagating in poroelastic random media. Neglecting the ordinary elastic scattering, we only accounted for conversion scattering from fast P into Biot's slow P wave. This process of conversion scattering is equivalent to the mechanism of pore-pressure relaxation due to wave-induced perturbations. Thus, our results describe the relationship between the dynamic properties of the coherent wavefield and the mechanism of wave-induced fluid flow. In particular, we have derived an explicit expression for the effective P wave number [Eq. (49)] by applying first-order statistical smoothing of Biot's equations of poroelasticity with randomly varying coefficients. This wave number is complex and involves an integral over the correlation properties of the medium fluctuations. From this result it can be seen that the associated phase velocity is smaller than in the homogeneous background medium and that the wave is exponentially damped. We have shown that the previously reported effective P wave number for randomly layered media¹⁷ can be derived from the more general 3-D result.

Our approach is limited to the case of weak-contrast, mesoscopic inhomogeneities [conditions (58) and (61)]. In this paper we focused the analysis to wave propagation in statistically isotropic random media. However, the results can be probably generalized to the case of statistically anisotropic random media. An advantage of the statistical approach is its flexibility to handle complex geometrical distributions of the inhomogeneities. Only the spatial correlation of the fluctuations need to be known in order to compute the dynamic wavefield attributes. A detailed analysis of frequency dependencies of attenuation and dispersion due to wave-induced fluid flow and the potential applicability of the results to real rocks will be the subject of a companion paper.²⁴

APPENDIX A: POROELASTIC GREEN'S TENSORS

The complete set of Green's tensors for a homogeneous and isotropic poroelastic continuum—including electroseismic coupling—was derived by Pride and Haartsen.²⁵ We reproduce only those parts of the Green's tensors, which are related to poroelastic wave propagation. Furthermore, we can simplify these tensors for low frequencies with $|k_p|/|k_{ps}| \ll 1$. We obtain

$$G_{ij}^F(\mathbf{r}-\mathbf{r}_0) = \frac{1}{4\pi\rho\omega^2} \left([k_s^2\delta_{ij} + \partial_i\partial_j] \frac{e^{ik_sR}}{R} - \partial_i\partial_j \frac{e^{ik_pR}}{R} \right) - \frac{C^2}{H^2} \frac{1}{4\pi q\omega^2} \partial_i\partial_j \frac{e^{ik_{ps}R}}{R}, \quad (\text{A1})$$

$$G_{ij}^f(\mathbf{r}-\mathbf{r}_0) = \frac{C}{H} \frac{1}{4\pi q\omega^2} \partial_i\partial_j \frac{e^{ik_{ps}R}}{R} \quad (\text{A2})$$

$$G_{ij}^w(\mathbf{r}-\mathbf{r}_0) = -\frac{1}{4\pi q\omega^2} \partial_i\partial_j \frac{e^{ik_{ps}R}}{R}, \quad (\text{A3})$$

where $R = |\mathbf{r}-\mathbf{r}_0|$. In homogeneous and isotropic media the Green's tensors only depend on R . In the low-frequency version of Biot's equations, the wave numbers of fast P , S , and slow P waves are defined as

$$k_p = \omega \sqrt{\frac{\rho}{H}}, \quad k_s = \omega \sqrt{\frac{\rho}{G}}, \quad k_{ps} = \sqrt{\frac{i\omega\eta}{\kappa_0 N}} = \omega \sqrt{\frac{q}{N}}, \quad (\text{A4})$$

where $N = MP_d/H$. Note that the first three terms of G_{ij}^F are formally identical to the elastodynamic Green's tensor.²⁹ Indeed, in the elastic limit ($K_d \rightarrow K_g$, $\alpha \rightarrow 0$ and $\phi \rightarrow 0$, $\kappa_0 \rightarrow 0$), the set of Green's tensors (A1)–(A3) reduces to the single elastodynamic Green's tensor,

$$G_{ij}^{\text{elast}}(\mathbf{r}-\mathbf{r}_0) = \frac{1}{4\pi\rho\omega^2} \left([k_s^2\delta_{ij} + \partial_i\partial_j] \frac{e^{ik_sR}}{R} - \partial_i\partial_j \frac{e^{ik_pR}}{R} \right), \quad (\text{A5})$$

where the P wave number is now given by $k_p = \omega \sqrt{\rho/(K_d + 4/3G)}$.

We define the spatial Fourier transform pair in the following way:

$$G_{ij}(\mathbf{r}-\mathbf{r}') = \int d^3\mathbf{K} g_{ij}(\mathbf{K}) \exp[i\mathbf{K} \cdot (\mathbf{r}-\mathbf{r}')], \quad (\text{A6})$$

$$g_{ij}(\mathbf{K}) = \frac{1}{(2\pi)^3} \int d^3(\mathbf{r}-\mathbf{r}') G_{ij}(\mathbf{r}-\mathbf{r}') \exp[-i\mathbf{K} \cdot (\mathbf{r}-\mathbf{r}')]. \quad (\text{A7})$$

In the wave number domain the Green's tensors (A1)–(A3) read as

$$g_{ij}^F(\mathbf{K}) = -\frac{1}{8\pi^3} \frac{1}{\rho\omega^2} \left(\frac{k_s^2\delta_{ij} - K_iK_j}{k_s^2 - K^2} + \frac{K_iK_j}{k_p^2 - K^2} \right) - \frac{1}{8\pi^3} \frac{C^2}{H^2} \frac{1}{q\omega^2} \frac{K_iK_j}{k_{ps}^2 - K^2}, \quad (\text{A8})$$

$$g_{ij}^f(\mathbf{K}) = \frac{1}{8\pi^3} \frac{C}{H} \frac{1}{q\omega^2} \frac{K_iK_j}{k_{ps}^2 - K^2}, \quad (\text{A9})$$

$$g_{ij}^w(\mathbf{K}) = -\frac{1}{8\pi^3} \frac{1}{q\omega^2} \frac{K_iK_j}{k_{ps}^2 - K^2}. \quad (\text{A10})$$

APPENDIX B: COMPUTATION OF THE OPERATOR $\mathcal{Q}_{ik}^{(1)}$

In this appendix we compute the kernel-of-mass operator $\mathcal{Q}_{ik}^{(1)}(\mathbf{r}'-\mathbf{r}'')$ defined in Eq. (37). First we note that the three terms in Eq. (37) are of the same structure,

$$\mathcal{Q}_{ik}(\mathbf{r}'-\mathbf{r}'') = \langle (L_{ij}^{(X)})' G_{jl}^Z(\mathbf{r}'-\mathbf{r}'') (L_{lk}^{(Y)})'' \rangle, \quad (\text{B1})$$

where $X=1,2$, $Y=1,2$, $Z=F,f,w$ while single and double primes indicate whether in the differential operator L_{ij} differentiation is with respect to \mathbf{r}' or \mathbf{r}'' . It is therefore sufficient to present the detailed manipulations only for one term. For example, for the differential operators $(L_{ij}^{(1)})' = \partial_i' \tilde{H}' \partial_j'$ and $(L_{ij}^{(2)})'' = \partial_i'' \tilde{C}'' \partial_j''$, we have

$$\mathcal{Q}_{ik} = \langle \partial_i' \tilde{H}' \partial_j' G_{jl}^Z(\mathbf{r}'-\mathbf{r}'') \partial_l'' \tilde{C}'' \partial_k'' \rangle. \quad (\text{B2})$$

We now use partial integrations to shift the spatial derivatives ∂_j' and ∂_l'' to the Green's function [and make use of the property $G^Z(R \rightarrow \infty) = 0$]. Averaging Eq. (B2) yields

$$\mathcal{Q}_{ik} = \partial_i' (B_{HC}(\mathbf{r}'-\mathbf{r}'') G_{jl,jl}^Z(\mathbf{r}'-\mathbf{r}'')) \partial_k'', \quad (\text{B3})$$

where we made use of the assumption of statistically homogeneous random fields [Eq. (19)]. The Fourier transform of \mathcal{Q}_{ik} is defined as

$$q_{ik}(\mathbf{K}) = \frac{1}{8\pi^3} \int d^3(\mathbf{r}'-\mathbf{r}'') \mathcal{Q}_{ik}(\mathbf{r}'-\mathbf{r}'') \exp[-i\mathbf{K} \cdot (\mathbf{r}'-\mathbf{r}'')]. \quad (\text{B4})$$

Noting that spatial derivatives correspond to multiplications in the wave number domain ($\partial_j \leftrightarrow iK_j$), we can express q_{ik} as

$$q_{ik}(\mathbf{K}) = \frac{-K_i K_k}{8\pi^3} \int d^3\mathbf{r} B_{HC}(\mathbf{r}) G_{jl,jl}^Z(\mathbf{r}) \exp[-i\mathbf{K} \cdot \mathbf{r}]. \quad (\text{B5})$$

Next, we need to compute the spatial derivatives of the Green's tensors. The poroelastic part of Green's tensor in Eq. (A1) as well as Green's tensors in Eqs. (A2) and (A3) are of the form $G_{ij}^{\text{poro}} \propto \partial_i \partial_j (e^{ik_{ps}R}/R)$. After differentiation we obtain

$$G_{ij,ij}^{\text{poro}}(\mathbf{r}) \propto -k_{ps}^2 \left(k_{ps}^2 \frac{e^{ik_{ps}R}}{R} + 4\pi\delta(\mathbf{r}) \right). \quad (\text{B6})$$

Analogously, for the derivatives of the elastic part of Green's tensor (A1) given by equation (A5) we find

$$G_{ij,ij}^{\text{elast}}(\mathbf{r}) \propto -k_p^2 \left(k_p^2 \frac{e^{ik_pR}}{R} + 4\pi\delta(\mathbf{r}) \right). \quad (\text{B7})$$

Note that the derivatives in (B6) and (B7) are of the same functional form, despite the fact that G_{ij}^{elast} includes S wave contributions. These contributions, however, cancel out when $G_{ij,ij}^{\text{elast}}$ is computed. The parts of the differential operator $L_{ik}^{(1)}$ involving fluctuations of the shear modulus require the computation of the terms $G_{33,33}^{\text{elast}}$ and $G_{3j,3j}^{\text{elast}}$. It can be shown that these derivatives can be expressed in terms of $G_{ij,ij}$:

$$G_{33,33} = G_{ij,ij} \left(\frac{1}{2} \int_0^\pi d\theta \sin\theta \cos^4\theta + O(k_p^2 R^2) \right). \quad (\text{B8})$$

$$= G_{ij,ij} \left(\frac{1}{5} + O(k_p^2 R^2) \right). \quad (\text{B9})$$

Analogously,

$$G_{3j,3j} = G_{ij,ij} \left(\frac{1}{3} + O(k_p^2 R^2) \right). \quad (\text{B10})$$

Neglecting terms of the order $O(k_p^2 R^2)$ will produce no additional inaccuracy because of the restriction to low frequencies. Because of the same argument, we also neglect the first term in (B7). It is this term that is responsible for dynamic effects of elastic scattering and that is left out in the present analysis.

Inserting expressions (B6) and (B7) into Eq. (B5), introducing spherical coordinates, assuming statistical isotropy [$B(\mathbf{r})=B(|\mathbf{r}|)$], and integrating over the angular coordinates, we obtain

$$q_{33} = -\frac{1}{4\pi^3} \frac{C^2}{N} \left(k_p^2 B_{HC}(0) + k_p k_{ps}^2 \int_0^\infty dr B_{HC}(r) \exp[ik_{ps}r] \sin(k_p r) \right). \quad (\text{B11})$$

In accordance with our low-frequency assumption, we replace the sine function by its argument and obtain Eq. (45). Repeating these computations for the remaining terms involving correlations and cross-correlation between the random fields of H, G , and C yields Eqs. (43)–(48).

Linear and nonlinear propagation of higher order modes in hard-walled circular ducts containing a real gas

Stefan Scheichl^{a)}

Acoustics Research Institute, Austrian Academy of Sciences, A-1010 Vienna, Austria

(Received 10 September 2004; revised 14 January 2005; accepted 21 January 2005)

This paper deals with the linear and nonlinear propagation of sound waves through a real gas contained in a circular tube with rigid, isothermal walls. Special emphasis is placed on the asymptotically correct treatment of the higher order modes and their interaction with the acoustic boundary layer. In the first part, a linear perturbation analysis is carried out to calculate the correction terms arising from the viscothermal damping mechanisms present in the system. In extension to previous work, the propagation length is assumed to be so large that the exponentially growing boundary layer effects do not only affect the second order terms of the sound pressure but also the leading order terms. The series expansions derived for the propagation parameters extend the results given in the literature with additional terms resulting from viscosity and heat conduction in the core region. The second part is concerned with the nonlinear modulation of a wave packet transmitted through a real gas. A damped nonlinear Schrödinger equation is derived and its solutions for positive as well as negative values of the nonlinearity parameter are studied. In particular, the case of wave propagation in ducts containing a so-called BZT fluid is discussed. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1869113]

I. INTRODUCTION

Since the end of the 19th century the problem of extending the classical Kirchhoff “wide tube” result¹ for the viscothermal attenuation of plane waves, which was derived from a general dispersion relation, to other cases, such as narrow tubes, higher order modes, and finite amplitude sound waves propagation, has been subject of a number of papers. Rayleigh² was one of the first to obtain useful approximations for the narrow tube, i.e., the case where the driving frequencies are so low that the viscothermal boundary extends itself over the whole tube diameter. In 1949 Zwicker and Kosten³ introduced an approximate theory based on the so-called low reduced frequency assumptions that enabled the simplification of the basic equations such that the transmission line parameters of the fundamental mode could be given in closed form for a wide range of driving frequencies. A thorough discussion of this approach including comparisons with the investigations of other authors and with numerical solutions of Kirchhoff’s general dispersion equations can be found in the 1975 paper by Tijdeman (see Ref. 4 and the references therein). Later Keefe⁵ derived more accurate higher order series expansions of the plane wave transmission line parameters for the cases of high and low frequency waves. The applicability and validity of these results from the viewpoint of a systematic perturbation analysis have recently been studied by Scheichl.⁶

By applying the method of boundary layer admittance, Beatty⁷ calculated the leading order boundary layer attenuation caused by the viscous and thermal losses of all higher modes which opened the way to more refined analyses with respect to higher order corrections and the frequency range

around the cutoff frequencies (see, e.g., Refs. 8 and 9). A detailed investigation on that topic within the framework of a linear multiple scales perturbation theory is presented in Ref. 6. However, this study is confined to the case of axisymmetric wave motion.

Moreover, in many physical problems, the sound pressure levels involved might become so high that the problem cannot be treated using a linear analysis. Again, by adopting the assumption that the frequencies are sufficiently high such that the flow field can be split into a thin viscous wall layer and an essentially inviscid core layer, Chester¹⁰ and independently also Blackstock¹¹ were able to derive a generalized Burgers equation for (almost) plane waves where the boundary layer effects are described by a dissipative-dispersive memory term. It should be mentioned that the same equation may also be used to calculate the slowly time-varying distortions of the profiles of counterpropagating waves and the buildup of standing nonlinear oscillations in resonators (cf. the articles by Gusev *et al.*¹² and Menguy and Gilbert¹³). The experiments reported in the latter paper are in good accordance with the theoretically predicted pressure amplitudes. In extension to Blackstock’s studies, by adopting the Khokhlov-Zabolotskaya-Kuznetsov model, Makarov and Vatrushina¹⁴ analyzed the case of the wavelengths being so short that the losses in the core region are of the same order of magnitude as the boundary layer effects and, after averaging the sound pressure over the cross section, arrived at a modified Blackstock equation. For a more in-depth discussion of these and other theoretical models, the reader is referred to the review paper by Makarov and Ochmann.¹⁵

As far as the nonlinear propagation of higher order modes in circular ducts is concerned, the investigation by Keller and Millman¹⁶ should be mentioned, who, using the method of strained parameters, determined the nonlinear

^{a)}Electronic mail: stefan.scheichl@oew.ac.at

wave number shift for the symmetrical modes. In the 1998 paper by Foda¹⁷ the same technique is used in order to investigate the nonlinear interaction of different modes. Furthermore, Nayfeh¹⁸ derived a nonlinear Schrödinger equation for the propagation of a wave packet centered at the wave number and the frequency of a higher order carrier mode by applying the method of multiple scales. This is the study the second part of this present paper is based on.

In contrast to previous work where the fluid, in general, is assumed to be perfect gas, the investigations presented here are concerned with the physical processes taking place when sound is transmitted through a real gas. Both, linear as well as nonlinear wave propagation in a hard walled circular tube, will be studied. In order to ensure that the acoustic motion is not dominated by thermoviscous effects, the driving frequencies are presupposed to be sufficiently high such that the spatial range consumed by the boundary layer is small compared to the tube diameter. Consistent with that, the characteristic wavelength is assumed to be of the same order of magnitude as the diameter or smaller and, consequently, the occurrence of higher order modes has to be taken into account. The paper is structured as follows.

The first part deals with the linear wave propagation under the action of boundary layer and core layer attenuation. The primary aim pursued in this study is to derive the asymptotically correct solutions for the involved field quantities *including* the second-order terms that are uniformly valid over a considerably larger spatial range than that constituted by the wavelengths. To this end, the *method of multiple scales* is applied. Additionally, the *method of matched asymptotic expansions* is used, in order to analyze the changes in lateral direction within the boundary layer. As already shown in Ref. 6 for the symmetrical modes, a higher-order perturbation analysis also incorporating the dissipative losses in the core region turns out to be necessary if the length of the tube becomes so large that the exponentially growing effects due to viscosity and heat conduction in the wall layer do not only affect the second-order correction terms of the sound pressure but also the leading order terms. The thus obtained results extend the solutions for the radial modes given in Ref. 6 with the corresponding expressions for the asymmetrical modes and, furthermore, also account for the effects arising from the adoption of a general equation of state.

In the second part, beginning with Sec. IV, the same perturbation techniques as before are used to derive an envelope evolution equation for the temporal and spatial modulation of nonlinear, dispersive waves propagating in a long circular duct containing a real gas. This equation will turn out to be a nonlinear Schrödinger equation, extended with a dissipative damping term resulting from the thermoviscous boundary layer effects. In addition, the expressions for the second-order correction terms are calculated.

As mentioned before, a similar analysis, however, restricted to the case of a perfect gas was carried out by Nayfeh.¹⁸ Extending this study to real gases is motivated by the following observations: It is well known that the propagation of weakly nonlinear plane waves in homogeneous, nondissipative media can be described by an inviscid Bur-

gers equation in which the so-called *fundamental derivative* (at constant entropy \bar{s}),

$$\Gamma = \frac{1}{\bar{c}} \left(\frac{\partial(\bar{\rho}\bar{c})}{\partial\bar{\rho}} \right)_{\bar{s}} = 1 + \frac{B}{2A}, \quad (1)$$

accounts for the rate of change of the sound speed \bar{c} with density $\bar{\rho}$ (see, e.g., Ref. 15). In this definition, as usual, the ratio B/A denotes the so-called *acoustic nonlinearity parameter*, whereas the quantity Γ is sometimes also referred to as the *intrinsic gasdynamic nonlinearity parameter*. For perfect gases with constant specific heats, $\Gamma = (\gamma + 1)/2 > 0$, where γ represents the ratio of the specific heats, and the fluid motion is said to exhibit positive nonlinearity. In this case only *compression shocks* can form and propagate in the gas. The possibility that also *rarefaction shocks* can form in real fluids, i.e., that Γ might become negative, seems to have been recognized first by Bethe¹⁹ and independently by Zel'dovich.²⁰ A class of fluids involving gases with high specific heats can be identified for which the curvature of the isentropes in the pressure-density state space is reversed near the coexistence curve in the vicinity of the critical point and, consequently, Γ changes sign. More sophisticated studies based on the Martin-Hou equation of state are due to Thompson and co-workers,^{21,22} who gave specific examples of such fluids, which include hydrocarbons and fluorocarbons of moderate complexity. In recognition of these investigations, fluids having the distinguishing property that the fundamental derivative can change sign are commonly referred to as BZT fluids. Two impressive analyses of several commercially available fluorocarbons by means of the Martin-Hou equation are given in the 1989 paper by Cramer²³ and the 1997 paper by Monaco *et al.*²⁴ and clearly substantiate the existence of negative nonlinearity regions. Recently, also fluids belonging to the group of the so-called siloxanes were shown to be possible candidates for media with a negative Γ region in the gaseous state.²⁵ Furthermore, Kluwick²⁶ demonstrated that if the equilibrium state of the BZT fluid is chosen to be in the neighborhood to the transition line where $\Gamma = 0$, the propagation of planar, weakly nonlinear acoustic waves in rigid tubes is governed by a modified Burgers equation very similar to that derived by Blackstock,¹¹ however, extended with an additional cubic nonlinearity term.

The consequence of the above discussion is that the possibility of $\Gamma < 0$ obviously provides new physical phenomena in gas dynamics and acoustics and, thus, may also be of importance for the case considered in the second part, namely, the evolution of a wave packet centered at the wave number and the frequency of a higher order carrier mode. As it will turn out, the type of nonlinearity is then not only determined by the fundamental derivative, but also by its first derivative with respect to the density.

II. PROBLEM FORMULATION

In this paper, the linear and the weakly nonlinear wave propagation in a rigid circular tube with isothermal walls containing a real gas will be investigated. The problem considered and the notation used are shown in Fig. 1.

FIG. 1. Sketch showing duct geometry and notation.

A. General assumptions

Throughout the investigations, the following assumptions are adopted:

$$\text{Re} = \frac{\bar{c}_0 \bar{\lambda} \bar{\rho}_0}{\bar{\mu}_0} \gg 1, \quad l = \frac{\bar{R}}{\bar{\lambda}} \gg \frac{1}{\sqrt{\text{Re}}}, \quad M = \frac{\bar{W}}{\bar{c}_0} \ll 1. \quad (2)$$

Here, the quantities $\bar{c} = \sqrt{(\partial \bar{p} / \partial \bar{\rho})_{\bar{s}}}$, \bar{p} , $\bar{\rho}$, \bar{s} , $\bar{\mu}$, $\bar{\lambda}$, \bar{R} , and \bar{W} , and the parameters Re , l , and M denote the speed of sound, the fluid pressure, the density of the fluid, the specific entropy, the dynamic viscosity, the characteristic wavelength, the radius of the tube, the characteristic particle velocity, the acoustic Reynolds number, the reduced frequency,⁴ and the Mach number. Quantities evaluated at the equilibrium reference state are indicated by the subscript 0.

Furthermore, it is assumed that the fluid is a gas such that the equilibrium quantities satisfy

$$\begin{aligned} \bar{\beta}_0 \bar{\vartheta}_0 &= O(1), \quad \gamma_0 - 1 = \frac{\bar{C}_{p0}}{\bar{C}_{v0}} - 1 = O(1), \\ \text{Pr} &= \frac{\bar{\mu}_0 \bar{C}_{p0}}{\bar{\kappa}_0} = O(1), \end{aligned} \quad (3)$$

$$\Gamma_0 = O(1), \quad \Lambda_0 = \left[\bar{\rho} \left(\frac{\partial \Gamma}{\partial \bar{\rho}} \right)_{\bar{s}} \right]_0 = 0(1),$$

where $\bar{\beta} = -(1/\bar{\rho})(\partial \bar{p} / \partial \bar{\vartheta})_{\bar{p}}$, $\bar{\vartheta}$, γ , $\bar{\kappa}$, Pr , and Λ represent the coefficient of thermal expansion, the temperature, the ratio of the specific heats, the thermal conductivity, the Prandtl number, and the first derivative of the fundamental derivative (1).

Since $\text{Pr} = O(1)$, the thermal and the viscous boundary layer thicknesses are of the same order of magnitude (see, e.g., Ref. 15):

$$\bar{\delta}_r \sim \bar{\delta}_v \sim \sqrt{\frac{\bar{\mu}_0}{\bar{\omega} \bar{\rho}_0}} \sim \frac{\bar{\lambda}}{\sqrt{\text{Re}}}, \quad (4)$$

with $\bar{\omega}$ being the radian driving frequency. Consequently, the first and second restrictions in Eq. (2) can be interpreted as defining two ordering relationships for the most relevant geometrical scales, i.e., the wavelength, the radius, and the spatial range consumed by the boundary layer: As a result of

$$\text{Re} \sim \frac{\bar{\lambda}^2}{\bar{\delta}_v^2} \gg 1, \quad l^2 \text{Re} \sim \text{He}^2 \text{Re} \sim \text{St}^2 = \frac{\bar{R}^2}{\bar{\delta}_v^2} \gg 1, \quad (5)$$

where

$$\text{He} = \frac{\bar{\omega} \bar{R}}{\bar{c}_0}, \quad \text{St} = \sqrt{\frac{\bar{\omega} \bar{\rho}_0 \bar{R}^2}{\bar{\mu}_0}}, \quad (6)$$

the quantity $\bar{\delta}_v$ turns out to be small compared to the characteristic wavelength as well as the radius. Here, the quantities $\text{He} \sim l$ and St are the Helmholtz number and the Stokes number, respectively.

In order to capture the most relevant effects arising from the excitation of higher order radial and azimuthal modes, the linear investigations in Sec. III will proceed from the assumption that the characteristic wavelength $\bar{\lambda}$ is comparable to the diameter of the duct, i.e., $l = O(1)$, whereas the propagation length will be presupposed to be much larger than $\bar{\lambda}$. In extension to that, the case of \bar{R} being much larger than the wavelengths, will be considered in Sec. III B. As mentioned in the Introduction, the opposite case, i.e., linear plane wave propagation with $l \ll 1$, has already been extensively discussed in the literature.

For the study in Sec. IV dealing with the nonlinear propagation of a wave packet, it will again be assumed that $\bar{R} \sim \bar{\lambda}$. However, as explicated in Ref. 18, the fundamental mode has to be excluded as a potential carrier mode. This is due to the fact that it propagates as a nearly plane wave and, thus, at the same speed as its harmonics. Consequently, it cannot be excited without strongly exciting the higher harmonics as well since the effect of gas nonlinearity leads to a cumulative distortion of the wave and a shift of energy among the several harmonics. Analyzing this case within the framework of an asymptotic perturbation theory would require the application of the plane wave evolution equation proposed by Blackstock¹¹ and others^{10,12,13} or, respectively, its generalized version by Kluwick²⁶ (see the Introduction).

B. Basic equations and perturbation approach

It is reasonable to formulate the problems under consideration in terms of nondimensional quantities by involving the wavelength $\bar{\lambda}$, the radius \bar{R} , and the equilibrium quantities $\bar{\rho}_0$, \bar{c}_0 , $\bar{\beta}_0$, \bar{C}_{p0} , and $\bar{\mu}_0$ introduced above:

$$\begin{aligned} z &= \frac{\bar{z}}{\bar{\lambda}}, \quad r = \frac{\bar{r}}{\bar{R}}, \quad t = \frac{\bar{t} \bar{c}_0}{\bar{\lambda}}, \quad \omega = \frac{\bar{\omega} \bar{\lambda}}{\bar{c}_0}, \quad v_z = \frac{\bar{v}_z}{\bar{c}_0}, \\ v_r &= \frac{\bar{v}_r}{\bar{c}_0}, \quad v_\phi = \frac{\bar{v}_\phi}{\bar{c}_0}, \quad p = \frac{\bar{p}}{\bar{\rho}_0 \bar{c}_0^2}, \\ \rho &= \frac{\bar{\rho}}{\bar{\rho}_0}, \quad \vartheta = \bar{\vartheta} \bar{\beta}_0, \quad c = \frac{\bar{c}}{\bar{c}_0}, \quad s = \frac{\bar{s}}{\bar{C}_{p0}}, \\ \beta &= \frac{\bar{\beta}}{\bar{\beta}_0}, \quad C_p = \frac{\bar{C}_p}{\bar{C}_{p0}}, \quad \eta = \frac{\bar{\eta}}{\bar{\mu}_0}. \end{aligned} \quad (7)$$

Here, v_z , v_r , v_ϕ , and η denote, respectively, the velocities in axial, radial, and azimuthal directions, and the bulk viscosity. Furthermore, the scaling parameter

$$\alpha = d \frac{\bar{\lambda}}{\bar{R} \sqrt{\text{Re}}} = \frac{d}{l \sqrt{\text{Re}}} \quad (8)$$

is introduced where d is an arbitrary constant of order $O(1)$, which, together with Eqs. (2) and (5), leads to the relationship $\alpha \sim \text{St}^{-1}$.

In the following analysis it will be assumed that the variations of the thermal conductivity and the dynamic viscosities are so small that these quantities can be regarded as constant, i.e., $\tilde{\kappa} = \tilde{\kappa}_0$, $\tilde{\mu} = \tilde{\mu}_0$, and $\tilde{\eta} = \tilde{\eta}_0$. However, it should be emphasized that due to the assumption of a very small Mach number [see Eq. (2)] the results derived below would remain unchanged even if the commonly used approximative power laws $\tilde{\kappa} = \tilde{\kappa}_0(\tilde{\vartheta}/\tilde{\vartheta}_0)^\sigma$ and $\tilde{\mu} = \tilde{\mu}_0(\tilde{\vartheta}/\tilde{\vartheta}_0)^\sigma$, where the coefficient $\sigma = O(1)$, were adopted.

The three-dimensional Navier-Stokes equations in cylindrical coordinates, the continuity equation, the energy equation, and the general equation of state then read

$$\rho \frac{dv_z}{dt} = \frac{\alpha^2 l^2}{d^2} \left(\frac{4}{3} + \eta_0 \right) \frac{\partial^2 v_z}{\partial z^2} + \frac{\alpha^2}{d^2} \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial v_z}{\partial r} \right) + \frac{\alpha^2}{d^2} \frac{1}{r^2} \frac{\partial^2 v_z}{\partial \phi^2} + \frac{\alpha^2 l}{d^2} \left(\frac{1}{3} + \eta_0 \right) \times \frac{1}{r} \left[\frac{\partial}{\partial r} \left(r \frac{\partial v_r}{\partial z} \right) + \frac{\partial^2 v_\phi}{\partial z \partial \phi} \right] - \frac{\partial p}{\partial z}, \quad (9)$$

$$\rho \left(\frac{dv_r}{dt} - \frac{1}{l} \frac{v_\phi^2}{r} \right) = \frac{\alpha^2 l^2}{d^2} \frac{\partial^2 v_r}{\partial z^2} + \frac{\alpha^2}{d^2} \left(\frac{4}{3} + \eta_0 \right) \frac{1}{r} \left[\frac{\partial}{\partial r} \left(r \frac{\partial v_r}{\partial r} \right) - \frac{v_r}{r} \right] + \frac{\alpha^2}{d^2} \frac{1}{r^2} \frac{\partial^2 v_r}{\partial \phi^2} + \frac{\alpha^2 l}{d^2} \left(\frac{1}{3} + \eta_0 \right) \frac{\partial^2 v_z}{\partial z \partial r} + \frac{\alpha^2}{d^2} \left(\frac{1}{3} + \eta_0 \right) \times \frac{1}{r} \left(\frac{\partial^2 v_\phi}{\partial r \partial \phi} + \frac{1}{r} \frac{\partial v_\phi}{\partial \phi} \right) - \frac{\alpha^2}{d^2} \frac{2}{r^2} \frac{\partial v_\phi}{\partial \phi} - \frac{1}{l} \frac{\partial p}{\partial r}, \quad (10)$$

$$\rho \left(\frac{dv_\phi}{dt} + \frac{1}{l} \frac{v_r v_\phi}{r} \right) = \frac{\alpha^2 l^2}{d^2} \frac{\partial^2 v_\phi}{\partial z^2} + \frac{\alpha^2}{d^2} \frac{1}{r} \left[\frac{\partial}{\partial r} \left(r \frac{\partial v_\phi}{\partial r} \right) - \frac{v_\phi}{r} \right] + \frac{\alpha^2}{d^2} \left(\frac{4}{3} + \eta_0 \right) \frac{1}{r^2} \frac{\partial^2 v_\phi}{\partial \phi^2} + \frac{\alpha^2 l}{d^2} \left(\frac{1}{3} + \eta_0 \right) \frac{1}{r} \frac{\partial^2 v_z}{\partial z \partial \phi} + \frac{\alpha^2}{d^2} \left(\frac{1}{3} + \eta_0 \right) \frac{1}{r^2} \frac{\partial}{\partial r} \left(r \frac{\partial v_r}{\partial \phi} \right) + \frac{\alpha^2}{d^2} \frac{2}{r^2} \frac{\partial v_r}{\partial \phi} - \frac{1}{l r} \frac{\partial p}{\partial \phi}, \quad (11)$$

$$\frac{d\rho}{dt} + \rho \nabla \cdot \mathbf{v} = 0, \quad (12)$$

$$\rho \vartheta \frac{ds}{dt} = \rho C_p \frac{d\vartheta}{dt} - G_0 \vartheta \beta \frac{d\rho}{dt} = \frac{\alpha^2 l^2}{d^2 \text{Pr}} \Delta \vartheta + \frac{\alpha^2 l^2}{d^2} (\gamma - 1) \Phi, \quad (13)$$

$$c^2 (\delta\rho) = \left(1 + G_0 \frac{c^2 \vartheta \beta^2}{C_p} \right) (\delta p) - c^2 \rho \beta (\delta \vartheta). \quad (14)$$

The quantity Φ appearing in the last term in Eq. (13) is the so-called dissipation function nondimensionalized by $(\tilde{c}_0^2 \tilde{\mu}_0)/\tilde{\lambda}^2$; its explicit form can be found, e.g., in Ref. 27. However, the term $\alpha^2 \Phi$ will turn out to be negligibly small. Furthermore, d/dt denotes the substantial derivative of a scalar A ,

$$\frac{dA}{dt} = \frac{\partial A}{\partial t} + \mathbf{v} \cdot \nabla A, \quad \text{with } \nabla = \left(\frac{\partial}{\partial z}, \frac{1}{l} \frac{\partial}{\partial r}, \frac{1}{lr} \frac{\partial}{\partial \phi} \right)^T, \quad (15)$$

and the divergence of a vector \mathbf{A} and the Laplacian are defined by

$$\nabla \cdot \mathbf{A} = \left(\frac{\partial A_z}{\partial z} + \frac{1}{lr} \frac{\partial}{\partial r} (r A_r) + \frac{1}{lr} \frac{\partial A_\phi}{\partial \phi} \right), \quad \Delta A = \nabla \cdot \nabla A. \quad (16)$$

Please note that in Eqs. (13) and (14) the nondimensional Grüneisen parameter G ,

$$G = \frac{\tilde{p}}{\tilde{\vartheta}} \left(\frac{\partial \tilde{\vartheta}}{\partial \tilde{p}} \right)_{\tilde{s}} = \frac{\tilde{c}^2 \tilde{\beta}}{\tilde{C}_p} = \frac{\gamma - 1}{\tilde{\vartheta} \tilde{\beta}} = \frac{\gamma - 1}{\vartheta \beta}, \quad (17)$$

evaluated at the unperturbed reference state has been introduced; Eq. (3) shows that $G_0 = O(1)$. In the case of a perfect gas, one obtains $c^2 = \gamma p / \rho$, $\beta = 1 / \vartheta$, $c^2 \vartheta \beta^2 / C_p = G / G_0$, $G = \gamma - 1$ and, as expected, Eq. (14) reduces to

$$\frac{(\delta\rho)}{\rho} = \frac{(\delta p)}{p} - \frac{(\delta\vartheta)}{\vartheta} \Rightarrow \frac{p}{\rho \vartheta} = \frac{1}{\gamma_0} = \text{const.} \quad (18)$$

Equations (9)–(14) will be solved subject to the boundary conditions at the tube wall,

$$r = 1: \quad v_z = v_r = v_\phi = 0, \quad \vartheta = \tilde{\vartheta}_0 \tilde{\beta}_0, \quad (19)$$

and the condition that the solutions are bounded at the center of the tube.

Utilizing the parameter introduced in Eq. (8) and assuming that $\tilde{\lambda} = O(\tilde{R})$, the conditions (2) and (5) can be written as

$$\alpha \ll 1, \quad l = O(1), \quad M \ll 1 \quad (20)$$

since then $\text{Re}^{-1} \sim \alpha^2 \ll 1$ and $\text{St}^{-1} \sim \alpha \ll 1$, suggesting the use of M and α as perturbation parameters for an asymptotic analysis. Hence, the velocity components and the relevant thermodynamic quantities are expressed in the form

$$\begin{aligned} v_i &= M(v_{i1} + \alpha v_{i\alpha} + \alpha^2 v_{i\alpha^2} + \dots) \\ &\quad + M^2(v_{iM} + \alpha v_{iM\alpha} + \dots) + \dots, \\ p &= \frac{\tilde{p}_0}{\tilde{\rho}_0 \tilde{c}_0^2} + M(p_1 + \alpha p_\alpha + \alpha^2 p_{\alpha^2} + \dots) \\ &\quad + M^2(p_M + \alpha p_{M\alpha} + \dots) + \dots, \\ \rho &= 1 + M(\rho_1 + \alpha \rho_\alpha + \alpha^2 \rho_{\alpha^2} + \dots) \\ &\quad + M^2(\rho_M + \alpha \rho_{M\alpha} + \dots) + \dots, \\ \vartheta &= \tilde{\vartheta}_0 \tilde{\beta}_0 + M(\vartheta_1 + \alpha \vartheta_\alpha + \alpha^2 \vartheta_{\alpha^2} + \dots) \\ &\quad + M^2(\vartheta_M + \alpha \vartheta_{M\alpha} + \dots) + \dots, \end{aligned} \quad (21)$$

$$c = 1 + Mc_1 + \dots, \quad \beta = 1 + M\beta_1 + \dots,$$

$$C_p = 1 + MC_{p1} + \dots,$$

where $i = z, r, \phi$, respectively. The sound pressure is thus given by $p_s = p - \bar{p}_0 / (\bar{\rho}_0 \bar{c}_0^2)$.

As will be shown in the following, significant simplifications of these expansions are possible if either the Mach number is assumed to be very small (linear case) or M and α can be related to each other such that only one perturbation parameter is necessary (nonlinear case).

III. THE LINEAR CASE

In order to avoid nonlinear effects entering the resulting equations or, more precisely, those that are relevant to solving the problem, the Mach number is assumed to satisfy

$$M \ll \alpha^2. \quad (22)$$

Consequently, each unsteady perturbation w can be decomposed into a steady modal amplitude and a time-harmonic function such that

$$w(z, r, \phi, t) = \Re(\hat{w}(z, r, \phi)e^{j\omega t}). \quad (23)$$

Here and in the following, the accents “ $\hat{}$ ” denote complex-valued quantities.

As shown in Ref. 6, the investigation of the most significant features of the leading order and second-order terms generated by acoustic waves emerging over spatial ranges in the longitudinal direction of the order $O(\alpha^{-1})$ requires the introduction of the length scales z , $z_1 = \alpha z$, and $z_2 = \alpha^2 z$ according to

$$\hat{w}(z, r, \phi) \rightarrow \hat{w}(z, z_1, z_2, r, \phi), \quad \frac{\partial}{\partial z} \rightarrow \frac{\partial}{\partial z} + \alpha \frac{\partial}{\partial z_1} + \alpha^2 \frac{\partial}{\partial z_2}, \quad (24)$$

because otherwise the occurrence of secular terms could not be avoided.

Substitution of the expressions (21) into the system (9)–(14) generates a set of equations which is valid in the entire width of the tube except the boundary region and, therefore, is called the *outer* expansion. Close to the tube wall, where the stretched lateral coordinate

$$y = \frac{1-r}{\alpha} \quad (25)$$

is of $O(1)$, viscosity and heat conduction play an important role; these effects have to be accounted for by a separate investigation of the boundary layer. Consequently, for the *inner* expansion, the coordinate r then has to be replaced with $1 - \alpha y$ and, furthermore,

$$\frac{\partial}{\partial r} \rightarrow -\frac{1}{\alpha} \frac{\partial}{\partial y}. \quad (26)$$

Please note that in the inner expansion, the density terms will be denoted by Ψ , whereas all other inner quantities will be written in capital letters, for example $V_{z\epsilon}$. In order to match the quantities arising from the two expansions, Van Dyke's *asymptotic matching principle* (see, e.g., Ref. 28, pp. 173–179) will be applied.

Evaluation of the continuity equation (12) together with the boundary conditions (19) then yields

$$\frac{\partial \hat{V}_{r1}}{\partial y} = 0 \Rightarrow \hat{V}_{r1} = 0, \quad (27)$$

$$j\omega \hat{\Psi}_1 + \frac{\partial \hat{V}_{z1}}{\partial z} + \frac{1}{l} \left(-\frac{\partial \hat{V}_{r\alpha}}{\partial y} + \frac{\partial \hat{V}_{\phi 1}}{\partial \phi} \right) = 0, \quad (28)$$

$$j\omega \hat{\Psi}_\alpha + \frac{\partial \hat{V}_{z\alpha}}{\partial z} + \frac{\partial \hat{V}_{z1}}{\partial z_1} + \frac{1}{l} \left(-\frac{\partial \hat{V}_{r\alpha^2}}{\partial y} + \hat{V}_{r\alpha} + \frac{\partial \hat{V}_{\phi\alpha}}{\partial \phi} + y \frac{\partial \hat{V}_{\phi 1}}{\partial \phi} \right) = 0, \quad (29)$$

$$j\omega \hat{\rho}_1 + \nabla \cdot \hat{\mathbf{v}}_1 = 0, \quad (30)$$

$$j\omega \hat{\rho}_\alpha + \frac{\partial \hat{v}_{z1}}{\partial z_1} + \nabla \cdot \hat{\mathbf{v}}_\alpha = 0, \quad (31)$$

$$j\omega \hat{\rho}_{\alpha^2} + \frac{\partial \hat{v}_{z\alpha}}{\partial z_1} + \frac{\partial \hat{v}_{z1}}{\partial z_2} + \nabla \cdot \hat{\mathbf{v}}_{\alpha^2} = 0. \quad (32)$$

The inner and outer expansions of the Navier-Stokes equation (10) governing the radial motion give

$$\frac{\partial \hat{P}_1}{\partial y} = \frac{\partial \hat{P}_\alpha}{\partial y} = 0, \quad (33)$$

$$j\omega \hat{V}_{r\alpha} - \frac{1}{l} \frac{\partial \hat{P}_{\alpha^2}}{\partial y} = 0, \quad (34)$$

$$j\omega \hat{v}_{r1} + \frac{1}{l} \frac{\partial \hat{p}_1}{\partial r} = 0, \quad j\omega \hat{v}_{r\alpha} + \frac{1}{l} \frac{\partial \hat{p}_\alpha}{\partial r} = 0, \quad (35)$$

$$j\omega \hat{v}_{r\alpha^2} - \frac{l^2}{d^2} \frac{\partial^2 \hat{v}_{r1}}{\partial z^2} - \frac{1}{d^2} \left(\frac{4}{3} + \eta_0 \right) \left[\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \hat{v}_{r1}}{\partial r} \right) - \frac{\hat{v}_{r1}}{r^2} \right] - \frac{1}{d^2 r^2} \frac{\partial^2 \hat{v}_{r1}}{\partial \phi^2} - \frac{l}{d^2} \left(\frac{1}{3} + \eta_0 \right) \frac{\partial^2 \hat{v}_{z1}}{\partial z \partial r} - \frac{1}{d^2 r} \left(\frac{1}{3} + \eta_0 \right) \times \left(\frac{\partial^2 \hat{v}_{\phi 1}}{\partial r \partial \phi} - \frac{1}{r} \frac{\partial \hat{v}_{\phi 1}}{\partial \phi} \right) + \frac{2}{d^2 r^2} \frac{\partial \hat{v}_{\phi 1}}{\partial \phi} + \frac{1}{l} \frac{\partial \hat{p}_1}{\partial r} = 0. \quad (36)$$

Having substituted the expansions (21) into the Navier-Stokes equations for the axial and azimuthal directions (9) and (11) and using Eq. (27), one obtains

$$j\omega \hat{V}_{z1} - \frac{1}{d^2} \frac{\partial^2 \hat{V}_{z1}}{\partial y^2} + \frac{\partial \hat{P}_1}{\partial z} = 0, \quad (37)$$

$$j\omega \hat{V}_{\phi 1} - \frac{1}{d^2} \frac{\partial^2 \hat{V}_{\phi 1}}{\partial y^2} + \frac{1}{l} \frac{\partial \hat{P}_1}{\partial \phi} = 0,$$

$$j\omega \hat{V}_{z\alpha} - \frac{1}{d^2} \frac{\partial^2 \hat{V}_{z\alpha}}{\partial y^2} + \frac{1}{d^2} \frac{\partial \hat{V}_{z1}}{\partial y} + \frac{\partial \hat{P}_\alpha}{\partial z} + \frac{\partial \hat{P}_1}{\partial z_1} = 0,$$

$$j\omega \hat{V}_{\phi\alpha} - \frac{1}{d^2} \frac{\partial^2 \hat{V}_{\phi\alpha}}{\partial y^2} + \frac{1}{d^2} \frac{\partial \hat{V}_{\phi 1}}{\partial y} + \frac{1}{l} \left(\frac{\partial \hat{P}_\alpha}{\partial \phi} + y \frac{\partial \hat{P}_1}{\partial \phi} \right) = 0, \quad (38)$$

$$j\omega \hat{v}_{z1} + \frac{\partial \hat{p}_1}{\partial z} = 0, \quad j\omega \hat{v}_{\phi 1} + \frac{1}{lr} \frac{\partial \hat{p}_1}{\partial \phi} = 0, \quad (39)$$

$$j\omega\hat{v}_{z\alpha} + \frac{\partial\hat{p}_\alpha}{\partial z} + \frac{\partial\hat{p}_1}{\partial z_1} = 0, \quad j\omega\hat{v}_{\phi\alpha} + \frac{1}{lr} \frac{\partial\hat{p}_\alpha}{\partial\phi} = 0, \quad (40)$$

$$j\omega\hat{v}_{z\alpha^2} - \frac{l^2}{d^2} \left(\frac{4}{3} + \eta_0 \right) \frac{\partial^2\hat{v}_{z1}}{\partial z^2} - \frac{1}{d^2 r} \frac{\partial}{\partial r} \left(r \frac{\partial\hat{v}_{z1}}{\partial r} \right) - \frac{1}{d^2 r^2} \frac{\partial^2\hat{v}_{\phi1}}{\partial\phi^2} - \frac{l}{d^2 r} \left(\frac{1}{3} + \eta_0 \right) \left[\frac{\partial}{\partial r} \left(r \frac{\partial\hat{v}_{r1}}{\partial r} \right) + \frac{\partial^2\hat{v}_{\phi1}}{\partial z \partial\phi} \right] + \frac{\partial\hat{p}_{\alpha^2}}{\partial z} + \frac{\partial\hat{p}_\alpha}{\partial z_1} + \frac{\partial\hat{p}_1}{\partial z_2} = 0. \quad (41)$$

$$j\omega\hat{v}_{\phi\alpha^2} - \frac{l^2}{d^2} \frac{\partial^2\hat{v}_{\phi1}}{\partial z^2} - \frac{1}{d^2 r} \left[\frac{\partial}{\partial r} \left(r \frac{\partial\hat{v}_{\phi1}}{\partial r} \right) - \frac{\hat{v}_{\phi1}}{r} \right] - \frac{1}{d^2 r^2} \left(\frac{4}{3} + \eta_0 \right) \frac{\partial^2\hat{v}_{\phi1}}{\partial\phi^2} - \frac{l}{d^2 r} \left(\frac{1}{3} + \eta_0 \right) \frac{\partial^2\hat{v}_{z1}}{\partial z \partial\phi} - \frac{1}{d^2 r^2} \left(\frac{1}{3} + \eta_0 \right) \frac{\partial}{\partial r} \left(r \frac{\partial\hat{v}_{r1}}{\partial r} \right) - \frac{2}{d^2 r^2} \frac{\partial\hat{v}_{r1}}{\partial\phi} + \frac{1}{lr} \frac{\partial\hat{p}_{\alpha^2}}{\partial\phi} = 0.$$

The set of equations following from the inner expansion of Eq. (14) reads

$$\hat{\Psi}_1 = \gamma_0 \hat{P}_1 - \hat{\Theta}_1, \quad \hat{\Psi}_\alpha = \gamma_0 \hat{P}_\alpha - \hat{\Theta}_\alpha, \quad (42)$$

$$\hat{\Psi}_{\alpha^2} = \gamma_0 \hat{P}_{\alpha^2} - \hat{\Theta}_{\alpha^2},$$

which holds for the outer expansion as well. Here, the relationship $G_0 \tilde{\partial}_0 \tilde{\beta}_0 = \gamma_0 - 1$ resulting from Eq. (17) has been used.

The term in the energy equation (13) containing the dissipation function turns out to be of the order $O(M^2\alpha^2)$ in the core region and $O(M^2)$ in the boundary layer. Therefore, the expansions of Eq. (13) take the form

$$j\omega\hat{\Theta}_1 - j\omega(\gamma_0 - 1)\hat{P}_1 - \frac{1}{d^2 \text{Pr}} \frac{\partial^2\hat{\Theta}_1}{\partial y^2} = 0, \quad (43)$$

$$j\omega\hat{\Theta}_\alpha - j\omega(\gamma_0 - 1)\hat{P}_\alpha - \frac{1}{d^2 \text{Pr}} \frac{\partial^2\hat{\Theta}_\alpha}{\partial y^2} + \frac{1}{d^2 \text{Pr}} \frac{\partial\hat{\Theta}_1}{\partial y} = 0, \quad (44)$$

$$\hat{\vartheta}_1 = (\gamma_0 - 1)\hat{p}_1, \quad \hat{\vartheta}_\alpha = (\gamma_0 - 1)\hat{p}_\alpha, \quad (45)$$

$$j\omega\hat{\vartheta}_{\alpha^2} - j\omega(\gamma_0 - 1)\hat{p}_{\alpha^2} - \frac{l^2}{d^2 \text{Pr}} \frac{\partial^2\hat{\vartheta}_1}{\partial z^2} - \frac{1}{d^2 \text{Pr}} \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial\hat{\vartheta}_1}{\partial r} \right) - \frac{1}{d^2 \text{Pr}} \frac{1}{r^2} \frac{\partial^2\hat{\vartheta}_1}{\partial\phi^2} = 0, \quad (46)$$

whereupon substitution of Eqs. (42) into Eqs. (45) yields

$$\hat{p}_1 = \hat{p}_1, \quad \hat{p}_\alpha = \hat{p}_\alpha. \quad (47)$$

Inspection of Eqs. (27), (30), (35), and (39) shows that the leading order pressure perturbations in the core region \hat{p}_1 satisfy the Helmholtz equation

$$\omega^2 \hat{p}_1 + \Delta \hat{p}_1 = 0, \quad (48)$$

together with the boundary condition

$$r=1: \quad \frac{\partial\hat{p}_1}{\partial r} = 0. \quad (49)$$

The solution is given by the modal decomposition

$$\hat{p}_1 = \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left(\hat{C}_{1nm1}(z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} e^{-j(\hat{k}_{nm}z + m\phi)} + \hat{C}_{2nm1}(z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} e^{j(\hat{k}_{nm}z + m\phi)} \right), \quad (50)$$

where the parameters $\gamma_{nm} = \gamma_{n(-m)}$, $n=0,1,2,\dots$, are the zeros of the first derivatives of the Bessel functions $\partial J_m(\xi)/\partial\xi$, with $\gamma_{00}=0$, and the quantities

$$\hat{k}_{nm} = \hat{k}_{n(-m)} = \begin{cases} \sqrt{\omega^2 - \gamma_{nm}^2/l^2}, & \omega > \gamma_{nm}/l, \\ -j\sqrt{\gamma_{nm}^2/l^2 - \omega^2}, & \omega < \gamma_{nm}/l, \end{cases} \quad (51)$$

are, respectively, the axial wave numbers for the propagating and evanescent modes.

Combining Eqs. (31), (35), (39), and (40) yields the inhomogeneous Helmholtz equation for the second-order term \hat{p}_α :

$$\omega^2 \hat{p}_\alpha + \Delta \hat{p}_\alpha = -2 \frac{\partial^2 \hat{p}_1}{\partial z \partial z_1}. \quad (52)$$

Upon applying Van Dyke's matching rules to the expressions for \hat{V}_{z1} , \hat{v}_{z1} , $\hat{V}_{\phi1}$, $\hat{v}_{\phi1}$, $\hat{\Theta}_1$, and $\hat{\vartheta}_1$ resulting from Eqs. (37), (39), (43), (45), and (19), one obtains

$$\hat{V}_{z1} = \hat{v}_{z1}|_{r=1} (1 - e^{-(1+j)dy\sqrt{\omega/2}}),$$

$$\hat{V}_{\phi1} = \hat{v}_{\phi1}|_{r=1} (1 - e^{-(1+j)dy\sqrt{\omega/2}}), \quad (53)$$

$$\hat{\Theta}_1 = \hat{p}_1|_{r=1} (\gamma_0 - 1) (1 - e^{-(1+j)dy\sqrt{\omega \text{Pr}/2}}).$$

It then follows from Eqs. (28) and (42) that

$$\frac{\hat{V}_{r\alpha}}{l} = \hat{p}_1|_{r=1} \left[j\omega y + \frac{1+j}{d} \sqrt{\frac{\omega}{2}} \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} (1 - e^{-(1+j)dy\sqrt{\omega \text{Pr}/2}}) \right] + \left(\frac{\partial^2 \hat{p}_1}{\partial z^2} + \frac{1}{l^2} \frac{\partial^2 \hat{p}_1}{\partial\phi^2} \right) \Big|_{r=1} \times \frac{1}{\omega^2} \left[j\omega y - \frac{1+j}{d} \sqrt{\frac{\omega}{2}} (1 - e^{-(1+j)dy\sqrt{\omega/2}}) \right]. \quad (54)$$

As a consequence, the matching principle gives the boundary condition for the outer expansion term \hat{p}_α in the form

$$r=1: \quad \frac{\partial\hat{p}_\alpha}{\partial r} = l^2 \frac{1-j}{d} \omega \sqrt{\frac{\omega}{2}} \left[\hat{p}_1 \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} - \left(\frac{\partial^2 \hat{p}_1}{\partial z^2} + \frac{1}{l^2} \frac{\partial^2 \hat{p}_1}{\partial\phi^2} \right) \frac{1}{\omega^2} \right]. \quad (55)$$

The solution \hat{p}'_α to the homogeneous part of Eq. (52) subject to the homogeneous boundary conditions at $r=1$ assumes the same form as the expression for \hat{p}_1 from Eq. (50). However, the functions \hat{C}_{1nm1} and \hat{C}_{2nm1} have to be replaced with $\hat{C}_{1nm\alpha}$ and $\hat{C}_{2nm\alpha}$, respectively. In order to determine a particular solution \hat{p}''_α such that $\hat{p}_\alpha = \hat{p}'_\alpha + \hat{p}''_\alpha$ the ansatz

$$\begin{aligned} \hat{p}''_{\alpha} = & \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left[\left(\hat{f}_{1nm\alpha}(z, z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \right. \right. \\ & + \hat{g}_{nm\alpha}(r) \hat{C}_{1nm1}(z_1, z_2) \left. \right) e^{-j(\hat{k}_{nm}z + m\phi)} \\ & + \left(\hat{f}_{2nm\alpha}(z, z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \right. \\ & \left. \left. + \hat{g}_{nm\alpha}(r) \hat{C}_{2nm1}(z_1, z_2) \right) e^{j(\hat{k}_{nm}z + m\phi)} \right] \end{aligned} \quad (56)$$

is made, which is required to be bounded at $r=0$ and to fulfill the condition (55). Furthermore, the functional dependence on the coordinate r of the terms that are generated by the left-hand side of Eq. (52) for each mode (n, m) upon substituting Eq. (56) must be given by the radial eigenfunctions $J_m(\gamma_{nm}r)$. Hence, these requirements imply that

$$\begin{aligned} \hat{g}_{00\alpha} = & \frac{l^2 \omega^2 \hat{F}_{00}}{2} r^2, \quad \hat{g}_{nm\alpha} = l^2 \hat{k}_{nm}^2 \hat{F}_{nm} \frac{r J_{m+1}(\gamma_{nm}r)}{\gamma_{nm} J_m(\gamma_{nm})}, \\ & (n, m) \neq (0, 0), \end{aligned} \quad (57)$$

with the parameters \hat{F}_{nm} defined as

$$\hat{F}_{nm} = \frac{1-j}{d \sqrt{2\omega(1-m^2/\gamma_{nm}^2)}} \left(1 + \frac{m^2}{l^2 \hat{k}_{nm}^2} + \frac{\omega^2}{\hat{k}_{nm}^2} \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} \right). \quad (58)$$

Substitution of the expression (56) into Eq. (52) then results in

$$\begin{aligned} & \frac{\partial^2 \hat{f}_{1nm\alpha}}{\partial z^2} - 2j\hat{k}_{nm} \frac{\partial \hat{f}_{1nm\alpha}}{\partial z} \\ & = -2\hat{F}_{nm} \hat{k}_{nm}^2 \hat{C}_{1nm1} + 2j\hat{k}_{nm} \frac{\partial \hat{C}_{1nm1}}{\partial z_1}, \\ & \frac{\partial^2 \hat{f}_{2nm\alpha}}{\partial z^2} + 2j\hat{k}_{nm} \frac{\partial \hat{f}_{2nm\alpha}}{\partial z} \\ & = -2\hat{F}_{nm} \hat{k}_{nm}^2 \hat{C}_{2nm1} - 2j\hat{k}_{nm} \frac{\partial \hat{C}_{2nm1}}{\partial z_1}. \end{aligned} \quad (59)$$

The forcing terms on the right-hand sides are resonant and would produce secular terms in the functions $\hat{f}_{1nm\alpha}$ and $\hat{f}_{2nm\alpha}$. Therefore, they must be annihilated, yielding

$$\begin{aligned} \hat{C}_{1nm1}(z_1, z_2) & \rightarrow \hat{C}_{1nm1}(z_2) e^{-j\hat{k}_{nm} \hat{F}_{nm} z_1}, \\ \hat{C}_{2nm1}(z_1, z_2) & \rightarrow \hat{C}_{2nm1}(z_2) e^{j\hat{k}_{nm} \hat{F}_{nm} z_1}, \end{aligned} \quad (60)$$

whereupon the functions $\hat{f}_{1nm\alpha}$ and $\hat{f}_{2nm\alpha}$ can simply be set to zero since any other solution would lead to expressions for \hat{p}''_{α} that could be incorporated into the homogeneous solution \hat{p}'_{α} . Please note that the solvability conditions (60) could also have been derived by employing the so-called *Fredholm alternative* (see, for example, Ref. 29). This method will be used in Sec. IV.

The quantities $\mathfrak{J}(-\omega \hat{F}_{00})$ and $\mathfrak{J}(-\hat{k}_{nm} \hat{F}_{nm})$, $(n, m) \neq (0, 0)$, turn out to be, respectively, the leading order decay rate of the fundamental mode and the leading order decay rates of the higher order modes due to boundary layer attenuation. This is in accordance with Beatty's results⁷ obtained by using the concept of boundary layer admittance.

In order to calculate the corresponding expressions for the third-order problem, a procedure very similar to that used before is performed: A combination of Eqs. (32), (36), (39)–(41), (45), and (46) and multiple application of Eq. (48) shows that

$$\hat{v}_{z\alpha^2} = -\frac{l^2}{d^2} \frac{\partial \hat{p}_1}{\partial z} \left(\frac{4}{3} + \eta_0 \right) + \frac{j}{\omega} \left(\frac{\partial \hat{p}_1}{\partial z_2} + \frac{\partial \hat{p}_{\alpha}}{\partial z_1} + \frac{\partial \hat{p}_{\alpha^2}}{\partial z} \right) \quad (61)$$

and that \hat{p}_{α^2} has to satisfy the inhomogeneous equation

$$\begin{aligned} \omega^2 \hat{p}_{\alpha^2} + \Delta \hat{p}_{\alpha^2} = & -2 \frac{\partial^2 \hat{p}_1}{\partial z \partial z_2} - \frac{\partial^2 \hat{p}_1}{\partial z_1^2} + l^2 \frac{j\omega^3}{d^2} \\ & \times \hat{p}_1 \left(\frac{4}{3} + \eta_0 + \frac{\gamma_0 - 1}{\text{Pr}} \right) - 2 \frac{\partial^2 \hat{p}_{\alpha}}{\partial z \partial z_1}, \end{aligned} \quad (62)$$

where the third term on the right-hand side obviously incorporates the effects of heat conduction and viscosity in the core region associated with the propagation of the leading order pressure fluctuations \hat{p}_1 . Moreover, Eqs. (38) and (44) are solved for the axial and the azimuthal velocity and the temperature in the boundary layer, leading to

$$\begin{aligned} \hat{V}_{z\alpha} = & \hat{v}_{z\alpha}|_{r=1} (1 - e^{-(1+j)y\sqrt{\omega/2}}) \\ & - \hat{v}_{z1}|_{r=1} \frac{y}{2} e^{-(1+j)y\sqrt{\omega/2}}, \\ \hat{V}_{\phi\alpha} = & \hat{v}_{\phi\alpha}|_{r=1} (1 - e^{-(1+j)y\sqrt{\omega/2}}) \\ & + \hat{v}_{\phi1}|_{r=1} y (1 - \frac{1}{2} e^{-(1+j)y\sqrt{\omega/2}}), \end{aligned} \quad (63)$$

$$\begin{aligned} \hat{\Theta}_{\alpha} = & \hat{p}_{\alpha}|_{r=1} (\gamma_0 - 1) (1 - e^{-(1+j)y\sqrt{\omega \text{Pr}/2}}) \\ & - \hat{p}_1|_{r=1} (\gamma_0 - 1) \frac{y}{2} e^{-(1+j)y\sqrt{\omega \text{Pr}/2}}. \end{aligned}$$

After substituting for $\hat{\Psi}_{\alpha}$, \hat{V}_{z1} , $\hat{V}_{\phi1}$, $\hat{V}_{r\alpha}$, $\hat{V}_{z\alpha}$, and $\hat{V}_{\phi\alpha}$ from Eqs. (42), (53), (54), and (63), respectively, integration of Eq. (29) with respect to the inner coordinate y gives

$$\begin{aligned}
\frac{\hat{V}_{r\alpha^2}}{l} = & \hat{p}_1|_{r=1} \frac{1}{2} \left[j\omega y^2 - \frac{\gamma_0 - 1}{d^2 \text{Pr}} (1 - e^{-(1+j)dy\sqrt{\omega \text{Pr}/2}}) + \frac{1+j}{d} \sqrt{\frac{\omega}{2}} \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} y (2 - e^{-(1+j)dy\sqrt{\omega \text{Pr}/2}}) \right] \\
& + \frac{\partial^2 \hat{p}_1}{\partial z^2} \Big|_{r=1} \frac{1}{2\omega^2} \left[j\omega y^2 + \frac{1}{d^2} (1 - e^{-(1+j)dy\sqrt{\omega/2}}) - \frac{1+j}{d} \sqrt{\frac{\omega}{2}} y (2 - e^{-(1+j)dy\sqrt{\omega/2}}) \right] \\
& + \frac{1}{l^2} \frac{\partial^2 \hat{p}_1}{\partial \phi^2} \Big|_{r=1} \frac{1}{2\omega^2} \left[3j\omega y^2 - \frac{1}{d^2} (1 - e^{-(1+j)dy\sqrt{\omega/2}}) - \frac{1+j}{d} \sqrt{\frac{\omega}{2}} y \left(2 - \frac{3}{2} e^{-(1+j)dy\sqrt{\omega/2}} \right) \right] \\
& + \hat{p}_\alpha|_{r=1} \left[j\omega y + \frac{1+j}{d} \sqrt{\frac{\omega}{2}} \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} (1 - e^{-(1+j)dy\sqrt{\omega \text{Pr}/2}}) \right] + \left(\frac{\partial^2 \hat{p}_\alpha}{\partial z^2} + \frac{1}{l^2} \frac{\partial^2 \hat{p}_\alpha}{\partial \phi^2} + 2 \frac{\partial^2 \hat{p}_1}{\partial z \partial z_1} \right) \Big|_{r=1} \\
& \times \frac{1}{\omega^2} \left[j\omega y - \frac{1+j}{d} \sqrt{\frac{\omega}{2}} (1 - e^{-(1+j)dy\sqrt{\omega/2}}) \right]. \tag{64}
\end{aligned}$$

With the matching rules applied to the inner and outer expansions of the radial velocity, the boundary condition

$$\begin{aligned}
r=1: \quad \frac{\partial \hat{p}_{\alpha^2}}{\partial r} = & l^2 \frac{j\omega}{2d^2} \left[\hat{p}_1 \frac{\gamma_0 - 1}{\text{Pr}} - \left(\frac{\partial^2 \hat{p}_1}{\partial z^2} - \frac{1}{l^2} \frac{\partial^2 \hat{p}_1}{\partial \phi^2} \right) \frac{1}{\omega^2} \right] \\
& + l^2 \frac{1-j}{d} \omega \sqrt{\frac{\omega}{2}} \left[\hat{p}_\alpha \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} - \left(\frac{\partial^2 \hat{p}_\alpha}{\partial z^2} \right. \right. \\
& \left. \left. + \frac{1}{l^2} \frac{\partial^2 \hat{p}_\alpha}{\partial \phi^2} + 2 \frac{\partial^2 \hat{p}_1}{\partial z \partial z_1} \right) \frac{1}{\omega^2} \right] \tag{65}
\end{aligned}$$

is derived.

A particular solution \hat{p}''_{α^2} to Eq. (62) can be found by employing the ansatz

$$\begin{aligned}
\hat{p}''_{\alpha^2} = & \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left[\left(\hat{f}_{1nm\alpha^2}(z, z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \right. \right. \\
& + \hat{g}_{nm\alpha^2}(r) \hat{C}_{1nm1}(z_2) e^{-j\hat{F}_{nm}\hat{k}_{nm}z_1} \\
& + \hat{h}_{nm\alpha^2}(r) \hat{C}_{1nm\alpha}(z_1, z_2) \left. \right) e^{-j(\hat{k}_{nm}z + m\phi)} \\
& + \left(\hat{f}_{2nm\alpha^2}(z, z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \right. \\
& + \hat{g}_{nm\alpha^2}(r) \hat{C}_{2nm1}(z_2) e^{j\hat{F}_{nm}\hat{k}_{nm}z_1} \\
& \left. \left. + \hat{h}_{nm\alpha^2}(r) \hat{C}_{2nm\alpha}(z_1, z_2) \right) e^{j(\hat{k}_{nm}z - m\phi)} \right] \tag{66}
\end{aligned}$$

such that the boundary condition (65) is satisfied and the operators on the left-hand side of Eq. (62) produce terms that have the same functional dependence on r as the terms on the right-hand side. Consequently, one obtains

$$\hat{g}_{00\alpha^2} = \frac{l^2 \omega^2}{2} \left(\hat{G}_{00} + \frac{\omega^2 \hat{F}_{00}^2}{4} \right) r^2 + \frac{l^4 \omega^4 \hat{F}_{00}^2}{16} r^4,$$

$$\begin{aligned}
\hat{g}_{nm\alpha^2} = & l^2 \hat{k}_{nm}^2 \left[\hat{G}_{nm} + \left(m + \frac{1}{1 - m^2/\gamma_{nm}^2} \right) \right. \\
& \times \frac{l^2 \hat{k}_{nm}^2 \hat{F}_{nm}^2}{\gamma_{nm}^2} \left. \frac{r J_{m+1}(\gamma_{nm}r)}{\gamma_{nm} J_m(\gamma_{nm})} \right. \\
& \left. - \frac{l^4 \hat{k}_{nm}^4 \hat{F}_{nm}^2}{2} \frac{r^2 J_m(\gamma_{nm}r)}{\gamma_{nm}^2 J_m(\gamma_{nm})} \right], \quad (n, m) \neq (0, 0), \tag{67}
\end{aligned}$$

$$\begin{aligned}
\hat{h}_{00\alpha^2} = & \frac{l^2 \omega^2 \hat{F}_{00}}{2} r^2, \quad \hat{h}_{nm\alpha^2} = l^2 \hat{k}_{nm}^2 \hat{F}_{nm} \frac{r J_{m+1}(\gamma_{nm}r)}{\gamma_{nm} J_m(\gamma_{nm})}, \\
& (n, m) \neq (0, 0),
\end{aligned}$$

where

$$\begin{aligned}
\hat{G}_{nm} = & - \frac{j}{2d^2 \omega (1 - m^2/\gamma_{nm}^2)^2} \left[3 + \frac{m^2}{\gamma_{nm}^2} + \frac{m^2}{l^2 \hat{k}_{nm}^2} \left(5 - \frac{m^2}{\gamma_{nm}^2} \right) \right. \\
& \left. - \frac{\omega^2}{\hat{k}_{nm}^2} (\gamma_0 - 1) \left(\left(1 - \frac{m^2}{\gamma_{nm}^2} \right) \frac{1}{\text{Pr}} - \frac{4}{\sqrt{\text{Pr}}} \right) \right]. \tag{68}
\end{aligned}$$

Substitution of Eq. (56) into Eq. (62) then yields

$$\begin{aligned}
& \frac{\partial^2 \hat{f}_{1nm\alpha^2}}{\partial z^2} - 2j\hat{k}_{nm} \frac{\partial \hat{f}_{1nm\alpha^2}}{\partial z} \\
& = \left(-2\hat{H}_{nm} \hat{k}_{nm}^2 \hat{C}_{1nm1} + 2j\hat{k}_{nm} \frac{\partial \hat{C}_{1nm1}}{\partial z_2} \right) e^{-j\hat{F}_{nm}\hat{k}_{nm}z_1} \\
& \quad - 2\hat{F}_{nm} \hat{k}_{nm}^2 \hat{C}_{1nm\alpha} + 2j\hat{k}_{nm} \frac{\partial \hat{C}_{1nm\alpha}}{\partial z_1},
\end{aligned}$$

$$\begin{aligned} & \frac{\partial^2 \hat{f}_{2nm\alpha^2}}{\partial z^2} + 2j\hat{k}_{nm} \frac{\partial \hat{f}_{2nm\alpha^2}}{\partial z} \\ &= \left(-2\hat{H}_{nm}\hat{k}_{nm}^2 \hat{C}_{1nm1} - 2j\hat{k}_{nm} \frac{\partial \hat{C}_{2nm1}}{\partial z_2} \right) e^{j\hat{F}_{nm}\hat{k}_{nm}z_1} \\ & \quad - 2\hat{F}_{nm}\hat{k}_{nm}^2 \hat{C}_{2nm\alpha} - 2j\hat{k}_{nm} \frac{\partial \hat{C}_{2nm\alpha}}{\partial z_1}, \end{aligned} \quad (69)$$

where

$$\begin{aligned} \hat{H}_{00} &= \hat{G}_{00} - \frac{\hat{F}_{00}^2}{2} + \frac{l^2 \omega^2 \hat{F}_{00}^2}{4} - l^2 \frac{j\omega}{2d^2} \left(\frac{4}{3} + \eta_0 + \frac{\gamma_0 - 1}{\text{Pr}} \right) \\ &= -\frac{j}{d^2 \omega} \left[1 + \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} \left(1 - \frac{\gamma_0}{2\sqrt{\text{Pr}}} \right) \right] \\ & \quad - l^2 \frac{j\omega}{2d^2} \left[\frac{11}{6} + \eta_0 + \frac{\gamma_0 - 1}{2\sqrt{\text{Pr}}} \left(2 + \frac{1 + \gamma_0}{\sqrt{\text{Pr}}} \right) \right], \end{aligned} \quad (70)$$

$$\begin{aligned} \hat{H}_{nm} &= \hat{G}_{nm} - \frac{\hat{F}_{nm}^2}{2} + \frac{l^2 \hat{k}_{nm}^2 \hat{F}_{nm}^2}{\gamma_{nm}^2} - \frac{m^2}{\gamma_{nm}^2 - m^2} - l^2 \frac{j\omega^2}{2d^2 \hat{k}_{nm}^2} \\ & \quad \times \left(\frac{4}{3} + \eta_0 + \frac{\gamma_0 - 1}{\text{Pr}} \right), \quad (n, m) \neq (0, 0). \end{aligned}$$

As before, the right-hand sides of Eqs. (69) have to be annihilated in order to rule out secular terms in the functions $\hat{f}_{1nm\alpha^2}$ and $\hat{f}_{2nm\alpha^2}$. The resulting solvability conditions thus read

$$\begin{aligned} & 2\hat{F}_{nm}\hat{k}_{nm}^2 \hat{C}_{1nm\alpha} - 2j\hat{k}_{nm} \frac{\partial \hat{C}_{1nm\alpha}}{\partial z_1} \\ &= \left(-2\hat{H}_{nm}\hat{k}_{nm}^2 \hat{C}_{1nm1} + 2j\hat{k}_{nm} \frac{\partial \hat{C}_{1nm1}}{\partial z_2} \right) e^{-j\hat{F}_{nm}\hat{k}_{nm}z_1}, \end{aligned} \quad (71)$$

$$\begin{aligned} & 2\hat{F}_{nm}\hat{k}_{nm}^2 \hat{C}_{2nm\alpha} + 2j\hat{k}_{nm} \frac{\partial \hat{C}_{2nm\alpha}}{\partial z_1} \\ &= \left(-2\hat{H}_{nm}\hat{k}_{nm}^2 \hat{C}_{2nm1} - 2j\hat{k}_{nm} \frac{\partial \hat{C}_{2nm1}}{\partial z_2} \right) e^{j\hat{F}_{nm}\hat{k}_{nm}z_1}, \end{aligned}$$

and, furthermore, $\hat{f}_{1nm\alpha^2}$ and $\hat{f}_{2nm\alpha^2}$ can be set to zero. The right-hand sides of Eqs. (71) are again identified as resonant forcing terms. Their elimination leads to

$$\hat{C}_{1nm1}(z_2) e^{-j\hat{F}_{nm}\hat{k}_{nm}z_1} \rightarrow \hat{C}_{1nm1} e^{-j\hat{k}_{nm}(\hat{F}_{nm}z_1 + \hat{H}_{nm}z_2)}, \quad (72)$$

$$\hat{C}_{2nm1}(z_2) e^{j\hat{F}_{nm}\hat{k}_{nm}z_1} \rightarrow \hat{C}_{2nm1} e^{j\hat{k}_{nm}(\hat{F}_{nm}z_1 + \hat{H}_{nm}z_2)},$$

and, finally,

$$\hat{C}_{1nm\alpha}(z_1, z_2) \rightarrow \hat{C}_{1nm\alpha}(z_2) e^{-j\hat{k}_{nm}\hat{F}_{nm}z_1}, \quad (73)$$

$$\hat{C}_{2nm\alpha}(z_1, z_2) \rightarrow \hat{C}_{2nm\alpha}(z_2) e^{j\hat{k}_{nm}\hat{F}_{nm}z_1}.$$

A. Results

Combining the expressions derived so far yields the following solution for the sound pressure, which is valid in the complete spatial range defined by $z = O(\alpha^{-1})$:

$$\begin{aligned} \hat{p}_1 &= \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left(\hat{C}_{1nm1} \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \right. \\ & \quad \times e^{-j[\hat{k}_{nm}(z + \hat{F}_{nm}z_1 + \hat{H}_{nm}z_2) + m\phi]} + \hat{C}_{2nm1} \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \\ & \quad \times e^{j[\hat{k}_{nm}(z + \hat{F}_{nm}z_1 + \hat{H}_{nm}z_2) + m\phi]} \Big), \end{aligned} \quad (74)$$

$$\begin{aligned} \hat{p}_\alpha &= \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left[\left(\hat{C}_{1nm\alpha} \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} \right. \right. \\ & \quad \left. \left. + \hat{C}_{1nm1} \hat{g}_{nm\alpha}(r) \right) e^{-j[\hat{k}_{nm}(z + \hat{F}_{nm}z_1) + m\phi]} \right. \\ & \quad \left. + \left(\hat{C}_{2nm\alpha} \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} + \hat{C}_{2nm1} \hat{g}_{nm\alpha}(r) \right) \right. \\ & \quad \left. \times e^{j[\hat{k}_{nm}(z + \hat{F}_{nm}z_1) + m\phi]} \right], \end{aligned} \quad (75)$$

where \hat{F}_{nm} and \hat{H}_{nm} are the quantities already introduced in Eqs. (58) and (70), respectively; the function $\hat{g}_{nm\alpha}$ is given by Eq. (57). Please note that the next higher order correction,

$$\begin{aligned} \hat{p}_{\alpha^2} &= \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left(\hat{C}_{1nm\alpha^2}(z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} e^{-j(\hat{k}_{nm}z + m\phi)} \right. \\ & \quad \left. + \hat{C}_{2nm\alpha^2}(z_1, z_2) \frac{J_m(\gamma_{nm}r)}{J_m(\gamma_{nm})} e^{j(\hat{k}_{nm}z + m\phi)} \right) + \hat{p}_{\alpha^2}''', \end{aligned} \quad (76)$$

with \hat{p}_{α^2}''' given by Eq. (66), is valid over ranges of the order $z = O(1)$ only because the dependence of the functions $\hat{C}_{1nm\alpha^2}$ and $\hat{C}_{2nm\alpha^2}$ on the scales z_1 and z_2 remains undetermined at the level of approximation to be reached here.

In order to define the propagation parameters $\hat{\Gamma}_{nm}$, each mode has to be treated separately:

$$\hat{\Gamma}_{nm} = \sqrt{\frac{1}{\hat{p}_{nms} \hat{v}_{nmz}} \frac{\partial \hat{p}_{nms}}{\partial z} \frac{\partial \hat{v}_{nmz}}{\partial z}}, \quad (77)$$

where \hat{p}_{nms} and \hat{v}_{nmz} denote the sound pressures and the axial velocities associated with the modes $n=0,1,2,\dots$, $m = \dots, -1, 0, 1, \dots$. Inspection of Eqs. (39), (40), and (61) shows that \hat{v}_{nmz} can be expanded as

$$\hat{v}_{nmz} = \frac{j}{\omega} \frac{\partial \hat{p}_{nms}}{\partial z} - \alpha^2 \frac{l^2}{d^2} \frac{\partial \hat{p}_{nms}}{\partial z} \left(\frac{4}{3} + \eta_0 \right) + \dots, \quad (78)$$

keeping in mind that the partial derivatives with respect to z have to be understood in the sense of derivatives with respect to the three length scales introduced by Eq. (24). Since, after substitution of Eq. (78) into Eq. (77) and expansion with respect to α , all terms proportional to $(\frac{4}{3} + \eta_0)$ cancel out, the definition of the propagation parameters can be equivalently written as

$$\hat{\Gamma}_{nm} = \sqrt{\frac{1}{\hat{p}_{nms}} \frac{\partial^2 \hat{p}_{nms}}{\partial z^2} + \dots} \quad (79)$$

Once the derivative $\partial^2/\partial z^2$ has been replaced with derivatives with respect to the multiple scales $z, z_1,$ and z_2 , application of Eqs. (74)–(76) implicates that the parameters $\hat{\Gamma}_{nm}$ are given by the relationship

$$\hat{\Gamma}_{nm} = \sqrt{-\hat{k}_{nm}^2 [1 + 2\alpha \hat{F}_{nm} + \alpha^2 (2\hat{H}_{nm} + \hat{F}_{nm}^2)] + \dots} \quad (80)$$

Interestingly, \hat{H}_{00} and thus $\hat{\Gamma}_{00}$ cannot be derived from \hat{H}_{nm} and $\hat{\Gamma}_{nm}$ for the higher order modes simply by setting $\hat{k}_{nm} = \omega, \gamma_{nm} = 0,$ and $m = 0.$

If $|\hat{k}_{nm}| = O(1),$ the result (80) simplifies to

$$\hat{\Gamma}_{nm} = j\hat{k}_{nm} + \alpha j\hat{k}_{nm}\hat{F}_{nm} + \alpha^2 j\hat{k}_{nm}\hat{H}_{nm} + \dots \quad (81)$$

In contrast to that, inspection of the definitions (58) and (70) shows that in the limiting case of a mode $(n, m) \neq (0, 0)$ being driven so close to its cutoff frequency that $|\hat{k}_{nm}| \ll 1,$ the orders of magnitude of the different terms appearing in Eq. (80) may change completely. Moreover, the solvability conditions resulting from Eqs. (59) and (69) turn out to be singular at the cutoff frequencies $\omega = \gamma_{nm}/l,$ predicting that in the limit as $\omega \rightarrow \gamma_{nm}/l, \hat{k}_{nm} \rightarrow 0,$ the attenuation of the mode $(n, m) = (\bar{n}, \bar{m})$ takes place over a much shorter spatial range than that defined by $z_1 = O(1).$ As explicated in Scheichl,⁶ however, the expression for $\hat{\Gamma}_{nm}$ from Eq. (80) retains its validity even for those driving frequencies that are very close to the cutoff frequency of this mode. Expanding ω as $\omega = \omega_{nm} + \alpha\omega_\alpha,$ with $\omega_{nm} = \gamma_{nm}/l,$ one obtains the following expression for the propagation parameter

$$\hat{\Gamma}_{nm} = \alpha^{1/2} \hat{\Gamma}_{nm\alpha^{1/2}} + \alpha^{3/2} \hat{\Gamma}_{nm\alpha^{3/2}} + \dots, \quad (82)$$

where

$$\begin{aligned} \hat{\Gamma}_{nm\alpha^{1/2}} &= j(2\hat{F}_{nm} + 2\omega_{nm}\omega_\alpha)^{1/2}, \\ \hat{\Gamma}_{nm\alpha^{3/2}} &= \frac{j}{2}(2\hat{F}_{nm} + 2\omega_{nm}\omega_\alpha)^{1/2} \left(\frac{\omega_\alpha}{2\omega_{nm}} \right. \\ &\quad \left. + \frac{\omega_\alpha \hat{F}_{nm} + \sqrt{2\omega_{nm}\omega_\alpha}[(1-j)/d] + \hat{K}_{nm}}{\hat{F}_{nm} + \omega_{nm}\omega_\alpha} \right), \quad (83) \end{aligned}$$

$$\hat{F}_{nm} = \lim_{\omega \rightarrow \omega_{nm}} k_{nm}^2 \hat{F}_{nm}, \quad \hat{K}_{nm} = \lim_{\omega \rightarrow \omega_{nm}} k_{nm}^2 \left(\hat{H}_{nm} + \frac{\hat{F}_{nm}^2}{2} \right),$$

which is valid for all frequencies ω arbitrarily near the cutoff frequency $\gamma_{nm}/l,$ i.e., even for $\omega_\alpha = 0.$ When truncated after the first expansion term, this solution agrees perfectly with the approximation derived by Hudde⁹ using the concept of boundary layer admittance.

Another interesting property of the general expression for the propagation parameters from Eq. (80) is that its formal representation would have remained unchanged if a perfect gas had been considered since the only quantities de-

FIG. 2. Graphs of $\Re(\hat{\Gamma}_{nm}c_0/\omega)$ as functions of He in double logarithmic scale, $R = 0.001$ m, i.e., $St = \sqrt{\text{He Re}_R}$ with $\text{Re}_R = c_0 R \rho_0 / \mu_0;$ $\text{Pr} = 0.707, \gamma_0 = 1.402, \eta_0 / \mu_0 = 0.6, c_0 \rho_0 / \mu_0 = 221.3732 \times 10^5 \text{ m}^{-1}$ (air at 300 K and 10^5 Pa); $\gamma_{00} = 0, \gamma_{01} = 1.84118, \gamma_{02} = 3.05424, \gamma_{10} = 3.83171, \gamma_{11} = 5.33144,$ and $\gamma_{20} = 7.01559.$

pending on the thermodynamic equilibrium state of the fluid that enter the definitions (58) and (70) of \hat{F}_{nm} and \hat{H}_{nm} are the parameters $\gamma_0 = \tilde{C}_{p0} / \tilde{C}_{v0}, \text{Pr},$ and $\eta_0.$

The dimensional form of Eq. (80) is given in the Appendix and can be compared with results given in the literature: Kergomard *et al.*³⁰ calculated the propagation parameters for the higher order modes, starting from a generalized dispersion equation (see also Refs. 8 and 31). However, in the intermediate steps that then followed, only boundary layer effects were taken into account [see Eq. (2) in Ref. 30] and some other simplifying hypotheses were applied. Thus, their solutions, i.e., Eqs. (7) and (8) in Ref. 30, differ quite significantly from the expressions for the propagation parameters $\hat{\Gamma}_{nm}$ presented in Eqs. (80) and (A1). When, though, the quantity X in that paper is recalculated without using the simplifications concerning the involved quantities $D_a, D_{v0},$ and D_{h0} and expanded with respect to $St^{-1},$ one obtains a solution for the propagation parameter which is in complete accordance with the results from Eq. (80), provided that the last bracket term appearing in the definition (70) of \hat{H}_{nm} is formally omitted. However, it should be kept in mind that in the case of $l = O(1),$ the terms in \hat{H}_{nm} arising from boundary layer attenuation and the viscous and thermal effects in the core region are of the same order of magnitude. Therefore, they cannot be subject to *a posteriori* changes within the framework of an asymptotically correct analysis.

In order to illustrate the behavior of the modal damping rates when the driving frequency is successively increased, it seems reasonable to scale the dimensional propagation parameters from Eqs. (A1) and (A2) with ω/c_0 since the thus-obtained quantities can be expressed in terms of the parameters $St, \text{He}, \text{Pr}, \gamma_0,$ and $\eta_0/\mu_0.$ The influence of the viscothermal damping mechanisms in the core region on $\hat{\Gamma}_{00}$ and the propagation parameters of the radial modes has already been discussed in Ref. 6. In extension to that, in Fig. 2 the graphs of $\Re(\hat{\Gamma}_{nm}c_0/\omega)$ for all symmetrical and asym-

FIG. 3. Comparison of the results for $\Re(\hat{\Gamma}_{01}c_0/\omega)$ obtained from different theories solid lines: (a) complete asymptotic result from Eq. (A1), (b) wide tube solution Eq. (8) from Kergomard *et al.*,³⁰ (c) corrected wide tube solution based on the dispersion relation (2) in Ref. 30, this corresponds to Eq. (A1) without the core region terms. Dashed line: Beatty's solution,⁷ i.e., Eq. (A1) truncated after the first correction term.

metrical modes (n, m) with $n + |m| \leq 2$ are depicted as functions of the Helmholtz number $He = O(1)$. Again, the (large) Stokes number has been eliminated using the relationship $St = \sqrt{He} Re_R$, where $Re_R = c_0 R \rho_0 / \mu_0 \sim Re \gg 1$ denotes the radial Reynolds number. The results plotted in this figure ($R = 0.001$ m) clearly show that the sudden drops of the damping rates when the frequency is increased such that a new mode becomes propagational are in conformity with Eq. (82): $\Re(\hat{\Gamma}_{nm}c_0/\omega) = O(1)$ if $He < \gamma_{nm}$ and $\gamma_{nm} - He = O(1)$, $\Re(\hat{\Gamma}_{nm}c_0/\omega) = O(St^{-1/2})$ if $|He - \gamma_{nm}| \ll 1$, and $\Re(\hat{\Gamma}_{nm}c_0/\omega) = O(St^{-1})$ if $He > \gamma_{nm}$ and $He - \gamma_{nm} = O(1)$. In addition, Fig. 3 exemplarily compares the attenuation rate for the mode $(0, 1)$ in the region $He > \gamma_{01}$ with the different solutions that can be derived from the other theories mentioned before. It well illustrates the fact that for a propagating mode, the damping mechanisms in the core region make an important contribution to the correction of Beatty's solution⁷ and, therefore, cannot be neglected if higher order effects are to be considered.

B. The case $l \gg 1$

Inspection of the expression for the propagation parameters (80) shows that if the scaling parameter $l \sim He$ is assumed to be so large that $\alpha l^2 = O(1)$, the boundary layer effects and the viscothermal effects in the core region become of the same order of magnitude. In order to investigate this case in an asymptotically correct way and to maintain the linearity of the problem, l has to be scaled as

$$l = \alpha^{-1/2} l_1, \quad l_1 = O(1), \quad (84)$$

and M has to be chosen such that

$$M \ll \alpha. \quad (85)$$

Consequently, $Re^{-1} \sim St^{-1} \sim \alpha \ll 1$ and the conditions (2) and (5) are satisfied.

By performing a perturbation analysis very similar to that before, however, with $\alpha^{1/2}$ rather than α used as perturbation parameter, one obtains the following wave equations for the first-, second-, and third-order quantities:

$$\omega^2 \hat{p}_1 + \frac{\partial^2 \hat{p}_1}{\partial z^2} = 0, \quad (86)$$

$$\omega^2 \hat{p}_{\alpha^{1/2}} + \frac{\partial^2 \hat{p}_{\alpha^{1/2}}}{\partial z^2} = 0, \quad (87)$$

$$\omega^2 \hat{p}_{\alpha} + \frac{\partial^2 \hat{p}_{\alpha}}{\partial z^2} = -\frac{1}{l_1^2 r} \frac{\partial}{\partial r} \left(r \frac{\partial \hat{p}_1}{\partial r} \right) - \frac{1}{l_1^2 r^2} \frac{\partial \hat{p}_1}{\partial \phi^2} - 2 \frac{\partial^2 \hat{p}_1}{\partial z \partial z_1} + l_1^2 \frac{j \omega^3}{d^2} \hat{p}_1 \left(\frac{4}{3} + \eta_0 + \frac{\gamma_0 - 1}{Pr} \right). \quad (88)$$

Furthermore, the matching rules yield

$$r = 1: \quad \frac{\partial \hat{p}_1}{\partial r} = l_1^2 \omega^2 \hat{F} \hat{p}_1, \quad \hat{F} = \frac{1-j}{d \sqrt{2} \omega} \left(1 + \frac{\gamma_0 - 1}{\sqrt{Pr}} \right). \quad (89)$$

Obviously, the terms on the right-hand side of Eq. (88) are resonant and have to be annihilated since they would inevitably lead to secular solutions for \hat{p}_{α} . This generates a partial differential equation which, together with the boundary condition (89), determines the evolution of the leading order pressure fluctuations over distances of the order $O(\alpha^{-1})$:

$$2 \frac{\partial^2 \hat{p}_1}{\partial z \partial z_1} + \frac{1}{l_1^2 r} \frac{\partial}{\partial r} \left(r \frac{\partial \hat{p}_1}{\partial r} \right) + \frac{1}{l_1^2 r^2} \frac{\partial \hat{p}_1}{\partial \phi^2} - l_1^2 \frac{j \omega^3}{d^2} \hat{p}_1 \left(\frac{4}{3} + \eta_0 + \frac{\gamma_0 - 1}{Pr} \right) = 0. \quad (90)$$

Worth mentioning is the fact that Eqs. (86) and (90) constitute the linearized version of the Khokhlov-Zabolotskaya-Kuznetsov (KZK) model the nonlinear study by Makarov and Vatrushina¹⁴ is based on. Proceeding from the same assumptions concerning the thickness of the boundary layer and the ratio $\tilde{\lambda}/\tilde{R}$ as made here, they derived a boundary condition which is formally almost identical to Eq. (89). However, while adopting a general equation of state (for a real gas), the energy equation for a perfect gas was used and, thus, the result given in Ref. 14, Eq. (36), is not completely correct: The term $\beta c_0^2 / (Pr^{1/2} c_p)$ in this equation should read $T_0 \beta^2 c_0^2 / (Pr^{1/2} c_p)$, which, expressed in the notation used here, then simplifies to $G_0 \tilde{\delta}_0 \tilde{\beta}_0 / Pr^{1/2} = (\gamma_0 - 1) / Pr^{1/2}$.

The system (86), (89), and (90) can be solved to give

$$\hat{p}_1 = \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \left(\hat{C}_{1nm1} \frac{\hat{J}_m(\hat{\gamma}_{nm} r)}{\hat{J}_m(\hat{\gamma}_{nm})} e^{-j[\omega(z + \hat{L}_{nm} z_1) + m\phi]} + \hat{C}_{2nm1} \frac{\hat{J}_m(\hat{\gamma}_{nm} r)}{\hat{J}_m(\hat{\gamma}_{nm})} e^{j[\omega(z + \hat{L}_{nm} z_1) + m\phi]} \right), \quad (91)$$

where the coefficients $\hat{\gamma}_{nm} = \hat{\gamma}_{n(-m)}$, $n = 0, 1, 2, \dots$, are the complex roots of

FIG. 4. Graphs of $\Re(\hat{\Gamma}_{nm}c_0/\omega)$ as function of $\text{He} \sim \text{St}^{1/2} \sim \text{Re}^{1/3} \gg 1$ in double logarithmic scale, $R=0.001$ m, i.e., $\text{St} = \sqrt{\text{He}} \text{Re}_R$ with $\text{Re}_R = c_0 R \rho_0 / \mu_0$; $\text{Pr}=0.707$, $\gamma_0=1.402$, $\eta_0/\mu_0=0.6$, $c_0 \rho_0 / \mu_0 = 221.3732 \times 10^5 \text{ m}^{-1}$ (air at 300 K and 10^5 Pa).

$$\hat{\mathbf{J}}_{m+1}(\hat{\gamma}_{nm})\hat{\gamma}_{nm} - m\hat{\mathbf{J}}_m(\hat{\gamma}_{nm}) + l_1^2 \omega^2 \hat{\mathbf{F}}\hat{\mathbf{J}}_m(\hat{\gamma}_{nm}) = 0 \quad (92)$$

and

$$\hat{L}_{nm} = -\frac{\hat{\gamma}_{nm}^2}{2l_1^2 \omega^2} - l_1^2 \frac{j\omega}{2d^2} \left(\frac{4}{3} + \eta_0 + \frac{\gamma_0 - 1}{\text{Pr}} \right). \quad (93)$$

This reveals the fact that in the case $l \sim \text{St}^{1/2}$ even the lowest mode $(n,m)=(0,0)$ does not propagate as a plane wave since all $\hat{\gamma}_{n0} \neq 0$.

Using the relationship (79), the propagation parameters turn out to be given by the expansion

$$\hat{\Gamma}_{nm} = j\omega + \alpha j\omega \hat{L}_{nm} + \dots \quad (94)$$

The corresponding expressions in terms of dimensional quantities are presented in Appendix A. As can be seen from comparison of the graphs of $\Re(\hat{\Gamma}_{nm}c_0/\omega)$ depicted in Fig. 4 with the results plotted in Figs. 2 and 3(a), the solutions from Eqs. (94) and (A3) indeed continue the solutions derived for the case $l \sim \text{He} = O(1)$ to the region $l \sim \text{He} = O(\text{St}^{1/2})$. Furthermore, one can immediately observe from Fig. 4 the growing influence of the viscothermal losses in the core region on the damping rates as the Helmholtz number increases.

IV. THE NONLINEAR CASE

In the following, the propagation and modulation of a finite-amplitude wave packet centered at the frequency ω_c and the wave number \hat{k}_c in a long hard-walled cylindrical duct shall be considered. As in Sec. III, the characteristic wavelength $\tilde{\lambda}$ is presupposed to be comparable to the radius of the tube \tilde{R} . Therefore, the scaling parameter $l \sim \text{He}_c \sim 1$ can be set to unity without loss of generality, resulting in $\omega_c = \text{He}_c$. The fluid is assumed to be an initially quiescent real gas featuring a uniform equilibrium state which satisfies the conditions (3). Furthermore, the analysis proceeds from the assumption that the spatial range consumed by the viscothermal boundary layer is so small that

$$\text{St}^{-1} \sim M^2, \quad \text{i.e., } \alpha = \sigma M^2, \quad (95)$$

holds, where $\sigma = O(1)$ or smaller. As shown by Nayfeh¹⁸ for the case of a perfect gas, then the evolution of the leading order pressure fluctuations are governed by an equation where boundary layer dissipation might become of the same order of magnitude as the nonlinear effects. For the level of approximation to be reached in this study, the thermoviscous losses in the core region will turn out to be negligibly small since these effects are an order of magnitude smaller than those of the wall layer.

According to Eq. (95), the perturbation analysis can be carried out with respect to the remaining parameter M only. However, the determination of an asymptotically correct solution, incorporating the effects of the wave modulation with time and space as well as the nonlinearity, necessitates the introduction of the following spatial and temporal scales:

$$\frac{\partial}{\partial z} \rightarrow \frac{\partial}{\partial z} + M \frac{\partial}{\partial z_1} + M^2 \frac{\partial}{\partial z_2}, \quad \frac{\partial}{\partial t} \rightarrow \frac{\partial}{\partial t} + M \frac{\partial}{\partial t_1} + M^2 \frac{\partial}{\partial t_2}. \quad (96)$$

In this connection it should be noted that in the linear case discussed in Sec. III, the use of additional temporal scales $t_1 = \alpha t$ and $t_2 = \alpha^2 t$ would lead to solutions which can be written in the form [cf. Eqs. (23) and (24)]

$$w(z, z_1, z_2, r, \phi, t, t_1, t_2) = \Re(\hat{w}_{st}(z, z_1, z_2, r, \phi) e^{j(\omega t + \omega_\alpha t_1 + \omega_{\alpha^2} t_2)}), \quad (97)$$

where $\omega_\alpha = O(1)$ and $\omega_{\alpha^2} = O(1)$ denote arbitrary frequency detunings. Consequently, they can again be decomposed into steady amplitude function \hat{w}_{st} and time-harmonic functions. The same results would be obtained, however, by letting $\omega \rightarrow \omega + \alpha \omega_\alpha + \alpha^2 \omega_{\alpha^2}$ and expanding the parameters \hat{k}_{nm} , \hat{F}_{nm} and \hat{H}_{nm} appearing in the solutions (74) and (75) with respect to α . As demonstrated in Sec. III A, this method can even be applied to calculate the linear propagation parameters for driving frequencies close to the cutoff frequency of a particular mode, where the attenuation of this mode takes place over spatial ranges $z = O(\alpha^{-1/2})$.

A further consequence of the condition (95) is that in the core region where $r = O(1)$ the right-hand side of Eq. (13) is of the order $O(M^5)$. Utilizing the asymptotic expansions for ρ , ϑ , and s , the energy equation thus reduces to

$$\frac{ds_1}{dt} = \frac{ds_M}{dt} = \frac{ds_{M^2}}{dt} = 0. \quad (98)$$

Hence, after expanding the total derivative

$$(\delta p) = \left(\frac{\partial p}{\partial \rho} \right)_s (\delta \rho) + \left(\frac{\partial p}{\partial s} \right)_\rho (\delta s) \quad (99)$$

with respect to M and substituting the parameters Γ_0 and Λ_0 defined in Eqs. (1) and (3), integration yields

$$\begin{aligned} \rho_1 &= p_1, & \rho_M &= p_M - (\Gamma_0 - 1)p_1^2, \\ \rho_{M^2} &= p_{M^2} - 2(\Gamma_0 - 1)p_1 p_M - \frac{1}{3}(\Lambda_0 - 4\Gamma_0^2 + 7\Gamma_0 - 3)p_1^3. \end{aligned} \quad (100)$$

Furthermore, evaluation of the Navier-Stokes equations (9)–(11) for the leading order perturbations in the core region implies that

$$\frac{\partial}{\partial t}(\nabla \times \mathbf{v}_1) = \mathbf{0} \Rightarrow \nabla \times \mathbf{v}_1 = \mathbf{0}, \quad (101)$$

in which

$$\nabla \times \mathbf{A} = \left(\frac{1}{r} \left(\frac{\partial(rA_\phi)}{\partial r} - \frac{\partial A_r}{\partial \phi} \right), \frac{1}{r} \frac{\partial A_z}{\partial \phi} - \frac{\partial A_\phi}{\partial z}, \frac{\partial A_r}{\partial z} - \frac{\partial A_z}{\partial r} \right)^T \quad (102)$$

denotes the vorticity of an arbitrary vector \mathbf{A} . This enables to define a velocity potential Φ_1 ,

$$\mathbf{v}_1 = \nabla \Phi_1, \quad (103)$$

whereupon substitution for ρ_1 and \mathbf{v}_1 from Eqs. (100) and (103) into the leading order outer expansions of the Navier-Stokes equations and the continuity equation (12) gives

$$p_1 = -\frac{\partial \Phi_1}{\partial t}, \quad \frac{\partial^2 \Phi_1}{\partial t^2} - \Delta \Phi_1 = 0. \quad (104)$$

The equations of motion (9)–(11) together with Eq. (98) show that for all expansion terms at least up to the order $O(M^3)$, the flow in the core region can be regarded as isentropic and inviscid. By invoking Helmholtz's theorems of vorticity, one thus can expect Eq. (101) to hold for \mathbf{v}_M and \mathbf{v}_{M^2} as well. Indeed, evaluation of the outer expansions of Eqs. (9)–(11) for the second-order terms immediately verifies this assumption in the generalized sense that now

$$\nabla \times \left(\mathbf{v}_M - \left(\frac{\partial \Phi_1}{\partial z_1}, 0, 0 \right)^T \right) = \mathbf{0} \Rightarrow \mathbf{v}_M = \nabla \Phi_M + \left(\frac{\partial \Phi_1}{\partial z_1}, 0, 0 \right)^T. \quad (105)$$

Combining this result with Eq. (100) and the second-order expansion of the continuity equation (12), then the set

$$p_M = -\frac{\partial \Phi_M}{\partial t} - \frac{\partial \Phi_1}{\partial t_1} - \frac{1}{2} \left[(\nabla \Phi_1)^2 - \left(\frac{\partial \Phi_1}{\partial t} \right)^2 \right], \quad (106)$$

$$\frac{\partial^2 \Phi_M}{\partial t^2} - \Delta \Phi_M = 2 \left(\frac{\partial^2 \Phi_1}{\partial z \partial z_1} - \frac{\partial^2 \Phi_1}{\partial t \partial t_1} \right) - 2(\Gamma_0 - 1) \Delta \Phi_1 \frac{\partial \Phi_1}{\partial t} - \frac{\partial}{\partial t} (\nabla \Phi_1)^2.$$

is obtained.

Proceeding in very much the same way as before, the expansions of the Navier-Stokes equations governing the third-order perturbations in the core region show that

$$\nabla \times \left(\mathbf{v}_{M^2} - \left(\frac{\partial \Phi_1}{\partial z_2} + \frac{\partial \Phi_M}{\partial z_1}, 0, 0 \right)^T \right) = \mathbf{0} \Rightarrow \mathbf{v}_{M^2} = \nabla \Phi_{M^2} + \left(\frac{\partial \Phi_1}{\partial z_2} + \frac{\partial \Phi_M}{\partial z_1}, 0, 0 \right)^T. \quad (107)$$

This leads to an expression for p_{M^2} in terms of the potentials, which together with the expansion terms for ρ from Eq. (100) is substituted into the third-order outer expansion of Eq. (12). Thus, the resulting equations read

$$\begin{aligned} p_{M^2} = & -\frac{\partial \Phi_{M^2}}{\partial t} - \frac{\partial \Phi_M}{\partial t_1} - \frac{\partial \Phi_1}{\partial t_2} + \frac{\partial \Phi_M}{\partial t} \frac{\partial \Phi_1}{\partial t} - \nabla \Phi_M \cdot \nabla \Phi_1 \\ & + \frac{\partial \Phi_1}{\partial t} \frac{\partial \Phi_1}{\partial t_1} - \frac{\partial \Phi_1}{\partial z} \frac{\partial \Phi_1}{\partial z_1} + \frac{1}{6} \frac{\partial \Phi_1}{\partial t} \left[2\Gamma_0 \left(\frac{\partial \Phi_1}{\partial t} \right)^2 \right. \\ & \left. - 3 \left(\frac{\partial \Phi_1}{\partial t} \right)^2 + 3(\nabla \Phi_1)^2 \right], \\ & \frac{\partial^2 \Phi_{M^2}}{\partial t^2} - \Delta \Phi_{M^2} \\ = & 2 \left(\frac{\partial^2 \Phi_M}{\partial z \partial z_1} - \frac{\partial^2 \Phi_M}{\partial t \partial t_1} + \frac{\partial^2 \Phi_1}{\partial z \partial z_2} - \frac{\partial^2 \Phi_1}{\partial t \partial t_2} \right) + \frac{\partial^2 \Phi_1}{\partial z_1^2} - \frac{\partial^2 \Phi_1}{\partial t_1^2} \\ & - 2(\Gamma_0 - 1) \left[\left(\Delta \Phi_M + 2 \frac{\partial^2 \Phi_1}{\partial z \partial z_1} \right) \frac{\partial \Phi_1}{\partial t} \right. \\ & \left. + \Delta \Phi_1 \left(\frac{\partial \Phi_M}{\partial t} + \frac{\partial \Phi_1}{\partial t_1} \right) \right] \\ & - 2 \frac{\partial}{\partial t} \left(\nabla \Phi_M \cdot \nabla \Phi_1 + \frac{\partial \Phi_1}{\partial z} \frac{\partial \Phi_1}{\partial z_1} \right) - \frac{\partial}{\partial t_1} (\nabla \Phi_1)^2 \\ & + \Lambda_0 \Delta \Phi_1 \left(\frac{\partial \Phi_1}{\partial t} \right)^2 - (\Gamma_0 - 1) \Delta \Phi_1 (\nabla \Phi_1)^2 \\ & - \frac{1}{2} \nabla \Phi_1 \cdot \nabla (\nabla \Phi_1)^2. \end{aligned} \quad (108)$$

In order to find the boundary conditions for the three wave equations governing the potential functions Φ_1 , Φ_M , and Φ_{M^2} , respectively, it is necessary to investigate the acoustic motion in the wall layer. Since the scaling parameter α is presupposed to be of the order $O(M^2)$, the equations resulting from the inner expansion will turn out to be linear, suggesting the application of a complex Fourier transform

$$\hat{F}[A](\omega) = \int_{-\infty}^{\infty} A(t) e^{-j\omega t} dt \quad (109)$$

with respect to the ‘‘fast’’ time t . Thus, most of the results already derived in Sec. III for the inner radial velocity terms up to the order $O(\alpha)$ carry over almost unchanged to the case considered here: As a consequence of $\hat{F}[V_{r1}] = 0$ and, in extension to Eq. (27), $\hat{F}[V_{rM}] = 0$, Van Dyke's matching conditions imply that

$$r = 1: \quad \frac{\partial \Phi_1}{\partial r} = 0, \quad \frac{\partial \Phi_M}{\partial r} = 0. \quad (110)$$

In addition, by setting $\alpha = \sigma M^2$, $l = 1$, and applying the matching rules to the inner and outer leading order terms of the axial and azimuthal velocities and the density, Eq. (53) can be recast into

$$\begin{aligned} \hat{F}[V_{z1}] &= \hat{F} \left[\frac{\partial \Phi_1}{\partial z} \right]_{r=1} (1 - e^{-(1+j)(d/\sigma)y\sqrt{\omega/2} \operatorname{sgn}(\omega)}), \\ \hat{F}[V_{\phi 1}] &= \hat{F} \left[\frac{\partial \Phi_1}{\partial \phi} \right]_{r=1} (1 - e^{-(1+j)(d/\sigma)y\sqrt{\omega/2} \operatorname{sgn}(\omega)}), \end{aligned} \quad (111)$$

$$\hat{F}[\Psi_1] = -j\omega\hat{F}[\Phi_1]_{r=1} [1 + (\gamma_0 - 1) \times (1 - e^{-(1+j)(d/\sigma)y\sqrt{\omega\text{Pr}/2} \text{sgn}(\omega)})].$$

The solution for $\hat{F}[V_{rM^2}]$ corresponding to Eq. (54) then assumes the form

$$\begin{aligned} \hat{F}[V_{rM^2}] = & -j\omega\hat{F}[\Phi_1]_{r=1} \left[j\omega y + \sigma \frac{1+j}{d} \sqrt{\frac{\omega}{2}} \text{sgn}(\omega) \right. \\ & \times \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} (1 - e^{-(1+j)(d/\sigma)y\sqrt{\omega\text{Pr}/2} \text{sgn}(\omega)}) \left. \right] \\ & - \frac{j}{\omega} \hat{F} \left[\frac{\partial^2 \Phi_1}{\partial z^2} + \frac{\partial^2 \Phi_1}{\partial \phi^2} \right]_{r=1} \left[j\omega y - \sigma \frac{1+j}{d} \sqrt{\frac{\omega}{2}} \right. \\ & \times \text{sgn}(\omega) (1 - e^{-(1+j)(d/\sigma)y\sqrt{\omega/2} \text{sgn}(\omega)}) \left. \right], \quad (112) \end{aligned}$$

and the matching principle applied to the expansion terms of v_r and V_r yields the boundary condition

$$\begin{aligned} r=1: \quad \hat{F} \left[\frac{\partial \Phi_{M^2}}{\partial r} \right] = & \sigma \frac{1-j}{d} \omega \sqrt{\frac{\omega}{2}} \text{sgn}(\omega) \\ & \times \left[\hat{F}[\Phi_1] \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} - \left(\hat{F} \left[\frac{\partial^2 \Phi_1}{\partial z^2} \right] + \hat{F} \left[\frac{\partial^2 \Phi_1}{\partial \phi^2} \right] \right) \frac{1}{\omega^2} \right]. \quad (113) \end{aligned}$$

The goal pursued in the study presented here is to derive the evolution equation for the spatial and temporal modulation of a traveling wave packet centered at the frequency $\omega_c > 0$ and the real wave number $k_c > 0$. Therefore, the solution to Eq. (104) subject to the boundary condition for Φ_1 from Eq. (110) is taken to be the right-running wave

$$\begin{aligned} \Phi_1 = \hat{\Phi}_1 + \hat{\Phi}_1^* = & \hat{A}_1(z_1, z_2, t_1, t_2) \frac{J_{m_c}(\gamma_c r)}{J_{m_c}(\gamma_c)} e^{j\zeta} + \text{CC}, \\ \zeta = \omega_c t - k_c z - m_c \phi, \quad (114) \end{aligned}$$

where the superscript “*” denotes the conjugate complex of a quantity, CC stands for the conjugate complex of the preceding terms, \hat{A}_1 is the weakly varying shape function of the carrier mode $(n, m) = (n_c, m_c)$, $\gamma_c = \gamma_{n_c, m_c}$ is a zero of $\partial J_{m_c}(\xi)/\partial \xi$, and k_c necessarily satisfies the leading order dispersion relation (51) for a propagating mode with $\omega_c > \gamma_c > 0$ ($l=1$). As outlined in Sec. II A, the case of the carrier mode being a plane wave, i.e., $m_c = \gamma_c = 0$, has to be excluded since otherwise the interaction with all its harmonics would have to be considered as well. Hence, by taking advantage of the solution (114), the boundary condition (113) for the wave equation (108) is modified to

$$r=1: \quad \frac{\partial \Phi_{M^2}}{\partial r} = \sigma \hat{\Phi}_1 \frac{1-j}{d\sqrt{2\omega_c}} \left(\omega_c^2 \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} + k_c^2 + m_c^2 \right) + \text{CC}. \quad (115)$$

When evaluated for a perfect gas with constant specific heats, i.e., $\Gamma_0 = (\gamma + 1)/2$, $\gamma = \text{const}$, and $\Lambda_0 = 0$, the set of equations (104), (106), and (108) immediately turns out to be

in complete conformity with the wave equations that form the basis for Nayfeh’s investigations.¹⁸ Following the line of reasoning given in Ref. 18, the derivations of the evolution equations determining the behavior of the amplitude \hat{A}_1 over the long spatial and temporal ranges z_1, z_2, t_1 , and t_2 can thus be developed in a straightforward way invoking the solvability conditions provided by the *Fredholm alternative* in the second- and third-order problems. This concept is also known as the so-called *reductive perturbation method*.³²

The solutions for the second-order problem, i.e., Eq. (106) subject to condition (110), can be summarized as follows:

$$k_c \frac{\partial \hat{A}_1}{\partial z_1} + \omega_c \frac{\partial \hat{A}_1}{\partial t_1} = 0, \quad (116)$$

$$\begin{aligned} \Phi_M = & \frac{\hat{A}_1^2}{J_{m_c}^2(\gamma_c)} (\hat{C}_1 J_{m_c}^2(\gamma_c r) + \hat{C}_2 r J_{m_c}(\gamma_c r) J_{m_c+1}(\gamma_c r) \\ & + \hat{C}_3 J_{2m_c}(2\gamma_c r)) + \text{CC}, \\ \hat{C}_1 = & j\omega_c \left(\Gamma_0 \frac{\omega_c^2}{\gamma_c^2} m_c + 1 \right), \quad \hat{C}_2 = -j\Gamma_0 \frac{\omega_c^3}{\gamma_c}, \quad (117) \end{aligned}$$

$$\hat{C}_3 = -\hat{C}_2 \frac{J_{m_c}(\gamma_c)}{2\gamma_c J'_{2m_c}(\gamma_c)} (J_{m_c+1}(\gamma_c) + \gamma_c J'_{m_c+1}(\gamma_c)).$$

Please note that the expression for \hat{C}_3 printed in Ref. 18 [Eq. (39b)] is incorrect and had to be recalculated.

The evolution equation governing the propagation of the leading order solution Φ_1 over distances and periods of the order $O(M^{-2})$ can be determined in a very similar manner, that is, by substituting the expressions for Φ_1 and Φ_M from Eqs. (114) and (117) into the third-order wave equation (108) and calculating the solvability condition for the forcing terms proportional to $\exp(j\zeta)$. In contrast to the second-order problem, however, the application of the Fredholm alternative [see Eq. (35) in Ref. 18] leads to an integral condition which has to be evaluated using the inhomogeneous boundary condition (115) at $r=1$. The resulting equation then reads

$$\begin{aligned} 2j \left(k_c \frac{\partial \hat{A}_1}{\partial z_2} + \omega_c \frac{\partial \hat{A}_1}{\partial t_2} \right) - \frac{\partial^2 \hat{A}_1}{\partial z_1^2} + \frac{\partial^2 \hat{A}_1}{\partial t_1^2} \\ = -2N \hat{A}_1^2 \hat{A}_1^* + 2\sigma k_c^2 \hat{F}_c \hat{A}_1, \quad (118) \end{aligned}$$

where $\hat{F}_c = \hat{F}_{n_c, m_c}$ is the quantity given by Eq. (58) and the nonlinearity parameter N is defined as

$$N = \frac{1}{J_{m_c}^4(\gamma_c) (1 - m_c^2/\gamma_c^2)} \int_0^1 r M(r) J_{m_c}(\gamma_c r) dr, \quad (119)$$

in which

$$\begin{aligned}
M(r) = & \gamma_c^2 J_{m_c}(\gamma_c r) J_{m_c}'^2(\gamma_c r) \left[(\Gamma_0 - 1) \omega_c^2 + \frac{m_c(5m_c - 3)}{r^2} - 3\gamma_c^2 + 2k_c^2 \right] - \gamma_c J_{m_c}^2(\gamma_c r) J_{m_c}'(\gamma_c r) \left[\frac{m_c^2}{r^3} - 2j\omega_c \left(\frac{2\hat{C}_1 m_c}{r} + \hat{C}_2 \gamma_c r \right) \right] \\
& + \frac{3\gamma_c^3}{r} J_{m_c}'^2(\gamma_c r) J_{m_c+1}(\gamma_c r) + 2j\omega_c \gamma_c J_{m_c}'(\gamma_c r) \left(-\hat{C}_2 \gamma_c r J_{m_c+1}^2(\gamma_c r) - 2\hat{C}_1 \gamma_c J_{m_c}(\gamma_c r) J_{m_c+1}(\gamma_c r) \right. \\
& \left. + \frac{2\hat{C}_3 m_c}{r} J_{2m_c}(2\gamma_c r) - 2\hat{C}_3 \gamma_c J_{2m_c+1}(2\gamma_c r) \right) - \left[2(\Gamma_0 - 1) \omega_c^2 + \frac{2m_c^2}{r^2} + 2k_c^2 \right] \\
& \times \left[J_{m_c}^3(\gamma_c r) \left(\frac{m_c^2}{2r^2} + \frac{k_c^2}{2} + 2(\Gamma_0 - 1) \omega_c^2 - 2j\hat{C}_1 \omega_c \right) - 2j\omega_c J_{m_c}(\gamma_c r) (\hat{C}_2 r J_{m_c}(\gamma_c r) J_{m_c+1}(\gamma_c r) + \hat{C}_3 J_{2m_c}(2\gamma_c r)) \right] \\
& + \Lambda_0 \omega_c^4 J_{m_c}^3(\gamma_c r). \tag{120}
\end{aligned}$$

Surprisingly, with the expressions for \hat{C}_1 , \hat{C}_2 , and \hat{C}_3 from Eq. (117) substituted into Eq. (120), all imaginary terms in $M(r)$ cancel out, leading to N being a purely real quantity. Furthermore, when Γ_0 is formally replaced with $(\gamma + 1)/2$, Λ_0 is set to zero, and j is replaced with $-i$, one obtains precisely the function $F(r)$ derived in Ref. 18 for the case of a perfect gas. In this connection it should be mentioned that the terms $3\kappa^2/r J_m'^2(\kappa r) J_{m+1}(\kappa r)$ and $\Gamma_2 \gamma J_m(\kappa r) J_{m+1}(\kappa r)$ appearing in the definition of $F(r)$ should read $3\kappa^3/r J_m'^2(\kappa r) J_{m+1}(\kappa r)$ and $\Gamma_2 r J_m(\kappa r) J_{m+1}(\kappa r)$, respectively. Moreover, upon neglecting the nonlinear and the temporal modulation terms in Eqs. (116) and (118), the solvability condition (59) from Sec. III for a linear monochromatic wave is recovered.

By exploiting Eq. (116) to eliminate the derivative $\partial^2 \hat{A}_1 / \partial z_1^2$ appearing in Eq. (118), it follows that

$$\frac{\partial \hat{A}_1}{\partial z_2} + \frac{1}{\omega_g} \frac{\partial \hat{A}_1}{\partial t_2} + j \frac{\omega_g'}{2\omega_g^3} \frac{\partial^2 \hat{A}_1}{\partial t_1^2} = j \frac{N}{k_c} \hat{A}_1^2 \hat{A}_1^* - j \sigma k_c \hat{F}_c \hat{A}_1, \tag{121}$$

where

$$\begin{aligned}
\omega_g &= \left(\frac{\partial \omega}{\partial \hat{k}_{nm}} \right)_c = \left(\frac{\partial}{\partial \hat{k}_{nm}} \sqrt{\hat{k}_{nm}^2 + \gamma_c^2} \right) \Big|_{\hat{k}_{nm}=k_c} = \frac{k_c}{\omega_c} > 0, \\
\omega_g' &= \left(\frac{\partial^2 \omega}{\partial \hat{k}_{nm}^2} \right)_c = \frac{1}{\omega_c} \left(1 - \frac{k_c^2}{\omega_c^2} \right) > 0
\end{aligned} \tag{122}$$

are, respectively, the group velocity and its first derivative with respect to the axial wave number. Furthermore, adding Eq. (116) multiplied with M/k_c to Eq. (121) multiplied with M^2 , reintroducing the original temporal and spatial coordinates t and z , and neglecting terms of the order $O(M^3)$ (which is asymptotically correct) results in

$$\begin{aligned}
\frac{\partial \hat{A}_1}{\partial z} + \frac{1}{\omega_g} \frac{\partial \hat{A}_1}{\partial t} + j \frac{\omega_g'}{2\omega_g^3} \frac{\partial^2 \hat{A}_1}{\partial t^2} \\
= j M^2 \frac{N}{k_c} \hat{A}_1^2 \hat{A}_1^* - j M^2 \sigma k_c \hat{F}_c \hat{A}_1. \tag{123}
\end{aligned}$$

To simplify the following discussions, the suitably scaled quantities \hat{U} , D , X and the wave coordinate ξ , with

$$Z = M^2 z, \quad \xi = M \sqrt{\frac{\omega_g}{\omega_g'}} (\omega_g t - z), \tag{124}$$

$$D = -k_c \Im(\hat{F}_c) = k_c \Re(\hat{F}_c) > 0, \quad \hat{U} = \sqrt{\frac{|N|}{k_c}} \hat{A}_1^* e^{-j\sigma D Z},$$

are introduced, and one arrives at a linearly damped *nonlinear Schrödinger equation* (NLS) in normalized form:

$$j \frac{\partial \hat{U}}{\partial Z} + \frac{1}{2} \frac{\partial^2 \hat{U}}{\partial \xi^2} - \text{sgn}(N) \hat{U}^2 \hat{U}^* = -j \sigma D \hat{U}, \tag{125}$$

where the term involving the second derivative represents the dispersive effects induced by the temporal modulation of the wave packet, the third term on the left-hand side describes the nonlinearity of the system, and the term proportional to σ results from the dissipative effects of the viscothermal boundary layer.

A. Comments on the damping parameter

For Eq. (125) to provide an asymptotically correct description of the most relevant physical mechanisms present in the problem, in principle, the damping parameter σ has to be assumed to be an order $O(1)$ quantity; that is to say, a balance between dispersion, nonlinearity, and dissipation has to exist. However, if the boundary layer effects are small but not so small that additional nonlinear effects of higher order come into play as well, i.e., if $M \ll \sigma \ll 1$ or, equivalently, $M^6 \ll \text{Re}^{-1} \sim \alpha^2 \ll M^4$ [see Eqs. (8) and (95)], one may try to expand the scaled shape function \hat{U} with respect to the damping parameter and introduce an additional “long” length scale Z_σ which will account for the slow variations in longitudinal direction:

$$\hat{U} = \hat{U}_1 + \sigma \hat{U}_\sigma + \dots, \quad \frac{\partial}{\partial Z} \rightarrow \frac{\partial}{\partial Z} + \sigma \frac{\partial}{\partial Z_\sigma}. \tag{126}$$

These expressions substituted into Eq. (125) then generate the system

$$M \ll \sigma \ll 1: \quad j \frac{\partial \hat{U}_1}{\partial Z} + \frac{1}{2} \frac{\partial^2 \hat{U}_1}{\partial \xi^2} - \text{sgn}(N) \hat{U}_1^2 \hat{U}_1^* = 0, \tag{127}$$

$$j \frac{\partial \hat{U}_\sigma}{\partial Z} + \frac{1}{2} \frac{\partial^2 \hat{U}_\sigma}{\partial \xi^2} - \text{sgn}(N) \hat{U}_1 (2 \hat{U}_1^* \hat{U}_\sigma + \hat{U}_1 \hat{U}_\sigma^*)$$

$$= -j \frac{\partial \hat{U}_1}{\partial Z_\sigma} - j D \hat{U}_1. \quad (128)$$

The same set of equations would have been obtained if the velocity potential Φ had been expanded with respect to the parameters M and σ from the beginning and, in addition to z_1, t_1, z_2, t_2 , also the spatial and temporal scales $z_\sigma = \sigma M^2 z, t_\sigma = \sigma M^2 t$ had been introduced. In other words, Eqs. (127) and (128) can be interpreted as constituting the solvability conditions for the problems at the orders $O(M^3)$ and $O(\sigma M^3)$, respectively. Consequently, Eq. (125) turns out to retain its validity even under conditions where dissipation is small, i.e., for all values of σ within the range $M \ll \sigma \leq O(1)$. If, however, $M \ll \sigma \ll 1$, the (linear) Eq. (128) can be used to derive an additional solvability condition that determines the variation of the leading order perturbation $\Phi_1 \propto \hat{U}_1$ over distances of the order $O(\sigma^{-1} M^{-2})$ and the changes of $\Phi_\sigma \propto \hat{U}_\sigma$ over ranges of the order $O(M^{-2})$.

B. Comments on the nonlinearity parameter

The integrand $rM(r)J_{m_c}(\gamma_c r)$ appearing in the definition (119) of the nonlinearity parameter N can be simplified significantly by expressing it in terms of the functions $J_{m_c}^4(\gamma_c r)r, J_{m_c}^2(\gamma_c r)J_{m_c+1}^2(\gamma_c r)r$ and the derivatives of $J_{m_c}^4(\gamma_c r)r^2, J_{m_c}^4(\gamma_c r), J_{m_c}^4(\gamma_c r)/r^2, J_{m_c}^3(\gamma_c r)J_{m_c}'(\gamma_c r)r, J_{m_c}^3(\gamma_c r)J_{m_c}'(\gamma_c r)/r, J_{m_c}^2(\gamma_c r)J_{m_c}''(\gamma_c r)r^2, J_{m_c}^2(\gamma_c r)J_{m_c}''(\gamma_c r), J_{m_c}(\gamma_c r)J_{m_c}'''(\gamma_c r)r, J_{m_c}'(\gamma_c r)r^2, J_{m_c}(\gamma_c r)J_{2m_c}(2\gamma_c r), J_{m_c}^2(\gamma_c r)J_{2m_c}(2\gamma_c r)r^2, J_{m_c}(\gamma_c r)J_{m_c}'(\gamma_c r)J_{2m_c}'(2\gamma_c r)r^2, J_{m_c}''(\gamma_c r)J_{2m_c}(2\gamma_c r)r^2, J_{m_c}^2(\gamma_c r)J_{2m_c+1}(2\gamma_c r)r, J_{m_c}^2(\gamma_c r)J_{2m_c+1}(2\gamma_c r)/r, J_{m_c}^2(\gamma_c r)J_{2m_c+1}'(2\gamma_c r)$. Integration with respect to r then yields

$$N = N_0 + \Gamma_0(\omega_c^2 N_1 + \omega_c^4 N_2) + \Gamma_0^2(\omega_c^4 N_3 + \omega_c^6 N_4) + \Lambda_0 \omega_c^4 N_5, \quad (129)$$

where

$$N_0 = -4\gamma_c^4 I_0 + \frac{3\gamma_c^4 - 8\gamma_c^4 m_c^2 + 8\gamma_c^2 m_c - 2\gamma_c^2 m_c^2 - 32\gamma_c^2 m_c^3 + 16\gamma_c^2 m_c^4 + 3m_c^4 - 8m_c^6}{4(1 - 4m_c^2)(1 - m_c^2/\gamma_c^2)},$$

$$N_1 = 8\gamma_c^2 I_0 - \frac{4m_c}{1 - m_c^2/\gamma_c^2}, \quad N_2 = -3I_1, \quad N_3 = -4I_1,$$

$$N_4 = \frac{1}{\gamma_c^2} \left(2I_1 - \frac{1}{1 - m_c^2/\gamma_c^2} \right) + \left(1 - \frac{m_c^2}{\gamma_c^2} \right) \frac{J_{2m_c}(2\gamma_c)}{\gamma_c J_{2m_c+1}(2\gamma_c) - m_c J_{2m_c}(2\gamma_c)}, \quad (130)$$

$$N_5 = I_1, \quad I_0 = \frac{1}{J_{m_c}^4(\gamma_c)(1 - m_c^2/\gamma_c^2)} \int_0^1 r J_{m_c}^2(\gamma_c r) (J_{m_c}^2(\gamma_c r) - J_{m_c+1}^2(\gamma_c r)) dr,$$

$$I_1 = \frac{1}{J_{m_c}^4(\gamma_c)(1 - m_c^2/\gamma_c^2)} \int_0^1 r J_{m_c}^4(\gamma_c r) dr.$$

The numerical effort for the evaluation of N thus reduces to the determination of the integrals I_0 and I_1 . Moreover, for the symmetrical carrier modes, the expressions from Eq. (130) simplify to

$$m_c = 0: \quad N_0 = -\frac{8\gamma_c^4 I_1}{3} + \frac{3\gamma_c^4}{4}, \quad N_1 = \frac{16\gamma_c^2 I_1}{3},$$

$$N_2 = -3I_1, \quad N_3 = -4I_1, \quad (131)$$

$$N_4 = \frac{2I_1 - 1}{\gamma_c^2} + \frac{J_0(2\gamma_c)}{\gamma_c J_1(2\gamma_c)}, \quad N_5 = I_1,$$

$$I_1 = \frac{1}{J_0^4(\gamma_c)} \int_0^1 r J_0^4(\gamma_c r) dr.$$

In this case, $I_0 = 2I_1/3$ and, therefore, only the computation of I_1 is necessary.

The values of γ_c, I_0 , and I_1 calculated for various radial and azimuthal modes are presented in Table I, which enables convenient evaluation of the parameter N for different frequencies. For example, by setting $\Gamma_0 = 1.20$ and $\Lambda_0 = 0$ (air as perfect gas), the results given by the curves in Figs. 1 and 2 of Ref. 18 are reobtained. Please note that in that study, the nonlinearity parameter is defined as $\Lambda = 2NJ_0^2(\gamma_c)$. Furthermore, an error in the labeling of the mentioned figures has to be corrected here: the ordinates should be labeled $1/2\Lambda k^{-1}$ rather than $1/8\Lambda k^{-1}$. As far as the symmetrical modes are concerned, the solution for N from Eqs. (129) and (131) can also be compared with the results for the nonlinear wave number shift in a perfect gas derived by Keller and Millman¹⁶ using the method of strained parameters. Table I in Ref. 16 displays the numerical values for the coefficient $c^2 R^5 k_n^{(2)}$ at $\omega/c = 1.5\gamma_5$, which, according to the notation used here, equals $-N/(2\pi k_c)$ at

$\omega = 24.70594$. Precisely the same results are obtained when the parameter N is evaluated by utilizing Table I and setting $\Gamma_0 = 1.20$ and $\Lambda_0 = 0$.

As it will be discussed in the following, the type of (stable) solutions the damped NLS equation (125) has crucially depends on the sign of the nonlinearity parameter. For all modes considered in Table I, the following relationships hold: $N_0 < 0$, $N_1 > 0$, $N_4 > 0$, $N_5 = -1/3N_2 = -1/4N_3 > 0$. When the driving frequency becomes considerably large, $N \propto \Gamma_0^2 \omega_c^6 N_4$ and, consequently, the nonlinearity parameter will always be positive in the high-frequency range. However, in the low- and mid-frequency range, terms proportional to ω_c^2 and ω_c^4 come into play as well. In order for the latter to become negative, it is necessary and sufficient that $\Lambda_0 < 3\Gamma_0 + 4\Gamma_0^2$. Therefore, N is very likely to be negative within a finite band of frequencies if the gas parameter Λ_0 at the equilibrium reference state is sufficiently large and negative and Γ_0 is positive, but rather small such that the magnitude of the terms $\propto \omega_c^6$ is reduced.

For a wide range of fluids, such as perfect gases, the fundamental derivative is so large that N will turn out to be positive in the complete frequency range $\omega_c > \gamma_c > 0$. (In Ref. 18 this was shown for the case of air.) However, as mentioned in the Introduction, there exists a special class of real gases called BZT fluids which have a negative Γ region extending over a finite range of pressures and densities in the vicinity of the critical point. If such a fluid, therefore, expands along an isentrope crossing that region, starting from conditions with $\Gamma > 0$, the fundamental derivative changes its sign twice and will, eventually, become positive again. Obviously, at the second transition point where $\Gamma_0 = 0$ the parameter Λ_0 is negative and, hence, $N < 0$. Generally speaking, a BZT fluid always has equilibrium states where the nonlinearity parameter N is negative for a very wide range of driving frequencies.

To demonstrate this graphically, numerical results for N for the fluorocarbon FC-71^{23,24} are depicted in Fig. 5. The values for Γ_0 and Λ_0 at two different equilibrium reference states were calculated by applying the Martin-Hou equation

FIG. 5. Negative N regions for FC-71 at two different equilibrium reference states: Graphs of $-N$ for different carrier modes (n_c, m_c) as functions of ω_c/γ_c in double logarithmic scale. Critical values of FC-71: $\bar{\vartheta}_{cr} = 646.2$ K, $\bar{p}_{cr} = 9.423 \times 10^5$ Pa, $\bar{\rho}_{cr} = 619.3$ kg/m³; dashed lines: $\bar{\vartheta}_0 = \bar{\vartheta}_{cr}$, $\bar{p}_0 = 0.911\bar{p}_{cr}$, $\bar{\rho}_0 = 0.475\bar{\rho}_{cr}$, $\Gamma_0 = 0.0$, $\Lambda_0 = -1.162$; solid lines: $\bar{\vartheta}_0 = \bar{\vartheta}_{cr}$, $\bar{p}_0 = 0.887\bar{p}_{cr}$, $\bar{\rho}_0 = 0.441\bar{\rho}_{cr}$, $\Gamma_0 = 0.101$, $\Lambda_0 = -1.131$.

of state and taking the input parameters from Ref. 23. The first reference state was chosen to be somewhere on the (second) transition line mentioned above where $\Gamma_0 = 0$ and $\Lambda_0 < 0$; the other is located on the same isotherm as the first one, however, it corresponds to a lower density. Similar results obtained for the siloxane MD₆M are displayed in Fig. 6. Here, the values for Γ_0 were taken from Fig. 10 in Ref. 25. The solutions presented there are based on the Peng-Robinson equation of state. Furthermore, for each reference state, Λ_0 was computed by exploiting the fact that BZT fluids have large specific heats and, thus, the isentropes and the

Critical values of MD₆M: $\bar{\vartheta}_{cr} = 688.9$ K, $\bar{p}_{cr} = 6.770 \times 10^5$ Pa, $\bar{\rho}_{cr} = 246.1$ kg/m³; dashed lines: $\bar{\vartheta}_0 = \bar{\vartheta}_{cr}$, $\bar{p}_0 = 0.975\bar{p}_{cr}$, $\bar{\rho}_0 = 0.641\bar{\rho}_{cr}$, $\Gamma_0 \approx 0.0$, $\Lambda_0 \approx -0.87$; solid lines: $\bar{\vartheta}_0 = \bar{\vartheta}_{cr}$, $\bar{p}_0 = 0.946\bar{p}_{cr}$, $\bar{\rho}_0 = 0.555\bar{\rho}_{cr}$, $\Gamma_0 \approx 0.15$, $\Lambda_0 \approx -0.95$.

isothermes in the pressure-density state space almost coincide.²² As a consequence, the isentropic derivative of Γ with respect to the density [see Eq. (3)] can roughly be estimated from its isothermal derivative.

C. Solutions

In the (unreal) case of vanishing dissipation, i.e., $\sigma=0$, Eq. (125) can easily be shown to be satisfied by the so-called *continuous wave* (CW) solution

$$\hat{U}_{cw} = a e^{j(w\xi - (w^2/2)Z - \text{sgn}(N)a^2Z + \phi_0)}, \quad (132)$$

with the real parameters a and ϕ_0 being the amplitude and the initial phase, respectively. The arbitrary real constant w characterizes the frequency shift due to dispersion. It is well known that if the nonlinearity parameter N is negative, a solution of this form is *modulationally unstable* to small periodic perturbations $\propto \exp(j\Omega\xi)$, provided that the modulation frequencies Ω are selected in a finite band $-2a < \Omega < 2a$ (see, for example, Ref. 33). In other words, in this case the nonlinearity is obviously no longer able to balance the dispersion and one can expect the generation of new stable solutions. Indeed, by applying the method of the *inverse scattering transform* (IST) such a solution called the *bright* NLS soliton,

$$N < 0: \quad \hat{U}_{bs} = a \text{sech}(a(\xi - wZ - \xi_0)) \times e^{j(w\xi - (w^2/2)Z + (a^2/2)Z + \phi_0)}, \quad (133)$$

can be found,³⁴ where the parameter ξ_0 stands for the initial position of the soliton and a and w now also play the roles as measures for the inverse pulse width and the inverse pulse velocity relative to the inverse group velocity ω_g , respectively. The condition $N < 0$ is thus said to define the type of the *focusing* cubic nonlinearity. As explicated in Sec. IV B, this case is of great importance if the evolution of a wave packet through a BZT fluid is considered. The properties of solitons have been studied extensively in the past; a detailed discussion of their most significant features and the extension to the multiple-soliton solution is presented, e.g., in Ref. 35 (Chap. 1 and pp. 182–183). Other exact solutions to the focusing NLS equation of practical relevance can be found, for instance, in Ref. 36 and the references therein.

In contrast to that, if $N > 0$, the result (132) proves to be *modulationally stable* to spatial periodic perturbations¹⁸ and the problem is said to be governed by the *defocusing* version of the NLS equation (125). Worth mentioning is the fact that in this case solutions in the form of “dark” pulses, i.e., rapid dips in the intensity, created on the CW background are also possible.³⁷ The general form of these so-called *dark* NLS solitons corresponding to the boundary condition $|\hat{U}| \rightarrow a$ at $\xi \rightarrow \pm\infty$ is

$$N > 0: \quad \hat{U}_{ds} = (c - jd \tanh(ad[\xi - (w + ac)Z - \xi_0])) \hat{U}_{cw}, \quad c^2 + d^2 = 1, \quad (134)$$

where the independent parameter d characterizes the soliton intensity. However, as brought out in the literature on pulse propagation in optical fibers (see, e.g., Ref. 38), the generation of dark solitons in an experimental setup is a rather

difficult task since it requires the background wave to be finely tuned to satisfy their demand for a local change in phase and amplitude.

In order to derive the wave number shift for purely monochromatic waves, i.e., single frequency waves without temporal modulation, that is induced by the cubic nonlinearity, the parameter w appearing in the CW solution (132) simply has to be set to 0. Returning to the original coordinate z by using Eq. (124), one then obtains the following expression^{16,18} for the velocity potential Φ_1 from Eq. (114):

$$N > 0: \quad \Phi_1 = A \frac{J_{m_c}(\gamma_c r)}{J_{m_c}(\gamma_c)} e^{j[\omega_c t - (k_c + k_{nl})z - m_c \phi - \phi_0]} + CC, \quad (135)$$

$$k_{nl} = -M^2 A^2 \frac{N}{k_c},$$

where k_{nl} and $A = a\sqrt{k_c}/N$ denote, respectively, the nonlinear wave number shift and the amplitude of the leading order perturbation.

For the type of waves considered in the present study, the dissipative effects cannot be neglected. As a consequence, the acoustic motion in the duct will be governed by the full version of the NLS equation (125), provided that the condition $M \ll \sigma \ll O(1)$ is satisfied. Equivalently, the set of Eqs. (127) and (128) can be used if the damping parameter is so small that $M \ll \sigma \ll 1$ holds. Moreover, please note that once the solutions for \hat{U} and thus Φ_1 are obtained, the expression for Φ_M can readily be derived from Eq. (117).

Finding the damped CW solution for the defocusing case is attempted by substitution of the ansatz $\hat{U} = a(Z) \exp(j(w\xi - w^2Z/2 + \phi(Z)))$ into Eq. (125), whereupon integration leads to

$$N > 0: \quad \hat{U}_{cwd} = a_0 e^{-\sigma DZ + j[w\xi - (w^2/2)Z + (a_0^2/2\sigma D)(e^{-2\sigma DZ} - 1) + \phi_0]}. \quad (136)$$

Worth emphasizing is the fact that this is an asymptotically correct result for all values of σ within the range $M \ll \sigma \ll O(1)$, and it reduces to the unperturbed solution when formally the limit $\sigma \rightarrow 0$ is taken. The expression for the velocity potential of a purely monochromatic wave thus reads

$$N > 0: \quad \Phi_1 = A_0 \frac{J_{m_c}(\gamma_c r)}{J_{m_c}(\gamma_c)} e^{-\hat{\Gamma}_c z + j(\omega_c t - \int_0^z k_{nl} d^2 z - m_c \phi - \phi_0)} + CC, \quad (137)$$

$$\hat{\Gamma}_c = jk_c + \alpha jk_c \hat{F}_c, \quad k_{nl} = -M^2 A_0^2 \frac{N}{k_c} e^{-2\alpha k_c \Re(\hat{F}_c)z}.$$

Here, k_{nl} and $A_0 = a_0\sqrt{k_c}/N$ denote, respectively, the *local* nonlinear wave number shift under the action of damping and the amplitude of Φ_1 at $z=0$, and \hat{F}_c is the quantity defined in Eq. (58), with $(n, m) = (n_c, m_c)$. According to what was stated before, the perturbation parameter $\alpha = \sigma M^2 \sim \text{Re}^{-1/2}$ has to be chosen such that $M^3 \ll \alpha \ll O(M^2)$. As expected, in the limit as $z \rightarrow \infty$ the nonlinear effects are damped away and the result from Eq. (137) ap-

proaches the solution for linear sound propagation truncated after the first correction term [see Eq. (81)].

The subject of bright and dark soliton dynamics in weakly dissipative or otherwise perturbed systems that can be described by an extended NLS equation has been attracting considerable interest over the last 30 years (see, e.g., the review papers by Kivshar *et al.*^{38,39}). In particular, recent progress in communication systems technology has presented many research problems in connection with pulse propagation in optical fibers where, similar to the problem studied here, the soliton represents the envelope of a wave packet. The analytical description of solitons under the action of (small) perturbations can be approached by different methods. Analyzing the prototype case of linear damping (125), Nicholson and Goldman⁴⁰ derived the general expressions for the evolution of the bright soliton parameters by exploiting the modified conservation laws of the perturbed NLS equation. Theories based on the IST for $N < 0$ were introduced by Kaup⁴¹ and independently also by Karpman and Maslov,⁴² whereas Keener and McLaughlin⁴³ and Ablowitz and Segur³⁵ (pp. 270–271) obtained equivalent results by solving the multiple scales secularity conditions of the higher order problem [here given by Eq. (128)] that derive from the Fredholm alternative or related concepts. These so-called direct perturbation techniques and the IST methods have the advantage that, in addition to the evolution of the leading order soliton solution, the effects arising in the higher orders in σ can be taken into account as well.

Here, a more intuitive approach strongly related to the technique applied in Sec. III shall be used in order to reveal the most significant features of a bright soliton propagating in the system given by Eqs. (127) and (128): The solvability conditions are derived by insisting on \hat{U}_σ not having worse behavior as Z and ξ tend to infinity than \hat{U}_1 . To this end, solutions of the form

$$\begin{aligned}\hat{U}_1 &= a(Z_\sigma) \hat{f}_1(Z, Z_\sigma, \xi) e^{j(w\xi - (w^2/2)Z)}, \\ \hat{U}_\sigma &= a(Z_\sigma) \hat{f}_\sigma(Z, Z_\sigma, \xi) e^{j(w\xi - (w^2/2)Z)}\end{aligned}\quad (138)$$

are sought. Moreover, the following coordinate transformation

$$\begin{aligned}s(Z) &= \int_0^{\sigma Z} \frac{a^2(Z_\sigma)}{\sigma} dZ_\sigma + s_0, \\ \eta(Z, Z_\sigma, \xi) &= a(Z_\sigma)(\xi - wZ - \xi_0), \quad \bar{Z}_\sigma(Z_\sigma) = Z_\sigma\end{aligned}\quad (139)$$

is applied, which requires the real-valued function $a(Z_\sigma)$ to be determined such that s and η are order $O(1)$ quantities within the spatial and temporal ranges defined by $Z \sim z_2 = O(1)$ and $\xi \sim (\omega_g t_1 - z_1) = O(1)$ and, thus, can take over the roles of the “shorter” scales formerly played by Z and ξ . It should be mentioned that a very similar procedure was used in Crighton *et al.*²⁸ (pp. 214–219) in order to analyze the effect of gradual sound speed variation on acoustic waves. Having substituted Eq. (138) into Eqs. (127) and (128), the transformation (139) leads to

$$j \frac{\partial \hat{f}_1}{\partial s} + \frac{1}{2} \frac{\partial^2 \hat{f}_1}{\partial \eta^2} - \text{sgn}(N) \hat{f}_1 \hat{f}_1^* = 0, \quad (140)$$

$$\begin{aligned}j \frac{\partial \hat{f}_\sigma}{\partial s} + \frac{1}{2} \frac{\partial^2 \hat{f}_\sigma}{\partial \eta^2} - \text{sgn}(N) \hat{f}_1 (2 \hat{f}_1^* \hat{f}_\sigma + \hat{f}_1 \hat{f}_\sigma^*) \\ = -j \frac{1}{a^2} \left(\frac{\partial \hat{f}_1}{\partial \bar{Z}_\sigma} + D \hat{f}_1 \right) - j \frac{1}{a^3} \frac{da}{d\bar{Z}_\sigma} \left(\eta \frac{\partial \hat{f}_1}{\partial \eta} + \hat{f}_1 \right).\end{aligned}\quad (141)$$

Obviously, the solutions to Eq. (140) are subject to the same stability conditions that hold for the solutions of the undamped case discussed before. Hence, the function \hat{f}_1 is taken to be

$$N < 0: \quad \hat{f}_1 = \text{sech}(\eta) e^{js/2}. \quad (142)$$

Since, furthermore, $\partial \hat{f}_1 / \partial s$ also constitutes a solution to the homogeneous part of Eq. (141), a particular solution can be expected to be found by making the ansatz

$$\hat{f}_\sigma = h(s, \bar{Z}_\sigma, \eta) \frac{\partial \hat{f}_1}{\partial s}, \quad (143)$$

where h is a real-valued function. Separating real and imaginary parts of the terms that are generated by substituting Eq. (143) into Eq. (141) and solving the resulting equations yields $\partial h / \partial s = 0$ and

$$\begin{aligned}h = -\frac{\eta^2}{a^3} \frac{da}{d\bar{Z}_\sigma} + \frac{\eta}{a^3} \left(\frac{da}{d\bar{Z}_\sigma} + 2Da + 2h_1(\bar{Z}_\sigma) \right) \\ - \frac{e^{-2\eta}}{2a^3} \left(\frac{da}{d\bar{Z}_\sigma} + 2Da + h_1(\bar{Z}_\sigma) \right) + \frac{e^{2\eta}}{2a^3} h_1(\bar{Z}_\sigma) + h_2(\bar{Z}_\sigma).\end{aligned}\quad (144)$$

The terms in Eq. (145) proportional to $\exp(2\eta)$ and $\exp(-2\eta)$ obviously have to be annihilated since they would involve secular terms in \hat{f}_σ . This implies that $h_1 = 0$ and

$$a = a_0 e^{-2D\bar{Z}_\sigma}. \quad (146)$$

Consequently, the leading order solution for the damped bright soliton and the particular solution for its first-order correction read

$N < 0, \quad M \ll \sigma \ll 1:$

$$\begin{aligned}\hat{U}_{1bsd} &= a_0 \text{sech}(a_0 e^{-2\sigma DZ} (\xi - wZ - \xi_0)) \\ &\times e^{-2\sigma DZ + j[w\xi - (w^2/2)Z - (a_0^2/8\sigma D)(e^{-4\sigma DZ} - 1) + \phi_0]}, \\ \hat{U}_{\sigma bsd} &= -jD(\xi - wZ - \xi_0)^2 \hat{U}_{1bsd}.\end{aligned}\quad (147)$$

These solutions are in complete conformity with the results from Refs. 35 and 40–43, and, utilizing Eqs. (114) and (124), they can easily be recast into the expressions for the velocity potentials $\Phi_1 \propto \hat{U}_1$ and $\Phi_\sigma \propto \hat{U}_\sigma$; the next higher order correction Φ_M is then obtained from Eq. (117). It should be emphasized that this combined solution is valid over spatial and temporal ranges of the order $O(\sigma^{-1} M^{-1})$ only.

As far as the propagation of dark solitons for the damped defocusing case is concerned, the study by Lisak *et al.*⁴⁴ based upon the modified conservation laws and the more refined analysis by Kivshar *et al.*³⁸ using the IST per-

turbation theory should be mentioned. To the author's knowledge, the most complete investigation is presented in the 1998 paper by Chen *et al.*,⁴⁵ who, applying a direct perturbation technique to the system (127) and (128), arrived at the relationships $a(\bar{Z}_\sigma) = a_0 \exp(-D\bar{Z}_\sigma)$ and, additionally, $\xi_0(\bar{Z}_\sigma) = \xi_{00} + D\bar{Z}_\sigma/(2a_0d)$. Thus, the expression for the damped dark soliton assumes the form

$N > 0, \quad M \ll \sigma \ll 1:$

$$\hat{U}_{1dsd} = (c - jd \tanh(\beta)) \hat{U}_{c wd}, \quad c^2 + d^2 = 1, \quad (148)$$

$$\beta = a_0 e^{-\sigma D Z} d \left[\xi - (w + a_0 e^{-\sigma D Z} c) Z - \xi_{00} \right] - \frac{\sigma D Z}{2} e^{-\sigma D Z},$$

in which $U_{c wd}$ is the solution for the damped background wave (136). The (very complex) result for the first-order correction $U_{\sigma dsd}$ can also be found in Ref. 45.

Despite being valid for a wide range of wave numbers and frequencies, the solvability condition for the third-order problem in the form (123) obviously breaks down in the limit as $k_c \rightarrow 0$. That is to say, the solutions above cease to be valid for driving frequencies near the linear cutoff frequency of the carrier mode. However, this difficulty can be overcome by using instead of Eq. (123) the more general conditions (116) and (118). With k_c set to zero, they read $\partial \hat{A}_1 / \partial t_1 = 0$ and

$$2j\gamma_c \frac{\partial \hat{A}_1}{\partial t_2} - \frac{\partial^2 \hat{A}_1}{\partial z_1^2} = -2N \hat{A}_1^2 \hat{A}_1^* + 2\sigma \hat{F}_c \hat{A}_1, \quad (149)$$

respectively. Here, \hat{F}_c is the parameter defined by Eq. (83), with $\omega_{\bar{m}} = \omega_c = \gamma_c$ and $(\bar{n}, \bar{m}) = (n_c, m_c)$. Introduction of the scaled quantities

$$Z = M^2 t, \quad \xi = M \sqrt{\gamma_c} z, \quad D = \frac{\Re(\hat{F}_c)}{\gamma_c} > 0, \quad (150)$$

$$\hat{U} = \sqrt{\frac{|N|}{\gamma_c}} \hat{A}_1^* e^{-j\sigma D Z}$$

then again yields the damped NLS equation (125).

Please note that upon neglecting the nonlinear terms in Eqs. (149) and recalling that $\sigma = \alpha/M^2$, the solution for Φ_1

$$\Phi_1 = A \frac{J_{m_c}(\gamma_c r)}{J_{m_c}(\gamma_c)} e^{-\hat{\Gamma}_c z + j(\Omega_c t - m_c \phi - \phi_0)} + \text{CC}, \quad (151)$$

$$\hat{\Gamma}_c = \alpha^{1/2} j(2\hat{F}_c + 2\gamma_c \omega_\alpha)^{1/2}, \quad \Omega = \gamma_c + \alpha \omega_\alpha,$$

where $\omega_\alpha = O(1)$ is an arbitrary detuning frequency, agrees perfectly with the linear solution from Eq. (82) truncated after the leading order term. On the other hand, if the viscous effects are neglected, the CW solution (132) for $N > 0$ with $w = 0$ gives Nayfeh's solution¹⁸ for the nonlinear shift ω_{nl} of the cutoff frequency of a monochromatic wave:

$$N > 0, \quad \sigma = 0: \quad \Phi_1 = A \frac{J_{m_c}(\gamma_c r)}{J_{m_c}(\gamma_c)} e^{j[(\gamma_c + \omega_{nl})t - m_c \phi - \phi_0]} + \text{CC}, \quad (152)$$

$$\omega_{nl} = M^2 A^2 \frac{N}{\gamma_c}.$$

However, inspection of Eq. (136) immediately shows that in the presence of boundary layer effects, the concept of using the (damped) CW solution in order to find analytical expressions for Φ_1 as $k_c \rightarrow 0$ and the corresponding boundary condition at $z = 0$ fails since any such solution, propagating ($w \neq 0$) or not propagating ($w = 0$), would involve the term $\exp(-\alpha \Re(\hat{F}_c) t / \gamma_c)$ and, thus, would become unbounded as $t \rightarrow -\infty$. Notwithstanding, if $N > 0$, the damped NLS equation (125) can be solved numerically for any bounded boundary condition. In contrast to Eq. (136), if $N < 0$, $M \ll \sigma \ll 1$, and $k_c \rightarrow 0$, the damped soliton solution (147) in combination with Eqs. (114) and (150) *does* provide a valid solution for Φ_1 that is bounded for all values of t and x .

V. CONCLUSIONS

The work presented here analyzes the linear and the nonlinear propagation of sound waves in circular, hard-walled tubes containing a real gas. The investigations primarily proceed from the assumption that the acoustic boundary layer is thin compared to the diameter of the duct and that the characteristic wavelength and the diameter are of the same order of magnitude. In the first part, dealing with the linear problem, the method of matched asymptotic expansions in combination with the method of multiple scales has been applied in order to derive the first- and second-order terms of the sound pressure and the expansion of the propagation parameters up to third order. These solutions generalize the results given in the literature for real gases and for the cases where the tube length becomes so large that the effects resulting from bulk viscosity and heat conduction in the core region have to be taken into account as well.

The second part deals with the nonlinear evolution of a wave packet centered at the frequency and the wave number of a higher order carrier mode. Using the same perturbation methods as before, the damped nonlinear Schrödinger equation (125) has been derived, which proves to be applicable even if the driving frequency of the carrier mode is close to its cutoff frequency. Furthermore, special emphasis has been placed on a detailed discussion of the sign of the nonlinearity parameter N : In the case of a perfect gas the nonlinearity parameter is a strictly positive quantity and, thus, the evolution of the wave packet is governed by the defocusing version of the Schrödinger equation. In contrast to that, for special combinations of the parameters characterizing the equilibrium reference state of a real gas, also the focusing version can be obtained, enabling the formation of stable soliton solutions. Particularly, the so-called BZT fluids have turned out to be possible candidates for applications where the nonlinearity parameter becomes negative.

The asymptotic analysis which has led to Eq. (125), obviously, assumes that $N = O(1)$ and will break down in the

vicinity of a transition points where the nonlinear parameter vanishes; that such transition points might occur can be seen from Figs. 5 and 6. For values of ω_c away from these points, the wave evolution will be described by Eq. (125) with either $N > 0$ or $N < 0$. However, within a $N = O(M)$ neighborhood of these points, small terms neglected in constructing Eq. (125) become of the same order as the already included nonlinear correction term and a separate analysis is then required. In a different physical context, asymptotic expansions to analyze this case have been developed by Grimshaw *et al.*³⁶ and Parkes.⁴⁶ Neglecting all dissipative effects, they arrived at a modified nonlinear Schrödinger equation featuring additional cubic and quintic nonlinearity terms. It would be interesting to know whether a similar evolution equation that also incorporates the boundary layer effects can be derived for the problem studied here.

ACKNOWLEDGMENT

The author would like to thank Marcus Wrabel at the Institute of Fluid Mechanics and Heat Transfer, Vienna University of Technology, for providing the numerical code to evaluate the Martin-Hou equation of state for the BZT fluid FC-71.

APPENDIX: PROPAGATION PARAMETERS IN DIMENSIONAL FORM

Please note that here the accents “ \sim ” introduced in Sec. I to indicate dimensional quantities have been omitted. Equation (80):

$$\hat{\Gamma}_{nm} = \sqrt{-\hat{k}_{nm}^2 \left(1 + 2 \frac{\hat{F}_{nm}}{\text{St}(\omega)} + \frac{2\hat{H}_{nm} + \hat{F}_{nm}^2}{\text{St}(\omega)^2} \right) + O(\text{St}^{-3})}, \quad (\text{A1})$$

where

$$\hat{k}_{mn} = \begin{cases} 1/R \sqrt{\text{He}(\omega)^2 - \gamma_{nm}^2}, & \text{He}(\omega) > \gamma_{nm}, \\ -j/R \sqrt{\gamma_{nm}^2 - \text{He}(\omega)^2} & \text{He}(\omega) < \gamma_{nm}, \end{cases}$$

$$\hat{F}_{nm} = \frac{1-j}{-\sqrt{2}(1-m^2/\gamma_{nm}^2)} \times \left(1 + \frac{m^2}{R^2 \hat{k}_{nm}^2} + \frac{\text{He}(\omega)^2}{R^2 \hat{k}_{nm}^2} \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} \right),$$

$$\hat{H}_{00} = -j \left[1 + \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} \left(1 - \frac{\gamma_0}{2\sqrt{\text{Pr}}} \right) \right] - \frac{j\text{He}(\omega)^2}{2} \left[\frac{11}{6} + \frac{\eta_0}{\mu_0} + \frac{\gamma_0 - 1}{2\sqrt{\text{Pr}}} \left(2 + \frac{1 + \gamma_0}{\sqrt{\text{Pr}}} \right) \right],$$

$$\hat{H}_{nm} = \hat{G}_{nm} - \frac{\hat{F}_{nm}^2}{2} + \frac{R^2 \hat{k}_{nm}^2 \hat{F}_{nm}^2}{\gamma_{nm}^2} \frac{m^2}{\gamma_{nm}^2 - m^2} - \frac{j\text{He}(\omega)^4}{2\hat{k}_{nm}^2 R^2} \left(\frac{4}{3} + \frac{\eta_0}{\mu_0} + \frac{\gamma_0 - 1}{\text{Pr}} \right), \quad (n, m) \neq (0, 0),$$

$$\hat{G}_{nm} = -\frac{j}{2(1-m^2/\gamma_{nm}^2)^2} \left[3 + \frac{m^2}{\gamma_{nm}^2} + \frac{m^2}{R^2 \hat{k}_{nm}^2} \left(5 - \frac{m^2}{\gamma_{nm}^2} \right) - \frac{\text{He}(\omega)^2}{R^2 \hat{k}_{nm}^2} (\gamma_0 - 1) \left(\left(1 - \frac{m^2}{\gamma_{nm}^2} \right) \frac{1}{\text{Pr}} - \frac{4}{\sqrt{\text{Pr}}} \right) \right],$$

$$(n, m) \neq (0, 0),$$

$$\text{St}(\omega) = \sqrt{\frac{\omega \rho_0 R^2}{\mu_0}} \gg 1, \quad \text{He}(\omega) = \frac{\omega R}{c_0} = O(1),$$

$$\text{Pr} = \frac{\mu_0 C_p}{\kappa_0} = O(1). \quad (\text{A2})$$

Equation (94):

$$\hat{\Gamma}_{nm} = \frac{j\text{He}(\omega)}{R} \left(1 + \frac{\hat{L}_{nm}}{\text{St}(\omega)} + O(\text{St}^{-2}) \right), \quad (\text{A3})$$

where

$$\hat{L}_{nm} = -\frac{\hat{\gamma}_{nm}^2 \text{St}(\omega)}{2\text{He}(\omega)^2} - \frac{j\text{He}(\omega)^2}{2\text{St}(\omega)} \left(\frac{4}{3} + \frac{\eta_0}{\mu_0} + \frac{\gamma_0 - 1}{\text{Pr}} \right),$$

$$\hat{J}_{m+1}(\hat{\gamma}_{nm}) \hat{\gamma}_{nm} - m \hat{J}_m(\hat{\gamma}_{nm}) + \frac{\text{He}(\omega)^2 \hat{F}}{\text{St}(\omega)} \hat{J}_m(\hat{\gamma}_{nm}) = 0,$$

$$\hat{F} = \frac{1-j}{\sqrt{2}} \left(1 + \frac{\gamma_0 - 1}{\sqrt{\text{Pr}}} \right),$$

$$\text{St}(\omega) = \sqrt{\frac{\omega \rho_0 R^2}{\mu_0}} \gg 1, \quad \text{He}(\omega) = \frac{\omega R}{c_0} = O(\text{St}^{1/2}),$$

$$\text{Pr} = \frac{\mu_0 C_p}{\kappa_0} = O(1). \quad (\text{A4})$$

Simultaneous measurement of acoustic and streaming velocities in a standing wave using laser Doppler anemometry^{a)}

Michael W. Thompson^{b)} and Anthony A. Atchley^{c)}

Graduate Program in Acoustics, The Pennsylvania State University, University Park, Pennsylvania 16802

(Received 1 August 2004; revised 27 November 2004; accepted 29 December 2004)

Laser Doppler anemometry (LDA) with burst spectrum analysis (BSA) is used to study the acoustic streaming generated in a cylindrical standing-wave resonator filled with air. The air column is driven sinusoidally at a frequency of approximately 310 Hz and the resultant acoustic-velocity amplitudes are less than 1.3 m/s at the velocity antinodes. The axial component of fluid velocity is measured along the resonator axis, across the diameter, and as a function of acoustic amplitude. The velocity signals are postprocessed using the Fourier averaging method [Sonnenberger *et al.*, Exp. Fluids **28**, 217–224 (2000)]. Equations are derived for determining the uncertainties in the resultant Fourier coefficients. The time-averaged velocity-signal components are seen to be contaminated by significant errors due to the LDA/BSA system. In order to avoid these errors, the Lagrangian streaming velocities are determined using the time-harmonic signal components and the arrival times of the velocity samples. The observed Lagrangian streaming velocities are consistent with Rott's theory [N. Rott, Z. Angew. Math. Phys. **25**, 417–421 (1974)], indicating that the dependence of viscosity on temperature is important. The onset of streaming is observed to occur within approximately 5 s after switching on the acoustic field. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1861233]

I. INTRODUCTION

Rayleigh streaming¹ is a form of time-averaged fluid flow that is generated when an acoustic wave in a fluid interacts viscously with a solid surface. The streaming associated with a one-dimensional monofrequency acoustic standing wave in a resonator has previously been investigated by Sharpe *et al.*,² Arroyo and Greated,³ Hann and Greated,⁴ and Rockliff *et al.*⁵ using the particle image velocimetry (PIV) technique. The laser Doppler anemometry (LDA) technique has also been applied to the study of streaming by Thompson and Atchley.^{6,7} Although these studies establish the basic validity of the streaming theory, none of them represents a thorough investigation of the phenomenon.

The present study builds on the previous work of Thompson and Atchley by developing a high-precision method for the simultaneous measurement of acoustic and streaming velocities based on the LDA/BSA technique. This method is used to measure the acoustic streaming generated by a relatively low-amplitude acoustic standing wave in a long cylindrical resonator. The results are compared to the theories of Rott⁸ and Qi.⁹

Section II contains a discussion of the relevant stream-

ing theories, and Sec. III contains a discussion of the previous measurements of the phenomenon. Section IV provides an overview of the LDA technique and the burst spectrum analysis (BSA) method¹⁰ for determining fluid velocity, and Sec. V provides an overview of the Fourier averaging (FA) method¹¹ for analyzing the LDA/BSA data. A description of the experimental apparatus and procedure is given in Sec. VI, an extension of the FA method is presented in Sec. VII, and a method for determining the Lagrangian streaming velocity is presented in Sec. VIII. Sections IX and X present a comparison of the measurements of streaming velocity to the theory.

II. THEORY

The theoretical result for the streaming-velocity field generated by a monofrequency acoustic standing wave in a tube of circular cross section was given by Schuster and Matz.¹² They assumed: (1) that the resonator inner radius R is small relative to the acoustic wavelength λ ; (2) that R is large relative to the thickness of the viscous acoustic boundary layer, $\delta_v = \sqrt{2\nu/\omega}$, where ν is the kinematic viscosity of the fluid and ω is the angular acoustic frequency; (3) that thermal effects are negligible; and (4) that terms higher than second order in the acoustic Mach number $M = U_1/c$ are negligible, where U_1 is the amplitude of the acoustic velocity at its antinode and c is the sound speed in the fluid.

Consider a long cylindrical tube filled with air driven sinusoidally at one end and terminated by a rigid end cap at the other. The acoustic- and streaming-velocity fields in this system can be described in two spatial dimensions: (1) an axial coordinate that runs parallel to the tube centerline and (2) a transverse coordinate that runs perpendicular to the cen-

FIG. 1. Profile view of a streaming cell in the outer streaming-velocity field, calculated from Eqs. (2) and (3). The flow along the resonator walls ($r = \pm R$) is toward the acoustic-velocity node ($x=0$), and the return flow along the centerline ($r=0$) is toward the acoustic-velocity antinode ($x=L$). Neighboring cells, to the left and to the right of the cell shown here, circulate in the opposite direction. The variation of the axial component of streaming velocity with respect to x is sinusoidal, with the maximum value occurring at $x=L/2$. The variation of the axial component of streaming velocity with respect to r is parabolic, with the average flow over the cross section (x held constant) equal to zero. As r approaches $\pm R$ within the boundary layer (not shown), the velocity goes to zero.

terline. The velocity fields are assumed to be symmetric about the centerline.

The axial component of the acoustic-velocity field well outside the boundary layer is

$$u_1 = \Re(\tilde{U}_1 e^{j\omega t}) \sin\left(\frac{2\pi x}{\lambda}\right), \quad (1)$$

where \tilde{U}_1 is the complex amplitude of the acoustic velocity at its antinode, t is time, x is the axial coordinate, $j = \sqrt{-1}$, and \Re denotes taking the real part of the complex argument. The transverse component of the acoustic-velocity field well outside the boundary layer is negligible.

The axial component $\langle u_2 \rangle$ and transverse component $\langle v_2 \rangle$ of the streaming-velocity field well outside the boundary layer (the outer streaming-velocity field) are^{12,13}

$$\langle u_2 \rangle = \frac{3}{8} \frac{U_1^2}{c} \left(1 - \frac{2r^2}{R^2}\right) \sin\left(\frac{\pi x}{L}\right), \quad (2)$$

and

$$\langle v_2 \rangle = -\frac{3}{8} \frac{U_1^2}{c} \frac{2\pi r}{\lambda} \left(1 - \frac{r^2}{R^2}\right) \cos\left(\frac{\pi x}{L}\right), \quad (3)$$

where U_1 is the magnitude of \tilde{U}_1 , r is the transverse coordinate ($-R \leq r \leq R$), $L = \lambda/4$, and angled brackets $\langle \dots \rangle$ are used to denote time-averaged quantities. This outer streaming-velocity field consists of a series of toroidal streaming cells of length L , an example of which is shown in Fig. 1. (Within the boundary layer near the resonator walls, there exists an inner streaming-velocity field with vortices circulating in the direction opposite the outer streaming vortices shown here.)

Rott⁸ extended the theory by addressing the effects of heat conduction, including: (1) the acoustic temperature fluctuations; (2) the thermal acoustic boundary layer, with thickness $\delta_\kappa = \sqrt{2\kappa/\omega}$, where κ is the thermal diffusivity of the fluid; (3) the variation of mean temperature T_0 with respect

to the axial coordinate x ; and (4) the dependence of viscosity μ and thermal conductivity on temperature T , assuming a form for the viscosity of $\mu \propto T^\beta$, where β is a constant that depends on the properties of the fluid. [The assumptions of Schuster and Matz¹² numbered (1), (2), and (4) in the first paragraph of this section also hold.]

For a nearly uniform axial temperature distribution ($\partial T_0 / \partial x \approx 0$), Rott obtained an axial streaming velocity of

$$\langle u_2 \rangle = (1 + \alpha_1) \frac{3}{8} \frac{U_1^2}{c} \left(1 - \frac{2r^2}{R^2}\right) \sin\left(\frac{\pi x}{L}\right). \quad (4)$$

The constant α_1 represents a correction to the magnitude of the streaming velocity and is given by

$$\alpha_1 = \frac{2}{3} (1 - \beta)(\gamma - 1) \frac{\sqrt{\text{Pr}}}{1 + \text{Pr}}, \quad (5)$$

where γ is the ratio of the isobaric to isochoric specific heats and $\text{Pr} = \nu/\kappa$ is the Prandtl number. A typical value for α_1 in air ($\gamma = 1.4$, $\text{Pr} = 0.71$, and $\beta = 0.77$) is $\alpha_1 = 0.030$, which predicts an axial streaming velocity that is 3.0% larger than the result given by Eq. (2).

A result similar to Eq. (4) was later obtained independently by Qi.⁹ However, his proposed correction,

$$\alpha_1 = \frac{2}{3} (\gamma - 1) \frac{\sqrt{\text{Pr}}}{1 + \text{Pr}}, \quad (6)$$

neglects the dependence of viscosity and thermal conductivity on temperature ($\beta = 0$), predicting an axial streaming velocity that is 13.1% larger ($\alpha_1 = 0.131$) than the result given by Eq. (2).

Hamilton *et al.*¹⁴ considered analytically how heat conduction and the dependence of viscosity and thermal conductivity on temperature affect the acoustic streaming generated by standing waves in tubes of arbitrary width. For the case of a wide tube ($R \gg \delta_\nu$), their results are in agreement with the results of Rott.⁸

The influence of fluid inertia on the streaming-velocity field was studied computationally by Menguy and Gilbert.¹⁵ They concluded that the effect of fluid inertia is to distort the shape of the outer streaming cells: the location of maximum streaming velocity along the centerline ($r=0$) shifts from the midpoint ($x=L/2$) toward the velocity antinode ($x=L$), while the streaming velocity just outside the acoustic boundary layer ($r \approx \pm R$) remains unchanged. This distortion scales with the Reynolds number

$$\text{Re} = \left(\frac{U_1}{c}\right)^2 \left(\frac{R}{\delta_\nu/\sqrt{2}}\right)^2, \quad (7)$$

and is negligible for $\text{Re} \ll 1$.

III. PREVIOUS MEASUREMENTS

Only a few studies pertaining to the measurement of the streaming-velocity field in a standing-wave resonator are available in the literature. In all of these studies, optical methods were used to measure the motion of smoke particles suspended in air ($c \approx 345$ m/s).

The first known study was by Andrade,¹⁶ who photographed the smoke patterns produced by streaming in a cylindrical resonator ($2R=3.5$ cm, $\lambda=56.5$ cm, $U_1=1.3$ m/s, $Re\approx 0.5$). From these photographs, the flow streamlines were obtained and compared to the theoretical results of Rayleigh with good success.

A more quantitative investigation was carried out by Sharpe *et al.*² using the particle image velocimetry (PIV) technique. (A typical PIV system consists of a sheet of light for illuminating small tracer particles suspended in the working fluid and a photographic system for imaging the particle motion in two dimensions.) Sharpe *et al.* measured the axial and transverse components of the streaming-velocity field in the vicinity of an acoustic-velocity node ($x\approx 0$) in a cylindrical resonator ($2R=2.35$ cm, $\lambda\approx 13$ cm, $U_1\approx 2.5$ m/s, $Re\approx 1.0$). They showed the axial streaming velocity to vary parabolically with respect to the transverse coordinate, with a magnitude consistent with the measured acoustic-pressure amplitude.

Arroyo and Greated³ used stereoscopic PIV to measure all three spatial components of the streaming-velocity field in the vicinity of an acoustic-velocity node ($x\approx 0$) in a resonator of rectangular cross section (transverse dimensions= 2.22 cm \times 2.34 cm, $\lambda=18.0$ cm, $U_1\approx 1.6$ m/s, $Re\approx 0.3$). They, too, reported a parabolic variation of axial streaming velocity with respect to the transverse coordinate, with a magnitude consistent with the measured acoustic-pressure amplitude. Additionally, the precision of these measurements was better than that reported by Sharpe *et al.*²

Hann and Greated⁴ used PIV to simultaneously measure two of the spatial components of both the acoustic- and the streaming-velocity fields in the vicinity of an acoustic-velocity node ($x\approx 0$) in a resonator of square cross section (transverse dimension= 3.0 cm, $\lambda=21.4$ cm, $U_1=2.1$ m/s, $Re\approx 1.0$). Because their work focused primarily on the signal-processing technique used to separate the acoustic- and streaming-velocity fields, they did not address the spatial variation of the streaming velocity.

Rockliff *et al.*⁵ used PIV to measure the axial and transverse components of the streaming-velocity field in the vicinity of an acoustic-velocity node ($x\approx 0$) in a cylindrical resonator ($2R$ =not specified, $\lambda\approx 17$ cm, $U_1\approx 2$ m/s, Re =unknown). However, no new observations were reported.

Thompson and Atchley⁶ used the laser Doppler anemometry (LDA) technique to simultaneously measure the axial components of the acoustic- and streaming-velocity fields in a cylindrical resonator ($2R=4.65$ cm, $\lambda=1.11$ m). They reported that at low to moderate acoustic amplitudes ($U_1=0.57$ and 2.3 m/s, $Re=0.36$ and 5.7) the variation of axial streaming velocity with respect to the transverse coordinate r midway along the streaming cell ($x=L/2$) was parabolic, whereas at higher acoustic amplitudes ($U_1=4.2$ m/s, $Re=19$) the variation was not parabolic, but rather resembled a sixth-order polynomial. Although the precision of these measurements was not as good as that reported by Sharpe *et al.*² and Arroyo and Greated,³ the magnitudes of the measured streaming were consistent with the measured acoustic-velocity amplitudes.

Although several of these previous studies reported a parabolic variation of axial streaming velocity with respect to the transverse coordinate, none of them addressed the variation of axial streaming velocity with respect to the axial coordinate, the variation with respect to the acoustic amplitude at low Reynolds numbers ($Re<1$), or the corrections to the streaming magnitude proposed by Rott⁸ and Qi⁹ (see Sec. II).

IV. LDA AND BSA

The LDA technique was first applied to the measurement of acoustic fluid velocity by Taylor,¹⁷ who studied monofrequency standing waves in air. The technique was later refined and extended by Vignola *et al.*,¹⁸ who used water as a working fluid. More recently, LDA with burst spectrum analysis (BSA) has been used: by Bailliet *et al.*¹⁹ to measure acoustic velocity and power flow within a thermoacoustic resonator; by Thompson and Atchley⁶ to measure acoustic-streaming velocity in a standing-wave resonator (see Sec. III); and by Biwa *et al.*²⁰ to measure acoustic-streaming velocity and acoustic intensity associated with planar traveling waves in a cylindrical wave guide.

In a typical LDA system, two coherent laser beams intersect to form a series of interference fringes at the location where fluid velocity is to be measured (the fringe volume). When a small tracer particle suspended in the fluid passes through these fringes, the intensity of the light scattered from the particle is modulated at a frequency proportional to the spatial component of particle velocity that is normal to the fringes. It is assumed that the tracer particle follows the motion of the fluid, which Taylor¹⁷ showed to be the case for smoke in air at acoustic frequencies below approximately 5 kHz.

If one of the laser beams is frequency shifted by an amount ΔF relative to the other using an acousto-optic modulator (Bragg cell), then the intensity of the light scattered from a stationary tracer particle will be modulated at a frequency of ΔF (instead of at a frequency of zero, as in the non-frequency-shifted case). In addition to enabling the detection of stationary or low-speed particles, this frequency shift enables the determination of the sign of the velocity: a modulation frequency greater than ΔF corresponds to a particle moving in the "positive" direction, whereas a modulation frequency less than ΔF corresponds to a particle moving in the "negative" direction.

Whenever a tracer particle enters the fringe volume, a detection event known as a "burst" occurs. If the peak-to-peak particle displacements are much larger than the fringe volume, then velocity information can be extracted from these bursts using the BSA method.¹⁰ The intensity of the scattered light is measured using a photodetector, and an analog voltage is produced. This signal is bandpass filtered and frequency demodulated by $-\Delta F$ to produce both in-phase and quadrature signals that can be treated as the real and imaginary components of a single complex signal. This signal is low-pass filtered and sampled during a time interval (the BSA record interval) short relative to the acoustic period $\tau=2\pi/\omega$, such that the modulation frequency of the signal (which corresponds to the particle velocity) remains nearly

constant during that interval. The discrete Fourier transform (DFT) of the sampled signal is then calculated and the center frequency of the main spectral peak is obtained by curve fitting and interpolation. From this frequency, which can be either positive or negative, the tracer-particle velocity is obtained.²¹

V. FOURIER AVERAGING

The particle velocities obtained from a large number of bursts constitute a record of the fluid velocity at the measurement location sampled as a function of time. Analysis of this sample record is complicated by several factors: (1) The spatial distribution of tracer particles within the fluid is random, resulting in a nonuniform time interval between velocity samples. (2) The rate at which samples are acquired (the data rate) is proportional to the fluid velocity, causing the probability distribution of the samples to be skewed symmetrically away from zero in favor of high-speed samples. (3) The data rate is often less than the Nyquist rate (twice the highest acoustic frequency being sampled), resulting in acoustic-frequency aliasing. (4) The time-averaged signal component, which corresponds to the desired acoustic-streaming velocity, is typically orders of magnitude smaller than the oscillatory signal component.²⁴

The velocity waveform can be reconstructed from the sample record using the Fourier averaging (FA) method proposed by Sonnenberger *et al.*¹¹ The acoustic period τ is divided into N equal-width phase bins (indexed by bin number $n=1,2,\dots,N$) and the velocity samples are sorted by phase into the appropriate bins (e.g., all samples having an arrival time approximately equal to an integer multiple of τ are grouped together into a single phase bin at $t=\tau$; all samples having an arrival time approximately equal to an integer multiple of τ plus some value $0 < t_1 \leq \tau$ are grouped together into a single phase bin at $t=t_1$). The mean velocity within each bin, $\bar{y}[n]$, is calculated from

$$\bar{y}[n] = \frac{1}{I[n]} \sum_{i=1}^{I[n]} y[n,i], \quad (8)$$

where $y[n,i]$ is the i th sample in the n th bin, $I[n]$ is the total number of samples in the n th bin, and square brackets [...] are used to denote that the arguments are integer indices. The values $\bar{y}[n]$ represent N evenly spaced samples of the average velocity waveform during one period.

A series of complex Fourier coefficients $\tilde{Y}[z]$ (indexed by harmonic number $z=0,1,\dots,Z$) is then calculated from the phase-bin-averaged velocity data using the discrete Fourier transform

$$\tilde{Y}[z] = \frac{2}{N} \sum_{n=1}^N \bar{y}[n] e^{-j2\pi zn/N}, \quad (9)$$

for the harmonics $z=1,2,\dots,Z$ (the time-harmonic signal components, which correspond to the acoustic velocity), and

$$Y[0] = \frac{1}{N} \sum_{n=1}^N \bar{y}[n], \quad (10)$$

FIG. 2. The experimental apparatus. (A) Two compression drivers are connected to (B) a stainless-steel tee on top of (C) a 40 cm stainless-steel tube. This vertical section is connected by (D) a stainless-steel 90 deg elbow to a horizontal section comprised of (E) a 122 cm borosilicate-glass tube and (F) a 20 cm stainless-steel tube. The resonator is terminated by (G) a rigid stainless-steel end cap. The horizontal section is suspended inside (H) a glass-walled enclosure. The dotted box indicates the location of the streaming cell where measurements are made, which is similar to the cell shown in Fig. 1.

for $z=0$ (the time-averaged signal component, which corresponds to the streaming velocity). A smoothed velocity waveform can then be synthesized using the inverse transform

$$y(t) = \Re \left(\sum_{z=0}^{Z'} \tilde{Y}[z] e^{j\omega z t} \right), \quad (11)$$

where the Fourier series is truncated at harmonic number $Z' < Z$, below which the coefficients are considered statistically significant.²⁶

VI. PROCEDURE

The apparatus shown in Fig. 2 has been used to study the outer streaming-velocity field generated by a monofrequency acoustic standing wave in air at low Reynolds numbers ($Re < 1$). The standing-wave resonator is constructed primarily of stainless-steel tubing (type 304, inner diameter $2R=4.75$ cm, wall thickness=1.7 mm) and has a long section made of borosilicate glass (inner diameter $2R=4.65$ cm, wall thickness=2.0 mm) for making velocity measurements using an LDA/BSA system. The individual pieces are joined together using quick-connect clamps that facilitate the introduction of smoke from burned cotton rope and the cleaning of smoke residue from inside the resonator. (The diameters of the smoke particles are on the order of $1 \mu\text{m}$, measured using a Philips XL30 ESEM scanning electron microscope.)

The two compression drivers (University Sound 1828C or 1829BT) are driven sinusoidally in phase to produce a

standing wave at the fourth natural mode of the air column, which corresponds to a wavelength of $\lambda=1.11$ m and a fundamental frequency of $f=\omega/2\pi=311$ Hz when using the 1828C drivers, or $\lambda=1.13$ m and $f=308$ Hz when using the 1829BT drivers. (At these frequencies in air, the thickness of the viscous acoustic boundary layer is $\delta_v=0.13$ mm). The amplitude of the first harmonic of pressure at its antinode is monitored using a piezoresistive gauge-pressure transducer (Endevco 8510B-5) mounted flush in the rigid end cap.

The glass-walled enclosure helps to isolate the resonator from temperature gradients within the laboratory that can cause unwanted ambient convection currents. In preliminary experiments done without the enclosure, thermally induced currents were observed within the resonator that were as large in magnitude as the acoustic streaming. Elevating the drivers also helps to reduce unwanted ambient convection currents by trapping the heat generated by the drivers within the vertical section of the resonator. Several type-E thermocouples (Omega Engineering TT-E-30-SLE) are attached to the outer wall of the resonator at various locations in order to monitor the spatial distribution of mean temperature, which has a nominal value of 23 °C and is uniform within 0.1 °C along the streaming cell of interest, even in the presence of a steady-state acoustic field.

A barometric-pressure transducer (SenSym ASCX15AN) is located within the enclosure so that, in combination with the gauge-pressure transducer, the mean absolute pressure within the resonator (nominally 97 kPa) can be determined.

The axial component of streaming velocity is measured using a single-component LDA system (Dantec Measurement Technology FlowLite). The HeNe laser has an optical wavelength of 632.8 nm, a power of 10 mW, and a frequency shift of $\Delta F=40$ MHz in one of the beams. The dimensions of the fringe volume are $77 \mu\text{m}$ in the direction of measurement by $636 \mu\text{m}$ wide, and the fringe spacing is $2.63 \mu\text{m}$ (determined by measuring the intersection angle of the two beams geometrically). The LDA probe is mounted on a linear positioning system that translates in both the axial and the transverse directions in the horizontal plane. Each time a tracer particle passes through the LDA fringe volume, its velocity is sampled and the corresponding arrival time and transit time are recorded by a BSA system (Dantec Measurement Technology 57N11) connected to the LDA photomultiplier output. The absolute accuracy of the velocity measurements is approximately 0.3%, based on the uncertainty in the intersection angle of the two LDA laser beams. However, the random errors in the individual velocity samples are much larger than 0.3% and vary with the BSA settings used.

A schematic diagram of the instrumentation is shown in Fig. 3. The BSA system, the sine-wave generator, and the two data-acquisition systems are synchronized to prevent any timing jitter or drift from interfering with the phase-bin-averaging procedure (see Sec. V). In preliminary measurements, it was observed that not having the clocks synchronized resulted in cumulative errors in the phases of the velocity samples, causing the samples to be incorrectly sorted into the wrong phase bins.

In preparation for making measurements, the electronics

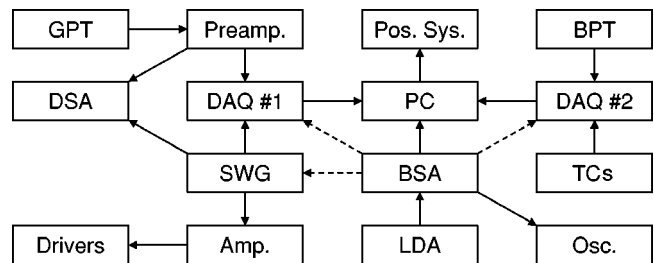

FIG. 3. Schematic diagram of the instrumentation. The sine-wave generator (SWG) is connected to the two compression drivers through an amplifier (Amp.). The signal from the gauge-pressure transducer (GPT) flows through a preamplifier (Preamp.) before being sampled by a data-acquisition system (DAQ #1). The signals from the GPT preamplifier and the SWG are also monitored using a dynamic signal analyzer (DSA). The signal from the LDA system is processed by the BSA system. The envelope of the LDA signal is also monitored using an oscilloscope (Osc.). The barometric pressure transducer (BPT) and thermocouples (TCs) are connected to another data-acquisition system (DAQ #2). The BSA and the two DAQs are connected to a personal computer (PC) that also controls the positioning system (Pos. Sys.) for the LDA probe. The BSA, SWG, and the two DAQs are synchronized (dashed lines).

are allowed to warm up, the resonator is allowed to reach a uniform temperature distribution, and the rigid end cap and one of the compression drivers are temporarily removed so that smoke from burned cotton rope can be introduced into the resonator. Once a sufficient smoke density has been achieved at the location where measurements are to be made, the end cap and the compression driver are replaced and the air within the resonator is allowed to come to rest. The acoustic field is then switched on and measurements of velocity, gauge pressure, barometric pressure, and temperature are made every few minutes. Between measurements, the standing wave is maintained at a constant wavelength and amplitude by adjusting the frequency and amplitude produced by the sine-wave generator.

VII. COEFFICIENT UNCERTAINTIES

The sample records of velocity contain between 1000 and 30 000 samples acquired during a time interval of 10 to 115 s. For each record, the FA method¹¹ (see Sec. V) is used to calculate a series of complex Fourier coefficients representing the time-averaged ($z=0$) and time-harmonic ($z=1,2,\dots,Z$) signal components.

The uncertainties in the magnitudes and phases of these Fourier coefficients can be calculated based on the scatter of the samples within each phase bin. Propagation-of-error analysis allows the uncertainty in a function $g(\chi_1, \chi_2, \dots, \chi_N)$ with uncorrelated arguments $\chi_1, \chi_2, \dots, \chi_N$ to be computed from the uncertainties in the arguments, $\sigma_{\chi_1}, \sigma_{\chi_2}, \dots, \sigma_{\chi_N}$, according to the formula

$$\sigma_g = \left\{ \sum_{n=1}^N \left(\frac{\partial g}{\partial \chi_n} \sigma_{\chi_n} \right)^2 \right\}^{1/2}. \quad (12)$$

The function $g(\chi_1, \chi_2, \dots, \chi_N)$ represents the magnitude or phase of a Fourier coefficient calculated from Eq. (9) or Eq. (10), and the arguments $\chi_1, \chi_2, \dots, \chi_N$ represent the mean bin velocities $\bar{y}[n]$ calculated from Eq. (8). The uncertainties in the mean bin velocities are first calculated using the

equation for the standard error of the mean (SEM)

$$\sigma_{\bar{y}}[n] = \frac{1}{\sqrt{I[n]}} \left\{ \sum_{i=1}^{I[n]} \frac{(y[n,i] - \bar{y}[n])^2}{I[n] - 1} \right\}^{1/2}. \quad (13)$$

A. Uncertainty in the acoustic-velocity magnitude

The form of Eq. (12) used to compute the uncertainty in $Y[z]$, the magnitude of $\tilde{Y}[z]$, is

$$\sigma_Y[z] = \left\{ \sum_{n=1}^N \left(\frac{\partial Y[z]}{\partial \bar{y}[n]} \sigma_{\bar{y}}[n] \right)^2 \right\}^{1/2}, \quad (14)$$

for $z = 1, 2, \dots, Z$, where $\sigma_{\bar{y}}[n]$ is given by Eq. (13). Using the relations

$$Y[z] = \{\tilde{Y}[z](\tilde{Y}[z])^*\}^{1/2}, \quad (15)$$

and

$$\tilde{Y}[z] = Y[z]e^{j\phi[z]}, \quad (16)$$

where $\phi[z]$ is the phase of $\tilde{Y}[z]$ and $(\tilde{Y}[z])^*$ is the complex conjugate of $\tilde{Y}[z]$, the partial derivative in Eq. (14) is written as

$$\frac{\partial Y[z]}{\partial \bar{y}[n]} = \frac{1}{2} \left\{ e^{j\phi[z]} \frac{\partial (\tilde{Y}[z])^*}{\partial \bar{y}[n]} + e^{-j\phi[z]} \frac{\partial \tilde{Y}[z]}{\partial \bar{y}[n]} \right\}. \quad (17)$$

Substituting the expression for $\tilde{Y}[z]$ given by Eq. (9) into Eq. (17) yields

$$\frac{\partial Y[z]}{\partial \bar{y}[n]} = \frac{2}{N} \cos\left(2\pi z \frac{n}{N} + \phi[z]\right). \quad (18)$$

When this result is substituted into Eq. (14), the uncertainty in $Y[z]$ is given by

$$\sigma_Y[z] = \left(\frac{4}{N^2} \sum_{n=1}^N \left\{ \sigma_{\bar{y}}[n] \cos\left(2\pi z \frac{n}{N} + \phi[z]\right) \right\}^2 \right)^{1/2}, \quad (19)$$

for $z = 1, 2, \dots, Z$.

B. Uncertainty in the streaming velocity

The form of Eq. (12) used to compute the uncertainty in $Y[0]$ is given by Eq. (14) for $z=0$, where the partial derivative is equal to

$$\frac{\partial Y[0]}{\partial \bar{y}[n]} = \frac{1}{N}, \quad (20)$$

from Eq. (10), and $\sigma_{\bar{y}}[n]$ is given by Eq. (13). When these results are combined, the uncertainty in $Y[0]$ is given by

$$\sigma_Y[0] = \left\{ \frac{1}{N^2} \sum_{n=1}^N (\sigma_{\bar{y}}[n])^2 \right\}^{1/2}. \quad (21)$$

C. Uncertainty in the acoustic-velocity phase

The form of Eq. (12) used to compute the uncertainty in $\phi[z]$, the phase of $\tilde{Y}[z]$, is

$$\sigma_{\phi}[z] = \left\{ \sum_{n=1}^N \left(\frac{\partial \phi[z]}{\partial \bar{y}[n]} \sigma_{\bar{y}}[n] \right)^2 \right\}^{1/2}, \quad (22)$$

for $z = 1, 2, \dots, Z$, where $\sigma_{\bar{y}}[n]$ is given by Eq. (13). An expression containing the partial derivative in Eq. (22) is obtained by equating Eqs. (9) and (16) and taking the partial derivative with respect to $\bar{y}[n]$

$$\frac{2}{N} e^{-j2\pi zn/N} = e^{j\phi[z]} \frac{\partial Y[z]}{\partial \bar{y}[n]} + jY[z] e^{j\phi[z]} \frac{\partial \phi[z]}{\partial \bar{y}[n]}. \quad (23)$$

Substituting the expression for $\partial Y[z]/\partial \bar{y}[n]$ given by Eq. (18) into Eq. (23) and solving for $\partial \phi[z]/\partial \bar{y}[n]$ yields

$$\frac{\partial \phi[z]}{\partial \bar{y}[n]} = -\frac{1}{Y[z]} \frac{2}{N} \sin\left(2\pi z \frac{n}{N} + \phi[z]\right). \quad (24)$$

When this result is substituted into Eq. (22), the uncertainty in $\phi[z]$ is given by

$$\sigma_{\phi}[z] = \frac{1}{Y[z]} \left(\frac{4}{N^2} \sum_{n=1}^N \left\{ \sigma_{\bar{y}}[n] \sin\left(2\pi z \frac{n}{N} + \phi[z]\right) \right\}^2 \right)^{1/2}, \quad (25)$$

for $z = 1, 2, \dots, Z$.

D. Discussion

In a canonical implementation of the FA method, all of the coefficients lying above a fixed cutoff frequency would be discarded. In the present study, however, the statistical significance of each coefficient is determined based on whether its magnitude is greater than the 4σ uncertainty in its magnitude, $Y[z] > 4\sigma_Y[z]$ (which corresponds to the 99.99% confidence interval). Insignificant coefficients are discarded, and the significant coefficients are used to synthesize a smoothed velocity waveform [compare to Eq. (11)]

$$y(t) = \Re \left(\sum_{z'} \tilde{Y}[z'] e^{j\omega z' t} \right), \quad (26)$$

where the index z' indicates that the sum includes only the statistically significant coefficients.

Although this method is designed to process BSA velocity data that exhibit a nonuniform time between samples and a skewed sampling distribution, it has also been successfully used to process data that do not exhibit these shortcomings, such as would be sampled using a standard data acquisition unit (provided that the sample rate is not an integer multiple of the acoustic frequency).

VIII. LAGRANGIAN STREAMING VELOCITY

The velocity of the fluid sampled at a fixed position in space (the fringe volume) using the LDA technique is the Eulerian fluid velocity. However, the uncertainties [see Eq. (21)] in the Eulerian streaming velocities determined using the FA method¹¹ [see Eq. (10)] are unacceptably large relative to the magnitudes of the streaming predicted by theory. (In the present study, the 2σ uncertainties are on the order of ± 0.3 mm/s and the streaming velocities are on the order of 0.7 mm/s.) These errors can be reduced somewhat by acquiring and averaging over a greater number of samples.

More troubling, however, are bias errors observed in the sampled velocity signal. These errors, which are on the order of 0.4 mm/s or 0.1% of the amplitude of the fluid velocity

being measured, would be negligible under most circumstances. They do become significant, however, when measuring very small streaming velocities in the presence of a much larger acoustic field, as in the present study. The mechanism responsible for these errors is not well understood, but the source of these errors appears to be the LDA/BSA system itself.

Because of these difficulties, a more satisfying comparison to theory is made using the Lagrangian streaming velocity—defined as the time-averaged velocity of an individual tracer particle in the vicinity of the fringe volume.

A. Comparison of Eulerian and Lagrangian velocities

The relationship between the Eulerian and Lagrangian velocities in a one-dimensional standing wave is here considered. In the derivation that follows, **bold** typeface is used to denote vector quantities.

Let \mathbf{u} represent the Eulerian fluid velocity at a fixed position in space and \mathbf{u}_L represent the Lagrangian velocity of a particle moving with the fluid near that position. Furthermore, let \mathbf{u} and \mathbf{u}_L be expandable in terms of the acoustic Mach number M

$$\mathbf{u} = \mathbf{u}_1 + \mathbf{u}_2 + O(M^3), \quad (27)$$

$$\mathbf{u}_L = \mathbf{u}_{L1} + \mathbf{u}_{L2} + O(M^3), \quad (28)$$

where \mathbf{u}_1 and \mathbf{u}_{L1} are approximations valid to first order in M , \mathbf{u}_2 and \mathbf{u}_{L2} are second-order corrections to the first-order quantities, and $O(M^3)$ represents third- and higher-order corrections. The relationship between \mathbf{u} and \mathbf{u}_L valid to $O(M^2)$ is given by Nyborg²⁸ as

$$\mathbf{u}_{L1} + \mathbf{u}_{L2} = \mathbf{u}_1 + \mathbf{u}_2 + \left[\left(\int \mathbf{u}_1 dt \right) \cdot \nabla \right] \mathbf{u}_1. \quad (29)$$

For the one-dimensional acoustic standing-wave field given by [compare to Eq. (1)]

$$\mathbf{u}_1 = \Re(\tilde{U}_1 e^{j\omega t}) \sin\left(\frac{2\pi x}{\lambda}\right) \hat{\mathbf{x}}, \quad (30)$$

where $\hat{\mathbf{x}}$ is the unit vector in the $+x$ direction, Eq. (29) takes the form

$$\mathbf{u}_{L1} + \mathbf{u}_{L2} = \mathbf{u}_1 + \mathbf{u}_2 + \frac{1}{4c} \Im(\tilde{U}_1^2 e^{2j\omega t}) \sin\left(\frac{4\pi x}{\lambda}\right) \hat{\mathbf{x}}, \quad (31)$$

where \Im denotes taking the imaginary part of the complex argument. The first-order velocities are shown to be identical by limiting Eq. (31) to $O(M)$

$$\mathbf{u}_{L1} = \mathbf{u}_1. \quad (32)$$

The second-order streaming velocities are shown to be identical by taking the average of Eq. (31) with respect to time

$$\langle \mathbf{u}_{L2} \rangle = \langle \mathbf{u}_2 \rangle. \quad (33)$$

The second-order acoustic velocities differ only by the third term on the right side of Eq. (31), which represents a correction to the magnitude and phase of the second harmonic of velocity. For an acoustic-velocity amplitude U_1 on the order of 1 m/s (as in the present study), the magnitude of this second-harmonic correction is less than 0.08% of the magni-

tude of the first harmonic. Including such a small correction is unnecessary because it would result in a negligible change in the amplitude and shape of the velocity waveform.

B. Determination of Lagrangian streaming velocity

Figures 4(a) and (b) show samples of the axial component of the Eulerian velocity obtained from a single tracer particle. The particle oscillates axially due to the acoustic standing wave and is being convected in the positive axial direction by the streaming. A sample is usually recorded each time the particle passes through the fringe volume, which occurs twice per acoustic cycle.

An approximate expression for the particle's time-dependent axial position relative to the fringe volume is obtained by integrating Eq. (26) with respect to t

$$\xi(t) = \xi_0 + Y[0]t + \Re\left(\sum_{z'} \frac{\tilde{Y}[z']}{j\omega z'} e^{j\omega z' t}\right), \quad (34)$$

where ξ_0 is a constant of integration determined by the initial position of the particle and the index z' indicates that the sum includes only the statistically significant coefficients, except for $z'=0$, which is treated separately in the term $Y[0]t$. If the value of $Y[0]$ calculated using the FA method [see Eq. (10)] is used in Eq. (34), then the samples of the relative particle position—obtained by evaluating Eq. (34) for values of t equal to the arrival times of the velocity samples, $t[n,i]$ —will lie along a line having a nonzero slope, as shown in Fig. 5. This erroneous result is due neither to physical causes nor to the FA method, but rather to an instrumentation error in the LDA/BSA system. The correct value of $Y[0]$, in which this bias error is absent, is obtained by adjusting $Y[0]$ iteratively until the relative-position samples lie instead along a horizontal line, as shown in Figs. 4(c) and (d). The value of $Y[0]$ determined in this manner is the particle's Lagrangian streaming velocity.²⁹

An interpretation of the elliptical pattern formed by the velocity samples in Fig. 4(a) is now easily given. When the tracer particle first encounters the fringe volume at time $t = 6.45$ s, its observed speed is zero because the particle's equilibrium position lies in the $-x$ direction a distance equal to the peak acoustic displacement [$(U_1/\sqrt{2})/\omega = 0.30$ mm], and the particle is being sampled at the extreme of its motion. At time $t = 6.85$ s, the observed speed of the particle has increased to its maximum value because the particle has been convected a distance 0.30 mm in the $+x$ direction and its equilibrium position is centered on the fringe volume. At time $t = 7.26$ s, the observed speed of the particle has decreased to zero because the particle has been convected an additional 0.30 mm in the $+x$ direction and is once again being sampled at the extreme of its motion. The particle's Lagrangian streaming velocity is equal to the total distance convected divided by the corresponding elapsed time: $(0.60 \text{ mm})/(0.81 \text{ s}) = 0.74 \text{ mm/s}$.

If the particle motion is entirely in the axial direction, as in the example considered here, then the elliptical pattern formed by the velocity samples in Fig. 4(a) will be closed and the horizontal line segment formed by the relative-

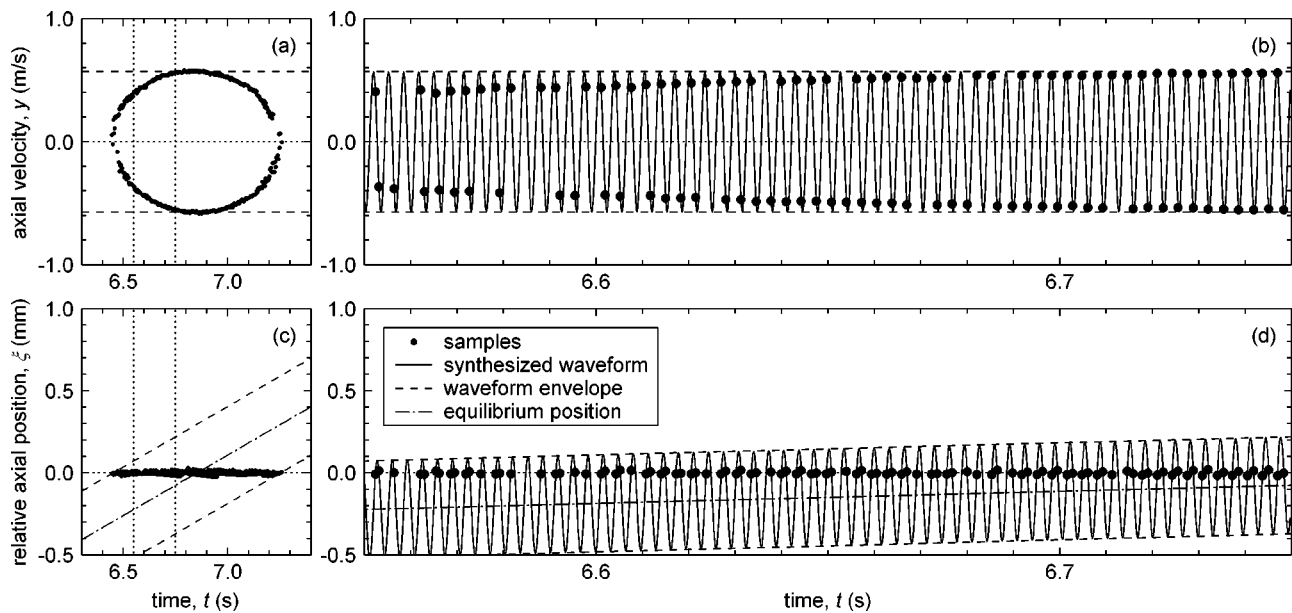

FIG. 4. Panel (a) shows samples of the axial component of the Eulerian velocity obtained from a single tracer particle oscillating near the center of the streaming cell ($x=L/2, r=0$). A detailed view of the area between the two vertical dotted lines is shown in panel (b). The solid line in (b) represents the velocity waveform calculated from Eq. (26) and the dashed lines show the waveform envelope ($U_1/\sqrt{2}=0.57$ m/s, $Re=0.36$). Panels (c) and (d) show corresponding samples of the particle's axial position relative to the fringe volume, calculated from Eq. (34). The solid line in (d) represents the relative-position waveform, also calculated from Eq. (34), and the dashed lines show the waveform envelope. The dot-dashed line represents the time-dependent equilibrium position of the particle as it is convected in the $+x$ direction by the streaming. The slope of that line (0.74 mm/s) is the particle's Lagrangian streaming velocity.

position samples in Fig. 4(c) will span the dashed lines. However, such will not be the case for a particle observed at a position where its motion also has a component in the transverse direction due to the streaming. Even so, the method presented here will still accurately determine the particle's Lagrangian streaming velocity.

IX. MEASURED ONSET OF STREAMING

In practice, each sample record contains observations of multiple tracer particles. Although the elliptical patterns formed by the different particles often overlap in time, it is

FIG. 5. Incorrect determination of Lagrangian streaming velocity. The value of $Y[0]$ calculated using the FA method [see Eq. (10)] contains a bias error produced by the LDA/BSA system. When this value of $Y[0]$ is used in Eq. (34) to obtain samples of the relative particle position, these samples lie along a line having a nonzero slope. This result implies incorrectly that the position where the particle is sampled (the LDA fringe volume) is not stationary, but moves instead at a constant speed in the negative direction. By contrast, the Lagrangian streaming velocity in Figs. 4(c) and (d) is determined correctly: the relative-position samples lie instead along a horizontal line, consistent with a stationary fringe volume.

not difficult to determine the Lagrangian streaming velocity of each particle using the method presented in Sec. VIII.

Figure 6 shows a measurement of the onset of streaming associated with the acoustic field being switched on. Each

FIG. 6. Onset of streaming measured at the center of the streaming cell ($x=L/2, r=0$) as a function of time after the acoustic field is switched on ($t=0$ s). In panel (a), samples of the axial component of fluid velocity are shown. The acoustic velocity increases rapidly from zero to its steady-state value ($U_1/\sqrt{2}=0.57$ m/s, $Re=0.36$) within approximately 0.3 s. In (b), the axial component of Lagrangian streaming velocity determined from the samples in (a) increases exponentially from zero to 95% of its steady-state value within approximately 5.2 s. The theoretical steady-state streaming velocities are calculated from Eq. (4) using $\alpha_1=0.030$ for Rott [see Eq. (5)] and $\alpha_1=0.131$ for Qi [see Eq. (6)].

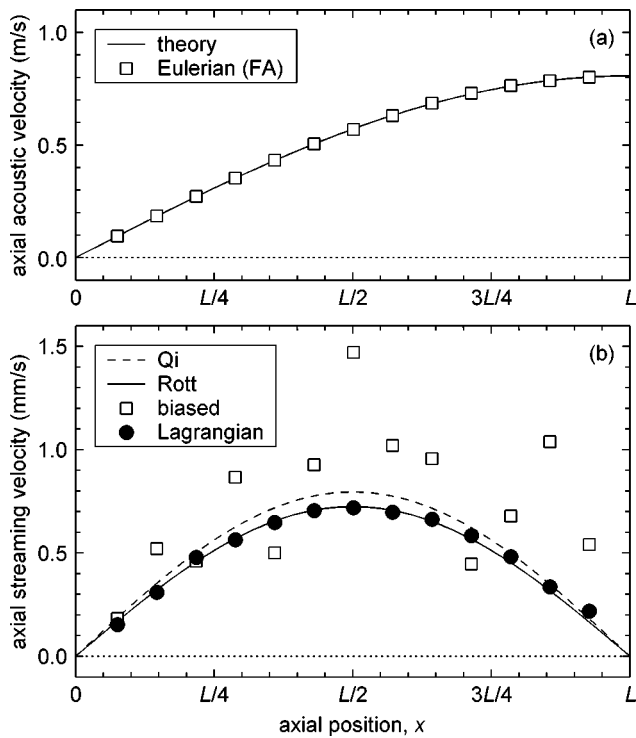

FIG. 7. Variation of the steady-state axial components of acoustic velocity and streaming velocity with respect to the axial coordinate x ($r=0$, $U_1 = 0.81$ m/s, $Re=0.36$). Panel (a) shows the amplitudes of the first harmonic of the Eulerian velocity determined using the FA method [see Eq. (9)] compared to a least-squares fit to the theory given by Eq. (1). Panel (b) shows the corresponding biased Eulerian streaming velocities determined using the FA method [see Eq. (10)] and the Lagrangian streaming velocities determined using the method presented in Sec. VIII compared to the theoretical streaming velocities calculated from Eq. (4) using $\alpha_1=0.030$ for Rott [see Eq. (5)] and $\alpha_1=0.131$ for Qi [see Eq. (6)].

value of the measured Lagrangian streaming velocity shown in Fig. 6(b) corresponds to a different tracer particle passing through the fringe volume, as indicated by the elliptical patterns shown in Fig. 6(a). (The particle at $t=6.8$ s is considered in detail in Fig. 4.) The steady-state value of the measured streaming velocity in Fig. 6(b)—given by the value of the curve fit for $t > 15$ s—corresponds to a correction to the magnitude of the streaming-velocity field of $\alpha_1=0.048$ in Eq. (4). Because the fluid is initially at rest (at $t=0$ s), it can be concluded that the ambient convection currents within the resonator are negligibly small at this location.

X. MEASURED STEADY-STATE STREAMING

When measuring the streaming velocity under steady-state conditions, all tracer particles in a given sample record have approximately the same Lagrangian streaming velocity. Therefore, an average value of the Lagrangian streaming velocity is determined that best represents the entire sample record.

Figure 7 shows the variation of the steady-state acoustic and streaming velocities with respect to the axial coordinate x . A least-squares fit between the measured values of the first harmonic of velocity and Eq. (1) is used to determine the values of the amplitude of the acoustic velocity at its antinode, U_1 , and the wavelength λ . A least-squares fit between the measured values of Lagrangian streaming velocity and

FIG. 8. Variation of the steady-state axial component of streaming velocity with respect to the transverse coordinate r ($x=L/2$, $U_1/\sqrt{2}=0.57$ m/s, $Re=0.36$). The biased Eulerian streaming velocities determined using the FA method [see Eq. (10)] and the Lagrangian streaming velocities determined using the method presented in Sec. VIII are compared to the theoretical streaming velocities calculated from Eq. (4) using $\alpha_1=0.030$ for Rott [see Eq. (5)] and $\alpha_1=0.131$ for Qi [see Eq. (6)].

Eq. (4) yields a correction to the magnitude of the streaming-velocity field of $\alpha_1=0.039$. The measured values of Eulerian streaming velocity determined using the FA method¹¹ exhibit large errors relative to the corresponding Lagrangian streaming velocities.

Figure 8 shows³⁰ the variation of the steady-state streaming velocity with respect to the transverse coordinate r . A least-squares fit between the measured values of Lagrangian streaming velocity and Eq. (4) yields a correction to the magnitude of the streaming-velocity field of $\alpha_1=0.031$.

The measured values of Eulerian streaming velocity determined using the FA method exhibit a large positive offset relative to the corresponding Lagrangian streaming velocities. When measurements of the streaming velocity are repeated with the polarity of the LDA probe reversed (by rotating the probe by 180 deg), the magnitude of the offset is approximately the same but the sign of the offset is reversed. This indicates that the offset is due neither to physical causes (see Sec. VIII A) nor to the FA method, but rather to the LDA/BSA system. The magnitude of the offset seems to vary slowly with time and to depend on the specific BSA settings used to acquire the data (such as the Doppler-frequency bandwidth, number of samples per burst, etc.).

Figure 9 shows the variation of the steady-state streaming velocity with respect to the amplitude of the acoustic velocity at its antinode, U_1 . A least-squares fit between the measured values of Lagrangian streaming velocity and Eq. (4) yields a correction to the magnitude of the streaming-velocity field of $\alpha_1=0.027$. The measured values of Eulerian streaming velocity determined using the FA method once again exhibit a large positive offset relative to the corresponding Lagrangian streaming velocities. As the BSA Doppler-frequency bandwidth is increased to accommodate larger acoustic amplitudes, the magnitude of the offset increases.

FIG. 9. Variation of the steady-state axial component of streaming velocity with respect to the amplitude of the acoustic velocity at its antinode, $U_1 < 1.3$ m/s ($Re < 0.94$). The amplitude of the acoustic velocity at its antinode ($x=L$) is determined by multiplying the acoustic-velocity amplitude at this location ($x=L/2$, $r=0$) by $\sqrt{2}$. The biased Eulerian streaming velocities determined using the FA method [see Eq. (10)] and the Lagrangian streaming velocities determined using the method presented in Sec. VIII are compared to the theoretical streaming velocities calculated from Eq. (4) using $\alpha_1=0.030$ for Rott [see Eq. (5)] and $\alpha_1=0.131$ for Qi [see Eq. (6)].

XI. CONCLUSIONS

The LDA/BSA technique (see Secs. IV and VI), when used in conjunction with the FA method¹¹ (see Sec. V) and the method presented in Sec. VIII for the determination of Lagrangian streaming velocity, is well suited to the simultaneous measurement of acoustic velocity and Lagrangian streaming velocity in a periodic acoustic field. This technique is capable of making high-precision measurements of velocity (see Sec. X) and of determining the variation of Lagrangian streaming velocity with respect to time (see Sec. IX). However, while the PIV technique (see Sec. III) is capable of collecting data simultaneously within a two-dimensional region, the LDA/BSA technique is limited to collecting data one position at a time.

The bias errors observed in the measured Eulerian streaming velocities (see Sec. X) are due neither to physical causes (see Sec. VIII A) nor to the FA method, but rather to the LDA/BSA system. This type of instrumentation error becomes inconsequential, however, when determining the Lagrangian streaming velocity using the method presented in Sec. VIII—only the measured acoustic velocity and the arrival times of the velocity samples are used; the time-averaged component of the velocity signal is irrelevant.

Equations (19), (21), and (25) (see Sec. VII), which are used to determine the uncertainties in the Fourier coefficients, represent an improvement to the FA method.¹¹ Whereas the FA method assumes a single cutoff frequency below which all of the coefficients are statistically significant, these equations permit the determination of the significance of each coefficient individually. The uncertainties computed in this manner are in agreement with the observed repeatability of the measurements.

In the previous experimental studies of acoustic streaming (see Sec. III) as well as in the present study, various smoothing methods have been used to reduce random fluctuations in the streaming measurements. Because of this, it is not straightforward to quantitatively compare the precisions of the LDA and PIV measurement techniques used. Nonethe-

less, the precisions achieved in the present study appear to be better than the precisions achieved previously.

All of the measurements of the axial component of streaming velocity presented in Secs. IX and X are consistent with the theory given by Rott⁸ (see Sec. II): the variation of axial streaming velocity with respect to the axial coordinate is sinusoidal, the variation with respect to the transverse coordinate is parabolic, and the variation with respect to the acoustic-velocity amplitude is quadratic. The corrections to the magnitude of the streaming-velocity field [see Eq. (4)] determined from the curves fit to the measured data range from $\alpha_1=0.027$ to 0.048. These values show better agreement with Rott's predicted correction of $\alpha_1=0.030$ [see Eq. (5)] than with Qi's predicted correction⁹ of $\alpha_1=0.131$ [see Eq. (6)], indicating that the magnitude of the streaming is noticeably influenced by the dependence of viscosity and thermal conductivity on temperature.

Although these results are limited to the case of a relatively low-amplitude acoustic standing wave ($Re < 1$) in the presence of a spatially uniform temperature distribution, the methods employed in the present study are also expected to be of use in the investigation of three other cases of interest: (1) the influence of fluid inertia on acoustic streaming at high Reynolds numbers ($Re > 1$), (2) the behavior of acoustic streaming in the presence of a temperature gradient, and (3) the acoustic streaming associated with a low-amplitude traveling wave in a guide.

(Received 1 August 2004; revised 27 November 2004; accepted 29 December 2004)

Following the experimental method of Thompson and Atchley [J. Acoust. Soc. Am. **117**, 1828–1838 (2005)] laser Doppler anemometry (LDA) is used to investigate the influences of a thermoacoustically induced axial temperature gradient and of fluid inertia on the acoustic streaming generated in a cylindrical standing-wave resonator filled with air driven sinusoidally at a frequency of 308 Hz. The axial component of Lagrangian streaming velocity is measured along the resonator axis and across the diameter at acoustic-velocity amplitudes of 2.7, 4.3, 6.1, and 8.6 m/s at the velocity antinodes. The magnitude of the axial temperature gradient along the resonator wall is varied between approximately 0 and 8 K/m by repeating measurements with the resonator either surrounded by a water jacket, suspended within an air-filled tank, or wrapped in foam insulation. A significant correlation is observed between the temperature gradient and the behavior of the streaming: as the magnitude of the temperature gradient increases, the magnitude of the streaming decreases and the shape of the streaming cell becomes increasingly distorted. The observed steady-state streaming velocities are not in agreement with any available theory. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1859992]

I. INTRODUCTION

The acoustic streaming generated by a monofrequency acoustic standing wave in a long cylindrical resonator has been studied experimentally by Thompson and Atchley¹ using the laser Doppler anemometry (LDA) technique. At relatively low acoustic amplitudes, the measured axial component of the outer streaming-velocity field is in agreement with the theory of Rott:² the variation with respect to the axial coordinate is sinusoidal, the variation with respect to the transverse coordinate is parabolic, and the variation with respect to the acoustic amplitude is quadratic. These results are consistent with previous measurements made in the vicinity of the acoustic-velocity node by Sharpe *et al.*,³ Arroyo and Greated,⁴ Hann and Greated,⁵ and Rockliff *et al.*⁶ using the particle image velocimetry (PIV) technique.

Thompson and Atchley⁷ previously observed that the variation of the axial component of streaming velocity with respect to the transverse coordinate is not parabolic at relatively large acoustic amplitudes. They noted the qualitative consistency between their measurements and the computational results of Menguy and Gilbert,⁸ who studied the influence of fluid inertia on acoustic streaming.

In thermoacoustic engines and refrigerators, the pres-

ence of any acoustic streaming within the acoustical resonator tends to reduce the efficiency of the device.⁹ The influence of an axial temperature gradient on acoustic streaming has been considered theoretically by Rott,² Olson and Swift,¹⁰ and Bailliet *et al.*¹¹

In the present study, the influences of a thermoacoustically induced axial temperature gradient and of fluid inertia on the outer streaming-velocity field generated by a monofrequency acoustic standing wave in a long cylindrical resonator are investigated experimentally using the method of Thompson and Atchley:¹ the fluid velocity is measured using laser Doppler anemometry with burst spectrum analysis (BSA), and the Lagrangian streaming velocity is determined using the observed acoustic motion and the arrival times of the velocity samples.

The relevant theories are reviewed in Sec. II, the experimental procedure is described in Sec. III, and measurements are presented in Sec. IV.

II. THEORY

A. Influence of a temperature gradient on streaming

Rott² derived an expression for the axial component of the streaming-velocity field generated in a long cylindrical tube filled with a fluid supporting a monofrequency acoustic standing wave. The coordinate system necessary to describe the fluid motion consists of an axial coordinate running parallel to the tube centerline and a transverse coordinate running perpendicular to the centerline; the fluid motion is assumed to be symmetric about the centerline. The axial component of acoustic velocity outside the acoustic boundary layer has the form

$$u_1 = \Re(\tilde{U}_1 e^{j\omega t}) \sin\left(\frac{2\pi x}{\lambda}\right), \quad (1)$$

where \tilde{U}_1 is the complex amplitude of the acoustic velocity at its antinode, ω is the angular acoustic frequency, t is time, x is the axial coordinate, λ is the acoustic wavelength, $j = \sqrt{-1}$, and \Re denotes taking the real part of the complex argument. The transverse component of acoustic velocity is negligible outside the acoustic boundary layer.

In his derivation, Rott assumed: (1) that the inner radius of the resonator, R , is small relative to the acoustic wavelength λ but large relative to the thicknesses of both the viscous acoustic boundary layer, $\delta_\nu = \sqrt{2\nu/\omega}$, and the thermal acoustic boundary layer, $\delta_\kappa = \sqrt{2\kappa/\omega}$, where ν and κ are the kinematic viscosity and thermal diffusivity of the fluid; (2) that terms higher than second order in the acoustic Mach number $M = U_1/c$ are negligible, where U_1 is the magnitude of \tilde{U}_1 and c is the sound speed in the fluid; (3) a relationship between temperature T and viscosity μ of the form $\mu \propto T^\beta$, where β is a constant that depends on the properties of the fluid; and (4) a variation of mean temperature T_0 with respect to the axial coordinate x .

Rott's expression for the axial component of streaming velocity outside the acoustic boundary layer is

$$\begin{aligned} \langle u_2 \rangle = & (1 + \alpha_1) \frac{3}{8} \frac{U_1^2}{c} \left(1 - \frac{2r^2}{R^2}\right) \sin\left(\frac{\pi x}{L}\right) \\ & - \alpha_2 \frac{\theta u_1^2}{2\omega} \left(1 - \frac{2r^2}{R^2}\right), \end{aligned} \quad (2)$$

where r is the transverse coordinate ($-R < r < R$); $L = \lambda/4$ is the length of a streaming cell in the axial direction; u_1 is the axial component of acoustic velocity given by Eq. (1); and α_1 , α_2 , and θ are given by

$$\alpha_1 = \frac{2}{3} (1 - \beta)(\gamma - 1) \frac{\sqrt{\text{Pr}}}{1 + \text{Pr}}, \quad (3a)$$

$$\alpha_2 = \frac{(1 - \beta)(1 - \sqrt{\text{Pr}})}{2(1 + \sqrt{\text{Pr}})(1 + \text{Pr})}, \quad (3b)$$

$$\theta = \frac{1}{T_0} \frac{dT_0}{dx}, \quad (3c)$$

where γ is the ratio of the isobaric to isochoric specific heats and $\text{Pr} = \nu/\kappa$ is the Prandtl number. (This same result, for the case $\beta=0$ and $\theta=0 \text{ m}^{-1}$, was later obtained independently by Qi.¹²) Typical values of α_1 and α_2 in air ($\gamma=1.4$, $\text{Pr}=0.71$, $\beta=0.77$) are $\alpha_1=0.030$ and $\alpha_2=0.0057$.

For the conditions corresponding to the largest temperature gradient used in the present study ($dT_0/dx \approx 8 \text{ K/m}$, $T_0 \approx 297 \text{ K}$, $\theta \approx 0.03 \text{ m}^{-1}$, $U_1 = 8.5 \text{ m/s}$, $c \approx 346 \text{ m/s}$, $\omega = 1940 \text{ s}^{-1}$), the magnitude of the first term on the right-hand side of Eq. (2) has a maximum value of 8.1 cm/s , whereas the magnitude of the second term has a maximum value that is four orders of magnitude smaller: $3 \text{ } \mu\text{m/s}$. The second term is therefore negligible relative to the first and the axial streaming velocity given by Eq. (2) can be rewritten as

FIG. 1. Profile view of a streaming cell in the outer streaming-velocity field for the case of a relatively small axial temperature gradient. [The axial component of streaming velocity is calculated from Eq. (4).] The flow along the resonator walls ($r = \pm R$) is toward the acoustic-velocity node ($x = 0$), and the return flow along the centerline ($r = 0$) is toward the acoustic-velocity antinode ($x = L$). Neighboring cells, to the left and to the right of the cell shown here, circulate in the opposite direction. As r approaches $\pm R$ within the boundary layer (not shown), the velocity goes to zero. (Reprinted from Ref. 1 with permission.)

$$\langle u_2 \rangle = (1 + \alpha_1) \frac{3}{8} \frac{U_1^2}{c} \left(1 - \frac{2r^2}{R^2}\right) \sin\left(\frac{\pi x}{L}\right). \quad (4)$$

In this simplified expression, the variation of axial streaming velocity with respect to the axial coordinate x is sinusoidal, with the maximum value occurring at $x = L/2$; the variation with respect to the transverse coordinate r is parabolic, with the average flow over the cross section (x held constant) equal to zero; and the variation with respect to the acoustic amplitude U_1 is quadratic. Figure 1 shows a profile view of the theoretical streaming-velocity field within a single streaming cell (including the transverse component, which is not given here).

Olson and Swift¹⁰ extended Rott's theory² by deriving an expression for the axial component of the time-averaged mass-flux density generated by an acoustic field that is an arbitrary combination of monofrequency standing and traveling waves in a long resonator having a circular cross-sectional area that varies with respect to the axial coordinate x . For the case of a pure standing wave in a cylindrical resonator, their results are equivalent to those of Rott.

Bailliet *et al.*¹¹ derived equations from which the axial component of streaming velocity can be calculated numerically for arbitrary values of the ratio R/δ_κ . For the case of a monofrequency standing wave in a cylindrical resonator with $R \gg \delta_\kappa$ and with an axial temperature gradient on the order of $\theta = (dT_0/dx)/T_0 \sim 1 \text{ m}^{-1}$, they showed that the expected magnitude of the axial streaming velocity along the centerline ($r = 0$) is in agreement with the value predicted by Olson and Swift,¹⁰ while the variation of the axial streaming velocity with respect to the transverse coordinate r appears to be approximately parabolic. Although no results were given for the case of a relatively small temperature gradient (such as those used in the present study: $\theta \lesssim 0.03 \text{ m}^{-1}$), such results would also be expected to be in agreement with the theory of Olson and Swift.

B. Influence of fluid inertia on streaming

Lighthill¹³ discussed the influence of fluid inertia on acoustic streaming, concluding that the effect is significant in nearly all noticeable acoustic streaming motions. As the inertia of a fluid parcel being convected about the streaming cell becomes more significant at larger streaming velocities, it becomes more difficult for the magnitude and direction of the parcel's velocity to be changed.

The influence of fluid inertia on the shape of the streaming-velocity field generated by a monofrequency acoustic standing wave in a cylindrical resonator was studied computationally by Menguy and Gilbert.⁸ Following the work of Qi,¹² they neglected the variation of viscosity and thermal conductivity with respect to temperature ($\beta=0$) and assumed a uniform axial temperature distribution ($\theta=0$ m⁻¹).

They related the axial and transverse components of streaming velocity by considering the time-averaged equation of mass conservation to second order in the acoustic Mach number M and the time-averaged equation of momentum conservation to fourth order in M . In the equation of momentum conservation, the relationship between the axial and transverse components of streaming velocity is shown to scale according to the Reynolds number

$$\text{Re} = \left(\frac{U_1}{c} \right)^2 \left(\frac{R}{\delta_\nu / \sqrt{2}} \right)^2. \quad (5)$$

The case $\text{Re} \ll 1$ corresponds to the relatively slow streaming considered by Rott,² Qi,¹² Olson and Swift,¹⁰ and Bailliet *et al.*,¹¹ in which the variation of axial streaming velocity with respect to the transverse coordinate r is found to be parabolic using only the time-averaged equation of mass conservation.

The case $\text{Re} \geq 1$ is referred to as “nonlinear streaming.” Menguy and Gilbert's method for calculating the nonlinear outer streaming-velocity field proceeds as follows: The influence of fluid inertia within the boundary layer is first shown to be negligible. The axial component of streaming velocity calculated at the edge of the boundary layer is then used as a boundary condition in the calculation of the nonlinear outer streaming-velocity field. The axial and transverse components of the outer field are each expressed as the product of a Fourier series involving the axial coordinate x and a power series involving the transverse coordinate r , and the conservation equations are solved for the coefficients in the resulting expressions.

The results of these calculations predict that the fluid inertia at moderate Reynolds numbers ($1 \leq \text{Re} \leq 4$) distorts the shape of the outer streaming cells by causing the location of maximum streaming velocity along the centerline ($r=0$) to shift from the midpoint ($x=L/2$) toward the velocity antinode ($x=L$). As a result of this distortion, the variation of the axial component of streaming velocity with respect to the axial coordinate x is no longer sinusoidal and the variation with respect to the transverse coordinate r is no longer parabolic. The Reynolds number Re determines the degree to which the streaming-velocity field is distorted relative to the field in the slow-streaming case.

C. Thermoacoustic heat transport

For the case considered by Rott²—a monofrequency acoustic standing wave in a long cylindrical resonator—heat is transported thermoacoustically along the inner wall of the resonator from the acoustic-velocity antinodes toward the acoustic-velocity nodes. Merkli and Thomann¹⁴ worked out a basic theory predicting the time-averaged heat flux between the resonator wall and the enclosed fluid and made measurements confirming that the wall in the vicinity of the antinodes is cooled, while the wall in the vicinity of the nodes is heated.

A more recent treatment of this phenomenon has been given by Swift.¹⁵ An admittedly oversimplified explanation is as follows: Consider a parcel of fluid oscillating parallel to the resonator centerline at a distance of approximately one thermal penetration depth δ_κ from the resonator wall, which initially has a uniform temperature distribution, at a location somewhere between an acoustic-velocity antinode ($x=L$) and an acoustic-velocity node ($x=0$). At the extreme of the parcel's motion that is nearest the antinode, the parcel's volume is large and its temperature is lower than the wall temperature, causing net heat to flow from the wall into the parcel. The parcel transports this increase in entropy toward the other extreme of its motion that is nearest the node. At this location, the parcel's volume is small and its temperature is higher than the wall temperature, causing net heat to flow from the parcel into the wall. The parcel returns to its initial position and the process is repeated.

Due to the action of similar fluid parcels along the entire length of the resonator, a sort of “bucket brigade” is formed that transports net heat along the inner wall from the velocity antinodes toward the velocity nodes, causing the wall temperatures at the antinodes to decrease and the wall temperatures at the nodes to increase. Under most circumstances, the rate of thermoacoustic heat transport is eventually balanced by the rate at which heat is transported by other means (such as conduction axially within the resonator wall or conduction and convection radially outward from the resonator into the surrounding environment), and a steady-state axial temperature gradient is reached, the calculation of which is non-trivial. The thermoacoustic heat transport and the resultant steady-state temperature gradient are both proportional to U_1^2 , the square of the acoustic-velocity amplitude.

III. PROCEDURE

A. Experimental apparatus

The apparatus shown in Fig. 2 has been used to study the influences of a thermoacoustically induced temperature gradient and of fluid inertia on the outer streaming-velocity field generated by a monofrequency acoustic standing wave in air. It is identical to the apparatus used previously by Thompson and Atchley;¹ the details of its construction will not be repeated here.

The resonator is filled with air ($T_0 \approx 23^\circ\text{C}$, $c \approx 345$ m/s) in which a small amount of smoke from burned cotton rope (particle diameter ≈ 1 μm) has been introduced. A standing wave is produced by driving the two compression drivers (University Sound 1829BT) in phase at the fourth

FIG. 2. The experimental apparatus. (A) Two compression drivers are connected to (B) a stainless-steel tee on top of (C) a 40 cm stainless-steel tube. This vertical section is connected by (D) a stainless-steel 90 deg elbow to a horizontal section comprised of (E) a 122 cm borosilicate-glass tube and (F) a 20 cm stainless-steel tube. The resonator is terminated by (G) a rigid stainless-steel end cap. The horizontal section is suspended inside (H) a glass-walled enclosure. The dotted box indicates the location of the streaming cell where measurements are made, which is similar to the cell shown in Fig. 1. (Reprinted from Ref. 1 with permission.)

natural frequency of the air column ($f = \omega/2\pi = 308$ Hz, $\lambda = 1.13$ m). The smoke follows the motion of the air, serving as tracer particles for the velocity measurements. The relative humidity inside the resonator is not significantly affected by the presence of the smoke [verified using a portable thermohygrometer (TH Pen 8708)].

The axial component of fluid velocity within the long glass section of the resonator (inner diameter $2R = 4.65$ cm, wall thickness = 2.0 mm) is sampled as a function of time using a single-component laser Doppler anemometry (LDA) system (Dantec Measurement Technology FlowLite) connected to a burst spectrum analysis (BSA) system (Dantec Measurement Technology 57N11). The absolute accuracy of the velocity measurements is approximately 0.3%, based on the uncertainty in the intersection angle of the two LDA laser beams. However, the random errors in the individual velocity samples are much larger than 0.3% and vary with the BSA settings used. The LDA probe is mounted on a linear positioning system that translates in both the axial and the transverse directions in the horizontal plane.

For the largest acoustic amplitude used in the present study ($U_1 = 8.6$ m/s, $Re = 40$), the amplitude of the second harmonic of velocity at its antinode is approximately 10% of the amplitude of the first harmonic at its antinode. Even so, the assumption of a monofrequency acoustic field is still expected to be valid because the magnitude of the streaming generated by this second-harmonic standing wave is expected to be only 1% of the magnitude of the streaming generated by the first harmonic, and therefore too small to be detected.

The amplitude of the first harmonic of pressure at its antinode is monitored using a piezoresistive gauge-pressure transducer (Endevco 8510B-5) mounted flush in the rigid end cap. A barometric-pressure transducer (SenSymb ASCX15AN) is located within the glass-walled enclosure so that, in combination with the gauge-pressure transducer, the mean absolute pressure within the resonator (nominally 97 kPa) can be determined.

Several type-E thermocouples (Omega Engineering TT-E-30-SLE) are attached to the outer wall of the resonator at various locations in order to monitor the spatial distribution of mean temperature. Each thermocouple consists of a twisted wire pair that is soldered together and attached to the resonator using a $1.3 \text{ cm} \times 1.3 \text{ cm}$ piece of copper shielding tape that is then covered with transparent tape. The accuracy of the temperature measurements is approximately 0.1°C , determined using an ice-point bath at 0.0°C .

In order to vary the magnitude of the thermoacoustically induced axial temperature gradient while holding the Reynolds number Re constant, three different boundary conditions are imposed on the wall of the resonator.

- (1) In order to produce an insulated boundary condition, the glass section of the resonator is wrapped in two layers of 1.0-cm-thick polyethylene pipe insulation. The insulation extends a distance of approximately 90 cm in the axial direction and is centered on the streaming cell of interest. The laser beams of the LDA system pass into the resonator through a 0.8-cm-high slit in the insulation (at $r = R$) that extends 40 cm in the axial direction and is centered on the streaming cell of interest.
- (2) In order to produce an isothermal boundary condition, the glass section is replaced with an identical tube mounted inside a water jacket. The jacket consists of a larger-diameter borosilicate-glass tube mounted concentric to the smaller-diameter resonator tube using custom-built PVC collars at each end. The outer tube has an inner diameter of 7.5 cm and a wall thickness of 2.5 mm, resulting in a radial spacing of 1.2 cm between the outer wall of the inner tube and the inner wall of the outer tube. Water enters the jacket through an orifice in the collar at the end farthest from the drivers and exits through an orifice in the collar at the end nearest the drivers. Flexible reinforced PVC tubing is used to connect the jacket to a circulator bath (VWR Scientific 1156) that circulates water through the jacket at a rate of 7 L/min while maintaining the water at a constant temperature.
- (3) The third boundary condition corresponds to the glass section of the resonator being surrounded simply by air, and will be referred to as the “uncontrolled” boundary condition. Although this case is more difficult to model mathematically, it serves the purpose of producing an intermediate axial temperature gradient with a magnitude that lies between the insulated and isothermal gradients for a given Reynolds number Re .

Between sets of streaming measurements, the smoke residue is cleaned from the inner wall of the resonator using an ammonia-based household glass cleaner. In preliminary

experiments done with an isothermal boundary condition, spurious results were observed when measurements were made shortly after the resonator had been cleaned. To avoid this problem, the resonator is allowed to dry for several hours before measurements are made.

B. Determination of streaming velocity

The sample records of fluid velocity obtained using the LDA/BSA technique are postprocessed according to the method of Thompson and Atchley.¹ For each record, a complex Fourier series representing the velocity waveform is first calculated using the Fourier averaging (FA) method developed by Sonnenberger *et al.*¹⁶ The resultant Fourier coefficients corresponding to the time-harmonic waveform components are then used in conjunction with the arrival times of the velocity samples to determine the Lagrangian streaming velocities of individual tracer particles by imposing the constraint that the location where the particle velocities are sampled (the LDA fringe volume) is spatially fixed.¹ If the streaming changes negligibly with respect to time during a sample record, then a single value for the Lagrangian streaming velocity is determined that best represents all of the tracer particles within the record. The uncertainties in the Lagrangian streaming velocities determined using this method depend primarily on the random errors in the individual velocity samples. This method avoids an offset error observed in the Eulerian streaming velocity determined using the FA method. The source of this error is attributed to the LDA/BSA system.

The above-outlined method assumes that the Eulerian and Lagrangian acoustic-velocity fields are equivalent. For an acoustic standing wave of the type considered in the present study, the difference between the Eulerian and Lagrangian velocities amounts to a correction to the magnitude and phase of the second harmonic of velocity.¹ The magnitude of this correction is at most $U_1^2/4c$, which, for the largest acoustic amplitude used in the present study ($U_1 = 8.6$ m/s, $Re=40$), is only approximately 0.6% of the magnitude of the first harmonic. Such a small correction would produce a negligible change in the magnitude and shape of the velocity waveform (negligible for the purpose of determining the Lagrangian streaming velocity), and the correction can therefore be safely ignored.

IV. MEASUREMENTS

A. Influence of a temperature gradient

Figure 3 shows the observed correlation between the thermoacoustically induced axial temperature gradient along the resonator wall and the axial component of streaming velocity for the three boundary conditions: insulated, isothermal, and uncontrolled. When the acoustic field is switched on at time $t=0$ min, the axial temperature distribution is initially uniform [see Fig. 3(b)]. Due to thermoacoustic heat transport along the inner wall of the resonator, the wall temperature at the acoustic-velocity node ($x=0$) increases, as a function of time, relative to the temperature at the antinode ($x=L$). As the magnitude of the temperature gradient increases, the magnitude of the axial component of streaming

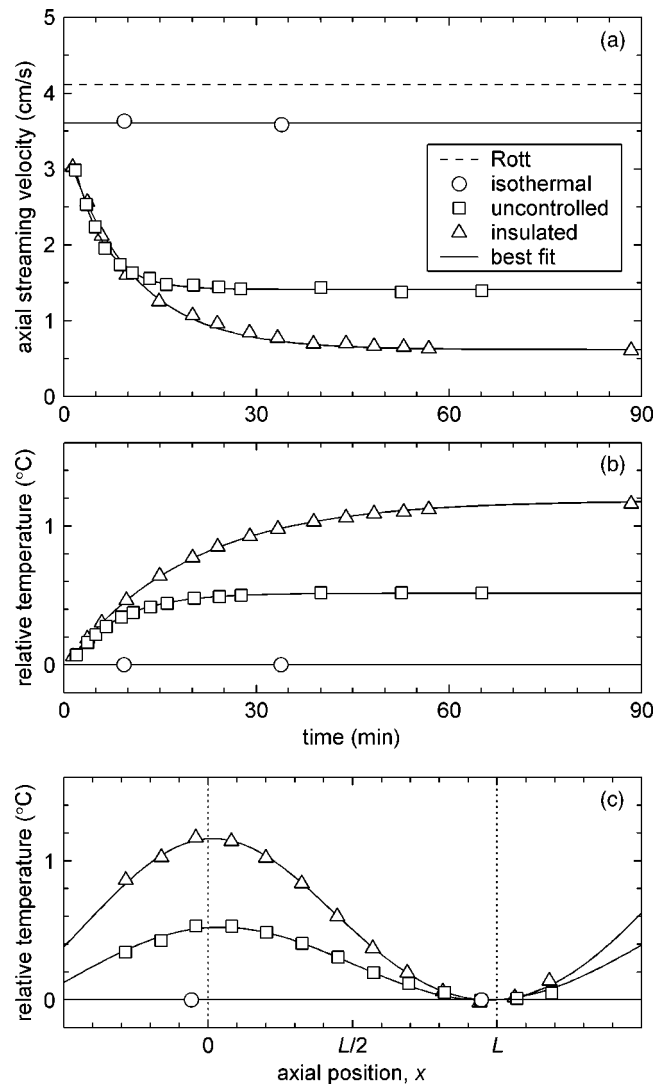

FIG. 3. In (a), the axial components of streaming velocity ($U_1=6.1$ m/s, $Re=20$) for the three boundary conditions, measured as functions of time at the center of the streaming cell ($x=L/2$, $r=0$), are compared to the theoretical streaming velocity predicted by Rott [see Eq. (4)]. In (b), corresponding measurements of the external wall temperatures at the acoustic-velocity node ($x=0$) relative to the temperatures at the antinode ($x=L$) are compared. As the magnitudes of the temperature gradients in (b) increase, the corresponding magnitudes of the streaming velocities in (a) decrease. In (c), the steady-state axial temperature distributions relative to the temperatures at the velocity antinode ($x=L$) are compared.

velocity decreases [see Fig. 3(a)] until a steady-state condition has eventually been reached. (The value of streaming velocity shown here at time $t=0$ min corresponds to the “steady-state” value of streaming velocity discussed by Thompson and Atchley.¹ This value is reached approximately 5 s after the acoustic field is switched on.)

For the case of an uncontrolled boundary condition, the axial streaming velocity reaches 95% of its steady-state value within approximately 14 min and the axial temperature gradient reaches 95% of its steady-state condition within approximately 23 min. For the case of an insulated boundary condition, the times are approximately 32 min for the axial streaming velocity and approximately 54 min for the axial temperature gradient. These times are independent of the acoustic amplitude. Additionally, the results of this experi-

ment do not depend significantly on whether the resonator is completely sealed with respect to the laboratory or whether a small leak is present.

The temperature-dependent behavior of the streaming observed in Fig. 3 is puzzling because it is not predicted by any of the available theories discussed in Sec. II. The largest discrepancies between the measured streaming velocities and the theory of Rott² are observed when using an insulated boundary condition, which produces the largest steady-state temperature gradient.

This experiment has been repeated with an initially large temperature gradient that is produced by switching on the acoustic field, allowing the temperature gradient and the streaming to reach steady-state conditions, and then switching off the acoustic field so that the fluid comes completely to rest but the temperature gradient remains. The acoustic field is then switched on again, and the streaming velocity observed just a few seconds later is in agreement with the steady-state value it had immediately before the acoustic field was switched off. This indicates that it is the temperature gradient that controls the streaming, and not *vice versa*.

The temperatures reported for the insulated and uncontrolled boundary conditions in Figs. 3(b) and (c) are determined using thermocouples attached along the top outer surface of the glass resonator tube. Corresponding thermocouples attached along the bottom outer surface give temperature readings that are lower than the top temperatures by less than 0.1 °C, indicating that there is occasionally a slight vertical temperature gradient within the resonator.

In a previous experiment done with an uncontrolled boundary condition, thermocouples were attached to the inner and outer surfaces of the glass tube near an acoustic-velocity node (where the temperature difference between the resonator wall and the surrounding air is greatest). For the largest acoustic amplitude used in the present study ($U_1 = 8.6$ m/s, $Re=40$), the inner temperature is less than 0.1 °C higher than the outer temperature, while the outer temperature difference between the two ends of the streaming cell is 2.3 °C. The temperature difference between the inner and outer surfaces of the glass tube near an acoustic-velocity antinode is negligible.

For the case of an isothermal boundary condition, thermocouples were originally attached to the outer surface of the resonator inside the water jacket. For the largest acoustic amplitude used in the present study ($U_1 = 8.6$ m/s, $Re=40$), the variation of steady-state temperature with respect to the axial coordinate x was observed to be uniform within 0.1 °C. However, these thermocouples eventually began giving spurious temperature readings because air was being drawn through the insulation surrounding the thermocouple wires and into the water jacket. So, the wires were cut and sealed to prevent further problems. [The observations of temperature reported for the isothermal boundary condition in Figs. 3(b) and (c) are set equal to zero and are included solely for illustrative purposes.]

For the case of an insulated boundary condition, a noticeable increase in local temperature was observed if the LDA laser beams were permitted to shine for prolonged periods of time on the inner surface of the insulation covering

FIG. 4. Steady-state temperatures at the acoustic-velocity node ($x=0$) relative to the temperatures at the antinode ($x=L$) as a function of Reynolds number Re and boundary condition.

the far side of the resonator (the side at $r = -R$, opposite the slit and the LDA probe). Therefore, a shutter mechanism is used to temporarily block the beams whenever a measurement of velocity is not being made.

Figure 4 shows the steady-state axial temperature difference across the streaming cell as a function of Reynolds number Re and boundary condition. For each boundary condition, the data show good agreement with a linear fit. This is expected from the theory (see Sec. II) because the thermoacoustic heat transport, the steady-state axial temperature gradient, and the Reynolds number are each proportional to U_1^2 , the square of the acoustic-velocity amplitude. The value reported at $Re=10$ for the uncontrolled boundary condition is artificially low by about 0.1 °C due to an opposing linear temperature gradient extending axially along the resonator. (The temperature differences reported for the isothermal boundary condition are set equal to zero and are included solely for illustrative purposes.)

B. Steady-state streaming

Figure 5 shows the axial component of the steady-state streaming-velocity field at a Reynolds number of $Re=4$ for isothermal and insulated boundary conditions. In Fig. 5(a), there is a noticeable difference between the isothermal and insulated data even though the steady-state axial temperature difference across the streaming cell is only 0.2 °C for the insulated boundary condition (see Fig. 4). This behavior is repeatable and is not predicted by any of the available theories discussed in Sec. II.

Previous measurements made by Thompson and Atchley¹ at a Reynolds number of $Re=0.36$ showed that the magnitude of the streaming-velocity field is noticeably influenced by the dependence of viscosity and thermal conductivity on temperature, consistent with the theory of Rott² (see Sec. II A). However, Menguy and Gilbert⁸ neglected this effect (see Sec. II B), causing their computationally predicted streaming velocities to be larger than Rott's predictions by a factor of 1.097. In order to correct for this discrepancy, the results of Menguy and Gilbert shown in Fig. 5 have been scaled by a factor of $1/1.097=0.912$. Even so, the isothermal data shown in Fig. 5 are in better agreement with the theory

FIG. 5. Axial component of the steady-state streaming-velocity field at a Reynolds number of $Re=4$ ($U_1=2.66$ m/s) for isothermal and insulated boundary conditions. In (a), the variation of axial streaming velocity with respect to the axial coordinate x ($r=0$) is compared to the theories of Rott [see Eq. (4)] and of Menguy and Gilbert (Ref. 8) (see Sec. II B). In (b) and (c), the variation of axial streaming velocity with respect to the transverse coordinate r ($x=0.20L$ and $0.88L$) is compared to theory.

of Rott, suggesting that the influence of fluid inertia on the streaming-velocity field is not as significant as predicted by Menguy and Gilbert.

Figure 6 shows the axial component of the steady-state streaming-velocity field at a Reynolds number of $Re=10$ for all three boundary conditions: insulated, isothermal, and uncontrolled. The influence of the axial temperature gradient on the streaming is noticeable: when the steady-state axial temperature difference across the streaming cell is increased by using an uncontrolled or insulated boundary condition (see Fig. 4), the discrepancies between the measured streaming velocities and the theory of Rott also increase. Again, this behavior is repeatable and is not predicated by any of the available theories discussed in Sec. II.

For the isothermal data shown in Fig. 6(a), the location of maximum streaming velocity along the centerline is shifted slightly toward the acoustic-velocity antinode ($x=L$). This behavior is qualitatively consistent with the influence of fluid inertia. However, Menguy and Gilbert⁸ do not give any results for $Re>4$ because of convergence problems with their computational method. Additionally, their analysis is not expected to be valid for $Re\geq 10$.

Figures 7 and 8 show the axial components of the steady-state streaming-velocity fields at Reynolds numbers of $Re=20$ and 40 . As the Reynolds number and the axial temperature gradient are increased, the discrepancies between the measured data and the theory become even more pronounced. [The uncontrolled data in Fig. 7(c) are in agreement with the measurements reported previously for this lo-

cation and approximate Reynolds number ($Re=19.3$) by Thompson and Atchley.⁷]

For the insulated data in Fig. 7, the magnitude of the streaming velocity near the position $x=0.6L$ and $r=0$ appears to be a local minimum. This trend is continued in Fig. 8, where the streaming along a large section of the centerline ($r=0$) has been completely suppressed for both insulated and uncontrolled boundary conditions. At $Re=40$, the streaming velocity at the center of the cell ($x=L/2$, $r=0$), measured as a function of time, goes to zero within approximately 9 min after the acoustic field is switched on.

The insulated data in Figs. 7 and 8 exhibit some asymmetry with respect to the transverse coordinate r . This is most likely due to slight differences in temperature between the resonator walls at $r=\pm R$ caused by the slit in the insulation on the wall at $r=R$ (see Sec. III A). For the isothermal data in the vicinity of the acoustic-velocity antinode ($x=L$) in Figs. 7(a) and 8(a), the curves fit to the measured data (using a Fourier sine series) are troublesome and have therefore been omitted.

For each combination of Reynolds number and boundary condition considered in Figs. 5–8, the extent to which the measurements are consistent with the principle of conservation of mass can be determined by averaging the transverse profile of axial streaming velocity over the resonator cross section at each axial position. For the data shown in Figs. 5(b)–(c), 6(b)–(d), 7(b)–(d), and 8(b)–(d), the computed cross-sectional average velocities are on the order of only 1% of the magnitudes of the streaming velocities near

FIG. 6. Axial component of the steady-state streaming-velocity field at a Reynolds number of $Re=10$ ($U_1=4.26$ m/s) for all three boundary conditions. In (a), the variation of axial streaming velocity with respect to the axial coordinate x ($r=0$) is compared to the theory of Rott [see Eq. (4)]. In (b), (c), and (d), the variation of axial streaming velocity with respect to the transverse coordinate r ($x=L/4$, $L/2$, and $3L/4$) is compared to theory.

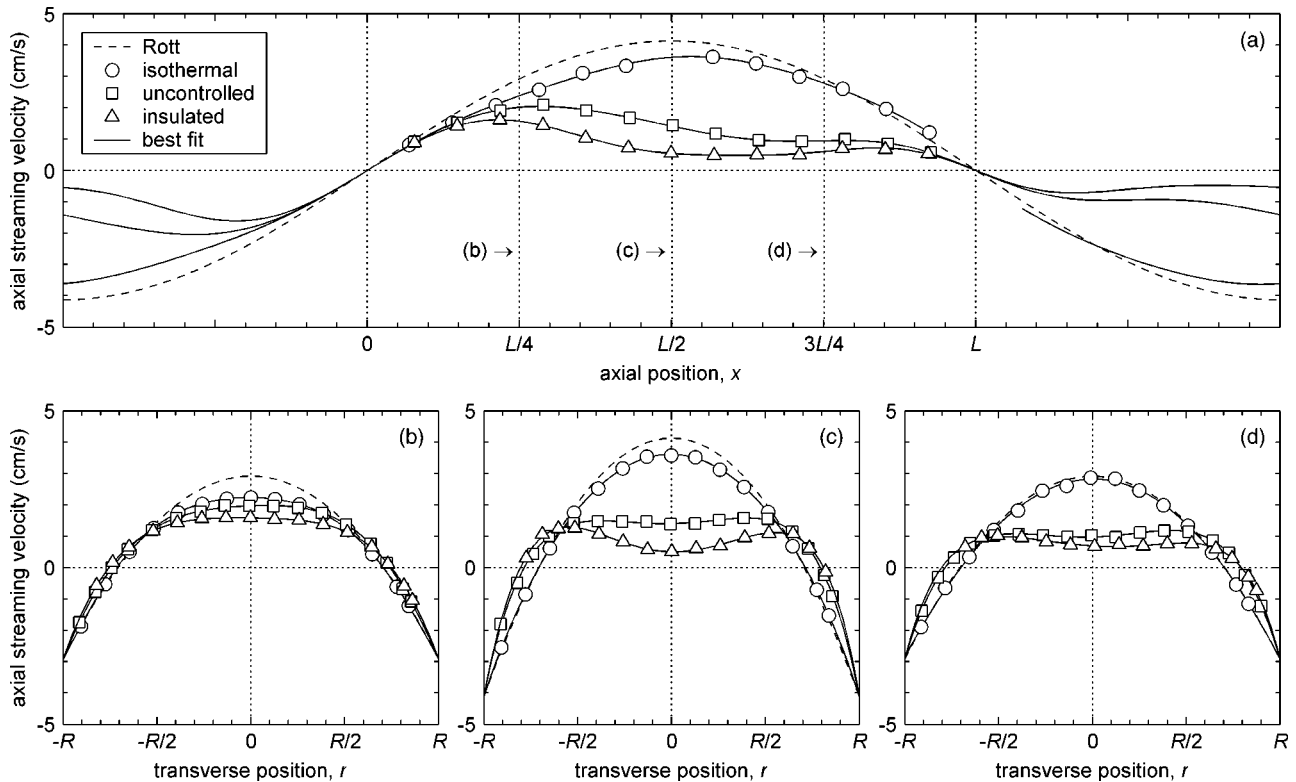

FIG. 7. Axial component of the steady-state streaming-velocity field at a Reynolds number of $Re=20$ ($U_1=6.11$ m/s) for all three boundary conditions. In (a), the variation of axial streaming velocity with respect to the axial coordinate x ($r=0$) is compared to the theory of Rott [see Eq. (4)]. In (b), (c), and (d), the variation of axial streaming velocity with respect to the transverse coordinate r ($x=L/4$, $L/2$, and $3L/4$) is compared to theory.

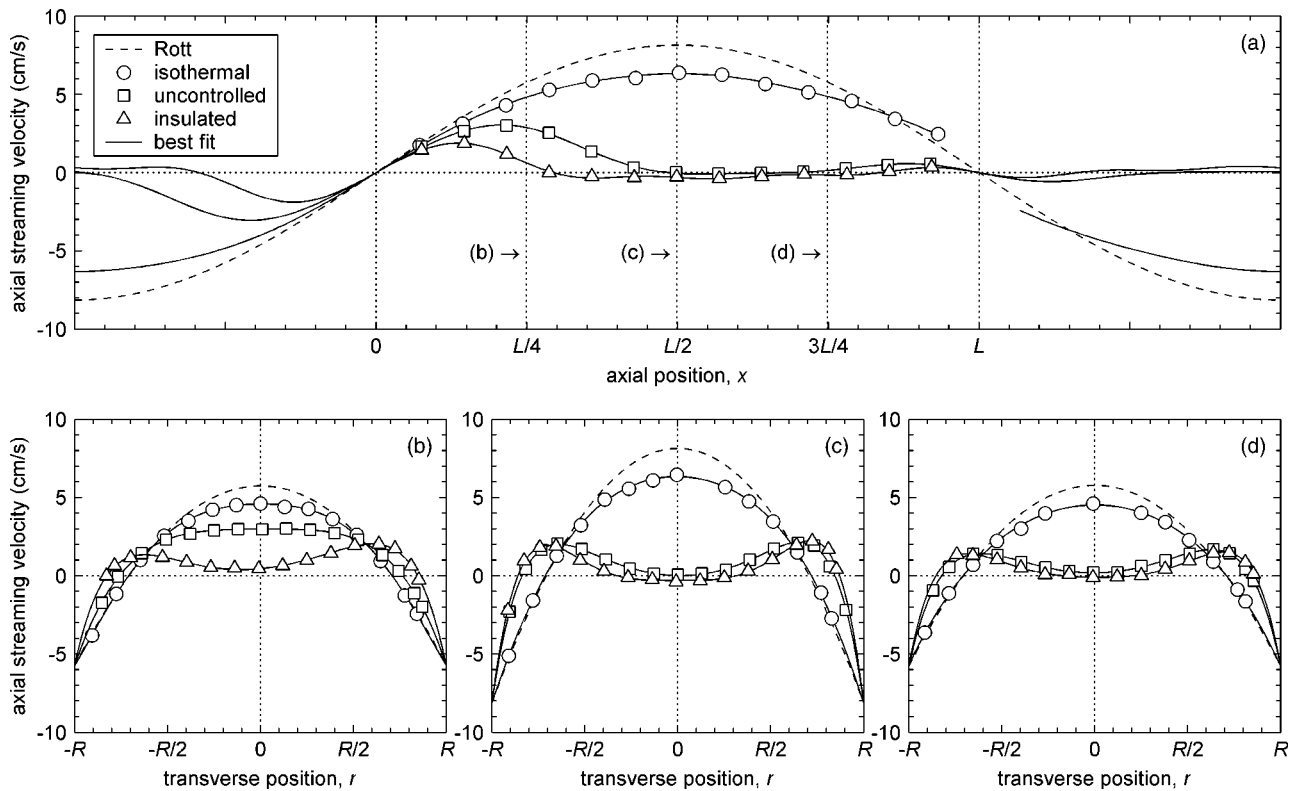

FIG. 8. Axial component of the steady-state streaming-velocity field at a Reynolds number of $Re=40$ ($U_1=8.6$ m/s) for all three boundary conditions. In (a), the variation of axial streaming velocity with respect to the axial coordinate x ($r=0$) is compared to the theory of Rott [see Eq. (4)]. In (b), (c), and (d), the variation of axial streaming velocity with respect to the transverse coordinate r ($x=L/4$, $L/2$, and $3L/4$) is compared to theory.

the resonator walls ($r \approx \pm R$), consistent with the expected cross-sectional average velocities of approximately zero.

Figure 9 shows the axial component of the steady-state streaming-velocity field measured in both the horizontal and vertical planes at a Reynolds number of $Re=40$ with an uncontrolled boundary condition. Measurements in the vertical plane are made using a mirror positioned above the resonator at a 45 deg angle with respect to the horizontal plane. Com-

FIG. 9. Axial component of the steady-state streaming-velocity field measured as a function of the transverse coordinate r in both the horizontal and vertical planes ($x=L/2$) at a Reynolds number of $Re=40$ ($U_1=8.5$ m/s) with an uncontrolled boundary condition. For the measurements made in the vertical plane, the position $r=R$ corresponds to the upper wall of the resonator and the position $r=-R$ corresponds to the lower wall. The measurements made in the horizontal plane are taken from Fig. 8(c).

parison of the two curves indicates that the streaming field is slightly asymmetric about the centerline ($r=0$).

C. Decay of streaming

Figure 10 shows the measured decay of streaming when the acoustic field is switched off. For both uncontrolled and insulated boundary conditions, the streaming velocities extrapolated back to time $t=0$ s are in agreement with the steady-state values shown in Fig. 7. The elapsed time of approximately 5 s required for the streaming to completely decay in Fig. 10(a) is in agreement with the time required for the streaming to initially reach its maximum value when the acoustic field is switched on, as measured by Thompson and Atchley.¹ For the larger steady-state axial temperature gradient associated with the insulated boundary condition in Fig. 10(b), the decay curve is more complex.

It is possible to explain the observed behavior in Fig. 10 by supposing the existence of two opposing mechanisms acting on the fluid simultaneously. The first mechanism exerts a force on the fluid in the positive axial direction, has a magnitude that is independent of the axial temperature gradient, and requires approximately 5 s to completely decay. For the smaller temperature gradient associated with the uncontrolled boundary condition in Fig. 10(a), only this first mechanism is observed. The second mechanism exerts a force on the fluid in the negative axial direction, has a magnitude that is a function of the axial temperature gradient, and requires approximately 12 s to completely decay. For the larger temperature gradient associated with the insulated

FIG. 10. The axial component of velocity at the center of the streaming cell ($x=L/2$, $r=0$), measured as a function of time after the acoustic field is switched off, for uncontrolled and insulated boundary conditions. The acoustic velocity (not shown) decays rapidly from its steady-state value ($U_1/\sqrt{2}=4.32$ m/s, $Re=20$) to zero within approximately 0.3 s. The subsequent decay of streaming velocity is then measured directly. In (a), the axial temperature difference between the two ends of the streaming cell is approximately 1.0°C (see Fig. 4) and the streaming decays exponentially within approximately 5 s. In (b), the axial temperature difference is approximately 2.3°C and the decay of the streaming is more complex. Note the difference in the scales of the vertical axes.

boundary condition in Fig. 10(b), both mechanisms are observed, causing the streaming velocity to briefly change direction ($t>3$ s) once the first mechanism has decayed sufficiently so that it is no longer dominant. However, this is purely speculative.

D. Ambient convection

After the streaming decays completely in Fig. 10, the ambient convection currents within the resonator are observed to be negligibly small at the center of the streaming cell ($x=L/2$, $r=0$).

For the conditions corresponding to the largest temperature gradient used in the present study ($U_1=8.6$ m/s, $Re=40$, insulated boundary condition), measurements of the streaming decay as a function of the axial and transverse coordinates in the horizontal plane indicate that the ambient convection currents in the horizontal plane are on the order of 1 mm/s—considerably less than the observed steady-state streaming velocities shown in Fig. 8, which are on the order of 80 mm/s near the resonator wall.

The ambient convection currents in the vertical direction (the direction perpendicular to the horizontal plane in which the measurements are made) are observed by rotating the LDA probe by 90° so that its axis of sensitivity points upward instead of sideways. The vertical component of the steady-state fluid velocity is measured as a function of the axial and transverse coordinates in the horizontal plane, and

the time-averaged velocity-signal components are determined. For the above-described conditions ($U_1=8.6$ m/s, $Re=40$, insulated boundary condition), the ambient convection currents in the vertical direction are on the order of 5 mm/s—also less than the observed steady-state axial streaming velocities shown in Fig. 8. The magnitude of the vertical convection is largest in the vicinity of the acoustic-velocity antinode ($x=L$). In this region, the fluid rises near the resonator centerline ($r=0$) and falls near the walls ($r=\pm R$). In the vicinity of the acoustic-velocity node ($x=0$), the magnitude of the vertical convection goes to zero.

V. CONCLUSIONS

The influence of a thermoacoustically induced axial temperature gradient on the axial component of the streaming-velocity field has been observed to be significant (see Sec. IV). In the presence of a relatively small temperature gradient, the measured streaming velocities are not in agreement with the theory of Rott² or with any other available theory (see Secs. II A and II B). The error between the measured and theoretical streaming velocities increases as the temperature gradient is increased. At a Reynolds number of $Re=40$ and with a temperature difference of approximately 1°C or more between the two ends of the streaming cell, the axial streaming along a large section of the centerline ($r=0$) near the acoustic-velocity antinode ($x\approx L$) is completely suppressed.

In the measurements of acoustic streaming reported previously in the literature (see Sec. I), the influence of a temperature gradient on the streaming-velocity field was not addressed. All of the previous measurements made using the PIV technique were limited to the vicinity of the acoustic-velocity node, where the influence of a temperature gradient is least noticeable (see Sec. IV B). Also, if these measurements were carried out shortly after switching on the acoustic field, a significant temperature gradient would not have had enough time to develop. Only Thompson and Atchley⁷ reported a nonparabolic variation of axial streaming velocity with respect to the transverse coordinate r . However, they failed to recognize that this result was due to the presence of a thermoacoustically induced axial temperature gradient, and instead suggested incorrectly that it might be due to the influence of fluid inertia.

Measurements of the axial component of the streaming-velocity field have been made with an isothermal boundary condition imposed in order to observe the influence of fluid inertia on the streaming (see Secs. IV A and IV B). At a Reynolds number of $Re=4$, these measurements are not in agreement with the computational results of Menguy and Gilbert⁸ (see Sec. II B), but rather with the theory of Rott² (see Sec. II A). Measurements made with an isothermal boundary condition at Reynolds numbers of $Re\geq 10$ do show significant discrepancies relative to the theory of Rott, but this effect is less significant than the influence of a temperature gradient on the streaming (see Sec. IV B).

These results suggest that the influence of small temperature gradients needs to be considered carefully when attempting to accurately model the outer streaming-velocity field in a real system. Although Rott,² Olson and Swift,¹⁰ and Bailliet *et al.*¹¹ all assumed a nonzero axial temperature gra-

dient in their analyses (see Sec. II A), their results fail to predict the observed behavior. Perhaps this is because they did not consider the convective heat transport due to the streaming, an effect that Mozurkewich¹⁷ has shown experimentally to be significant.

It may be possible that the heat carried by the streaming is significant enough to affect the spatial distribution of mean temperature within the streaming cell. Perhaps such a change in the mean-temperature distribution could, in turn, affect the streaming-velocity field. In order to investigate this possibility, it would be helpful to measure the mean-temperature distribution within the streaming cell in an unobtrusive manner, so as not to disturb the streaming-velocity field.

As mentioned in Sec. III A, spurious results were observed when measurements of streaming velocity were made shortly after cleaning the inner wall of the resonator using an ammonia-based household glass cleaner. Perhaps the heat transfer between the glass tube and the enclosed air is affected by any residue left on the glass by the cleaner, subsequently affecting the observed streaming motion.

It would be interesting to repeat the experiments described in the present study with the streaming cell oriented vertically instead of horizontally. However, special attention would be needed in order to avoid any thermally induced ambient convection currents that might occur in such a configuration.¹

In addition to investigating experimentally how the streaming-velocity field is affected by the presence of an axial temperature gradient along the resonator wall, it would also be helpful to model the problem mathematically. A simple model might consist of a cylinder of air having two boundary conditions imposed along its surface: (1) a sinusoidally varying axial streaming velocity of the form given by Eq. (4) evaluated for $r = \pm R$, and (2) a sinusoidally varying mean-temperature distribution similar to those observed in the present study (see Fig. 3).

On the interaction of counterpropagating acoustic waves in resonant rods composed of materials with hysteretic quadratic nonlinearity

Vitalyi Gusev^{a)}

Université du Maine, 72085 Le Mans, Cedex 09, France

(Received 18 May 2004; revised 2 July 2004; accepted 29 December 2004)

An ordinary inhomogeneous integrodifferential equation for the profile of the acoustic wave in a resonant rod, composed of a material with hysteretic quadratic nonlinearity, is derived. It explicitly takes into account the interaction of the counterpropagating acoustic waves. It also incorporates the boundary conditions in the sense that all possible solutions of the equation satisfy the appropriate boundary conditions at the ends of the rod. © 2005 Acoustical Society of America. I. INTRODUCTION

The interest in theoretical description of vibrations of rods composed of materials with hysteretic quadratic nonlinearity is related to the extended applications of the resonance acoustic phenomenon to the evaluation of polycrystalline metals,^{1–3} ceramics, and rocks.^{4–7} There is an increasing amount of experimental evidence that nonlinear acoustic phenomena are more sensitive to the mesoscopic structure of these materials than the linear ones.^{1,8} Importantly, by using resonators, it is easier to reach acoustic wave amplitudes sufficient for clear manifestation of the nonlinear effects than without acoustic energy accumulation.

The theoretical analysis of the nonlinear acoustic waves in a resonator with hysteretic quadratic nonlinearity might be expected to be more complicated in comparison to a resonator with an important role of “classical” elastic quadratic nonlinearity. An example of the latter, which has been extensively studied, is a closed-ended gas-filled tube.^{9–13} Significant simplification of the theoretical description in this system is due to the absence of such interactions between the counter-propagating waves which lead to the acoustic profile distortion accumulating at distances exceeding the acoustic wavelength. From a physics point of view the forces created by the interaction of the counterpropagating waves in the medium with elastic quadratic nonlinearity (which is even in its physical manifestations) are not moving forces. Because of this they are not synchronous with any of the counter-propagating waves and they are not inducing any accumulating changes in the wave profiles. The possibility to present acoustic field in the resonator with effective elastic quadratic nonlinearity as a linear superposition of two noninteracting nonlinear acoustic waves is an explicit result of Chester’s theory.⁹ It was also clearly stated by Ostrovsky¹⁰ and has been later used by a number of the authors to derive both the equations for the stationary wave profile¹¹ and the nonlinear evolution equations describing the build-up of the nonlinear

oscillations following the start-up of the resonator excitation.^{12,13}

The physics of the acoustic waves interaction in the resonators with hysteretic quadratic nonlinearity is quite different because being quadratic in wave amplitude (similar to elastic quadratic nonlinearity) it is odd in its physical manifestations^{14–17} (in contrast to elastic quadratic nonlinearity, which is even). For example this nonlinearity is predicted to induce self-focusing of the acoustic beams.¹⁴ For the current discussion it is important that the interaction of the counterpropagating waves due to hysteretic quadratic nonlinearity creates the forces, which are synchronous with the acoustic waves. Consequently the acoustic field in the resonant rods cannot be decomposed on two noninteracting nonlinear counterpropagating waves. The theory should explicitly account for the effective interaction between them. Traditionally for the description of the nonlinear standing acoustic waves in hysteretic rods the second-order nonlinear partial differential equations are used.^{1–3} To the best of our knowledge, the description of the nonlinear acoustic wave profile in the resonators with hysteretic quadratic nonlinearity in the form of an ordinary (i.e., not a partial) integrodifferential equation has never been proposed before. Perhaps, this is related to the above-discussed complexity.

Below an ordinary inhomogeneous integrodifferential equation for the profiles of nonlinear acoustic waves in rods with hysteretic quadratic nonlinearity is derived. The analysis of its approximate solutions demonstrates that the interaction of the counterpropagating waves leads to increased role of the hysteretic nonlinearity. The amplitude of oscillations in the resonance peak is lower and the frequency shift of the resonance peak is more pronounced in comparison with the theory where the interaction is neglected. It is demonstrated that these kind of phenomena are also expected in the rods with “classical” elastic cubic nonlinearity, which (similar to hysteretic quadratic nonlinearity) is odd in its physical manifestations, but does not induce nonlinear absorption of sound.

FIG. 1. Presentation in normalized (nondimensional) coordinates of the nonlinear (hysteretic) part of stress–strain relationship for a periodic process with single maximum and single minimum during a period. The arrowheads indicate path direction with increasing time.

II. THEORY

In materials with hysteretic quadratic nonlinearity, the dependence of the dominant strain dependent contribution σ_{hyst} to total stress σ on strain has a form of a cusped loop^{16–18}

$$\sigma_{\text{hyst}} = -hE \left[s^A s + \frac{1}{2} (s^2 - s_A^2) \text{sign} \left(\frac{\partial s}{\partial t} \right) \right]. \quad (1)$$

Here s denotes the strain, s^A denotes strain amplitude, E is the elastic modulus, and $h > 0$ is the nondimensional parameter of the hysteretic quadratic nonlinearity. The stress/strain dependence in Eq. (1) is valid in a periodic strain wave with zero average over a period and a single maximum and a single minimum during a period. In Fig. 1 the hysteretic contribution to stress is presented in nondimensional variables $\sigma'_{\text{hyst}} = \sigma_{\text{hyst}} / (hE)$, $s' = s / s^A$. In accordance with Eq. (1) the stress depends not only on the current value s of the strain but also on the direction of the strain variation (“loading” when $\partial s / \partial t < 0$, “unloading” when $\partial s / \partial t > 0$) and the strain amplitude s^A . The first part of the modulus in Eq. (1) is nonhysteretic (it does not depend on the strain rate $\partial s / \partial t$ at all). This part does not contribute to the nonlinear hysteretic absorption but strongly contributes to the amplitude-dependent sound velocity. The second term in Eq. (1) describes hysteresis in the stress behavior.

It is well established that in the micro-inhomogeneous materials the hysteretic nonlinearity dominates over classical elastic nonlinearity in the stress/strain relationship,^{2,8} and that the kinematic nonlinearity (due to the nonlinear relation between strain and displacement gradient) is also negligible. Due to this, approximating the strain by the displacement gradient $s \approx \partial u / \partial x$, the nonlinear wave equation is presented in the form

$$\begin{aligned} \frac{\partial^2 u}{\partial t^2} - c_0^2 \frac{\partial^2 u}{\partial x^2} = & -c_0^2 h \left\{ \left[\left(\frac{\partial u}{\partial x} \right)^A + \frac{\partial u}{\partial x} \text{sign} \left(\frac{\partial^2 u}{\partial x \partial t} \right) \right] \frac{\partial^2 u}{\partial x^2} \right. \\ & \left. + \left[\frac{\partial u}{\partial x} - \left(\frac{\partial u}{\partial x} \right)^A \text{sign} \left(\frac{\partial^2 u}{\partial x \partial t} \right) \right] \frac{\partial}{\partial x} \left(\frac{\partial u}{\partial x} \right)^A \right\}. \end{aligned} \quad (2)$$

FIG. 2. The rod of a finite length L . The motion of the end at $x=L$ is predetermined by the external loading and is assumed to be known in advance. The end at $x=0$ is mechanically free.

In Eq. (2) $c_0 = \sqrt{E / \rho_0}$ denotes the velocity of the infinitely weak acoustic disturbances (the linear sound velocity), ρ_0 is the equilibrium density, and $(\partial u / \partial x)^A$ is the amplitude of the displacement gradient.

The solution of the nonlinear partial differential equation of the second order (2) should satisfy the boundary conditions at the ends of the rod. The geometry of the system under consideration is sketched in Fig. 2. In most of the experiments^{1–7} the external excitation controls the motion of one of the rod ends (the end at $x=L$ in Fig. 2) while the other end (at $x=0$ in Fig. 2) is left mechanically free. The boundary conditions can be written in the form

$$v(x=L, t) = v_0 f(t), \quad (3)$$

$$\rho_0 c_0^2 \partial u / \partial x(x=0, t) + \sigma_{\text{hyst}}(x=0, t) = 0. \quad (4)$$

Here $v = \partial u / \partial t$ denotes the particle velocity, the normalized function $f(t)$ describes the motion of the boundary $x=L$ due to external loading, v_0 is the particle velocity amplitude provided by the external excitation.

It is worth mentioning here that even if the classical elastic quadratic nonlinearity was included in Eq. (2) for generality it would not lead in the system under consideration (Fig. 2) to distortions accumulating at distances exceeding the acoustic wavelength. This is due to mechanically free boundary $x=0$, where the polarity of the incident acoustic wave is inverted in each reflection. Actually if, for example, maximum of v profile moves faster than linear sound in the incident acoustic wave (propagating from $x=L$ to $x=0$) then in the reflected wave (propagating from $x=0$ to $x=L$) it becomes a minimum of v profile moving slower than linear sound. As a result there is no accumulation of the wave profile distortion after each two round-trips of the acoustic wave in the rod, unless the shock front is formed at a single round trip. The latter opportunity will be excluded in the analysis presented in the following. It will be assumed that the wave profile transformations at the scale of the resonator length are weak. Note that in the gas filled resonators with rigid walls^{9–12} the situation is completely different because there is no inversion of acoustic wave polarity in reflection from rigid boundaries. There the elastic quadratic nonlinearity is effective.

The solution u of Eq. (2) can be presented in form of a linear superposition of two interacting counterpropagating waves u_+ and u_- with slowly varying profiles,

$$u = \mu u_+(\mu x, \tau_+ = t - x/c_0) + \mu u_-(\mu x, \tau_- = t + x/c_0). \quad (5)$$

Here the dimensionless symbolic small parameter $\mu \ll 1$ characterizes weakness of the acoustic disturbances and slowness of their nonlinear transformation in propagation.

The accumulation of the wave profile distortion is assumed to take place at distances significantly exceeding the acoustic wavelength λ (which is of the order of the resonator length L). When Eq. (5) is substituted in Eq. (2) the terms of the first order in μ are mutually cancelled. If only the terms of the second order in μ are retained, then Eq. (2) takes the form

$$\begin{aligned} \frac{\partial}{\partial x}(v_+ - v_-) + \frac{h}{2c_0^2} & \left\{ \left[(v_+ - v_-)^A + (v_+ - v_-) \right. \right. \\ & \times \text{sign} \left(\frac{\partial v_+}{\partial \tau_+} - \frac{\partial v_-}{\partial \tau_-} \right) \left. \left. \left(\frac{\partial v_+}{\partial \tau_+} + \frac{\partial v_-}{\partial \tau_-} \right) \right] \right. \\ & + 2 \left[(v_+ - v_-) - (v_+ - v_-)^A \text{sign} \left(\frac{\partial v_+}{\partial \tau_+} - \frac{\partial v_-}{\partial \tau_-} \right) \right] \\ & \left. \times \frac{\partial}{\partial (\tau_+ - \tau_-)} (v_+ - v_-)^A \right\} = 0, \end{aligned} \quad (6)$$

where $v_{\pm} = \partial u_{\pm} / \partial t = \partial u_{\pm} / \partial \tau_{\pm}$ are particle velocities in the counterpropagating waves. Importantly, although the amplitudes of both waves are slowly varying in space [see Eq. (5)], the amplitude of the total strain $(\partial u / \partial x)^A$ (which is a function of x only) does not necessarily vary slowly in space. In other words the derivative $\partial / \partial x$ applied in Eq. (2) to the distribution of the total strain amplitude $(\partial u / \partial x)^A$ does not necessarily diminishes the order of this term by μ factor. The term $\partial(\partial u / \partial x)^A / \partial x$ might be of the first order in μ and not of the second order as it is in the case of the uni-directional (co-propagating) waves.^{14,15,17,18} A simple illustrative example is the following. If we have only a right-propagating wave of a constant amplitude A ($u = u_+(\tau_+) = A \sin[\omega(t - x/c_0)]$), then clearly $(\partial u / \partial x)^A = A \omega / c_0 = \text{const}$ and $\partial(\partial u / \partial x)^A / \partial x = 0$. But if we have two counter-propagating waves of equal and constant amplitudes ($u = u_+(\tau_+) + u_-(\tau_-) = A \sin[\omega(t - x/c_0)] + A \sin[\omega(t + x/c_0)] = 2A \sin(\omega t) \cos(\omega x / c_0)$), then $(\partial u / \partial x)^A = 2A(\omega / c_0) \sin(\omega x / c_0) \neq \text{const}$ and $\partial(\partial u / \partial x)^A / \partial x = 2A(\omega / c_0)^2 \text{sign}[\sin(\omega x / c_0)] \cos(\omega x / c_0) \neq 0$. The latter is an obvious result of the wave interference, providing spatial modulation of the total strain

amplitude at the scale of the acoustic wavelength even without any variation in space of the amplitudes of each of the counter-propagating waves (i.e., even when $\mu = 0$). Due to the fact that $\partial(\partial u / \partial x)^A / \partial x$ is in general of the order of μ terms in Eq. (2), which include this spatial derivative, contribute to the evolution equation (6) where all the terms are of the second order in μ . To distinguish this derivative from the derivative over the slow coordinate μx the former is represented in Eq. (6) by the form $\partial / \partial x = -(2/c_0) \partial / \partial (\tau_+ - \tau_-)$, which just takes into account that $\tau_+ - \tau_- = -2x/c_0$.

Equation (6) formally contains two unknowns (v_+ and v_-) and three variables (fast variables τ_+ , τ_- and slow variable μx). However the variables are not independent: there is an evident relation ($\tau_- = \tau_+ + 2x/c_0$) between them. Due to this relation in the coordinate system $(\mu x, \tau_+)$, accompanying the wave propagating to the right, the function $v_-(\mu x, \tau_-) = v_-(\mu x, \tau_+ + 2x/c_0)$ is a fast varying function of x co-ordinate. This is due to the explicit dependence of the second (fast) argument on x in this system of coordinates. Consequently the term $\partial v_- / \partial x$ in Eq. (6) can be eliminated by averaging in this accompanying coordinate system over the wavelength λ in space (or equivalently over acoustic period T in time). When applying to Eq. (6) the operator $(1/\lambda) \int_{x_0 - \lambda/2}^{x_0 + \lambda/2} (\dots) dx$, it should be taken into account that the first (slow) argument μx of the functions does not provide any significant distortion at the spatial scale λ , and that odd nonlinearity cannot induce average fields. Because of this

$$\begin{aligned} \frac{1}{\lambda} \int_{x_0 - \lambda/2}^{x_0 + \lambda/2} v_- \left(\mu x', \tau_+ + \frac{2x'}{c_0} \right) dx' \\ = \frac{1}{T} \int_{-T/2}^{T/2} v_-(\mu x, \tau_+ + 2t') dt' \\ = \frac{1}{2T} \int_{-T}^T v_-(\mu x, \tau_+ + t') dt' = 0. \end{aligned}$$

Accordingly, Eq. (6) takes the form

$$\begin{aligned} \frac{\partial v_+}{\partial x} = -\frac{h}{2c_0^2} \frac{1}{2T} \int_{-T}^T & \left\{ \left[v_+(\mu x, \tau_+) - v_-(\mu x, \tau_+ + t') \right]^A + \left[v_+(\mu x, \tau_+) - v_-(\mu x, \tau_+ + t') \right] \right. \\ & \times \text{sign} \left[\frac{\partial v_+(\mu x, \tau_+)}{\partial \tau_+} - \frac{\partial v_-(\mu x, \tau_+ + t')}{\partial \tau_-} \right] \left[\frac{\partial v_+(\mu x, \tau_+)}{\partial \tau_+} + \frac{\partial v_-(\mu x, \tau_+ + t')}{\partial \tau_-} \right] \\ & - 2 \left\{ \left[v_+(\mu x, \tau_+) - v_-(\mu x, \tau_+ + t') \right] - \left[v_+(\mu x, \tau_+) - v_-(\mu x, \tau_+ + t') \right]^A \right. \\ & \left. \times \text{sign} \left[\frac{\partial v_+(\mu x, \tau_+)}{\partial \tau_+} - \frac{\partial v_-(\mu x, \tau_+ + t')}{\partial \tau_-} \right] \right\} \frac{\partial}{\partial t'} \left[v_+(\mu x, \tau_+) - v_-(\mu x, \tau_+ + t') \right]^A \Bigg\} dt' \\ = -\frac{h}{2c_0^2} \frac{1}{2T} \int_{-T}^T & \Phi[v_+(\mu x, \tau_+), v_-(\mu x, \tau_+ + t')] dt'. \end{aligned} \quad (7)$$

Obviously the application of the same averaging procedure in the coordinate system $(\mu x, \tau_-)$, accompanying the wave propagating to the left, results in

$$\begin{aligned}
\frac{\partial v_-}{\partial x} &= \frac{h}{2c_0^2} \frac{1}{2T} \int_{-T}^T \left\{ \left[v_+(\mu x, \tau_- - t') - v_-(\mu x, \tau_-) \right]^A + \left[v_+(\mu x, \tau_- - t') - v_-(\mu x, \tau_-) \right] \right. \\
&\quad \times \text{sign} \left[\frac{\partial v_+(\mu x, \tau_- - t')}{\partial \tau_+} - \frac{\partial v_-(\mu x, \tau_-)}{\partial \tau_-} \right] \left. \left[\frac{\partial v_+(\mu x, \tau_- - t')}{\partial \tau_+} + \frac{\partial v_-(\mu x, \tau_-)}{\partial \tau_-} \right] \right. \\
&\quad - 2 \left\{ \left[v_+(\mu x, \tau_- - t') - v_-(\mu x, \tau_-) \right] - \left[v_+(\mu x, \tau_- - t') - v_-(\mu x, \tau_-) \right]^A \right. \\
&\quad \times \text{sign} \left[\frac{\partial v_+(\mu x, \tau_- - t')}{\partial \tau_+} - \frac{\partial v_-(\mu x, \tau_-)}{\partial \tau_-} \right] \left. \left. \frac{\partial}{\partial t'} \left[v_+(\mu x, \tau_- - t') - v_-(\mu x, \tau_-) \right]^A \right\} dt' \right. \\
&\equiv \frac{h}{2c_0^2} \frac{1}{2T} \int_{-T}^T \Phi[v_+(\mu x, \tau_- - t'), v_-(\mu x, \tau_-)] dt'. \tag{8}
\end{aligned}$$

In Eqs. (7) and (8) compact notations for the right-hand sides (r.h.s.) has been introduced. These equations provide the system of coupled partial integrodifferential equations for v_+ and v_- . Each of these equations is only in two independent variables. The averaging procedure applied to nonlinear terms retains in Eq. (7) and in Eq. (8) only those components of the nonlinear force which are synchronous with the right-propagating wave and left-propagating wave, respectively.

In the resonator (Fig. 2) the solution of Eqs. (7) and (8) should be subjected to boundary conditions (3) and (4). It is useful to incorporate the boundary conditions in the equations. This can be done by applying the method of successful approximations developed by Chester.^{9,12} Chester noticed that when Eqs. (7) and (8) are integrated over x at spatial scales of the order of the resonator wavelength L it is possible to neglect the dependence of v_+ and v_- on slow coordinate μx in the r.h.s. of these equations. This is due to assumed weak distortion of the wave profiles at the distances of the order of the acoustic wavelength. Consequently, the unknowns $v_{\pm}(\mu x, \tau_{\pm})$ on the r.h.s. of Eqs. (7) and (8) can be replaced by the profiles $v_{\pm}(\tau_{\pm})$ explicitly independent of space coordinate,

$$\begin{aligned}
\frac{\partial v_+}{\partial x} &= -\frac{h}{2c_0^2} \frac{1}{2T} \int_{-T}^T \Phi[v_+(\tau_+), v_-(\tau_+ + t')] dt', \\
\frac{\partial v_-}{\partial x} &= \frac{h}{2c_0^2} \frac{1}{2T} \int_{-T}^T \Phi[v_+(\tau_- - t'), v_-(\tau_-)] dt'.
\end{aligned}$$

The integration of these equations results in

$$\begin{aligned}
v_+(\mu x, \tau_+) &= g_+(\tau_+) - \frac{h}{2c_0^2} \left\{ \frac{1}{2T} \right. \\
&\quad \times \left. \int_{-T}^T \Phi[v_+(\tau_+), v_-(\tau_+ + t')] dt' \right\} x, \tag{9}
\end{aligned}$$

$$\begin{aligned}
v_-(\mu x, \tau_-) &= g_-(\tau_-) + \frac{h}{2c_0^2} \left\{ \frac{1}{2T} \right. \\
&\quad \times \left. \int_{-T}^T \Phi[v_+(\tau_- - t'), v_-(\tau_-)] dt' \right\} x, \tag{10}
\end{aligned}$$

where $g_{\pm}(\tau_{\pm})$ are unknown functions (of a single argument each) to be determined from the boundary conditions. Actu-

ally from Eqs. (9) and (10) it follows that $g_{\pm}(t)$ are the particle velocities in the counterpropagating waves at the mechanically free end $x=0$,

$$\begin{aligned}
v_+(\mu x, \tau_+)^{x=0} &= v_+(0, t) = g_+(t), \\
v_-(\mu x, \tau_-)^{x=0} &= v_-(0, t) = g_-(t).
\end{aligned}$$

They are related by the boundary condition (4). Importantly only the relation of the first order in $\mu \ll 1$ should be retained in Eq. (4),

$$v_+(0, t) - v_-(0, t) = 0. \tag{11}$$

It is verified that all the higher order corrections to Eq. (11) [like those coming from the nonlinear stress σ_{hyst} in Eq. (4)] provide contributions to the equation for the acoustic wave profile of the orders higher than μ^2 . In accordance with Eq. (11) $g_-(t) = g_+(t) \equiv g(t)$ and the solutions (9) and (10) take the form

$$\begin{aligned}
v_+(\mu x, \tau_+) &= g(\tau_+) - \frac{h}{2c_0^2} \left\{ \frac{1}{2T} \int_{-T}^T \Phi[g(\tau_+), g(\tau_+ + t')] dt' \right\} x, \tag{12}
\end{aligned}$$

$$\begin{aligned}
v_-(\mu x, \tau_-) &= g(\tau_-) + \frac{h}{2c_0^2} \left\{ \frac{1}{2T} \int_{-T}^T \Phi[g(\tau_- - t'), g(\tau_-)] dt' \right\} x. \tag{13}
\end{aligned}$$

Here the space-independent profiles v_{\pm} on the r.h.s. are approximated by their form at the mechanically free boundary. The substitution of the solutions (12) and (13) at the other end of the rod (that is evaluated at $x=L$) into the boundary condition (3) leads to the closed form integrodifferential equation for the wave profile $g(t)$,

$$g(t-L/c_0) + g(t+L/c_0) - \frac{h}{2c_0^2} \left\{ \frac{1}{2T} \int_{-T}^T \Phi[g(t-L/c_0), g(t-L/c_0+t')] - \Phi[g(t+L/c_0-t'), g(t+L/c_0)] \right\} dt' = v_0 f(t). \quad (14)$$

In Eq. (14) both the nonlinear term (in the form of the integral) and the external loading (r.h.s.) are of the second order in $\mu \ll 1$. Consequently, in the first order the relation $g(t-L/c_0) = -g(t+L/c_0)$ is valid. The latter relation is used to simplify the nonlinear term in Eq. (14). Using also the symmetry and periodicity properties of the operator Φ , Eq. (14) is reduced to the form

$$g(t-L/c_0) + g(t+L/c_0) - \frac{hL}{c_0^2} \left\{ \frac{1}{T} \int_{-T/2}^{T/2} \Phi[g(t-L/c_0), g(t-L/c_0+t')] \right\} dt' = v_0 f(t).$$

Introducing the notations $t-L/c_0 \equiv \tau$ and $f(\tau+L/c_0) \equiv \bar{f}(\tau)$ it can be rewritten as

$$g(\tau) + g(\tau+2L/c_0) - \frac{hL}{c_0^2} \left\{ \frac{1}{T} \int_{-T/2}^{T/2} \Phi[g(\tau), g(\tau+t')] \right\} dt' = v_0 \bar{f}(\tau). \quad (15)$$

Considering periodic harmonic excitation, the function $\bar{f}(\tau)$ is chosen in the form $\bar{f}(\tau) = \cos(\omega\tau)$. Then the smallness

($\propto \mu^2$) of the sum $g(\tau) + g(\tau+2L/c_0)$ in Eq. (15) requires a small deviation of $2L/c_0$ from the half-period $T/2 = \pi/\omega$ of the excitation ($2L/c_0 = T/2 + 2\Delta L/c_0$, $\Delta L/L \propto \mu \ll 1$) and the symmetry $g(\tau+T/2) \equiv -g(\tau)$ of the wave profile. Because of small deviation ΔL of rod length from the linear resonance length $L = Tc_0/4$ (for the fundamental $\lambda/4$ resonance con-

sidered in the following) the function $g(\tau+2L/c_0)$ can be approximated by Taylor expansion as $g(\tau+2L/c_0) \equiv -g(\tau) - \partial g / \partial \tau (\tau) (2\Delta L/c_0)$. With the help of this relation, Eq. (15) is rewritten

$$\frac{2\Delta L}{c_0} \frac{\partial g}{\partial \tau} + \frac{hL}{c_0^2} \frac{1}{T} \int_{-T/2}^{T/2} \Phi[g(\tau), g(\tau+t')] dt' = v_0 \cos(\omega\tau), \quad (16)$$

where all the terms are of the same (μ^2) order of smallness.

For the subsequent analysis it is useful to introduce dimensionless time $\theta = \omega\tau$ and dimensionless particle velocity $V = g/v_{NL}$, where $v_{NL} = c_0 \sqrt{v_0/h\omega L} \equiv \sqrt{2c_0 v_0/\pi h}$ is the characteristic amplitude of acoustic wave in the hysteretic rod. Note that v_{NL} is proportional to square root of the excitation velocity ($v_{NL} \propto \sqrt{v_0}$) as is expected for the quadratic nonlinearity.^{10,19,20} The dimensionless form of Eq. (15) is

$$\begin{aligned} \delta \frac{\partial V}{\partial \theta} + \frac{1}{2\pi} \int_{-\pi}^{\pi} \left\{ [V(\theta) - V(\theta+\theta')]^A \right. \\ \left. + [V(\theta) - V(\theta+\theta')] \text{sign} \left[\frac{\partial V(\theta)}{\partial \theta} - \frac{\partial V(\theta+\theta')}{\partial \theta} \right] \right\} \\ \times \left[\frac{\partial V(\theta)}{\partial \theta} + \frac{\partial V(\theta+\theta')}{\partial \theta} \right] - 2 \left\{ [V(\theta) - V(\theta+\theta')] \right. \\ \left. - [V(\theta) - V(\theta+\theta')]^A \text{sign} \left[\frac{\partial V(\theta)}{\partial \theta} - \frac{\partial V(\theta+\theta')}{\partial \theta} \right] \right\} \\ \times \frac{\partial}{\partial \theta'} [V(\theta) - V(\theta+\theta')]^A \Big|_{d\theta'} = \cos \theta. \end{aligned} \quad (17)$$

Equation (17) belongs to the class of the equations describing excitation of the nonlinear waves by moving quasisynchronous sources.^{19,20} In accordance with Eq. (17) the profiles of the waves traveling in the rod depend on a single dimensionless parameter δ , which characterizes the detuning of the system from the linear resonance. It can be expressed in terms of a deviation $\Delta\omega = \omega - \omega_0$ of the excitation frequency ω from linear resonance frequency $\omega_0 = \pi c_0/2L$ as $\delta = \Delta\omega/\omega_{NL}$, where $\omega_{NL} = (\omega_0/\pi)(v_0/v_{NL}) = (\sqrt{hv_0/2\pi c_0})\omega_0$ is the characteristic shift of the resonance frequency. The shift of the resonance by hysteretic quadratic nonlinearity is expected due to odd character of its physical manifestations. For comparison, the elastic quadratic nonlinearity (which has even character) does not cause any shift of the resonance in closed tubes.^{9,11,12} The above-developed theory clearly predicts that the shift of the resonance in vibrating rod is proportional to the wave amplitude because from $v_{NL} \propto \sqrt{v_0}$ and $\omega_{NL} \propto \sqrt{v_0}$ it follows that $\omega_{NL} \propto v_{NL}$. This theoretical result correlates with numerous experimental observations.^{1,2,4,6}

The derived inhomogeneous ordinary integrodifferential equation (17) is the primary result of the developed theory. It takes into account the influence on the profile of the acoustic wave of its interaction with the counterpropagating wave. These are the profiles $V(\theta+\theta')$ and $\partial V(\theta+\theta')/\partial \theta$ that might be identified in Eq. (17) with the counterpropagating wave. From a physics point of view the closed form single integrodifferential equation is obtainable due to the existing relation $[g_+(t) = g_-(t)]$ between the profiles of the counterpropagating waves in the resonator. Qualitatively speaking, in the resonator a traveling wave interacts with itself, but delayed in time and propagating in the opposite direction.

Unfortunately currently the precise solutions of Eq. (17) are not available. To find an approximate solution at fundamental excitation frequency ω the excitation of the higher harmonics can be neglected in first approximation. A similar approach has been applied earlier^{1,2} to solve directly the nonlinear partial differential equations of the type of Eq. (2). First, the solution of the assumed form $V = V_A \sin(\theta+\varphi)$ is substituted in Eq. (17) and then cosine and sine Fourier amplitudes of the different terms of the equation are balanced separately. This results in the system of equations for the amplitude V_A and the phase φ of the acoustic wave,

$$\delta V_A + 2aV_A^2 = \cos \varphi, \quad a^2 V_A^2 = \sin \varphi, \quad (18)$$

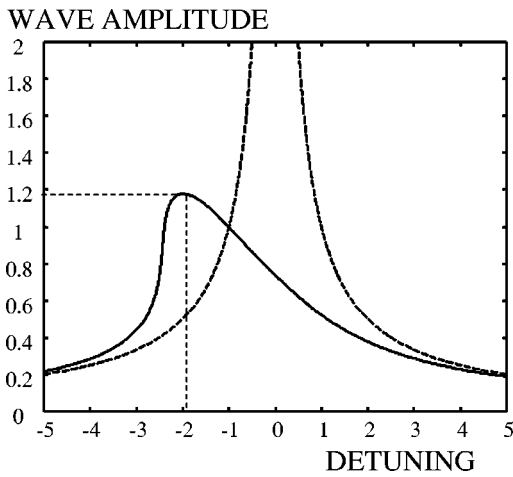

FIG. 3. Theoretical dependence of the dimensionless amplitude V_A of the traveling acoustic wave in the rod on the dimensionless detuning δ of the excitation frequency from the linear resonance condition (corresponding to $\delta=0$). The dashed curves represent linear resonance. The continuous curve depicts the saturation of the wave amplitude and the shift of the resonance peak due to hysteretic quadratic nonlinearity of material composing the rod.

where the constant $a=8/(3\pi)$. Excluding phase from Eq. (18) the description of the resonance curve $V_A=V_A(\delta)$ is obtained in the implicit form

$$\delta = \frac{1}{V_A} [-2aV_A^2 \pm \sqrt{1-a^4V_A^4}]. \quad (19)$$

In accordance with Eq. (19) the maximum amplitude $V_A^{\max}=1/a \approx 1.18$ is achieved for the detuning $\delta = \delta_{\max} = -2$. It is suitable to rewrite Eq. (19) as

$$\delta = \frac{1}{V_A} [-2aV_A^2 + \sqrt{1-a^4V_A^4} \text{sign}(\delta+2)]. \quad (20)$$

The resonance curve (20) is presented in Fig. 3, where for comparison the linear resonance curve $V_A=1/|\delta|$ [when the nonlinear term in Eq. (17) is neglected] is also depicted. Note that diminishing of the resonance frequency ($\delta_{\max} < 0$) predicted by the solution (20) (see Fig. 3) is in accordance with experimental observations, confirming softening of materials with hysteretic quadratic nonlinearity with increased amplitude of the acoustic loading.^{1-4,6-8}

III. DISCUSSION

The derived solution for the resonance peak ($V_A^{\max} \approx 1.18, \delta_{\max} \approx -2$) takes into account the interaction of the counterpropagating waves. If the counterpropagating wave is omitted in Eq. (17) this equation simplifies

$$\delta(\partial V/\partial \theta) + [V^A - V \text{sign}(\partial V/\partial \theta)](\partial V/\partial \theta) = \cos \theta. \quad (21)$$

The solution of this equation by the same mathematical method leads to

$$\delta = \frac{1}{V_A} \left[-V_A^2 + \sqrt{1 - \frac{1}{4}a^2V_A^4 \text{sign}(\delta + \sqrt{2/a})} \right].$$

Consequently, when the interaction of the counterpropagating waves in the rod is neglected the maximum amplitude $\bar{V}_A^{\max} = \sqrt{2/a} \approx 1.53$ is higher and the resonance peak shift

$\bar{\delta}_{\max} = -\sqrt{2/a} \approx -1.53$ is smaller than in the case when the interaction is taken into account. This means that the interaction of the counterpropagating waves amplifies the manifestation of the hysteretic quadratic nonlinearity. If one imagines this interaction to be switched off, then the vibration amplitude will increase and the resonance shift will diminish. Thus the interaction of the counterpropagating waves additionally absorbs each of the waves and makes the material softer.

It is important to evaluate the role in the analyzed phenomenon of the amplitude grating [the term proportional to $\partial(\partial u/\partial x)^A/\partial x$ in Eq. (2)]. If this term is neglected then the nonlinearity of the medium in the wave equation will be accounted for only by the modified local elastic modulus. Actually the coefficient on the right-hand side of Eq. (2) in front of the term $\partial^2 u/\partial x^2$ describes the so-called “bow-tie” contribution to modulus in materials with hysteretic quadratic nonlinearity.^{8,21,22} If only this nonlinear term is retained in Eq. (2) then the solution for the resonance curve will be modified for

$$\delta = \frac{1}{V_A} \left[-aV_A^2 + \sqrt{1 - \frac{1}{4}a^4V_A^4 \text{sign}(\delta + \sqrt{2})} \right],$$

with the maximum amplitude $(V_A^{\max})' = \sqrt{2}/a \approx 1.66$ for the detuning $(\delta_{\max})' = -\sqrt{2} \approx -1.41$. Note that the amplitude is larger (and the shift of the resonance is smaller) not just in comparison with the case where amplitude grating (interference pattern) is taken into account, but also in comparison with the case where the interaction of the counterpropagating waves is switched off. Consequently local variation of the material modulus leads separately (i.e., when separated from the amplitude grating) to the tendency in nonlinear phenomena, which is just opposite to the one predicted above. If only local modulus modifications are taken into account then the interaction of the counterpropagating waves partially suppresses the manifestation of the hysteretic quadratic nonlinearity. If one imagines that only the nonlinear interaction of counterpropagating waves through the local hysteresis modulus is switched on, then the wave amplitude will increase and the resonance shift will diminish. This indicates, in particular, that the interaction of the counterpropagating waves through the bow-tie contribution to modulus may amplify the waves. The effect of the amplification of a weak acoustic wave by a strong counterpropagating acoustic wave in materials with “bow-tie” hysteretic contribution to modulus was predicted earlier in Refs. 21 and 22. The above-presented theory clearly demonstrates that in the case of the counterpropagating waves of comparable amplitudes there is important contribution to nonlinear processes originating from the amplitude grating and that the contribution from the amplitude grating overcompensates for the amplification effects related to local hysteretic modulus. This indicates that the amplitude grating might play a role in the case of the counterpropagating waves of significantly different amplitudes as well, and that the theory developed in Refs. 21 and 22 should be revised.

It is interesting to compare the above-mentioned predictions with those for the rods with “classical” elastic cubic

nonlinearity. A properly normalized equation neglecting interaction of the counterpropagating waves is expected to have the form

$$\delta(\partial V/\partial\theta) + V^2(\partial V/\partial\theta) = \cos\theta. \quad (22)$$

Surely v_{NL} and ω_{NL} for the normalization of Eq. (22) are different from those in Eq. (21). The solution of Eq. (22) is

$$\delta = \frac{1}{V_A} \left[\frac{V_A^3}{3} \pm 1 \right]. \quad (23)$$

If the interaction of the counterpropagating waves is taken into account then Eq. (22) is expected to take the form

$$\delta \frac{\partial V}{\partial\theta} + \frac{1}{2\pi} \int_{-\pi}^{\pi} [V(\theta) - V(\theta + \theta')]^2 \times \left[\frac{\partial V(\theta)}{\partial\theta} + \frac{\partial V(\theta + \theta')}{\partial\theta} \right] d\theta' = \cos\theta. \quad (24)$$

Please compare the transition from Eq. (24) to Eq. (22) with the one from Eq. (17) to Eq. (21). The solution of Eq. (24) is

$$\delta = \frac{1}{V_A} \left[\frac{3V_A^3}{4} \pm 1 \right]. \quad (25)$$

Comparison of Eqs. (25) and (23) demonstrates that the interaction of the counterpropagating waves increases the role of the elastic cubic nonlinearity (the coefficient in front of V_A^3 increases) similar to the case of the hysteretic quadratic nonlinearity. The important difference between the two cases is, however, in the absence of the nonlinear absorption in materials with elastic cubic nonlinearity and in different dependence of the frequency shift on the wave amplitude.

It is instructive to compare the approximate solution $\bar{V}_A^{\max} = \sqrt{3\pi/4} \approx 1.53$, $\bar{\delta}_{\max} = -\sqrt{3\pi/4} \approx -1.53$ of Eq. (21) with its exact solution $\bar{V}_A^{\max} = \sqrt{2} \approx 1.41$, $\bar{\delta}_{\max} = -\sqrt{2} \approx -1.41$, which is available.²³ This comparison demonstrates that neglecting the inverse influence of the generated higher harmonics $[\omega_n = (2n+1)\omega, n=1,2,\dots]$ on the fundamental frequency ω leads only to a slight ($\approx 10\%$) overestimation of both maximum vibration amplitude and the resonance frequency shift. Similar overestimation might be expected in the obtained approximate solution of Eq. (17) in comparison with its exact solution.

Finally it is worth mentioning that the derived Eq. (17) can be extended, if necessary, to account for the effects of weak linear sound velocity dispersion^{24,25} and/or weak linear absorption^{2,9,11,26} by adding corresponding terms in the equation. In the case of weak linear dispersion the corresponding term is proportional to $\partial^3 V/\partial\theta^3$, for example.^{24,25}

IV. CONCLUSIONS

An ordinary inhomogeneous integrodifferential equation for the profile of the acoustic wave in a resonant rod, composed of a material with hysteretic quadratic nonlinearity, is derived. This equation incorporates the boundary conditions in the sense that all possible solutions of this equation satisfy the necessary boundary conditions "automatically." It explicitly takes into account the interaction of the counterpropagating acoustic waves. It is demonstrated that this in-

teraction amplifies the nonlinear phenomena. In particular the maximum vibration amplitude predicted by this theory is lower and the shift of the resonance peak is larger in comparison with the case when the interaction of the counterpropagating waves is neglected. The interaction due to hysteretic quadratic nonlinearity suppresses both counterpropagating waves and also enhances softening of the material with increasing wave amplitude.

(Received 27 April 2004; revised 11 January 2005; accepted 29 January 2005)

The concept of an *effective apodization* was introduced to describe the field pattern for the nonlinearly generated second harmonic ($2f$) within the focal zone using a linear propagation model. Our objective in this study was to investigate the validity of the concept of an effective apodization at $2f$ as an approach to approximating the field of the second harmonic over a wide range of depths. Two experimental setups were employed: a vascular imaging array with a water path and an adult cardiac imaging array with an attenuating liver path. In both cases the spatial dependencies of the ultrasonic fields were mapped by scanning a point-like hydrophone within a series of planes orthogonal to the propagation direction. The sampling distances were located before, within, and beyond the focal zone. The signals were Fourier transformed and the complex values at $2f$ were linearly backpropagated to the transmit plane in order to obtain an effective apodization. The measured results demonstrated a relatively constant effective apodization at $2f$ as a function of propagation distance. Finite amplitude computer simulations were found to be in agreement with these measurements. Thus the measure of the effective apodization at $2f$ provides an approximation to the second harmonic field outside the focal zone. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1874612]

I. INTRODUCTION

Our aim in this paper is to investigate the concept of an effective apodization as a tool for approximating the field pattern of the nonlinearly generated second harmonic ($2f$) portion of a finite amplitude ultrasonic field using a linear propagation model. In previous work the effective apodizations at $2f$ were derived from measurements obtained within the focal zone of the ultrasonic field.^{1–3} In this paper, the determinations of the effective apodizations at $2f$ are extended to include estimates arising from a range of axial positions before, within, and beyond the focal zone. To address the effect of attenuation, two experimental setups using one-dimensional arrays on transmit were studied: a vascular imaging transducer with a lossless water path, and an adult cardiac imaging probe with an attenuating tissue mimicking path. In addition to experimental measurements, results from computer simulations are reported.

The effective apodization at $2f$ is a descriptor of the field pattern of the nonlinearly generated second harmonic. The effective apodization at $2f$ is determined from measurements of the ultrasonic field in a plane perpendicular to the direction of propagation. These measured signals are Fourier transformed and the complex values at the second harmonic frequency are backpropagated to the source plane and the

effective apodization is extracted. (Methods for determining the effective apodization are discussed in greater detail in Sec. II.)

Use of the nonlinearly generated second harmonic has become commonplace in applications of diagnostic imaging.⁴ The shift from using the fundamental to using the second harmonic for image formation is largely driven by observed improvements in image quality. Reasons cited for this improved image quality include the following: reduced sidelobe levels,^{5–7} higher frequencies without the corresponding attenuation penalty,⁷ reduced effects due to phase aberration,^{7–9} and reduced interference from multiple reverberations.^{4,7,8} At this point it is not clear which of the suggested reasons provides the greatest impact on image quality for specific clinical imaging applications.⁴

The nonlinearly generated second harmonic portion of an ultrasonic field has lower sidelobes and a narrower beam than the fundamental portion of the field.^{5,6} The experimental measurements by Ward, Baker, and Humphrey⁶ demonstrated that the full width at half-maximum (FWHM) for the nonlinearly generated harmonics (second, third, and fourth) are related to the fundamental FWHM by $w_n/w_1 = 1/n^m$, where w_n is the width of the harmonic corresponding to the harmonic number n . The value of m was found to be 0.78 for their experimental arrangement. Considering only linear propagation, the value of m would be expected to be unity.¹⁰ Thus the main lobe is slightly wider than would be expected for a simple change in frequency. In addition these authors

noted a decrease in the sidelobe levels for the second harmonic.⁶ In related work by Christopher,⁵ the lateral beam profiles of nonlinearly generated second harmonic fields were compared to the lateral beam profiles of second harmonic fields produced by transmitting at the second harmonic frequency. This work also demonstrated that the nonlinearly generated second harmonic has a wider main lobe and lower sidelobes than a field linearly propagated at the second harmonic frequency.

For a linearly propagating field, the application of a more aggressive transmit apodization results in a wider mainlobe with lower sidelobes.¹⁰ The concept of an effective apodization was introduced as a way of accounting for the field pattern of the nonlinearly generated second harmonic.¹ Changing the transmit apodization has been shown to result in a different effective apodization at the second harmonic frequency² and thus different mainlobe widths and sidelobe levels for the nonlinearly generated second harmonic.¹¹ In addition, the effective apodization at $2f$ has been found to be independent of the F number, focal distance, frequency, and propagation medium for clinically relevant ranges for cases of weakly nonlinear propagation and for data obtained from the focal zone.¹

In a recent publication, the field patterns for the nonlinearly generated second harmonic were compared to linear propagation at $2f$ using the effective apodization at $2f$ determined from the nonlinearly generated second harmonic field.¹² This work demonstrated that the nonlinear field pattern may be approximated by a linear interpretation of the effective apodization at $2f$ descriptor for propagation distances before, within, and beyond the focal zone. These results would indicate that the effective apodization at $2f$ is at most slightly dependent on the propagation distance at which the field is sampled.

For linear propagation, the pulse echo version of the Van Cittert–Zernike theorem relates the transmit apodization to the spatial coherence of backscatter from the focal zone.¹³ By replacing the transmit apodization with the effective apodization at $2f$, the pulse echo version of the Van Cittert–Zernike theorem can be extended to the case of weakly nonlinear propagation (far from shock formation).¹ Thus, the autocorrelation of the effective apodization at $2f$ yields a prediction of the spatial coherence of backscatter that has been shown to be distinct from the spatial coherence of backscatter for the fundamental.^{1–3}

Investigators have reported either an increased^{14,15} or relatively unchanged¹⁶ depth of field for the nonlinearly generated second harmonic component compared with the ultrasonic field produced by transmitting at the same second harmonic frequency (fundamental at second harmonic frequency). The depth of field was determined using three different approaches: single transmit imaging with parallel receive beam forming,^{14,15} Van Cittert–Zernike imaging,¹⁵ and axial pullback measurements.¹⁶ The single transmit imaging with parallel receive beamforming started with a record of signals received on each element.^{14,15} Then offline a receive aperture was synthetically scanned across the received signals to form an image of the transmitted beam. These images demonstrated an extended depth of field for

the second harmonic portion of the field compared with the field produced by transmitting at the second harmonic. Comparable results were achieved by measuring the spatial coherence of backscattered signals using the Van Cittert Zernike theorem to produce an image of the incoherent source.¹⁵ The incoherent source in this case was produced from the interaction of the transmitted signal and the ensemble of randomly distributed, small scatterers. The pullback measurement of received power as a function of propagation distance demonstrated a slight increase in the depth of field for the nonlinearly generated second harmonic field.¹⁶

The apparent disagreement between these reported measurements of the depth of field arises from the different definitions employed by the investigators. The pullback measurement used the positions corresponding to -3 dB with respect to the peak pressure along the propagation axis of a transducer with circular geometry.¹⁶ In contrast, the single transmit imaging with parallel receive beamforming and Van Cittert–Zernike imaging approaches used changes in the beamwidth as a function of axial position.^{14,15} The pullback measurement of depth of field can be affected by attenuation within the sample. In addition, work by others has demonstrated that the pullback definition of the depth of field for the second harmonic can be increased by using multiple foci on transmit.¹⁷ Based on the work in Ref. 17, it appears that having an elevational focus that differs from the azimuthal focus would also extend the pullback measure of the depth of field. However, previous work has shown that the elevational focus has little to no effect on the (azimuthal) effective apodization at $2f$.¹ The pullback measurements supply a measure of the depth of field in terms of the signal to noise ratio. In contrast, the single transmit imaging with parallel receive beamforming and Van Cittert–Zernike imaging approaches provide a depth of field measurement relating to the lateral resolution for the case of having ideal time gain compensation.

In the present work, the concept of an effective apodization is related to the beamwidth as a function of propagation distance and will be shown to agree with the reported observations of an extended depth of field. Both simulations and experimental measurements were performed for the cases of a vascular imaging transducer with a lossless propagation path and a cardiac imaging transducer with an attenuation propagation path. In Sec. II, the methods used for both the experiment and the simulation are discussed in detail. In Sec. III the results are presented in two formats: effective apodizations and apodization widths. In Sec. IV, a discussion of the implications arising from the results is presented. In particular, an effective apodization at $2f$ is used to approximate the field pattern for a nonlinearly generated second harmonic before, within, and beyond the focal zone.

II. METHODS

In order to investigate the field pattern for finite amplitude ultrasonic fields, the effective apodizations at the fundamental ($1f$) and second harmonic ($2f$) were obtained. The effective apodization is determined by measuring the ultrasonic field in a plane perpendicular to the direction of propagation (an orthogonal plane). The complex amplitudes of a

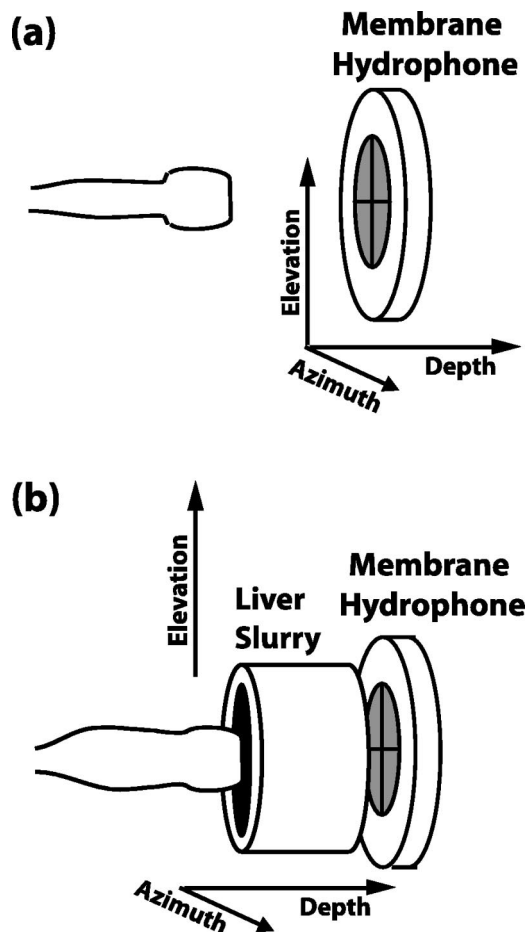

FIG. 1. Experimental arrangements used for measuring ultrasonic fields. Panel (a) depicts the water path setup. Panel (b) depicts the attenuating liver path setup.

single frequency are extracted and used in a linear angular spectrum backpropagation to the source plane.^{18,19} The effective apodization is then obtained as a profile of the magnitude of the backpropagated values. If a frequency within the fundamental band is chosen, the resultant effective apodization at $1f$ is equivalent to the actual transmit apodization.¹⁹ As expected, if a frequency within the nonlinearly generated second harmonic band is chosen, the effective apodization at $2f$ has been shown to be narrower than the transmit apodization for data acquired from the focal zone of the ultrasonic field in both simulation^{2,20,21} and experiment.^{1,2} In the following paragraphs, the experiments and simulations employed to obtain the effective apodizations at $1f$ and $2f$ for propagation depths before, within, and after the focal zone are discussed.

A. Experiment

The two experimental arrangements are shown in Fig. 1. The differences in the two experimental approaches are in the type of transmit array utilized and the type of propagation medium. For the lossless water path depicted in panel (a) of Fig. 1, the ultrasonic field was propagated from a vascular imaging transducer array into water, whereas for the attenuating liver slurry path depicted in panel (b) of Fig. 1, the ultrasonic field was produced by an adult cardiac imaging transducer array. For both setups the ultrasound was propa-

gated perpendicular to the face of a one-dimensional array (i.e., there was no beam steering) using an HDI-5000 ultrasonic imaging system (Philips Medical Systems, Bothell, WA). The transmit F number was approximately 5 for both cases. The two-dimensional pseudoarray scans were performed with a 0.6 mm diameter membrane hydrophone (Sonic Industries, Hatboro, PA) at set distances from the transmit transducer position.

The transmit apodization function was the same for both transducer arrays, and previous work has indicated that the effective apodization at $2f$ at the focus for the adult cardiac imaging transducer agrees with the effective apodization at $2f$ at the focus for the vascular imaging transducer.¹ Thus, the choice of changing both the type of the transducer array and the propagation medium was deemed to be acceptable. The results shown below support this choice.

1. Nonattenuating water path

A drawing of the experimental setup is shown in panel (a) of Fig. 1. Two-dimensional pseudoarray scans were performed at axial positions of 3.0, 22.6, 42.9, 62.6, and 84.3 mm from the face of a one-dimensional vascular imaging array (linear array) transducer. The array elements were focused at 56 mm in the azimuthal direction with a Riesz window apodization, and the elevation direction was focused at 20 mm. Data were acquired by translating the hydrophone receiver in 0.25 mm steps through a 57 by 57 grid (14 mm by 14 mm) and digitizing the RF signal at each position (250 MS/Sec with 8 bits, temporally averaged 32 times). A more detailed description of the experimental setup and data acquisition was published previously.¹

The recorded broadband time-domain signals were Fourier transformed and the complex amplitudes at 5.6 MHz (fundamental) and 11.2 MHz (nonlinearly produced second harmonic) were obtained at each position. These two-dimensional arrays of complex narrow-band values were linearly backpropagated to the plane of the transmit aperture yielding an apparent source from which the effective apodization was determined. (See Refs. 1, 2 for further details on this analysis approach.) The effective apodization for each axial position was determined by averaging the azimuthal profiles contained within the -3 dB elevational source width. Before averaging each of these profiles was normalized by their respective maximum value. The standard deviation of these normalized azimuthal profiles was computed and used as an error measurement.

2. Attenuating liver slurry path

The drawing in panel (b) of Fig. 1 depicts the setup for the one-dimensional adult cardiac imaging transducer array (phased array) with the attenuating liver slurry path. This array was focused at a depth of 100 mm in the azimuthal direction with a Riesz window apodization. The focus in the elevational direction was 47 mm. Two-dimensional pseudoarray scans were performed at axial positions of 2.5, 35, 53, 83, 103, and 162 mm from the face of phased array transducer. A detailed description of the experimental setup, data acquisition, and liver slurry phantom can be found in a

TABLE I. Propagation pathlengths in water and attenuating liver slurry phantom for the through transmission signals associated with the attenuating liver path setup.

Total propagation distance (mm)	Liver slurry phantom length (mm)	Water pathlength (mm)
2.5	...	2.5
35	33.0	2.0
53	50.5	2.5
83	80.0	3.0
103	100.5	2.5
162	159.0	3.0

previous publication² that used the data obtained at the 2.5, 53, and 103 mm axial positions. The propagation distances for the attenuating phantom and nonattenuating water for each axial position from the phased array are listed in Table I.

The effective apodization was obtained using the same approach employed for the nonattenuating water path dataset. In this case, the complex narrow-band data at 1.76 MHz (fundamental) and 3.52 MHz (nonlinearly produced second harmonic) were extracted from the measured rf signals.

B. Simulation

The two experimental transmit configurations (nonattenuating water path and attenuating liver path) were simulated using an approach that incorporated the nonlinear Burgers equation into an angular spectrum propagation model.^{22–24} Each experimental setup was simulated with a Riesz window applied in the azimuthal direction and a rectangular window applied in the elevational direction. The axial propagation step size was 2 mm.

The water path simulation propagated a 51.2 mm by 51.2 mm (256 points by 256 points) source plane a distance of 100 mm. The azimuthal direction was geometrically focused at 56 mm for a speed of sound of 1.54 mm/ μ s corresponding to the programmed speed of sound for the imaging system. We chose acoustic parameters representative of nonattenuating water with the speed of sound set to 1.49 mm/ μ s, the attenuation coefficient set to zero, and the nonlinearity parameter (β) set to 3.6.²⁵ The fundamental frequency was chosen to be 5.6 MHz based on the nonattenuating water path experiment.

The simulation, for an attenuating liver path, propagated a 76.8 mm by 76.8 mm (256 points by 256 points) source plane a distance of 166 mm. The azimuthal direction was geometrically focused at 100 mm, assuming a 1.54 mm/ μ s speed of sound as per the clinical imaging system. We chose an ultrasonic speed of 1.53 mm/ μ s and a slope of attenuation of 0.59 dB/cm/MHz to characterize the attenuating liver slurry phantom within the simulation in agreement with the measured values. A representative value for the nonlinearity parameter (β) of 4.5 was chosen to fall within a range of reported bovine liver measurements.²⁵ The fundamental frequency was chosen to be 1.76 MHz, corresponding to the attenuating liver path experiment.

For both simulations, the complex values for the fundamental and second harmonic frequencies were saved at each 2 mm propagation step. The effective apodization for the fundamental ($1f$) and the second harmonic ($2f$) were determined at each propagation step, as described above. The magnitudes of the effective apodizations were normalized to a peak value of one.

III. RESULTS

Two types of results are presented in this paper: (a) The effective apodizations at $1f$ and $2f$ are compared for a Riesz window transmit apodization, and (b) the widths of the effective apodizations as functions of axial distance.

A. Effective apodizations

The experimentally determined effective apodizations are displayed in Fig. 2 for the water path and for the attenuating liver path. The effective apodizations at $1f$ in panel (a) and panel (c) of Fig. 2 overlie the transmit apodization (Riesz window) for both experimental setups. The effective apodizations at $2f$ in panel (b) of Fig. 2 are all narrower than the Riesz window transmit apodization. Similar results are depicted in panel (d) of Fig. 2 for the attenuating liver path. The lone exception is the measurement at 2.5 mm.

The measurement at 2.5 mm for the attenuating liver path appears to overlie the transmit apodization for positions near the edge of the transmit aperture. There is very little production of second harmonic content arising from nonlinear propagation up to this modest distance of 2.5 mm from the array. A possible explanation for the unexpected second harmonic content is that the ultrasonic source is transmitting a weak (undesirable) signal at the second harmonic frequency. This weak second harmonic signal is attenuated relatively quickly within the attenuating liver slurry phantom. Thus we suggest that the results at 35, 53, 83, 103, and 162 mm are dominated by the nonlinearly produced second harmonic frequency. (This statement is supported by comparisons with the simulation results in the following paragraphs.) The second harmonic results for the water path do not exhibit this second harmonic feature for a field sampled at 3 mm. This suggests that the effect seen in the attenuating liver path may be a result of the transmit characteristics for the adult cardiac imaging array as compared to the vascular imaging array used for the water path.

In Fig. 3, the simulated effective apodizations are shown for the fundamental and the nonlinearly generated second harmonic for both the nonattenuating water path and the attenuating liver path, respectively. The displayed values have been normalized to a peak value of one at each transmit propagation distance. The results for the effective apodization at $1f$ remain unchanged with propagation distance (as expected). Remarkably, the nonlinearly generated second harmonic results are also relatively constant with depth, displaying only a slight decrease in width as the transmit propagation distance increases.

The simulation results (shown in Fig. 3) and experimental results (shown in Fig. 2) for the effective apodizations at $2f$ are compared in Fig. 4. At each distance there is reasonable agreement with the simulation results for both the at-

FIG. 2. Experimental results for the effective apodization are displayed for the water path [panels (a) and (b)] and for the attenuating liver path [panels (c) and (d)]. The top row compares the measured effective apodization at $1f$ [5.6 MHz for panel (a) and 1.76 MHz for panel (c)] for each propagation distance. The bottom row compares the measured effective apodizations at $2f$ [11.2 MHz for panel (b) and 3.52 MHz for panel (d)] for all propagation distances from the transmit apodization that were sampled. Error bars represent the standard deviation.

tenuating liver path and the nonattenuating water path. The worst agreement occurs at the shortest propagation distances where the signal to noise ratio of the measured second harmonic is at its lowest.

B. Width of the effective apodization

An estimate of the aperture width for the effective apodizations at the fundamental ($1f$) and second harmonic ($2f$) was determined by finding the positions corresponding to 20% of the peak amplitude in the profiles (approximately a -14 dB level). This metric will be referred to as the *width of the effective apodization*. For a Riesz apodization of full width L , the width of the effective apodization is computed

to be $0.89 L$. For the simulation results, the widths of the effective apodizations were determined from the values displayed in Fig. 3. In order to obtain a measure of the variation in the experimental measurement, a variation of the analysis described in Sec. II was performed. The width was determined for each profile contained within the -3 dB elevational source width before averaging the profiles together. These measurements of the apodization width were then averaged and the standard deviation is reported as the error.

In Fig. 5, the widths of the effective apodizations are displayed as a function of the backpropagation distance for both measured and simulated results. Two normalizations were performed on the data in order to facilitate a comparison

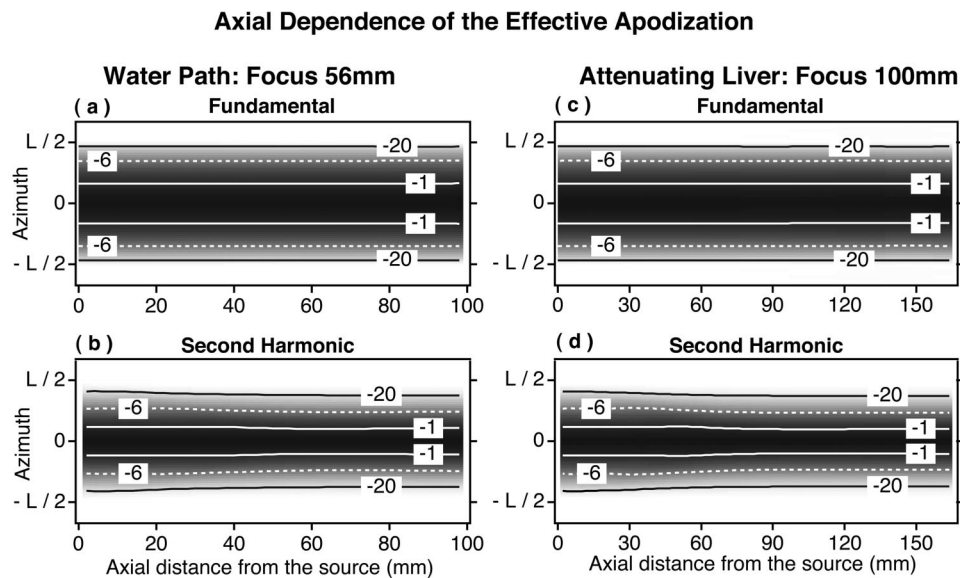

FIG. 3. Results for simulations of the water path and the attenuating liver path are shown. The panels depict the effective apodizations at $1f$ and $2f$ as a function of the backpropagation distance. The top row displays the results for the fundamental. As expected for linear propagation, the contours are horizontal lines. The bottom row displays the results for the nonlinearly generated second harmonic. The effective apodizations for both $1f$ and $2f$ were normalized by their peak value for each backpropagation distance. Contour labels are in units of dB and the linear gray scale is mapped to black for a value of 1.0 and white for a value of 0.0. [The left axis is in units of the full width of the transmit aperture (L).]

FIG. 4. Effective apodizations at $2f$ for both simulation (solid lines) and experiment (circles) are compared for the water path (first column) and the attenuating liver path (second column). The geometric focus was at 56 mm for the water path and at 100 mm for the attenuating liver path. Error bars represent standard deviation.

son of the results for the two experimental setups. The widths of the effective apodizations were normalized by the transmit aperture full width (L) and the propagation distance was normalized by the geometric focal distance (F).

The widths of the effective apodizations for the fundamental ($1f$) are shown in panel (a) of Fig. 5 and exhibit good agreement between the experiment and simulation for the two different experimental setups. In panel (b) of Fig. 5, the widths of the effective apodizations for the nonlinearly generated second harmonic ($2f$) are displayed. The second harmonic experimental results show reasonable agreement with the simulation results and indicate a slight reduction in width as a function of propagation distance. Comparing panels (a) and (b), the widths for the nonlinearly generated second harmonic are distinctly less than the widths for the fundamental.

The agreement among the widths of the effective apodizations for the second harmonic is notable because (1) a linear array transducer with a geometric focus of 56 mm was compared with a phased array transducer with a geometric focus of 100 mm. (2) The propagation medium for the

water path was nonattenuating, whereas the propagation medium for the attenuating liver path exhibited a 0.59 dB/cm/MHz slope of attenuation. (3) The second harmonic frequencies were 3.52 and 11.2 MHz for the attenuating liver path and water path, respectively.

IV. DISCUSSION

The results from both simulation and experiment demonstrate that the effective apodization of the nonlinearly generated second harmonic field is narrower than the transmit apodization, as can be seen in Fig. 2, Fig. 3, and Fig. 5. The effective apodization at $2f$ exhibits a slight decrease in width as a function of propagation distance, which is much smaller than the difference between any of the effective apodizations at $2f$ and the transmit apodization. In Fig. 5, the most rapid variation in the effective apodization at $2f$ appears to be at a distance around four tenths of the geometric focal distance. Around the focal position and beyond the effective apodization at $2f$ is relatively invariant.

FIG. 5. Widths of the effective apodizations are displayed for the fundamental (a) and the nonlinearly generated second harmonic (b). The widths correspond to the difference in positions determined by the -14 dB value with respect to the peak value for each effective apodization. The propagation distance was normalized by the geometric focus (F). Error bars represent the standard deviation.

The potential influence of the hydrophone's active element size on measurements of the effective apodization can be addressed by examination of Fig. 4 and Fig. 5. Here the results of measurements using a finite-sized aperture hydrophone are compared with the simulation results that are based on point sampling of the simulated field. The agreement between the experimental and simulation results suggest that the finite size of the hydrophone introduced relatively little error. In addition, in the context of this study, the agreement between simulation and measured results shown in Fig. 4 and Fig. 5 suggests that the effective apodization from either pulsed wave (experiment) or continuous wave (simulation) sources exhibit comparable results.

In the following two subsections, the applicability of using the effective apodization at $2f$ to approximate the nonlinearly generated second harmonic is investigated. In the first subsection the field pattern at the second harmonic frequency is compared for two simulations with different transmit conditions: (1) transmitting at the fundamental frequency using a Riesz window apodization; (2) transmitting at the second harmonic frequency using the effective apodization at $2f$ obtained from the results of the first transmit condition. In Sec. IV B the effective apodization at $2f$ is related to reports of an increased depth of field for the nonlinearly generated second harmonic.^{14,16,26} A third subsection contains a discussion about the phase of the effective apodization at $2f$.

FIG. 6. Contour plots of the normalized field pattern from simulation demonstrating the concept of an effective apodization. The second harmonic portion of an ultrasonic field created by nonlinear propagation of a fundamental transmit with a Riesz window transmit apodization is compared to the ultrasonic field for a linearly propagated signal at the second harmonic frequency that was transmitted using the effective apodization at $2f$ associated with the Riesz window. At each propagation distance the simulation results have been normalized and the contours are reported in units of dB.

A. Estimation of the field pattern

In Fig. 6, simulated field patterns are compared for a nonlinearly generated second harmonic and linear propagation at the second harmonic frequency with the effective apodization determined from the nonlinear field. A simulation of nonlinear propagation in a water path was performed with a fundamental frequency of 5.6 MHz and a Riesz window transmit apodization. The nonlinearly generated second harmonic portion of the field was extracted at every 0.5 mm axial increment. At each propagation distance the power of the second harmonic portion of the field was computed in dB relative to the peak. The complex values of the second harmonic field at the geometric focal position of 56 mm were used to determine the effective apodization at $2f$ (see Sec. II). This effective apodization at $2f$ was then used as a transmit apodization for transmitting at 11.2 MHz. The linear fundamental result from transmitting at 11.2 MHz with the effective apodization at $2f$ overlays the nonlinear result in Fig. 6. Further evidence of this agreement is shown using both experiment and simulation in a recent publication.¹²

The close agreement between the results in Fig. 6 demonstrates the potential usefulness of the concept of an effective apodization at $2f$ for beam formation design. Tool sets developed for linear analysis (such as k -space analysis,^{27,28} spatial impulse response,^{29,30} and the Fraunhofer approximation³¹) may be used to investigate weakly nonlinear propagation by applying the concept of an effective apodization. The main assumption involved in the extension of these tools is that the system has an adequate signal to noise ratio for the second harmonic portion of the field. In addition, the analysis in this paper has assumed no aberration of the signal. The effect of increasing the transmitted pressure on the effective apodization at $2f$ has not been investigated. Thus, the stated restrictions to weakly nonlinear

propagation is a limitation of the current and previous studies.^{1-3,12}

B. Depth of field estimation

The widths of the effective apodizations for the nonlinearly generated second harmonic were found to be considerably less than the transmit aperture widths, as seen in Fig. 5. Reducing the extent of the transmit apodization results in extending the depth of field.¹⁰ Other investigators have observed the apparent extended depth of field for the nonlinearly generated second harmonic portion of the beam as compared with transmitting at the second harmonic frequency using the same transmit apodization.^{14,16,26} Our measurements and simulations of the effective apodization at $2f$ also imply that the depth of field for the nonlinearly generated second harmonic is longer than the depth of field for a transmitted second harmonic that utilized the original transmit apodization.

An estimate of the extension in the depth of field associated with the nonlinearly generated second harmonic is obtained by considering the reduced width of the effective apodization at $2f$. Beginning with a geometric definition of the depth of field (D),

$$D = 7\lambda \left(\frac{F}{L} \right)^2, \quad (1)$$

where F is the geometric focal distance, λ is the wavelength, and L is the aperture width, assuming uniform apodization.¹⁰ Using this equation, the change in the depth of field for transmitting with a Riesz window can be compared to transmitting with the corresponding effective apodization at $2f$. For each case, the same frequency and focal distance are used. Thus, the only difference in the depth field resides in the aperture width (L). The aperture width is computed from the simulation results for the effective apodization at $2f$ for a Riesz transmit apodization. In order to estimate the aperture width, the integral of each apodization is computed and then normalized by a uniform apodization of width L (the transmit aperture width). For the Riesz window and the corresponding effective apodization at $2f$, the resulting values are 0.66 and 0.47, respectively. Thus, the effective apodization at $2f$ indicates an increase in the depth of field of ~ 2.0 times the depth of field obtained by transmitting at $2f$ with the original transmit apodization.

The concept of the effective apodization at $2f$ implies that the depth of field for the nonlinearly generated second harmonic is comparable to the depth of field for the fundamental ($1f$) portion of the field. The difference in frequency is approximately countered by the effective apodization at $2f$ being narrower than the transmit apodization. This estimation for the depth of field does not account for the following: (1) slight changes in the shape of the effective apodization at $2f$ as a function of propagation distance; (2) errors associated with a calculation of the equivalent widths of nonuniform apodization windows; (3) possible changes in the relative phase (geometric focus) of the effective apodization at $2f$ as a function of propagation distance. A brief discussion on the last point is given below.

FIG. 7. *Effective geometric focus* as a function of propagation distance for the simulation results of the attenuating liver path are shown.

C. Changes in the phase of the complex effective apodization as a function of propagation distance

The effective apodization is defined above as the magnitude of backpropagated complex values. In this section the phase of these complex values is discussed. Saito reported changes in the phase of the second harmonic with respect to the fundamental as a function of transmit propagation distance for a geometrically focused single element transducer receiving signals from a geometrically focused single element transmitter.³² By analogy, these reported changes may affect the phase of the complex effective apodization at $2f$ as a function of propagation distance. The phase of the complex effective apodization is comparable to the geometric focus for a linearly propagating field. Thus, the nonlinearly generated second harmonic field may be expected to exhibit a dynamically changing *effective geometric focus* as a function of propagation distance.

The phase of the effective apodization can be related to the geometric focus of the apodization. For the simulations described in Sec. II, the *effective geometric focus* was obtained from the phase information within the complex effective apodizations as a function of propagation distance using

$$\Theta(x) = k\sqrt{R^2 + (x-A)^2} - B, \quad (2)$$

where Θ is the phase as a function of aperture position, k is the wave number, R is the geometric focus, and x is the aperture position. The coefficients A and B account for beam steering and a constant phase shift, respectively. A chi-square minimization approach was implemented in the software package IgorPro (WaveMetrics, Inc., Lake Oswego, OR) using Eq. (2) and the simulated complex effective apodization results. The values of k and x were fixed while the values of A , B , and R were determined from the curve fitting routine. The *effective geometric focus* is defined as the resulting value of the geometric focus (R) obtained from the phase of the complex effective apodization.

The *effective geometric focus* predicted from the simulation of the attenuating liver path is shown in Fig. 7. The *effective geometric focus* at $1f$ displays agreement with the known result of the actual geometric transmit focus (F) (100 mm in this case). The *effective geometric focus* at $2f$ demonstrates a difference of, at most, 8% from the value of F and crosses the actual transmit geometric focus at a propagation

distance slightly greater than the actual geometric focus (F). Thus the *effective geometric focus* at $2f$ demonstrates a slight variation as a function of the propagation distance. This variation may result in slightly extending the depth of field for the nonlinearly generated second harmonic. The previous choice to concentrate on the magnitude of the complex effective apodization is supported by the results shown in Fig. 6, where the field pattern of the nonlinearly generated second harmonic is fairly well approximated by a linear propagation using only the magnitude of the complex effective apodization at $2f$.

The effective geometric foci were also determined experimentally. However the errors in the measurements at both $1f$ and $2f$ were much greater than the differences exhibited in Fig. 7 and did not follow any trend as a function of propagation distance. Slight shifts in phase were found to have a significant effect on the value of the *effective geometric focus*. The experimental results were not strong enough to either support or refute the variation in the simulated *effective geometric focus* results shown in Fig. 7.

V. CONCLUSIONS

The concept of effective apodization provides a descriptor of the nonlinearly generated second harmonic portion of an ultrasonic field in terms of linear propagation. The results in Fig. 2 and Fig. 3 show that the widths of the effective apodization at $2f$ are narrower than the effective apodization at $1f$, in agreement with previous measurements.¹⁻³ Furthermore, for an effective apodization at $2f$ obtained from measurements in the focal zone, reasonable agreement to the nonlinearly generated field is observed not only within the focal zone but also well before and beyond the focal zone, as demonstrated in Fig. 6.

In Fig. 5, the widths of the effective apodizations for the nonlinearly generated second harmonic are grouped together for the two different experimental setups for both simulation and experiment. Both experimental setups used a Riesz window transmit apodization and had F numbers of approximately 5. The agreement between the widths is remarkable given that the two experimental setups had different frequencies, different propagation media, different focal distances, and different clinical transducer arrays. Thus, the results shown in Fig. 5 imply that the concept of the effective apodization at $2f$ provides an estimate of the nonlinearly generated second harmonic field for a broad range of experimental conditions.

The impetus for this work was to further the understanding of the underlying principles associated with the improved image quality sometimes observed with harmonic imaging. The concept of an effective apodization provides a tool that may be useful in developing a better understanding of the nonlinearly generated second harmonic field pattern for a homogenous medium. Although imaging in a clinical setting introduces aberrating propagation media, understanding the case for a homogenous propagation medium provides a reference for investigating more complex propagation paths. Furthermore, an application of the concept of an effective apodization may provide a useful tool in the design of ultrasonic imaging systems.

Acoustic pulse propagation through a fluctuating stably stratified atmospheric boundary layer

Igor Chunchuzov,^{a)} Sergey Kulichkov, Alexander Otrezov, and Vitaly Perepelkin
Obukhov Institute of Atmospheric Physics, 109017 Moscow, 3 Pyzhevskii Per., Russia

(Received 30 June 2004; revised 30 November 2004; accepted 8 January 2005)

Mesoscale wind speed and temperature fluctuations with periods from 1 min to a few hours significantly affect temporal variability and turbulent regime of the stable atmospheric boundary layer (ABL). Their statistical characteristics are still poorly understood, although the knowledge of such statistics is required when modeling sound propagation through the stable ABL. Several field experiments have been conducted to study the influence of mesoscale wind speed fluctuations on acoustic pulse propagation through the stable ABL. Some results of these experiments are described in this paper. A special acoustic source was used to generate acoustic pulses by the detonation of an air–propane mixture with a repetition period 30 s. The mean wind speed and temperature profiles were continuously measured by Doppler sodar and temperature profiler, whereas mesoscale wind fluctuations were measured by anemometers placed on a 56-m mast. From the measurements of the pulse travel time fluctuations at different distances from the source, the statistical characteristics of the mesoscale wind fluctuations, such as frequency spectra, coherences, horizontal phase speeds and scales, have been obtained. Some of the obtained results are interpreted with the use of a recently developed model for the internal wave spectrum in a stably stratified atmosphere. © 2005 Acoustical Society of America. I. INTRODUCTION

There are problems of practical importance in atmospheric acoustics which require taking into account the influence of both the mean stratification and the fluctuations of wind speed and temperature on acoustic signal propagation through the atmosphere. These problems include a localization of various acoustic sources in the atmosphere, a prediction of sound levels from pulse and noise sources, and acoustic remote sensing of the atmosphere. To solve them, one needs to parametrize the statistical characteristics of wind speed and temperature fluctuations needed for calculating the amplitude and phase fluctuations of acoustic waves.

Most sound propagation models use a parametrization of turbulence based on well-known models such as the Kolmogorov–Obukhov model of locally isotropic and homogeneous turbulence (Tatarskii, 1971), the von Karman model (Ostashev *et al.*, 1998), and Gaussian models for both isotropic (Chernov, 1960) and anisotropic turbulence (Wilson and Thomson, 1994).

However, in stably a stratified atmospheric boundary layer (ABL), the parametrization of the turbulence statistics is still a problem, since these characteristics at high Richardson numbers, Ri , cannot be described by means of the existing similarity theories, most of which are based on the assumption that the turbulence is locally homogeneous and stationary (statistically). The widely used models of the ABL based on a large-eddy simulation do not capture flows with very stable stratification (Derbyshire, 1999; Wilson *et al.*, 2001) and fail to simulate layers with the sharp vertical gradients that are often observed in the ABL.

It is recognized now that different types of instabilities of internal gravity waves (IGWs) may be a source of small-scale turbulence and meso-scale eddy structures (such as “cat eyes,” “filaments,” “banks,” and others) in stable ABLs (Chimonas, 1978; Gossard *et al.*, 1985; Danilov and Chunchuzov, 1992; Chunchuzov, 1996; Chimonas, 1999; Galaktionov and Maderich, 1999; Blumen *et al.*, 2001; Anderson, 2002). Such turbulence coexists and continuously interacts with the IGWs, so the statistical properties of these waves affect both the statistics of turbulence and the fine vertical structure of the wind field in a stably stratified ABL (Weinstock, 1984; Einaudi and Finnigan, 1993).

The IGWs themselves induce meso-scale wind speed and temperature fluctuations in the stable ABL with periods from a few minutes to a few hours, and with horizontal scales from hundreds of meters to a few kilometers. These fluctuations cause the corresponding fluctuations of the parameters of acoustic signals propagating through the ABL, such as travel time, amplitude, duration, and the angles of arrival of the acoustic signals. To understand how IGWs influence the statistical characteristics of the parameters of acoustic signals, and the turbulent fluxes of heat and momentum in the stable ABL, one needs to know the form of the frequency-wavenumber spectrum of the wind speed and temperature fluctuations induced by IGWs. Such a need motivated our study of the effects of meso-scale wind speed and temperature fluctuations associated with IGWs on the statistical characteristics of the parameters of acoustic pulses in the stable ABL. The experimental results of this study are described in Sec. II. In Sec. III A these results are interpreted by using a theoretical model for the frequency spectra of the wind speed fluctuations induced by internal waves. Based on this model a theoretical form for the frequency spectrum of

travel time fluctuations is obtained in Sec. III B and compared with the measured spectral forms (Sec. III C). The obtained results of the paper are discussed in Sec. 4.

II. EXPERIMENTAL STUDY OF THE INFLUENCE OF MESO-SCALE WIND SPEED FLUCTUATIONS ON THE PARAMETERS OF ACOUSTIC SIGNALS

A. Acoustic pulse sounding method

To measure meso-scale wind speed and temperature fluctuations, we used an acoustic pulse sounding method previously developed for this purpose (Chunchuzov *et al.*, 1990, 1996, 1997; Chunchuzov, 2002). This method is a type of acoustic tomography of the stable ABL based on the existence of an acoustic wave guide near ground surface due to formation of the temperature inversion and vertical wind shear near the ground surface.

The scheme of the field experiment conducted in August 2002 at the base of the Institute of Atmospheric Physics near Zvenigorod is shown in Fig. 1. It consists of an acoustic pulse generator (G), receivers (R1–R4), Doppler sodar (S), a temperature profiler (T) and a meteorological mast (M) with the acoustic anemometers mounted at heights of 6 and 56 m above ground surface.

Acoustic pulses of stable form were generated by detonation of an air-propane mixture in the special tube shown in Fig. 2. We chose a repetition period of 30 s for sounding of the meso-scale wind speed and temperature fluctuations with temporal scales ranging from 1 min to 1 h. One of the acoustic pulses received at a distance of 20 m from the generator is shown in the upper panel (a) of Fig. 3. When propagating in the acoustic wave guide the initial signal “splits” at a distance of 2.5 km into a set of arrivals A, B, C, and D, as

FIG. 2. Detonation generator.

shown in Fig. 3(c). These arrivals are readily identified in the records of the signal [shown in Figs. 3(b)–3(d)] detected by the receivers R1, R2, and R3, which form a 5-m horizontal triangle. Such evolution of the pulse waveform with distance was earlier explained theoretically by using exact solutions of the Helmholtz equation for the sound field in a moving stratified layer (Chunchuzov *et al.*, 1990, 1996).

For each signal radiated at the time t we measured the time interval $\Delta T(t)$ between arrivals (D) and (A) with the accuracy of 2 ms. By measuring temporal variations $\delta T(t) = \Delta T(t) - \Delta T_0$ of the interval $\Delta T(t)$ relative to its value ΔT_0 at some initial moment t_0 , we were able to calculate the temporal variations $\delta c_{\text{eff}}(t) = c_{\text{eff}}(t) - c_{\text{eff}}(t_0)$ of the effective sound speed $c_{\text{eff}} = c + V_e$ averaged over the selected ray trajectory Γ_A connecting the source and each receiver. Here c is the sound speed, V_e is the projection of the wind velocity along the radius-vector from the source to the receiver, and the trajectory Γ_A is thought to have a maximum elevation angle relative to the ground surface and one turning point.

As earlier shown by Chunchuzov *et al.* (1997) the variations $\delta T(t)$ are caused mostly by the variations of the pulse travel time along the ray Γ_A , because their contributions to the value of $\delta T(t)$ are much greater than those from the travel time variations along the nearly horizontal ray path Γ_D for an arrival D. The latter has an elevation angle close to 0.

For small relative variations of the effective sound

FIG. 3. One of the acoustic signals generated by a detonation source on 10 August 2002, 22:40. This signal at a distance of 20 m is shown in the upper panel (a). The same signal was also recorded far from the source (2550 m for the receiver R1) by a 5-m triangle array R1, R2, and R3. These recordings at the points R1, R2, and R3 are shown in the panels (b), (c), and (d), respectively. A, B, C, and D are different arrivals of the same signal.

speed, $|\delta c_{\text{eff}}(t)/c_{\text{eff}}|$, we can express $\delta T(t)$ as $\int_{\Gamma_A} ds (\delta c_{\text{eff}}(t) \cdot c_{\text{eff}}^{-2}) = \langle \delta c_{\text{eff}}(t) \rangle \int_{\Gamma_A} ds (c_{\text{eff}}^{-2})$, where the second-order terms $O(|\delta c_{\text{eff}}(t)/c_{\text{eff}}|^2)$ are neglected, and $\langle \delta c_{\text{eff}}(t) \rangle$ is the value of $\delta c_{\text{eff}}(t)$ averaged over the initial ray path Γ_A for the arrival A (Chunchuzov *et al.*, 1997). If the relative increase of the effective sound speed from the ground to the height of the ray turning point is small, then in the first-order approximation the initial time interval ΔT_0 may be expressed as $\int_{\Gamma_A} ds ((c_{\text{eff}}(s) - c_0) c_{\text{eff}}^{-2}) = \langle \Delta c_{\text{eff}} \rangle \int_{\Gamma_A} ds (c_{\text{eff}}^{-2})$, where c_0 is the initial value of sound speed c near ground surface $z=0$, and $\langle \Delta c_{\text{eff}} \rangle$ is the average value of the difference $\Delta c_{\text{eff}}(s) = (c_{\text{eff}}(s) - c_0)$ over the ray path Γ_A at the initial moment t_0 (note that under this approximation we have replaced the integration over Γ_D by the integration over Γ_A). As a result the relation between averaged time fluctuations $\langle (\delta c_{\text{eff}})_m(t) \rangle$ and the fluctuations $\delta T(t)$ becomes

$$\langle (\delta c_{\text{eff}})_m(t) \rangle \approx \langle \Delta c_{\text{eff}} \rangle \delta T(t) / \Delta T_0. \quad (1)$$

The value of $\langle \Delta c_{\text{eff}} \rangle$ may be readily estimated for the initial ray trajectories calculated for the wind speed and temperature profiles measured by the sodar and temperature profiler, respectively, so from measured values of $\delta T(t)$ and

ΔT_0 one can calculate from (1) the averaged effective sound speed fluctuations $\langle (\delta c_{\text{eff}})_m(t) \rangle$.

B. Experimental results

For the signal in Fig. 3(c) the acoustic pressure field calculated by a parabolic equation method (Aivilov, 1995) is displayed in Fig. 4. A constructive interference of normal modes forms the ray paths, which are clearly seen in this figure. For the totally reflecting ray (A), with a maximum elevation angle relative to the ground, the height of the turning point is about 99 m. For this height the estimated average increase in the effective sound speed $\langle \Delta c_{\text{eff}} \rangle$ is about 3 m/s.

Since the initial time interval ΔT_0 between arrivals A and D was 70 ms, then from the fluctuations $\delta T(t)$ measured by means of a horizontal triangle array R1–R3, one can calculate the average fluctuations of the effective sound speed $\langle (\delta c_{\text{eff}})_m(t) \rangle$. As shown by Chunchuzov *et al.* (1997), the main contribution to the value of $\langle (\delta c_{\text{eff}})_m(t) \rangle$ comes from the small portion of the ray trajectory Γ_A near its turning point. The time series of the fluctuations $\langle (\delta c_{\text{eff}})_m(t) \rangle$ for the ray paths Γ_A that connect the source G with each of the receivers R1, R2, and R3 are shown in Fig. 5(a). For the same time period Fig. 5(b) shows the time series for the fluctuations of the horizontal wind speed projection (v_x) along the x -axis directed from R1 to R2 (i.e., northward). These are measured by the anemometer at a height of 56 m (the receivers R1–R3 and the mast with the anemometers are shown in Fig. 1).

The obtained time series of $\langle (\delta c_{\text{eff}}) \rangle$ and v_x reveal similar oscillations with the periods ranging from 8 min to about 20 min. To estimate the horizontal speed and direction of the propagation of such oscillations, the receiver R2 was placed 200 m northward (x -axis) from R1, whereas the receiver R3 was placed 170 m eastward from R1 so that these receivers formed a horizontal triangle array (Fig. 1).

The fluctuations of the pulse travel time measured by the triangle array R1–R3 in the night time hours of 13 August 2002 are shown in Fig. 6. For these time series we have calculated the coherences K_{ij} and the corresponding phase spectra $\varphi_i - \varphi_j$ between the points i and j of the triangle, where $i, j = 1, 2, 3$. The coherences K_{ij} and the multi-coherence function defined by Grachev *et al.* (1978) as

$$K_0 = (K_{12}^2 + K_{23}^2 + K_{31}^2 - 2K_{12}K_{23}K_{31} \cos \Sigma \varphi)^{1/2}, \quad (2)$$

FIG. 4. Ray trajectories for the signal in Fig. 3(b). The height of the turning point for the totally reflected ray with a maximal elevation angle is 99 m (this ray corresponds to the arrival A), the average effective sound speed increase $\langle \Delta c_{\text{eff}} \rangle$ from the ground to this height is 3 m/s, and the time interval between arrivals A and D is 70 ms.

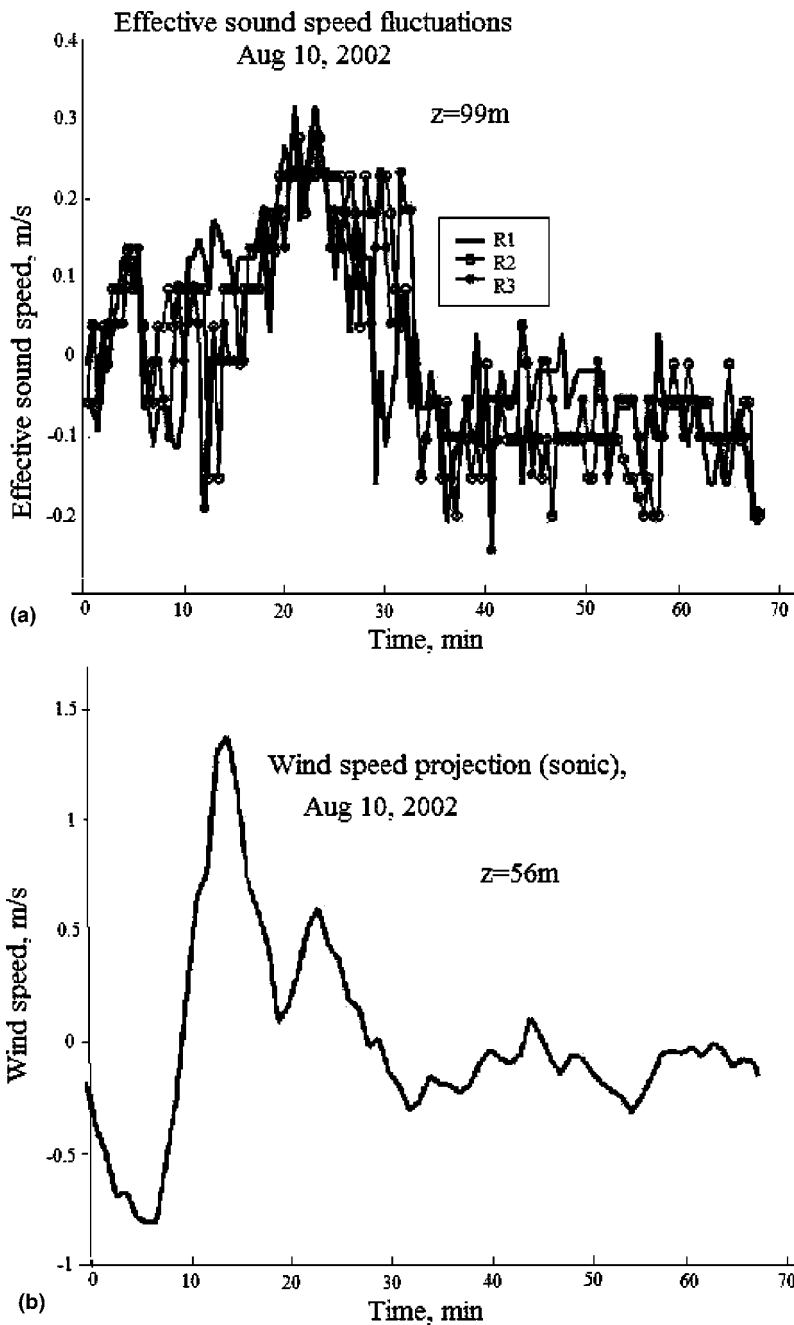

FIG. 5. The time series (a) of the effective sound speed fluctuations $\langle(\delta c_{\text{eff}})_m(t)\rangle$ reconstructed from the travel time measurements by a 5-m triangle array, and the horizontal wind speed fluctuations (b) measured by acoustic anemometer at a height of 56 m.

where $\Sigma\varphi = (\varphi_1 - \varphi_2) + (\varphi_2 - \varphi_3) + (\varphi_3 - \varphi_1)$ is the sum of the phase differences, were estimated by means of standard procedures (Bendat and Piersol, 1967). If $K_{12} = K_{23} = K_{31} = 1$ and $\Sigma\varphi = 0$, then $K_0 = 1$, so the existence within some frequency interval of the maximum of the multi-coherence function K_0 along with the condition $\Sigma\varphi = 0$ may be considered as an indication of the occurrence of wavelike fluctuations within the same interval.

As seen from Fig. 7, all the calculated coherences show a low-frequency peak with the maximum between 0.7 and 0.98 and within a low-frequency interval of 0.6–1.7 mHz, where 1 mHz = 10^{-3} Hz (the corresponding periods are between 10 and 28 min). Within the same frequency range the sum of phase differences $\Sigma\varphi$ becomes close to zero (Fig. 7), and this fact indicates a wavelike character of the observed low-frequency fluctuations. Note that the central frequencies

of the peaks of different coherences K_{ij} may be slightly shifted relative to each other, and this seems to be associated with the azimuthal anisotropy of the speed of the wavelike fluctuations with respect to the mean wind velocity. In this case only those frequencies have been selected, for which all the coherences reached a maximum along with the condition $\Sigma\varphi \approx 0$. Beside the low-frequency peak in the interval 0.6–1.7 mHz, this condition was also met for the frequencies 6.7 mHz (period 2.5 min) and 10 mHz (period 1.5 min). Thus there exists a number of dominant frequencies in the observed fluctuations of the pulse travel time. For these frequencies we have calculated the phase differences between the three turning points of the refracting rays Γ_A connecting a source with the receivers R1, R2, and R3 (the distances between these turning points are $\Delta x = 100$ m and $\Delta y = 85$ m).

FIG. 6. Pulse travel time fluctuations $\delta T(t)$ measured on 13 August 2002 (22:40–22:50) by a 200-m triangle array R1–R3 (see Fig. 1).

The calculated phase velocities V_p of the effective sound speed fluctuations versus frequency are shown in Fig. 8(a). The value of V_p as seen decreases from 5.5 m/s at a frequency $f=0.6$ mHz (corresponding period is 28 min) to about 2 m/s at $f=2$ mHz (period is about 8 min). The obtained periods and corresponding phase velocities are typical for the internal waves often observed in the stably stratified ABL (Kjelaas *et al.*, 1974; Gossard and Hooke, 1975; Aggarwal *et al.*, 1980). The calculated azimuthal direction of propagation of the wavelike fluctuations is within the interval 100° – 105° with respect to the x axis as shown in Fig. 8(b). The corresponding horizontal wavelengths of these fluctuations $\lambda = V_p/f$ decrease from 8.6 km at a period of 28 min to 960 m at a period of 8 min. At a shorter period of 2.5 min, the azimuth of the fluctuations is about 100° and $\lambda \approx 270$ m.

C. Stratification of the ABL and throposphere during observations

The observed fluctuations within the range of periods (2.5–10 min) may be induced by trapped internal wave modes propagating in the wave guide formed near ground surface by the mean stratification of the Brunt-Väisälä (BV) frequency $N(z)$ (Gossard and Hooke, 1975) and wind speed in the stable ABL. This is seen from the vertical profiles of temperature [Fig. 9(a)], BV frequency $N(z)$ [Fig. 9(b)], and horizontal wind speed [Figs. 9(c) and 9(d)] in the lower 400-m atmospheric layer. Indeed, the value of N^2 decreases from its maximum $N_{\max}^2 \sim 1.2 \times 10^{-3} \text{ rad}^2/\text{s}^2$ at the height of 75 m to its minimum $N_{\min}^2 \sim (0.2\text{--}0.3) \times 10^{-3} \text{ rad}^2/\text{s}^2$, which is between the heights of 350 and 500 m.

Thus, the lower 350-m layer of the ABL may serve as a wave guide for internal gravity wave modes with the frequencies $\omega' = \omega - \mathbf{k}\mathbf{V}(z) > 0$, satisfying the condition $N_{\min} < \omega' < N_{\max}$, where an intrinsic frequency ω' is taken relative to the mean wind speed $\mathbf{V}(z)$ at a given height z , and \mathbf{k} is the horizontal wave number of a trapped mode (Lighthill, 1978).

The corresponding interval of periods $2\pi/\omega'$ for the trapped modes is between the values $2\pi/N_{\max} \approx 3$ min and $2\pi/N_{\min} \approx 6\text{--}8$ min.

Note that above the 70-m layer of strong temperature inversion the value of the mean vertical wind shear is less than 0.02 Hz, and the corresponding Richardson number Ri is between 1 and 3 (this estimate was done for the 50-m vertical resolution of temperature and wind speed). Hence the atmospheric layer between 70 and 350 m was stable both statically and dynamically. The linear frequencies $f = \omega/2\pi$ of the trapped wave modes relative to the ground are in the interval

$$(N_{\min} + \mathbf{k}\mathbf{V})/2\pi < f < (N_{\max} + \mathbf{k}\mathbf{V})/2\pi. \quad (3)$$

It follows from (3) that the wave number values $k = 2\pi f/V_p$ of the observed wavelike fluctuations vary from 7.4 rad/m at $f=0.6$ mHz to 3.1×10^{-3} rad/m at $f=2$ mHz, whereas the direction of the horizontal wind speed \mathbf{V} (relative to the x axis) is between 60° and 170° . In this case the angle α between vectors \mathbf{k} and \mathbf{V} is within the interval 120° – 160° , hence the observed wavelike fluctuations propagate almost opposite to the mean wind velocity.

For $k = 3.1 \times 10^{-3} \text{ m}^{-1}$, $\alpha = 100^\circ$ and for the maximum of wind speed $V = 6$ m/s within a 350-m layer the estimated frequencies for the trapped wave modes are in the range $1.5 \times 10^{-3} \text{ Hz} < f < 4 \times 10^{-3} \text{ Hz}$ (the corresponding periods are between 4 and 11 min). The modes with periods of more than 11 min are not trapped within the lower 350-m layer, so they can freely propagate through the tropospheric layers that are aloft. One possible source of these waves may be an unstable wind shear which occurred in the lower troposphere during the night hours of 13 August 2002. As follows from the radiosonde data obtained during the pulse soundings, an unstable wind shear layer with $Ri < 0.25$ existed in the height range between 1 and 1.8 km. The wind speed in this layer reached a maximum of about 6 m/s, which was close to the horizontal phase speed of the observed wavelike fluctuations

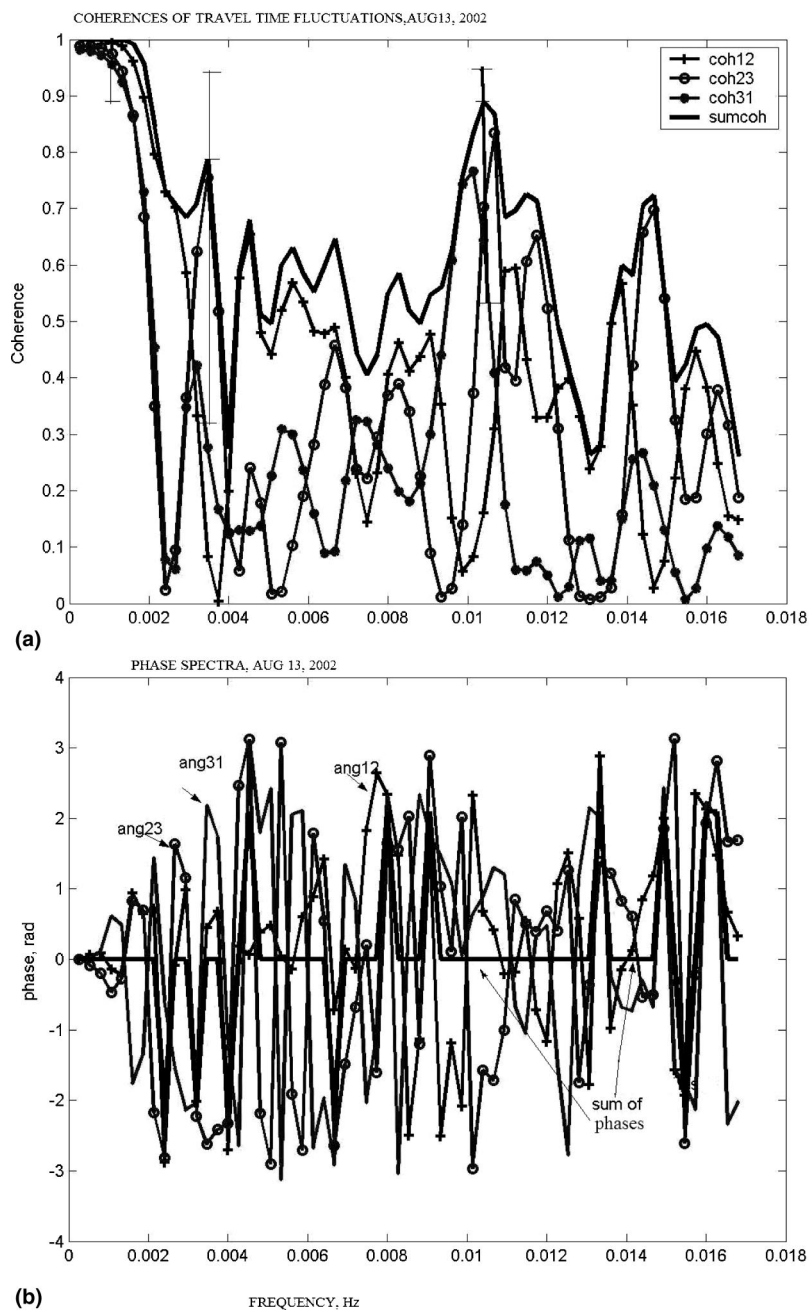

FIG. 7. Coherences and phase spectra for the time series in Fig. 6, 13 August 2002. (a) Coherences between the points R_i and R_j , ($i, j = 1, 2, 3$) and a multi-coherence function (continuous line). Vertical bars show 90% confidence intervals. (b) Phase spectra $\varphi_i - \varphi_j$ and their sum (continuous line).

with a period of 28 min. Such conditions were favorable for the generation of internal waves by an unstable tropospheric wind shear, and for the downward propagation of these waves through a stable ABL to the ground surface (Gossard and Hooke, 1975).

Thus, the frequency range 0.6–1.7 mHz corresponding to the observed peak of coherence may be caused by the untrapped IGWs with periods of 11–28 min propagating downward from tropospheric source. The fluctuations with higher frequencies (periods from 4 to 11 min) may be induced by the trapped wave modes in the lower 350-m layer.

Under the weak mean wind shear the trapped (standing) wave modes may induce wind shears that reach critical values at certain heights (depending on the forms of wind speed and BV-frequency profiles), where the Richardson number Ri becomes less than $\frac{1}{4}$ (Chimonas, 1978; Gossard *et al.*,

1985; Danilov and Chunchuzov, 1992). At these heights, the field of internal wave modes breaks down and generates thin layers of turbulence. During the night time measurements of 13 August 2002, the existence of the trapped IGWs under the weak mean wind shear ($\ll 0.02 \text{ s}^{-1}$) was a likely source of the horizontal layers of intense turbulence in the stable ABL. These layers are seen in the sodar echogram (Fig. 10) during the time period 22:40–00:30 LT as the dark isolated layers at the altitudes of 100–150 m and 300–350 m. Note that these layers are undulating with periods (4–5 min) inherent in the trapped internal wave modes. The vertical displacements of the undulating layers reach values of about 100 m, which are comparable to the vertical length scales of the trapped wave modes. The wave modes with such large relative amplitudes should be strongly nonlinear and, therefore, strongly interact between each other. The importance of nonlinear effects for

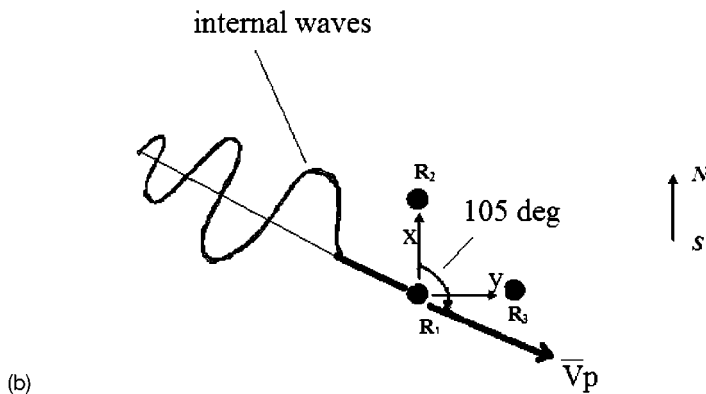

FIG. 8. Horizontal phase speed V_p of the effective sound speed fluctuations (a) (obtained from the time series in Fig. 6) as a function of frequency. (b) Illustration of the propagation of the observed internal waves with respect to the triangle array R1, R2, and R3.

the observed internal waves in the ABL also follows from the comparison (see Sec. III A) of the obtained values of phase speeds for these waves with the rms values of the horizontal wind speed fluctuations.

III. FREQUENCY SPECTRA OF TRAVEL TIME FLUCTUATIONS

A. Model of the temporal internal wave spectrum

The rms values σ of the wind speed fluctuations obtained from the anemometer measurements at a 56-m height during periods of acoustic pulse sounding of stable ABIs (from 10 to 13 August 2002) ranged from 0.1 to 0.5 m/s. At the same time the horizontal phase speeds of the internal waves detected in the stable ABL are about several meters per second. These values are close to the mean horizontal wind speed values in the ABL, so the wave phase velocities relative to the mean wind speed may be comparable to the rms values σ of the wind speed fluctuations. In this case, the advective term $(\mathbf{v}\nabla)\mathbf{v}$ in the Eulerian motion equation becomes comparable in magnitude to the linear term $\partial\mathbf{v}/\partial t$ that describes the acceleration of fluid parcels at a fixed point.

This means that the effects of advection of the IGWs by a fluctuating wind play a key role in the formation of the wave energy distribution among IGWs of different scales in the Eulerian frame of reference. There is also a dynamic nonlinearity of the equation of state that affects the energy spectrum of IGWs along with advective nonlinearity.

The influence of both advective and dynamic nonlinearities of the Eulerian motion equations on shaping of the energy spectrum of IGWs was taken into account in the model of the IGW spectrum in the ocean developed by Allen and Joseph (1989). This model was then adopted and modified for the atmosphere (Churchuzov, 1996, 2002; Hines, 2001). The theory developed in these works predicts universal forms for both spatial and temporal spectra of the wind speed and temperature fluctuations induced by an ensemble of gravity wave modes with randomly independent phases and amplitudes. Some theoretical results on the frequency spectrum of IGWs will be used here to interpret the obtained experimental frequency spectra of the acoustic pulse travel time fluctuations in a stably stratified ABL.

The simplest two-layer model of the stably stratified and nonrotating atmosphere [$N(z)=N_1$ for $0\leq z\leq h$, and $N(z)$

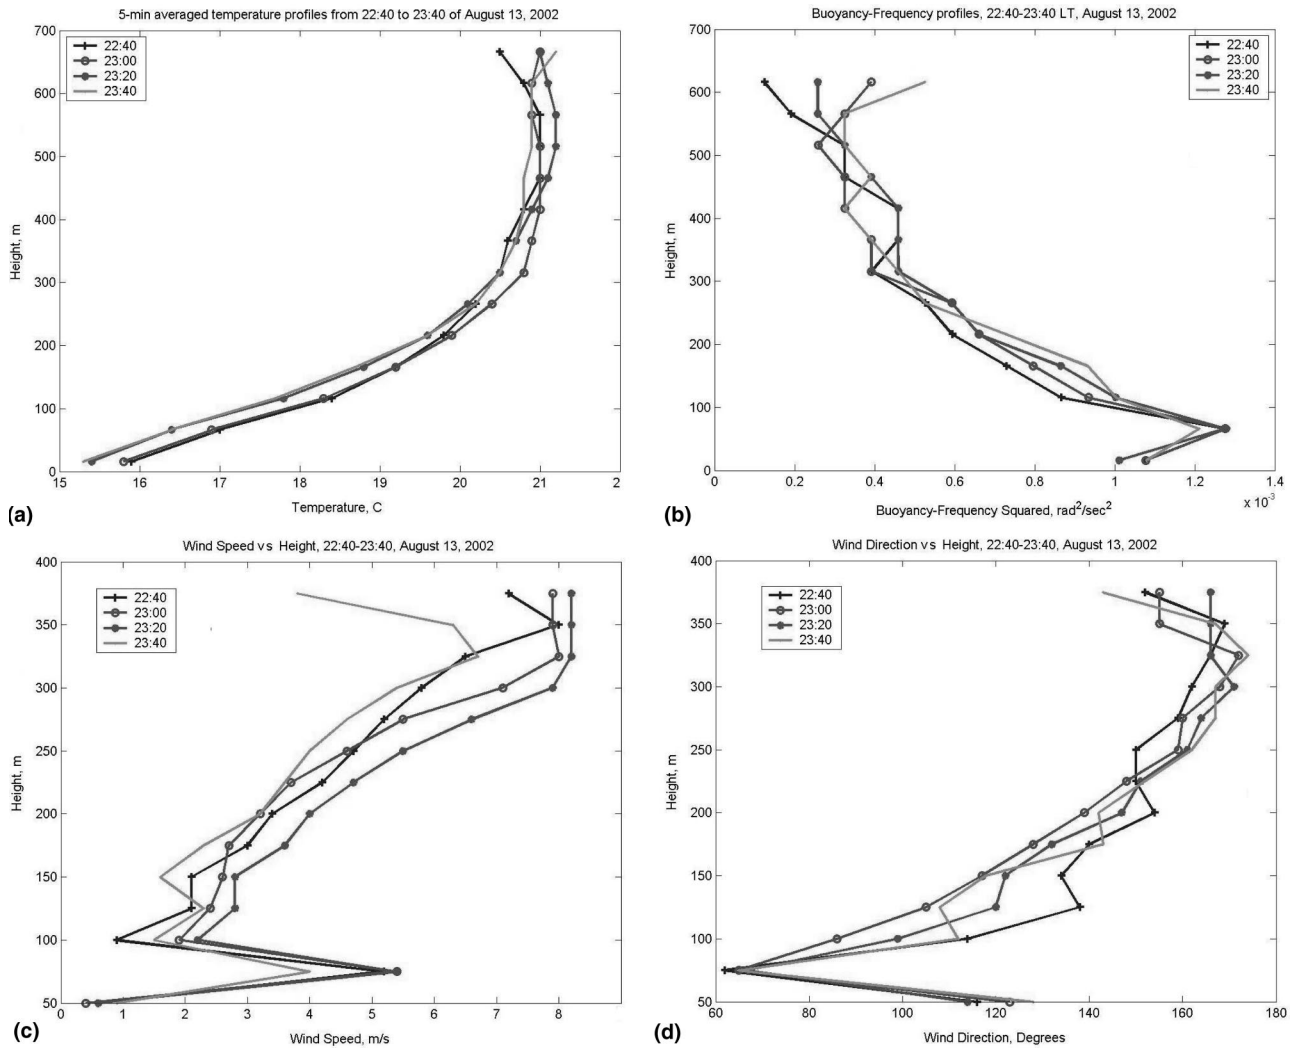

FIG. 9. Vertical profiles of temperature measured by temperature profiler, BV frequency, wind speed, and wind direction (measured by Doppler sodar), 13 August 2002, 22:40–23:50. These profiles are averaged over 5 min. (a) Temperature; (b) BV frequency; (c) wind speed; and (d) wind direction.

$=N_2$ for $h \leq z \leq \infty$, where $N_2 \ll N_1$] was chosen to find an equilibrium energy spectrum of the random internal wave field in the lower atmospheric layer. This model may be used when the lower atmospheric layer with a depth h of about 1–2 km has a mean static stability (over the entire thickness of the layer) N_1 higher than the tropospheric layer aloft (Gossard and Hooke, 1975). This is the case shown in Fig. 11. As seen from the tropospheric BV-frequency profile (Fig. 11) obtained from radiosonde data of 13 August 2002, the value of $N(z)$ decreased with a height z from about 3 mHz

FIG. 10. Sodar echogram during the time period 22:40–00:30 of 13 August.

near the ground surface to values less than 1 mHz at the heights between 1- and 3 km. Despite a presence of vertical oscillations in the profile of $N(z)$, the value of $N(z)$ averaged over the thickness of the lower 1-km atmospheric layer is higher than the average value of N in the layer between 1 and 3 km. Such a stratification of $N(z)$ leads to the formation of a wave guide for internal waves in the lower atmospheric layer with a height of about 1 km.

The obtained theoretical form for the frequency spectrum $S_{1E}(\omega)$ of the vertical displacements of fluid parcels in the Eulerian frame may be presented as a sum of two terms (Chunchuzov, 2003, Chunchuzov *et al.*, 2004): $S_{1E}(\omega) = S'_{1E}(\omega) + S''_{1E}(\omega)$, where $S'_{1E}(\omega)$ and $S''_{1E}(\omega)$ are the contributions to the frequency spectrum from the low-wavenumber and high-wavenumber parts of the 4D frequency-wavenumber spectrum, respectively. Similarly for the frequency spectrum of the horizontal wind speed fluctuations, we have $V_{1E}(\omega) = V'_{1E}(\omega) + V''_{1E}(\omega)$.

In the range $\Omega_0^2 \ll \omega^2 < N_1^2$ the obtained approximate forms for the terms $S'_{1E}(\omega)$ and $V'_{1E}(\omega)$ are given by expressions (Chunchuzov *et al.*, 2004)

$$S'_{1E}(\omega) \approx \nu_0^2 \Omega_0 / (2\omega^2), \quad V'_{1E}(\omega) \approx \epsilon / (2\omega^2),$$

FIG. 11. BV-frequency profile calculated from the radiosonde measurements of the temperature in the troposphere, 13 August 2002, 23:00.

$$\epsilon = \sigma^2 \Omega_0, \quad (4)$$

where ν_v is the rms value of the vertical parcel displacements caused by a random internal wave field, $\sigma^2 = N_1^2 \nu_v^2$ is the mean square value of the wind speed fluctuations, and Ω_0 is the characteristic frequency of the internal wave field. This frequency is connected by a dispersion equation $\Omega_0 = N_1 k_0 / m_0$ to the horizontal and vertical wavenumbers, k_0 and m_0 , of the maximum of the 3D wave number spectrum of the vertical displacements. Hence Ω_0 may be treated as the frequency for which a maximum of wave energy is “pumped” from random internal wave sources to the wave system.

The ratio between the characteristic wave numbers $\chi \equiv k_0 / m_0$ is of the same order as the ratio σ_\perp / σ_v , where σ_\perp and σ_v are the rms values of the fluctuations of horizontal and vertical wind velocity, respectively. Under stable stratification, vertical velocities are significantly suppressed, therefore $\chi \gg 1$, and $\Omega_0^2 \ll N_1^2$. According to (4) the coefficient ϵ is the product of the rms velocity σ of the parcels and their acceleration $\sigma \Omega_0$, where $\Omega_0 = N_1 / \chi$. Therefore ϵ may be treated as the mean rate of wave energy input from the random internal wave sources.

For comparison with the experimental data we have to use the one-sided frequency spectra defined as $2S_{1E}(\omega)$ and $2V_{1E}(\omega)$ for $\omega \geq 0$ and 0 for $\omega < 0$. These spectra decay as ω^{-2} in the range $\Omega_0^2 \ll \omega^2 < N_1^2$. However, as ω approaches the values close to N_1 the spectrum $2S_{1E}(\omega)$ shows a local maximum [Fig. 12(a)]. This maximum is caused by a constructive interference between the incident and reflected internal waves from the jump of the BV-frequency value at $z = h$. When ω tends to N_1 , the parcel displacements induced by trapped IGWs become almost vertical, whereas horizontal displacements and velocities tend to zero (Gossard and Hooke, 1975).

At high vertical wave numbers, the horizontal phase speeds of the internal wave modes are comparable to the values of σ , therefore the nonlinear interactions (both reso-

nant and Γ_A nonresonant) between these modes play a key role in the formation of the IGW spectrum. These interactions generate in the frequency-wavenumber spectrum of the internal wave field the spectral components with high vertical wave numbers and high frequencies (Churchuzov, 2002, 2003). Particularly, the nonlinear interactions between any two spectral components with the frequencies $\omega_1 < N_1$ and $\omega_2 < N_1$ can generate the new spectral components with the combinative frequencies $\omega_1 + \omega_2 > N_1$. These interactions do not necessarily satisfy resonant conditions $\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}$, $\omega_1 + \omega_2 = \omega$, where $\omega = \omega(\mathbf{k})$ is the dispersion relation for the linear internal wave modes, and $\omega_1 = \omega(\mathbf{k}_1)$, $\omega_2 = \omega(\mathbf{k}_2)$. Therefore, the nonresonant interactions are not selective ones: each wave mode may interact with any other mode, generating new modes so that a wave energy cascade is developing. This cascade leads to the wave energy transfer from the frequency region $\omega < N_1$ to the high-frequency region $\omega > N_1$, thereby generating a high-frequency tail in the frequency internal wave spectrum. This tail is similar in its origin to the k^{-3} -tail in the vertical-wave number spectrum of internal wave field (Hines, 2001; Churchuzov, 2002).

The high-frequency parts of the one-sided frequency spectra $2S_{1E}''(\omega)$ and $2V_{1E}''(\omega)$, generated by the nonlinearity of the internal wave field, is described by the following expressions (Churchuzov *et al.*, 2004):

$$2S_{1E}''(\omega) \approx \beta \sigma_v^2 / \omega^3, \quad 2V_{1E}''(\omega) \approx \alpha N_1^2 \sigma_v^2 / \omega^3 \quad (\omega^2 \gg \Omega_0^2). \quad (5)$$

Here, α and β are the numerical coefficients depending on the mean square vertical gradient $\langle (\partial s_3 / \partial z)^2 \rangle$ of the vertical displacements s_3 caused by IGWs, and σ_v^2 is the mean square value of the vertical wind velocity fluctuations. The magnitudes of α and β increase with a growth of the value of $\langle (\partial s_3 / \partial z)^2 \rangle$ up to some maximum of the order of 0.1, which characterizes a nonlinear saturation of the amplitude of the spectral tail. Thus a strong nonlinearity of the internal wave field forms a universal high-frequency tail with a -3

FIG. 12. Frequency spectra of the vertical displacements and travel time fluctuations calculated from the model of internal wave spectrum in stably stratified atmosphere. (a) Frequency spectrum of the vertical displacements defined by expressions (4) and (5) and calculated for $m_0 z = 10$, $N_1 = 0.001$ Hz, $\chi = 11.5$, $\epsilon = 10^{-5}$ $\text{m}^2 \text{s}^{-3}$, $\beta = 0.23$; $\sigma_v = 0.03$ m/s. (b) Normalized frequency spectrum of travel time fluctuations.

power law decay. This tail, shown in Fig. 12(a), becomes important at frequencies $\omega > N_1$.

B. Model of the frequency spectrum of travel time fluctuations for the acoustic pulses propagating through a random internal wave field

The knowledge of the frequency-wave number spectrum $G_\mu[\mathbf{k}, \omega, z]$ of the acoustic refractive index $\mu(\mathbf{x}, t)$ in a moving inhomogeneous medium allows one to calculate the form of the frequency spectrum $R_T(\omega)$ of the pulse travel time fluctuations $\delta T(t)$ along a selected ray trajectory Γ (Chunchuzov, 2003):

$$R_T(\omega) = 2\pi c_0^{-2} \int_{\Gamma} dx \int dk_3 \int dk_2 G_\mu \times [-k_3 \tan \theta(x), k_2, k_3, \omega, z(x)], \quad (6)$$

where $\mathbf{k} = (k_1, k_2, k_3)$ is the wave number vector, x is the horizontal distance from a point acoustic source, $z = z(x)$ is the function that describes a form of the refractive ray trajectory Γ in the acoustic wave guide caused by the mean temperature and wind speed stratification near the ground

surface, and $\theta(x)$ is the elevation angle of the ray trajectory at some point $(x, z(x))$. The calculation of the statistics of travel time fluctuations is similar to those in the ocean (Flatté *et al.*, 1979), but here we take into account the wind speed fluctuations, which play a substantial role in the atmosphere.

As shown by Chunchuzov (2003) the spectrum $G_\mu[\mathbf{k}, \omega, z]$ for a random internal wave field may be expressed as a sum,

$$G_\mu[\mathbf{k}, \omega, z] = S_{4E}(\mathbf{k}, \omega, z) (N^2 g^{-1})^2 / 4 + c^{-2} G_{11}(\mathbf{k}, \omega, z), \quad (7)$$

in which the first term describes a spectral contribution coming from the relative temperature fluctuations T'/T_0 (they are proportional to the vertical parcel displacements), g is the gravity acceleration, and second term $G_{11}(\mathbf{k}, \omega, z)$ is the 4D spectrum of the fluctuations of the horizontal wind speed projection v_x along a ray trajectory Γ .

The approximate forms for the frequency wave number spectra $S_{4E}(\mathbf{k}, \omega, z)$ and $G_{11}(\mathbf{k}, \omega, z)$ have been provided in Chunchuzov (2002). By substituting these forms into the expression (7), and taking this integral in the case of small elevation angles [$\theta(x) \approx 0$], one obtains the form of the

FREQUENCY SPECTRA OF THE EFFECTIVE SOUND SPEED FLUCTUATIONS
IN STABLE ABL, Aug 10-13, 2002

FIG. 13. Normalized frequency spectra of the pulse travel time (or effective sound speed) fluctuations measured at the points R1–R4 during 10–13 August 2002. Horizontal axis: frequency normalized by $N_1=0.001$ Hz; vertical axis: frequency spectrum normalized by ϵ/N_1^2 . Theoretical spectrum $\epsilon\omega^{-2}$ is shown by a straight continuous line.

travel time spectrum $R_\tau(\omega)$ shown in Fig. 12(b) [taken from Churchuzov (2003)]. In this figure the frequency ω is normalized by the BV frequency N_1 (horizontal axis), whereas the spectrum $R_\tau(\omega)$ is normalized by $[(\sqrt{2}\langle\mu^2\rangle r/m_0c^2)/N_1]$, which is proportional to the mean square value of the pulse travel time fluctuations at a distance $x=r$, where $\langle\mu^2\rangle\approx\langle T'^2/4T_0^2\rangle+\langle v_x^2/c^2\rangle$ is the mean square value of the acoustic refractive index fluctuations in the moving atmosphere. This spectrum decays as ω^{-2} with an increase of ω , but reaches a local maximum near $\omega\approx N_1$ similarly to the frequency spectrum of the vertical displacements.

C. Comparison between theoretical and observed frequency spectra

The frequency spectra for the effective sound speed fluctuations $\langle(\delta c_{\text{eff}})_m(t)\rangle$ near ray turning points obtained during the period from 10 to 13 August 2002 are shown in Fig. 13. These spectra are calculated from the time series of the acoustic pulse travel time fluctuations measured at the points R1–R4 (shown in Fig. 1) and are normalized by the value of ϵ/N_1^2 , where N_1 is the mean value of the BV frequency in the lower atmospheric layer with a thickness of 1 km. According to the radiosonde data during measurements of the fluctuations $(\delta c_{\text{eff}})_m(t)$, this value ranged from 1 to 2 mHz.

The value of $\epsilon=\sigma^2 N_1/\chi$ was estimated from the rms value of the measured fluctuations $\langle(\delta c_{\text{eff}})_m(t)\rangle$, which are of the same order as the rms value of the wind speed fluctuations σ . The ratio $\chi=\sigma_\perp/\sigma_v$ was estimated from the obtained time series of the fluctuations of horizontal wind speed components, v_x , v_y , and vertical component, w , by calculating the ratio between their rms values σ_\perp and σ_v . For instance, during 10 August 2002, $\sigma\approx 0.12$ at the height of 99 m, and $\chi=\sigma_\perp/\sigma_v\approx 11.5$, so ϵ is about $10^{-5}\text{ m}^2\text{ s}^{-3}$.

As shown in Fig. 13 the obtained frequency spectra decrease with increasing normalized frequency f/N_1 in the range 0.6–2, where $N_1=1\times 10^{-3}$ Hz (the corresponding periods range from 28 to 8 min). At higher relative frequencies f/N_1 , between 2 and 10 (the corresponding periods are between 8 and 1.5 min), the spectral density has a number of local peaks. Note that for the frequencies more than 2 mHz, internal waves are trapped in the lower layer with the height of a few hundred meters, where a static stability $N(z)$ reaches a maximum [Fig. 9(b)]. As seen from Fig. 13, the frequencies of the spectral peaks and the distribution of the spectral density over frequencies vary slightly from case to case, but despite such variability of the observed spectra, their mean slopes and amplitudes are close to those predicted theoretically.

IV. CONCLUSIONS

The method of acoustic pulse sounding of stable ABLs allowed us to obtain new data about variances, coherences, and horizontal speeds of propagation of meso-scale wind speed fluctuations in the stable ABL. Several dominant periods were found in the coherences and frequency spectra of the wind speed and pulse travel time fluctuations. These periods, and the corresponding horizontal speeds and scales of the observed fluctuations, are typical for the internal gravity waves in the lower atmosphere. Among these waves are both the trapped modes in the lower part of the ABL with a maximum static stability and the freely propagating modes, which may be generated by the tropospheric internal wave sources such as unstable wind shears. The existence of the wave guide near the ground surface was confirmed by the analysis of the vertical profiles of the horizontal wind speed and temperature (or BV frequency) in the stable ABL. The latter were continuously monitored by a Doppler sodar and temperature profiler.

Based on the model of an internal wave spectrum in the stably stratified atmospheric layer we obtained theoretical forms for the frequency spectra of both the wind speed and pulse travel time fluctuations induced by internal waves. Despite a temporal variability of the obtained experimental spectra, their average power law decay was close to the predicted theoretical power law $\epsilon\omega^{-2}$, where ϵ is the mean rate of wave energy input from the random internal wave sources. The value of ϵ obtained from the experimental data gives a satisfactory estimate of the spectral density of meso-scale wind speed fluctuations in a stable ABL.

Rosette spatial filters are used at International Monitoring System infrasound array sites to reduce noise due to atmospheric turbulence. A rosette filter consists of several clusters, or rosettes, of low-impedance inlets. Acoustic energy entering each rosette of inlets is summed, acoustically, at a secondary summing manifold. Acoustic energy from the secondary manifolds are summed acoustically at a primary summing manifold before entering the microbarometer. Although rosette filters have been found to be effective at reducing infrasonic noise across a broad frequency band, resonance inside the filters reduces the effectiveness of the filters at high frequencies. This paper presents theoretical and observational evidence that the resonance inside these filters that is seen below 10 Hz is due to reflections occurring at impedance discontinuities at the primary and secondary summing manifolds. Resonance involving reflections at the inlets amplifies noise levels at frequencies above 10 Hz. This paper further reports results from theoretical and observational tests of impedance matching capillaries for removing the resonance problem. Almost total removal of resonant energy below 5 Hz was found by placing impedance matching capillaries adjacent to the secondary summing manifolds in the pipes leading to the primary summing manifold and the microbarometer. Theory and recorded data indicate that capillaries with resistance equal to the characteristic impedance of the pipe connecting the secondary and primary summing manifolds suppresses resonance but does not degrade the reception of acoustic signals. Capillaries at the inlets can be used to remove resonant energy at higher frequencies but are found to be less effective due to the high frequency of this energy outside the frequency band of interest. © 2005 Acoustical Society of America. I. INTRODUCTION

A. Infrasonic and global nuclear monitoring

The Comprehensive Nuclear Test-Ban Treaty (CTBT) was made available for signature at the United Nations in September of 1996. This has led to increased interest in monitoring globally for nuclear testing activity at all yields which in turn has led to the development of the four-network International Monitoring System (IMS). The IMS includes infrasound, radionuclide, seismic, and hydroacoustic stations. Although the primary goal of the system is to monitor Earth's atmosphere, solid interior, and oceans for nuclear testing activity, an additional benefit of the continuously monitoring system is that it will allow detection, tracking, and analysis of other man-made and natural phenomena on an unprecedented global scale.

This paper is concerned with the infrasound component of the IMS (Christie *et al.*, 2001). As of November 2001, 10 of the planned 60 microbarograph arrays were operating and another 10 were under construction. Completion of the entire network is expected to take several more years. Each infra-

sound array will comprise four to eight sensors with a baseline of 1 to 3 km. Sensors in the infrasound network are designed to detect signals between 0.01 and 8 Hz, but the array geometry is designed for optimal detection in the 0.1–1 Hz range. Infrasonic pressure data are collected at each site at 20 samples per second (sps) along with wind speed and direction sampled at 1 sps. The operating arrays transmit data to the International Data Center (IDC) in Vienna, Austria. One array (Fig. 1) is in the Anza-Borrego desert south of Palm Springs, CA.

B. Reduction of infrasonic noise

The principal source of noise in the frequency band of interest to the nuclear monitoring community is atmospheric turbulence. As a result, all pressure data are filtered in the field by a spatial wind-noise-reducing system (Daniels, 1959; Burrige, 1971; Grover, 1971). The filter averages out pressure variations that are due to local turbulence and increases the signal-to-noise ratio (SNR).

The infrasound monitoring network is designed to provide monitoring of the atmosphere at all points on the globe. As a result, the noise reducing systems are required to be omnidirectional. A recent design of a spatial filter by Alcov-

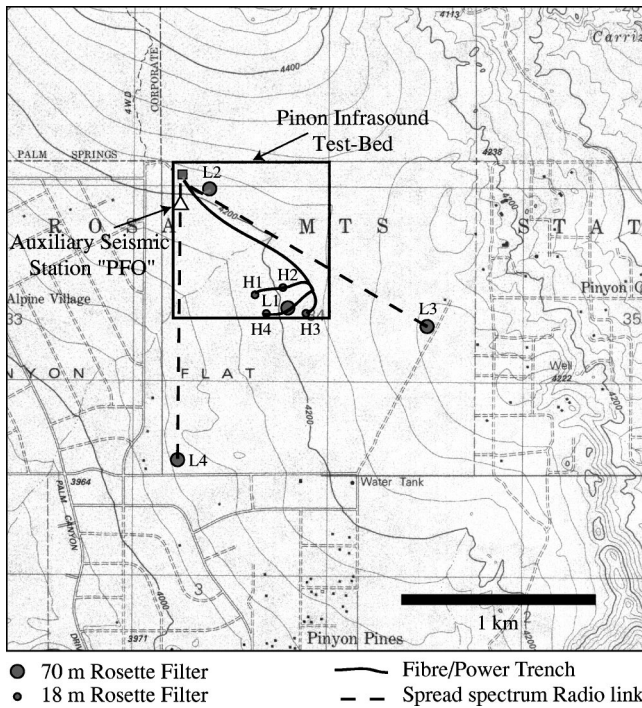

FIG. 1. The eight-element infrasound array at Pinon Flat, CA comprises four long-period elements (L1–L4) in a centered triangle spanning less than 2 km and four short-period elements (H1–H4) in an irregular quadrilateral near the center. The terrain slopes down gently to the southwest. The contour interval is 40 ft. (12.2 m).

erro (1998) consists of several clusters, or rosettes, of low-impedance inlets. Low-impedance inlets are preferred as they require essentially no maintenance. Each inlet in a cluster is connected to a “secondary” summing manifold by a solid pipe. A solid pipe connects each secondary summing manifold to one primary summing manifold or directly to the sensor. All pipes are solid, and thus all acoustic energy that propagates to the sensor enters the filter via the inlets. The signals are integrated acoustically at the summing manifolds. Christie (Provisional Technical Secretariat, Comprehensive Nuclear-Test-Ban Treaty Organization) has proposed several modifications to Alcoverro’s original rosette design (Christie, 1999). The Christie rosette filters range from 92 ports distributed over an area 18 m across to 144 ports spanning an area 70 m across (Fig. 2). The smaller filter is considered to be more effective at high frequencies at windy sites. The 70-m aperture filter is considered appropriate for windy sites that require suppression of noise between 0.02 and 0.7 Hz.

C. Resonance in rosette filters

As discussed by Hedlin *et al.* (2003) and Alcoverro and LePichon (2004), one drawback of the rosette filter design currently in use at IMS array sites is internal resonance. Impedance discontinuities exist at the inlets to the summing manifolds, the microbarometer, and the inlets. The resonance is predicted and observed above 3 Hz in data from the 18-m rosette systems (Fig. 3). Resonance peaks exist above 0.7 Hz and peaks at 2.65 and 7.95 Hz in data from the 70-m rosette systems (Fig. 3). Due to attenuation, the resonant energy is seen in data from the 70-m rosettes at all frequencies above 0.7 Hz. Higher overtones are believed to exist at higher fre-

FIG. 2. Two rosette filters considered in this paper are shown to scale with a National Football League playing surface (dashed rectangle). The playing surface is 50 m wide by 112 m long. The 18-m filter comprises 92 low-impedance inlets in four rosettes. The 70-m filter comprises 144 inlets arranged in eight rosettes. In both filter designs, the inlets are connected by solid pipe to secondary summing manifolds at the center of each rosette. The secondary manifolds are connected to a primary manifold, which is connected by a short pipe to the sensor. Each inlet is located the same distance along solid pipe from the sensor. Signals arriving from directly above the filter are summed in phase. Adjacent ports in the 70-m filter are separated by 2.79 m. Adjacent ports in the 18-m filter are 0.85 m apart. For this study, we used the filters at locations L2 and H1 in the array IS57. The first experiment involved simplified rosette filters consisting of eight 27 m pipes attached to a primary summing manifold. These filters are shown to scale in this figure as the solid black lines. The inlets in some of the filters were fitted with capillaries.

quencies but are removed in our data by the anti-aliasing filter, which takes effect at 8 Hz. The resonance is observed at all wind speeds (Hedlin *et al.*, 2003; Alcoverro and LePichon, 2004). The resonance results in an increase in noise levels and the signal waveform may be significantly distorted.

D. Rationale for this study

There are two primary objectives for this study. The first is to identify the reflection points that give rise to resonant energy in the passband below 8 Hz in the 18- and 70-m rosette filters. Toward this end we present data collected by simplified rosette filters that comprise just eight inlets and span 54 m (Fig. 2). We use the theory of Alcoverro and LePichon (2004) to model the frequency response of the simplified and full rosette filters. The second, and key, objective of this paper is to investigate the use of impedance matching capillaries to suppress, or remove, resonance from these fil-

FIG. 3. Predicted amplitude and phase response of the 18-m/92-rosette filter (dashed curve) and the 70-m/144-rosette filter (solid curve) for one inlet. The resonance peaks coincide with significant change in the phase response of the filter. The long-period response is given by $-20 \log_{10}(N)$, where N is the number of inlets.

ters. We predict theoretically the response of simple and full rosette filters equipped with impedance matching capillaries and compare the theoretical results with recorded data. We use continuous recordings of atmospheric noise and a large acoustic signal to validate the theoretical results.

II. THE PINON FLAT INFRASOUND TEST-BED

All of our experiments have been conducted at the infrasound test-bed at the Pinon Flat Observatory in southern California. The observatory is described in detail by Hedlin *et al.* (2003) and so only a brief description is given here. The observatory is located in the desert south west of Palm Springs. This site has been useful for studies of infrasonic wind-noise reducing systems as wind speeds vary from near zero at night to above 15 m/s during the day. The observatory is sparsely vegetated with Pinon pine trees and there is essentially no ground cover. The IMS infrasound array IS57 is located at the observatory (Fig. 1). The array comprises eight sensors on a baseline of 2 km and uses both the high-frequency, 18-m, and low-frequency, 70-m, rosette filters described earlier.

III. EXPERIMENTAL LAYOUT

A typical experimental layout is as described by Hedlin *et al.* (2003). Each site includes an MB2000 aneroid microbarometer. The pressure data are low-pass filtered below 8 Hz and sampled at 20 sps by a Reftek digitizing system. Air temperature and wind velocity were collected at 1 sps at heights of 1 and 2 m, respectively. Data from the temporary sites were transmitted in real-time to our laboratory in La Jolla via a 2.2-GHz spread-spectrum radio link. All recording

devices were housed in insulating cases to shield them from the extreme desert conditions. In all experiments, one microbarograph sensor was attached to a single, low-impedance, inlet located 5 cm above the ground and was used to indicate the level of background noise. All other sensors were attached to a noise-reducing system. With the exception of two sites, all systems were deployed temporarily. Two of the sites used for this study are in the IMS infrasound array IS57. Data from the array sites were transmitted to our laboratory via phone lines.

IV. PRELIMINARY TESTS OF CAPILLARIES

A. Observed and predicted resonance

The infrasonic noise-reducing filter developed by Daniels in the late 1940s comprised a single pipe with inlets distributed along its length (Daniels, 1959). The prototype was 603 m long with 100 inlets. The pipe diameter, and thus its characteristic impedance, changed, in steps, at each of the inlets, the section increasing toward the sensor. The acoustic impedance of each inlet was selected in the aim that the parallel combination of the inlet and the characteristic impedance of the small pipe was equal to the characteristic impedance of the larger pipe at the location of the inlet. Acoustic energy propagating in the pipe away from the sensor would not reflect back to the sensor, but impedance and time lag at each inlet are different.

As shown in Fig. 2, a rosette filter consists of inlets connected via solid pipes and summing manifolds to a microbarograph located at the center. In the 70-m rosette filters in use at the IMS array IS57, the pipes connecting the central, primary, summing manifold with the secondary summing manifolds are 27 m long, with an internal diameter of 2.1 cm. The characteristic acoustic impedance of these pipes is 1.202 mega-ohms ($M\Omega$), where acoustic resistance is calculated using SI units (i.e., Ns/m^5). The secondary summing manifolds are connected via 8-m-long pipes to the inlets. These pipes have an inner diameter of 1.6 cm and a characteristic impedance of 2.07 $M\Omega$. As discussed by Hedlin *et al.* (2003), resonance peaks are observed at 2.65 and 7.95 Hz. Resonance modeling reproduces these resonance peaks (Fig. 3) and indicates that the reflections that give rise to these peaks occur at the secondary and primary summing manifolds. Data from the 18-m rosette filters do not exhibit a prominent spectral peak due to resonance, but a gradual increase in energy with increasing frequency above 2 Hz. Peaks above the Nyquist frequency at 10 Hz are predicted (Fig. 3).

To verify that the reflections that produce significant resonance peaks below 10 Hz are caused by reflections at the summing manifolds, and not at the inlets, and that capillaries can remove the resonant energy without also attenuating the signals of interest, we conducted a field experiment with simple, eight-arm, filters. As shown in Fig. 2, we constructed filters that spanned 54 m, or exactly the area inside the secondary summing manifolds in a 70-m rosette filter. A simple, eight-arm, filter is depicted in Fig. 2 as the solid black lines.

The experiment with simple filters occurred from 1 November, 2001 to 14 January, 2002. For this experiment, we

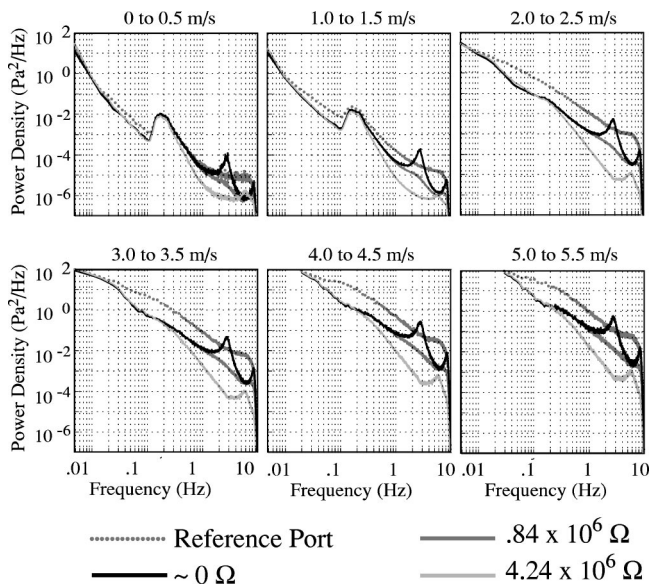

FIG. 4. Robust estimates of the dependence of infrasonic noise on wind speed and frequency can be obtained by stacking spectral estimates taken at different times but during similar wind conditions. To accomplish this, we associate each spectral estimate with a single wind-speed value: the average wind speed from the 15-m interval spanned by the spectrum. We stack spectral estimates after binning them by wind speed into bins that span 0.5 m/s starting at 0.0 m/s. The six panels in this figure show binned and stacked spectra taken at the reference port (dotted) and three eight-arm simple “rosette” filters. The filters were identical except for the acoustic resistances installed at the inlets. The black curves represent data from the filter with no acoustic resistance installed at the inlets. The dark gray and light gray curves represent data from filters with intermediate and high acoustic impedance capillaries installed at the inlets.

co-located three simple filters with a reference site. The simple filters used in this test were identical, except at the inlets. One filter (black curves in Fig. 4) was equipped with low-impedance inlets. The other two filters were equipped with capillaries at each of the inlets. One filter (dark gray curves) included acoustic resistances at the inlets of 0.84 MΩ. The other (light gray curves) was equipped with higher acoustic resistance at the inlets of 4.24 MΩ. These resistances were selected to bracket the characteristic impedance of the 27-m pipes connecting the inlets with the primary summing manifold and the microbarograph at each site.

Spectra from the four sites are displayed in Fig. 4. In this figure, we show binned and stacked spectral density from the four sites at wind speeds ranging from 0–0.5 m/s to 5.0–5.5 m/s. In each panel, the dotted curves represent ambient noise levels recorded at the reference site. The growth of infrasonic noise levels with increasing wind speed is evident. As shown in Fig. 4, the system with open inlets produces a substantial resonance peak in the data at 2.65 Hz at all wind speeds. The first resonance peak in data from the full 70-m rosette filters was also observed at 2.65 Hz (Hedlin *et al.*, 2003). This provides empirical evidence of the finding made by Hedlin *et al.* (2003) that the reflections that give rise to the resonance at this frequency are occurring at the secondary summing manifolds, and not at the inlets. The lowest resonant frequency is determined by the propagation time in the longer (27 m) pipe in the noise filter.

As shown in Fig. 4, it is possible to blunt, or entirely remove, the resonance peak at 2.65 Hz by adding acoustic

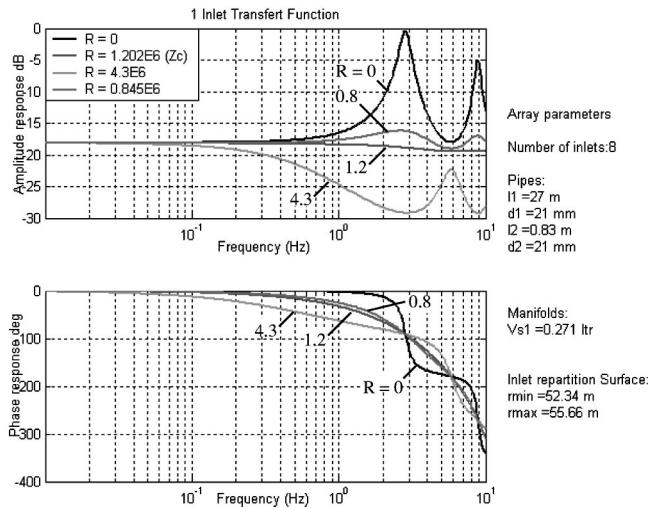

FIG. 5. Theoretical predictions of amplitude and phase response for the eight-arm “rosette” filter systems. The theoretical predictions match closely the spectra obtained from recorded data.

resistance at the inlets. The system with inlet resistance that is less than the characteristic impedance of the pipe shows some evidence of resonance. The system with the high inlet resistance shows a marked decrease in noise levels at 0.3 Hz with no resonance peak at 2.65 Hz. A resonance peak is observed at 5.3 Hz, or exactly double the frequency of the unmodified system. The spectral results indicate that resonance can be controlled by adding acoustic resistance at the inlets, but suggests that high resistance will attenuate the energy across a broad band.

The response of the eight-arm “simple” filters has been calculated using the method of Alcoverro and Le Pichon (2004). Four simple filters were considered. The first three were exactly as tested in the field. The fourth filter included acoustic resistance at the inlets of 1.202 MΩ, equal to the characteristic impedance of the 27-m pipes leading to the primary summing manifold. The capillaries are modeled as a pure resistance with a value depending on the diameter and the length of the small pipe used. These elements are inserted in the electro-acoustic scheme described by Alcoverro and Le Pichon (2004) between manifold and pipe or between the radiating impedance and the pipes at the input of the circuit. The capillaries could be inserted elsewhere inside the model if required. The frequency response is calculated from this modified electro-acoustic scheme by a matrix method. Using this method, noise reduction could also be simulated but is not presented here. These results are summarized in Fig. 5. The simulations correctly predict both the position of the resonance peaks and the amplitude for each of the systems tested in the field. The system with no acoustic resistance at the inlets is predicted to yield resonance at 2.65 Hz, 15 dB above the system with intermediate resistance. The system with 4.24 MΩ capillaries shows an 11-dB attenuation near 3 Hz. This is exactly what was observed in the recorded data (Fig. 4). The anti-aliasing filter applied to the recorded data complicates comparison of the higher frequency resonance peak at 7.95 Hz. Only the synthetics calculated for the system with capillaries at the inlets with acoustic resistance

FIG. 6. An acoustic signal recorded by the reference site and the eight-arm filters. As expected, the system with the high acoustic impedance capillaries at the inlets overattenuates both the noise and the signal. The system with no acoustic resistance at the inlets (second trace from the bottom) produces highly resonant recordings. Only the system with the intermediate acoustic resistance capillaries ($0.84 \text{ M}\Omega$) installed at the inlets provided a recording that closely resembles the one provided by the reference site.

equal to the characteristic resistance of the pipes leading to the primary summing manifold are predicted to have no resonance peaks.

B. Analysis of a signal

On 21 November, 2001, a large signal was recorded by all systems in this experiment. Analysis of IS57 array data places the source at an azimuth of 240° . The phase velocity of the energy was 330 m/s . Although the cause of this signal remains unknown, the signal was coherent across the IS57 array and the simple spatial filters considered in this experiment, and provides an opportunity to examine the effect of capillaries on incident signals. As shown in Fig. 6, the incident wavetrain spans $\sim 40 \text{ s}$. The recordings of the signal via the reference site, and via the simple filter equipped with low impedance inlets, are similar, however the data from the filter exhibits a substantial coda. The signals recorded by the reference system are more impulsive. The system with intermediate acoustic resistances ($1.202 \text{ M}\Omega$) installed at the inlets produced a recording of the event that matches, much more closely, the character of the reference recording. The system with high resistance capillaries ($4.3 \text{ M}\Omega$) installed at the inlets produced a heavily attenuated copy of the signal. As predicted by the theory, the resistance above the characteristic impedance of the pipe overattenuates signal and noise at frequencies above 0.1 Hz by 11 dB . The high-impedance capillaries are predicted to low-pass filter the data below 0.2 Hz . The high inlet resistance that has proved able to remove much of the resonance has had an obvious, negative, effect on the incident signal.

V. TESTS OF CAPILLARIES ON ROSETTE FILTERS

The theory of Alcoverro and LePichon (2004) has been used successfully to estimate the effect of acoustic resistance

FIG. 7. Simulations of the original and modified 70-m aperture rosette filter frequency responses are shown in this figure. The systems with capillaries at the inlets (modification 1), at secondary summing manifolds in the pipes leading to the primary summing manifold (modification 2), at both the inlets and the secondary summing manifolds (modification 3), at the inlets and both summing manifolds (modification 4) are represented by the heavy black, heavy gray, heavy dashed black, and heavy dashed gray curves, respectively. The unmodified system is represented by the light dashed curves.

at the inlets of simplified rosette filters on resonance. The theory has further indicated that adding acoustic resistance at the inlet equal to the characteristic impedance of the 27-m -long pipe will remove all evidence of resonance near 2.65 Hz . Having validated the theory on simple filters, we now turn to full rosette filters.

A. Predictions of noise reduction in 70-m rosettes

We begin with the 70-m rosette filters in use at the IS57 infrasound array and shown in detail in Fig. 2. As shown in Fig. 7 (heavy solid black curve; modification 1), adding $2.07 \text{ M}\Omega$ acoustic resistance at the inlets, equal to the characteristic impedance of the 8-m pipe connecting the inlets with the secondary summing manifolds, reduces the resonance peak corresponding to the first fundamental frequency inside the 8-m pipes, near the Nyquist frequency. As shown by the heavy solid gray curve in the same figure, installing $1.202 \text{ M}\Omega$ acoustic resistance (capillaries 0.051 and 0.024 m in diameter) at each secondary summing inside the 27-m pipes leading to the primary summing manifold (modification 2) removes the main resonance peak near 2.65 Hz and its odd overtone near 7.95 Hz . The resistance at the secondary summing manifolds removes the fundamental resonance peak at 2.65 Hz and the first, odd, overtone near the Nyquist, but leaves the fundamental resonance occurring in the shorter pipes in the rosette clusters. The 180° phase shift that occurs at 2.65 Hz in the open system is blurred across a broader frequency band in the system that includes capillaries at the secondary summing manifolds.

It is possible to attack both the resonance occurring in

FIG. 8. Wind speeds during the experiment with the 70-m rosette filters.

the 27-m pipes, and the resonance in the 8-m pipes, by adding capillaries at the secondary summing manifolds and at the inlets (modification 3). A simulation of this is represented by the heavy dashed black curve in Fig. 7. Resonance energy above 5.0 Hz can be largely removed by modifying the filter in this manner. The resonance peak observed above 10 Hz (the heavy dashed black curve in Fig. 7) is due to resonance in the pipe that connects the primary summing manifold to the sensor. This can be removed by installing another 2.07 M Ω capillary adjacent to the primary summing manifold in that pipe. Synthesis of this modification (the fourth) is represented by the heavy dashed gray curves in Fig. 7.

As pointed out by Hedlin *et al.* (2003), the additional labor of installing capillaries at the 144 inlets and in the pipe between the primary summing manifold and the sensor is unlikely to be beneficial as the plane wave response of the filter to nonvertically incident signals severely attenuates energy above 3–4 Hz. The response of the system with capillaries at the primary and secondary summing manifolds as well as at the inlets is also not flat above 1 Hz. For these reasons, we proceeded with a test of capillaries at the secondary summing manifolds only.

B. Experiments with 70-m filters

To test the theoretical predictions, we installed 1.202 M Ω capillaries adjacent to the secondary summing manifolds in the main pipes leading to the primary summing manifold at the “L2” site in the array IS57. The other three 70-m filters (L1, L3, and L4 identified in Fig. 1) were left unchanged to provide a reference. We also collected pressure data with a microbarometer attached to a single inlet. The wind speed during this experiment before, during and after the modifications at L2 is shown in Fig. 8. The experiment spanned 11 days in March 2002. Diurnal variations in the wind speed are seen throughout the experiment with wind

FIG. 9. Spectral density estimates taken from data collected at four 70-m rosette filters before any were modified. All spectra show significant resonance peaks at 2.65 and 7.95 Hz.

speeds varying from near zero to above 3.5 m/s. The wind speeds before the modification of L2 were slightly higher than those recorded after the change.

Stacked power spectral estimates from all 70-m filters prior to the installation of the capillaries at site L2 are shown in Fig. 9. The resonance peaks are evident in the data from all sites. In Fig. 10 we show a photograph of one capillary and a diagram showing its location in relation to the secondary summing manifold. The installation of each capillary required one person \sim 2 h. In Fig. 11, we show power spectral estimates taken from data collected after all eight capillaries were installed in the L2 filter. The results are striking. Very significant resonance peaks are observed in the data from the unmodified filters. No evidence of resonance in the data from the modified filter is seen below 5.0 Hz. The only sign of resonance, as predicted by the calculations shown in Fig. 7, is seen between 5 and 8 Hz. This is beyond the optimal pass-band of the 70-m rosette filters (Hedlin *et al.*, 2003).

C. Theory and experiment with 18-m rosette filters

As predicted in Fig. 3, resonance is expected to become apparent in data collected via the 18-m rosette filter at \sim 2.0 Hz. It is expected to rise to \sim 15 dB above background by 10 Hz. The problem with resonance in the 18-m rosette filters is less significant than it is in the large-aperture rosette filter considered in the previous section. As shown in Fig. 12, simulations of 18-m rosette filter frequency response equipped with impedance matching capillaries at both the secondary summing manifolds and at the inlets indicate that these can further improve the amplitude response of the filter. However, the phase shift is predicted to deviate from zero at frequencies below 1 Hz. In Fig. 12, we show the predicted amplitude and phase response of three 18-m rosette filters. The unmodified filter response is given by the dashed curve. The first resonance peak is centered just above 11 Hz and is due to resonance between the summing manifolds. A 180 $^\circ$ phase shift occurs at that frequency. A second reso-

FIG. 10. A photograph of a capillary plug installed in a pipe connecting the primary and secondary summing manifolds. The capillary was installed 30 cm from the secondary summing manifold as shown in the lower diagram. The other pipes shown in the photograph connect the secondary summing manifold with inlets.

nance peak is observed near 19 Hz and is due to resonance in the inlet clusters between the inlets and the secondary summing manifolds. Installing 2.07 M Ω capillaries at the inlets removes the higher frequency resonance peak but leaves most of the resonant energy below the Nyquist frequency at 10 Hz. Installing 2.07 M Ω capillaries adjacent to the second-

FIG. 11. Spectral density estimates taken from data collected after the capillary plugs were installed at site "L2" (black curve). The capillaries have removed the resonance peak at 2.65 Hz.

FIG. 12. Theoretical predictions of amplitude and phase response for the 18-m filter with and without capillaries. The unmodified filter is represented by the dashed curves. The filter with capillaries at the inlets, at the secondary summing manifolds, and at both locations are represented by the solid black, dotted black, and solid gray curves.

ary summing manifolds in the pipes leading to the primary summing manifold effectively removes the resonance between the summing manifolds. The amplitude response is improved by 13 dB at 10 Hz (dotted black curve in Fig. 12). When the system is equipped with capillaries at both inlets and secondary manifolds, the frequency response is flat up to 20 Hz (gray curve in Fig. 12). In Fig. 13, we show stacked spectra taken from all four 18-m rosette filters at the IS57 array before any were modified. The unmodified 18-m filters are inferior to the modified long-period 70-m filter at all frequencies. As shown by Hedlin *et al.* (2003) and by Alcoverro and LePichon (2004), unmodified 70-m filters outperform the 18-m filters only at frequencies below ~ 1.0 Hz.

Figure 14 shows spectral density estimates from the reference site and from an 18-m rosette filter before and after the capillaries were installed at the secondary summing manifolds. The capillaries remove the resonance above 1 Hz. The overall decrease of noise levels at all frequencies above 0.05 Hz is due to atmospheric conditions and is not due to the capillaries. Data from the unmodified 18-m filters showed the same decrease in energy.

VI. CONCLUDING REMARKS

Our research indicates that the reflections that produce resonance below 10 Hz in the 18- and 70-m rosette filters occur at the summing manifolds connected to the end of the longer pipe. Reflections that occur at the inlets artificially inflate spectral amplitudes at frequencies above 5 Hz. We find the theoretical method of Alcoverro and LePichon (2004) accurately predicts the frequency response of rosette

After Installation of Capillaries at L2

FIG. 13. Spectral density estimates from sites L1, L2 (both 70-m rosettes) and the 18-m rosettes. The data were taken after the L2 filter (black curve) was modified with the capillaries but before any modifications were made to the 18-m filters. The modified L2 70-m filter outperforms the unmodified 18-m filters at all frequencies. The resonance energy is first seen in the data from the 18-m rosette filters (the dark gray curve) at ~ 1 –2 Hz. The peak observed in all spectra between 0.1 and 0.2 Hz is due to microbaroms (Donn and Posmentier, 1967).

filters. The method also accurately predicts the effect of capillaries installed at any point inside the filters.

We conclude that the greatest gain in performance of the rosette filters is produced by installing impedance matching capillaries adjacent to the secondary summing manifolds in the pipes leading to the primary summing manifold. Installation of capillaries at the inlets is physically demanding, due to the large number of inlets involved, and offers little if any benefit to sensitivity of the filters due to the plane-wave response of the filters. As shown by Hedlin *et al.* (2003), the

FIG. 14. Spectral density estimates from the reference site (upper curve) and from an 18-m rosette filter before (gray curve) and after (lower black curve) the capillaries were installed at the secondary summing manifolds. The capillaries have removed the resonance above 1 Hz. The observed decrease of noise levels at all frequencies above 0.05 Hz is not due to the capillaries but is due to atmospheric conditions.

plane wave response of the 70-m system is strongly dependant on frequency above 3 Hz. Above 5.0 Hz, much of the energy is attenuated. Adding capillaries at the inlets attacks resonant energy in a band that is already of limited value for the study of infrasonic signals.

There is an additional, practical, motive for not installing capillaries at the inlets but placing them in the interior of the filter. The capillary plugs installed in the 70- and 18-m rosette filters have an inner diameter of 2.4 mm. The desired acoustic resistance was achieved by varying the length of the capillary. Although the capillaries have been shown to provide an effective reduction of resonance inside the rosette filters, it will take long-term exposure to the elements to determine if the capillaries will, in practice, remain clear and remain effective without adverse side effects. If, with time, the capillaries become partially, or fully, occluded, the response of the overall rosette filter will be degraded. A fully occluded capillary will reduce the overall reduction of long-period noise provided by the filter by rendering useless an entire rosette of inlets. Partially occluded capillaries would have other adverse effects on the data as we have seen; the phase shift of the filter is determined, to some extent, by the capillary resistances. The rosette filters are not used alone, but as part of an array. It is essential that the amplitude and phase response of all filters in the array be matched. If changes in the acoustic resistance of the capillaries changes with time, and in a manner that differs between filters, the overall response of the array could be degraded. A bias could be introduced into the azimuths obtained from the array data.

Regardless of the location of the capillaries, theoretical tests using the method presented by Alcoverro and LePichon (2004) are required to determine the effect of one or more of the capillary plugs becoming partially or fully blocked by water, insects, etc. on the response of the individual filters and of the entire array. The long-term maintenance of these systems might involve periodic inspection and clearing of the capillary plugs.

Rosette spatial filters are used at almost all IMS infrasound arrays. All new filters include resonance-suppressing capillaries installed adjacent to the secondary summing manifolds, as described in this paper. Many of the existing filters are now being retro-fitted with capillaries. As a result, we anticipate an abundance of data in the near future will allow researchers to address these issues.

ACKNOWLEDGMENTS

The authors are indebted Chris Hayward (SMU) and Doug Christie (CTBTO) for suggesting that we experiment with capillaries. (Received 8 October 2004; revised 13 January 2005; accepted 17 January 2005)

A wide variety of acoustic systems has multiple sources and receivers. This paper proposes a technique for making acoustic measurements simultaneously for multiple sources. The proposed technique features a collection of excitation signals of the maximum-length sequence (MLS) and MLS-related classes. Each signal in the set has a pulse-like autocorrelation function, and the cross-correlation functions between arbitrary pairs of signals drawn from the set have peak values that are significantly lower than the peak magnitude of the autocorrelation functions. The proposed method is particularly valuable when characterization of multisource, multireceiver system must be accomplished in a limited time period. Both simulation and experimental results are presented that demonstrate the feasibility and fidelity of the proposed techniques in characterizing acoustic systems. © 2005 Acoustical Society of America. I. INTRODUCTION

A previous paper¹ presented a technique using reciprocal pairs of maximal-length sequences (MLSs) in simultaneous dual-source channel measurements. Impulse responses between two separate sources and one or several receivers of acoustic systems can be determined simultaneously. The simultaneous dual-source measurements exploit excellent cross-correlation properties of reciprocal MLS pairs. Once the number of simultaneous sources is higher than two, straightforward use of reciprocal MLS pairs cannot meet the need. Special attention must then be given to generation of a larger set of source signals that has acceptable properties for performing the simultaneous measurements.

Because of their favorable cross-correlation properties, certain sets of MLSs and MLS-related sequences have gained considerable attention in spread spectrum communication systems.² They are, however, not yet widely applied to acoustic systems, particularly in the area of simultaneous acoustic measurements. Recent research in sound propagation through atmosphere^{3,4} particularly calls for the simultaneous measurement technique. For this purpose, we propose here the application of a set of the MLSs and MLS-related classes in which all sequences of the set possess a *pulse-like* periodic autocorrelation function, while the periodic cross-correlation function between any pair of sequences drawn from the set has a peak value that is significantly lower than the peak value of the autocorrelation function. In general, the proposed technique is particularly valuable where multi-

source, multireceiver system characterization tasks must be accomplished in a limited time period.

In Sec. II we discuss the desired correlation properties of acoustic excitation signals that would be needed to accomplish simultaneous multiple source measurements in an ideal case. We then briefly describe suitable sets of acoustic signals based on binary MLSs and MLS-related sequences. This briefing relies heavily on the literature in the spread spectrum communication.^{2,5,6} Using these sets, simultaneous channel characterization can be accomplished to a suitable degree of accuracy. In Sec. III we present simulation and field measurements that demonstrate the feasibility of simultaneous channel characterization. Finally, we draw some conclusions in Sec. IV.

II. CORRELATION PROPERTIES OF MLS AND RELATED SEQUENCES

For simultaneous multiple acoustic source measurements (SMASM), let n and p denote the number of sources and receivers, respectively. Then, the p -element vector of received signals, \mathbf{r} , can be obtained from

$$\mathbf{r} = \mathbf{h} * \mathbf{s}, \quad (1)$$

where \mathbf{s} is the $n \times 1$ source signal vector, $\mathbf{h} = [h_{ij}]$ is the impulse response matrix of dimension $p \times n$, and “*” denotes the matrix periodic (circular) convolution operator. Each element of \mathbf{r} , \mathbf{h} , and \mathbf{s} is, again, a discrete function of time, but time dependency is suppressed for brevity. If the periodic cross-correlation function (PCCF) of excitation signals is

^{a)}Parts of this work have been presented at the 18th ICA, Kyoto, Japan.

^{b)}Electronic mail: xiangn@rpi.edu

$$\mathbf{s} \otimes \mathbf{s}^T = [\delta], \quad (2)$$

where the operator \otimes stands for the cross correlation, $[\delta]$ denotes the matrix each of whose diagonal elements is a discrete periodic delta function and each of whose off-diagonal elements are the all-zero function, then the impulse response matrix can be directly determined from¹

$$\mathbf{h} = \mathbf{r} \otimes \mathbf{s}^T. \quad (3)$$

Equation (3) indicates that the individual impulse response sequences, h_{ij} , between source j and receiver i , can be conveniently determined by cross correlating each received signal with each source signal provided the source signals possess the desired correlation property expressed in Eq. (2). Lüke⁵ pointed out, however, that signals that exactly fulfill this condition [Eq. (2)] neither exist nor can be constructed. Nevertheless, a careful selection or combination among MLSs of the same degree may yield a set of sequences approximately possessing the desired correlation property.

An n -stage linear feedback shift-register device can generate a binary MLS, $\{a(i)\}$, with a period of $L = 2^n - 1$. The positive integer, n , is said to be the degree of the MLS.^{7,8} The sequence obtained through correlation of one bipolar MLS $\{m(i)\}$ with $m_i = 1 - 2a_i$ or MLS-related sequence with another of the same degree, or cross correlation, is of practical significance for the SMASM technique, which has been known in the communication community for many years. They are, however, considerably less widely known in the acoustics community; therefore, a brief description of cross-correlation properties of various sets of sequences drawn from MLS and MLS-related classes is sufficient in the following.

A. Preferred MLS pairs and maximum connected sets

The sequence $\{b(i)\}$, where $b(i) = a(di)$ and d is appropriately chosen, is itself an MLS, known as a *factor-d decimation of the sequence* $\{a(i)\}$,⁶ the cross correlation of the sequences $\{b(i)\}$ and $\{a(i)\}$, will yield very small values. If the degree of an MLS is a multiple of 4, then a decimation factor⁹ $d(n) = 2^{(n+2)/2} - 1$ will lead to an MLS pair whose PCCF takes on only four values. For such decimations, the upper bounds on the four-valued PCCF is

$$l_4(n) = \frac{d(n)}{2^n - 1}. \quad (4)$$

If the degree of an MLS is not a multiple of 4, then an appropriate decimation of that MLS will yield pairs of MLSs having relatively small three-valued PCCF.^{6,10} For MLSs whose degrees are not a multiple of 4, some of decimation factors are of the form $d = 2^k + 1$ or $d = 2^{2k} - 2^k + 1$, where k is chosen such that $n/\text{gcd}(n,k)$ is odd,⁶ with $\text{gcd}()$ standing for the greatest common divider, the cross-correlation bounds take on preferred small values expressed by

$$l_3 = \frac{2^{\lfloor (n+2)/2 \rfloor + 1}}{2^n - 1}, \quad (5)$$

where $\lfloor x \rfloor$ denotes the integer part of the real number x . This paper will refer to both the three-valued and four-valued MLS pairs as preferred pairs. Their bound values are of prac-

tical significance for the SMASM techniques.

In addition to the preferred MLS pairs, reciprocal pairs of every binary MLS of degree n also possess small-valued PCCF (Refs. 1, 11) bounded by

$$l_r = \frac{2^{(n+2)/2} - 1}{2^n - 1}, \quad (6)$$

but not limited to three or four values.

Table I lists all bound values of preferred and reciprocal MLS pairs between degree 8 and 24 for an easy comparison. Figure 1 also shows the smallest bounds (logarithmic peak values) of the PCCF of preferred and reciprocal MLS pairs between degree 8 and 24. A careful comparison between columns in Table I and between Eq. (5) and Eq. (6) reveals that the small-valued PCCFs of the preferred MLS pairs are close to that of reciprocal ones for even-numbered degrees, while for the odd-numbered degrees the preferred MLSs are ap-

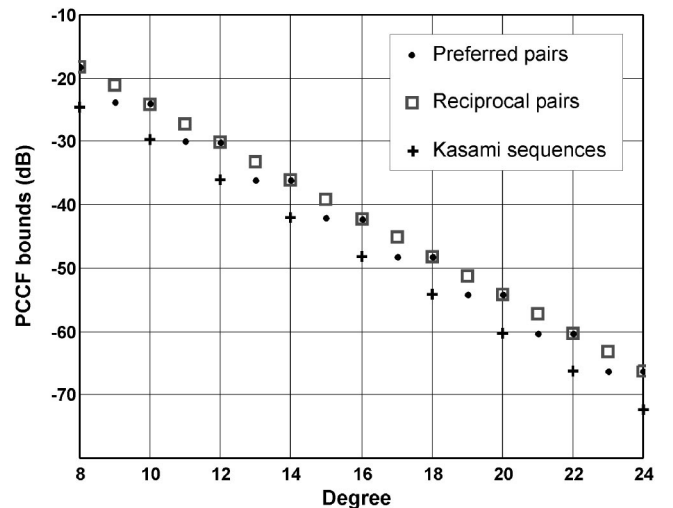

FIG. 1. Bound values of the cross-correlation functions of preferred and reciprocal MLS pairs along with bound values of Kasami sequences. The bound values are expressed in dB relative to the peak value of their auto-correlation function.

proximately one-half that for the reciprocal MLSs. For the current applications, one should not necessarily insist on having three- or four-valued PCCF as long as both their PACF and PCCF approximate the desired condition expressed in Eq. (2).

When specific applications require up to four simultaneous source signals, however, even one preferred MLS pair along with their individual reciprocal pairs will not yield the preferred smallest bound values among four of them. To be more precise, let $\{a(i)\}$ and $\{b(i)\}$ denote a preferred MLS pair of degree 14, and $\{a(i)\}$ and $\{a_r(i)\}$, $\{b(i)\}$, and $\{b_r(i)\}$ denote reciprocal pairs of each individual MLS, respectively. The PCCFs between $\{a(i)\}$ and $\{b(i)\}$, and between $\{a_r(i)\}$ and $\{b_r(i)\}$ are bounded by a preferred value of 0.0157, while the PCCFs between $\{a(i)\}$ and $\{a_r(i)\}$, and between $\{b(i)\}$ and $\{b_r(i)\}$ are bounded at a preferred value of 0.0156, as listed in Table I. However, the PCCFs between $\{a(i)\}$ and $\{b_r(i)\}$, and between $\{b(i)\}$ and $\{a_r(i)\}$ are bounded by 0.03, which is roughly twice the preferred small values.

Practical applications often need more than two simultaneous source channels. While a pair of MLSs selected from two different preferred pairs of the same degree may not possess the preferred small-valued PCCF as listed in Table I and plotted in Fig. 1, some pairs selected from different pairs do. A set of the MLSs for which each pair of the set has this preferred small PCCF values is referred to as a connect set. The largest possible connected set is termed a maximum connect set (MCS) (Ref. 10) and the size of such a MCS is denoted by M_n . In the literature,⁶ one can find the values of M_n for $n \leq 16$ with $M_n \leq 4$. The length of MLSs of these degrees and their reasonably low PCCF bound values are of practical interest in a wide variety of acoustic measurements. However, the number of MLSs in the MCS are strongly limited. One needs to use properly combined MLSs to form Gold and Kasami sequences.

B. Combination of MLS pairs

A binary Gold sequence $\{G_\rho(i)\}$ can be generated by combining a preferred, or a reciprocal binary MLS pair $[\{a(i)\}, \{b(i)\}]$ as¹⁰ $G_\tau(i) = a(i) \oplus b(i + \tau)$, with \oplus denoting addition module 2. In stepping τ point-by-point, a large number of Gold sequences result including the preferred MLS pair to yield a finite set $\{\{a\}, \{b\}, \{G_0\}, \{G_1\}, \dots\}$ containing exactly $L + 2$ sequences. Sequences in this finite set approximately fulfill the condition expressed in Eq. (2). PACFs of bipolar Gold sequences associated with $\{G_\tau\}$ are peaked at zero lag, but they also possess small-valued sidelobes. The PCCFs of Gold sequences possess the same bound value as that of the sidelobes of the corresponding PACF. In fact, the bound values are the same as those of the PCCF of the preferred and reciprocal MLS pairs from which the Gold sequences are derived.

For even-numbered degree n , a decimation from an MLS $\{a(i)\}$ with factor $\lambda(n) = 2^{n/2} + 1$ can lead to a pair $\{a(i)\}$ and $\{c(i)\}$ with $c(i) = a(\lambda i)$. In this case, $\{c(i)\}$ is not an MLS of degree n . A binary Kasami sequence $K_\tau(i)$ can be generated by combining $\{a(i)\}$ and $\{c(i)\}$ as $K_\tau(i) = a(i) \oplus c(i + \tau)$. In similar fashion, a set of Kasami se-

FIG. 2. Normalized correlation functions of Kasami sequences of degree 14. (a) Periodic autocorrelation function (PACF) of one sequence. (b) Periodic cross-correlation function (PCCF) between two Kasami sequences (shifted downwards beneath the autocorrelation function for a convenient comparison). The peak value of the PCCF is 42.1 dB lower than that of PACF. (c) Zoomed presentation of a segment from (a) showing three-valued sidelobes of the PACF. Their peak values are the same as those of the PCCF in (b).

quences $\{\{a\}, \{K_0\}, \{K_1\}, \dots\}$ can be constructed¹² containing $2^{n/2}$ sequences. The sidelobes of PACFs and the amplitude of PCCFs among these sequences present even lower bounds, approximately half of those of preferred pairs and Gold sequences

$$l_k(n) = \frac{\lambda(n)}{2^n - 1}, \quad (7)$$

where n must be a positive even number. Figure 1 also shows the bounds values of Kasami sequences in logarithmic scale along with those of preferred and reciprocal MLS pairs for comparison. The power spectral density functions of Gold and Kasami sequences are the same as that of MLSs, being of broadband nature and covering the entire frequency range. In order to demonstrate the excellent correlation properties of Gold and Kasami sequences, Fig. 2 shows the PACF and PCCF of a pair of Kasami sequences, derived from an MLS of degree 14 decimated by a factor of 129. In the example, the PCCF values and the sidelobes of the PACF are bounded by 0.007 87, or 42.1 dB below the peak value of the individual PACF. Unlike MLSs, the PACFs of Gold and Kasami sequences are pulse-like functions with small-valued sidelobes. They approximate the condition expressed in Eq. (2) to the required degree of accuracy, and they are equivalent to the MLSs drawn from MCSs with regard to their usefulness in the SMASM technique.

III. SIMULATION AND EXPERIMENTAL RESULTS

In this section we present simulation and experimental results to demonstrate usefulness of the lack of correlation among the MLSs from MCS and combined MLSs. Unlike applications in the spread spectrum technology, where MLS-related sequences are primarily used for coding or modulation, the acoustic measurement technique discussed in this paper employs the sequences directly for acoustic excita-

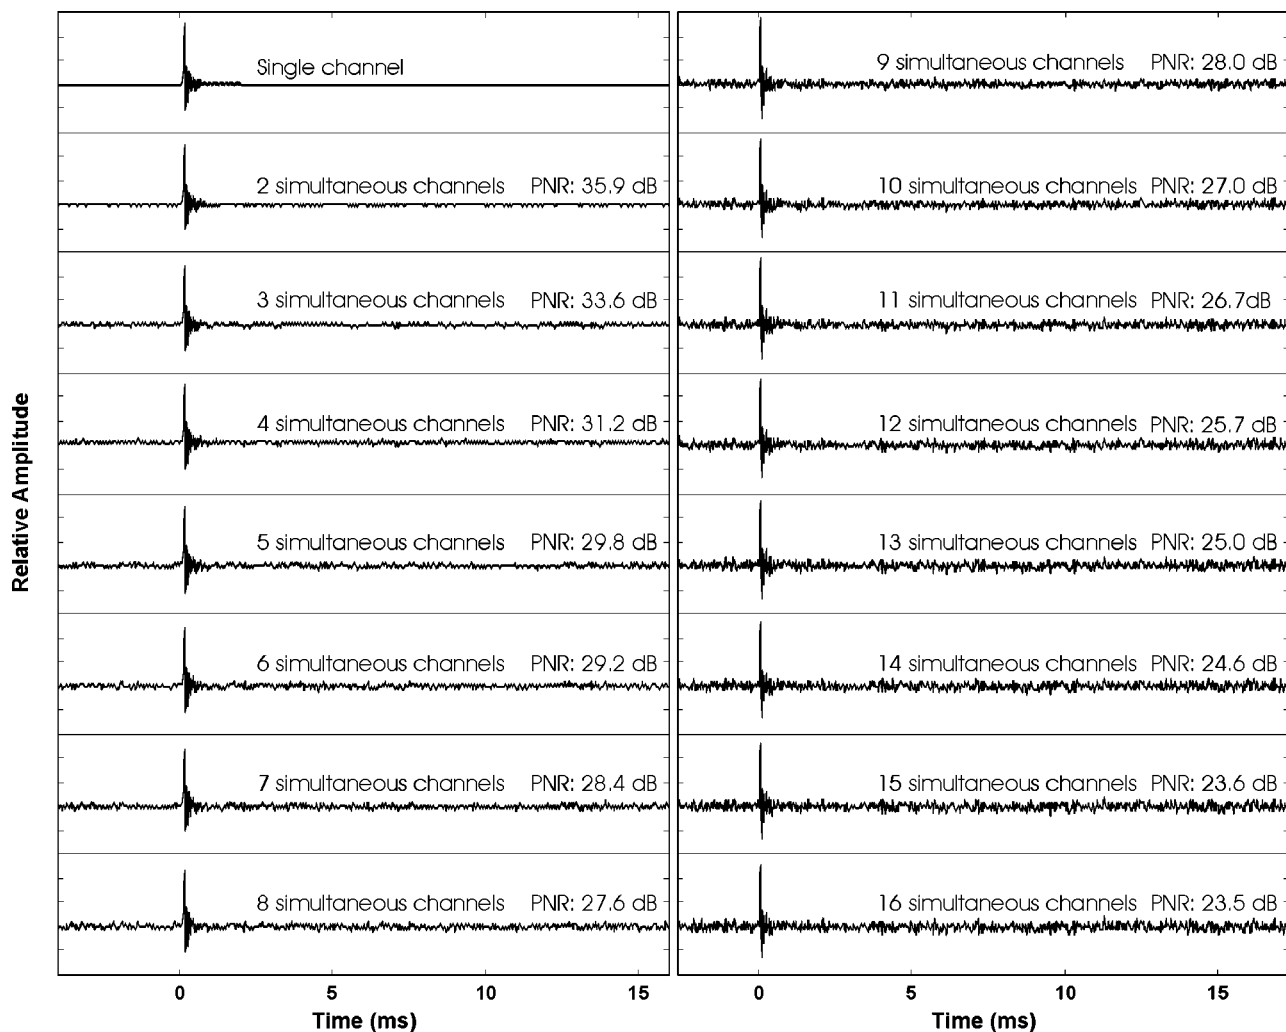

FIG. 3. Simulation results using digital filters to study the noise behavior of simultaneous multiple source measurements, Single channel, 2, 3,... and 16 simultaneous source channels are simulated. Impulse responses obtained using increasing number of simultaneous Kasami sequences of degree 14 are label by the number of simultaneous source channels and the peak-to-noise ratio (PNR).

tions. The acoustic channel responses are then cross correlated with the excitation sequences. Since these sequences are of length $2^n - 1$, conventional FFT cannot be employed directly. Fortunately the fast MLS transform (based on fast Hadamard transform) can be employed for MLSs and reciprocal MLSs.¹ When using combined sequences, however, one needs to exploit a specialized algorithm¹³ for calculating the PCCF.

A. Digital simulation

In order to understand the signal-to-noise ratio achievable in the SMASM applications, we apply a set of 16 bipolar Kasami sequences $\{\{k_1\}, \{k_2\}, \dots, \{k_{16}\}\}$ transmitted at a rate of 50 kHz to simulate acoustic channel experiments. Among them, $\{k_1\}$ is a single MLS of degree 14 and $\{k_2\}, \dots, \{k_{16}\}$ are Kasami sequences constructed by combining $\{k_1\}$ and $\{b\}$, with $b(i) = k_1(129i)$. The PCCFs among the 16 sequences possess the same small values as given in Table I.

Eighth-order low-pass Chebyshev filters, each having a cutoff frequency of 16 kHz, are used to simulate individual acoustic channels. Each individual sequence is filtered by

one low-pass filter separately. First one, then two, ..., then all 16 of the filter responses are summed to simulate the signal that would be received at one point and at a common point from two, three, ..., and all 16 simultaneous sources. The summed signals are then cross correlated with the MLS $\{k_1\}$ to obtain the impulse response associated with the source sending $\{k_1\}$. Figure 3 shows the impulse responses of a single source channel and of simultaneous multiple channels.

To quantify the quality of the impulse response, we define peak-to-noise ratio (PNR) as the ratio of its peak value to the rms value of noise, which is the difference between the exact value of the impulse response and the value calculated using our technique at each time epoch. More precisely, the signal received at receiver i is

$$r_i = \sum_{j=1}^{16} h_{ij} * s_j. \quad (8)$$

If we now correlate the received signal with s_k , we obtain the following approximation for h_{ik} :

$$\hat{h}_{ik} = h_{ik} + h_{ik} * (s_k \otimes s_k - \delta) + \sum_{j=1, j \neq k}^{16} h_{ij} * (s_j \otimes s_k). \quad (9)$$

Thus, the sequence

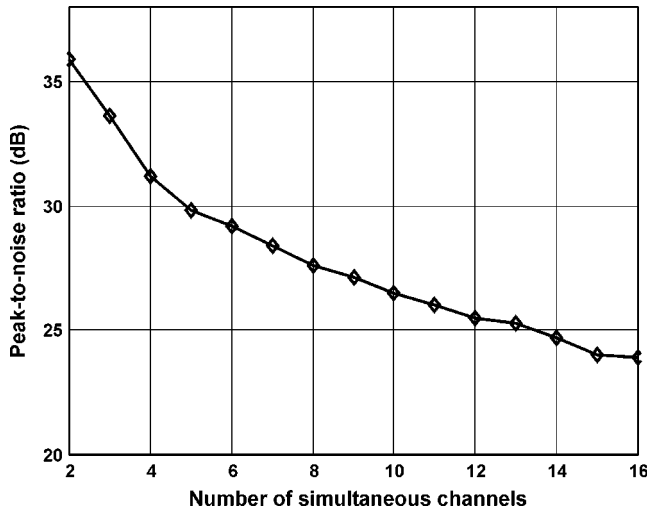

FIG. 4. Peak-to-noise ratios (PNR) as a function of simultaneous source channels, achieved using digital filters to simulate the acoustic channels. PNR obtained using Kasami sequences of degree 14 ranges from 35.9 dB down to 23.5 dB when the number of simultaneous source changes from 2 to 16.

$$e_{ik} = \hat{h}_{ik} - h_{ik} = h_{ik} * (s_k \otimes s_k - \delta) + \sum_{j=1, j \neq k}^{16} h_{ij} * (s_j \otimes s_k), \quad (10)$$

represents the error between the approximation for h_{ik} and its actual value, that is, it is a noise sequence. Thus

$$\overline{E_{ik}^2} = \frac{1}{L} \sum_{z=0}^{L-1} e_{ik}^2(x), \quad (11)$$

is the mean-squared error between h_{ik} and its approximation, \hat{h}_{ik} . If the autocorrelation function of s_k were a δ function, and s_j and s_k were uncorrelated for $j \neq k$, then the mean-squared error would be zero. Otherwise, the ratio of the peak value of h_{ik} to the rms noise value gives a measure of the quality of the estimate of h_{ik} .

Figure 4 shows the PNR achieved at individual numbers of simultaneous sources. The simulation results as shown in Fig. 3 and Fig. 4 indicate that the PNR in the SMASM decreases with increasing number of simultaneous source signals. The noise stems from the sidelobes of the autocorrelation and nonzero residuals of the cross-correlation operations as shown in Fig. 2. The higher the degree of the sequences used, the higher the PNR will be, as Fig. 1 implies. In a similar fashion, when cross correlating the resulting receiver signal in the simultaneous multiple source mode with MLS $\{k_2\}, \{k_3\}, \dots$, the impulse responses $\{h_{12}\}, \{h_{13}\}, \dots$ would be resolved.

The fast M-sequence transform¹ is used in an efficient calculation of cross correlation between MLS $\{k_1\}$ and the summed filter responses. When resolving impulse responses associated with combined MLSs $\{k_2\}, \{k_3\}, \dots$, the fast MLS transform cannot be used, but a specialized algorithm may be used for calculating PCCF.¹³

FIG. 5. Experimental results of times of flight for outdoor sound propagation analysis. (a) Four simultaneous sound sources and a single receiver. (b) Impulse response between a single source (#2) and the receiver (for comparison with h_{12}).

B. Experimental results

We now present a group of field measurement results achieved from exploratory experiments conducted outdoors. Four loudspeakers, which serve as sources, are separated 2 m from each other along a straight line. Perpendicular to this line, a microphone (receiver) is set 10 m away from the first sound source. The receiver to the farthest source is about 11 m. The sound sources and receivers are set 1.1 m above the outdoor ground surface. The sampling frequency for these measurements is 25 kHz. Four MLSs' selected from the MCS of degree 13 are used to simultaneously drive the sound sources. Figure 5(a) illustrates impulse response segments of the first 40 ms associated with four simultaneous sound sources. They are obtained by using the fast MLS transform¹ of the received receiver signal with each of the individual MLSs'. These simultaneous measurements of channel impulse responses yield slightly different arrival times due to different propagation distances of the acoustic wave, corresponding well to the geometry of the setup. Figure 5(b) shows the measured single source impulse responses of the channel between the second source and the receiver when only source two is energized. Although the single source measurement yields a better PNR, the single- and multiple source measurements clearly yield similar results.

An achievable PNR depends upon, among other things, available source power, the sensitivity and bandwidth of the sensors or receivers, the attenuation of the propagation channels, and the length of sequences. In practice, the achievable PNR can also be influenced by other unwanted noise, background noise, nonlinear or time-variant components within the system under test, resulting in a lower PNR. While SMASM cannot provide results of the identical quality that may be obtained through sequential measurement, a well-

designed SMASM can produce results meeting the requirements of all but the most demanding applications.

IV. CONCLUSIONS

The cross-correlation properties of maximum-length sequences (MLSs) and related signals make them good candidates for simultaneous multiple acoustic source measurements (SMASM). In this paper we have demonstrated that, by exploiting the cross-correlation properties of MLSs and MLS-related sequences—Gold and Kasami, in particular—SMASM becomes feasible. Both simulation and experimental results achieved from exploratory outdoor measurement have demonstrated the feasibility of using MLSs and combined MLSs for the SMASM technique. This proposed measurement technique would be especially useful when an application demands simultaneous, rather than sequential, excitation of multiple sources.^{3,4} When a sufficient number of single MLSs from a maximum connect set (MCS) can meet the need, a fast algorithm, the so-called fast MLS transform^{14–17} can be applied directly to retrieving impulse responses between simultaneous multiple sources and one or several receivers. Otherwise, additional Gold and Kasami sequences can be selected to meet the need. In the latter case, a specialized algorithm, such as the one documented in Ref. 13, must be applied.

Phase speed and attenuation in bubbly liquids inferred from impedance measurements near the individual bubble resonance frequency

Preston S. Wilson,^{a)} Ronald A. Roy, and William M. Carey

Department of Aerospace and Mechanical Engineering, Boston University, 110 Cummington Street, Room 101, Boston, Massachusetts 02215

(Received 30 July 2004; revised 21 December 2004; accepted 22 December 2004)

In the ocean, natural and artificial processes generate clouds of bubbles that scatter and attenuate sound. Measurements have shown that at the individual bubble resonance frequency, sound propagation in this medium is highly attenuated and dispersive. The existing theory to explain this behavior is deemed adequate away from resonance. However, due to excessive attenuation near resonance, little experimental data exists for a comparison with model predictions. An impedance tube was developed specifically for exploring this regime. The effective medium phase speed and attenuation were inferred from measurements of the surface impedance of a layer of bubbly liquid composed of air bubbles and distilled water, for void fractions from 6.2×10^{-5} to 5.4×10^{-4} and bubble sizes centered around 0.62 mm in radius. Improved measurement speed, accuracy, and precision is possible with the new instrument, and both instantaneous and time-averaged measurements were obtained. The phase speed and attenuation at resonance was observed to be sensitive to the bubble population statistics and agreed with an existing model [J. Acoust. Soc. Am. **85**, 732–746 (1989)], within the uncertainty of the bubble population parameters. Agreement between the model and the data reported here is better than for the data that was available when the model was originally published. © 2005 Acoustical Society of America.

I. INTRODUCTION

The acoustics of bubbly liquids is important to many areas of study, including acoustical oceanography, shallow water sonar, ship wakes, air/sea interfacial mass transfer, medical ultrasound, and nuclear reactor technology.^{1,2} Sound speed dispersion and attenuation in clean suspensions of bubbles is well understood when the acoustic excitation frequency is well below the resonance frequency of any bubble and the volume fraction of air is below a few percent. The volume fraction (VF) of air, or void fraction β , is defined as

$$\beta = V_g / V_m, \quad (1)$$

where V_g is the volume of the gas phase and V_m is the total volume of the mixture.

As the excitation frequency approaches the range of bubble resonance frequencies, the dispersion and attenuation grows rapidly. This effect is amplified further for bubble size distributions with sharp peaks. Commander and Prosperetti³ compared their propagation model to the experimental data available at the time and found poor agreement in such cases, even for void fractions as low as 3.7×10^{-4} . This has been attributed to the effects of multiple scattering between neighboring bubbles³ and experimental difficulties in measuring acoustic properties in the presence of high attenuation.⁴ Recently, a number of authors^{5–8} have put forward models that address multiple scattering. Unfortunately, experimental un-

certainty in the data that exists, and the absence of data for much of the parameter space, prevents an adequate evaluation of competing models.^{3,9} The fact that the data obtained by Silberman in 1957 is the most commonly cited data further emphasizes this situation.

There are two reasons for the scarcity of reliable experimental data for cases where resonance is important. (1) The attenuation, which is of $O(10)$ dB/cm and higher, prevents the use of traditional standing wave techniques. Even pulse propagation techniques fail because sound transmission beyond the near field of the source is not readily achieved. (2) Propagation in bubbly liquids is very sensitive to the void fraction, and to the bubble size and spatial distributions. A sufficiently accurate experimental determination and control of these parameters is difficult.

An approach designed to overcome these difficulties is described in the present work. In order to deal with the problem of high attenuation, measurement directly within the highly attenuating region of bubbly liquid was avoided. Instead, the frequency-dependent, complex impedance z_s at the surface of a layer of bubbly liquid was measured using a modified version of the standard two-sensor impedance tube.¹⁰ This was accomplished by measuring the acoustic pressures at two known positions within the bubble-free section of the impedance tube. Equations of plane wave acoustics^{10,11} were used to relate these acoustic pressures to the impedance at the interface between the bubble-free liquid and the bubbly liquid. This impedance is equivalent to the acoustic pressure/velocity ratio that would exist just inside the bubbly liquid if it were a homogeneous fluid. In the

^{a)}Current affiliation: University of Texas at Austin, Department of Mechanical Engineering; electronic mail: pswilson@mail.utexas.edu

present case, this measured impedance is equivalent to the effective impedance of the bubbly liquid and the effective propagation parameters are inferred from the measured impedance z_s . For the level of attenuation encountered in the present work, only plane progressive waves cross the measurement surface; therefore z_s is equivalent to the specific acoustic impedance $z = \rho c$. Since z is measured and the effective mixture density ρ is known, the phase speed and attenuation can be calculated from the complex sound speed c . Measurements of the phase speed and attenuation obtained in this way for a bubbly liquid composed of air and distilled water are presented. Void fractions ranging from 6.2×10^{-5} to 5.4×10^{-4} and bubble sizes centered around 0.62 mm in radius were investigated.

These measurements were compared with the model put forth by Commander and Prosperetti.³ The sensitivity of the model to input parameters is discussed in Sec. II. A description of the experiment is given in Sec. III. The results of a time-averaged experiment are discussed in Sec. IV. Finally, the results of a time-resolved experiment, used to investigate the effects of bubble population variability, are discussed in Sec. V.

II. OVERVIEW OF PROPAGATION MODEL

In 1989, Commander and Prosperetti³ brought together previously published results and composed a model for sound propagation in bubbly liquid which accounted for energy dissipation in a detailed way. Their final result is shown below for reference. Consider a host liquid with sound speed c_l , density ρ_l , viscosity μ , surface tension σ , and equilibrium pressure P_∞ . This liquid contains bubbles composed of a gas with thermal diffusivity D_g and ratio of specific heats γ . The bubbly liquid is treated like a homogeneous mixture in which the complex mixture sound speed c_m is given by

$$\frac{c_l^2}{c_m^2} = 1 + 4\pi c_l^2 \int_0^\infty \frac{a\varphi(a)da}{\omega_0^2 - \omega^2 + 2ib\omega}, \quad (2)$$

where ω is the circular excitation frequency and $\varphi(a)da$ is the number of bubbles per unit volume with equilibrium radius between a and $a+da$. The damping coefficient for a bubble of radius a driven at frequency ω is given by

$$b = \frac{2\mu}{\rho_l a^2} + \frac{P_{b,e}}{2\rho_l a^2 \omega} \text{Im} \Phi + \frac{\omega^2 a}{2c_l}, \quad (3)$$

where the three terms are due to viscous, thermal, and acoustic dissipation effects, respectively and $\text{Im} \Phi$ is the imaginary part of

$$\Phi = \frac{3\gamma}{1 - 3(\gamma - 1)iX[(i/X)^{1/2} \coth(i/X)^{1/2} - 1]}. \quad (4)$$

The bubble resonance frequency is

$$\omega_0^2 = \frac{P_{b,e}}{\rho_l a^2} \left(\text{Re} \Phi - \frac{2\sigma}{aP_{b,e}} \right), \quad (5)$$

where $\text{Re} \Phi$ is the real part of Φ . The definition,

$$X = D_g / \omega a^2, \quad (6)$$

TABLE I. Values of the physical parameters used for evaluation of Eq. (2).

$c_l = 1481 \text{ m/s}$	$D_g = 2.08 \times 10^{-5} \text{ m}^2/\text{s}$
$\rho_l = 998 \text{ kg/m}^3$	$P_\infty = 101.3 \text{ kPa}$
$\sigma = 0.0725 \text{ N/m}$	$\mu = 0.001 \text{ Pa s}$
$\gamma = 1.4$	

has been used and the quantity $P_{b,e}$ represents the equilibrium pressure in the bubble,

$$P_{b,e} = P_\infty + \frac{2\sigma}{a}, \quad (7)$$

where P_∞ is the hydrostatic pressure in the liquid. The wave number for propagation within the bubbly mixture can then be written from Eq. (2) as

$$k_m^2 = \frac{\omega^2}{c_l^2} + 4\pi\omega^2 \int_0^\infty \frac{a\varphi(a)da}{\omega_0^2 - \omega^2 + 2ib\omega}. \quad (8)$$

A. Sensitivity to small changes in bubble size

Small changes in bubble population parameters (or small uncertainties in their experimental determination) can have large effects on the (predicted) phase speed and attenuation in bubbly fluids. This will be demonstrated for different bubble size distributions using Eq. (2), assuming air bubbles in pure water at 20 °C and the corresponding physical parameters given in Table I.

Consider a monodisperse bubble population, given by

$$\varphi(a) = n\delta(a - \bar{a}), \quad (9)$$

where n is the number of bubbles per unit volume with equilibrium radius \bar{a} and the void fraction is

$$\beta = \frac{4}{3}\pi\bar{a}^3 n. \quad (10)$$

Substitution into Eq. (2) yields

$$\frac{1}{c_m^2} = \frac{1}{c_l^2} + \frac{4\pi\bar{a}n}{\omega_0^2 - \omega^2 + 2ib\omega}. \quad (11)$$

Phase speed V and attenuation coefficient A were calculated using Eq. (11) for void fraction $\beta = 10^{-4}$ and three bubble radii, $\bar{a} = 0.558, 0.62,$ and 0.682 mm. Both the phase speed and the attenuation curves, shown in Fig. 1, shift along the frequency axis as bubble size is varied. A small increase in peak attenuation is seen as bubble size decreases and the minimum phase speed increases slightly. The latter effect is not prominent on the logarithmically scaled axis, but is indeed present. The behavior of the attenuation for these parameters is governed by thermal dissipation, which is inversely proportional to the bubble radius squared.

Note that the pronounced effects shown in Fig. 1 are induced by only a 10% variation in bubble radius, or specifically, $\pm 62 \mu\text{m}$. The experimental ability to discern the difference between acoustic signals of 5.3 and 5.8 kHz (the frequencies of peak attenuation for the two smaller bubble sizes shown in Fig. 1) is often greater than our ability to discern the difference in the two corresponding bubble populations. If one were only interested in the size of a few

FIG. 1. The effect of the bubble size is demonstrated. Phase speed (upper) and attenuation (lower) is shown for void fraction $\beta = 10^{-4}$ and three bubble radii, which represent a $\pm 10\%$ change in radius.

bubbles this would not be the case; high magnification optical methods would provide sufficient resolution. However, when one endeavors to measure the sizes of hundreds of bubbles in motion, the statement bears a much greater significance.

B. Sensitivity to small changes in bubble size distribution width

The behavior of continuous bubble size distributions will now be considered. Foreshadowing what will be discussed in the experimental part of this work, the normal distribution will be explored. The probability density function of a normally distributed random variable is defined by

$$\varphi(a) = \frac{C}{s\sqrt{2\pi}} \exp\left[-\frac{(a-a_0)^2}{2s^2}\right], \quad (12)$$

where a_0 and s represent the mean value and the standard deviation of the distribution, respectively. Here, a_0 is taken to be the mean bubble radius, and C is used as a scaling parameter such that the void fraction β is given by

$$\beta = \frac{4\pi}{3} \int_{a_{\min}}^{a_{\max}} \varphi(a) a^3 da. \quad (13)$$

The purpose is to isolate the effect of increasing the standard deviation of the distribution, that is, the effect of widening the distribution.

Three distribution widths are considered, $s = 0.02, 0.03,$ and 0.04 mm, along with the following parameters: $\beta = 10^{-4}$, and $a_{\min} = 0.50, a_0 = 0.62, a_{\max} = 0.75$ mm. With $\varphi(a)$ thus described, Eq. (2) was evaluated numerically using an adaptive Simpson quadrature technique. The results are shown in Fig. 2. The peak attenuation varies about 1.8 dB/cm and the minimum phase speed varies by about 100 m/s. Again, the ability to acoustically detect the effects of

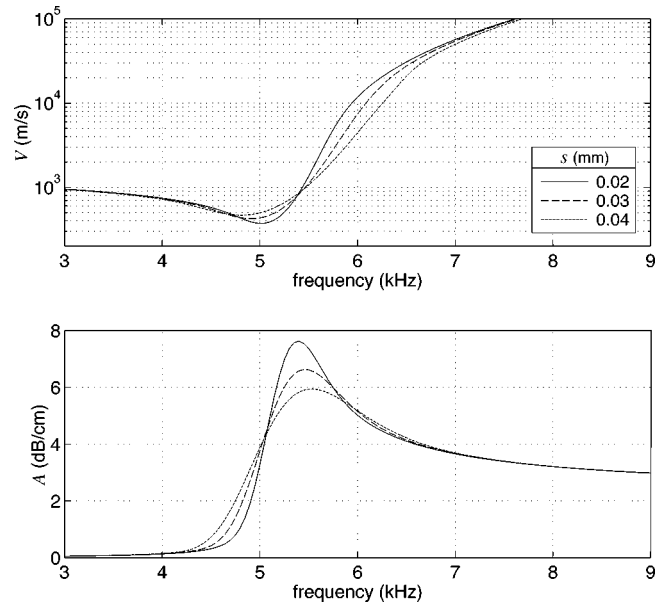

FIG. 2. The sensitivity to the distribution width is demonstrated. Phase speed (upper) and attenuation (lower) is shown for void fraction $\beta = 10^{-4}$ and three standard deviations s . The legend applies to both plots. Additional bubble population details are given in the text.

these distribution changes may be greater than the ability to detect and control the bubble population parameters in an experiment.

III. DESCRIPTION OF EXPERIMENT

An overview of the measurement procedure is given first and then the various subsystems will be described in greater detail. The bubbles were generated directly at the measurement plane of the impedance tube, by either a single needle, which was lowered down into the impedance tube, or with a bubble injection manifold (BIM) that fit inside the impedance tube and deployed multiple needles for higher void fractions. The needle and the BIM can be moved between the impedance tube and two other systems that were used to measure the bubble size distribution and the overall void fraction. The experimental procedure was composed of four subprocedures. The first subprocedure was the calibration of the impedance tube. The needle or BIM was then installed in an optical apparatus for the measurement of the bubble size distribution. When the needle was used, the void fraction was also measured in the optical apparatus. When the BIM was used, it was moved to a third apparatus for void fraction measurement. Finally, the needle or BIM was installed in the impedance tube and the surface impedance of the bubble layer was measured.

A schematic of the impedance tube system is shown in Fig. 3. Its construction, calibration, and operation have been described previously.^{10,12} Briefly, the system consists of a heavy-walled stainless steel tube (5.178 cm inner diameter, 2.541 cm wall thickness) with two custom fabricated wall-mounted hydrophones. The system was designed to admit waves that are plane (to a high degree of approximation), despite some coupling between the fill material and the tube wall. Acoustic excitation was provided by a Kildare Corporation TP-400/A piston source at the lower end. The bubbly

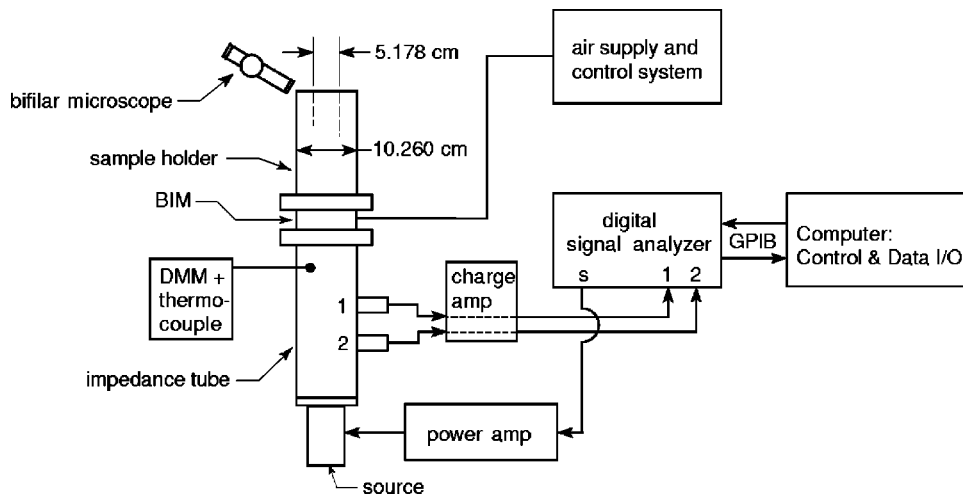

FIG. 3. The impedance tube system is shown in a schematic. The bifilar microscope is used during a calibration to measure the water height within the sample holder. The temperature of the impedance tube is monitored with a thermocouple and a digital multimeter. The remaining elements are discussed in the text.

liquid was contained within a sample holder mounted at the upper end. Signals were generated and received with a Hewlett-Packard HP89410A vector signal analyzer. The excitation signal was amplified by a Crown CE-1000 power amplifier and the hydrophone signals were conditioned with a Brüel & Kjær model 2692 charge amplifier. The transfer function between the two hydrophones was measured with the HP89410A and the data was transferred to a laptop computer for storage and processing. The effective plane wave surface impedance of the bubbly liquid is related to the measured transfer function using Eq. (1) of Ref. 10 and a set of calibration functions obtained in the calibration procedure.

A. Inversion procedure

In the present work, the high attenuation provided by the bubbly liquid suppressed reflections from the air–water interface at the top of the sample holder, giving it an effectively infinite length. Therefore, plane progressive waves crossed into the bubbly liquid and the complex sound speed (phase speed and attenuation) was available directly from the measured surface impedance. This condition existed for void fractions as low as $O(10^{-5})$, where on-resonance attenuation was $O(2)$ dB/cm. The sample holder used in these experiments was 14 cm in length and, therefore, minimum round trip attenuation was about 56 dB, which was sufficient to render the reflected signal indistinguishable from the background noise.

The phase speed and attenuation were obtained in the following way: Since $z_s = \rho c$ for the plane progressive waves incident on the surface of the bubbly liquid and $k = \omega/c$, the wave number k in the bubbly liquid is given by

$$k = \frac{\omega \rho}{z_s}, \quad (14)$$

where z_s is the measured impedance and ρ is obtained from the mixture density relationship $\rho = (1 - \beta)\rho_l + \beta\rho_g$. Finally, the phase speed is given by

$$V = \frac{\omega}{\text{Re}[k]}, \quad (15)$$

and the attenuation coefficient is given by

$$A = 20 \log_{10}(e) \text{Im}[k], \quad (16)$$

in dB/unit length.

The key assumption used in this analysis is that only a single plane wave mode exists in the sample holder at a given frequency. For waves propagating within a liquid-filled waveguide with elastic walls, at least two modes can be present at all frequencies. Both modes can have longitudinal and radial components, but the lowest-order mode approaches a true plane wave mode as the wall impedance increases.¹³ This impedance tube was designed such that when filled with bubble-free water, both the radial component of the plane wave mode and the higher-order mode are negligible and can be ignored.¹⁰ Below resonance, the bubbly liquid medium is acoustically soft in comparison to pure water and the elastic waveguide effects are minimized even further. Above resonance, the bubbly liquid is acoustically hard in comparison to pure water and the elastic waveguide effects are more prominent. An inversion scheme that properly accounts for both components of both modes does not exist and for now these elastic waveguide effects have been ignored. This will be discussed further in Sec. IV C.

B. Bubble production

The bubbly liquid consisted of air bubbles injected into distilled water using 30 gauge needles. The air was supplied from a compressed air bottle, through a primary regulator, then into a needle valve, a flow meter, and finally into the needle/s, either directly or through a manifold. A pressure gauge was connected between the flow meter and the needles. The flow rate and pressure measurements were used solely to ensure that the flow conditions, and hence the bubble population, remained as constant as possible throughout any given experiment. The bubble size distribution and overall void fraction were measured directly for each case.

For the first measurement presented in Sec. IV B, a single long needle (30 gauge, 0.31 mm diameter, 20.3 cm in length) was used. The needle was inserted into the sample holder from the open end of the tube and was positioned such that the bubbles were released at the measurement plane. Since changing the flow rate of air through a single needle changes the bubble size as well as the void fraction, one must add additional needles with the same per needle flow rate in order to independently increase the void fraction.

FIG. 4. A schematic diagram of the bubble injection manifold is shown. Part (a) is a cross-sectional view showing the injection manifold mounted between the impedance tube and the sample holder. Two needles are shown making bubbles. Part (b) shows a top view of the injection manifold separated from the impedance tube and the sample holder, with four needles in place. The needles were 30 gauge, 2.86 cm in length, and projected 1.27 cm into the tube.

Therefore, a bubble injection manifold (BIM) was developed to accurately position four 30 gauge needles at the measurement plane. The manifold body is of the same radial dimensions and material as the impedance tube itself, but contains an internal plenum that directs the air supply into the needles, as shown in Fig. 4(a). All the needles are coplanar with the impedance measurement plane. As the bubbles rose, they typically deviated from a directly upward path, yet they remained uniformly distributed along the longitudinal axis of the tube, and therefore the void fraction remained uniform in the direction of propagation. All but the first measurement presented in Sec. IV B were made using the BIM.

C. Measurement of bubble size

The bubble size distribution was determined by the direct photographic observation of the bubbles. Illumination was provided using a combination of direct and backlighting such that the outline of the bubbles appeared dark against a much lighter background. The single long needle or the BIM was placed within a small glass aquarium filled with distilled water. The height of water above the opening of the needles was the same as when installed in the impedance tube. The bubbles were free to rise up through the water column and they were photographed using a Kodak DC265 digital camera equipped with a macrolens and a strobe. The camera's maximum acquisition rate of about one photograph per 15 s was used. A machinist's scale located in the focal region was also photographed to provide a length reference. A schematic of the bubble size measurement system is shown in Fig. 5. Both the imaging and subsequent analysis were undertaken following guidelines published by The National Institute of Standards and Technology.¹⁴ A typical image obtained with this system is shown in Fig. 6(a) and the results of the image analysis are shown in Fig. 6(b). Note the relatively homogeneous distribution of bubbles both vertically and horizontally. A Cannon model GL1 digital video camera

FIG. 5. A schematic diagram of the bubble size measurement system is shown with the BIM producing bubbles. The height of the water column is the same as that inside the sample holder during impedance measurements. Not shown is the machinist's scale used for a length reference.

was used to obtain photographic data at the higher rate required for the time-resolved measurements in Sec. V.

The bubbles exhibited a shape well approximated by an oblate spheroid. The images were processed with the image analysis software package NIH image. The major and minor axes $2b$ and $2c$ appeared in the plane of the image, and were determined by the NIH image in number of pixels. The length reference l_{ref} (length/pixel) was taken from the machinist's scale. The spheroidal volume is given by $V = \frac{4}{3} \pi b^2 c l_{\text{ref}}^3$. The effective spherical radius a was then calculated based on an effective spherical volume,

$$a = \left(\frac{3V}{4\pi} \right)^{1/3} = l_{\text{ref}} (b^2 c)^{1/3}. \quad (17)$$

The number of individual bubbles analyzed varied from experiment to experiment, but a typical number was 200.

Two primary factors that contribute to the uncertainty of the bubble size measurement are a deviation of the actual bubble shape from the model shape, and the limited length

FIG. 6. A typical image obtained with the bubble size measurement system and four needles is shown in (a) along with a 1 cm scale bar. The same image after processing is shown in (b). The background was removed, each bubble was outlined, assigned a number, and the size data was stored in a file.

FIG. 7. An image of a typical bubble obtained by the imaging system is shown greatly enlarged in (a). Uncertainty due to pixelation is shown in (b). Equation (17) yields an effective spherical radius of 0.64 ± 0.05 mm for this bubble.

resolution of the pixelated images. Close scrutiny of a magnified image of a typical bubble reveals that the error due to pixelation is likely the greater of the two. This is demonstrated in Fig. 7. An image of a typical bubble used in this work is shown greatly enlarged in Fig. 7(a), so that individual pixels can be seen. The same bubble is again shown in part Fig. 7(b), but a slightly larger ellipse has been overlain and it is apparent that the shape is a good match to that of the bubble. There is some uncertainty about the boundary of the bubble, though. When the image was digitized, the pixels were assigned discrete values of brightness; therefore one cannot be sure exactly where the boundary was. The motion of the bubble during the exposure also contributes to this uncertainty. Consider the minor axis of the bubble, with length $2c$. If one assumes that the actual boundary lies somewhere between the outermost two pixels, then the minimum and maximum possible minor diameters are shown in the figure. For this bubble, $2c_{\min} = 20$ pixels and $2c_{\max} = 24$ pixels. Although not shown in the figure, a similar situation exists for the major axis, with $2b_{\min} = 32$ and $2b_{\max} = 36$ pixels, and for the length value, $1/l_{\text{ref}} = 230 \pm 2$ pixel/cm. Using Eq. (17) one finds the uncertainty in the measured effective spherical radius for this bubble is $a \pm 7.7\%$.

At this point a tradeoff is evident. For a given imaging system, one can increase the magnification and thereby increase the length resolution, but then the number of bubbles per image and the size of the statistical population is decreased. For fixed magnification, the uncertainty in bubble size is dependent on the bubble size. The uncertainty reported above was typical for this work. The maximum uncertainty in effective spherical bubble radius and did not exceed $a \pm 11\%$.

D. Determination of void fraction and low-frequency phase speed

For the single needle case, the bubbles were few enough in number that all could be counted individually and the total volume of air within the sample holder could be determined from the bubble size measurements.

When using the BIM, the void fraction was determined using a cylindrical acoustic resonator of length L , filled with the bubbly liquid of interest, and operating below the cutoff frequency of the first higher-order mode of the tube and well below the resonance frequency of the largest bubble. In this range, known as Wood's limit, the low-frequency mixture

FIG. 8. A schematic diagram of the void fraction resonator is shown.

sound speed c_{mlf} is dependent on void fraction β , as given by the relation¹⁵

$$\frac{1}{c_{mlf}^2} = \frac{(1-\beta)^2}{c_l^2} + \frac{\beta^2}{c_a^2} + \beta(1-\beta) \frac{\rho_a^2 c_a^2 + \rho_l^2 c_l^2}{\rho_l \rho_a c_l^2 c_a^2}, \quad (18)$$

and c_a and ρ_a refer to the sound speed and density of air.

The resonator was modeled as a rigid-walled, open-open tube filled with a homogeneous liquid with sound speed c_{mlf} and supporting only one-dimensional plane-wave modes. The fundamental resonance frequency is given by $f_1 = c_{mlf}/2L$. The void fraction was determined from the measured frequency of the fundamental mode and Eq. (18). Sound speeds from the higher-order modes were also obtained. The modal sound speed was determined at each resonance frequency from $f_n = nc_n/2L$. Depending on the position of the hydrophone relative to the spatial acoustic field for each case, one, two, or three higher-order modes were observed.

A schematic diagram of the void fraction resonator is shown in Fig. 8. An aluminum tube (30.13 cm length, 5.08 cm diameter, 0.635 cm wall thickness) was mounted to the top of the air injection manifold and sealed with an o ring. The lower pressure release boundary condition was achieved by closing the tube with a thin mylar membrane that was glued to a mounting fixture. The mounting fixture interfaces with the air injection manifold, sealing the tube with an o ring, and positions the membrane just below the needles. A Brüel and Kjær type 8103 hydrophone was typically positioned 2 cm from the open end of the tube. The hydrophone signal was conditioned with a Brüel and Kjær type 2692 low noise charge amp, which also provided bandpass filtering between 10 Hz and 10 kHz. The natural resonances of the tube were excited by the noise created by the bubbles pinching off the needles, in a manner similar to that reported by

TABLE II. The table contains the results of the resonator-based void fraction measurements and the parameters used with Eq. (19) for calculation of the associated uncertainty. For Case 1, β was obtained from optical measurements and its uncertainty is discussed in Sec. IV B.

Case	1	2	3	4
$\beta \times 10^5$	5.49	33	41	54
$\Delta\beta$ (%)	...	± 3.4	± 3.2	± 3.3
L (cm)	...	31.5	31.5	31.5
ϵ_L (cm)	...	± 0.2	± 0.2	± 0.2
f (Hz)	...	857.5	810.0	730.0
ϵ_f (Hz)	...	± 6.875	± 6.125	± 6.000
ϵ_c (m/s)	...	± 7.8	± 7.1	± 6.7

Nicholas *et al.*¹⁶ The resulting hydrophone signal was acquired and acoustic spectra calculated with the HP89410A Vector Signal Analyzer.

Uncertainty ϵ_L in the length of the resonator and uncertainty in the resonance frequency ϵ_f due to the finite resolution bandwidth of the measured acoustic spectra lead to uncertainty ϵ_c in the measured sound speeds obtained from the resonator method and is given by

$$\pm \epsilon_c = \pm 2(L\epsilon_f + f\epsilon_L \pm \epsilon_L\epsilon_f). \quad (19)$$

In turn, this leads to an uncertainty range $\beta \pm \Delta\beta$ in the void fraction, obtained by the satisfaction of Eq. (18) for $c_{mlf} = 2Lf_1 \pm \epsilon_c$. Numerical values for these parameters are given in Table II.

E. Bubble population statistics

The bubble size data must be cast in the form of a probability density function $\wp(a)$ for input into the propagation model. Histograms of this data indicated that a truncated normal probability density function (PDF) was a suitable statistical model. Four parameters describe this distribution: the minimum radius a_{\min} , the maximum radius a_{\max} , the mean a_0 , and the standard deviation s . The bubble radii data, obtained as described in Sec. III C, were ranked in ascending order. The minimum and maximum radii values were used as a_{\min} and a_{\max} , respectively, and a_0 and s were estimated by fitting a model cumulative distribution function (CDF), to an empirical CDF obtained from the measured radii.

The measured or empirical CDF is given by

$$P_{\text{meas}}(a) = \frac{\bar{n}(a)}{N}, \quad a_{\min} \leq a \leq a_{\max}, \quad (20)$$

where $\bar{n}(a)$ is the number of observations with values less than or equal to a , and N is the total number of observations. The model CDF is given by

$$P(a) = \int_{a_{\min}}^a \wp(\xi) d\xi, \quad [0 \leq P \leq 1], \quad (21)$$

where \wp is PDF for the truncated normal distribution and is given by

$$\wp(a) = \frac{1}{s\sqrt{2\pi}} \exp\left[-\frac{(a-a_0)^2}{2s^2}\right], \quad a_{\min} \leq a \leq a_{\max}. \quad (22)$$

FIG. 9. The statistical data reduction is shown for bubbles created by a single needle. The upper frame shows the empirical CDF and the best-fit model CDF. The lower frame shows the resulting PDF and a histogram of the data, shown only for reference. The resulting distribution parameters are also shown (all radius units are in mm).

Model CDFs were then computed for a range of a_0 and s values, and a two-dimensional minimization of the chi-squared parameter was performed, yielding the best-fit mean and standard deviation. The chi-squared parameter χ^2 is given by¹⁷

$$\chi^2 = \sum_{i=1}^N \frac{(P_{\text{meas}}(a_i) - P(a_i))^2}{P(a_i)}, \quad (23)$$

where a_i is the i th member of the rank ordered vector of size measurements. An example of this statistical analysis is shown in Fig. 9. The empirical CDF fitting method was used because it relied entirely on the data. The PDF can be fitted to a histogram of the data, but this requires an arbitrary choice to be made for the histogram bin size.

F. Additional experimental details

Two different types of experiments were conducted, time-averaged, and time-resolved. In both of these experiments, the goal was to measure the frequency-dependent phase speed and attenuation in bubbly liquid in the resonance regime. In the original experimental design, it was assumed that the bubble population statistics and the void fraction would be stationary in time, as long as the observable air injection parameters remained constant. Subsequent experimental observations revealed that the bubble population statistics were not stationary, even when observable bubble production parameters were stable. This type of behavior exhibited by needle manifolds has been reported before.¹⁸ Further, moving the bubble injection manifold from the bubble sizing apparatus, to the void fraction resonator, and finally to the impedance tube, resulted in slightly different bubble distributions, even when the observable flow parameters did not change. Because the bubble population parameters were changing, a relatively small degree of fitting was

usually necessary in order to bring the time-averaged measurements and model into agreement, as discussed in Sec. IV. The discovery of nonstationarity lead to the idea that instantaneous, or time-resolved measurements should also be performed, as discussed in Sec. V.

IV. TIME-AVERAGED MEASUREMENTS

A. Procedure

The procedure for the experiment was composed of four parts: impedance tube calibration, bubble size distribution measurement, void fraction measurement, and finally impedance measurement.

For both the calibration and the impedance measurements, transfer functions between the signals from the two impedance tube hydrophones were measured using the HP89410A vector signal analyzer. Pseudorandom noise was used as the excitation signal over a frequency range of 5–9 kHz. The hydrophone signals were Hann windowed and processed to yield a frequency resolution bandwidth of 2.5 Hz. The calibration was performed first, using a procedure described in Ref. 10. Second, the single needle or the BIM was installed in the size distribution apparatus, shown in Fig. 5. The bubble size distribution was measured, as described in Sec. III C, which also yielded the void fraction for the single needle case. For the single needle case, bubble observation was limited to three photographs taken over a time frame of about 45 s, yielding 30 bubble images. When the BIM was used, 16 photographs were taken over a time frame of about four minutes yielding about 200 bubble measurements. The BIM was then installed in the void fraction apparatus shown in Fig. 8, and the void fraction was measured, as described in Sec. III D. This step also produced some additional phase speed data below 5 kHz.

Finally, either the single needle was inserted into the impedance tube, or the BIM was installed [as shown in Fig. 4(a)], and the tube was filled with distilled water. The bubble production was then initiated and the airflow rate and pressure were allowed to equilibrate. These flow parameters were kept constant throughout the size distribution, void fraction, and impedance measurement procedures. Because noise is produced by the bubble generation, the acoustic drive level was dependent upon the experiment. The coherence function between the two wall-mounted sensors was monitored with the vector signal analyzer. The minimum power amplifier gain necessary to obtain a near-unity coherence function was used. This ensured a sufficient signal-to-noise ratio and a linear bubble response.

The impedance measurement was then conducted by obtaining 100 spectral averages of the transfer function between the two wall-mounted sensors, using the signal analyzer. The averaged transfer function y was processed onboard the analyzer using

$$y = \frac{G_{12}(f)}{G_{11}(f)}, \quad (24)$$

where G_{12} is the averaged cross-spectrum given by

FIG. 10. Measured and predicted phase speed V and attenuation A for case 1, using the population parameters from Fig. 9.

$$G_{12}(f) = \frac{1}{N} \sum_{n=1}^N S_{2,n} S_{1,n}^*, \quad (25)$$

G_{11} is the averaged autospectrum, given by

$$G_{11}(f) = \frac{1}{N} \sum_{n=1}^N S_{1,n} S_{1,n}^*, \quad (26)$$

and individual spectra S_i are given by

$$S_i(f) = \text{FFT}[W(t)p_i(t)]. \quad (27)$$

In the above expressions, FFT is the fast-Fourier transform, $W(t)$ is the Hann window function, $p_i(t)$ is the acoustic pressure signal at the i th sensor position, the $*$ indicates the complex conjugate, and $N=100$ is the number of averages. Finally, the averaged transfer function y was sent to a computer over GPIB and the impedance was calculated off-line, as described in Ref. 10.

The above procedure was repeated for a total of four different void fractions, using a single long needle and four needles installed in the BIM. Note that when the single long needle was used, the BIM was not installed. The sample holder and the impedance tube were bolted directly together.

B. Results

The results for the single needle (case 1) are presented first. The results of the bubble population analysis is shown in Fig. 9. In the top part of the figure, the measured and the model CDFs are shown, along with the population size N , and the minimum and maximum bubble radii. In the bottom part of the figure, the best-fit model PDF is shown along with its parameters a_0 and s . A histogram of the bubble size data is also shown for reference, although it was not used in the analysis. The measured void fraction was $\beta = 5.49 \times 10^{-5}$.

The phase speed and attenuation measured for this bubbly liquid is shown in Fig. 10, along with the theoretical predictions given by Eq. (2), where $\varphi(a)$ is given by Eq. (12) and the four bubble population parameters from Fig. 9. A complete list of the parameters used in the production of Fig. 10 is given in Table III. The measured data and the

TABLE III. The table contains the parameters used to produce Figs. 10–15. All the physical parameters listed in Table I, except c_l , were also used. The bubble-free liquid sound speeds c_l were measured inside the impedance tube and show variation due to temperature. The presence of the asterisk (*) in a cell indicates that the parameter was fitted.

Case	1	1	2	3	4
Figure	10	11	13	14	15
$\beta(\times 10^{-5})$	5.49	6.20*	33	41	54
c_l (m/s)	1455.5	1455.5	1457.4	1455.8	1458.0
a_{\min} (mm)	0.603	0.627*	0.580*	0.580*	0.580*
a_0 (mm)	0.612	0.636*	0.600*	0.622*	0.638*
a_{\max} (mm)	0.620	0.645*	0.750*	0.710*	0.750*
s (mm)	0.005	0.005	0.031*	0.038*	0.035*

model are qualitatively similar, but they are shifted by about 2 kHz in frequency. Recall that the bubble size uncertainty is about $\pm 8\%$, and that the size data and the acoustic data are not taken at the same time. Taking this into account by adjusting the radius so that the frequency of the measured and predicted peak attenuation are the same yields Fig. 11, where the radii a_{\min} , a_0 , and a_{\max} were multiplied by 1.04. The volume-based void fraction estimate was also multiplied by $(1.04)^3$, yielding $\beta = 6.2 \times 10^{-5}$. Agreement is now much better across the entire frequency range. Because of the low attenuation at this void fraction, a reduced frequency range is shown. Outside of this range, the nonreflecting condition at the top of the tube was surely violated, which causes the inversion process to fail. Note that the data presented in this chapter has an inherent uncertainty associated with the impedance measurement of $\pm 2.2\%$.¹² Also note that other, less quantifiable sources of error are discussed in Sec. IV C.

The measurements obtained with the BIM are shown next. Four 30-gauge needles, 2.86 cm in length, were installed in the BIM for cases 2, 3, and 4. Each represents a different void fraction, which was achieved by slightly varying the overall flow rate. The needles were spaced 90° apart around the circumference of the BIM, and projected 1.27 cm into the tube. A single bubble size distribution measurement

FIG. 11. The measured data for case 1 is shown again, but the predicted phase speed V and attenuation A was obtained by adjusting the bubble radius by +4%. The resulting bubble population parameters are also shown.

FIG. 12. The statistical data reduction is shown for bubbles created by the BIM with four needles and void fraction $\beta = 41.0 \times 10^{-5}$. The upper frame shows the empirical CDF and the best-fit model CDF. The lower frame shows the resulting PDF and a histogram of the data, shown only for reference. The resulting distribution parameters are also shown (all units in mm).

obtained with four needles and the intermediate flow rate is shown in Fig. 12. The measured phase speed and attenuation for cases 2, 3, and 4 are shown along with their associated predictions in Figs. 13, 14, and 15, respectively. A complete list of the model input parameters is given in Table III, and for convenience, the bubble population parameters are also shown in the figures.

In general, better agreement between the measurements and the model was found by fitting the bubble population statistical parameters within the uncertainty range of those measurements. Therefore, only the best-fit predictions are shown. Fitting the four bubble population statistics is easier

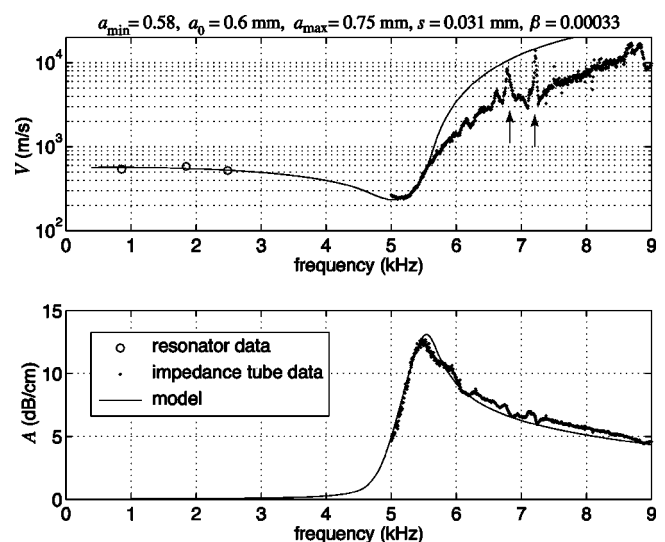

FIG. 13. The measured phase speed V and attenuation A for case 2 is shown. The predicted phase speed and attenuation that best fits the measured data is also shown along with the resulting bubble population parameters. The two vertical arrows near 7 kHz indicate sharp fluctuations in phase speed that are discussed in the text.

FIG. 14. The measured phase speed V and attenuation A for case 3 is shown. The predicted phase speed and attenuation that best fits the measured data is also shown along with the resulting bubble population parameters.

than one might expect because each parameter has a fairly unique effect. The fitting was done one parameter at a time, by hand. The difference between the data and the model in a certain range was minimized in a least squares sense by adjusting each parameter in turn. The mean bubble radius a_0 was fit using the frequency of peak attenuation. Standard deviation s was fit using the slope of the attenuation curve on the low-frequency side of the peak attenuation. Minimum bubble radius a_{\min} was fit using the width of the attenuation peak on the low-frequency side of the peak. Maximum bubble radius a_{\max} was fit using the width of the attenuation peak on the high-frequency side of the peak. No attempt was made to automatically fit all four parameters simultaneously to the absolute minimum error across the frequency range. The region around resonance was given priority.

FIG. 15. The measured phase speed V and attenuation A for case 4 is shown. The predicted phase speed and attenuation that best fits the measured data is also shown along with the resulting bubble population parameters.

C. Discussion of time-averaged results

A number of general comments about the phase speed and attenuation data will be made and then these points will be discussed more fully. The predicted phase speeds above the resonance regime are generally higher than the measured values. The agreement is generally better for attenuation and is actually quite good. The deviation between the peak measured attenuation and the predicted value ranges from about 0.14 to 0.92 dB/cm. This agreement is better than that originally reported for peak attenuation in Ref. 3, where the minimum data/model deviation was about 2.5 dB/cm in Fig. 13 and was typically 10–15 dB/cm. The case 2–4 measurements display sharp fluctuations that case 1 does not. The fitted bubble population was always narrower than the measured bubble population. The low-frequency phase speed measurements obtained from the VF resonator (the open circles in Figs. 13–15) agreed well with the resonance regime phase speed measurements obtained from the impedance; the theoretical predictions tied them together.

1. Elastic waveguide effects

Elastic waveguide effects were mentioned in reference to the impedance data inversion procedure in Sec. III A. It has been shown that the phase speed in a liquid-filled waveguide with elastic walls is reduced relative to the liquid's intrinsic sound speed and is dispersive.¹³ As the frequency increases through resonance, the bubbly liquid changes from acoustically soft to acoustically hard (relative to the bubble-free water) and the elastic waveguide effects should become more pronounced. This could explain the mismatch between measurement and prediction above resonance. The effect was investigated theoretically by starting with an idealized case. Propagation in the impedance tube was modeled using an elastic waveguide dispersion relation from the literature [Eq. (5) in Ref. 13]. In this lossless model, the modal phase speeds of waves propagating in the internal liquid are determined as a function of frequency, waveguide geometry, and the intrinsic (free-field) sound speed of the internal liquid. A frequency of 7 kHz was used in the calculations. This frequency is above the bubble resonance frequency and a supersonic (relative to bubble-free water) phase speed is predicted for the unconfined bubbly liquid. This frequency is below the cutoff frequency for the first higher-order mode if this were a rigid-walled waveguide. For the elastic-walled case, two modes are predicted to propagate in the internal liquid and their phase speeds were calculated for a range of free-field sound speeds. Equation (5) of Ref. 13 is a lossless model, so the attenuation in the bubbly fluid was neglected. This is a major simplifying assumption, but the results are still useful for insight, if not absolute accuracy.

These results are presented in Fig. 16. The predicted phase speed of each of the two modes is plotted as a function of the intrinsic bubbly liquid sound speed. In other words, according to the elastic waveguide model, if the internal liquid sound speed was that given on the x axis; then the phase speed of each mode would be that given by the solid lines labeled “elastic mode 00” and “elastic mode 01.” The leading 0 indicates these are axisymmetric modes. If the waveguide was truly rigid, there would be only one mode and the

FIG. 16. The predicted phase speeds in an elastic waveguide are shown for supersonic regime bubbly fluid at 7 kHz. The mode labeled “00” is the plane wave mode, and “01” is the next higher-order mode. The dashed line represents the phase speed of the only mode present at this frequency for a rigid-walled waveguide.

waveguide phase speed would be the same as the intrinsic bubbly fluid sound speed. This case is represented by the dashed line labeled “rigid.” (The plot would be straight on a linear scale but is curved because the x axis is represented with a log scale.) The vertical dashed lines represent a transition region. Below this region, mode 00 has a phase speed close to the rigid waveguide sound speed and nearly plane wave fronts with little radial displacement. Mode 01 has curved wave fronts (concave down) and is not excited easily by plane disturbances. Above the transition region, both modes have curved wave fronts of almost the same concave up shape and similar radial components. Within the transition region, the phase speeds of the two modes are similar. Also notice that from midway through the transition region and higher in frequency, the two elastic mode speeds are always lower than the rigid-walled sound speed. This is a possible explanation why higher phase speeds are not measured, but it also brings up another issue.

According to the elastic waveguide model in Ref. 13, the 00 mode becomes nonplanar in the transition region. Now consider the situation within the impedance tube. An incoming plane wave begins to interact with the bubbly fluid at the interface between the tube and the sample holder and finds no suitable plane wave mode to excite. Part of the incident energy is reflected and the transmitted energy must get divided up into two propagating modes, and possibly a great number of evanescent modes. In such a case, the inversion that is used to extract phase speed and attenuation from the impedance measurements would break down, because it assumes only a single plane progressive mode for the transmitted wave.

Further evidence in support of this is available directly from the measured results. Consider the data in Fig. 11, which show a measured phase speed greater than 10 000 m/s at 7 kHz. According to Fig. 16, the maximum phase speed for mode 00 is less than 5000 m/s and about 7000 m/s for mode 01. This is still below cutoff for the next higher-order mode, so nothing should be able to propagate at 10 000 m/s. The existence of other modes must be interfering in such a way that an effective single mode phase speed is obtained from the inversion. An initial attempt was made using an

inversion technique that accounts for the higher-order mode, but it was not successful.¹² This remains an unresolved issue for phase speed measurements made with the present technique above resonance frequency, but plays a negligible role at resonance.

2. Signal and noise issues

The phase speed measurements exhibited an increase in sharp, rapid fluctuations with frequency when the BIM was used. The largest two of these features are indicated in Fig. 13 with small vertical arrows. The resulting increase in void fraction was accompanied by an increase in noise level produced as the bubbles broke off the needles. This noise represents energy entering the impedance tube from a direction not accounted for and, therefore, it could have corrupted the impedance measurements.

The measured coherence function was used to investigate this potential signal-to-noise issue. A coherence function greater than zero but less than unity implies one or a combination of the following:¹⁹ (1) The presence of extraneous noise in the measurements. (2) The output signal includes the result of excitation not measured by the input. (3) Some non-linearity between sensors 1 and 2. (4) Resolution bias errors are present.

Items (3) and (4) were ruled out because coherence functions obtained from measurements with a bubble-free transmission line termination were always close to unity, except in narrow bands. These bands are associated with nulls in the field that happen to be co-located with one of the pressure sensors. The acoustic drive level was always well below the threshold for nonlinear effects in distilled water; there were no bubbles between the measurement sensors. The resolution bandwidth of the measurement was not changed when bubbles were introduced.

Items (1) and (2) were possibilities, though, and an experiment was done to investigate this. Impedance measurements were conducted for five signal-to-noise ratios (SNR), in increments of 10 dB, with bubble production, and hence bubble-induced noise production constant. The SNR had no influence on the fluctuations. They did not increase as the SNR was decreased. At the lowest SNR, the coherence function was below 0.4 for much of the frequency range, but the rapid fluctuations did not deviate from the higher SNR cases. Therefore, excess bubble noise was ruled out as the cause.

What else could cause these perturbations? Perhaps it was the needles, or more specifically, the needles and the air inside. Case (1) shows none of these fluctuations. It was made with a single long needle lowered from the top. For the remaining cases, four needles were positioned parallel to and residing directly in the measurement plane. They present a larger cross section than did the long needle inserted from the top, and are positioned completely in the plane of interest. These are accompanied by an increased fluctuation level. This trend was observed to increase as the number of needles increased.¹² The presence of needles in the measurement plane certainly deviates from a homogenous bubbly liquid and could possibly cause the fluctuations.

These fluctuations could also be caused by smaller bubbles attached to the ends of the needles. Before a bubble

FIG. 17. Time lines for the time-resolved impedance measurements are shown. The impedance was measured in $66 \mu\text{s}$ segments once every 15 s. These measurement times are shown by the symbol “X.” The video recorded continuously, as indicated with the thin horizontal arrow. Individual frames were acquired from the video for six second blocks every minute.

detaches from its needle and rises upward, it spends some time attached to the end of the needle during the growth phase. During that time, it is certainly being interrogated by the incoming sound wave and therefore contributing to the impedance of the bubbly fluid. Because the bubble is interrogated multiple times, the net effect is to increase the influence that particular bubble size has on the final results. A multiple delta function bubble distribution present at the measurement plane could possibly account for the sharp phase speed peaks and fluctuations.

3. Bubble population parameters and void fraction

When the BIM was used (cases 2–4), the bubble radii standard deviation required to fit the propagation model to the impedance tube data was smaller than the standard deviation obtained from the photographic data. It was subsequently determined that the bubble population statistics varied on a time scale of about two minutes, even when the observable bubble production parameters were stationary. Therefore, bubble size distributions (BSDs) observed optically over several minutes were wider than the best-fit model BSDs used to match acoustic data gathered over about 45 s. Further, knowledge of the bubble population needs to be at least an order of magnitude more accurate to absolutely validate any propagation model. The bubble population parameter measurement should be conducted *in situ* with the impedance measurements. The low-frequency void fraction measurement technique proved to be reliable and agreement was found with both the resonance regime measurements and calculations. The *in situ* incorporation of the void fraction measurement would be ideal, but this task could be continued off-line. Finally, the increased control of bubble production would be beneficial, but if *in situ* population measurements are actually available, this is less important.

V. TIME-RESOLVED EXPERIMENT

An assumption made early in this work was that the experimental bubble populations would exhibit statistics that were stationary in time. As previously discussed, this was not the case. Since the bubble population characterization and the impedance measurement could not be done at the same time, an absolute comparison between the propagation model and experimental measurement was not possible. An investigation of the relative variability was possible and became the goal of the time-resolved experiment. In order to do this, the bubble population parameters and the acoustic impedance were sampled on similar time scales.

A. Procedure

The procedure for instantaneous impedance measurements was almost the same as that for the time-averaged measurements just described. Four subprocedures were again performed, but in the following order: calibration, void fraction measurement, impedance measurement, and then bubble size distribution measurement. The void fraction measurement procedures were unchanged from the time-averaged experiment.

The goal of this experiment was to observe the time variation of both the bubble size distribution and the propagation parameters. A periodic chirp was used as the excita-

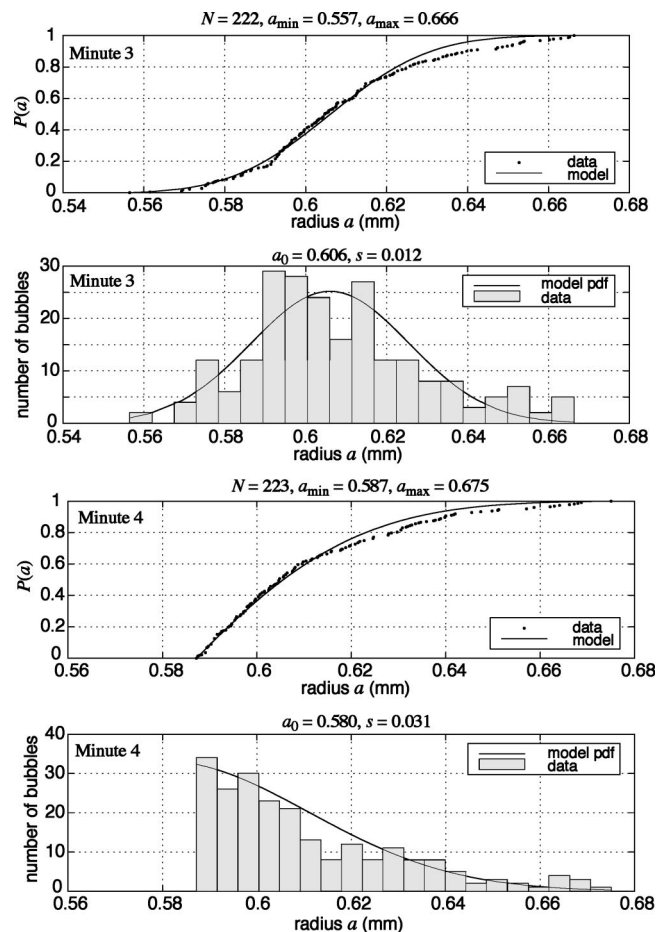

FIG. 18. Bubble population statistics at minutes 3 and 4 of the time-resolved experiment. For each case, the upper frame shows the empirical CDF and the best-fit model CDF. The lower frame shows the resulting PDF and a histogram of the data, shown only for reference. The resulting distribution parameters are also shown (all units in mm).

FIG. 19. Mean bubble radius a_0 and standard deviation s are shown as a function of time. The thick horizontal lines represent the global means, $\langle a_0 \rangle$ and $\langle s \rangle$, and the thin horizontal lines represent two standard deviations above and below the global means.

tion signal because it requires no averaging and could be used to obtain near-instantaneous measurements. The signal was periodic with respect to the data acquisition time window and was 66 ms in length. A Hann window was used, which resulted in a resolution bandwidth of 15 Hz for a frequency range of 4–10 kHz. The data from 4–5 kHz and 9–10 kHz was discarded.

The calibration was performed using the periodic chirp, then the void fraction measurements were performed. The impedance measurement procedure began as it did in the previous section, but instead of taking 100 back-to-back averages, one chirp-excited impedance measurement was taken every 15 s for 16 min. This was done for a single void fraction case, using the BIM and four needles.

The still camera could not operate fast enough to sample the bubble size distribution on the same time scale as the impedance, so a digital video camera was used. The resolution of this video camera was not high enough to image many bubbles in the same frame, so high magnification was used and one or two bubbles from a single needle were imaged instead. After the bubble production was initiated and the flow parameters were stabilized, video was recorded continuously for 16 min, but only 6 s blocks taken every 60 s were processed. Therefore, 6 s of video for each event translated into 180 frames and about 220 bubbles per event. Under such circumstances, the bubble population is sampled photographically for bubble size in 33 1/3 ms intervals, and the impedance measurements sample 66 ms of the bubble population. A time line relating the impedance measurements and the size measurements is shown in Fig. 17. These images were all processed for bubble size, as described in Sec. III C.

B. Results

Using the technique given in Sec. III E, the bubble population statistics were obtained for each of the 16 populations. The CDF/PDF plots for the entire dataset are presented in Ref. 12 along with additional details about the data acquisi-

tion and analysis. The uncertainty in these bubble size measurements was $\pm 11\%$. The histograms of two neighboring bubble populations, generated one minute apart, are presented in Fig. 18. It is clear that the bubble population is changing dramatically on this time scale. The statistical bubble population parameters are plotted as a function of time in Figs. 19 and 20. The following notation and definitions were used. The global mean of a variable x is given by $\langle x \rangle$, where

$$\langle x \rangle = \frac{1}{16} \sum_{i=1}^{16} x(t_i), \quad (28)$$

and the standard deviation of x is given by

$$\sigma = \left\{ \frac{1}{16-1} \sum_{i=1}^{16} [x(t_i) - \langle x \rangle]^2 \right\}^{1/2}. \quad (29)$$

The variation of the mean bubble radius $a_0(t)$ and the radius standard deviation $s(t)$ is shown in Fig. 19. It may appear that a start-up transient was captured at the beginning of the upper plot, but recall that the observable control parameters of the bubble production process had reached steady state prior to the image acquisition and were not fluctuating. The curves shown in Figs. 19 and 20 confirm that the bubble population parameters are fluctuating dramatically and rapidly. Variation greater than two standard deviations can occur within a minute, and there is also evidence of long term trends, specifically in the standard deviation.

The void fraction, determined just prior to the impedance measurements using the resonator technique, was 3.9×10^{-4} . Phase speed V and attenuation A were obtained from each impedance measurement. For compatibility with the bubble size data, V and A for four consecutive measurements were averaged together to represent one minute of time, then the next four were averaged, and so on, until 16 min of measured V and A were obtained. Predicted phase speeds and attenuations were then calculated using Eqs. (2)

FIG. 20. Minimum and maximum bubble radius is shown as a function of time.

and (12), the measured bubble population parameters from Figs. 19 and 20, and the measured void fraction.

In order to compare the variability of these multifaceted measurements and calculations, attention will be focused on two parameters: the maximum attenuation $A_{max}(t)$ and the frequency at which that maximum attenuation occurs, $f_m(t)$. Since the relative variation is of interest, the results will be presented in normalized form, $A_{max}/\langle A_{max} \rangle$ and $f_m/\langle f_m \rangle$, where the brackets represent the global mean as defined in Eq. (28), and the normalized standard deviation of parameter x is given by

$$\bar{\sigma} = \left\{ \frac{1}{16-1} \sum_{i=1}^{16} \left[\frac{x(t_i)}{\langle x \rangle} - 1 \right]^2 \right\}^{1/2}. \quad (30)$$

The results are given in Figs. 21 and 22 for attenuation and

frequency, respectively. When cast in this form, the predicted variation of the acoustic properties due to changes in the bubble population is quite similar to the observed variation. For the normalized frequency parameter, a $\bar{\sigma}$ variation of 0.87% is predicted and 0.84% is observed. For the normalized attenuation parameter, a $\bar{\sigma}$ variation of 4.9% is predicted and 5.3% is observed.

C. Discussion

The similarity between predicted and observed statistical variability of the peak attenuation and its frequency is quite good. Making comparisons of the relative, as opposed to absolute quantities minimized the problems relating to the

FIG. 21. Measured and calculated maximum attenuation is shown as a function of time, normalized by the global mean.

FIG. 22. Measured and calculated frequency of maximum attenuation is shown as a function of time, normalized by the global mean.

uncertainty of the instantaneous bubble population, including the uncertainty in the absolute size of the bubbles.

In the region around peak attenuation, the phase speed is near its minimum, hence the elastic waveguide effects are minimized. Therefore, the inversion problems that are evident well above resonance play no role here. In addition to the inherent errors already discussed, there is an additional source of bias error for this experiment. The resolution bias error was made negligible in the time-averaged experiment, as confirmed by near unity measured coherences. The short excitation time in the present experiment lead to a resolution bandwidth of 15 Hz, which increased the maximum estimated resolution bias errors a small amount. The level of error is still significantly smaller than the observed fluctuation, which can confidently be attributed to changes in the medium itself.

It has long been predicted from theory that propagation in bubbly fluids is sensitive to the bubble population parameters. The present work has reinforced this notion both theoretically and experimentally. The significance of these results is the following: Existing theory, specifically that represented by Eq. (2), is capable of predicting the *relative variability* of sound propagation parameters in bubbly liquids at resonance, if the bubble population parameters are known, up to a void fraction of 5.4×10^{-4} . This appears to be the case, despite the fact that the *absolute accuracy* of the model represented by Eq. (2) has not been verified experimentally.

VI. SUMMARY AND CONCLUSIONS

In this work, the acoustics of bubbly liquid was investigated. Experiments were conducted that focused on linear plane wave propagation parameters in the frequency range surrounding individual bubble resonance. An impedance tube system was used to measure the phase speed and attenuation in fluids composed of air bubbles and distilled water for a

range of void fractions between 6.2×10^{-5} and 5.4×10^{-4} . The bubble size distributions were centered around 0.62 μm in radius. The void fraction and size distribution parameters were obtained from secondary measurements done just prior to or just after the measurement of impedance. It was found that the bubble population statistics were not stationary in time. They were changing during the experiments, even though the observable bubble production controls were stationary in time. Despite this discrepancy, it was found that the model discussed in Sec. II could be used to describe measurements near resonance. In order to do so, some of the bubble population parameters were used to fit the model to the measurements. This fitting was within the uncertainty of the population parameter measurements and yielded good agreement between the model and the observations near resonance for both phase speed and attenuation. This agreement is better than the agreement obtained between the model and measurements previously reported.³ Above resonance, the model overpredicted the observed phase speed, however, it was determined that the inversion technique used to obtain the phase speed and attenuation from the impedance measurements was not appropriate for use when the phase speed rose above approximately 2000 m/s. Therefore, further use of the impedance tube technique for an investigation of the supersonic regime above resonance will require additional work on the inversion process.

In a second round of experiments, the *variability* of both the bubble population statistics and the propagation parameters were investigated. The population statistics measurements and impedance measurements were still done in succession, but, here, the time scales of the two sets of measurements were much more similar than in the time-averaged experiment. It was found that Eq. (2) could indeed predict the *relative variability* of the propagation parameters at resonance frequency, specifically the peak attenuation and

the frequency at which it occurred. This is the case despite the fact that the *absolute accuracy* of Eq. (2) has not been experimentally verified. Another general conclusion drawn from these results is the following: the observation of acoustical parameters in bubbly liquids must be done on the same time scale as the observation of the associated bubble population parameters.

Finally, these results indicate that the *absolute accuracy* of Eq. (2) and of other competing theories can be verified near resonance using the existing impedance tube system. In order to do this, a colocated instrument to simultaneously measure bubble population statistics, or more stable bubble production equipment is required. In either case, the resolution and accuracy of the sizing apparatus must be increased by an order of magnitude over the present system, and the number of bubbles observed per unit time should also be increased by an order of magnitude.

(Received 29 June 2004; revised 14 December 2004; accepted 23 January 2005)

A Gaussian beam (GB) summation representation for rough surface scattering is introduced. In this scheme, the coherent and incoherent scattered fields are described by a phase-space summation of GBs that emanate from the rough surface at discrete set of points and directions. It thus involves stochastic GB2GB scattering matrices for the coherent and incoherent fields, and deterministic GB propagators. It benefits from the simplicity and accuracy of the latter, and can be used in applications involving propagation in complex scenarios comprising inhomogeneous media with rough surface boundaries. The GB2GB matrices are calculated from the statistical moments of the scattering amplitude, which are given either analytically or empirically. An analytical and numerical example for weakly rough surface is presented and discussed. Applications to the more complicated propagation scenario of doubly rough surface waveguide with multiple reflection phenomena will be presented in a follow-up publication. © 2005 Acoustical Society of America.

I. INTRODUCTION

Wave propagation in complex environments containing rough surface boundaries represents one of the main topics both of electromagnetics (Beckmann and Spizzichino, 1987) and acoustics (Ellis *et al.*, 1993; McDaniel, 1993) (see Etter, 2001, 2003 for references in underwater propagation). Rigorous analysis of rough surface scattering is based on plane-wave spectrum (Voronovich 1999), yet tracking of the plane-wave basis function through interaction with rough surfaces is rather complicated and computationally inefficient because, in addition to the specular rays, there are multiple nonspecular incoherent contributions originating from different spatial locations of the rough surfaces, thus leading to highly nonlocal integral representations. These difficulties become critical when the scattered field needs to be tracked through complex inhomogeneous medium, since the plane waves need to be adapted locally to the medium inhomogeneity. Localization of the rough surface scattering and of the propagation model can be affected asymptotically via ray theory: Prescriptions for how to adopt the ray theory for analyzing high-frequency phenomena in such structures are summarized in the stochastic geometrical theory of diffraction (SGTD), which has been formalized as an extension of its deterministic counterpart (GTD), when the parameters of the medium exhibit random spatial and temporal variations (Mazar and Felsen, 1989). The difficulties of the ray formulation stem from the nonuniform asymptotic structure of the ray field that fails near focal and caustic regions. Furthermore, a proper coverage of the propagation domain requires

the tracking of a dense lattice of rays, which becomes computationally intensive in complicated medium.

To circumvent these difficulties, in this work a new method based on the frame-based Gaussian beam summation (GBS) is proposed. In the GBS method, the source field is expanded into a spectrum of GBs that emanate from the source domain in all directions and thereafter are tracked locally in the medium. Unlike the plane-wave basis functions, GBs can be easily and efficiently propagated in inhomogeneous media and, unlike ray representations, they are insensitive to caustic and foci regions. Furthermore, when properly formulated, the GBS does not require a dense set of beams. Thus, the GBS representation combines the localization properties and algorithmic ease of the ray representation with the uniform features of the plane-wave representation.

There are essentially two classes of GBS representations, one that addresses point source configurations, e.g., Červený *et al.*, 1982; Babich and Popov, 1989; Porter and Bucker, 1987; Porter, 1997, and one that deals with distributed (or aperture) source configurations, e.g., Bastiaans, 1980; Steinberg *et al.*, 1991; Lugara *et al.*, 2003; Shlivinski *et al.*, 2004 [see Figs. 1(b) and (a), respectively]. In this paper we apply the latter to the problem of rough surface scattering. Originally, this scheme was based on Gabor's series expansion (Bastiaans, 1980; Steinberg *et al.*, 1991); hence, it suffered from certain inherent difficulties of this representation, but later on it was reformulated using the theory of windowed Fourier transform (WFT) frames (Lugara *et al.*, 2003; Shlivinski *et al.*, 2004), which remedied these difficulties (see an overview in Shlivinski *et al.*, 2004). The theory now provides a rigorous phase-space framework that decomposes any field in an aperture of a real or virtual source to a set of simple GBs that emanate from a discrete set of points

^{a)}Deceased.

FIG. 1. Beam expansion of the source field field. (a) A phase-space beam expansion of an aperture source. (b) An expansion of a point source to GBs emerging from the source in a discrete set of directions.

in the aperture into a discrete set of directions.

The implementation of the GB procedure in the present rough surface scattering application is managed by a GB-to-GB (GB2GB) scattering matrix, where the incident field is decomposed into GBs, and each GB is then scattered into a discrete spectrum of GBs. This scattering matrix is the Gaussian equivalent of the scattering cross section of plane waves in the conventional spectral analysis of rough surface scattering. It can now be used in the overall problem of an inhomogeneous medium with rough surface boundaries, by propagating the GBs easily within the medium and using the GB2GB scattering matrix to acquire the relevant GBs scattered from the rough surface.

Concerning the presentation layout, we start with brief overviews of rough surface formulation and of the frame-based GBS (Secs. II and III A, respectively). In Sec. IV we combine the two to analyze rough surfaces using the GBS method, and provide general definitions for the coherent and the noncoherent GB2GB scattering matrices. An analytical example of a weakly rough surface, for which the scattering matrices can be calculated in closed form via the small perturbation approximation, is presented in Sec. V, together with a numerical example that demonstrates the phase-space footprints of the rough surface scattering processes. The presentation ends in Sec. VI with concluding remarks.

II. ROUGH SURFACE FORMULATION

A. Spectral representation

We consider the wave field in the lower half-space $z > h(\mathbf{x})$, with an upper rough surface $z = h(\mathbf{x})$. Here, z is the depth coordinate, defined to be positive in the downward direction in a 3D coordinate frame $\mathbf{r} = (\mathbf{x}, z)$, where $\mathbf{x} = (x_1, x_2)$ denotes the horizontal coordinate. The surface is illuminated by a general incident field $u^i(\mathbf{r})$, expressed as a sum of plane waves

$$u^i(\mathbf{r}) = \left(\frac{1}{2\pi}\right)^2 \int \tilde{u}^i(\mathbf{k}_x) e^{i\mathbf{k}_x \cdot \mathbf{x} - ik_z z} d^2 k_x, \quad (1)$$

where $\mathbf{k}_x = (k_{x1}, k_{x2})$, $\tilde{u}^i(\mathbf{k}_x)$ is the Fourier transform of the field at $z=0$, and $k_z = \sqrt{k - |\mathbf{k}_x|^2}$, with $\text{Im}(k_z) \geq 0$ so that the field decays at $z \rightarrow \infty$. The scattered field is given by

$$u^s(\mathbf{r}) = \left(\frac{1}{2\pi}\right)^2 \int \tilde{u}^s(\mathbf{k}_x) e^{i\mathbf{k}_x \cdot \mathbf{x} + ik_z z} d^2 k_x, \quad (2)$$

where

$$\tilde{u}^s(\mathbf{k}_x) = \int \tilde{u}^i(\mathbf{k}'_x) S(\mathbf{k}_x, \mathbf{k}'_x) d^2 k'_x, \quad (3)$$

with $S(\mathbf{k}_x, \mathbf{k}'_x)$ being the ‘‘scattering amplitude’’ (Voronovich, 1999). This definition refers to a single realization of the rough surface, but also contains the statistical characteristics of the random surface. If the roughness statistics is spatially homogeneous in the horizontal plane, then S has the form (Voronovich, 1999)

$$S(\mathbf{k}_x, \mathbf{k}'_x) = \bar{V}(\mathbf{k}_x) \delta(\mathbf{k}_x - \mathbf{k}'_x) + \Delta S(\mathbf{k}_x, \mathbf{k}'_x), \quad (4)$$

where $\bar{V}(\mathbf{k}_x)$ is the ‘‘mean reflection coefficient’’ while ΔS represents the fluctuation in the scattering amplitude with zero ensemble average. Its statistical moments satisfy

$$\begin{aligned} \overline{\Delta S} &= 0, \quad \overline{\Delta S(\mathbf{k}_{x1}, \mathbf{k}'_{x1}) \Delta S^*(\mathbf{k}_{x2}, \mathbf{k}'_{x2})} \\ &= \Delta E(\mathbf{k}_{av}, \mathbf{k}'_{av}; \delta_k) \delta(\delta_k - \delta'_k), \end{aligned} \quad (5)$$

where $\mathbf{k}_{av} = (\mathbf{k}_{x1} + \mathbf{k}_{x2})/2$, $\mathbf{k}'_{av} = (\mathbf{k}'_{x1} + \mathbf{k}'_{x2})/2$, $\delta_k = (\mathbf{k}_{x2} - \mathbf{k}_{x1})$, and $\delta'_k = (\mathbf{k}'_{x2} - \mathbf{k}'_{x1})$. The special case $\delta_k = \delta'_k = 0$ defines the ‘‘scattering cross section’’

$$\Delta E(\mathbf{k}_x, \mathbf{k}'_x; 0) = \sigma(\mathbf{k}_x, \mathbf{k}'_x). \quad (6)$$

B. Field observables: Coherent and noncoherent fields

The physical observables are the average field and the average intensity. The former, also called ‘‘the coherent field,’’ is defined by

$$u_c^s(\mathbf{r}) = \bar{u}^s(\mathbf{r}), \quad (7)$$

where the overbar denotes an average over an ensemble of realizations, and u_c^s can be described by the spectral integral (2) where, from (4), the spectral amplitude is given by

$$\tilde{u}_c^s(\mathbf{k}_x) = \tilde{u}^i(\mathbf{k}_x) \bar{V}(\mathbf{k}_x). \quad (8)$$

The scattered intensity is defined by $I^s(\mathbf{r}) = u^s(\mathbf{r}) u^{s*}(\mathbf{r})$. Averaging the measured intensity over the ensemble results yields

$$\bar{I}^s(\mathbf{r}) = I_c^s(\mathbf{r}) + I_{nc}^s(\mathbf{r}), \quad (9)$$

where $I_c^s = u_c^s u_c^{s*}$ is the coherent intensity; hence, I_{nc}^s is defined as the ‘‘noncoherent intensity.’’ It is a measure of the field fluctuations above the average (or the coherent) field. It can be expressed in terms of the second moment of S in (5), but the general expression is quite cumbersome. A simple relation is obtained in the far-field zone [see (12b)].

1. Far-zone observables

Of particular importance in various applications and in analysis are the far-zone observables. By an asymptotic evaluation of (2) for $|\mathbf{r}| \equiv r \rightarrow \infty$, one obtains

$$\begin{aligned} u^{\text{FF}}(\mathbf{r}) &= -2ik \cos \theta \frac{e^{ikr}}{4\pi r} \\ &\times \tilde{u}^s(\mathbf{k}_x) \Big|_{\mathbf{k}_x = k\mathbf{x}/r = k \cos \theta (\cos \phi, \sin \theta)}, \end{aligned} \quad (10)$$

where (θ, ϕ) are the conventional spherical angles; hence, the intensity is given by

$$I^{\text{FF}}(\mathbf{r}) = \frac{k^2 \cos^2 \theta}{4 \pi^2 r^2} \left| \tilde{u}^s(\mathbf{k}_x) \tilde{u}^{s*}(\mathbf{k}_x) \right|_{\mathbf{k}_x = k\mathbf{x}/r}. \quad (11)$$

Inserting (3) and averaging over the ensemble as in (9) results in the following expressions for the far-field coherent and noncoherent intensities:

$$I_c^{\text{FF}}(\mathbf{r}) = \frac{k^2 \cos^2 \theta}{4 \pi^2 r^2} |\bar{u}^i(\mathbf{k}_x)|^2 |\bar{V}(\mathbf{k}_x)|_{\mathbf{k}_x = k\mathbf{x}/r}^2 \quad (12a)$$

$$I_{\text{nc}}^{\text{FF}}(\mathbf{r}) = \frac{k^2 \cos^2 \theta}{4 \pi^2 r^2} \int |\bar{u}^i(\mathbf{k}'_x)|^2 \sigma(\mathbf{k}_x, \mathbf{k}'_x) d^2 k'_x |_{\mathbf{k}_x = k\mathbf{x}/r}. \quad (12b)$$

2. Noncoherent field

The noncoherent intensity $I_{\text{nc}}^s(\mathbf{r})$ is a measure of the field fluctuations above the coherent (i.e., average) field. To propagate this constituent we define the noncoherent field $u_{\text{nc}}^s(\mathbf{r})$, which provides the mathematical way to calculate the propagation of the observable $I_{\text{nc}}^s = |u_{\text{nc}}^s|^2$. In other words, u_{nc}^s can be regarded as a “deterministic realization” of a field that gives rise to the stochastic observable I_{nc}^s and particularly $I_{\text{nc}}^{\text{FF}}$.

One way to define u_{nc}^s is to construct its spectral amplitude \tilde{u}_{nc}^s from the far-field observable $I_{\text{nc}}^{\text{FF}}$ via (11), and then to propagate it via (2). The GBS representation with the GB2GB scattering matrices, introduced later on in this paper, provides an alternative to the spectral approach that can be used to propagate the stochastic observables in inhomogeneous medium.

Referring to the noncoherent part in (11), we define the spectral amplitude \tilde{u}_{nc}^s as

$$\begin{aligned} |\tilde{u}_{\text{nc}}^s(\mathbf{k}_x)| &= \frac{2 \pi r}{k \cos \theta} \sqrt{I_{\text{nc}}^{\text{FF}}(\mathbf{r})|_{\mathbf{x}/r = \mathbf{k}_x/k}} \\ &= \sqrt{\int |\bar{u}^i(\mathbf{k}'_x)|^2 \sigma(\mathbf{k}_x, \mathbf{k}'_x) d^2 k'_x}, \end{aligned} \quad (13)$$

where the second form follows from (12b).

By definition, the phase of $\tilde{u}_{\text{nc}}^s(\mathbf{k}_x)$ cannot be recovered. Yet, $\tilde{u}_{\text{nc}}^s(\mathbf{k}_x)$ contains a deterministic phase term that describes the localization of the incident wave. We recall that scattering cross section $\sigma(\mathbf{k}_x, \mathbf{k}'_x)$ is found from the far-field intensity measured with respect to a certain origin. Defining the center of mass of the incident field

$$\mathbf{x}^i = \|\mathbf{x} u^i(\mathbf{x})\| / \|u^i(\mathbf{x})\|, \quad (14)$$

where $\|\cdot\|$ represents the conventional L_2 norm, the noncoherent spectral amplitude becomes

$$\tilde{u}_{\text{nc}}^s(\mathbf{k}_x) = e^{-i \mathbf{k}_x \cdot \mathbf{x}^i} \sqrt{\int |\bar{u}^i(\mathbf{k}'_x)|^2 \sigma(\mathbf{k}_x, \mathbf{k}'_x) d^2 k'_x}. \quad (15)$$

The phase in (15) should be understood in the context of the noncoherent scattered field. It is a deterministic parameter due to the incident field localization, and not “phase reconstruction” of \tilde{u}_{nc}^s as such phase is undefined.

III. FRAME-BASED GAUSSIAN BEAM SUMMATION (GBS) METHOD

The frame-based GBS method provides an alternative to the conventional plane-wave representation. In this section we briefly review the basic concepts of this formulation, while in Sec. IV we shall use it to formulate a local spectrum representation for rough surface scattering, as an alternative to the spectral formulation of Sec. II.

We start in Sec. III A with a brief discussion on the windowed Fourier transform (WFT) frames that provide the mathematical framework for the GBS method to be presented in Sec. III B.

A. Signal representation using windowed Fourier transform (WFT) frame

For simplicity, we consider functions of one space coordinate (only in Sec. III A). The formulation is based on the construction of two dual frame sets in $L_2(\mathbb{R})$

$$\psi_{\boldsymbol{\mu}}(x) = \psi(x - m\bar{x}) e^{i n \bar{k}_x (x - m\bar{x})}, \quad (16)$$

$$\varphi_{\boldsymbol{\mu}}(x) = \varphi(x - m\bar{x}) e^{i \bar{k}_x (x - m\bar{x})}, \quad (17)$$

where $\psi(x)$ is a proper window function, $\varphi(x)$ is its dual (see below), and $\boldsymbol{\mu} = (m, n) \in \mathbb{Z}^2$ is an index. The parameters (\bar{x}, \bar{k}_x) define spatial and spectral displacement units in the continuous phase-space (x, k_x) , so that $(m\bar{x}, n\bar{k}_x)$ constitutes a discrete phase-space grid that defines the phase-space centers of the elements in $\{\psi(x)\}$ and $\{\varphi(x)\}$. For these sets to be frames, it is necessary that the unit-cell area satisfies the condition

$$\bar{x} \bar{k}_x = 2 \pi \nu, \quad \text{where } \nu < 1. \quad (18)$$

The parameter ν is the overcompleteness (or oversampling) factor of the frame. The frame is overcomplete for $\nu < 1$ and it is complete in the Gabor limit $\nu \uparrow 1$.

It is desired (though not necessary) that the windows provide a balance spatial and spectral coverage of the unit cell. This is achieved if ψ is “matched” to the grid so that

$$\Delta_x / \bar{x} = \Delta_{k_x} / \bar{k}_x, \quad (19)$$

where $\Delta_x = \|x \psi(x)\| / \|\psi(x)\|$ and $\Delta_{k_x} = \|k_x \tilde{\psi}(k_x)\| / \|\tilde{\psi}(k_x)\|$ are the spatial and spectral widths of ψ , respectively.

In general, the dual window φ in (17) needs to be calculated numerically for a given ψ and grid (\bar{x}, \bar{k}_x) , but for small ν it can be approximated analytically as

$$\varphi(x) \simeq C_0 \psi(x), \quad \text{where } C_0 = \nu / \|\psi\|^2. \quad (20)$$

A given function $u(x) \in L_2(\mathbb{R})$ can be expanded now as

$$u(x) = \sum_{\boldsymbol{\mu}} a_{\boldsymbol{\mu}} \psi_{\boldsymbol{\mu}}(x), \quad (21)$$

$$a_{\boldsymbol{\mu}} = \langle u(x), \varphi_{\boldsymbol{\mu}}(x) \rangle, \quad (22)$$

where $\langle f(x), g(x) \rangle = \int dx f(x) g^*(x)$ is the conventional L_2 inner product. In view of (17), $a_{\boldsymbol{\mu}}$ are readily identified as WFT of $u(x)$ with respect to the window $\varphi(x)$, centered about the phase-space lattice point $(m\bar{x}, n\bar{k}_x)$. Referring to

Eqs. (21)–(22), $\{\varphi_{\mu}(x)\}$ and $\{\psi_{\mu}(x)\}$ are also termed the “analysis” and “synthesis” frames, respectively.

As an example, consider a Gaussian window of the form

$$\psi(x) = e^{-x^2/2\sigma^2}, \quad \sigma^2 > 0. \quad (23)$$

From (19), this window is matched to the grid if $\sigma^2 = \bar{x}/\bar{k}_x$. From (20), $C_0 = \nu/\sqrt{\pi}\sigma$ giving, for $\nu < 0.5$

$$\varphi(x) \approx \frac{\nu}{\sqrt{\pi}\sigma} e^{-x^2/2\sigma^2}. \quad (24)$$

B. Phase-space Gaussian beam expansion

The WFT frame expansion can be used to describe the propagation of a given wave field $u(\mathbf{x}, z=0) \equiv u_0(\mathbf{x})$, which is defined on the $z=0$ plane in the three-dimensional coordinate space $\mathbf{r} = (x, z)$. To this end, we expand the data $u_0(\mathbf{x})$ using the WFT frame theory which is extended now to two space dimensions. Using properly chosen Gaussian windows, the synthesis elements $\psi_{\mu}(\mathbf{x})$ give rise to Gaussian beam (GB) propagators $B_{\mu}(\mathbf{r})$ that are used to represent the propagated field.

The 2D expansion of the WFT frame using a Gaussian window is obtained by a simple Cartesian multiplication of the 1D frame expansion. The phase-space lattice is

$$\begin{aligned} \mathbf{x}_m &= (m_1 \bar{x}_1, m_2 \bar{x}_2), \quad \mathbf{k}_{x\mathbf{n}} = (n_1 \bar{k}_{x1}, n_2 \bar{k}_{x2}), \\ \boldsymbol{\mu} = (\mathbf{m}, \mathbf{n}) &= (m_1, m_2, n_1, n_2), \end{aligned} \quad (25)$$

where \bar{x}_j and \bar{k}_{xj} , $j=1,2$ are the translation steps in the spatial and spectral domains along the x_j axes. Note that the x_1 and x_2 lattices need not be identical, but both should satisfy (18), i.e., $\bar{x}_j \bar{k}_{xj} = 2\pi\nu_j$, with $\nu_j < 1$. To be specific, we choose a square lattice with $\bar{x}_1 = \bar{x}_2 = \bar{x}$ and $\bar{k}_{x1} = \bar{k}_{x2} = \bar{k}_x$.

The WFT frame expansion of the 2D data field $u_0(\mathbf{x})$ is

$$u_0(\mathbf{x}) = \sum_{\boldsymbol{\mu}} a_{\boldsymbol{\mu}} \psi_{\boldsymbol{\mu}}(\mathbf{x}), \quad \psi_{\boldsymbol{\mu}}(\mathbf{x}) = \psi(\mathbf{x} - \mathbf{x}_m) e^{i\mathbf{k}_{x\mathbf{n}} \cdot (\mathbf{x} - \mathbf{x}_m)}. \quad (26)$$

The expansion coefficients $a_{\boldsymbol{\mu}}$ are calculated by projecting $u_0(\mathbf{x})$ onto the dual frame via [see also (50)]

$$a_{\boldsymbol{\mu}} = \langle u_0(\mathbf{x}), \varphi_{\boldsymbol{\mu}}(\mathbf{x}) \rangle. \quad (27)$$

Having expanded the field $u_0(\mathbf{x})$ in the $z=0$ plane to Gaussian frames, we propagate it into the lower homogeneous half-space $z > 0$, giving

$$u(\mathbf{r}) = \sum_{\boldsymbol{\mu}} a_{\boldsymbol{\mu}} B_{\boldsymbol{\mu}}(\mathbf{r}), \quad (28)$$

where the propagator $B_{\boldsymbol{\mu}}(\mathbf{r})$ is the radiated field due to the field distribution $\psi_{\boldsymbol{\mu}}(\mathbf{k}_x)$ on the $z=0$ plane. It is given by either one of the following alternatives:

$$B_{\boldsymbol{\mu}}(\mathbf{r}) = 2 \int d^2x' \psi_{\boldsymbol{\mu}}(\mathbf{x}') \partial_z G(\mathbf{r}|\mathbf{r}')|_{z'=0} \quad (29a)$$

$$= \left(\frac{1}{2\pi} \right)^2 \int d^2k_x \tilde{\psi}_{\boldsymbol{\mu}}(\mathbf{k}_x) e^{i\mathbf{k}_x \cdot \mathbf{x} + ik_x z}. \quad (29b)$$

FIG. 2. The discrete phase-space beam summation representation. The beams emerge from the lattice points \mathbf{x}_m in the spectral directions $\mathbf{k}_{x\mathbf{n}}$. (\bar{x}, \bar{k}_x) are the spatial and spectral unit cell dimensions, respectively.

Expression (29a) is the Kirchhoff representation, with $G(\mathbf{r}|\mathbf{r}') = \exp\{ik|\mathbf{r} - \mathbf{r}'|\}/4\pi|\mathbf{r} - \mathbf{r}'|$ being the free-space Green's function and ∂_z denotes the derivative with respect to z' at the source point \mathbf{r}' . Expression (29b) is the plane-wave representation, with $\tilde{\psi}_{\boldsymbol{\mu}}(\mathbf{k}_x) = \tilde{\psi}(\mathbf{k}_x - \mathbf{k}_{x\mathbf{n}}) e^{-i\mathbf{k}_x \cdot \mathbf{x}_m}$ being the spectral counterpart of $\psi_{\boldsymbol{\mu}}(\mathbf{x})$.

Since $\psi_{\boldsymbol{\mu}}$ are localized about $(\mathbf{x}_m, \mathbf{k}_{x\mathbf{n}})$ in the phase space, $B_{\boldsymbol{\mu}}$ describes a beam field that emerges from \mathbf{x}_m in the $z=0$ plane in the direction (unit vectors are denoted by a caret)

$$\hat{\mathbf{k}}_{\mathbf{n}} = (\mathbf{k}_{x\mathbf{n}}, k_{z\mathbf{n}})/k = (\cos \phi_{\mathbf{n}} \sin \theta_{\mathbf{n}}, \sin \phi_{\mathbf{n}} \sin \theta_{\mathbf{n}}, \cos \theta_{\mathbf{n}}). \quad (30)$$

Thus, propagating beams are obtained only for small \mathbf{n} such that $|\mathbf{k}_{x\mathbf{n}}| < k$: For $|\mathbf{k}_{x\mathbf{n}}| > k$ the field of $B_{\boldsymbol{\mu}}$ decays away from the $z=0$ plane. In practice we ignore all the evanescent beams and use in (28) only the beams with $|\mathbf{k}_{x\mathbf{n}}| < 1$, thereby expressing the radiated field as a discrete phase-space superposition of beams that emerge from all lattice points \mathbf{x}_m in the aperture plane and in all real lattice directions $\mathbf{k}_{x\mathbf{n}}$; Fig. 2.

It should be noted that for a given observation point \mathbf{r} , we truncate the summation in (28) so that only those beam propagators that pass near \mathbf{r} are included [actually we include those that pass within a 3-beamwidth distance from \mathbf{r} (Steinberg *et al.*, 1991; Shlivinski *et al.*, 2004)]. Viewed from a phase-space perspective, this localizes the summation to the vicinity of the so-called *geometrical observation manifold* that defines the initiation points and directions of the beams whose axis pass through the observation point. In free space, this manifold is defined by

$$(\mathbf{x} - \mathbf{x}_m)/z \approx \mathbf{k}_{x\mathbf{n}}/k_{z\mathbf{n}}. \quad (31)$$

This truncation greatly reduces the computation cost.

Next, we consider the Gaussian windows of (23), which will be rewritten henceforth in the form

$$\begin{aligned} \psi(x) &= e^{-k|x|^2/2b}, \quad \text{and} \\ \varphi(x) &\approx \nu^2(k/\pi b) e^{-k|x|^2/2b}, \quad b = k\bar{x}/\bar{k}_x, \end{aligned} \quad (32)$$

where, for analytic simplicity, we use $\nu < 0.5$ so that φ can be approximated as in (24), while the condition on b follows from (19). We also use $kb \gg 1$ so that ψ is wide on a wavelength scale and it yields collimated Gaussian beams (GB) propagators. Analytic expressions for $B_{\boldsymbol{\mu}}$ can be obtained by evaluating the integral (29b) asymptotically via saddle-point integration as detailed in Melamed (1997). One finds that $B_{\boldsymbol{\mu}}$ is an astigmatic GB that can be described in the most physically appealing format by utilizing the beam coordinates $\mathbf{r}_b = (x_{b1}, x_{b2}, z_b)$ defined for a given phase-space point $\boldsymbol{\mu}$. The

FIG. 3. The beam coordinate system (33)–(34) corresponding to a given beam propagator B_μ . Here, \hat{z}_{b_n} is the beam axis and $\hat{x}_{b_{1,2}}$ are the transverse axes as defined there.

beam axis z_b emerges from $\mathbf{r}_m = (\mathbf{x}_m, z=0)$ in the direction $\hat{\mathbf{k}}_n$ of (30). The transverse coordinates $\mathbf{x}_b = (x_{b_1}, x_{b_2})$ are chosen such that the projection of the unit vector \hat{x}_{b_1} on the $z=0$ plane coincides with the direction of \mathbf{k}_{x_n} , while $\hat{x}_{b_2} = \hat{z}_b \times \hat{x}_{b_1}$. With this choice, the linear phase $\mathbf{k}_{x_n} \cdot \mathbf{x}$ implied by the window function ψ_μ [see (26)] is operative in the x_{b_1} direction *but not* in the x_{b_2} direction. The beam and physical coordinates are related by (see Fig. 3)

$$\mathbf{r}_b = \mathbf{\Omega}_n(\mathbf{r} - \mathbf{r}_m), \quad (33)$$

where the unitary rotation matrix $\mathbf{\Omega}_n$ is defined so that the transverse coordinates are rotated about the z_b axis such that $\mathbf{x}_{b_2} \cdot \mathbf{k}_{x_n} = 0$

$$\mathbf{\Omega}_n = \begin{pmatrix} \cos \theta_n \cos \phi_n & \cos \theta_n \sin \phi_n & -\sin \theta_n \\ -\sin \phi_n & \cos \phi_n & 0 \\ \sin \theta_n \cos \phi_n & \sin \theta_n \sin \phi_n & \cos \theta_n \end{pmatrix}. \quad (34)$$

Along this axis, the astigmatic GB field can be expressed as

$$B_\mu(\mathbf{r}) \approx \left(\frac{\det \Gamma(z_b)}{\det \Gamma(0)} \right)^{1/2} e^{ikz_b} e^{i(k/2)\mathbf{x}_b^T \Gamma(z_b) \mathbf{x}_b}, \quad (35)$$

where $\Gamma(z_b)$ is a 2×2 complex symmetric matrix with $\text{Im} \Gamma(z_b)$ positive definite. As a result, the imaginary part of the quadratic form $\mathbf{x}_b^T \Gamma(z_b) \mathbf{x}_b = x_{b_1}^2 \Gamma_{11} + 2x_{b_1} x_{b_2} \Gamma_{12} + x_{b_2}^2 \Gamma_{22}$ increases away from the z_b axis, leading to the Gaussian decay of the beam field. In free space it is found from the initial condition $\Gamma(0)$ via

$$\Gamma(z_b) = [z_b \mathbf{I} + \Gamma^{-1}(0)]^{-1}, \quad (36)$$

where \mathbf{I} is the unit matrix. One observes that indeed $\text{Im} \Gamma(z_b)$ is positive definite for all z_b provided that $\text{Im} \Gamma(0)$ is positive definite. In inhomogeneous medium, $\Gamma(z_b)$ is calculated by solving a proper differential equation (the so-called “dynamic ray-tracing equation”) along the ray trajectory that defines the beam axis (Červený *et al.*, 1982; Babich and Popov, 1989).

In the coordinate system defined above, $\Gamma(0)$, and thereby $\Gamma(z_b)$, is diagonal and is given by

$$\Gamma_{\ell,\ell}(0) = i/F_\ell, \quad F_1 = b \cos^2 \theta_n, \quad F_2 = b, \quad \ell = 1, 2. \quad (37)$$

Substituting in (35)–(36), the GB field in that system is given, explicitly, by

$$B_\mu(\mathbf{r}) \approx \sqrt{\frac{-iF_1}{z_b - iF_1} \frac{-iF_2}{z_b - iF_2}} \times \exp \left\{ ik \left[z_b + \frac{x_{b_1}^2/2}{z_b - iF_1} + \frac{x_{b_2}^2/2}{z_b - iF_2} \right] \right\}. \quad (38)$$

The beam characteristics in the x_{b_ℓ} cuts are found by separating the corresponding phase term in (38) into real and imaginary parts in the form

$$ik \frac{x_{b_\ell}^2/2}{z_b - iF_\ell} = ik \frac{x_{b_\ell}^2/2}{R_\ell(z_b)} - \frac{x_{b_\ell}^2/2}{W_\ell^2(z_b)}, \quad (39)$$

giving

$$W_\ell(z_b) = W_{0_\ell} \sqrt{1 + (z_b/F_\ell)^2}, \quad W_{0_\ell} = \sqrt{F_\ell/k}, \quad (40)$$

$$R_\ell = z_b + F_\ell^2/z_b.$$

Thus, $W_\ell(z_b)$ is the beamwidth, W_{0_ℓ} is the waist, $R_\ell(z_b)$ is the wavefront radius of curvature. F_ℓ is readily identified as the diffraction length in the x_{b_ℓ} cut. For $z_b \ll F_\ell$ we have $W_\ell(z_b) \approx W_{0_\ell}$, while for $z_b \gg F_\ell$ the beam opens up along the constant diffraction angles $\Theta_\ell = 1/\sqrt{F_\ell k}$.

The GB model (35)–(40) is an asymptotic approximation to the exact propagators as defined in (29). The validity increases with the beam collimation kb , but it deteriorates for large inclination angles $\theta_n = 0$ (see Shlivinski *et al.*, 2004, Fig. 7 for a detailed study of the error as a function of these parameters). In the numerical simulations of Sec. VC we used $kb = 5000$; hence, the propagator error for $\theta_n = 60^\circ$ is less than 1%.

IV. GAUSSIAN BEAM SUMMATION (GBS) ANALYSIS OF ROUGH SURFACE SCATTERING

We now use the GBS theory from the previous section for phase-space (local spectrum) analysis of the rough surface scattering phenomenology discussed in Sec. II. The scattered field will be analyzed using the frame $\{\psi_\mu\}$ with respect to the $z=0$ plane (as discussed in Sec. III).

A. GB modeling of the incident field

We shall consider two options to describe the incident field $u^i(\mathbf{r})$ that hits the rough surface from below (i.e., from $z > 0$). The first is to expand u^i using the same frame $\{\psi_\mu\}$ which is used to expand the scattered field. The other is to describe u^i using a GBS with reference to a different frame and a different reference plane.

An example for the latter approach is when the field of a source located below the rough surface is expanded using a frame $\{\psi_\mu^{(i)}\}$ with respect to the source aperture plane (the aperture can be horizontal, vertical, or at any other convenient angle) or with respect to a point source; see Fig. 1. In any case, the incident field hitting the upper surface at $z=0$ has the general form [see (28)]

$$u^i(\mathbf{r}) = \sum_{\mu^i} a_{\mu^i} B_{\mu^i}^i(\mathbf{r}), \quad (41)$$

where $B_{\mu^i}^i(\mathbf{r})$ are GBs of the form (38) emerging from the source domain toward the rough surface, μ^i is an index, and a_{μ^i} are the expansion coefficients.

Another example for the second approach appears in Gordon *et al.*, 2005, where we consider wave propagation between two rough surfaces and use, in general, different frames $\{\psi_{\mu_1}^{(1)}\}$ and $\{\psi_{\mu_2}^{(2)}\}$ for expansion in the upper and lower surfaces, respectively. In that case, the incident field hitting the upper surface at $z=0$ is expanded in terms of the GBs $B_{\mu_2}^{(2)}(\mathbf{r})$ that emerge from the lower surface and hit the upper surface, i.e., it has the general form in (41) except that the superscript i is now replaced by (2).

Henceforth, we shall consider the second approach discussed in (41) above, since the first approach, namely to expand u^i using $\{\psi_{\mu^i}\}$, can be treated as a special simplified case of the second approach.

B. GB-to-GB scattering matrices

Without loss of generality, we shall assume below that the incident field is described by a single element in (41) and has the typical GB form in (35)

$$u^i(\mathbf{r}) = B^i(\mathbf{r}) = A^i(z_b^i) e^{ik[z_b^i + (1/2)\mathbf{x}_b^{iT} \mathbf{\Gamma}^i(z_b^i) \mathbf{x}_b^i]}, \quad (42)$$

where (\mathbf{x}_b^i, z_b^i) are the beam coordinates with respect to the axis of this beam, $A(z_b^i)$ is the slowly varying amplitude of this beam along the z_b^i axis, and $\mathbf{\Gamma}^i(z_b^i)$ is a complex symmetric matrix with $\text{Im } \mathbf{\Gamma}^i$ positive definite as discussed in (35) and (36).

At the scattering reference plane $z=0$, the incident field is identified by the following parameters:

- (i) A_0^i and $\mathbf{\Gamma}_0^i$, which are the values of A^i and $\mathbf{\Gamma}^i$ at the point where the beam axis intersects the $z=0$ plane. We use these values to describe the incident GB even at off-axis points on the plane $z=0$ plane (clearly this is an approximation since $\mathbf{\Gamma}^i$ are functions of z_b^i so that for tilted beams they are not constant on the $z=0$ plane, yet it is legitimate for narrow beams).
- (ii) The phase-space center of the beam at $z=0$: $\mathbf{x}^i = (x_1^i, x_2^i)$ and $\mathbf{k}_x^i = (k_{x1}^i, k_{x2}^i) = k \sin \theta^i (\cos \phi^i, \sin \phi^i)$ where (θ^i, ϕ^i) , with $\theta^i > \pi/2$, define the beam direction.
- (iii) Without loss of generality we use the coordinate convention in (33) and choose the beam coordinate system $\mathbf{x}_b^i = (x_{b1}^i, x_{b2}^i)$ in (42) such that the projection of $\hat{\mathbf{x}}_{b1}^i$ on the $z=0$ plane is along the \mathbf{k}_x^i axis, while $\hat{\mathbf{x}}_{b2}^i = \hat{z}_b^i \times \hat{\mathbf{x}}_{b1}^i$ (in other words, $\hat{\mathbf{x}}_{b2}^i \cdot \mathbf{k}_x^i = 0$) (compare Fig. 3).

In order to evaluate the scattered field as in (2)–(3), we need to calculate the plane-wave spectrum of the incident field via

$$\tilde{B}^i(\mathbf{k}_x) = \int B^i(\mathbf{x}, z=0) e^{i\mathbf{k}_x \cdot \mathbf{x}} d^2x. \quad (43)$$

To this end, we need to express the incident beam field in terms of the physical (or geographical) coordinates \mathbf{x} at $z=0$.

Recalling the coordinate definition above, we note that \mathbf{x}_b^i are related to the geographical coordinates via [cf. (33)]

$$\mathbf{x}_b^i = \boldsymbol{\zeta}^i (\mathbf{x} - \mathbf{x}^i), \quad (44)$$

where the 2×2 matrix $\boldsymbol{\zeta}^i$ is defined via [cf. (33)]

$$\begin{aligned} \boldsymbol{\Omega}^i &= \begin{pmatrix} \begin{bmatrix} -\cos \theta^i \cos \phi^i & -\cos \theta^i \sin \phi^i \\ \sin \phi^i & -\cos \phi^i \end{bmatrix} & \begin{bmatrix} \sin \theta^i \\ 0 \end{bmatrix} \\ \begin{bmatrix} \sin \theta^i \cos \phi^i & \sin \theta^i \sin \phi^i \end{bmatrix} & \cos \theta^i \end{pmatrix} \\ &= \begin{pmatrix} \boldsymbol{\zeta}^i & \boldsymbol{\eta}_1^i \\ \boldsymbol{\eta}_2^i & \boldsymbol{\epsilon}^i \end{pmatrix}. \end{aligned} \quad (45)$$

Note that $\boldsymbol{\Omega}^i$ is slightly different from $\boldsymbol{\Omega}_n$ (34) due to the difference between an incoming and an outgoing direction of the beam, respectively. Using these definitions

$$B^i(\mathbf{x}, z=0) = A_0^i e^{(ik/2)(\mathbf{x} - \mathbf{x}^i)^T \boldsymbol{\zeta}^i \mathbf{\Gamma}_0^i \boldsymbol{\zeta}^i (\mathbf{x} - \mathbf{x}^i) + i\mathbf{k}_x^i \cdot \mathbf{x}}. \quad (46)$$

Inserting (46) into (43) and evaluating the resulting integral via saddle-point integration, which, in this case, coincides with the exact solution, yields

$$\tilde{B}^i(\mathbf{k}_x) = A_0^i \frac{2\pi i}{k \sqrt{\det(\mathbf{\Gamma}_k^i)^{-1}}} e^{(-i/2k)(\mathbf{k}_x - \mathbf{k}_x^i)^T \mathbf{\Gamma}_k^i (\mathbf{k}_x - \mathbf{k}_x^i) - i(\mathbf{k}_x - \mathbf{k}_x^i) \cdot \mathbf{x}^i}, \quad (47)$$

where

$$\mathbf{\Gamma}_k^i = (\boldsymbol{\zeta}^{iT} \mathbf{\Gamma}_0^i \boldsymbol{\zeta}^i)^{-1}, \quad (48)$$

with the subscript k (or x , see below) indicating that the matrix relates to \mathbf{k}_x (or \mathbf{x}), and we take the root of $\sqrt{\det(\mathbf{\Gamma}_k^i)^{-1}}$, which has a positive imaginary part (recall that $\text{Im } \mathbf{\Gamma}_0^i$ is positive definite, so that $\text{Im } \mathbf{\Gamma}_k^i$ is negative definite; hence, this definition of the square root provides a continuous function of $\text{Re } \mathbf{\Gamma}_k^i$).

Finally, the plane-wave representation of the coherent and incoherent scattered fields is given by (8) and (15), with $\tilde{u}^i(\mathbf{k}_x)$ replaced by $\tilde{B}^i(\mathbf{k}_x)$ of (47).

Here, however, we shall describe the coherent and incoherent scattered fields by using the frame expansion of Sec. III B. Thus, at the $z=0$ plane, the fields are given by

$$u_c^s(\mathbf{x}, z=0) = \sum_{\mu} S_c(B^i, \psi_{\mu}) \psi_{\mu}(\mathbf{x}), \quad (49a)$$

$$u_{nc}^s(\mathbf{x}, z=0) = \sum_{\mu} S_{nc}(B^i, \psi_{\mu}) \psi_{\mu}(\mathbf{x}). \quad (49b)$$

The expansion coefficients, the GB-to-GB (GB2GB) scattering matrices, are obtained by projecting B^i onto the dual frame functions as in (27). Instead of (27), however, we shall use its spectral counterpart

$$a_{\mu} = \left(\frac{1}{2\pi} \right)^2 \langle \tilde{u}_0(\mathbf{k}_x), \tilde{\varphi}_{\mu}(\mathbf{k}_x) \rangle. \quad (50)$$

Thus, using (8) and (15) with $\tilde{B}^i(\mathbf{k}_x)$ of (47), the scattering matrices are calculated via

$$S_c(B^i, \psi_\mu) = \left(\frac{1}{2\pi}\right)^2 \int \bar{B}^i(\mathbf{k}_x) \bar{V}(\mathbf{k}_x) \bar{\varphi}_\mu^*(\mathbf{k}_x) d^2k_x, \quad (51a)$$

$$S_{nc}(B^i, \psi_\mu) = \left(\frac{1}{2\pi}\right)^2 \times \int e^{-i\mathbf{k}_x \cdot \mathbf{x}^i} \sqrt{|\sigma(\mathbf{k}_x, \mathbf{k}'_x)| \bar{B}^i(\mathbf{k}'_x)|^2 d^2k'_x} \times \bar{\varphi}_\mu^*(\mathbf{k}_x) d^2k_x, \quad (51b)$$

where $\bar{\varphi}_\mu(\mathbf{k}_x) = \bar{\varphi}(\mathbf{k}_x - \mathbf{k}_{xn}) e^{-i\mathbf{k}_x \cdot \mathbf{x}_m}$ is the spectral counterpart of $\varphi_\mu(\mathbf{x})$. For the Gaussian mother windows in (32) which are used here, we have

$$\bar{\varphi}_\mu(\mathbf{k}_x) = \nu^2 \frac{k}{\pi b} \tilde{\psi}_\mu(\mathbf{k}_x) = 2\nu^2 e^{-b|\mathbf{k}_x - \mathbf{k}_{xn}|^2/2k - i\mathbf{k}_x \cdot \mathbf{x}_m}. \quad (52)$$

Finally, the field representation in (49) is propagated using the GBS representation of (41), giving GBS representation for the scattered coherent and noncoherent fields

$$u_c^s(\mathbf{r}) = \sum_\mu S_c(B^i, \psi_\mu) B_\mu(\mathbf{r}), \quad (53a)$$

$$u_{nc}^s(\mathbf{r}) = \sum_\mu S_{nc}(B^i, \psi_\mu) B_\mu(\mathbf{r}). \quad (53b)$$

An analytical example of a weakly rough surface, for which the scattering matrices can be calculated in closed form via the small perturbation approximation, is presented in Sec. V.

V. EXAMPLE: WEAKLY ROUGH SURFACE

The formulation above can be applied to any rough surface using either measured or numerically generated scattering data. Here, we shall derive analytic results for weakly rough surface with Gaussian spectrum with l_h correlation length, where the standard deviation of the roughness satisfies $k\sigma_h \ll 1$. Using the small perturbation approximation, the statistical moments are given by (Voronovich, 1999)

$$\bar{V}(\mathbf{k}_x) = -1 + 8\pi^2 \sigma_h^2 k_z^2, \quad (54)$$

$$\sigma(\mathbf{k}_x, \mathbf{k}'_x) = 4\pi \sigma_h^2 l_h^2 k_z'^2 e^{-|\mathbf{k}_x - \mathbf{k}'_x|^2 l_h^2/4}. \quad (55)$$

The coherent and noncoherent S matrices of (51) can be evaluated analytically using saddle-point integration. It is assumed here that the incident beam and the expansion beams are collimated, i.e., $kb \gg 1$. This validates the use of the saddle-point evaluation.

Below, we shall calculate the S matrices and then compare numerically the coherent and noncoherent fields obtained via the GB2GB formulation to the those calculated via the plane-wave formulation.

A. Coherent field

For the coherent field, inserting (54), (47), and (52) into (51a) results in the following S matrix:

$$S_c(B^i, \psi_\mu) = \left(\frac{1}{2\pi}\right)^2 \int \frac{A_0^i 2\pi i}{k \sqrt{\det(\Gamma_k^i)^{-1}}} \times e^{(-i/2k)(\mathbf{k}_x - \mathbf{k}'_x)^T \Gamma_k^i (\mathbf{k}_x - \mathbf{k}'_x) - i(\mathbf{k}_x - \mathbf{k}'_x) \cdot \mathbf{x}^i} \times (-1 + 8\pi^2 \sigma_h^2 k_z^2) 2\nu^2 \times e^{-b|\mathbf{k}_x - \mathbf{k}_{xn}|^2/2k - i\mathbf{k}_x \cdot \mathbf{x}_m} d^2k_x, \quad (56)$$

where Γ_k^i is given by (48) with (73), and we note that $\text{Im} \Gamma_k^i$ is negative definite.

The integral in (56) has the standard form addressed in the Appendix; its saddle-point evaluation is

$$S_c(B^i, \psi_\mu) = \frac{iA_0^i 2\nu^2}{\sqrt{\det(\Gamma_k^i)^{-1}} \sqrt{\det(\Gamma_x^c)^{-1}}} e^{i\mathbf{k}_x \cdot \mathbf{x}^i} \times (-1 + 8\pi^2 \sigma_h^2 k_z^2) \times \exp \left[-\frac{i}{2k} (\mathbf{k}_{xn} - \mathbf{k}'_x)^T \Gamma_k^c (\mathbf{k}_{xn} - \mathbf{k}'_x) + i/2k (\mathbf{x}_m - \mathbf{x}^i)^T \Gamma_x^c (\mathbf{x}_m - \mathbf{x}^i) + i\mathbf{k}^c \cdot (\mathbf{x}_m - \mathbf{x}^i) \right], \quad (57)$$

where

$$\Gamma_x^c = (\Gamma_k^i - ib\mathbf{I})^{-1}, \quad (58)$$

$$\Gamma_k^c = -ib\Gamma_x^c \Gamma_k^i = ((\Gamma_k^i)^{-1} + ib^{-1}\mathbf{I})^{-1}, \quad (59)$$

$$\mathbf{k}^c = \Gamma_x^c (\Gamma_k^i \mathbf{k}'_x - ib\mathbf{k}_{xn}), \quad (60)$$

$$\mathbf{k}_s = \mathbf{k}^c + k\Gamma_x^c (\mathbf{x}_m - \mathbf{x}^i), \quad k_{z_s} = k_z(\mathbf{k}_s), \quad (61)$$

and, referring to (58), $\text{Im}(\Gamma_x^c)^{-1}$ is negative definite; hence, we take the root of $\sqrt{\det(\Gamma_x^c)^{-1}}$ which has a negative imaginary part. Also, \mathbf{k}_s is the stationary point of the integral (56) and is required for the mean reflection coefficient.

As can be seen, the S matrix is localized in phase space, around $(\mathbf{x}_m, \mathbf{k}_{xn}) = (\mathbf{x}^i, \mathbf{k}'_x)$, with the localization parameters Γ_x^c and Γ_k^c , respectively, which are determined by the Γ^i matrix of the incident beam, and also by the collimation parameter b used for the expansion beams. This corresponds to the δ function usually associated with the spectrum of the coherent field. If we take both incident and scattered beams to be very wide (i.e., approximating plane waves) we will get complete coherent reflection in the specular direction, with no space localization. On the other hand, if we take very narrow beams that spread like a point-sources field, we get a specular scattering emerging from the point where the incident beam hits the surface. Due to the independence of the mean reflection coefficient on the roughness spectrum in the small perturbation method, the roughness determines the amplitude of the coherent S matrix and not its localization in phase space. These results are readily discerned in Fig. 5(b).

B. Noncoherent field

The noncoherent S matrix is obtained by inserting (55), (47), and (52) into (51b). We start by evaluating the inner integral in (51b) for the spectral noncoherent scattered intensity [see (13)]

$$|\bar{u}_{\text{nc}}^s(\mathbf{k}_x)|^2 = \int 4\pi\sigma_h^2 l_h^2 k_z'^2 e^{-|\mathbf{k}'_x - \mathbf{k}_x|^2 l_h^2 / 4} \left| \frac{A_0^i 2\pi i}{k \sqrt{\det(\mathbf{\Gamma}_k^i)^{-1}}} \right. \\ \left. \times e^{(-i/2k)(\mathbf{k}'_x - \mathbf{k}_x^i)^T \mathbf{\Gamma}_k^i (\mathbf{k}'_x - \mathbf{k}_x^i) - i(\mathbf{k}'_x - \mathbf{k}_x^i) \cdot \mathbf{x}^i} \right|^2 d^2 k'_x. \quad (62)$$

This integral has the same form as before, and its saddle-point evaluation is

$$|\bar{u}_{\text{nc}}^s(\mathbf{k}_x)|^2 = \frac{32\pi^4 \sigma_h^2 l_h^2 |A_0^i|^2}{|\det(\mathbf{\Gamma}_k^i)^{-1}| k} \sqrt{\det(\mathbf{\Gamma}_k^i)} \\ \times k_{z_s}^2 e^{-(\mathbf{k}_x - \mathbf{k}_x^i)^T \mathbf{\Gamma}_k^i (\mathbf{k}_x - \mathbf{k}_x^i) / k}, \quad (63)$$

where

$$\mathbf{\Gamma}_k^i = (kl_h^2/4\mathbf{I} - \text{Im} \mathbf{\Gamma}_k^i)^{-1}, \quad (64)$$

$$\mathbf{k}_s = \mathbf{\Gamma}_k^i (2 \text{Im} \mathbf{\Gamma}_k^i \mathbf{k}_x^i - \mathbf{k}_x k l_h^2 / 2). \quad (65)$$

Note that $\mathbf{\Gamma}_k^i$ is real positive.

The spectral intensity in (63) has the form of a Gaussian centered on the specular direction. The spectral localization, via the matrix $\mathbf{\Gamma}_k^i$, is affected by an interplay between the rough surface correlation length l_h and the width of the incident beam [recall from (46)–(48) that $-\text{Im} \mathbf{\Gamma}_k^i$ in (64) is proportional to kW_x^i , where W_x^i is the projected width of the incident beam on the $z=0$ plane]. Thus, if $W_x^i \gg l_h$, then $\mathbf{\Gamma}_k^i \approx kl_h^2/4\mathbf{I}$ and the spectral intensity is governed by $\sigma(\mathbf{k}_x, \mathbf{k}'_x)$, whereas if $l_h \gg W_x^i$, then $\mathbf{\Gamma}_k^i \approx -\text{Im} \mathbf{\Gamma}_k^i$ and the parameters of the rough surface vanish from the exponent.

Inserting (62) together with (52) into (51b) results in the noncoherent S matrix, again in a similar integral form

$$S_{\text{nc}}(B^i, \psi_\mu) = \left(\frac{1}{2\pi} \right)^2 \int d^2 k_x \frac{8\sqrt{2}\pi^2 \sigma_h l_h |A_0^i|}{\sqrt{k|\det(\mathbf{\Gamma}_k^i)^{-1}|}} \nu^2 \\ \times k_{z_s} [\det(\mathbf{\Gamma}_k^i)]^{1/4} e^{-(\mathbf{k}_x - \mathbf{k}_x^i)^T \mathbf{\Gamma}_k^i (\mathbf{k}_x - \mathbf{k}_x^i) / 2k - i\mathbf{k}_x \cdot \mathbf{x}^i} \\ \times e^{-b|\mathbf{k}_x - \mathbf{k}_{\text{xn}}|^2 / 2k - i\mathbf{k}_x \cdot \mathbf{x}_m}, \quad (66)$$

The saddle-point evaluation of this integral results in

$$S_{\text{nc}}(B^i, \psi_\mu) = \frac{i|A_0^i| 4\pi \nu^2 \sqrt{2k} \sigma_h l_h k_z' [\det(\mathbf{\Gamma}_k^i)]^{1/4}}{\sqrt{|\det(\mathbf{\Gamma}_k^i)^{-1}|} \sqrt{\det(\mathbf{\Gamma}_x^{\text{nc}})^{-1}}} \\ \times \exp[-(\mathbf{k}_{\text{xn}} - \mathbf{k}_x^i)^T \mathbf{\Gamma}_k^{\text{nc}} (\mathbf{k}_{\text{xn}} - \mathbf{k}_x^i) / 2k \\ - k(\mathbf{x}_m - \mathbf{x}^i)^T \mathbf{\Gamma}_x^{\text{nc}} (\mathbf{x}_m - \mathbf{x}^i) / 2 \\ + i\mathbf{k}^{\text{nc}} \cdot (\mathbf{x}_m - \mathbf{x}^i)], \quad (67)$$

where

FIG. 4. Incident field intensity in dB. $b^i=1$, $k=1000$. Origin of incident field is at $(0, 0, 0.5)$ and exit angle is at $\theta=20^\circ$, $\varphi=0^\circ$. The figure is plotted in the (x_1, z) plane for $x_2=0$.

$$\mathbf{\Gamma}_x^{\text{nc}} = (\mathbf{\Gamma}_k^i + b\mathbf{I})^{-1}, \quad (68)$$

$$\mathbf{\Gamma}_k^{\text{nc}} = b\mathbf{\Gamma}_x^{\text{nc}} \mathbf{\Gamma}_k^i = ((\mathbf{\Gamma}_k^i)^{-1} + b^{-1}\mathbf{I})^{-1}, \quad (69)$$

$$\mathbf{k}_s^{\text{nc}} = \mathbf{\Gamma}_x^{\text{nc}} (\mathbf{\Gamma}_k^i \mathbf{k}_x^i + b\mathbf{k}_{\text{xn}}), \quad (70)$$

$$\mathbf{k}_s = \mathbf{k}_s^{\text{nc}} + k\mathbf{\Gamma}_x^{\text{nc}} (\mathbf{x}_m - \mathbf{x}^i), \quad (71)$$

$$\mathbf{k}'_s = \mathbf{\Gamma}_x^i \left(2 \text{Im} \mathbf{\Gamma}_k^i \mathbf{k}_x^i - \frac{kl_h^2}{2} \mathbf{k}_s \right), \quad k'_{z_s} = k_z(\mathbf{k}'_s). \quad (72)$$

Note that $\mathbf{\Gamma}_x^{\text{nc}}$ is real positive.

The noncoherent S matrix in (67) is localized in phase space around $(\mathbf{x}_m, \mathbf{k}_{\text{xn}}) = (\mathbf{x}^i, \mathbf{k}'_x)$, with the localization parameters $\mathbf{\Gamma}_x^{\text{nc}}$ and $\mathbf{\Gamma}_k^{\text{nc}}$, respectively, which are determined by the $\mathbf{\Gamma}$ matrices of the incident and scattered beams and the correlation length of the rough surface. As discussed following (63), one readily observes that for small correlation lengths compared to the incident beamwidth, S_{nc} is spectrally wide and its spatial localization is determined by the ratio between the correlation length and the scattered beam's parameter, b . For large correlation lengths compared to the incident beamwidth, the localization of S_{nc} is determined by the incident and scattered $\mathbf{\Gamma}$'s only.

C. Numerical comparison

1. Problem setup

We consider a homogeneous medium with wave number $k=1000$. The rough surface at $z=0$ is illuminated by a collimated, circular-symmetric Gaussian beam with $b^i=1$, originating from $\mathbf{r}_0=(0,0,0.5)$ with initial direction $\theta=20^\circ$, $\varphi=0^\circ$ (see Fig. 4). From (35) and (36), it has the form

$$B^i(\mathbf{r}) = \frac{-ib^i}{z_b - ib^i} \exp\left[ik \left(z_b + \frac{1}{2} \frac{|\mathbf{x}_b|^2}{z_b - ib^i} \right) \right], \quad (73)$$

where (\mathbf{x}_b, z_b^i) are the incident beams coordinates measured along the beam axis from the point \mathbf{r}_0 . The matrix $\mathbf{\Gamma}_0^i$ in (42) is then given by $\mathbf{\Gamma}_0^i = (0.5/\cos 20^\circ - ib^i)^{-1} \delta_{ij}$.

The rough surface parameters are $k\sigma_h=0.1$ for the small perturbation approximation and the correlation length is smaller than the width of the incident beam such that

FIG. 5. GB2GB scattering matrices for the incident beam in Fig. 4, shown in the (x_1, k_{x_1}) plane where $(x_2, k_{x_2}) = (0, 0)$. Expansion parameters: $b = 5$, $\nu = 0.45$, $\bar{x} = 0.118\ 890$, $\bar{k} = 23.779\ 964$. Surface parameters: $k\sigma = 0.1$, $kl^2/b^i = 0.1$. Each point in the discrete lattice represents a single beam. (a) Phase-space coefficients of the incident field. (b) Coherent GB2GB scattering matrix. (c) Noncoherent GB2GB scattering matrix.

$l_h^2/W_0^2 = 0.1$, where $W_0 = \sqrt{b^i/k}$ [see (40)]. The expansion frame utilizes Gaussian windows of the form in (32) and (52), where we choose $b = 5$ for collimated propagators (i.e., $kb = 5000$). From (32) and (18) we find $\bar{x} = \sqrt{2\pi\nu b/k}$ and $\bar{k}_x = \sqrt{2\pi\nu k/b}$. It should be recalled that in all the field computations we include only those beams that pass near the observation point [see the geometrical observation approach discussed in connection with (31)].

2. Results

The coherent and noncoherent scattering matrices S_c and S_{nc} are shown in Figs. 5(b) and (c), respectively. In order to understand these results we also show in Fig. 5(a) the expansion coefficients $S_i(B^i, \psi_\mu)$ of the incident field with respect to the same frame $\psi_\mu(x)$. These coefficients can be calculated by setting $\bar{V}(\mathbf{k}_x) = 1$ in (51a). The plots show phase-space distributions of the matrices in the (x_1, k_{x_1}) plane for $(x_2, k_{x_2}) = (0, 0)$.

As can be seen, S_c represents essentially a specular scattering; hence, its phase-space distribution in Fig. 5(b) replicates the phase-space distribution of the incident field in Fig. 5(a) except for the multiplication term $\bar{V}(\mathbf{k}_x)$. S_{nc} , on the other hand, is still localized in space within the support of the incident field, but it is weaker and has a much wider spectral spread. These observations are supported by the analytical analysis in Secs. V A and V B.

Finally, the propagating coherent and noncoherent intensities calculated via the GBS representation are shown in Figs. 6(a) and 7(a), respectively. The coherent field is described by specular spectral reflections [see (8)] and therefore has the structure of the incident beam, whereas the noncoherent field spreads away and decays from the center point \mathbf{x}_0 of the incident field.

The high accuracy of our GBS approach to calculate the coherent and noncoherent fields is demonstrated in Figs. 6(b) and 7(b). Figure 6(b) depicts the absolute error of the GBS calculations in Fig. 6(a) for the coherent intensity, compared to the plane-wave reference solutions obtained by inserting (8) in (2). Figure 7(b) depicts the absolute error of the noncoherent intensity in the far-field zone normalized to r . Here, the GBS result has been calculated by propagating the beams to the far zone, while the reference solution has been calculated directly from the plane-wave solution via (12b).

VI. CONCLUDING REMARKS

We presented a new scheme for rough surface scattering that is based on the Gaussian beam summation (GBS) method. The scheme localizes the scattering process in terms of stochastic GB2GB scattering matrices and deterministic GB propagators. It benefits from the simplicity and accuracy of the latter, and can therefore be used in various applications involving propagation in complex environments and in inverse imaging.

FIG. 6. Beam summation representation of the coherent intensities for the problem in Figs. 4 and 5, for the (x_1, z) plane for $x_2=0$. (a) Coherent intensity in dB calculated using the GBS. (b) Absolute error in dB compared to plane-wave reference solution.

The GB2GB scattering matrices in (51), are the beam equivalent of the known plane-wave scattering strength. They can be obtained either analytically, by applying the frame decomposition in conjunction with existing rough surface theories, as was done in the analytic example in Sec. V, or by applying it to measured (McDaniel, 1993) or numerically computed (Warnick and Chew, 2001) scattering moments. A more direct way to ascertain these matrices is to directly measure them, by way of inverse imaging.

In this work we presented the general formulation and applied it to a weakly rough surface, for which the scattering moments are known in closed form via the small perturbation approximation. The accuracy of the GBS representation for the calculation of the propagated coherent and noncoherent intensities has been demonstrated via an example in a homogeneous domain. In more complex scenarios with inhomogeneous media, the beam propagators provide a more efficient and accurate alternative to their plane-wave counterparts (Heilpern, 2004).

From a wave theoretic point of view, the GB2GB matrices represent the phase-space footprint of the rough surface scattering process. In more general propagation scenarios,

e.g., the doubly rough surface waveguide with multiple reflection phenomena which is studied in (Gordon *et al.*, 2005), the phase-space representation combines the footprints of the stochastic multiple scattering events and the deterministic propagation between the surfaces.

APPENDIX: ANALYTICAL EVALUATION OF 2D GAUSSIAN-TYPE INTEGRALS

Throughout the development of the analytical example, a common form of an integral is repeated. The integral is of the form of a 2D slowly varying function $f(\mathbf{k}_x)$ multiplied by a 2D Gaussian exponent. The general form is

FIG. 7. Beam summation representation of the noncoherent intensities for the problem in Figs. 4 and 5, for the (x_1, z) plane for $x_2=0$. (a) Noncoherent intensity in dB calculated using the GBS. (b) Far-field normalized absolute error in dB compared to plane-wave reference solution, at $r=10b^i$.

$$I(\mathbf{k}'_x, \mathbf{k}''_x) = \int f(\mathbf{k}_x) e^{i(\mathbf{k}_x - \mathbf{k}'_x)^T \mathbf{A}(\mathbf{k}_x - \mathbf{k}'_x)/2} \times e^{i(\mathbf{k}_x - \mathbf{k}''_x)^T \mathbf{B}(\mathbf{k}_x - \mathbf{k}''_x)/2} e^{i\mathbf{k}_x \cdot \mathbf{x}} d^2 k_x, \quad (\text{A1})$$

where \mathbf{A} and \mathbf{B} are 2×2 symmetric matrices with positive definite imaginary parts.

Such integrals are obtained, usually, by the projection of a Gaussian beam on another function (e.g., another Gaussian beam of different parameters). Doing the saddle-point evaluation, one equates the first derivative of the exponent to zero to get the stationary point

$$\mathbf{k}_s = (\mathbf{A} + \mathbf{B})^{-1} (\mathbf{A}\mathbf{k}'_x + \mathbf{B}\mathbf{k}''_x - \mathbf{x}). \quad (\text{A2})$$

Using this stationary point, one can get the proper evaluation

$$I(\mathbf{k}'_x, \mathbf{k}''_x) = f(\mathbf{k}_s) \frac{2\pi i}{\sqrt{\det(\mathbf{A} + \mathbf{B})}} \exp \left[\frac{i}{2} (\mathbf{k}'_x - \mathbf{k}''_x)^T \times (\mathbf{A} + \mathbf{B})^{-1} \mathbf{A} \mathbf{B} (\mathbf{k}'_x - \mathbf{k}''_x) - \frac{i}{2} \mathbf{x}^T (\mathbf{A} + \mathbf{B})^{-1} \mathbf{x} + i\mathbf{x}^T (\mathbf{A} + \mathbf{B})^{-1} (\mathbf{A}\mathbf{k}'_x + \mathbf{B}\mathbf{k}''_x) \right], \quad (\text{A3})$$

where we take the root $\sqrt{\det(\mathbf{A} + \mathbf{B})}$ which has a positive imaginary part.

(Received 30 August 2004; revised 14 December 2004; accepted 18 December 2004)

A Gaussian beam summation (GBS) formulation is introduced for a doubly rough boundary waveguide, wherein the coherent and incoherent scattered fields are decomposed into a discrete phase-space summation of Gaussian beams (GB) that emanate from the rough surfaces in all directions. The scheme involves deterministic GB propagators and stochastic GB-to-GB (GB2GB) scattering matrices for the coherent and incoherent fields, where each scattered beam is propagated inside the waveguide and is scattered again from the rough boundaries. The GB2GB matrices are calculated from the statistical moments of the scattering amplitude, which are given either analytically or empirically. An analytical and numerical example for a waveguide with weak boundary roughness is presented and discussed. The formulation reveals explicitly the phase-space footprint of the stochastic multiple scattering process at the rough boundaries, thus providing a cogent physical interpretation and an effective mathematical representation to the field. The formulation also accommodates the receiver's pattern in the same phase-space format. Bistatic reverberations inside a rough surface waveguide as a function of the range and of the source and the receiver directions are thus examined as an implementation example. © 2005 Acoustical Society of America. I. INTRODUCTION

Calculating the field inside a doubly rough surface waveguide arises naturally in the characterization of transport properties related to, for instance, sonar, shallow-water waves, geophysical probing, remote sensing, radiowave propagation, as well as optical waveguides and fibers (Sheng, 1990; Etter, 2001, 2003, and references therein). Calculating the guided field may be performed via many approaches such as plane-wave spectrum (Voronovich, 1999), stochastic modes (Snchez-Gil *et al.*, 1998), rays, and other methods (Etter, 2001, 2003). However, keeping track of the field through the nonspecular, noncoherent multiple reflections at the waveguide rough boundaries, and treating these reflected wave species collectively to form the guided field, poses a problem of considerable complexity, which increases even further if the propagation medium is inhomogeneous.

For the coherent field, the plane-wave formulation is based on the mean reflection coefficient in the specular direction. The resulting series of multiple interactions may therefore be treated collectively, leading to a closed-form modal solution (Voronovich, 1999). Such collective procedure is not applicable for the noncoherent field due to the nonspecular nature of the interactions. The latter problem may be addressed via perturbations, as was done in Schmidt and Kuperman (1995) for low frequencies in stratified waveguides with rough surface boundaries. The modal solu-

tion may be formulated, alternatively, by using a coupled-modes approach, but for high frequencies and inhomogeneous media, the coupling matrices become large and unpractical (Beenakker, 1997). Alternatively, the noncoherent field can be described by tracking the series of multiple nonspecular, noncoherent reflections. The complexity of this approach increases with the interaction order, and thereby with the range, but it may be reduced by applying localization using ray representations (Mazar and Felsen, 1989). The latter may also be extended to range-dependent nonuniform waveguides, but, on the other hand, since they are stripped of the spectral flash, they are sensitive to nonphysical artifacts such as caustics and shadow zones.

To overcome the difficulties of the ray and spectral approaches, we utilize here the Gaussian beam summation (GBS) representation of the rough surface scattering, introduced by us in Gordon *et al.* (2005). This formulation is structured on the localized ray skeleton but retains the spectral characteristics of the plane-wave formulations. As a result, it combines the localization and algorithmical properties of the ray representation with the uniform features of the plane-wave representation.

The GBS method was introduced originally for tracking source-excited wave fields in deterministic configurations (see the review articles in Babich and Popov, 1989; Nowack, 2003; Heyman and Felsen, 2001). Its extension in Gordon *et al.* (2005) to rough surface scattering applications is managed by the coherent and noncoherent GB-to-GB (GB2GB) scattering matrices, where the incident field is decomposed into GBs and each GB is then scattered coherently and non-

^{a)}Deceased.

FIG. 1. The Gaussian beam summation (GBS) in a waveguide with rough surface boundaries at $z_{1,2}$ and roughness $h_{1,2}$. The coordinate frame is $\mathbf{r} = (x_1, x_2, z) = (\mathbf{x}, z)$ with “downward” coordinate z . The transmitter T and receiver R are located at $\mathbf{r}_T = (x_T, z_T)$ and $\mathbf{r}_R = (x_R, z_R)$, respectively. In the examples it is assumed that both have a Gaussian pattern and are looking toward the z_1 surface as depicted. The scattered fields from $z_{1,2}$ are decomposed into discrete sets of GB propagators $B_{\mu_{1,2}}^{(1,2)}$, where $\mu_{1,2}$ are the phase-space indices. The rough surface scattering is described by the GB2GB matrices $\mathbf{S}_c^{(1,2)}$ and $\mathbf{S}_{nc}^{(1,2)}$ for the coherent and the noncoherent fields, respectively.

coherently into a discrete spectrum of GBs. The formulation is based on the frame-based phase-space GBS representation in Shlivinski *et al.* (2004), where the scattered field is expressed as a sum of beams emanating from a phase-space lattice of points and directions on the rough surface, as depicted in Fig. 1 and summarized briefly in Sec. II.

In this paper the GBS approach of Gordon *et al.* (2005) for rough surface scattering is extended to accommodate propagation in inhomogeneous waveguides with rough surface boundaries, which are characterized by multiple interactions of the coherent and incoherent fields with the rough surfaces (see Figs. 1 and 5). The formulation utilizes GBs to propagate these fields locally within the medium, and the GB2GB scattering matrix to acquire the relevant GBs scattered from the rough surfaces. An important feature of this new representation is that it reveals explicitly the local phase-space footprint of the stochastic scattering process at the rough boundaries, thus providing a cogent physical interpretation to the field propagation within the waveguide. These localization features are utilized in the algorithm to obtain an effective mathematical representation of the problem, where we have also neglected multiple noncoherent scattering.

Concerning the presentation layout, we start in Sec. II with a brief overview of Gordon *et al.* (2005) for the GBS analysis of rough surface scattering. The application of the GBS method to the doubly rough surface waveguide problem is presented in Sec. III. Two alternative representations are presented: a series of successive interactions and a collective solution (Secs. III B and III C, respectively). An important feature of the formulation is the phase-space localization implied by the collimated propagators and by the GB2GB scattering matrices. The implication of the localization on the GBS algorithm, as well as the “proper” choice of the algorithm parameters, are discussed in Secs. III D–III F. Finally, all these properties are explored via a comprehensive numerical example in Sec. IV.

The theory of Sec. III is phrased in terms of field observables. In Sec. V it is rephrased in terms of the coupling

into the receiving antenna which is characterized by a receiving pattern. As an example the theory is applied in Sec. V C for the calculations of the bistatic reverberations in a two-antenna system. Finally, the extension of the method to an inhomogeneous waveguiding configuration is briefly discussed in Sec. VI, where we mainly consider the analysis of possible surface ducts near the rough surface boundaries. The presentation ends with concluding comments in Sec. VII.

II. PHASE-SPACE GAUSSIAN BEAM SUMMATION ANALYSIS OF ROUGH SURFACE SCATTERING: A BRIEF REVIEW

We consider the scattered wave field $u(\mathbf{r})$ in the half-space $z > h(\mathbf{x})$ due to a rough surface boundary $z = h(\mathbf{x})$, where z is the vertical coordinate in a 3D coordinate frame $\mathbf{r} = (\mathbf{x}, z)$ and $\mathbf{x} = (x_1, x_2)$ is the horizontal coordinate. The scattering observables are the average field and/or the average intensity, where the averaging is performed over the ensemble of realizations. The average field defines the so-called coherent field. The average intensity consists of two terms, the coherent and the noncoherent intensities, where the latter describes the intensity fluctuations due to rough surface. Our goal is to calculate and characterize these observables via the GBS. This will be done by calculating the coherent and the noncoherent fields u_c and u_{nc} , respectively, which may be understood as mathematical realizations that give rise to the statistical observables noted above (e.g., $|u_{nc}|^2$ describes the noncoherent intensity).

A. The phase-space Gaussian beam summation method

We start with a brief overview of this method and then apply it in Sec. II B to the rough surface problem. The method provides a rigorous framework that decomposes any field $u_0(\mathbf{x})$ in an aperture of a real or virtual source to a set of GBs that emanates from a discrete set of points in the aperture into a discrete set of directions. The starting point is the expansion of the aperture field $u_0(\mathbf{x})$ in a plane of constant z (say $z = 0$) using shifted and modulated window functions of the form

$$\psi_{\boldsymbol{\mu}}(\mathbf{x}) = \psi(\mathbf{x} - \mathbf{x}_m) e^{i\mathbf{k}_{x\mathbf{n}} \cdot (\mathbf{x} - \mathbf{x}_m)}, \quad \mathbf{x}_m = \mathbf{m}\bar{x}, \quad \mathbf{k}_{x\mathbf{n}} = \mathbf{n}\bar{k}_x, \quad (1)$$

where $\boldsymbol{\mu} = (\mathbf{m}, \mathbf{n}) = (m_1, m_2, n_1, n_2)$ is an index and ψ is a proper window function. The $\boldsymbol{\mu}$ elements are centered about the phase-space lattice points $(\mathbf{x}_m, \mathbf{k}_{x\mathbf{n}})$. This set of functions needs to be complete or even overcomplete to be able to expand any aperture function. When it is overcomplete it is called a windowed Fourier transform (WFT) frame. A necessary condition is that the lattice is overcomplete such that the spatial and spectral unit cell dimensions (\bar{x}, \bar{k}_x) satisfy

$$\bar{x}\bar{k}_x = 2\pi\nu, \quad \text{where } \nu < 1. \quad (2)$$

ν is the frame overcompleteness (or oversampling) factor. The frame is overcomplete for $\nu < 1$ and it is complete in the Gabor limit $\nu \uparrow 1$. The overcomplete frame in (1) can be used to expand the data $u_0(\mathbf{x})$ as

$$u_0(\mathbf{x}) = \sum_{\mu} a_{\mu} \psi_{\mu}(\mathbf{x}). \quad (3)$$

Since the frame is overcomplete, the coefficient set a is nonunique, i.e., there are many sets that can be used in (3) to reconstruct $u_0(\mathbf{x})$. A desirable set is obtained by projecting the data onto the dual frame $\varphi_{\mu}(\mathbf{x})$ via

$$a_{\mu} = \langle u_0(\mathbf{x}), \varphi_{\mu}(\mathbf{x}) \rangle = \int d^2x u_0(\mathbf{x}) \varphi_{\mu}^*(\mathbf{x}), \quad (4)$$

where $\varphi_{\mu}(\mathbf{x})$ has the same form as the frame ψ_{μ} in (1) except that the window $\psi(\mathbf{x})$ is now replaced by its dual $\varphi(\mathbf{x})$. Equation (4) can readily be identified as a WFT of u_0 with respect to the window φ , hence the name WFT frames. In view of (3) and (4), ψ and φ are also termed the synthesis and analysis windows, respectively. In general, $\varphi(\mathbf{x})$ needs to be calculated for a given $\psi(\mathbf{x})$ and (\bar{x}, \bar{k}_x) , but for small ν it can be found analytically [see (6)].

Henceforth, we use a matched Gaussian of the form

$$\psi(\mathbf{x}) = e^{-k|\mathbf{x}|^2/2b}, \quad b = k\bar{x}/\bar{k}_x, \quad (5)$$

where k is the wave number in the ambient medium and $b > 0$ is a parameter. The condition on b in (5) defines the window width $W_0 = \sqrt{b/k}$ such that ψ is matched to the lattice as discussed in [Gordon *et al.*, 2005, Eq. (19)]. In wave propagation applications we typically choose b such that $kb \gg 1$ so that W_0 is wide on the wavelength scale, giving rise to collimated GB propagators [see (7)]. Finally, one should note that choosing ν and b determines the lattice dimensions (\bar{x}, \bar{k}_x) via (1) and (5).

The overcompleteness parameter ν is chosen as a trade-off between analytic simplicity and numerical efficiency. The latter implies that ν should be as large as possible, while the former implies that it should be sufficiently small to yield a convenient dual window. Indeed, for $\nu < 0.5$, φ that corresponds to the matched Gaussian windows (5) is given approximately by Gordon *et al.* (2005), Eq. (32)

$$\varphi(\mathbf{x}) \approx \nu^2 (k/\pi b) e^{-k|\mathbf{x}|^2/2b}. \quad (6)$$

For $\nu=0.5$ the L_2 error in (6) is $\sim 8\%$, while for $\nu=0.3$ it is $\sim 1\%$, (Shlivinski *et al.*, 2004, Fig. 4). Thus, $\nu=0.5$ provides a reasonable choice for the present application.

Equation (3) may be propagated now away from the aperture, giving

$$u(\mathbf{r}) = \sum_{\mu} a_{\mu} B_{\mu}(\mathbf{r}), \quad (7)$$

where each $B_{\mu}(\mathbf{r})$ is the propagated field due to the aperture distribution $\psi_{\mu}(\mathbf{x})$. For the windows in (5) these propagators are GBs whose properties are discussed in Gordon *et al.*, 2005, Eqs. (32)–(40). They emerge from the points \mathbf{x}_m in the aperture plane in directions that are determined by $\mathbf{k}_{x,m}$ such that their angles with respect to the x_j axes, $j=1, 2$, are given by $\cos^{-1}(k_{x,m}/k)$. For $|\mathbf{k}_{x,m}| > k$, the fields $B_{\mu}(\mathbf{r})$ decay away from the aperture and hence are not included in the summation (7).

B. Rough surface scattering using GBS: The GB2GB scattering matrix

Applying the GBS to the rough surface scattering discussed above, the coherent and the noncoherent fields are expanded as (Gordon *et al.*, 2005)

$$u_c^s(\mathbf{r}) = \sum_{\mu} S_c(u^i, \psi_{\mu}) B_{\mu}(\mathbf{r}), \quad (8a)$$

$$u_{nc}^s(\mathbf{r}) = \sum_{\mu} S_{nc}(u^i, \psi_{\mu}) B_{\mu}(\mathbf{r}), \quad (8b)$$

where $S_c(u^i, \psi_{\mu})$ and $S_{nc}(u^i, \psi_{\mu})$ are the coherent and noncoherent scattering matrices from the incident field u^i to the scattering propagator $B_{\mu}(\mathbf{r})$. For a given surface they can be calculated via

$$S_c(u^i, \psi_{\mu}) = \frac{1}{(2\pi)^2} \int \tilde{u}^i(\mathbf{k}_x) \bar{V}(\mathbf{k}_x) \tilde{\varphi}_{\mu}^*(\mathbf{k}_x) d^2k_x, \quad (9a)$$

$$S_{nc}(u^i, \psi_{\mu}) = \frac{1}{(2\pi)^2} \int e^{-i\mathbf{k}_x \cdot \mathbf{x}^i} \times \sqrt{\int \sigma(\mathbf{k}_x, \mathbf{k}'_x) |\tilde{u}^i(\mathbf{k}'_x)|^2 d^2k'_x} \tilde{\varphi}_{\mu}^*(\mathbf{k}_x) d^2k_x, \quad (9b)$$

where $\tilde{u}^i(\mathbf{k}_x)$ is the spectral counterpart of $u^i(\mathbf{x})$, \mathbf{x}^i is the center of mass of $u^i(\mathbf{x})$, and $\tilde{\varphi}_{\mu}(\mathbf{k}_x)$ is the spectral counterpart of φ_{μ} . Here, $\bar{V}(\mathbf{k}_x)$ and $\sigma(\mathbf{k}_x, \mathbf{k}'_x)$ are the mean spectral reflection coefficient and the spectral scattering cross section. For certain classes of surfaces, these scattering characteristics of $h(\mathbf{x})$ can be found analytically; otherwise, they can be found empirically from the measured observables as discussed in Gordon *et al.*, 2005, Sec. V.

Finally, since u^i can be decomposed also into incident GBs, the scattered field can be expressed in terms of GB to GB (GB2GB) scattering matrices, which are given as in (9) except that u^i is now replaced by an incident beam B^i .

III. PHASE-SPACE ANALYSIS OF ROUGH SURFACE WAVEGUIDE

The GB2GB scattering representation derived above provides the theoretical framework for the analysis of rough surface waveguides where the field undergoes a multiple scattering process between the rough surface walls. In this formulation, the field that is scattered by the wall in a given iteration is decomposed into a set of GBs that, in turns, constitutes the incident field on the other wall at the next iteration. This solution procedure can be addressed either iteratively, via an interactions series approach, or collectively (see Secs. III B and III C, respectively). Conceptually, these solution approaches are similar to plane-wave procedures in Voronovich (1999) [Chap. 10]. Yet, the beam formulation is not only *a priori* discrete, but it may also accommodate range-dependent inhomogeneous media.

A. The phase-space beam setup

The problem setup in Fig. 1 consists of a homogeneous waveguide, with two rough surface boundaries $z=z_1+h_1(\mathbf{x})$ and $z=z_2+h_2(\mathbf{x})$, where $z_1 < z_2$ while $h_{1,2}$ denote the surface roughnesses which are assumed to be statistically uncorrelated and \mathbf{x} -independent. As before, z is the vertical depth coordinate in a 3D coordinate frame $\mathbf{r}=(\mathbf{x},z)$ and $\mathbf{x}=(x_1,x_2)$ is the horizontal (or range) coordinate. Note that in principle the GBS formulation below may be applied to waveguides with weak range dependence of the propagation medium and of the surface roughness.

Since the two rough surfaces are noncorrelated, each one may be treated independently from the other. We thus construct two overcomplete lattices of Gaussian beams on the two rough surface boundaries, tagged by the indices $\boldsymbol{\mu}_j$ where $j=1, 2$ for z_1 and z_2 , respectively (Fig. 1). Since the frames on the z_1 and z_2 boundaries are not necessarily the same, we denote them as $(\bar{x}^{(j)}, \bar{k}_x^{(j)})$ and $\psi_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{x})$, and the corresponding GB propagators as $B_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{r})$. The field impinging on the j th boundary is thus expressed as a summation of

GBs $B_{\boldsymbol{\mu}_{j'}}^{(j')}(\mathbf{r})$ arriving from the other j' boundary, and the scattered field is then described in terms of the GB2GB scattering matrices $S^{(j'j)}$ from $B_{\boldsymbol{\mu}_{j'}}^{(j')}(\mathbf{r})$ to $B_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{r})$. The field inside the waveguide is then expressed by summing up all the multiply scattered beams.

B. Interaction series approach

The summation process starts by expressing the source excited field using GBs $u^i(\mathbf{r}) = \sum_{\boldsymbol{\mu}_0} a_{\boldsymbol{\mu}_0} B_{\boldsymbol{\mu}_0}^{(0)}(\mathbf{r})$ tagged by index $\boldsymbol{\mu}_0$ [the beam set $B_{\boldsymbol{\mu}_0}^{(0)}$ which is used to expand the source field is in general different than $B_{\boldsymbol{\mu}_j}^{(j)}$; see the discussion in Gordon *et al.*, 2005, Eq. (41), and Fig. 5(a)]. Without loss of generality, we assume that the source radiates only toward z_1 , where each $B_{\boldsymbol{\mu}_0}^{(0)}$ excites a spectrum of scattered beams $B_{\boldsymbol{\mu}_1}^{(1)}(\mathbf{r})$ residing on the lattice $\boldsymbol{\mu}_1$ that propagates toward z_2 . At z_2 each $B_{\boldsymbol{\mu}_1}^{(1)}$ scatter into a spectrum of beams $B_{\boldsymbol{\mu}_2}^{(2)}(\mathbf{r})$ on the lattice $\boldsymbol{\mu}_2$, and vice versa. This process is formalized in the following scheme:

$$u(\mathbf{r}) = u^i(\mathbf{r}) + \sum_{\boldsymbol{\mu}_0} \sum_{\boldsymbol{\mu}'_1} a_{\boldsymbol{\mu}_0} S(B_{\boldsymbol{\mu}_0}^{(0)}|_{z_1}, \psi_{\boldsymbol{\mu}'_1}^{(1)}) B_{\boldsymbol{\mu}'_1}^{(1)}(\mathbf{r}) + \sum_{\boldsymbol{\mu}_0} \sum_{\boldsymbol{\mu}'_1} \sum_{\boldsymbol{\mu}'_2} a_{\boldsymbol{\mu}_0} S(B_{\boldsymbol{\mu}_0}^{(0)}|_{z_1}, \psi_{\boldsymbol{\mu}'_1}^{(1)}) S(B_{\boldsymbol{\mu}'_1}^{(1)}|_{z_2}, \psi_{\boldsymbol{\mu}'_2}^{(2)}) B_{\boldsymbol{\mu}'_2}^{(2)}(\mathbf{r}) \\ + \sum_{\boldsymbol{\mu}_0} \sum_{\boldsymbol{\mu}'_1} \sum_{\boldsymbol{\mu}'_2} \sum_{\boldsymbol{\mu}''_1} a_{\boldsymbol{\mu}_0} S(B_{\boldsymbol{\mu}_0}^{(0)}|_{z_1}, \psi_{\boldsymbol{\mu}'_1}^{(1)}) S(B_{\boldsymbol{\mu}'_1}^{(1)}|_{z_2}, \psi_{\boldsymbol{\mu}'_2}^{(2)}) S(B_{\boldsymbol{\mu}'_2}^{(2)}|_{z_1}, \psi_{\boldsymbol{\mu}''_1}^{(1)}) B_{\boldsymbol{\mu}''_1}^{(1)}(\mathbf{r}) + \dots, \quad (10)$$

where

- (i) The first term is the incident field that propagates toward z_1 .
- (ii) The second term represents the scattering of the incident beams $B_{\boldsymbol{\mu}_0}^{(0)}$ evaluated at $z=z_1$ toward the set of beams $B_{\boldsymbol{\mu}'_1}^{(1)}$ on the lattice $\boldsymbol{\mu}_1$ with $S(B_{\boldsymbol{\mu}_0}^{(0)}|_{z_1}, \psi_{\boldsymbol{\mu}'_1}^{(1)})$ denoting the GB2GB scattering matrix (the prime in $\boldsymbol{\mu}'_1$ tags the first scattering at z_1 ; higher-order scattering are tagged by double primes, etc.). Note that in this term and in the following ones the sum $\sum_{\boldsymbol{\mu}_0} a_{\boldsymbol{\mu}_0} S(B_{\boldsymbol{\mu}_0}^{(0)}|_{z_1}, \psi_{\boldsymbol{\mu}'_1}^{(1)})$ can be replaced by $S(u^i|_{z_1}, \psi_{\boldsymbol{\mu}'_1}^{(1)})$, which represents the scattering matrix from u^i evaluated at $z=z_1$ toward the set of beams $B_{\boldsymbol{\mu}'_1}^{(1)}$. We use, however, the series format since it is expressed explicitly in terms of incident GBs and the GB2GB scattering matrix, whereas u^i is in general not Gaussian.
- (iii) The third term represents the scattering of each of the beams $B_{\boldsymbol{\mu}'_1}^{(1)}$ evaluated at z_2 toward the set of beams $B_{\boldsymbol{\mu}'_2}^{(2)}$ on the lattice $\boldsymbol{\mu}_2$, with $S(B_{\boldsymbol{\mu}'_1}^{(1)}|_{z_2}, \psi_{\boldsymbol{\mu}'_2}^{(2)})$ representing the GB2GB scattering matrix of boundary z_2 .

The iterative process in Eq. (10) can be expressed, con-

veniently, in a matrix format. We define the ‘‘propagators vectors’’ $\mathbf{B}^{(j)}(\mathbf{r}) = B_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{r})$, the ‘‘waveguide interaction matrices’’ $\mathbf{S}^{(jj')}$, and the ‘‘source scattering row vector’’ $\mathbf{S}^{(0)}$

$$\mathbf{B}^{(j)}(\mathbf{r}) = B_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{r}), \quad j=1,2 \quad (11)$$

$$\mathbf{S}^{(jj')} = S(B_{\boldsymbol{\mu}_j}^{(j)}|_{z_j}, \psi_{\boldsymbol{\mu}_{j'}}^{(j')}), \quad (j,j') = (1,2) \text{ or } (2,1) \quad (12)$$

$$\mathbf{S}^{(0)} = S(u^i, \psi_{\boldsymbol{\mu}_1}^{(1)}) = \sum_{\boldsymbol{\mu}_0} a_{\boldsymbol{\mu}_0} S(B_{\boldsymbol{\mu}_0}^{(0)}|_{z_1}, \psi_{\boldsymbol{\mu}_1}^{(1)}). \quad (13)$$

The vectors $\mathbf{B}^{(j)}$ consist of all phase-space beams emerging from the j boundary. The matrices $\mathbf{S}^{(jj')}$ account for the propagation from boundary j to boundary j' and for the subsequent scattering there. These matrices are source independent and can be calculated *a priori* for a given waveguide configuration (uniform as well as nonuniform). Finally, in the definition of $\mathbf{S}^{(0)}$ it has been assumed that the source illuminates surface 1 only.

The iterative solution in (10) may be rewritten now in a matrix format

$$u(\mathbf{r}) = u^i(\mathbf{r}) + \mathbf{S}^{(0)} \mathbf{B}^{(1)}(\mathbf{r}) + \mathbf{S}^{(0)} \mathbf{S}^{(12)} \mathbf{B}^{(2)}(\mathbf{r}) \\ + \mathbf{S}^{(0)} \mathbf{S}^{(12)} \mathbf{S}^{(21)} \mathbf{B}^{(1)}(\mathbf{r}) + \dots \quad (14)$$

Note that the matrices involve all the lattice points on the boundaries and are therefore infinite. Yet, due to beam local-

ization, the $\mathbf{S}^{(jj')}$ are rather sparse (each $\boldsymbol{\mu}_j$ incident beam gives rise to a small subset of $\boldsymbol{\mu}_{j'}$ scattered beams), and therefore they, as well as the iterative series in (14), may be truncated depending on the propagation range (see the discussion in Sec. III E).

C. A collective representation

The interactions series in (10) can be summed up collectively. Noting that (10) [or (14)] consists of two beam sets: $\mathbf{B}^{(1)}(\mathbf{r})$ that propagate from z_1 to z_2 and $\mathbf{B}^{(2)}(\mathbf{r})$ that propagate from z_2 to z_1 , these expressions can be rewritten as

$$u(\mathbf{r}) = u^i(\mathbf{r}) + \sum_{\boldsymbol{\mu}_1} F_{\boldsymbol{\mu}_1}^{(1)} B_{\boldsymbol{\mu}_1}^{(1)}(\mathbf{r}) + \sum_{\boldsymbol{\mu}_2} F_{\boldsymbol{\mu}_2}^{(2)} B_{\boldsymbol{\mu}_2}^{(2)}(\mathbf{r}) \quad (15a)$$

$$= u^i(\mathbf{r}) + \mathbf{F}^{(1)} \mathbf{B}^{(1)}(\mathbf{r}) + \mathbf{F}^{(2)} \mathbf{B}^{(2)}(\mathbf{r}). \quad (15b)$$

One may readily show that the coefficients vectors $\mathbf{F}^{(j)} = F_{\boldsymbol{\mu}_j}^{(j)}$ satisfy the equation set

$$\mathbf{F}^{(1)} = \mathbf{S}^{(0)} + \mathbf{F}^{(2)} \mathbf{S}^{(21)}, \quad (16a)$$

$$\mathbf{F}^{(2)} = \mathbf{F}^{(1)} \mathbf{S}^{(12)}. \quad (16b)$$

Equation (16) can be solved via iterations

$$\mathbf{F}^{(1)} = \mathbf{S}^{(0)} + \mathbf{S}^{(0)} \mathbf{S}^{(12)} \mathbf{S}^{(21)} + \dots, \quad (17a)$$

$$\mathbf{F}^{(2)} = \mathbf{S}^{(0)} \mathbf{S}^{(12)} + \mathbf{S}^{(0)} \mathbf{S}^{(12)} \mathbf{S}^{(21)} \mathbf{S}^{(12)} + \dots, \quad (17b)$$

thus recovering the field solution in (10).

Alternatively, a formal ‘‘collective solution’’ of (16) is given by

$$\mathbf{F}^{(1)} = \mathbf{S}^{(0)} [\mathbf{I} - \mathbf{S}^{(12)} \mathbf{S}^{(21)}]^{-1}, \quad (18a)$$

$$\mathbf{F}^{(2)} = \mathbf{S}^{(0)} [\mathbf{I} - \mathbf{S}^{(12)} \mathbf{S}^{(21)}]^{-1} \mathbf{S}^{(12)}, \quad (18b)$$

where \mathbf{I} is the identity matrix, and finally

$$u(\mathbf{r}) = u^i(\mathbf{r}) + \mathbf{S}^{(0)} [\mathbf{I} - \mathbf{S}^{(12)} \mathbf{S}^{(21)}]^{-1} \times \{\mathbf{B}^{(1)}(\mathbf{r}) + \mathbf{S}^{(12)} \mathbf{B}^{(2)}(\mathbf{r})\}. \quad (19)$$

As noted above, the $\mathbf{S}^{(jj')}$ matrices are in principle infinite but, depending on the propagation range, they may be truncated so that the inverse matrices in (18) can be calculated. Although the matrices’ dimension grows with the range, one may still utilize the matrices’ sparseness in order to reduce the complexity, as will be discussed in Sec. III E.

D. Coherent and noncoherent fields

As discussed in Sec. II, the total field is the sum of the coherent and noncoherent fields. Thus, in the formulations in Secs. III B and III C, we may express the scattering matrices as a sum of the coherent and noncoherent matrices $\mathbf{S} = \mathbf{S}_c + \mathbf{S}_{nc}$. However, depending on the observables, one wishes to distinguish these two contributions.

The coherent field is generated by coherent multiple scattering processes. It is therefore described by using only the coherent matrices \mathbf{S}_c in the interactions series (14) or in the collective solution (19).

For the noncoherent field (i.e., the average intensity as observable) one must take all the other combinations of co-

herent and noncoherent interactions, i.e., at least one \mathbf{S} matrix in each one of the additive terms in (14) must be \mathbf{S}_{nc} . A simple way to address this combinatorial problem is to set $\mathbf{S} = \mathbf{S}_c + \mathbf{S}_{nc}$ in (14) or (19) and then subtract the coherent field from the final result.

It should be noted, though, that \mathbf{S}_c contains mainly specular beams and thus only a few non-negligible elements, while \mathbf{S}_{nc} is spectrally wide and consists of nonspecular beam interactions and therefore of a large number of non-negligible elements (see Gordon *et al.*, 2004b, Fig. 5) and also Figs. 2 and 3 below). Consequently, the number of elements in the calculation of the noncoherent field via the interactions series (14) grows rapidly with the interaction order. However, in many cases the elements of \mathbf{S}_{nc} are weaker relative to those of \mathbf{S}_c , so that the n th additive term in the series can be described, to leading order, by *only one noncoherent interaction* where all the other $(n-1)$ interactions are coherent. The n th term is thus described as a sum of n permutations (e.g., for $n=3$: $\mathbf{S}_{nc}^{(0)} \mathbf{S}_c^{(12)} \mathbf{S}_c^{(21)} + \mathbf{S}_c^{(0)} \mathbf{S}_{nc}^{(12)} \mathbf{S}_c^{(21)} + \mathbf{S}_c^{(0)} \mathbf{S}_c^{(12)} \mathbf{S}_{nc}^{(21)}$ or, in short, $nc-c-c$, $c-nc-c$, and $c-c-nc$, whereas terms with two or more noncoherent interactions such as $nc-nc-c$, etc., are neglected). This reduces the total number of elements in the calculation of the noncoherent field. Each of these permutation yields a different physical structure, as will be demonstrated in the numerical example of Fig. 3.

E. Beam localization and computational aspects

In both the interactions series and collective approaches, the computational burden is divided into two aspects, one being the calculation of the propagators and then of the waveguide interaction matrices $\mathbf{S}^{(jj')}$, and the other is the summation of the beam contributions. Both can be considerably simplified by considering the beam localization.

The localization is affected via both the *propagation* and the *scattering* mechanisms. The latter implies that the scattering matrices are localized as shown in Gordon *et al.*, 2005, Fig. 5, where we explored the coherent and noncoherent scattering matrices for a given incident beam. The $\mathbf{S}_c^{(jj')}$ matrices represent essentially specular returns and are therefore localized about the phase-space footprint of the incident beams. For example, in homogeneous medium $\mathbf{S}_c^{(jj')}$ is non-negligible if $\boldsymbol{\mu}_j$ and $\boldsymbol{\mu}_{j'}$ are related via $\mathbf{k}_{x\mathbf{n}_j} \approx \mathbf{k}_{x\mathbf{n}_{j'}}$ and $\mathbf{x}_{\mathbf{m}_j} \approx \mathbf{x}_{\mathbf{m}_{j'}} + H \mathbf{k}_{x\mathbf{n}_j} k_{z\mathbf{n}_j}^{-1}$, where $H = z_2 - z_1$ and $k_{z\mathbf{n}_j} = \sqrt{k^2 - |\mathbf{k}_{x\mathbf{n}_j}|^2}$.

The $\mathbf{S}_{nc}^{(jj')}$ matrices are localized only about the *spatial* footprint of the incident beam but they have a wide spectral spread, which depends among other things on the correlation length [see the explicit example in Gordon *et al.* (2005)]. In homogeneous medium, they have non-negligible elements ‘‘for all’’ \mathbf{n}_j and $\mathbf{n}_{j'}$ while \mathbf{m}_j and $\mathbf{m}_{j'}$ are related via $\mathbf{x}_{\mathbf{m}_j} \approx \mathbf{x}_{\mathbf{m}_{j'}} + H \mathbf{k}_{x\mathbf{n}_j}^{-1} \mathbf{k}_{z\mathbf{n}_j}^{-1}$.

The sparseness of the $\mathbf{S}^{(jj')}$ matrices reduces the complexity and the overall computational cost of the calculation. Furthermore, the relevant matrix terms may be determined *a priori* by following the propagators’ trajectories, thus reducing the complexity further.

In the computational algorithm, we thus utilize both *source localization* and *observer localization* considerations. The former accounts for the phase-space footprint of the source by following the beams that are actually excited by the source through their interaction with the waveguide boundaries. The latter accounts for the phase-space footprint of the observer, i.e., the beams that pass near the observer and in the preferred direction of its receiving pattern.

To explain how the *source localization* is utilized, consider, as an example, the interaction series in (14). The incident field excites only a selected set of $\boldsymbol{\mu}_1$ in $\mathbf{S}^{(0)}$ which is known *a priori* for both $\mathbf{S}_c^{(0)}$ and $\mathbf{S}_{nc}^{(0)}$ in view of the discussion above. Each $\boldsymbol{\mu}_1$ beam then excites only a selected set of $\boldsymbol{\mu}_2$ in $\mathbf{S}^{(1)}$, and so forth. One notes that the *complexity* of the coherent field calculations increases slowly with the range due to the slow spectral spread of the coherent beam field. The complexity of the noncoherent field calculations increases faster, not only because of the permutations of $\mathbf{S}_{nc}^{(jj')}$ and $\mathbf{S}_c^{(jj')}$ that should be accounted for in each successive interaction (see the discussion in Sec. III D), but also since $\mathbf{S}_{nc}^{(jj')}$ is less sparse (spectrally wider) than $\mathbf{S}_c^{(jj')}$.

The *observer localization* is affected since the beam summation algorithm accounts only for the contribution of the beams that pass near the observation point (typically within a 3-beamwidth distance from that point). If, in addition, the observer has a receiving pattern, then the contributing beams should also be multiplied by this pattern, thus reducing further the number of relevant beams (see the discussion in Sec. V). For a given observation point and receiving pattern, these considerations define a submanifold in the phase space, denoted as the “geometrical observation manifold” (GOM) (Shlivinski *et al.*, 2004). The use of the GOM limits, *a priori*, the set of the phase-space propagators $B_{\boldsymbol{\mu}_1}^{(1)}(\mathbf{r})$ and $B_{\boldsymbol{\mu}_2}^{(2)}(\mathbf{r})$ that is needed at the observation point. The relevant propagator vectors $B_{\boldsymbol{\mu}_j}^{(j)}$ then define the relevant terms in the matrices that multiply propagator vectors $\mathbf{B}^{(j)}$ from the left in either the interaction series representations (14) or the collective representations (19), and so forth as we progress backward from the receiver to the source. One should recall here, again, the different localized scattering properties of $\mathbf{S}_c^{(jj')}$ and $\mathbf{S}_{nc}^{(jj')}$ as discussed above. These considerations will be demonstrated in the examples of Secs. IV and V C.

The matrix localization can be used to define the number of elements needed in the representation as a function of the observation range. Theoretically, the $\mathbf{S}^{(jj')}$ matrices are infinite since they involve all lattice points along the propagation range. However, one can take only a finite number of elements for a given range of calculation. Thus, the interaction series in (14) for the coherent field needs to be summed only until the specular reflections have passed the required range $|\mathbf{x}|$, whereas for the noncoherent field one should keep a few terms beyond this range due to the possible backward reflections associated with $\mathbf{S}_{nc}^{(jj')}$ (see the examples in Secs. IV and V C).

Similar considerations may also be used in the collective solution (19) where one can truncate the matrices at \mathbf{x}_m be-

yond the required range. This simplifies the calculation of the inverse matrix there.

F. Selecting the beam expansion parameters

The localization discussed in the preceding section is mainly affected by the properties of the frame propagators. By controlling these parameters one may change the expansion characteristics continuously from a ray-like solution to a plane-wave-like solution; hence, these parameters should be selected properly to match a given propagation configuration.

As discussed after (5) the only parameters that need to be chosen are the window parameters $b^{(j)}$ and the overcompleteness parameters $\nu^{(j)}$, which in turn determine the lattice parameter $(\bar{x}^{(j)}, \bar{k}_x^{(j)})$ via (1) and (5). As has been noted after (6), $\nu^{(j)}=0.5$ provides a convenient choice for the class of problems considered here. $b^{(j)}$ should be chosen according to the following criteria: (a) the ratio of the beamwidth $W_0^{(j)} = \sqrt{b^{(j)}/k}$ to the rough surface correlation length (see the discussion in Gordon *et al.*, 2005, Sec. V C). (b) the beamwidth should be large enough on the wavelength scale so that the propagating beams are well collimated and can be calculated locally along their propagation trajectories in the waveguide. Since $b^{(j)}$ represent the collimation distances of the beams, they should be chosen according to the spatial characteristics of the waveguide. To demonstrate these considerations in the homogeneous waveguide discussed here, we recall from Gordon *et al.*, 2005, Eq. (40) that the beamwidth is given roughly by $W(z_b) = \sqrt{b/k} \sqrt{1 + (z_b/b)^2}$, where z_b is the coordinate along the propagation trajectory, measured from the initiation point \mathbf{x}_m on the z_j boundary. Differentiating $\partial W(z_b)/\partial b$ for a given z_b , one finds that $W(z_b)$ is minimal if $b = z_b$. Thus, choosing $b^{(j)}$ roughly equal to or larger than the waveguide width $H = z_2 - z_1$ ensures that the footprint on the $z_{j'}$ plane of the beam that emanates from z_j is minimal.

G. Employing symmetries

In homogeneous media, the $\mathbf{S}^{(jj')}$ matrices have translation and left–right symmetries. Using the $\boldsymbol{\mu}=(\mathbf{m}, \mathbf{n})$ notations, they may be expressed as

$$S_{\mathbf{m}_j, \mathbf{n}_j, \mathbf{m}_{j'}, \mathbf{n}_{j'}}^{(jj')} = S_{(\mathbf{m}_j - \mathbf{m}_{j'}), \mathbf{n}_j, \mathbf{n}_{j'}}^{(jj')} = S_{-(\mathbf{m}_j - \mathbf{m}_{j'}), -\mathbf{n}_j, -\mathbf{n}_{j'}}^{(jj')} \quad (20)$$

This reduces the computational complexity of calculating \mathbf{S} , but does not reduce the *summation complexity*.

It should be noted that these symmetries still apply in vertically inhomogeneous media [though the matrix elements are different, as discussed, for example in (34)]. In range-dependent inhomogeneous configurations, on the other hand, the matrices lose these symmetries and the matrices need to be calculated for each initiation point and direction.

FIG. 2. The coherent field inside the waveguide. The parameters of the rough boundaries, of the illumination, and of the beam expansion are discussed in Sec. IV A. (a) The coherent intensity (dB) plotted in the (x_1, z) plane for $x_2=0$. Note the different scales of the x_1 and z axes. (b) and (c) The phase-space coefficient vectors (the beam amplitudes) $\mathbf{F}_c^{(1,2)}$ plotted in the (x_1, k_{x1}) phase space for $(x_2, k_{x2})=(0,0)$. Each point in the discrete lattice represents a single beam. The coefficient groups A, B, C, and D are associated with the corresponding fields in panel (a) as discussed in Sec. IV B.

IV. NUMERICAL EXAMPLE

The following example demonstrates the GBS method for the evaluation of the coherent and noncoherent fields and their phase-space characteristics within a doubly rough-surfaced waveguide.

A. Problem setup

Referring to Fig. 1, we consider a source-excited field in a homogeneous waveguide with wave number $k=1000$ and rough boundaries at $z_1=0$ and $z_2=H=0.5$ ($H \approx 80\lambda$), with Dirichlet boundary conditions. The source is a GB with collimation distance $b_T=1$ which emanates from $\mathbf{r}_T=(0,0,0.25)$ toward the surface z_1 at the initial direction $(\theta_T, \varphi_T)=(160^\circ, 0^\circ)$. Its field is thus given by

$$u^i(\mathbf{r}) = \frac{-ib_T}{z_b^i - ib_T} \exp\left[ik \left(z_b^i + \frac{1}{2} \frac{|\mathbf{x}_b^i|^2}{z_b^i - ib_T} \right) \right], \quad (21)$$

where (\mathbf{x}_b^i, z_b^i) are the incident beam's coordinates measured along the beam axis from the point \mathbf{r}_T . The beam waist at \mathbf{r}_T is $W_{0_T} = \sqrt{b_T/k} \approx 1/30$, and the far-zone diffraction angle is $\Theta_{D_T} = 1/\sqrt{kb_T} \approx (1/30)^\text{rad}$ [see Gordon *et al.*, 2005, Eqs. (40) and (73)].

For simplicity, the two rough surfaces have the same Gaussian spectra, with identical rms heights, $\sigma_{h1,2}$ and correlation lengths $l_{h1,2}$. They are given by $k\sigma_{h1,2} = 0.1$, implying that the scattering matrix can be calculated analytically

FIG. 3. Same as Fig. 2(a) for the noncoherent field and for the noncoherent phase-space coefficients $\mathbf{F}_{nc}^{(1,2)}$. The coefficient groups A, B, C, and D in panels (b), (c) are associated with the fields in panel (a) as discussed in Sec. IV C.

via the perturbation approach, and $l_{h1,2}^2 = 0.1W_{0_T}^2$, i.e., the correlation length is smaller than the incident beamwidth.

The collimation length of the expansion beams is now set to $b=0.5$, thus providing convenient GB propagators across the waveguide. This also facilitates the asymptotic evaluation of the projection integrals (9) for the GB2GB coherent and noncoherent scattering matrices.

The fields were calculated via the interactions series approach in Sec. III B with up to four successive reflections (the first one at z_1 , and then at z_2 , at z_1 , and at z_2 again). These reflections suffice in order to describe the field correctly up to the range $r=0.75 \approx 120\lambda$, beyond which the fields are weak. In Sec. V C we shall calculate the fields beyond this range up to $r=1.0$ in order to evaluate the bi-static reverberation as a function of the distance x_R between the source and the receiver, as described in Fig. 1.

B. Coherent field

The coherent intensity inside the waveguide, calculated via the GBS approach, is depicted in Fig. 2(a) in the plane of incidence (x_1, z) for $x_2=0$. This field has essentially the form of specular reflections. To gain further insight we also show in Figs. 2(b)–(c) the phase-space distribution of the beam coefficients $\mathbf{F}_c^{(1,2)}$ of (15) corresponding of the coherent fields. The plots in Figs. 2(b)–(c) depict slices of the four-dimensional phase space described by (x_1, k_{x1}) for $(x_2, k_{x2})=(0,0)$.

On each surface two non-negligible coefficient groups are readily discerned, denoted as A and C for $\mathbf{F}_c^{(1)}$ in Fig. 3(b) and B and D for $\mathbf{F}_c^{(2)}$ in Fig. 3(c). Group A corresponds to the first coherent reflections of the incident field from the

surface z_1 [i.e., the term $\mathbf{S}_c^{(0)}$ in (14)], group B corresponds to the second coherent reflections from z_2 [i.e., the term $\mathbf{S}_c^{(0)}\mathbf{S}_c^{(12)}$ in (14) corresponding to scattering at z_1 and then at z_2], while groups C and D correspond to the third and fourth coherent reflections from z_1 and then from z_2 , respectively (the terms $\mathbf{S}_c^{(0)}\mathbf{S}_c^{(12)}\mathbf{S}_c^{(21)}$ and $\mathbf{S}_c^{(0)}\mathbf{S}_c^{(12)}\mathbf{S}_c^{(21)}\mathbf{S}_c^{(12)}$ there). These phase-space distributions demonstrate the loss, spread, and advance of the specular reflections as the range is increased. Each successive interaction with the surfaces is weaker due to the propagation loss between the surfaces and the loss of energy to the noncoherent component [i.e., $\bar{V} < 1$ in (9a)]. Note also that the phase-space distributions are spatially wider, mainly due to the propagation spread of the coherent beam, but the spectral spread is essentially unchanged. These characteristics can also be seen from the field results in Fig. 2(a), where one may also discern the interference patterns between the coherently reflected fields.

C. Noncoherent field

The noncoherent intensity inside the waveguide is shown in Fig. 3(a). Unlike the coherent field, here the field is wide and has a rather intricate structure. To understand these features we refer to Figs. 3(b)–(c) for the phase-space coefficients $\mathbf{F}_{nc}^{(1,2)}$ at the $z_{1,2}$ surfaces, respectively. The presentation formats in these figures is the same as in Fig. 2.

Several coefficient groups are readily discerned in these figures. Group A in $\mathbf{F}_{nc}^{(1)}$ corresponds to the first noncoherent interaction of the incident field with z_1 , as described by $\mathbf{S}_{nc}^{(0)}$ in (17a). As explained in Gordon *et al.*, 2005, Fig. 5(c), it is localized about the center of mass of the incident beam and consists of noncoherent reflections from that point in all directions; hence, it is described by spectrally wide vertical trace in the phase space. These contributions are readily observed in terms of the fan beam in Fig. 3(a) that emerges from the center of mass of the incident beam (point $x_1 = 1$ on the z_1 surface).

Groups B1, B2 in $\mathbf{F}_{nc}^{(2)}$ correspond to the second internal scattering (i.e., scattering at z_1 and then at z_2). Group B1 is the noncoherent scattering from z_2 of the coherent scattered beams that propagated from z_1 [i.e., $\mathbf{S}_c^{(0)}\mathbf{S}_{nc}^{(12)}$ in (17b), also denoted briefly as $c\text{-}nc$]. This group has the typical noncoherent footprint of a vertical trace in the phase space, though it is centered now around the center of mass of the coherent reflection from z_1 (i.e., around $x_1 = 0.27$ there), and is wider due to the spreading of the incident beam. In Fig. 3(a), the resulting field is a fan beam emerging from $x_1 = 0.27$. Group B2 is the coherent scattering at z_2 of the noncoherent beams that propagated from z_1 [i.e., $\mathbf{S}_{nc}^{(0)}\mathbf{S}_c^{(12)}$ in (17b), also denoted $nc\text{-}c$]. The diagonal phase-space footprint is due to the fact that the noncoherent scattered beams from z_1 hit surface z_2 at points that depend on their exit directions from z_1 , and are then coherently reflected. This contribution is seen in Fig. 3(a) as the spread beams that originate from different points on the z_2 plane and at correspondingly different directions (this contribution can be visualized as a specular reflection of fan beam A at z_2). As discussed in Sec. III D, the noncoherent scattering of the noncoherent beams from the upper surface is neglected.

The coefficient group of the third internal scattering consists of two groups (C1, C2 in $\mathbf{F}_{nc}^{(1)}$), whose footprints are similar to group B. C1 represents the $c\text{-}c\text{-}nc$ scattering and its footprint is similar to B1 in $\mathbf{F}_{nc}^{(2)}$, except that here the vertical trace is farther away (around $x_1 = 0.45$) and wider (due to the beam spread of the incident coherent field). C2 represents the $nc\text{-}c\text{-}c$ and $c\text{-}nc\text{-}c$ scattering (the footprints of these two scattering events are almost indistinguishable and they are therefore considered as a single group). It is of the same type as B2, where the diagonal phase-space trace is due to the relationship between the exit point and the direction of the coherent specular reflection at z_1 . These contributions are already too weak to be noticed in Fig. 3(a).

Finally, the coefficient group of the fourth internal scattering consists also of two groups: D1 with vertical trace represents the $c\text{-}c\text{-}c\text{-}nc$ interaction and is similar to B1 and C1, while D2 is similar to B2 and C2 and is composed of $nc\text{-}c\text{-}c\text{-}c$, $c\text{-}nc\text{-}c\text{-}c$, and $c\text{-}c\text{-}nc\text{-}c$ interactions. Again, these contributions are too weak to be noticed in Fig. 3(a).

V. GBS REPRESENTATION OF THE RECEIVER PATTERN

The theory in Sec. III has been phrased for field calculations. In this section we would like to extend the theory so that it now includes the coupling between the multiply reflected beam propagators and the receiving antenna which is characterized by a receiving pattern.

One useful implementation of the aforementioned technique is the evaluation of bistatic reverberations in underwater sounding or communication systems. The problem setup is depicted in Fig. 1. A transmitter T with a given radiation pattern is positioned at (\mathbf{x}_T, z_T) and transmits (upward) within a doubly rough surface homogeneous waveguide with upper and lower boundaries at $z_{1,2}$, respectively. The receiver R with a given pattern $f_R(\theta, \phi)$ is located at $\mathbf{r}_R = (\mathbf{x}_R, z_R)$.

A. The receiver model

From antenna theory (Collin and Zucker, 1969), the signal at a receiving antenna when located in the origin is given by

$$R = C \int_{4\pi} \sin \theta d\theta d\phi f_R(\theta, \phi) \tilde{u}^i(\theta, \phi), \quad (22)$$

where the integral encompasses all directions of incidence with $\tilde{u}^i(\theta, \phi)$ being the spectral amplitude of the incidence field with respect to the (θ, ϕ) direction [normalized such that for an incident plane wave $u^i(\mathbf{r}) = e^{i\mathbf{k} \cdot \mathbf{r}}$, with $\mathbf{k}^i = -k(\sin \theta^i \cos \phi^i, \sin \theta^i \sin \phi^i, \cos \theta^i)$ one has $\tilde{u}^i(\theta, \phi) = (1/\sin \theta) \delta(\theta - \theta^i) \delta(\phi - \phi^i)$]. In (22), $f_R(\theta, \phi)$ is the radiation pattern of antenna R into the (θ, ϕ) direction once this antenna operates in “radiation mode,” normalized such that the field radiated by antenna R due to a unit excitation is

$$u_R^t(\mathbf{r}) = \frac{e^{i\mathbf{k} \cdot \mathbf{r}}}{4\pi|\mathbf{r}|} f_R(\theta, \phi). \quad (23)$$

Under these conditions, it follows via the reciprocity theorem that C in (22) is a universal proportionality constant (Collin and Zucker, 1969).

In order to embed the receiver within the GBS formulation, we need to express the spectral representation (22) within a Cartesian spectrum formulation. Thus, we note from (23) that the field radiated by this antenna, when located in the origin, can be expressed as

$$u_{\mathbf{R}}^i(\mathbf{r}) = \frac{1}{(2\pi)^2} \int d^2k_x \frac{1}{-2ik_z} \tilde{f}_{\mathbf{R}}^{\pm}(\mathbf{k}_x) e^{i\mathbf{k}_x \cdot \mathbf{x} + ik_z|z|}, \quad (24)$$

where upper and lower signs correspond to an observation point at $z \geq 0$, respectively, $k_z = \sqrt{k^2 - |\mathbf{k}_x|^2}$ with $\text{Im } k_z \geq 0$, and

$$\tilde{f}_{\mathbf{R}}^{\pm}(\mathbf{k}_x) = f_{\mathbf{R}}(\theta, \phi)|_{k_x = k \sin \theta (\cos \phi, \sin \phi)}, \quad (25)$$

where the \pm is for $0 < \theta < \pi/2$ and $\pi/2 < \theta < \pi$, respectively. Equation (22) can therefore be expressed instead as

$$R = \frac{C}{(2\pi)^2} \int d^2k_x [\tilde{f}_{\mathbf{R}}^{-}(-\mathbf{k}_x) \tilde{u}^{i+}(\mathbf{k}_x) + \tilde{f}_{\mathbf{R}}^{+}(-\mathbf{k}_x) \tilde{u}^{i-}(\mathbf{k}_x)], \quad (26)$$

where $\tilde{u}^{i\pm}(\mathbf{k})$ are the $\pm z$ propagating spectral components of the incident field u^i at the antenna plane $z=0$.

Finally, let the receiver be located in the waveguide at $\mathbf{r}_{\mathbf{R}} = (\mathbf{x}_{\mathbf{R}}, z_{\mathbf{R}})$, $z_1 \leq z_{\mathbf{R}} \leq z_2$. We also express the $\pm z$ -propagating spectra in terms of their values $\tilde{u}_1^{+}(\mathbf{k}_x)$ and $\tilde{u}_2^{-}(\mathbf{k}_x)$ at $z_{1,2}$, respectively. Then (26) becomes

$$R(\mathbf{r}_{\mathbf{R}}) = \frac{C}{(2\pi)^2} \int d^2k_x [\tilde{f}^{-}(-\mathbf{k}_x) \tilde{u}_1^{+}(\mathbf{k}_x) e^{ik_z(z_{\mathbf{R}} - z_1)} + \tilde{f}^{+}(-\mathbf{k}_x) \tilde{u}_2^{-}(\mathbf{k}_x) e^{ik_z(z_2 - z_{\mathbf{R}})}] e^{i\mathbf{k}_x \cdot \mathbf{x}_{\mathbf{R}}}. \quad (27)$$

B. GBS formulation

Next, we apply the frame decomposition and the Gaussian beam summation formulation to describe the downward/upward propagating waves in (27). Utilizing the matrix notation for brevity, one finds from (15), ignoring the u^i term, that

$$u_1^{+}(\mathbf{r})|_{z_1} = \mathbf{F}^{(1)} \boldsymbol{\Psi}^{(1)}(\mathbf{x}), \quad u_2^{-}(\mathbf{r})|_{z_2} = \mathbf{F}^{(2)} \boldsymbol{\Psi}^{(2)}(\mathbf{x}), \quad (28)$$

where we use the frame element vectors $\boldsymbol{\Psi}^{(j)}(\mathbf{x}) = \psi_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{x})$ and the coefficients row vectors $\mathbf{F}^{(j)}$. Substituting into (27), one finds that $R(\mathbf{r}_{\mathbf{R}})$ has the form in (15) with the u^i term ignored, except that the propagator vectors $\mathbf{B}^{(j)}$ are now replaced by the received (or measured) beam vectors $\mathbf{R}^{(j)}$, i.e.,

$$R_{\boldsymbol{\mu}}(\mathbf{r}_{\mathbf{R}}) = \mathbf{F}^{(1)} \mathbf{R}^{(1)}(\mathbf{r}_{\mathbf{R}}) + \mathbf{F}^{(2)} \mathbf{R}^{(2)}(\mathbf{r}_{\mathbf{R}}), \quad (29)$$

where

$$R_{\boldsymbol{\mu}_{1,2}}^{(1,2)}(\mathbf{r}_{\mathbf{R}}) = \frac{C}{(2\pi)^2} \int d^2k_x \tilde{\psi}_{\boldsymbol{\mu}_{1,2}}^{(1,2)}(\mathbf{k}_x) \times e^{i\mathbf{k}_x \cdot \mathbf{x}_{\mathbf{R}} + ik_z|z_{\mathbf{R}} - z_{1,2}|} \tilde{f}_{\mathbf{R}}^{\pm}(-\mathbf{k}_x). \quad (30)$$

(a) $|R_{c,nc}|^2$

(b) $\mathbf{R}^{(1)}(0)$

FIG. 4. Bistatic reverberations in double rough surface waveguide, for the system configuration depicted in Fig. 1 and the problem parameters in Sec. V C. (a) The coherent and noncoherent reception intensity $|R_c|^2$ and $|R_{nc}|^2$ (in dB) as a function of the range x_{R1} from the transmitter to the receiver. (b) The receiver's phase-space vector $\mathbf{R}^{(1)}(0)$ of (30).

Note from Gordon *et al.*, 2005, Eq. (29), and that for $C = \tilde{f}_{\mathbf{R}}^{\pm} = 1$ these integrals define the beam propagator contributions at $\mathbf{r}_{\mathbf{R}}$, i.e., $R_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{r}_{\mathbf{R}}) \rightarrow B_{\boldsymbol{\mu}_j}^{(j)}(\mathbf{r}_{\mathbf{R}})$. Thus, if $\tilde{f}^{r\pm}(\mathbf{k}_x)$ are slowly varying functions of \mathbf{k}_x relative to $\tilde{\psi}(\mathbf{k}_x)$, one finds via asymptotic evaluation that

$$R_{\boldsymbol{\mu}_{1,2}}^{(1,2)}(\mathbf{r}_{\mathbf{R}}) = C \tilde{f}_{\mathbf{R}}^{\pm}(-\mathbf{k}_{x\mathbf{n}}) \mathbf{B}_{\boldsymbol{\mu}_{1,2}}^{(1,2)}(\mathbf{r}_{\mathbf{R}}). \quad (31)$$

C. Numerical example: Bistatic reverberations

As a demonstration of the receiver's pattern effect, we shall calculate the bistatic reverberation in the two antenna system depicted in Fig. 1 as a function of the range from the transmitter T to the receiver R which is located in the plane of incidence $x_2=0$ at $\mathbf{r}_{\mathbf{R}} = (x_{R1}, 0, 0.25)$, where x_{R1} is the range. The pattern of R is Gaussian with a maximum in the $(\theta_{\mathbf{R}}, \phi_{\mathbf{R}}) = (160^\circ, 0^\circ)$ direction (i.e., it is aimed in the plane of incidence toward surface z_1 and away from T), and with beamwidth $\Theta_{\mathbf{R}} = 1/\sqrt{k b_{\mathbf{R}}} = (1/10)^{\text{rad}}$, where we used $b_{\mathbf{R}} = 0.1$. The beam is oblique but stigmatic (circular symmetric), and therefore we find from (25) that $\tilde{f}_{\mathbf{R}}^{+} = 0$ and

$$\tilde{f}_{\mathbf{R}}^{-}(\mathbf{k}_x) = \sqrt{2b_{\mathbf{R}}k/\cos \theta_{\mathbf{R}}} e^{-i(\mathbf{k}_x - \mathbf{k}_{\mathbf{R}})^T \boldsymbol{\Gamma}_{\mathbf{R}}(\mathbf{k}_x - \mathbf{k}_{\mathbf{R}})/2k}, \quad (32)$$

where $\mathbf{k}_{\mathbf{R}} = k \sin \theta_{\mathbf{R}} (\cos \phi_{\mathbf{R}}, \sin \phi_{\mathbf{R}})$, $\boldsymbol{\Gamma}_{\mathbf{R}}$ is a diagonal matrix with $\Gamma_{R,11} = b_{\mathbf{R}}/\cos^2 \theta_{\mathbf{R}}$ and $\Gamma_{R,22} = b_{\mathbf{R}}$, and the superscript T

in the exponent denotes a transposed vector. We have also used the gain-oriented normalization:

$$\frac{1}{2\pi} \int |\tilde{f}_R^-(\theta, \phi)|^2 d\Omega = 1. \quad (33)$$

Since $b_R \ll b$ here (i.e., the antenna pattern is wider than the spectral beamwidth), we may approximate $R_{\mu_1}^{(1)}(\mathbf{r}_R)$ by (31) with $\tilde{f}_R^-(\mathbf{k}_x)$ from (32). The other physical parameters are the same as in the example of Sec. IV.

The received coherent and noncoherent intensities $|R_c|^2$ and $|R_{nc}|^2$ as a function of the range x_{R1} are shown in Fig. 4(a). As can be seen, $|R_{nc}|$ is stronger and wider than $|R_c|$. This can be explained by noting that the receiving pattern of R is sensitive to waves that are scattered from surface z_1 and propagate backward towards T. Such components exist mainly in the noncoherent field.

To quantify this observation we refer to Fig. 4(b), which depicts the phase-space distribution of the receiver's vector $\mathbf{R}^{(1)}$ of (30) ($\mathbf{R}^{(2)}$ is negligible) at $\mathbf{r}_R = (0, 0, 0.25)$. As expected, $\mathbf{R}^{(1)}$ is centered spatially about $x_1 = x_{R1} - 0.25 \tan \theta_R$, which is the footprint of R at the z_1 plane, and spectrally about $k_{x1} = -k \sin \theta_R$. As x_{R1} changes, the footprints in Fig. 4(b) also move horizontally.

Now, following (29), the received signals $|R_c|$ and $|R_{nc}|$ are obtained by superimposing the phase-space distribution in Fig. 4(b) onto the distributions in Figs. 2(b)–(c) and 3(b)–(c). In other words, $\mathbf{R}^{(1)}$ enhances only those beams in Figs. 2(b)–(c) and 3(b)–(c) that fall within its footprint in Fig. 4(b). Thus, for $|R_c|$ one observes that none of the coefficient groups in Fig. 2(b) falls under the footprint of $\mathbf{R}^{(1)}$ in Fig. 4(b). One obtains, however, some weak contributions in the near zone from coefficient groups A and C. For $|R_{nc}|$, one readily observes two main contributions from coefficient groups A and C in Fig. 3(b).

VI. FUTURE WORK: EXTENSION TO INHOMOGENEOUS MEDIA

The GBs can be propagated in inhomogeneous media or through curved interfaces, where they retain their Gaussian functional form throughout the propagation process (see Babich and Popov, 1989; Popov, 1982; Porter and Bucker, 1987; Keenan and Weinberg, 2001; Heyman and Felsen, 2001; Nowack, 2003). Thus, the frame-based GBS representation for propagation in rough surface waveguide can readily be implemented in such media. One should distinguish though between range-independent media (purely vertically stratified) and range-dependent configurations. In both cases we use the uniform phase-space lattice discussed in Sec. III A, yet in the former, the matrix symmetries in (20) still apply [though the matrix elements are different, as discussed, for example in (34)], whereas in the latter there are no such symmetries and the matrices need to be calculated for each initiation point and direction. Since the beams and the scattering matrices are still localized, the \mathbf{S} matrices are sparse and one may still use the beam-based localization procedures discussed in Secs. III D and III E. The inhomogeneous media can create a situation depicted in Fig. 5 where a scattered beam is refracted and interacts with the same rough

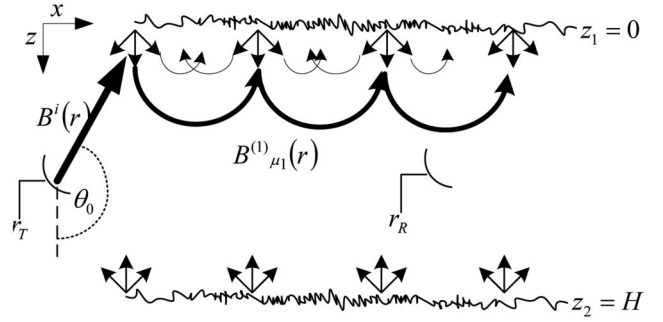

FIG. 5. The GBS setting in a doubly rough boundary nonhomogeneous waveguide which supports trapped fields near surface z_1 . The spectral constituents associated with the trapped field are described by the scattered beam emerging from the rough surface z_1 and refracting back to the same surface without interacting with the other boundary [see the scattering matrix $\mathbf{S}^{(11)}$ in (35)].

boundary it had originated from without reaching the other boundary (e.g., surface ducts). This situation is easily taken care of by adding two terms to Eqs. (16a)–(16b)

$$\mathbf{F}^{(1)} = \mathbf{S}^{(0)} + \mathbf{S}^{(21)}\mathbf{F}^{(2)} + \mathbf{S}^{(11)}\mathbf{F}^{(1)}, \quad (34a)$$

$$\mathbf{F}^{(2)} = \mathbf{S}^{(12)}\mathbf{F}^{(1)} + \mathbf{S}^{(22)}\mathbf{F}^{(2)}, \quad (34b)$$

where

$$\mathbf{S}^{(11)} = S(B_{\mu_1}^{(1)}|_{z_1}, \psi_{\mu_1}^{(1)}), \quad (35a)$$

$$\mathbf{S}^{(22)} = S(B_{\mu_2}^{(2)}|_{z_2}, \psi_{\mu_2}^{(2)}). \quad (35b)$$

Note that the $\mathbf{S}^{(11)}$ has nonvanishing elements only for those μ_1 for which the elements of $\mathbf{S}^{(12)}$ vanish, i.e., each beam originating from the upper surface either reaches the lower surface or refracts to the upper surface.

The equation set (34) may be set in the form

$$\begin{pmatrix} \mathbf{I} - \mathbf{S}^{(11)} & -\mathbf{S}^{(21)} \\ -\mathbf{S}^{(12)} & \mathbf{I} - \mathbf{S}^{(22)} \end{pmatrix} \begin{pmatrix} \mathbf{F}^{(1)} \\ \mathbf{F}^{(2)} \end{pmatrix} = \begin{pmatrix} \mathbf{S}^{(0)} \\ \mathbf{0} \end{pmatrix}, \quad (36)$$

and then solved either via successive approximations as in (17), or collectively via matrix inversion as in (18).

VII. CONCLUDING REMARKS

We introduced an extension of the GBS formulation of rough surface scattering to doubly rough surface waveguide scenario. The theory utilizes deterministic GB propagators and stochastic GB2GB scattering matrices to describe multiple scattering from the upper and lower rough boundaries. The resulting coherent and noncoherent fields were shown to be fully described by the phase-space beam amplitude vectors $\mathbf{F}^{(1,2)}$. Two alternative representations for $\mathbf{F}^{(1,2)}$ were presented: a series of successive interactions and a collective solution (Secs. III B and III C, respectively). As has been demonstrated by the numerical examples in Secs. IV and V C, these amplitude vectors reveal explicitly the local phase-space footprint of the stochastic scattering process, thus providing a cogent physical interpretation to the field propagation. These localization features were utilized to obtain an effective mathematical algorithm, as discussed in Secs. III D–III F. As discussed there, controlling the expan-

sion parameters (e.g., the beam collimation) changes the expansion characteristics continuously from a ray-like solution to a plane-wave-like solution; hence, these parameters should be selected properly to match a given propagation configuration.

In Sec. V the phase-space beam formulation has been extended to accommodate the reception by an antenna with a receiving pattern. An implementation to bistatic reverberations inside a rough surface waveguide as a function of the range and of the source and the receiver directions has been analyzed as an example. The GBS results should be compared with the spectral perturbation approach that was used in Schmidt and Kuperman (1995) to study reverberations in stratified waveguides with rough surface boundaries within the shallow angles and low frequencies regime.

Finally, a simple extension to inhomogeneous media has been discussed qualitatively in Sec. VI, where we mainly considered the formulation of possible surface ducts near the rough surface boundaries. Further work is needed to explore the full power of this elegant technique.

(Received 6 September 2004; revised 6 January 2005; accepted 8 January 2005)

A time domain geoacoustic inversion method using ship noise received on a towed horizontal array is presented. The received signal, containing ship noise as a source of opportunity, is time-reversed and then back-propagated to the vicinity of the ship. The back-propagated signal is correlated with the modeled signal which is expected to peak at the ship's location in case of a good match for the environment. This match is utilized for the geoacoustic parameter inversion. The objective function for this optimization problem is thus defined as the normalized power focused in an area around the source position, using a matched impulse response filter. A hybrid use of global and local search algorithms, i.e., GA and Powell's method is applied to the optimization problem. Applications of the proposed inversion method to MAPEX 2000 noise experiment conducted north of the island of Elba show promising results, and it is shown that the time domain inversion takes advantage of dominant frequencies of the source signature automatically. © 2005 Acoustical Society of America. I. INTRODUCTION

Nowadays the use of passive sonar systems to acquire the information of sources, especially in shallow water areas, is increasing. In addition, various numerical models have been used to simulate their performances with measured or estimated environments, among which the seabed properties are considered to be one of the most influential parameters on the shallow water sound propagation. Therefore, various techniques to estimate the geoacoustic parameters of the ocean bottom via remote sensing have been developed in order to resolve the problem of high cost and time consumption in relation to direct measurement of the sub-bottom properties.

Most areas of the ocean, especially in shallow waters, show varying seabed characteristics that require range-dependent parametrizations for geoacoustic inversion. However, a full range-dependent inversion that can identify the ocean bottom structure simultaneously has not yet been achieved due to computational burdens in forward modeling. A majority of the inversions in underwater acoustics have been performed with the assumption of range-independent environments using long-range propagation data received on a vertical line array (VLA) that produces spatially averaged output.^{1,2} In order to avoid this degradation of resolution, towed horizontal line array (HLA) inversion schemes have been proposed and implemented.^{3–6} The short distance between a sound source and HLA enables us to simplify the range dependence into local segments of range-independent sectors.⁶ The towed HLA system possesses additional advan-

tages of mobility and manageability, which are inherently suitable for a towed sonar system compared to a VLA.

Inversions which utilize the full structure of the bottom reflected signals usually require well controlled acoustic sources. Such dedicated sources may add extra burdens to an inversion experiment especially of the towed HLA system. Contrary to controlled sources, the noise of the tow ship or ship of opportunity can be a good alternative source for inversion.^{5,7} Most of the analyses with the acquired data are processed in the frequency domain, both at the narrowband and broadband, with the exception of a few that have been chosen to deal directly in the time domain.^{6,8–13} Since the ship noise shows a broadband characteristic, it is needed to extract strong tonal components in frequency domain inversions.⁵ On the contrary, time domain inversions can take advantage of a full broadband signal without having to go through the necessary processing.

The inversion is usually formulated as an optimization problem enabling various optimization techniques to be applied to the inverse problems, such as a global optimization^{14,15} and a hybrid form of global and local search.^{16,17} The solutions of the optimization can be regarded as the parameters which optimize the objective function defined to measure the difference (or similarity) between received and simulated data. Although it is common for all parameters to be inverted simultaneously, iterative optimizations can be performed after grouping the parameters based on their sensitivities.¹⁸

In this paper, a time domain inversion using ship noise

FIG. 1. An idealized data acquisition system where the received signal $d(t)$ is comprised of the propagated signal $p(t)$ and noise $n(t)$.

acquired on a towed HLA is proposed. An objective function is defined using a matched impulse response filter for the unknown source signal and the filtered output is implemented by back-propagating the time-reversed signal using a ray-based model. Then, a series of global and local searches is applied to measured data in order to find the optimum parameters of the inverse problem.

The paper is organized as follows. In Sec. II we describe a matched impulse response filter which is a basic theory used in defining the objective function. In Sec. III, a sensitivity test is also presented related to the objective function. In Sec. IV we describe the MAPEX 2000 noise experiment and the parametrization of the inversion. In Sec. V we present the geoacoustic inversion results using the source of opportunity.

II. MATCHED IMPULSE RESPONSE FILTER

It has been demonstrated that the sound wave received by a hydrophone and retransmitted backwards focuses at the source position.¹⁹ This phenomenon can be implemented numerically using a received signal as a virtual source, which was utilized in source localization.^{20,21} It has also been used in underwater applications such as pulse compressing for the communications in the name of time reversal or phase conjugation.^{22,23} The wave focusing is explained via matched filtering and array processing.

A data acquisition process can be represented by an idealized system of Fig. 1, where the received signal $d(t)$ is comprised of propagated signal $p(t)$ and noise $n(t)$. In the linear time invariant system, the propagation of source signal $s(t)$ through a medium can be simply expressed by convolution with an impulse response $h(t)$ as

$$d(t) = p(t) + n(t) = s(t) * h(t) + n(t). \quad (1)$$

The rigorous impulse response for wave propagating in the ocean can be found by solving the wave equation. However, for a set of source and receiver separated within a few water depths, the received signal can be approximated by the sum of eigen-rays weighted and delayed according to their propagation paths. Thus, ignoring the noise for the moment, the received signal can be expressed as

$$d(t) = s(t) * h(t) = s(t) * \sum_{i=1}^M a_i \delta(t - \tau_i), \quad (2)$$

where a_i and τ_i represent the amplitude decay and travel time of the signal component which are propagated through M different paths (eigen-rays), respectively.

If this signal is time reversed and back-propagated, then the medium impulse response simply becomes $h(-t)$, called

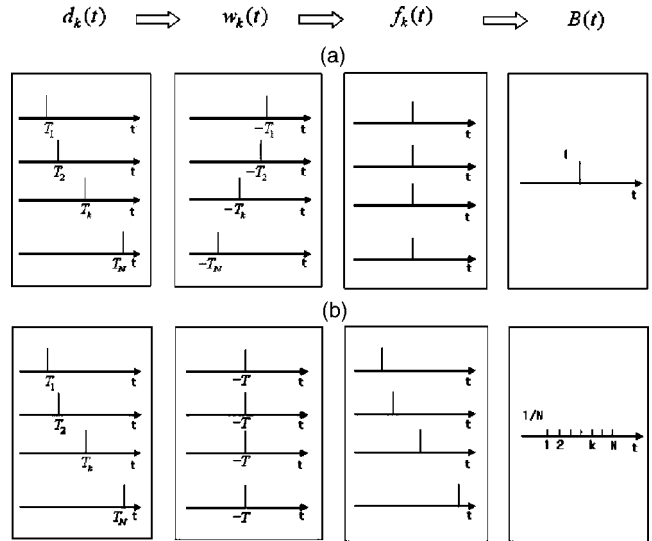

FIG. 2. Examples of beamforming using an impulse signal; (a) optimally beamformed signal and (b) nonoptimally beamformed signal.

the matched impulse response. Applying this as a filter $w(t)$ produces an output at the source location given by

$$f(t) = d(t) * h(-t) = \sum_{i=1}^M a_i^2 s(t) + \sum_{i=1}^M \sum_{j \neq i}^M a_i a_j s(t - (\tau_i - \tau_j)). \quad (3)$$

It can be seen from Eq. (3) that the filter output comprises of two components, $\sum_{i=1}^M a_i^2 s(t)$ and $\sum_{i=1}^M \sum_{j \neq i}^M a_i a_j s(t - (\tau_i - \tau_j))$, which correspond to a mainlobe and multiple sidelobes of the signal, respectively.

Now, the plane-wave beam-forming concept can be extended for an array with N receivers such that the back-propagated output power is defined as

$$B(t) = \frac{1}{N} \sum_{k=1}^N f_k(t) = \frac{1}{N} \sum_{k=1}^N \sum_{i=1}^M a_{i,k}^2 s(t) + \frac{1}{N} \sum_{k=1}^N \sum_{i=1}^M \sum_{j \neq i}^M a_{i,k} a_{j,k} s(t - (\tau_{i,k} - \tau_{j,k})). \quad (4)$$

If the filter is correct, the mainlobe will be reinforced whereas the sidelobes are cancelled by destructive interference. As a result, the mainlobe becomes dominant over the sidelobes as the number of channels increase [Fig. 2(a)]. If the filter is presumed incorrectly, which corresponds to an environmental mismatch, there will be multiple mainlobes along with additional sidelobes [Fig. 2(b)].

The ocean environment itself can be considered as a filter when the received signal is retransmitted reversely. Therefore, when the environment and also the source receiver configurations are modeled as when the signal was recorded at the receiver array, the retransmitted signal will be focused at the original source position.

III. GEOACOUSTIC INVERSION USING SHIP NOISE

Acoustic signals transmitted by a source convey information of the medium through which they propagated. There are numerous acoustic sources for ocean experiments, and the noise generated by a ship is one which will be present most of the time when experiments are carried out in the ocean. If the waveform of a ship noise is unknown, only the impulse response can be used in the geoacoustic inversion.

Inversion parameters which describe the environment are represented by a model vector $\bar{\mathbf{m}} = [\bar{m}_1, \bar{m}_2, \dots, \bar{m}_L]^T$, where $[]^T$ is a transpose operator. The normalized filter output of the channel is defined as

$$f_k(t, \bar{\mathbf{m}}) = \frac{d_k(T-t)}{\sqrt{\int_{-\infty}^{\infty} |d_k(T-t)|^2 dt}} * \frac{\bar{h}_k(t, \bar{\mathbf{m}})}{\sqrt{\int_{-\infty}^{\infty} |\bar{h}_k(t, \bar{\mathbf{m}})|^2 dt}}, \quad (5)$$

where $\bar{h}_k(t, \bar{\mathbf{m}})$ is an impulse response of the corresponding environment. Equation (5) is implemented by propagating the received and time-reversed signal through the environment using a forward model. The objective function to be

FIG. 3. The shallow water environment and the geometry of towed array system used for the sensitivity test. The power spectra of measured signals which are simulated based on the given environment are also shown in the figure.

maximized for the inversion using N receivers is defined as

$$\phi(\bar{\mathbf{m}}) = \max \left(\frac{1}{\Delta T} \int_{T_1}^{T_1 + \Delta T} |B(t, \bar{\mathbf{m}})|^2 dt \right), \quad 0 \leq T_1 \leq T - \Delta T, \quad (6)$$

where

FIG. 4. Sensitivity curves of various parameters which show the objective function values evaluated at the parameter values given in the x -axis. Meanwhile, other parameters are fixed at their reference values given in Fig. 3. Note that the function values are given in dB normalized to the maximum value.

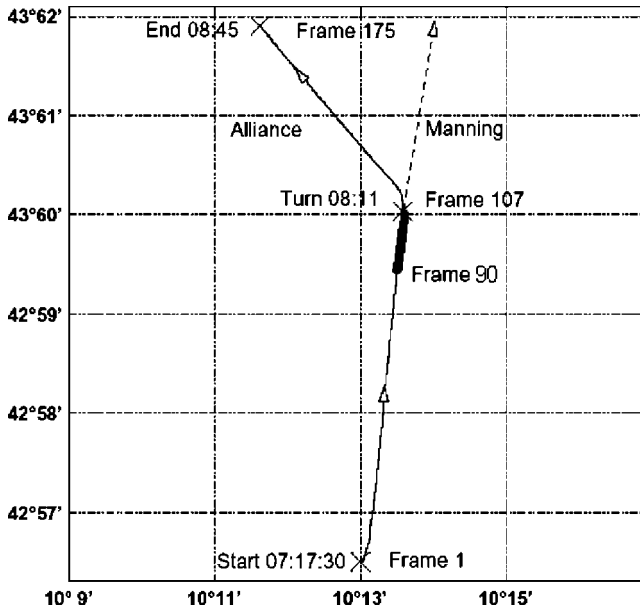

FIG. 5. The tracks of the RV *Alliance* and *Manning* during the experiment. The thick line indicates the track of *Manning* used as sources of opportunity in geoacoustic inversions.

$$B(t, \bar{\mathbf{m}}) = \frac{1}{N} \sum_{i=1}^N f_i(t, \bar{\mathbf{m}}). \quad (7)$$

A ray-based model is chosen for the forward model to calculate the objective function. In order to construct the impulse response in the ray-based model, we need information of amplitudes and phases of the rays that arrive at the receiver position within a predetermined error bound.⁶ It was found that a simple plane wave approximation is sufficient to calculate the phase and amplitude of a ray if the grazing angle of the ray is not near the critical angle, which corresponds to our inversion case presented in Sec. IV. However, if the grazing angle falls within near the critical angle, spherical reflection coefficients²⁴ instead of plane wave ones are calculated in the forward model in order to incorporate the spherical wave effects, especially for the low frequency component.

Since there are numerous results on matched field inversion with vertical line arrays, a relatively good understanding of the sensitivity exists. However, less information is known on the time-domain inversions using a towed system and ship noises. In order to get better insights on the objective function and its sensitivity characteristics with respect to the geoacoustic parameters, we investigated the behavior of the objective function as a function of the selected parameter with other parameters fixed at their reference values. This sensitivity test is commonly carried out in practice in geoacoustic inversions. Although the sensitivity estimates using one parameter may show biased results due to parameter couplings,²⁵ it is considered meaningful to compare the sensitivity for our time-domain inversion with that of other matched field inversions.

For the sensitivity test, we assumed that the tow ship was a sound source and emitted both the random noise and a 320 Hz tonal signal. The environment was the same as Fig. 3. The noise generated by a tow ship propagated through the

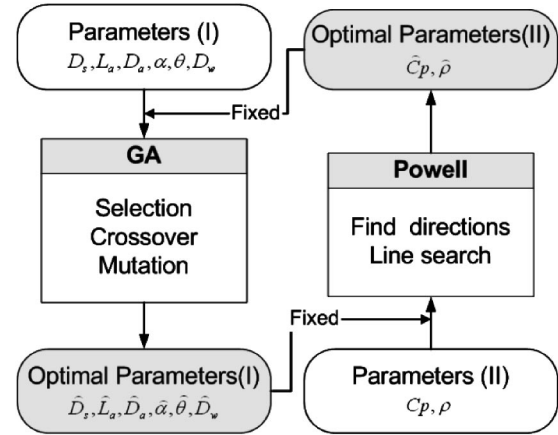

FIG. 6. Two-step optimization procedure.

water column and one layered ocean sediment and was measured on 32 receivers of the HLA. The power spectrums of measured signals for all receivers are also shown in Fig. 3.

Figure 4 shows the sensitivity curves of the parameters using 1 second data which correspond to 6000 time samples. The averaged time interval ΔT in Eq. (6) is chosen to be half the data length. The geometrical parameters such as the source position, the HLA configuration and the water depth show high sensitivities. The parameters of the layer and the sub-bottom show intermediate and low sensitivities, respectively. The sensitive parameters share a common characteristic in that they affect the travel times, i.e., phases, of the received signals. The least sensitive parameter which contributes to the wave amplitude is the density. The sound speed of the sub-bottom is also related with the amplitude in this simulation since a majority of the reflections from the sub-bottom interface occur before the total reflection range. In the simulated experimental setup, the covering angle of incidence with respect to vertical direction by the receivers ranges from 58° to 69° , but the critical angle of incidence is approximately 67° . The above results are mainly due to a nature of the matched impulse response filter. The physical meaning of the filtered output in Eq. (5) is the correlation between the measured signal and the simulated impulse response. The most influential factor in the correlation of the signals is the phase of each of the signal components. The differences in the phases result in a considerable reduction of correlation, but those of the amplitudes take little effect. Battle *et al.*⁵ calculated the sensitivity of the sound speed of half space with respect to the distance between the source and HLA. According to them, the sensitivity showed a rapid increase as the source–receiver range approaches the critical range. After the critical range where the dependence of the reflection coefficient switches from amplitude to phase, the sensitivity saturated and then oscillated showing higher values than before the critical range. This implies that the parameter affecting the phase of the signal is very sensitive in the inversion.

IV. EXPERIMENT AND PARAMETRIZATION

The MAPEX 2000 ship noise experiment was conducted by the SACLANT Undersea Research Center near the island

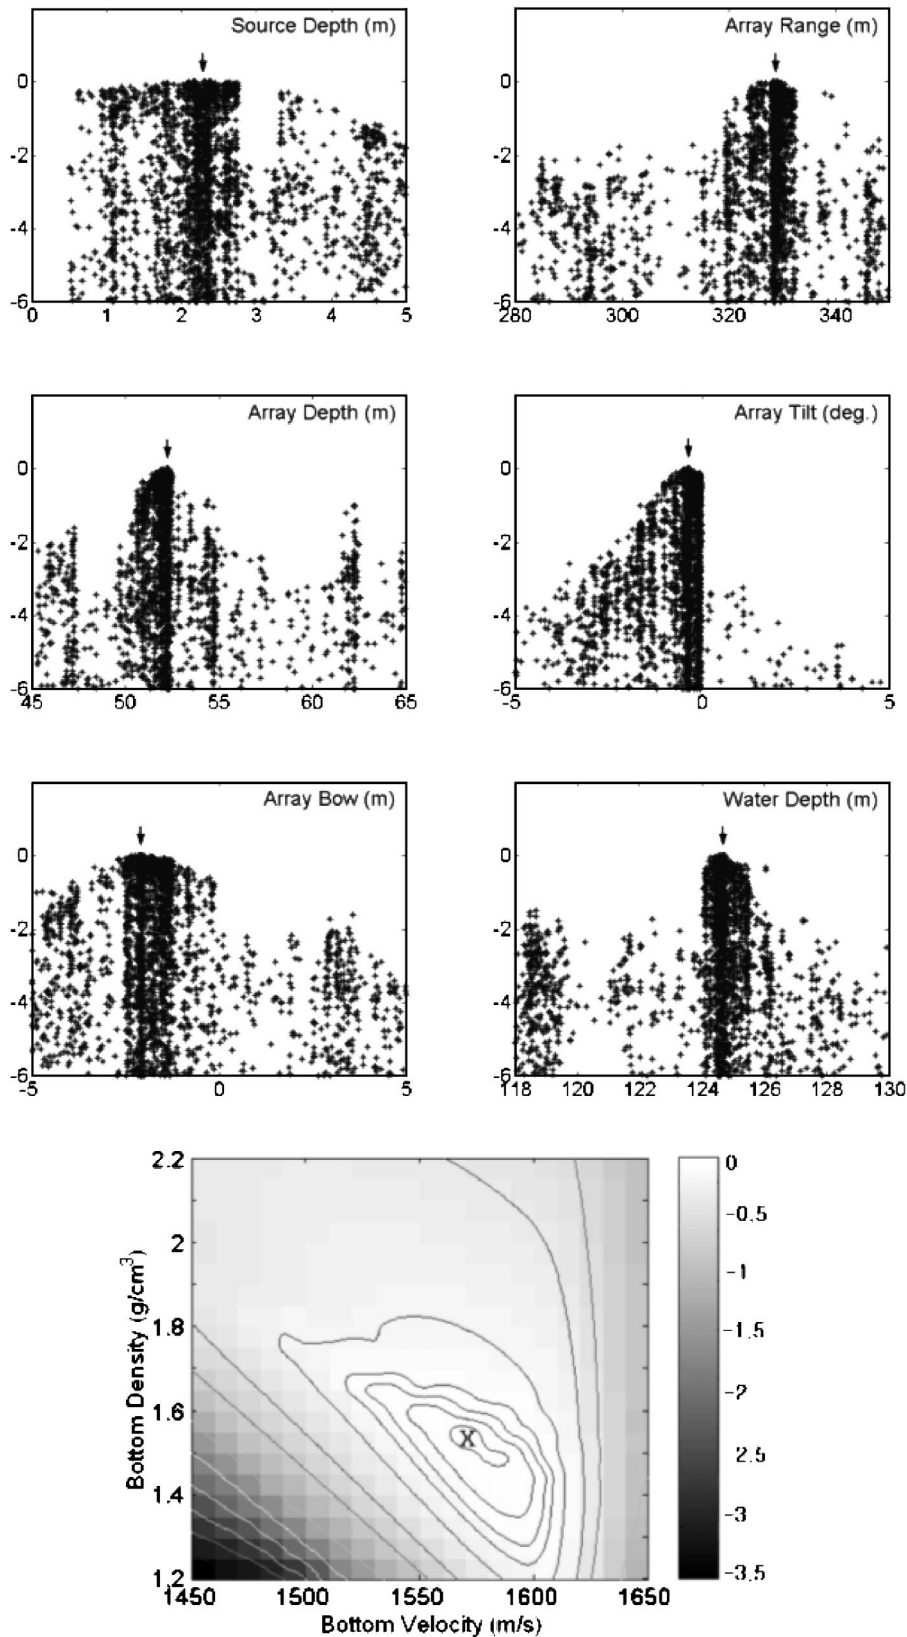

FIG. 7. Inversion results for data measured at 08:07:30 UTC (frame 100). The upper 6 figures are scatter plots of GA search and the lower two dimensional contour shows the objective function values which are re-evaluated based on the best parameters of GA and bottom parameters given in both x - and y -axes. Arrows and crosses represent the best solutions and all function values are given in dB normalized to the maximum value.

of Elba on November 29th. The data were received by a 254 m long HLA for 10 seconds every 30 seconds corresponding to data of 175 frames. The HLA was composed of 128 receivers with 2 m separations and was towed by the R/V *Alliance* along the track shown in Fig. 5.

From this figure, we can see that another R/V *Manning* was following the *Alliance* approximately 900 m behind along the same track from about frame 60 to frame 107. At frame 107, the *Alliance* started making a 45° turn, while the *Manning* proceeded on track as shown in Fig. 5. After frame

FIG. 8. Ambiguity surface of the source localization for the data measured at 08:07:30 UTC (frame 100) calculated using other inverted parameters except for the source location. The function values are given in dB normalized to the maximum value.

122, the *Manning* increased her speed and left the station. Since the distance between the *Alliance* and the nearest receivers to her was approximately 330 m, the horizontal range of the *Manning* from the tail of the array can be estimated to be about 320 m. Although the proximity of two ships may cause some interference, the *Manning* can still be utilized as a source of opportunity.

During the experiment, the depth-sounder recorded the bathymetry showing a slow growth from 116 m to 124 m for the entire track. The sound speed of the water column was kept almost constant at 1520 m/s according to expendable bathy-thermograph casts. The experimental sites have been studied for a long time and the bottom properties are well known. The bottom is comprised of a flat thin layer and a sub-bottom. The thin layer is composed of clay and clay-sand sediments and its thickness is approximately 2.5 m which is only a fraction of a wavelength at frequencies of a few hundred Hz. According to Gingras *et al.*,²⁶ the p-wave speed of the layer was estimated to increase linearly from 1505 m/s to 1556 m/s, which was *a posteriori* mean values based on the 40 observations. In each observation, however, the estimated upper and lower p-wave speeds of the layer showed high fluctuation. The estimated mean p-wave sound speed and density of the sub-bottom were 1578 m/s and 1.6 g/cm³, respectively. Therefore, the thin layer is disregarded in the present inversion and the environmental model of the inversion is treated as range-independent infinite half space. The effect of the thin layer, which is assumed to be small and insensitive to wave propagation, will be included in the infinite half bottom properties in a depth-averaged manner.

Even though the towed HLA is devised to be neutrally buoyant in the water, it still remains to be susceptible to deformations in shape during operations. Therefore, the array shape needs to be included in the inversion parameters for reliable inversion results. Battle *et al.*⁵ implemented the array shape deformation by defining the receiver depth as

$$z_i = \alpha \left(1 - \left(\frac{2x_i}{L} \right)^2 \right) - x_i \sin \theta, \quad (8)$$

where x_i and z_i are the relative positions of the receiver with respect to the center of the array whose length is L . The inversion parameters α and θ in Eq. (8) represent the array bow and tilt, respectively. The same definition is adopted for our inversion. Consequently, a total of eight parameters will be inverted in subsequent inversions; source depth D_s , distance between the source and the nearest receiver L_a , depth of the array center D_a , array tilt θ , array bow α , water depth D_w , bottom sound speed Cp , and bottom density ρ . The attenuation of bottom will be excluded in the inversion due to its extremely low sensitivity.

V. INVERSION USING SOURCE OF OPPORTUNITY

There were two available sources, *Alliance* and *Manning*, used in this experiment. Among these two, the *Manning* data measured from frame 90 to frame 107 which corresponds to the track of thick line in Fig. 5 were considered in this paper. The data of each frame consisted of 10 second signals. Among the 128 receivers, we used every fourth receiver data (32 receivers) for the inversion. In addition, we divided each signal into 10 segments of 1 second long and inverted all of them.

Frequent traffic was reported near the experimental site and the data are possibly contaminated by other ships. Therefore, it was recommended to reduce the unwanted interferences using a wavenumber filter before inversion.⁵ The wavenumber filter was implemented by a 2-D FFT for discrete time signals in a line array. It is noted when the wavenumber filtered data are used in the objective function (6), the simulated impulse response should also include only the corresponding rays. The wavenumber cutoff was set to include arrival angles falling within 50° of endfire to capture most of the expected multiple arrivals from the *Manning*.

The inversion was performed via an optimization process which searches the parameters to maximize the objective function in Eq. (6). Direct and surface reflected signals usually have large amplitudes. But they contain only the geometric information, such as the source and receiver positions, and thus are not useful for the inversion of bottom properties since they do not hit the bottom. If the geometry and bottom properties are inverted simultaneously, geometrical parameters will dominate over bottom parameters in the search process. In order to prevent such dominance in the optimization, the parameters should be inverted separately based on their sensitivities.

In geoacoustic inversion, global optimization methods such as the genetic algorithm and the simulated annealing are preferred due to their potential in finding a global optimum. However, they may have a drawback of slow convergence to the optimum. On the contrary, efficient local methods show quick and sure convergence to the optimum closest to the starting point, but it cannot guarantee to be the global optimum in the multi-modal function space. Presuming with reference to Fig. 4 that the multi-modality could be alleviated if we construct the objective function with only two parameters

FIG. 9. The summary of inversion results which shows the mean and the standard deviation of 10 consecutive inversions of each frame by a thick line and error bars, respectively. The dashed lines represent reference values which were estimated by Battle *et al.* (Ref. 5) via a frequency domain matched field processing using tonal frequencies of 131.8, 262.9 and 306.9 Hz.

of bottom sound speed and bottom density, we took advantage of both the global and the local methods as follows.

At first, the genetic algorithm was applied to the sensitive parameters; the source depth, the array configurations and the water depth, and others fixed at certain values. After one generation of GA was constructed through the selection-crossover-mutation process, the remaining parameters were optimized using a local search method while already optimized parameters were kept at the best values among the

population. And the GA search for the next generation was performed again with the insensitive parameters fixed at optimal values of the local search. The above two-step search process was repeated until a pre-determined number of generations. This optimization procedure is summarized in Fig. 6.

In the inversion, the GA searches were performed for 50 generations and each generation contained 60 populations. The crossover and mutation occurred with probabilities of

FIG. 10. A comparison of the spectrogram beamformed (a) and the Bartlett powers (b). The spectrogram was computed from beamformed time series in the *Manning* direction and the frequency dependent Bartlett powers were calculated with the inverted parameters of corresponding frame via time domain inversions. The function values are given in dB normalized to the maximum value.

0.9 and 0.05, respectively. Powell's method²⁷ was used as the local optimizer, since it does not need gradient information for finding its search direction.

A set of inversion results for a segment signal of frame 100 is presented in Fig. 7. Although one dimensional marginal *a posteriori* probability display of the results is a common practice,¹⁴ we plotted all objective function values with respect to the corresponding parameter values visited during the GA search. By doing so, we could obtain information about the optimizer (GA) such as its behavior related to the parameter sensitivity and sampled parameter space.¹⁰ For the insensitive bottom parameters, which are the main targets of the inversion, we re-evaluated the objective functions based on the best results of GA and showed them in a two dimensional contour plot in Fig. 7. In this figure, the arrows and the cross indicate the best solutions that were found during the inversion procedure. In the scatter plots of Fig. 7, all of the parameters of GA seem to have been resolved well. Besides, the two dimensional contour which shows the mono-modality of the objective function space may be a result that supports that the local optimization is useful.

For an additional check of the validity for the inverted parameter values, we simply performed a back-propagation of the received signals from the array using these environmental parameter results of Fig. 7. The ambiguity surface in Fig. 8 shows a good focus of the back-propagated signals to the correct source position, considering that the draft of *Manning* and estimated range from the nearest receiver to her are 2.5 m and 320 m, respectively.

In Fig. 9, we summarize the inversion results of all frames by the statistical mean and standard deviation estimated from 10 multiple inversions at each frame. The ranges of the y-axis are the same with the search intervals in the optimization procedures. The standard deviations imply uncertainties of the inversion which may arise from the varying data SNR and environments during the experiment and/or from the inherent errors of the optimizer that may occur if the search space is vast.²⁸ However, the mean estimates seem to be consistent especially for geometric parameters irrespective of their uncertainties at each frame. The relatively high variability in the bottom densities seem to be due to its in-

sensitivity to the wave propagation rather than to range dependencies, considering the experimental site has been known to be range independent. Besides, good agreements of our estimates with the reference values represented by the dashed lines in the figure are found. The reference values were estimated by Battle *et al.*⁵ via a frequency domain matched field processing using tonal frequencies of 131.8, 262.9 and 306.9 Hz, which were identified as prominent peaks in the spectrogram of Fig. 10(a). The spectrogram was computed from beamformed time series in the *Manning* direction.

In this paper, we define the Bartlett power as a function of frequency f by

$$B_i(f) = \frac{\mathbf{w}^\dagger(f, \mathbf{m}_i) \mathbf{R}_i(f) \mathbf{w}(f, \mathbf{m}_i)}{\text{tr}[\mathbf{R}_i(f)] \|\mathbf{w}(f, \mathbf{m}_i)\|^2}, \quad (9)$$

where \mathbf{R}_i is the estimated cross spectral density matrix of the i th segmented signals and $\mathbf{w}(\mathbf{m}_i)$ represents the replica vector calculated with the inverted parameters of the corresponding segment. Figure 10(b) shows the calculated Bartlett power. Comparing it with the beamformed spectrogram of Fig. 10(a), we can see a similarity between them. From the frequency dependent behavior of the Bartlett power, it seems that a few frequencies played dominant roles in the inversion and they coincide with those used by Battle *et al.*, which naturally explains the agreements between the two different inversion results. Therefore, we can conclude that the proposed time domain inversion takes advantage of dominant frequencies of the source signature automatically.

VI. CONCLUSION

Predicting bottom properties is important for various acoustic applications in shallow waters due to the significance of the bottom interaction. In this paper we propose a feasible geoacoustic inversion method using a towed HLA and ship noises as a source of opportunity. Such a simple system may make immediate use of geoacoustic parameters as an input to various sonar operations possible.

The inversion scheme is summarized as follows. The objective function was defined using a matched impulse re-

sponse filter for the unknown source signal. The filtered output was implemented by back-propagating the received and time-reversed signals using a ray-based forward model. Then, a series of global and local searches was performed using GA and Powell's method, respectively, to find the optimum parameters.

The present method was applied to the experimental data of the MAPEX2000 noise experiment. The *Manning* data were inverted successively and their results showed good consistency for all parameters. The inverted parameters were compared with the reference values estimated via a frequency domain matched field processing using three dominant tonal frequencies and results showed good agreements. In addition, analyses of Bartlett power revealed that the proposed time domain inversion takes advantage of dominant frequencies of the source signature automatically.

Effects of environmental uncertainties on sonar detection performance prediction

Liewei Sha and Loren W. Nolte^{a)}

Department of Electrical and Computer Engineering, Box 90291, Duke University, Durham, North Carolina 27708-0291

(Received 8 June 2003; accepted for publication 31 January 2005)

The development of effective passive sonar systems depends upon the ability to accurately predict the performance of sonar detection algorithms in realistic ocean environments. Such environments are typically characterized by a high degree of uncertainty, thus limiting the usefulness of performance prediction approaches that assume a deterministic environment. Here we derive closed-form receiver operating characteristic (ROC) expressions for an optimal Bayesian detector and for several typical suboptimal detectors, based on a statistical model of environmental uncertainty. Various scenarios extended from an NRL benchmark shallow-water model were used to check the analytical ROC expressions and to illustrate the effect of environmental uncertainty on detection performance. The results showed that (1) optimal detection performance in an uncertain environment in diffuse noise depends primarily on the signal-to-noise ratio at the receivers and the rank of the signal matrix, where the rank is an effective representation of the scale of environmental uncertainty; (2) the ROC expression for the optimal Bayesian detector provides a more realistic performance upper bound than that obtained from conventional sonar equations that do not incorporate environmental uncertainty; and (3) detection performance predictions can be performed much faster than with commonly used numerical methods such as Monte Carlo performance evaluations. © 2005 Acoustical Society of America. I. INTRODUCTION

To detect the presence of an underwater acoustic source, an optimal detector must combine array data with knowledge about the source position, the propagation channel, and the receiving array configuration. Although the receiving array configuration is typically known, the knowledge of sensor positions is imperfect. The source position is usually unknown. Of particular concern is the uncertainty associated with the propagation channel. The spatial and temporal variations in the channel parameters, such as the ocean bottom depth and the sound speed profile, make accurate characterization of the channel difficult. The set of propagation channel parameters together with the source position parameters constitute an uncertain ocean acoustic environment. Environmental uncertainty can cause severe performance degradation to sonar detection algorithms that rely on precise knowledge of the environmental parameters.^{1–4} Sonar detection performance prediction methods that fail to consider environmental uncertainty do not capture the performance degradation it causes, leading to overestimation of detection performance. Thus, a practical sonar detection performance prediction method that incorporates the effects of environmental uncertainty, and consequently predicts sonar detection performance more accurately, is of practical interest.

Detection performance prediction typically involves both a detection algorithm and a methodology for evaluating the algorithm's performance. Several algorithms that are ro-

bust to environmental uncertainty have been proposed, including the spatial stationarity test,⁵ the focalization approach,⁶ and generalized matched field processing (MFP) algorithms, etc. In the focalization approach,⁶ key environmental parameters are adjusted in an attempt to bring the source into focus before localization. Generalized MFP algorithms include the minimum variance beamformer with multiple neighboring location constraints (MV_NCL),³ the minimum variance beamformer with environmental perturbation constraints (MV_EPC),⁷ the optimum uncertain field processor (OUFP),^{8,9} and the reduced-rank MFP algorithms.¹⁰ Although most of the MFP algorithms were originally proposed for source localization, with a few modifications they can be used to detect the presence of a target. The performance of detection algorithms for an uncertain ocean environment has been evaluated in the past. However, few statistically valid detection performance predictions have been reported. The robustness of the spatial stationarity test⁵ was demonstrated using Mediterranean vertical array data.¹¹ The detection performance of reduced-rank MFP algorithms was tested using data from the Santa Barbara Channel experiment.¹⁰ These performance analyses generate *ad hoc* assessments but not general conclusions about the effects of environmental uncertainty on the detection performance. Some performance evaluations have used a quantitative environmental mismatch model.^{4,2,12} In one approach,⁴ the degradation of the localization performance of a matched-mode-processor was determined as a function of increasing bottom depth mismatch. Their predictions can be improved by including environmental uncertainties other than ocean depth mismatch or sound speed profile mismatch. Finally, most detection perfor-

FIG. 1. Detection performance prediction flow chart.

mance evaluations have been implemented using Monte Carlo simulations.^{9,13} In using the Monte Carlo approach to obtain the detection performance, one needs to generate Monte Carlo data samples over environmental uncertainties as well as implement Monte Carlo integration over the uncertainties of the data, which can be very computationally intensive. Furthermore, the Monte Carlo approach provides no direct insight into fundamental parameters that impact sonar detection performance.

Here we derive analytical performance predictions for an optimal Bayesian detector^{8,9} and for several suboptimal detectors, based on a statistical model of environmental uncertainty. The performance metric used in our prediction methodology is the receiver operating characteristic (ROC). The ROC is more relevant to source detection than metrics such as array gain. The optimal Bayesian detector is a modified version of the OUPF,^{8,9,14–16} which fully incorporates the *a priori* knowledge of the environment. Because the optimal Bayesian detector considers the presence of environmental uncertainty and fully incorporates the *a priori* knowledge, its performance prediction provides a practical performance upper bound. The approximate closed-form ROC expression presented in this paper for the optimal Bayesian detector, referred to as the optimal Bayesian predictor, is a new contribution. The optimal Bayesian predictor reveals that optimal detection performance in an uncertain environment in the presence of diffuse noise depends primarily on the signal-to-noise ratio (SNR) and on the approximate rank of the signal matrix, where the rank reflects the scale of environmental uncertainty. The computation is much faster than using Monte Carlo simulations. Another contribution of this paper is the derivation of precise analytical ROC expressions for the matched-ocean detector, the mean-ocean detector, and the energy detector as a function of environmental uncertainties. The analytical ROC expression for the mean-ocean detector can also be applied generally to predict the detection performance of a beamformer, when the signal wavefront, i.e., the normalized acoustic field, is mismatched with the data.

The organization of the paper is as follows. The detection performance prediction methodology is presented in Sec. II. The optimal Bayesian detector and several suboptimal detectors are presented in Sec. III. The analytical ROC expressions for those detection algorithms are derived in Sec. IV. In Sec. V, a group of simulated uncertain shallow-water environments are used to check the analytical detection performance predictions and to analyze the effects of environmental uncertainty. These simulated environments are extensions from a general mismatch benchmark environment

(“genlmis”) proposed in the May 1993 NRL Workshop on Acoustic Models in Signal Processing.^{5,9,17}

II. DETECTION PERFORMANCE PREDICTION METHODOLOGY

The detection performance prediction methodology is illustrated in Fig. 1, where the symbols are listed in Table I. Environmental uncertainty is explicitly modeled using a statistical approach. An ocean acoustic propagation model is used to transform environmental uncertainty into the uncertainty of the received array signal. The sonar detection problem is placed in a statistical hypothesis test framework. The detection algorithms under investigations are all in the form of a test statistic that is compared with a threshold to determine which hypothesis is true. Analytical detection performance predictions are derived using the ROC metric. This section presents the basic part of the methodology, which includes the environmental uncertainty model, the hypothesis test model, and the performance metric.

A. Environmental uncertainty model

The purpose of modeling environmental uncertainty is to quantitatively analyze its effects on detection performance. Here environmental uncertainty is quantified by assigning an *a priori* probability density function to both the uncertain channel parameters and the unknown source position parameters, over a finite *range* of possible values. The symbol Ψ is used to represent the channel parameters and the symbol \mathbf{S} is used to represent the source position parameters. It is assumed that Ψ and \mathbf{S} are statistically independent *a priori* with uniform probability density functions denoted by $p(\Psi)$ and $p(\mathbf{S})$, respectively. The advantage of this model com-

TABLE I. Symbol definitions for detection performance prediction methodology.

Symbol	Definition
Ψ	Acoustic propagation channel parameters
\mathbf{S}	Source position parameters
\mathbf{r}	Received frequency domain data
$\mathbf{H}(\Psi, \mathbf{S})$	Replica field
a	Frequency domain signal complex amplitude
σ_a^2	Source amplitude variance
\mathbf{n}	Frequency domain diffuse noise
σ_n^2	Noise variance
$p(\Psi, \mathbf{S})$	Probability density function of the environmental parameters
$\lambda'(\mathbf{r})$	Test statistic
β	Detection threshold
P_D	Probability of detection
P_F	Probability of false alarm

pared to the mismatched environmental uncertainty model^{4,2,12} is that it enables the performance prediction algorithm to incorporate an ensemble of possible realizations of the uncertain environment.

B. Hypothesis test

The detection problem is formulated as a decision problem: given the measurement data \mathbf{r} , accept the “noise only” hypothesis H_0 , or reject it to accept the “signal present” hypothesis H_1 , in the presence of channel parameter uncertainties and source position uncertainty. This differs from the source localization problem that often assumes the H_1 hypothesis only.

The two hypotheses are defined as

$$\begin{aligned} H_1: \mathbf{r} &= a_0 \mathbf{H}(\Psi, \mathbf{S}) + \mathbf{n}_0, \\ H_0: \mathbf{r} &= \mathbf{n}_0, \\ \mathbf{n}_0 &\sim \mathcal{N}(0, 2\sigma_n^2 \mathbf{I}_N), \quad a_0 \sim \mathcal{N}(0, 2\sigma_a^2). \end{aligned} \quad (1)$$

The data \mathbf{r} and the diffuse noise \mathbf{n}_0 are both $N \times 1$ spatial column vectors, corresponding to N spatially distributed sensors in the receiving array. The i th component of the data vector \mathbf{r} is assumed to be a narrow-band Fourier transform of the snapshot received by the sensor at the i th location. The ocean acoustic transfer function,¹⁶ $\mathbf{H}(\Psi, \mathbf{S})$, is the complex-valued acoustic pressure field sampled at the receiving array of N sensors in the frequency domain, given ocean environmental parameters Ψ and source position parameters \mathbf{S} . Note that $\mathbf{H}(\Psi, \mathbf{S})$ is known in the applied physics literature as the Green’s function, and is frequently denoted by \mathbf{G} . The scalar a_0 is a circulant complex Gaussian random variable that represents the unknown frequency-domain source amplitude and phase, with zero mean and known variance $2\sigma_a^2$. The diffuse noise present at the receiving array is represented by \mathbf{n}_0 in the frequency domain, which is a circulant complex Gaussian random vector. Denoting the expectation by $\mathbf{E}(\cdot)$ and the covariance matrix by $\mathbf{Cov}(\cdot)$, the assumptions are $\mathbf{E}(\mathbf{n}_0) = \mathbf{0}$ and $\mathbf{Cov}(\mathbf{n}_0) = 2\sigma_n^2 \mathbf{I}_N$, where \mathbf{I}_N is an identity matrix of size N .

The acoustic pressure field generated by a point source at depth z_s and range r_s is computed using normal mode theory,¹⁸

$$\begin{aligned} p(z; r_s, z_s) &= p_0 \sum_{m=1}^K \Phi_m(z_s) \Phi_m(z) \\ &\quad \times \exp(-jk_m r_s) / \sqrt{k_m r_s}, \end{aligned} \quad (2)$$

where z is the depth of the receiver and p_0 is a normalization constant. The number of propagating acoustic modes is represented by K . The terms k_m and Φ_m are the m th eigenvalue and eigenfunction of the Sturm-Liouville problem, which can be calculated using Porter’s KRAKEN¹⁹ code.

In addition, the signal wavefront, $\mathbf{s}(\Psi, \mathbf{S})$, i.e., the normalized acoustic field, is given by

$$\mathbf{s}(\Psi, \mathbf{S}) = \mathbf{H}(\Psi, \mathbf{S}) / \|\mathbf{H}(\Psi, \mathbf{S})\|. \quad (3)$$

Here $\|\cdot\|$ means the two-norm on a complex vector space.

The signal-to-noise ratio at the receivers is defined as

$$\text{SNR}(\Psi, \mathbf{S}) = \frac{\sigma_a^2 \|\mathbf{H}(\Psi, \mathbf{S})\|^2}{\sigma_n^2}. \quad (4)$$

The SNR includes the factors of the source variance, the diffuse noise variance, and the array gain. It is not an element-level SNR but an array-level SNR.

C. Performance metric

The detection performance metric, ROC, is a plot of the probability of detection, P_D , as a function of the probability of false alarm, P_F . From signal detection theory, P_D and P_F are defined as

$$\begin{aligned} P_F(\beta) &= P(\lambda'(\mathbf{r}|H_0) \geq \beta), \\ P_D(\beta) &= P(\lambda'(\mathbf{r}|H_1) \geq \beta), \end{aligned} \quad (5)$$

where $\lambda'(\cdot)$ is the test statistic produced by a detection algorithm and β is the threshold which is determined by the decision criterion. The decision criterion is beyond the scope of this paper. Only the test statistics and the ROC performance are discussed.

When the probability density functions $p(\lambda'|H_0)$ and $p(\lambda'|H_1)$ are available, P_F and P_D can be computed using

$$\begin{aligned} P_F(\beta) &= \int_{\beta}^{\infty} d\lambda' p(\lambda'|H_0), \\ P_D(\beta) &= \int_{\beta}^{\infty} d\lambda' p(\lambda'|H_1). \end{aligned} \quad (6)$$

III. DETECTION ALGORITHMS

Detection algorithms can be categorized according to the level of utilization of the *a priori* knowledge. In this section, four detection algorithms are presented: the optimal Bayesian detector, the matched-ocean detector, the mean-ocean detector, and an energy detector. The matched-ocean detector is not a realistic algorithm, because a complete match between the assumed signal wavefront and the data is practically impossible. We include it to provide a detection performance prediction upper bound for an ideal situation. The mean-ocean detector is a modified version of the conventional, or Bartlett, MFP processor.^{18,20} It represents the algorithms that might use mismatched model parameters. The energy detector represents the algorithms that do not utilize the *a priori* knowledge of the environment at all.

A. Optimal Bayesian detector

The optimal Bayesian detector differs from the OUPF^{8,9} in that it implements the likelihood ratio, while the OUPF forms the maximum *a posteriori* probability (MAP) intended for localization. The derivation of the likelihood ratio is presented here.

Under the H_0 hypothesis, the probability density function of the data at the receiving array is assumed to be

$$p(\mathbf{r}|H_0) = \frac{1}{(2\pi)^N \sigma_n^{2N}} \exp\left(-\frac{\mathbf{r}^\dagger \mathbf{r}}{2\sigma_n^2}\right). \quad (7)$$

Under the H_1 hypothesis, the probability density function of the data conditional to the channel and source position parameters is $p(\mathbf{r}|H_1, \Psi, \mathbf{S})$. The data, conditional to the environmental parameters, is a complex Gaussian random vector. Its probability density function depends only on the mean vector and the covariance matrix, which are

$$\begin{aligned} \mathbf{E}(\mathbf{r}|H_1, \Psi, \mathbf{S}) &= \mathbf{0}, \\ \mathbf{C}_r &= \text{Cov}(\mathbf{r}|H_1, \Psi, \mathbf{S}) \\ &= 2\sigma_n^2 \|\mathbf{H}(\Psi, \mathbf{S})\|^2 \mathbf{s}(\Psi, \mathbf{S}) \mathbf{s}(\Psi, \mathbf{S})^\dagger + 2\sigma_n^2 \mathbf{I}_N. \end{aligned} \quad (8)$$

Applying Woodbury's identity²¹ and the definition of the SNR [Eq. (4)],

$$\mathbf{C}_r^{-1} = (2\sigma_n^2)^{-1} \left(\mathbf{I} - \frac{\text{SNR}(\Psi, \mathbf{S}) \mathbf{s}(\Psi, \mathbf{S}) \mathbf{s}(\Psi, \mathbf{S})^\dagger}{1 + \text{SNR}(\Psi, \mathbf{S})} \right). \quad (9)$$

The determinant of \mathbf{C}_r is the product of all its eigenvalues. Considering that \mathbf{C}_r has $N-1$ identical eigenvalues $2\sigma_n^2$ and one eigenvalue $2\sigma_n^2 \|\mathbf{H}(\Psi, \mathbf{S})\|^2 \mathbf{s}(\Psi, \mathbf{S})^\dagger \mathbf{s}(\Psi, \mathbf{S}) + 2\sigma_n^2$, and using the definition of the SNR,

$$|\mathbf{C}_r| = (2\sigma_n^2)^N (\text{SNR}(\Psi, \mathbf{S}) + 1). \quad (10)$$

Using Eqs. (9) and (10),

$$\begin{aligned} p(\mathbf{r}|H_1, \Psi, \mathbf{S}) &= \exp(-\mathbf{r}^\dagger \mathbf{C}_r^{-1} \mathbf{r}) |\pi \mathbf{C}_r|^{-1}, \\ &= \exp(-\mathbf{r}^\dagger \mathbf{r} / 2\sigma_n^2 + B(\Psi, \mathbf{S}) |\mathbf{r}^\dagger \mathbf{s}(\Psi, \mathbf{S})|^2) / A(\Psi, \mathbf{S}) \\ &\quad \times (2\pi\sigma_n^2)^N, \\ A(\Psi, \mathbf{S}) &= \text{SNR}(\Psi, \mathbf{S}) + 1, \\ B(\Psi, \mathbf{S}) &= \text{SNR}(\Psi, \mathbf{S}) / 2\sigma_n^2 (\text{SNR}(\Psi, \mathbf{S}) + 1). \end{aligned} \quad (11)$$

The conditional likelihood ratio is

$$\lambda(\mathbf{r}|\Psi, \mathbf{S}) = \frac{p(\mathbf{r}|H_1, \Psi, \mathbf{S})}{p(\mathbf{r}|H_0)}. \quad (12)$$

The likelihood ratio combines the probability density function of the environmental parameters with the conditional likelihood ratio. Assuming Ψ and \mathbf{S} are statistically independent *a priori*, the likelihood ratio becomes

$$\begin{aligned} \lambda(\mathbf{r}) &= \int_{\Omega_\Psi} \int_{\Omega_S} d\Psi d\mathbf{S} \lambda(\mathbf{r}|\Psi, \mathbf{S}) p(\Psi) p(\mathbf{S}), \\ \lambda(\mathbf{r}|\Psi, \mathbf{S}) &= \exp(B(\Psi, \mathbf{S}) |\mathbf{r}^\dagger \mathbf{s}(\Psi, \mathbf{S})|^2) / A(\Psi, \mathbf{S}), \end{aligned} \quad (13)$$

where Ω_Ψ and Ω_S represent the ranges of environmental uncertainties.

The optimal Bayesian detector is the likelihood ratio test

$$\lambda(\mathbf{r}) \underset{H_0}{\overset{H_1}{\geq}} \beta, \quad (14)$$

where β is the threshold.

B. Matched-ocean detector

When the ocean environmental parameters and the source position are known, the probability density functions

$p(\Psi)$ and $p(\mathbf{S})$ are delta functions. This is the limiting case of the optimal Bayesian detector, where there is no environmental uncertainty. Substituting delta functions for $p(\Psi)$ and $p(\mathbf{S})$ in Eq. (13) generates $\lambda(\mathbf{r}) = \lambda(\mathbf{r}|\Psi, \mathbf{S})$. Since $A(\Psi, \mathbf{S})$ and $B(\Psi, \mathbf{S})$ in Eq. (13) are now positive constants, $\lambda'(\mathbf{r})_{\text{matched}}$, a monotonic function of the likelihood ratio, is also optimum.

$$\lambda'(\mathbf{r})_{\text{matched}} = |\mathbf{r}^\dagger \mathbf{s}(\Psi_{\text{matched}}, \mathbf{S}_{\text{matched}})|^2. \quad (15)$$

The subscript ‘‘matched’’ is used to indicate that the environmental parameters in the model are matched with the real data. The performance prediction based on the matched-ocean detector provides an ideal performance upper bound. However, it can be too optimistic to use as a predictor of detection performance in a realistic uncertain ocean environment.

C. Mean-ocean detector

The mean-ocean detector uses a test statistic of the same form as the matched-ocean detector. It assumes that the detector knows only mean values of the environmental parameters, which are mismatched with the true environmental parameters. Subscript ‘‘mean’’ is used to indicate this assumption. The test statistic for the mean-ocean detector is expressed as

$$\lambda'(\mathbf{r})_{\text{mean}} = |\mathbf{r}^\dagger \mathbf{s}(\Psi_{\text{mean}}, \mathbf{S}_{\text{mean}})|^2. \quad (16)$$

D. Energy detector

The energy detection algorithm is a conventional approach to the detection of ocean acoustic sources. The energy detector does not include environmental uncertainties in its algorithm. Although robust to environmental uncertainties, it does not exploit these uncertainties. Using the data model defined in the frequency domain [Eq. (1)], the test statistic for the energy detector is

$$\lambda'(\mathbf{r})_{\text{energy}} = \mathbf{r}^\dagger \mathbf{r}. \quad (17)$$

IV. ANALYTICAL ROC PERFORMANCE PREDICTIONS

In this section, analytical ROC performance expressions are derived for each of the four detection algorithms, in the presence of various amounts of ocean environmental and source position uncertainties. These analytical ROC expressions are referred to as the optimal Bayesian predictor, the matched-ocean predictor, the mean-ocean predictor, and the energy predictor. The concept of the signal matrix is introduced first, since it is central to each of the sonar performance predictors.

A. Signal matrix

The signal wavefront, $\mathbf{s}(\Psi, \mathbf{S})$, is a function of the continuous random variables Ψ and \mathbf{S} . To computationally predict the performance of the detection algorithms in an uncertain environment, a discrete representation of the uncertain signal wavefront is needed. A matrix composed of M realizations of the signal wavefront due to uncertainties of the environmental parameters, referred to as the signal matrix \mathfrak{R} , is defined by applying Monte Carlo sampling techniques:

$$\begin{aligned} \mathfrak{X} &= [\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_M], \\ &= [s((\Psi, \mathbf{S})_1), s((\Psi, \mathbf{S})_2), \dots, s((\Psi, \mathbf{S})_M)], \end{aligned} \quad (18)$$

where $(\Psi, \mathbf{S})_i$, $i = 1, \dots, M$, corresponds to the i th realization of the environmental parameters (Ψ, \mathbf{S}) , which follow the uniform probability density function $p(\Psi)p(\mathbf{S})$ that is defined on uncertainty ranges Ω_Ψ and Ω_S . Note that although the signal matrix is used to derive the ROC expressions, it is shown later that only its energy and rank information are needed in the resultant approximate ROC form of the optimal Bayesian predictor.

The finite signal matrix is a subset of the infinite set, which is composed of all possible realizations of the signal wavefronts. If the size of the signal matrix, M , is large enough, the subset could be a good representation of the whole set. Then the postprocessing of the signal matrix could be considered a good approximation to the postprocessing of the original infinite set. The criterion for determining M is problem dependent. Usually, M should be greater than the number of propagating modes, K , so that independent information carried by the propagation modes can be captured by the samples of the signal wavefronts. If the number of elements in the array, N , is smaller than the number of propagating modes, the amount of independent information is limited by N , and so M should be greater than $\min(N, K)$. In this paper, the rule of thumb used was $M \geq 2 \min(N, K)$. This rule has been checked using many simulation examples to show that further increase in M does not significantly change the ROC performance predictions discussed in this paper.

Using the definition of the signal matrix and multiplying both sides of Eq. (1) by the scalar $1/\sqrt{2}\sigma_n$, the hypotheses test simplifies to

$$\begin{aligned} \mathbf{r} &= a\sqrt{\text{SNR}_i}\mathbf{s}_i + \mathbf{n}, \quad i \in 1, \dots, M, \quad \mathbf{n} \sim \mathcal{N}(0, \mathbf{I}_N), \\ H_1: a &\sim \mathcal{N}(0, 1), \quad H_0: a = 0, \end{aligned} \quad (19)$$

where SNR_i is generated by substituting the i th realization of the environmental parameters into Eq. (4). Note that a and \mathbf{n} are normalized so that $\text{Cov}(a) = 1$ and $\text{Cov}(\mathbf{n})$ is an identity matrix of size N . In this discrete hypothesis test, environmental uncertainty is incorporated partly through the probability, $1/M$, of the i th realization of the signal wavefront in the received data and partly through the structure of the signal matrix.

B. Optimal Bayesian predictor

It is often difficult to express the ROC in closed-form for optimal Bayesian detectors. In this section, a useful approximate analytical expression to the ROC is developed.

The development of the optimal Bayesian predictor begins with the discrete likelihood ratio, obtained by utilizing the signal matrix:

$$\begin{aligned} \lambda(\mathbf{r}) &= \sum_{i=1}^M \lambda_i / M, \quad \lambda_i = \exp(B_i |\mathbf{r}^\dagger \mathbf{s}_i|^2) / A_i, \\ A_i &= \text{SNR}_i + 1, \quad B_i = \text{SNR}_i / 2\sigma_n^2 (\text{SNR}_i + 1), \end{aligned} \quad (20)$$

The first approximation is the decision rule approximation. The optimal decision rule “if $\lambda \geq \beta$, decide H_1 and if

$\lambda < \beta$, decide H_0 ” is approximated by “if $\lambda_i \geq \beta$ for any $i \in 1, \dots, M$, decide H_1 and if $\lambda_i < \beta$ for all $i = 1, \dots, M$, decide H_0 .” This approximation has been studied in general.²² However, the authors are not aware of it being used to derive detection performance in a physics-based uncertain environment. Using this approximation, the ROC can be expressed as

$$\begin{aligned} 1 - P_F(\beta) &= P(\lambda_i < \beta, i = 1, \dots, M | H_0), \\ 1 - P_D(\beta) &= P(\lambda_i < \beta, i = 1, \dots, M | H_1). \end{aligned} \quad (21)$$

A second approximation is a constant SNR approximation, i.e., $\text{SNR}_i = \text{SNR}$ for $i = 1, \dots, M$. This assumes that the received signal energy at the receiving array is relatively independent of the perturbations in the ocean transfer function due to ocean environmental and source position uncertainties. For a short vertical array or horizontal array, the constant SNR approximation and the resultant optimal Bayesian predictor might fail because the received signal energy is sensitive to source range variation.

Using this approximation and replacing A_i and B_i with constant A and B , Eq. (21) becomes

$$\begin{aligned} 1 - P_F(\beta') &= P(|\mathbf{r}^\dagger \mathbf{s}_i|^2 < \beta', i = 1, \dots, M | H_0), \\ 1 - P_D(\beta') &= P(|\mathbf{r}^\dagger \mathbf{s}_i|^2 < \beta', i = 1, \dots, M | H_1), \end{aligned} \quad (22)$$

where $\beta' = \log(\beta/A)/B$.

A third approximation is to estimate the rank of the signal matrix as the number of significant eigenvalues of the signal matrix. Assume the rank is R . It is shown²³ that the dimensionality of the data vector in the hypothesis testing problem can be reduced from N to R without affecting the detection performance. Here the hypothesis testing problem differs from Ref. 23 in that the signal vector \mathbf{s}_i is selected from the signal matrix of rank R with the probability $1/M$ whereas it is assumed in the reference that the signal vector is linearly transformed from a parameter vector with a known transform matrix of rank R . However, by considering the signal matrix as the transform matrix and using a column vector as the parameter vector whose i th element is one and whose other elements are zeros, the signal vector \mathbf{s}_i can be treated as a linear transformation of the parameter vector. The procedures in Ref. 23 can be applied here, yielding

$$\begin{aligned} \mathbf{u} &= \sqrt{\text{SNR}}a\mathbf{v}_i + \mathbf{w}, \quad i \in 1, \dots, M, \quad \mathbf{w} \sim \mathcal{N}(0, \mathbf{I}_R), \\ H_1: a &\sim \mathcal{N}(0, 1), \quad H_0: a = 0, \end{aligned} \quad (23)$$

where $\mathbf{u} = \mathbf{U}_1^\dagger \mathbf{r}$, $\mathbf{v}_i = \mathbf{U}_1^\dagger \mathbf{s}_i$, $\mathbf{w} = \mathbf{U}_1^\dagger \mathbf{n}$, and \mathbf{U}_1 is the significant R column of the $N \times N$ unitary matrix \mathbf{U} that is generated from a singular value decomposition of the signal matrix. Note that \mathbf{U}_1 is associated with R significant eigenvalues. The dimensionality of the data vector, the signal wavefront, and the diffuse noise are reduced from N to R .

Since assuming \mathbf{v}_1 as the reference signal wavefront does not change the derivations for P_F and P_D , substituting Eq. (23) in Eq. (22) results in

$$\begin{aligned} 1 - P_F(\beta') &= P(|\mathbf{w}^\dagger \mathbf{v}_1|^2 < \beta', i = 1, \dots, M), \\ 1 - P_D(\beta') &= P(|(\sqrt{\text{SNR}}a\mathbf{v}_1 + \mathbf{w})^\dagger \mathbf{v}_1|^2 < \beta', i = 1, \dots, M). \end{aligned} \quad (24)$$

Both P_D and P_F can be expressed as a multidimensional integral of the probability density function of an independent complex Gaussian vector of size R in a constrained space.

Let $\mathbf{r}_1 = \sqrt{\text{SNR}}a\mathbf{v}_1 + \mathbf{w}$, where \mathbf{r}_1 is a complex Gaussian random vector with covariance matrix $\text{Cov}(\mathbf{r}_1) = 1 + \text{SNR}\mathbf{v}_1\mathbf{v}_1^\dagger$. Using singular value decomposition generates $\text{Cov}(\mathbf{r}_1) = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^\dagger$, where \mathbf{Q} is a unitary matrix and $\text{diag}(\mathbf{\Lambda}) = [\text{SNR}+1, 1, \dots, 1]$. Then \mathbf{r}_1 can be transformed to an independent Gaussian vector \mathbf{z} with covariance matrix $\mathbf{\Lambda}$. Substituting $\mathbf{r}_1 = \mathbf{Q}\mathbf{z}$ in Eq. (24) and using $A = \text{SNR} + 1$ yields

$$1 - P_D(\beta') = P(|\mathbf{z}^\dagger \mathbf{Q}^\dagger \mathbf{v}_1|^2 < \beta', i=1, \dots, M)$$

$$= \int_D \exp\left(-|\mathbf{z}_1|^2 A^{-1} - \sum_{i=2}^R |\mathbf{z}_i|^2\right) \times \pi^{-R} A^{-1} d\mathbf{z}, \quad (25)$$

where the domain of the integration is $D = \{|\mathbf{z}^\dagger \mathbf{Q}^\dagger \mathbf{v}_1|^2 < \beta', i=1, \dots, M\}$.

Substituting $\mathbf{w}^\dagger = \mathbf{z}^\dagger \mathbf{Q}^\dagger$ in the P_F expression in Eq. (24) produces

$$1 - P_F(\beta') = \int_D \exp\left(-\sum_{i=1}^R |\mathbf{z}_i|^2\right) \pi^{-R} d\mathbf{z}. \quad (26)$$

Now the domain of the integration for both P_F and P_D is D , which is an irregular convex body in R space. Although accurate P_F and P_D can be obtained with intensive numerical computations, it is difficult to derive closed-form expressions for P_F and P_D because of the irregularity of the integration domain. To obtain an approximate ROC expression, a regular convex body $C = \{|\mathbf{z}_i|^2 < \gamma, i=1, \dots, R\}$ is used to replace D in Eqs. (25) and (26). Considering the integration functions are Gaussian for both P_F and P_D , whose energy is concentrated on the origin, the approximation error due to moderate integration domain differences that are close to the boundary can be moderate. However, it is difficult to derive an analytical error bound. The accuracy of this approximation, in terms of the final goal of obtaining the ROC, is verified in the simulation section.

Regardless of the approximation in the integration domain, the P_F and P_D approximation errors are zero at $\text{SNR}=0$ and $\text{SNR}=\infty$. When the SNR is zero, the P_D expression is the same as the P_F expression, and the parameter γ in domain C can be adjusted such that the integrations on C for P_F and P_D are accurate. When the SNR reaches infinity, the P_D computed using C or D equals to one. The parameter γ in C can be adjusted to compute P_F accurately.

With this approximation, Eqs. (25) and (26) become

$$1 - P_F(\gamma) \approx (1 - \exp(-\gamma))^R,$$

$$1 - P_D(\gamma) \approx (1 - \exp(-\gamma A^{-1}))(1 - \exp(-\gamma))^{R-1}. \quad (27)$$

Finally, combining P_F and P_D yields

$$P_D \approx 1 - (1 - P_F)^{(R-1)/R} \times (1 - (1 - (1 - P_F)^{1/R})^{1/(\text{SNR}+1)}), \quad (28)$$

where the parameter SNR is the signal-to-noise ratio at the receivers [Eq. (4)]. In real applications, the SNR can be re-

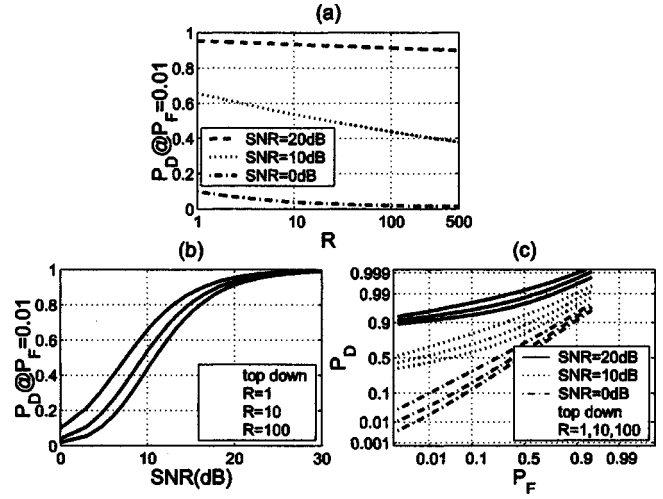

FIG. 2. Analytical detection performance predictions for the optimal Bayesian predictor. (a) P_D as a function of R at fixed $P_F=0.01$, (b) P_D as a function of SNR at fixed $P_F=0.01$, and (c) normal-normal ROC curves as a function of R and SNR.

placed by the average SNR over realizations of the uncertain environment, i.e.,

$$\text{SNR} = \frac{1}{M} \sum_{i=1}^M \text{SNR}_i. \quad (29)$$

The parameter R is the rank of the signal matrix. Strictly speaking, the rank is equal to the number of nonzero eigenvalues. For practical purposes, the rank is determined by the number of significant eigenvalues that exceed a threshold. As shown in Ref. 23, the eigenvalues can be considered as weights to the signal source a . Nonsignificant eigenvalues yield little information (whether $a=0$ or $a \neq 0$) for source detection. Therefore, we only consider the number of significant eigenvalues to estimate the rank in order to predict detection performance. Equation (28) is one of the key results of this paper. The accuracy of this approximate analytical ROC form of the optimal Bayesian predictor is verified in the simulation section.

The computational speed improvement of the optimal Bayesian predictor over the Monte Carlo performance evaluation approach is significant. The primary computational cost for the Monte Carlo approach is the generation of samples of the likelihood ratio for each hypothesis, which is about $O(LMN)$, where L is the number of samples, M is the number of columns in the signal matrix, and N is the number of array sensors. The primary computational cost for the optimal Bayesian predictor is the computation of the eigenvalues, in order to estimate the approximate rank of the signal matrix, which is $O(N^3)$.^{24,25} Typically, M is greater than N , and L is above 1000 to achieve a precision in P_D and P_F of about 0.001, which in turn is about ten times greater than N . Therefore, the analytical approach speedup is typically more than an order of magnitude over the Monte Carlo approach.

Figure 2 illustrates Eq. (28) by plotting P_D as a function of the uncertainty scale R , the SNR at the receivers, and P_F . Figure 2(a) plots P_D as a function of R on a logarithmic scale, assuming $P_F=0.01$ and for SNR=0, 10, or 20 dB. It is shown in Fig. 2(a) that P_D is approximately inversely pro-

portional to R on a logarithmic scale for all three SNR values. Figure 2(b) predicts the optimal detection performance as a function of SNR in the presence of environmental uncertainty of scale R for $P_F=0.01$. The degradation in P_D caused by environmental uncertainty is greater when SNR is less than about 20 dB. In Fig. 2(c), three groups of ROC curves for three SNR values are plotted using normal-normal coordinates. It is often convenient to plot the ROC on normal-normal coordinates. If the underlying distributions of the test statistics for the ROC are normal or Gaussian, the ROC plots as a straight line. In addition, this presentation of the ROC magnifies the region of low probability of false alarm, P_F , similar to log-log coordinates. This plot provides a good comparison of the impact of environmental uncertainty and SNR on the detection performance. It shows that varying R from 1 to 100 or decreasing SNR about 5 dB causes comparable detection performance degradation.

C. Matched-ocean predictor

Since the test statistic for the matched-ocean detector can be considered a chi-square random variable for both hypotheses, an accurate analytical ROC expression for the matched-ocean predictor is available. The resulting form is similar to the ROC for the matched filter detector²³ and the power-type ROC.²⁶

Using \mathbf{s}_k as an abbreviated notation for $\mathbf{s}(\Psi_{\text{known}}, \mathbf{S}_{\text{known}})$ in Eq. (15) results in

$$\begin{aligned} (\lambda'_{\text{matched}}|H_0, \mathbf{s}_k) &= |\mathbf{n}^\dagger \mathbf{s}_k|^2, \\ (\lambda'_{\text{matched}}|H_1, \mathbf{s}_k) &= |(a\mathbf{s}_k + \mathbf{n})^\dagger \mathbf{s}_k|^2. \end{aligned} \quad (30)$$

Let $x_0 = \mathbf{n}^\dagger \mathbf{s}_k$ and $x_1 = (a\mathbf{s}_k + \mathbf{n})^\dagger \mathbf{s}_k$. Since \mathbf{n} is a complex Gaussian vector, scalar a is a complex Gaussian random variable, and \mathbf{s}_k is a known vector, both x_0 and x_1 are complex Gaussian random variables. Their absolute squares are chi-square random variables, with two degrees of freedom. The resultant conditional probability density functions are

$$\begin{aligned} p(\lambda'_{\text{matched}}|H_0, \mathbf{s}_k) &= \exp(\lambda'/C_0)/C_0, \\ p(\lambda'_{\text{matched}}|H_1, \mathbf{s}_k) &= \exp(\lambda'/C_1)/C_1, \end{aligned} \quad (31)$$

where $C_0 = \text{Cov}(x_0) = 2\sigma_n^2 \mathbf{s}_k^\dagger \mathbf{s}_k$ and $C_1 = \text{Cov}(x_1) = C_0(\text{SNR}(\mathbf{s}_k) + 1)$.

Substituting the conditional probability density functions of the test statistics in Eq. (6) produces

$$\begin{aligned} P_F(\beta|\mathbf{s}_k) &= \int_{\beta}^{\infty} d\lambda'_{\text{matched}} p(\lambda'_{\text{matched}}|H_0, \mathbf{s}_k) \\ &= \exp(-\beta/C_0), \\ P_D(\beta|\mathbf{s}_k) &= \int_{\beta}^{\infty} d\lambda'_{\text{matched}} p(\lambda'_{\text{matched}}|H_1, \mathbf{s}_k) \\ &= \exp(-\beta/C_1), \end{aligned} \quad (32)$$

and the ROC expression

$$P_D = P_F^{C_0/C_1} = P_F^{1/(\text{SNR}(\mathbf{s}_k)+1)}. \quad (33)$$

Since the signal wavefront \mathbf{s}_k might be any \mathbf{s}_i in the signal matrix with probability $1/M$, the matched-ocean pre-

dictor is expressed as an average ROC expression

$$P_{D_{\text{matched}}} = \sum_{i=1}^M P_F^{1/(\text{SNR}(\mathbf{s}_i)+1)}/M. \quad (34)$$

This simple matched-ocean predictor is dependent only on the SNR of the known signals.

D. Mean-ocean predictor

To derive the mean-ocean predictor, we assume $\mathbf{r} = a\mathbf{s}_t + \mathbf{n}$ for the H_1 hypothesis, where \mathbf{s}_t represents the real signal wavefront. Replacing $\mathbf{s}(\Psi_{\text{mean}}, \mathbf{S}_{\text{mean}})$ by \mathbf{s}_m for simplicity in Eq. (16) yields the expressions for the test statistic, given \mathbf{s}_m and \mathbf{s}_t :

$$\begin{aligned} (\lambda'_{\text{mean}}|H_0, \mathbf{s}_m) &= |\mathbf{n}^\dagger \mathbf{s}_m|^2, \\ (\lambda'_{\text{mean}}|H_1, \mathbf{s}_t, \mathbf{s}_m) &= |(a\mathbf{s}_t + \mathbf{n})^\dagger \mathbf{s}_m|^2. \end{aligned} \quad (35)$$

Let $x_0 = \mathbf{n}^\dagger \mathbf{s}_m$ and $x_1 = (a\mathbf{s}_t + \mathbf{n})^\dagger \mathbf{s}_m$. Similar to the previous subsection, the absolute squares of both x_0 and x_1 are chi-square random variables, with two degrees of freedom. Their probability density functions are

$$\begin{aligned} p(\lambda'_{\text{mean}}|H_0, \mathbf{s}_m) &= \exp(\lambda'/D_0)/D_0, \\ p(\lambda'_{\text{mean}}|H_1, \mathbf{s}_m, \mathbf{s}_t) &= \exp(\lambda'/D_1)/D_1, \end{aligned} \quad (36)$$

where $D_0 = \text{Cov}(x_0) = 2\sigma_n^2 \mathbf{s}_m^\dagger \mathbf{s}_m$ and $D_1 = \text{Cov}(x_1) = 2\sigma_a^2 |\mathbf{s}_t^\dagger \mathbf{s}_m|^2 + 2\sigma_n^2 |\mathbf{s}_m|^2$.

Given the real signal wavefront \mathbf{s}_t and the mean-ocean signal wavefront \mathbf{s}_m , the analytical ROC form for this mismatched condition can be expressed as

$$P_{D_{\text{mismatched}}} = P_F^{D_0/D_1} = P_F^{1/(\rho(\mathbf{s}_t, \mathbf{s}_m)\text{SNR}(\mathbf{s}_t)+1)}, \quad (37)$$

where $\rho(\mathbf{s}_t, \mathbf{s}_m) = |\mathbf{s}_t^\dagger \mathbf{s}_m|^2 / |\mathbf{s}_t|^2 |\mathbf{s}_m|^2$. The above ROC expression depends on $\text{SNR}(\mathbf{s}_t)$ and $\rho(\mathbf{s}_t, \mathbf{s}_m)$ only, where $\rho(\mathbf{s}_t, \mathbf{s}_m)$ is the correlation of the true signal wavefront with that of the assumed. The parameter ρ characterizes the performance degradation caused by the mismatched environmental parameters in the model.

Considering \mathbf{s}_i might be any \mathbf{s}_i in the signal matrix with probability $1/M$, the ROC for the mean-ocean predictor can be expressed as an average of the mismatched cases:

$$P_{D_{\text{mean}}} = \sum_{i=1}^M P_F^{1/(\rho(\mathbf{s}_i, \mathbf{s}_m)\text{SNR}(\mathbf{s}_i)+1)}/M \quad (38)$$

The mean-ocean predictor predicts the average performance degradation due to environmental mismatch, which is determined primarily by the correlation coefficients $\rho(\mathbf{s}_i, \mathbf{s}_m)$, $i = 1, \dots, M$. It predicts that the performance of the mean-ocean detector decreases as source range increases, as the effects of small errors in the $\exp(-jk_m r_s)$ term [Eq. (2)] accumulate, resulting in mismatch between the mean-ocean signal and the data.

E. Energy predictor

The energy detection algorithm neither requires nor could it use any knowledge about the ocean variables and

source location, even if such information were available. The performance evaluation of the energy detector provides a simple but useful lower performance bound.

To derive the energy predictor, the distributions of the energy test statistic for both hypotheses are required. One special concern in deriving the distribution function for the H_1 hypothesis is that the data depend on the reference signal wavefront \mathbf{s}_i , which might be any column of the signal matrix with probability $1/M$. Another special concern is that the conditional test statistic given the reference signal wavefront, $\lambda'(\mathbf{r}|\mathbf{s}_i)_{\text{energy}} = (\mathbf{a}\mathbf{s}_i + \mathbf{n})^\dagger(\mathbf{a}\mathbf{s}_i + \mathbf{n})$, does not follow a chi-square distribution, as commonly assumed for the energy detector.⁵ The common assumption is made by ignoring data spatial correlations incurred by the presence of the signal.

Since the test statistic is now the sum of correlated gamma random variables, one can obtain analytical forms for the ROC, using the characteristic functions.^{27,28}

The characteristic functions of λ'_{energy} given H_1 and H_0 conditions are

$$\begin{aligned}\Phi(t|H_0) &= E\{\exp(jt\mathbf{r}^\dagger\mathbf{r})|H_0\} = 1/(1 - jt2\sigma_n^2)^N, \\ \Phi(t|H_1) &= \sum_{i=1}^M \Phi(t|H_1, \mathbf{s}_i)/M, \quad (39)\end{aligned}$$

$$\Phi(t|H_1, \mathbf{s}_i) = E\{\exp(jt\mathbf{r}^\dagger\mathbf{r})|H_1, \mathbf{s}_i\} = 1/|I - jtD|,$$

where $D = E\{(\mathbf{a}\mathbf{s}_i + \mathbf{n})(\mathbf{a}\mathbf{s}_i + \mathbf{n})^\dagger\} = 2\sigma_a^2\mathbf{s}_i\mathbf{s}_i^\dagger + 2\sigma_n^2\mathbf{I}$.

The characteristic function $\Phi(t|H_1, \mathbf{s}_i)$ is further decomposed into partial fractions²⁹ to produce Fourier transforms:³⁰

$$\begin{aligned}\Phi(t|H_1, \mathbf{s}_i) &= 1/(1 - jtd_0)^{(N-1)}(1 - jtd_{1i}) \\ &= \sum_{k=1}^{N-1} a_{ik}/(1 - jtd_0)^k + b_i/(1 - jtd_{1i}), \\ d_0 &= 2\sigma_n^2, \quad d_{1i} = d_0A_i, \\ a_{ik} &= (1 - 1/A_i)^{k-N}/A_i, \\ b_i &= -(1 - 1/A_i)^{-N+1}, \quad A_i = \text{SNR}(\mathbf{s}_i) + 1.\end{aligned} \quad (40)$$

The Fourier transforms of the characteristic functions generate the probability density functions of the test statistics:

$$\begin{aligned}p(\lambda'_{\text{energy}}|H_0) &= \gamma(\lambda'_{\text{energy}}/\sigma_n^2, N), \\ p(\lambda'_{\text{energy}}|H_1) &= \sum_{i=1}^M \left(\sum_{k=1}^{N-1} a_{ik} \gamma(\lambda'_{\text{energy}}/d_0, k) \right. \\ &\quad \left. + b_i \gamma(\lambda'_{\text{energy}}/d_{1i}, 1) \right) / M, \quad (41)\end{aligned}$$

$$\gamma(t, N) = t^N \exp(-t) / \Gamma(N).$$

Finally P_D and P_F can be obtained by substituting Eq. (41) in Eq. (6):

$$P_F(\beta) = 1 - \gamma_I(\beta, N),$$

FIG. 3. Benchmark ocean environment.

$$\begin{aligned}P_D(\beta) &= 1 + \sum_{i=1}^M \left(\sum_{k=1}^{N-1} (1 - 1/A_i)^{i-N} \gamma_I(\beta, k) / A_i \right. \\ &\quad \left. - (1 - 1/A_i)^{1-N} \gamma_I(\beta/A_i, 1) \right) / M, \\ A_i &= \text{SNR}_i + 1, \quad (42)\end{aligned}$$

$$\gamma_I(\beta, N) = \int_0^\beta t^{N-1} \exp(-t) dt / \Gamma(N),$$

where γ_I is the incomplete gamma function. The ROC for the energy detector depends on the number of array sensors and the signal-to-noise ratio at the receiving array.

V. RESULTS AND DISCUSSIONS

Simulation scenarios extended from the general mismatch benchmark model (“genlmis”) proposed in the May 1993 NRL Workshop on Acoustic Models in Signal Processing^{17,9,5} were used to check the analytical results. Figure 3 reviews the “genlmis” model, where the vertical line array contains 100 hydrophones spaced 1 m apart ranging from 1 to 100 m in depth. Table II lists the symbols shown in Fig. 3.

In Table II, the ranges of environmental uncertainties ($D, C_0, C_D^-, C_D^+, C_l, \rho, \alpha, z_s$) are denoted using Δ variables. The source range r_s and the upper sediment thickness t were assumed fixed at their mean values in the simulations.

Table III summarizes in four groups a total of 22 different uncertain environmental scenarios and one known environmental scenario. Since source depth D and water depth z_s are two of the most sensitive parameters, their uncertainty

TABLE II. Parameters of uncertain shallow-water environments.

Environmental parameter	Symbol	Value range
Bottom depth	D	102.5 ± ΔD m
Surface sound speed	C ₀	1500 ± ΔC ₀ m/s
Bottom sound speed	C _D ⁻	1480 ± ΔC _D ⁻ m/s
Upper sediment sound speed	C _D ⁺	1600 ± ΔC _D ⁺ m/s
Lower sediment sound speed	C _l	1750 ± ΔC _l m/s
Sediment density	ρ	1.7 ± Δρ g/cm ³
Sediment attenuation	α	0.35 ± Δα dB/A
Sediment thickness	t	100 m
Source depth	z _s	50 ± Δz _s m
Source range	r _s	6 km

TABLE III. Scenarios of environmental uncertainties. Define $\Delta\theta = (\Delta C_0, \Delta C_D^-, \Delta C_D^+, \Delta C_I, \Delta\rho, \Delta\alpha)$ and $\Delta\theta_0 = (2.5, 2.5, 50, 100, 0.25, 0.25)$ for simplicity.

Group of scenarios	Uncertainty configurations
A	$\Delta z_s = \{0, 10, 20, 30, 40, 50\}$
B	$\Delta D = \{0, 1, 2, 3, 4, 5\}$
C	$\Delta z_s = \{0, 10, 20, 30, 40, 50\}, \Delta D = 5, \Delta\theta = \Delta\theta_0$
D	$\Delta D = \{0, 1, 2, 3, 4, 5\}, \Delta\theta = \Delta\theta_0$

ranges, Δz_s and ΔD , are considered separately in groups A and B, respectively. Detection performance appears to be relatively less sensitive to uncertainty in the other environmental parameters taken individually. Therefore, we use $\Delta\theta$ to represent $(\Delta C_0, \Delta C_D^-, \Delta C_D^+, \Delta C_I, \Delta\rho, \Delta\alpha)$ for simplicity and use $\Delta\theta_0 = (2.5, 2.5, 50, 100, 0.25, 0.25)$ as a typical set of values for $\Delta\theta$. In Table III, group A considers six single-source depth-uncertain scenarios with Δz_s increasing from 0 to 50 m. Group B includes six single water-depth-uncertainty scenarios with ΔD increasing from 0 to 5 m. When $\Delta z_s = 0$ in group A or $\Delta D = 0$ in group B, the environmental parameters are configured with their mean values and the environment is known. Group C is group A plus the water depth uncertainty ($\Delta D = 5$ m) and the general ocean uncertainty ($\Delta\theta = \Delta\theta_0$). Group D is group B combined with the presence of the general ocean uncertainty.

A. Performance predictions using the optimal Bayesian predictor

The approximate optimal Bayesian predictor is checked by comparing its prediction results with those obtained using the Monte Carlo performance evaluation approach⁹ for all simulation scenarios listed in Table III.

In the simulations, the input data was generated using Monte Carlo sampling techniques over different ocean environmental, source position, diffuse noise, and signal amplitude and phase realizations based on the data model [Eq. (1)]. In using the Monte Carlo approach, 5000 single snapshot data samples were generated for each hypothesis to produce the samples of the likelihood ratio [Eq. (20)] and to compute P_F and P_D [Eq. (5)]. The ranges of environmental uncertainties and the ratio σ_a^2/σ_n^2 were assumed known *a priori*. Before generating the likelihood ratio samples, the signal matrix \mathfrak{R} was generated using 80 realizations of the signal wavefronts ($M = 80$) and the SNR_i was computed using Eq. (4).

The optimal Bayesian predictor [Eq. (28)] is a function of the approximate rank of the signal matrix and the SNR. Here, the SNR was estimated by computing the mean of the SNR_i 's. The procedure used for choosing an approximate rank is illustrated in Fig. 4(a) for an uncertain scenario. The eigenvalues come from the matrix $\mathfrak{R}^\dagger \mathfrak{R}$. A threshold is used to select the eigenvalues with significant energy, which in turn determines the approximation to the dimensionality of the signal matrix. A “best” threshold is not theoretically tractable. However, the plot of the eigenvalues shows that there is a sharp knee in the curve, which is close to an empirically determined threshold: 5% of the maximum eigenvalue. The

FIG. 4. Analytical detection performance predictions for the optimal Bayesian predictor, for an uncertain environment configured with $\Delta\theta = \Delta\theta_0$ and $\Delta D = 5$. The SNR at the receivers is about 10 dB. (a) Estimation of the approximate rank for the optimal Bayesian predictor, using thresholds of 10%, 5%, and 1% respectively, from left to right. (b) ROC curves for the optimal Bayesian predictor using 5% threshold (dash-dotted curve), 1%–10% thresholds (vertical lines), and the Monte Carlo approach (solid curve).

rank estimated from the empirical threshold and two other thresholds are shown in Fig. 4(a). Figure 4(b) shows that this empirical threshold gives good agreement between Monte Carlo simulation results and analytical ROC results. The variation in P_D due to changes in the threshold from 10% to 1% is illustrated by the short vertical lines in Fig. 4(b). The maximum variation in P_D is less than 0.03. These results illustrate that the ROC is not very sensitive to the threshold value chosen, at and below the knee of the eigenvalue plot.

For all scenarios defined in Table III, it was verified that the ROC results predicted by the optimal Bayesian predictor are consistent with those obtained using the Monte Carlo approach. The ROCs for three of the uncertain scenarios are plotted in Fig. 5 using normal-normal coordinates. These results show that the difference in P_D predicted by the Monte Carlo approach and the optimal Bayesian predictor is small

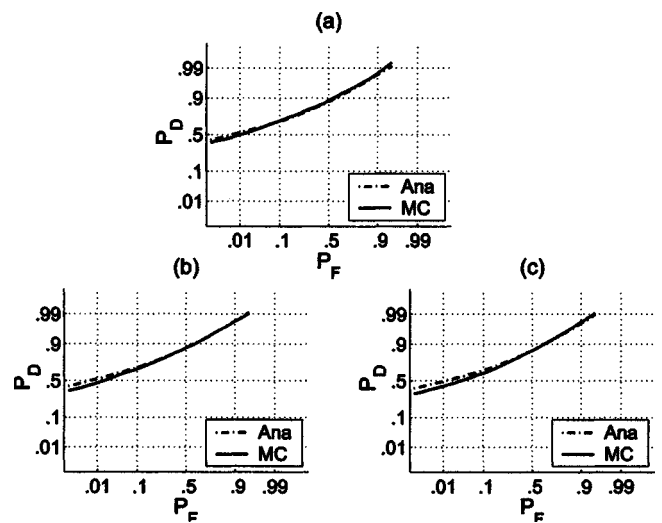

FIG. 5. Comparison of the detection performance predicted by the optimal Bayesian predictor (dash-dotted curve) with the Monte Carlo approach (solid curve) for (a) water depth uncertainty, $\Delta D = 5$, only; (b) water depth uncertainty, $\Delta D = 5$, plus general ocean uncertainty, $\Delta\theta = \Delta\theta_0$; and (c) water depth uncertainty, $\Delta D = 5$, source depth uncertainty, $\Delta z_s = 40$, and general ocean uncertainty, $\Delta\theta = \Delta\theta_0$. The SNR at the receivers is about 10 dB.

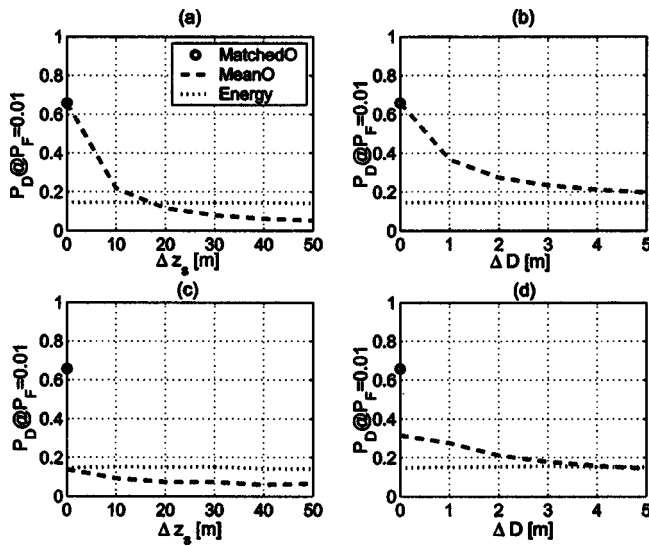

FIG. 6. Comparison of detection performance predictions of matched-ocean, mean-ocean, and energy predictors, plotting probability of correct detection, P_D , as a function of increasing environmental uncertainties. The SNR at the receivers is about 10 dB. Four groups of uncertain scenarios defined in Table III: (a) source depth uncertainty only, (b) water depth uncertainty only, (c) source depth uncertainty plus general ocean uncertainty, and (d) water depth uncertainty plus general ocean uncertainty.

for P_F greater than about 0.1 and is modest (<0.06) for P_F in the range of 0.001–0.1.

B. Quantitative effects of environmental uncertainties

Quantitative effects of environmental uncertainty on detection performance predictions are illustrated in Figs. 6 and 7. In these figures the probability of detection is plotted as a

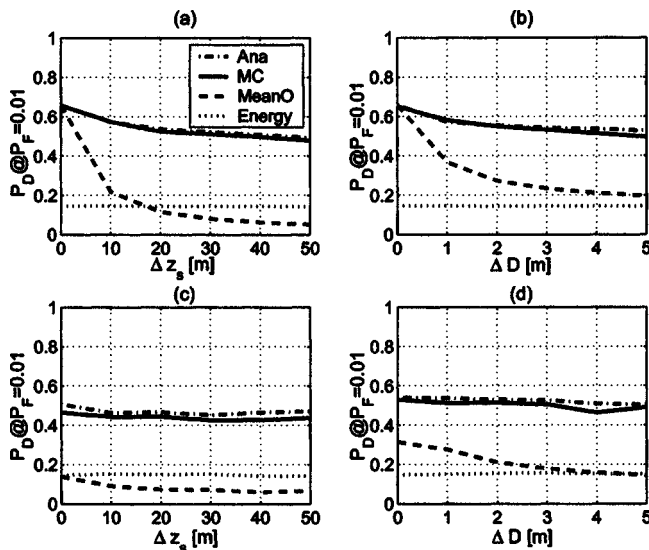

FIG. 7. Comparison of the analytical detection performance prediction, P_D , of the optimal Bayesian predictor (dash-dotted curve), with Monte Carlo evaluation techniques (solid curve) as a function of increasing environmental uncertainties. Also shown for comparison are the performance predictions of the mean-ocean predictor (dashed curve) and the energy predictor (dotted curve). The SNR at the receivers is about 10 dB. Four groups of uncertain scenarios defined in Table III: (a) source depth uncertainty only, (b) water depth uncertainty only, (c) source depth uncertainty plus general ocean uncertainty, and (d) water depth uncertainty plus general ocean uncertainty.

function of the range of environmental uncertainties for the four groups of scenarios defined in Table III.

Figure 6 illustrates the detection performance predicted by the matched-ocean predictor [Eq. (34)], the mean-ocean predictor [Eq. (38)], and the energy predictor [Eq. (42)], which are all precise analytical results. Scenario groups A–D defined in Table III were used to generate Figs. 6(a)–(d), respectively, at a fixed $P_F=0.01$ and for a SNR of about 10 dB at the receivers.

In Figs. 6(a) and (b), the P_D predicted by the matched-ocean predictor, corresponding to $\Delta z_s=0$ and $\Delta D=0$, is determined only by the SNR of the mean-ocean signal and P_F . In Figs. 6(c) and (d), the circles are P_D averaged over the fluctuating SNRs in uncertain environments. The ROCs of the matched-ocean detector in all scenarios provide performance prediction upper bounds for the ideal situation in which there is no environmental uncertainty.

The mean-ocean predictor predicts the same detection performance as that of the matched-ocean predictor when there is no environmental uncertainty. However, the mean-ocean prediction, P_D , falls off rapidly as the range of single parameter uncertainty increases, as shown in Figs. 6(a) and (b). In Figs. 6(c) and (d), the performance predicted by the mean-ocean predictor is even lower with the additional presence of general ocean uncertainty. Although one would expect the performance prediction to fall off as environmental uncertainty increases, it will be shown that it need not fall off this precipitously if the Bayesian optimal predictor is used.

Figures 6(a)–(d) also show P_D predicted by the energy predictor. Its prediction does not change with environmental uncertainties, but remains a small number. This is because the energy detection algorithm does not incorporate the *a priori* knowledge of the environment at all. The performance of the energy predictor provides a simple, yet useful performance lower bound.

Figure 7 illustrates the effects of environmental uncertainty on the optimal Bayesian predictor, at a fixed $P_F=0.01$, for about 10-dB SNR at the receivers. The Bayesian predictor incorporates the degree or range of environmental uncertainty in its prediction. First, this figure shows that the predictions made by the optimal Bayesian predictor agree with those obtained using the Monte Carlo approach for all four groups of scenarios in Table III. Secondly, in contrast to the mean-ocean predictor, the performance of the optimal Bayesian detector falls off more gradually with increasing environmental uncertainty. These results show the importance of fully incorporating environmental uncertainty into the sonar detection performance prediction algorithm.

C. Effects of wrong *a priori* knowledge

Although most of the physics is expressed in the likelihood function, $\lambda(\mathbf{r}|\Psi, \mathbf{S}) = \exp(B(\Psi, \mathbf{S})|\mathbf{r}^\dagger \mathbf{s}(\Psi, \mathbf{S})|^2)/A(\Psi, \mathbf{S})$, the *a priori* knowledge of the uncertain parameters can affect the performance of the Bayesian detector. If the *a priori* distribution of model parameters or the *a priori* ranges of environmental uncertainties are wrong, the Bayesian detection performance degrades, especially if the range of uncertainty of the parameters is underestimated. Figure 8 illustrates the effects of overestimating or underestimating the

FIG. 8. ROCs illustrating the effect of wrong *a priori* range of ocean depth uncertainty on Bayesian detection performance. From top to bottom, four cases are plotted: assumed and ground truth range of uncertainty are ± 1 m (dashed curve), assumed range of uncertainty is ± 5 m while the truth is ± 1 m (dash-dotted curve), assumed and ground truth range of uncertainty are ± 5 m (solid curve), and assumed range of uncertainty is ± 1 m range while the truth is ± 5 m (dotted curve).

ranges of ocean depth uncertainty on the performance of the Bayesian detector, using the Monte Carlo approach. The number of signal wavefronts is 80 and the simulated data samples for each hypothesis is 20 000.

The ROC curves are plotted using normal-normal coordinates, where the dashed curve denotes the case using a correct assumption of $\Delta D=1$; the dash-dotted curve is for the scenario assuming *a priori* $\Delta D=5$, while the truth is $\Delta D=1$; the solid line denotes the scenario using a correct assumption of $\Delta D=5$; and the dotted one denotes the scenario using an underestimated *a priori* $\Delta D=1$, while the truth is $\Delta D=5$. The maximum degradation from the dashed curve to the dash-dotted curve is 0.03, which shows that if the range of ocean depth uncertainty is overestimated, the performance degradation is modest. However, if the range of uncertainty is underestimated, the P_D performance degradation is as large as 0.1, which is significant. These results indicate that the ROC expression [Eq. (28)] is useful even if the range of uncertainty is overestimated. In summary, these preliminary results indicate that it is preferable to assume that the ocean environmental uncertainty range is somewhat greater than truth.

D. Comparison of performance predictions as a function of source range

In order to get an idea of the impact of ocean environmental uncertainty on detection range, the probability of detection as a function of source range is plotted in Fig. 9 for the general uncertain scenario configured with $\Delta\theta = \Delta\theta_0$ and $\Delta D=5$. From top to bottom, five approaches are illustrated: the matched-ocean predictor, the optimal Bayesian predictor, Monte Carlo performance evaluations for the optimal Bayesian detector, the energy predictor, and the mean-ocean predictor. Although these results are for a fixed source depth, additional simulation results indicate that the general pattern of P_D as a function of source range is relatively independent of source depth.

The difference between the P_D curves predicted by the matched-ocean predictor and the optimal Bayesian predictor reflects the performance degradation due to environmental

FIG. 9. Detection performance predictions, P_D , as a function of source range in the general ocean uncertainty. Source depth=41 m, $P_F=0.01$, and SNR about 10 dB at source range=6 km. Five performance prediction approaches: the matched-ocean predictor, the optimal Bayesian predictor, Monte Carlo performance evaluation for the optimal Bayesian detector, the energy predictor, and the mean-ocean predictor.

uncertainty, even if one optimally incorporated the environmental uncertainty in the Bayesian prediction algorithm. For example, for $P_D=0.6$, the detection range is in fact 4.9 km, not 6.8 km, as would be predicted by the matched-ocean predictor or classic sonar equation. On the other hand, the mean-ocean and energy predictors give too pessimistic a view of the detection range possible in this particular uncertain ocean environment.

VI. CONCLUSIONS

Analytical approximate ROC expressions, which can be computed rapidly, have been developed for sonar performance prediction. Using a statistical decision theory framework, detection performance prediction algorithms were derived that incorporate the uncertainty of the physics of the acoustic propagation channel as well as the uncertainty of source position in an optimal manner. These analytical expressions for the ROC enable one to compute sonar performance prediction in a much simpler manner than is usually possible using Monte Carlo methods.

Analytical forms were obtained for the ROC for the matched-ocean detector, the mean-ocean detector, and the energy detector. The matched-ocean predictor provides an upper limiting performance bound for the case where there is no uncertainty in the ocean environment. The mean-ocean predictor, which uses only the mean-ocean signal rather than the uncertain environmental knowledge available in the signal matrix, illustrates the degradation in performance due to mismatched model parameters.

The optimal Bayesian predictor incorporates the uncertainty of the physics of the acoustic propagation channel. An algebraic expression was obtained that was shown to be an excellent approximation for the ROC for several examples. This expression indicates that the optimal sonar detection performance (ROC) in diffuse noise depends primarily on the ocean environmental uncertainty, which is captured by the signal matrix, and the mean signal-to-noise ratio at the receivers. These results let one obtain the ROCs in a simple way, as contrasted to computationally intensive Monte Carlo techniques. These results also provide a more meaningful

and realistic performance prediction since it incorporates environmental uncertainty, a feature that is lacking in the classic sonar equation. These results are based on the model that assumes a single source in spatially white noise. However, even in this case, the results can aid in determining how much additional information about the environmental parameters is necessary for a desired improvement in sonar detection performance.

Bayesian sonar detection performance prediction in the presence of interference in uncertain environments

(Received 18 April 2004; revised 21 January 2005; accepted 25 January 2005)

The detection performance of sonar systems can be greatly limited by the presence of interference and environmental uncertainty. The classic sonar equation does not take into account these two limiting factors and is inaccurate in predicting sonar detection performance. Here we have developed closed-form receiver operating characteristic (ROC) performance expressions for the Bayesian detector in the presence of interference in uncertain environments. Various scenarios extended from a NRL benchmark shallow-water model were used to test the analytical ROC expressions and to analyze the effects of interference and environmental uncertainty on detection performance. The results show that (1) the degradation on detection performance due to interference is greatly magnified by the presence of environmental uncertainty; (2) Bayesian sonar detection performance depends on the following fundamental parameters: the signal-to-noise ratio, the rank of the signal matrix, and the signal-to-interference coefficient; (3) the proposed analytical ROC performance predictions can be computed much faster than performance evaluations with commonly used Monte Carlo techniques. © 2005 Acoustical Society of America.

I. INTRODUCTION

Sonar detection performance prediction has received significant attention by the underwater acoustic community. In many sonar systems,¹ the sonar equation is used as a means for predicting the detection performance. The classic sonar equation assumes that both the signal wavefront and the noise field directionality are known *a priori*. However, under practical circumstances, the signal wavefront and noise field directionality are usually uncertain. The signal wavefront is a function of the ocean environment, the source position, and the receiving array configuration. Ocean environmental parameters such as water depth, sound speed profile, bottom density, etc., have strong spatial and temporal variability, whose values are not known precisely. Source motion limits the accuracy of the estimate of the source position. Uncertainties in both the source position and ocean environmental parameters translate to uncertainty in the signal wavefront. The noise field directionality is usually uncertain due to the presence of interferers with uncertain locations in the uncertain ocean environment. In summary, the classic sonar equation does not take into account environmental uncertainty and hence is inaccurate, often too optimistic for a sonar detection performance prediction in a realistic circumstance.

The sensitivity of the localization algorithms to the uncertain ocean environmental parameters and the uncertain source position parameters has generated interest in the research community.^{2,3} Several localization algorithms that are robust to these uncertainties have been proposed, such as the minimum variance beamformer with multiple neighboring

location constraints (MV_NCL),³ the optimum uncertain field processor (OUFP),^{4,5} the minimum variance beamformer with environmental perturbation constraints (MV_EPC),⁶ and the reduced-rank MFP algorithms.⁷ With a few modifications, these algorithms can be used to detect the presence of a target. Robust algorithms directly proposed for detection problems include the stationarity test⁸ and the Bayesian detectors.^{5,9} The detection performance of those algorithms have been reported.^{5,7,8} For example, the detection performance of reduced-rank MFP algorithms has been tested using an array gain metric and using data from the Santa Barbara Channel experiment.⁷ The spatial stationarity test⁸ has been evaluated using Mediterranean vertical array data.¹⁰ However, those performance evaluations do not provide a fundamental relationship between environmental uncertainty and detection performance. Further, most performance evaluations^{5,9,11} are computed using Monte Carlo techniques rather than through analytical means, which is computationally intensive.

The presence of interference is another limiting factor to detection performance besides environmental uncertainty. Some detection algorithms assume a known plane wave interference model.^{12,13} The resultant performance analysis can be too optimistic. Other detection algorithms^{14,15} assume that the noise field is completely unknown, requiring either *in situ* measurements or adaptive estimations from noise-only data, which do not take advantage of available information about the environment and the interferers.

Here we develop a closed-form ROC expression for the Bayesian detector in the presence of interference in uncertain environments, which is different from previous work¹⁶ that does not take into account interference. The principal cause of the interference modeled here are the acoustic sources

^{a)}Electronic mail: lwn@ee.duke.edu

other than the target. The Bayesian detector is modified from the OUPF,⁴ which incorporates the *a priori* information of the interferers. The resultant ROC expression is an algebraic function of a few parameters: the signal-to-interference coefficient, which captures the effect of interference in uncertain environments; the rank of the signal matrix, which characterizes the degree of environmental uncertainty; and the signal-to-noise ratio, which characterizes the combined effect of the source level, the noise level, the propagation loss, and array gain. Simulated data generated using a NRL benchmark shallow-water model^{8,5,17} are used to verify the proposed Bayesian detection performance prediction approach, by comparing analytical results with Monte Carlo performance evaluation results. Good agreement of those results demonstrates that the simple analytical ROC expression derived here captures fundamental parameters of the performance of the Bayesian detectors. This provides a more realistic detection performance prediction than does the classic sonar equation. The simulation results also indicate that detection performance degradation due to interference is magnified by the presence of environmental uncertainty.

The paper is organized as follows. In Sec. II, the signal and interference model is defined. In Sec. III, the detection problem is formulated. In Sec. IV, the Bayesian detector that incorporates the *a priori* information of the interferers and uncertain environmental parameters is presented. In Secs. V, VI, and VII, analytical ROC expressions are developed for the Bayesian detector in known environments and in uncertain environments. In Sec. VIII we verify the proposed performance prediction approach and the effect of interference on detection performance using simulated data.

II. SIGNAL AND INTERFERENCE MODEL

Typical interference models include a conventional plane wave model for detection and parameter estimation problems,^{12,13} and the Gaussian distribution model in beamforming.¹⁸ Here, the uncertain signal and interference at the receivers are both expressed as a function of the uncertain ocean environmental parameters and acoustic source (signal source or interferer) position parameters. With this translation of uncertainties, the model enables a detection algorithm to incorporate the *a priori* knowledge at the ocean and source parameter level, rather than at the signal or interference wavefront level. The advantage of this translation is that it is much easier to get a stochastic description of the ocean and source parameters than to obtain the *a priori* probability density function for the signal and interference wavefronts.

Ocean and source position parameters are defined along with their stochastic descriptions. The ocean environmental parameters, Ψ , represent ocean properties affecting the acoustic propagation. Such properties include water depth, sound speed profile, surface roughness, bottom composition and roughness, etc. The signal source position relative to the receiving array is denoted by \mathbf{S} . The number of interferers, K , is assumed a known constant. The k th interferer position is denoted by \mathbf{S}_k and the set of all interferer positions is denoted by $\bar{\mathbf{S}}_f$. The set of parameters Ψ , \mathbf{S} , and $\bar{\mathbf{S}}_f$ together

constitute an uncertain environment. Environmental uncertainty is quantified by assigning an *a priori* probability density function (pdf) over a finite range of possible values. It is assumed that Ψ , \mathbf{S} , and $\bar{\mathbf{S}}_f$ are statistically independent *a priori*, with uniform pdf's denoted by $p(\Psi)$, $p(\mathbf{S})$, and $p(\bar{\mathbf{S}}_f)$ that are defined on uncertainty ranges Ω_Ψ , $\Omega_{\mathbf{S}}$, and $\Omega_{\bar{\mathbf{S}}_f}$. The uncertainty ranges are assumed known.

The received signal and interference are both assumed to be a spatial vector in the frequency domain, narrow band, centered at a known frequency f_0 . The received signal consists of three components: the signal wavefront, the signal source, and the received signal energy. The normalized signal wavefront $\mathbf{s}(\Psi, \mathbf{S})$ is given by

$$\mathbf{s}(\Psi, \mathbf{S}) = \mathbf{H}(\Psi, \mathbf{S}) / \|\mathbf{H}(\Psi, \mathbf{S})\|, \quad (1)$$

where $\mathbf{H}(\Psi, \mathbf{S})$ is the frequency-domain ocean acoustic transfer function, which is the acoustic pressure field sampled at an arbitrary receiving array of N sensors, given ocean environmental parameters Ψ and source position parameters \mathbf{S} . Here $\|\cdot\|$ means the 2-norm on a complex vector space.

The signal source a represents uncertainties in the amplitude and phase of the source in the frequency domain. It is a normalized random variable with zero mean and unit variance, $a \sim \mathcal{N}(0, 1)$. Here \sim means "is distributed as" and \mathcal{N} means complex Gaussian distribution.

Because the effects of the signal variance, σ_a^2 , the diffuse noise variance, σ_n^2 , and the norm of the ocean transfer function on the detection performance are indistinguishable, a single model parameter, the signal-to-noise ratio (SNR), is defined as

$$\text{SNR}(\Psi, \mathbf{S}) = \sigma_a^2 \|\mathbf{H}(\Psi, \mathbf{S})\|^2 / \sigma_n^2. \quad (2)$$

It is not an element-level SNR but an array-level SNR. The ratio σ_a^2 / σ_n^2 is assumed a known constant. The $\text{SNR}(\Psi, \mathbf{S})$ depends on σ_a^2 / σ_n^2 and the realizations of the signal wavefront due to uncertain environmental parameters. In practice, an estimate of the noise variance may be obtained using additional measurements at neighboring frequencies that contain only diffuse noise. The received signal energy, $\sigma_a^2 \|\mathbf{H}(\Psi, \mathbf{S})\|^2$, may be estimated from measurements at the source frequencies, and consequently the SNR may be obtained. Using the definition of the SNR, the received signal is expressed as $\sqrt{\text{SNR}(\Psi, \mathbf{S})} \sigma_n^2 a \mathbf{s}(\Psi, \mathbf{S})$.

The k th interference, $\sqrt{\text{INR}_k(\Psi, \mathbf{S}_k)} \sigma_n^2 b_k \mathbf{f}_k(\Psi, \mathbf{S}_k)$, also consists of three components. The normalized interference wavefront is given by

$$\mathbf{f}_k(\Psi, \mathbf{S}_k) = \mathbf{H}(\Psi, \mathbf{S}_k) / \|\mathbf{H}(\Psi, \mathbf{S}_k)\|. \quad (3)$$

The interference source, $b_k \sim \mathcal{N}(0, 1)$, represents normalized interferer amplitude and phase. The energy of the k th interference is given by $\text{INR}_k(\Psi, \mathbf{S}_k) \sigma_n^2$, where the array level interference-to-noise ratio (INR) depends on the source variance of the k th interferer, $\sigma_{b_k}^2$, the diffuse noise variance, and the norm of the ocean transfer function:

$$\text{INR}_k = \sigma_{b_k}^2 \|\mathbf{H}(\Psi, \mathbf{S}_k)\|^2 / \sigma_n^2. \quad (4)$$

Here, the ratio $\sigma_{b_k}^2/\sigma_n^2$ is assumed a known constant. In practice, an estimate of σ_{b_k} may be obtained from measurements at neighboring interference frequencies other than the signal frequency.

III. DETECTION PROBLEM

The detection problem is formulated as a doubly composite binary hypotheses testing problem. For an arbitrary array of N sensors, the observation is an $N \times 1$ spatial vector in the frequency domain, obtained using a narrow-band Fourier transform of the snapshot. The i th data element is transformed from the snapshot received by the sensor at the i th location. Given the observation, we must decide between two hypotheses: the “null” hypothesis H_0 and the “signal present” hypothesis H_1 , in the presence of interference and environmental uncertainty. The null hypothesis assumes that the data consist of diffuse noise and uncertain interference. The H_1 hypothesis assumes that the data consists of the received signal, in addition to diffuse noise and interference.

$$\begin{aligned} H_1: \mathbf{r} &= \sqrt{\text{SNR}(\boldsymbol{\Psi}, \mathbf{S})} \sigma_n^2 a \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S}) + \mathbf{n}_1, \\ H_0: \mathbf{r} &= \mathbf{n}_1, \\ \mathbf{n}_1 &= \sum_{k=1}^K \sqrt{\text{INR}_k(\boldsymbol{\Psi}, \mathbf{S}_k)} \sigma_n^2 b_k \mathbf{f}_k(\boldsymbol{\Psi}, \mathbf{S}_k) + \sigma_n \mathbf{n}_0, \\ \mathbf{n}_0 &\sim \mathcal{N}(0, \mathbf{I}_N), \\ \boldsymbol{\Psi} &\sim p(\boldsymbol{\Psi}), \quad \mathbf{S} \sim p(\mathbf{S}), \quad \mathbf{S}_k \sim p(\mathbf{S}_k), \end{aligned} \quad (5)$$

where diffuse noise $\sigma_n \mathbf{n}_0$ is modeled by a spatial complex Gaussian vector in the frequency domain.

In Eq. (5), the signal wavefront is a function of the continuous random variables $\boldsymbol{\Psi}$ and \mathbf{S} . To computationally predict the performance of detection algorithms in an uncertain environment, a discrete representation of the uncertain signal wavefront is needed. A matrix composed of M realizations of the signal wavefront due to environmental uncertainties, referred to as the signal matrix \mathfrak{R} , is defined by applying Monte Carlo sampling techniques,¹⁶

$$\begin{aligned} \mathfrak{R} &= [\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_M], \\ &= [\mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})_1, \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})_2, \dots, \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})_M], \end{aligned} \quad (6)$$

where $(\boldsymbol{\Psi}, \mathbf{S})_i (i = 1 \dots M)$ represents the i th realization of the environmental parameters $(\boldsymbol{\Psi}, \mathbf{S})$. If M is large enough, the signal matrix is a good representation of realizations of uncertain signal wavefronts. Therefore, the detection problem can be formulated based on the signal matrix rather than on a continuous form of the signal wavefronts.

The k th interference matrix is defined similarly to the signal matrix:

$$\begin{aligned} T_k &= [\mathbf{f}_{k1}, \mathbf{f}_{k2}, \dots, \mathbf{f}_{kL}], \\ &= [\mathbf{f}_k((\boldsymbol{\Psi}, \mathbf{S}_k)_1), \mathbf{f}_k((\boldsymbol{\Psi}, \mathbf{S}_k)_2), \dots, \mathbf{f}_k((\boldsymbol{\Psi}, \mathbf{S}_k)_L)]. \end{aligned} \quad (7)$$

Although the signal and interference both involve the same uncertain environment $(\boldsymbol{\Psi})$, their source position uncertainties $(\mathbf{S}$ vs $\mathbf{S}_k)$ may differ. The number of realizations for the interference is denoted by L .

By applying the concept of the signal and interference matrices, and multiplying by the scalar $1/\sigma_n$ on both sides of Eq. (5) for simplicity, the detection problem is formulated in a discrete form:

$$\begin{aligned} H_1: \mathbf{r} &= \sqrt{\text{SNR}_i} a \mathbf{s}_i + \mathbf{n}_1, \quad i \in 1 \dots M \\ H_0: \mathbf{r} &= \mathbf{n}_1, \\ \mathbf{n}_1 &= \sum_{k=1}^K \sqrt{\text{INR}_{kl}} b_k \mathbf{f}_{kl} + \mathbf{n}_0, \quad l \in \dots L \\ \mathbf{n}_0 &\sim \mathcal{N}(0, \mathbf{I}_N), \end{aligned} \quad (8)$$

where $\text{SNR}_i = \text{SNR}((\boldsymbol{\Psi}, \mathbf{S})_i)$, $\text{INR}_{kl} = \text{INR}_k((\boldsymbol{\Psi}, \mathbf{S}_k)_l)$, \mathbf{s}_i is an arbitrary column of the signal matrix with probability $1/M$, and \mathbf{f}_{kl} is an arbitrary column of the k th interference matrix with probability $1/L$.

In the detection problem, diffuse noise (\mathbf{n}_0) , interference source (b_k) , signal source (a) , and environmental parameters $(\boldsymbol{\Psi}, \mathbf{S}$, and $\mathbf{S}_k)$ are assumed statistically independent.

IV. BAYESIAN DETECTOR

From signal detection theory, the optimal detector is the Bayesian detector that fully incorporates the *a priori* knowledge of the uncertain parameters. The derivation of the Bayesian detector begins with the likelihood ratio²⁰

$$\lambda(\mathbf{r}) = \frac{p(\mathbf{r}|H_1)}{p(\mathbf{r}|H_0)}. \quad (9)$$

Based on the signal and interference model, the data vector under both hypotheses are assumed to be conditional complex Gaussian:

$$\begin{aligned} p(\mathbf{r}|H_1, \boldsymbol{\Psi}, \bar{\mathbf{S}}_f, \mathbf{S}) \\ = \exp(-\mathbf{r}^\dagger \mathbf{M}_1^{-1}(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f, \mathbf{S}) \mathbf{r}) / |\pi \mathbf{M}_1(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f, \mathbf{S})|, \end{aligned} \quad (10)$$

$$p(\mathbf{r}|H_0, \boldsymbol{\Psi}, \bar{\mathbf{S}}_f) = \exp(-\mathbf{r}^\dagger \mathbf{M}_0^{-1}(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f) \mathbf{r}) / |\pi \mathbf{M}_0(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f)|,$$

where

$$\mathbf{M}_1(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f, \mathbf{S}) = \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}^\dagger(\boldsymbol{\Psi}, \mathbf{S}) + \mathbf{M}_0(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f), \quad (11)$$

$$\mathbf{M}_0(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f) = \sum_{k=1}^K \text{INR}_k(\boldsymbol{\Psi}, \mathbf{S}_k) \mathbf{f}_k(\boldsymbol{\Psi}, \mathbf{S}_k) \mathbf{f}_k^\dagger(\boldsymbol{\Psi}, \mathbf{S}_k) + \mathbf{I}_N.$$

The likelihood ratio [Eq. (9)] is a doubly composite hypotheses test:

$$\begin{aligned} \lambda(\mathbf{r}) \\ = \frac{\int \boldsymbol{\Psi} \int \bar{\mathbf{S}}_f \int \mathbf{S} d\boldsymbol{\Psi} d\bar{\mathbf{S}}_f d\mathbf{S} p(\mathbf{r}|H_1, \boldsymbol{\Psi}, \bar{\mathbf{S}}_f, \mathbf{S}) p(\boldsymbol{\Psi}) p(\bar{\mathbf{S}}_f) p(\mathbf{S})}{\int \boldsymbol{\Psi} \int \bar{\mathbf{S}}_f d\boldsymbol{\Psi} d\bar{\mathbf{S}}_f p(\mathbf{r}|H_0, \boldsymbol{\Psi}, \bar{\mathbf{S}}_f) p(\boldsymbol{\Psi}) p(\bar{\mathbf{S}}_f)}. \end{aligned} \quad (12)$$

The probability density functions of the data vector with environmental and source position uncertainties for H_1 and H_0 hypotheses are given by the nominator and the denominator of the right side of Eq. (12), respectively. Both are non-Gaussian and are the result of integrating the conditional complex Gaussian probability density functions over the uncertain environmental parameters.

In order to capture analytically the detection performance in a tractable manner a simpler approximate test statistic is postulated. The approximation is that the noise field is a multivariate complex Gaussian distribution, characterized by the covariance matrix $\hat{\mathbf{M}}_0$, where $\hat{\mathbf{M}}_0$ is $\mathbf{M}_0(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f)$ [Eq. (11)] integrated over uncertain ocean environmental parameters and interferer positions:

$$\begin{aligned}\hat{\mathbf{M}}_0 &= \int_{\boldsymbol{\Psi}} \int_{\bar{\mathbf{S}}_f} d\boldsymbol{\Psi} d\bar{\mathbf{S}}_f p(\boldsymbol{\Psi}) p(\bar{\mathbf{S}}_f) \mathbf{M}_0(\boldsymbol{\Psi}, \bar{\mathbf{S}}_f) \\ &= \int_{\boldsymbol{\Psi}} \int_{\bar{\mathbf{S}}_f} d\boldsymbol{\Psi} d\bar{\mathbf{S}}_f p(\boldsymbol{\Psi}) p(\bar{\mathbf{S}}_f) \\ &\quad \times \sum_{k=1}^K \text{INR}_k(\boldsymbol{\Psi}, \mathbf{S}_k) \mathbf{f}_k(\boldsymbol{\Psi}, \mathbf{S}_k) \mathbf{f}_k^\dagger(\boldsymbol{\Psi}, \mathbf{S}_k) + \mathbf{I}.\end{aligned}\quad (13)$$

The covariance matrix $\hat{\mathbf{M}}_0$ incorporates the effect of environmental uncertainty and the presence of interference through integrations over uncertain ocean environmental parameters and interferer position parameters. The matrix $\hat{\mathbf{M}}_0$ is no longer an explicit function of interferer positions and environmental parameters, but a function of interference and environmental uncertainty ranges. This approach is different from the approach that assumes a known covariance matrix, which requires too much *a priori* information. It also differs from the approach that uses the estimation of the covariance matrix from the collection of noise-only data, which relies too much on the data, but does not take advantage of the available *a priori* information about the interferer positions and the environmental parameters.

The concept of the interference matrices is applied to numerically compute the covariance matrix, yielding

$$\hat{\mathbf{M}}_0 = \frac{1}{L} \sum_{l=1}^L \sum_{k=1}^K \text{INR}_{kl} \mathbf{f}_{kl} \mathbf{f}_{kl}^\dagger + \mathbf{I}.\quad (14)$$

Assuming that the noise field is multivariate complex Gaussian, the distributions of the data conditional to both hypotheses become

$$\begin{aligned}p(\mathbf{r}|H_1, \boldsymbol{\Psi}, \mathbf{S}) &= \exp(-\mathbf{r}^\dagger \hat{\mathbf{M}}_1^{-1} \mathbf{r}) / |\pi \hat{\mathbf{M}}_1|, \\ p(\mathbf{r}|H_0) &= \exp(-\mathbf{r}^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{r}) / |\pi \hat{\mathbf{M}}_0|,\end{aligned}\quad (15)$$

where $\hat{\mathbf{M}}_1 = \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})^\dagger + \hat{\mathbf{M}}_0$.

Therefore the likelihood ratio can be approximated by

$$\tilde{\lambda}(\mathbf{r}) = \int_{\boldsymbol{\Psi}} \int_{\mathbf{S}} d\boldsymbol{\Psi} d\mathbf{S} \lambda(\mathbf{r}|\boldsymbol{\Psi}, \mathbf{S}) p(\boldsymbol{\Psi}) p(\mathbf{S}),\quad (16)$$

where the conditional likelihood ratio is given by

$$\lambda(\mathbf{r}|\boldsymbol{\Psi}, \mathbf{S}) = p(\mathbf{r}|H_1, \boldsymbol{\Psi}, \mathbf{S}) / p(\mathbf{r}|H_0).\quad (17)$$

Using Woodbury's identity,²¹

$$\hat{\mathbf{M}}_1^{-1} = \hat{\mathbf{M}}_0^{-1} - \frac{\hat{\mathbf{M}}_0^{-1} \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})^\dagger \hat{\mathbf{M}}_0^{-1}}{1 + \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})}.\quad (18)$$

Using properties of the matrix determinant,

$$|\hat{\mathbf{M}}_1| = |\hat{\mathbf{M}}_0| (1 + \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})).\quad (19)$$

Substituting Eqs. (15), (18), and (19) in Eq. (17) results in

$$\begin{aligned}\lambda(\mathbf{r}|\boldsymbol{\Psi}, \mathbf{S}) &= \frac{1}{1 + \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) G(\boldsymbol{\Psi}, \mathbf{S})} \\ &\quad \times \exp\left(-\frac{\text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) |\mathbf{r}^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S})|^2}{1 + \text{SNR}(\boldsymbol{\Psi}, \mathbf{S}) G(\boldsymbol{\Psi}, \mathbf{S})}\right), \\ G(\boldsymbol{\Psi}, \mathbf{S}) &= \mathbf{s}^\dagger(\boldsymbol{\Psi}, \mathbf{S}) \hat{\mathbf{M}}_0^{-1} \mathbf{s}(\boldsymbol{\Psi}, \mathbf{S}),\end{aligned}\quad (20)$$

where the term $G(\boldsymbol{\Psi}, \mathbf{S})$ is referred to as the signal-to-interference coefficient. It includes uncertain interferer position parameters through the approximate covariance matrix of the noise field, $\hat{\mathbf{M}}_0$. The product of SNR and G can be referred to as the "signal-to-interference-plus-noise ratio (SINR)," which is comparable to the SINR defined in the literature.^{21,13} The difference between our definition of SINR and others is that the product of the SNR and G in Eq. (20) is derived from a Bayesian detection viewpoint. Other definitions of SINR are results from a beamforming perspective, concentrating on the total effect of the noise field, usually in a known environment.

Finally, the Bayesian detector that incorporates the *a priori* information of environmental uncertainties and the interferers is given by Eqs. (16), (20), and (13).

To numerically compute the likelihood ratio, the concept of the signal matrix is applied to generate a discrete version of the approximate likelihood ratio:

$$\begin{aligned}\tilde{\lambda}(\mathbf{r}) &= \frac{1}{M} \sum_{i=1}^M \lambda_i, \\ \lambda_i &= \frac{1}{1 + \text{SNR}_i G_i} \exp\left(-\frac{\text{SNR}_i |\mathbf{r}^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{s}_i|^2}{1 + \text{SNR}_i G_i}\right), \\ G_i &= \mathbf{s}_i^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{s}_i, \\ \text{SNR}_i &= \text{SNR}((\boldsymbol{\Psi}, \mathbf{S})_i).\end{aligned}\quad (21)$$

Note that the computation of G_i includes the inverse of $\hat{\mathbf{M}}_0$, which is sensitive to small eigenvalues of $\hat{\mathbf{M}}_0$. In the presence of small eigenvalues, an "eigenvalue threshold" method¹⁹ can be used to compute the matrix inversion.

V. PERFORMANCE PREDICTIONS IN KNOWN ENVIRONMENTS

In a known environment, it is assumed that the ocean and the source position parameters are known *a priori*. Consequently, the signal and interference wavefronts are assumed known. In this case, the ROC for the proposed Bayesian detector provides a benchmark to be compared with detection performance predictions in uncertain environments. Here, the analytical ROC performance prediction expressions are derived. The effect of interference on the detection performance in known environments is analyzed.

A known environment assumption is equivalent to assuming that the *a priori* distributions $p(\boldsymbol{\Psi})$, $p(\mathbf{S})$, and $p(\mathbf{S}_k)$ are delta functions. Substituting these conditions in Eq. (20) results in the likelihood ratio specific to a known environment:

$$\lambda(\mathbf{r}) = \frac{1}{1 + \text{SNR} * G} \exp\left(-\frac{\text{SNR} |\mathbf{r}^\dagger \mathbf{M}_0^{-1} \mathbf{s}|^2}{1 + \text{SNR} * G}\right),$$

$$G = \mathbf{s}^\dagger \mathbf{M}_0^{-1} \mathbf{s}, \quad (22)$$

where $\mathbf{M}_0 = \sum_{k=1}^K \text{INR}_k \mathbf{f}_k \mathbf{f}_k^\dagger + \mathbf{I}_N$, SNR , G , \mathbf{s} , INR_k , and \mathbf{f}_k denote $\text{SNR}(\Psi, \mathbf{S})$, $G(\Psi, \mathbf{S})$, $\mathbf{s}(\Psi, \mathbf{S})$, $\text{INR}_k(\Psi, \mathbf{S}_k)$, and $\mathbf{f}_k(\Psi, \mathbf{S}_k)$, respectively, for simplicity.

Since SNR and G are constants under the assumption of a known environment, λ' , a monotonic function of the likelihood ratio, is also optimal:

$$\lambda'(\mathbf{r}) = |\mathbf{r}^\dagger \mathbf{M}_0^{-1} \mathbf{s}|^2. \quad (23)$$

Since λ' can be considered a chi-square random variable with two degrees of freedom for both the H_1 and H_0 hypotheses, an accurate analytical ROC expression for the optimal Bayesian detector is available using similar derivations as in Ref. 16. First, the probability density functions of λ' to both hypotheses are given by

$$p(\lambda' | H_0) = \exp(\lambda' / G) / G, \quad (24)$$

$$p(\lambda' | H_1) = \frac{1}{\text{SNR} * G^2 + G} \exp(\lambda' / (\text{SNR} * G^2 + G)).$$

From signal detection theory,

$$P_F(\beta) = \int_{\beta}^{\infty} d\lambda' p(\lambda' | H_0), \quad (25)$$

$$P_D(\beta) = \int_{\beta}^{\infty} d\lambda' p(\lambda' | H_1).$$

Substituting Eq. (24) in Eq. (25) yields

$$P_F(\beta) = \exp(-\beta / G), \quad (26)$$

$$P_D(\beta) = \exp(-\beta / (\text{SNR} * G^2 + G)).$$

Combining P_D and P_F results in the ROC expression for the Bayesian detector in the presence of interference in known environments.

$$P_D = P_F^{1/(\text{SNR} * G + 1)}, \quad G = \mathbf{s}^\dagger \mathbf{M}_0^{-1} \mathbf{s}. \quad (27)$$

If only a single interferer is present, substituting $\mathbf{M}_0^{-1} = \mathbf{I} - \text{INR} \mathbf{f} \mathbf{f}^\dagger / (1 + \text{INR})$ in Eqs. (22) and (27) yields the detector statistic

$$\lambda'(\mathbf{r}) = |\mathbf{r}^\dagger \left(\mathbf{I} - \frac{\text{INR}}{1 + \text{INR}} \mathbf{f} \mathbf{f}^\dagger \right) \mathbf{s}|^2, \quad (28)$$

and the performance prediction

$$P_D = P_F^{1/(\text{SNR} * G + 1)}, \quad G = \left(1 - \frac{\text{INR}}{1 + \text{INR}} |\rho|^2 \right), \quad (29)$$

where \mathbf{f} denotes the known interference wavefront, and $\rho = \mathbf{s}^\dagger \mathbf{f}$ is the correlation coefficient between the signal wavefront and the interference wavefront.

With the simple analytical ROC expressions, the effect of interference on detection performance is captured by the role of the key parameter $G = \mathbf{s}^\dagger \mathbf{M}_0^{-1} \mathbf{s}$. Since the covariance matrix \mathbf{M}_0 is positive definite, G is a positive number. Since the eigenvalues of \mathbf{M}_0 are equal or greater than one, the

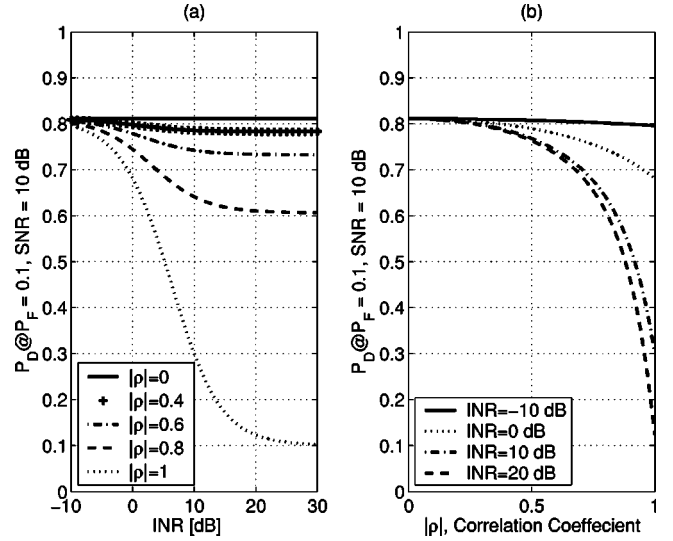

FIG. 1. Detection performance prediction in the presence of a single interference in a known ocean environment [Eq. (28)]. (a) P_D as a function of the interference-to-noise ratio, INR, at fixed $P_F = 0.1$ for various ρ values; (b) P_D as a function of ρ at fixed $P_F = 0.1$ for various INRs.

eigenvalues of \mathbf{M}_0^{-1} are in the range of zero and one. A singular value decomposition of \mathbf{M}_0^{-1} generates $\mathbf{M}_0^{-1} = \mathbf{U} \mathbf{\Lambda} \mathbf{U}^\dagger$, where \mathbf{U} is a unitary matrix and $\mathbf{\Lambda}$ is a diagonal matrix composed of the eigenvalues of \mathbf{M}_0^{-1} . Since the eigenvalues are in the range of zero and one, $G = \mathbf{s}^\dagger \mathbf{U} \mathbf{\Lambda} \mathbf{U}^\dagger \mathbf{s} \leq \mathbf{s}^\dagger \mathbf{U} \mathbf{U}^\dagger \mathbf{s} = \mathbf{s}^\dagger \mathbf{s} = 1$. Therefore, G is in the range of zero and one. Considering G is a weighting factor to the SNR in the ROC expression in Eq. (27), this range of G means that the presence of interference always decreases the SNR and consequently decreases the detection performance. The stronger the interference, the closer the G approaches zero, and the greater the performance degrades. On the other hand, if there is no interference, G is one, which does not impact the detection performance.

In the presence of a single interferer, G is determined by the INR and $|\rho|$, as shown in Eq. (29). The INR represents the energy of the interference as compared to the variance of diffuse noise at the receivers. The $|\rho|$ characterizes spatial similarity between the interference wavefront and the signal wavefront. This case is illustrated in Fig. 1. In Fig. 1(a), P_D is plotted as a function of INR for a set of $|\rho|$'s. It shows that the stronger the interference, the worse the detection performance. However, performance degradation is modest if the correlation coefficient between the interference and signal wavefronts is small. In Fig. 1(b), P_D is plotted as a function of $|\rho|$ for a set of INRs. It shows that when $|\rho|$ is less than 0.5, a single interferer has little impact on the detection performance, even if its energy is very strong.

The effect of interference on detection performance in known environments has been studied previously using different performance metrics.^{12,13} The performance metric used in Ref. 12 is a distance measure, and that used in Ref. 13 is array gain. Here we use the ROC metric, which is directly relevant to the ultimate goal of target detection. Figure 6.11 in Ref. 13 shows that the stronger the interference, the better the optimum array gain performance, which is different from our ROC performance result, as shown in Fig. 1.

The optimum array gain is an empirical metric defined as the array output to an input signal-to-noise ratio. When the noise field is diffuse noise only, the array gain metric is consistent with the ROC metric. In the presence of interference, the array gain metric cannot completely capture the effect of interference on detection performance. The utilization of array gain as the detection performance metric in the presence of interference can result in misleading conclusions.

VI. THE EFFECT OF UNDERESTIMATING THE NUMBER OF INTERFERERS

The Bayesian detector developed in this paper is designed for a known number of interferers. In practice, the Bayesian detection performance may be affected by the wrong *a priori* knowledge of the number of interferers. In this section, the effect of underestimating the number of interferers on Bayesian detection performance is quantified for a known ocean environment.

The data vector to both hypotheses are given by

$$\begin{aligned} H_1: \mathbf{r} &= \sqrt{\text{SNR}_i} a \mathbf{s}_i + \sqrt{\text{INR}_{K+1}} b_{K+1} \mathbf{f}_{K+1} + \mathbf{n}_1, \\ & i \in 1 \cdots M, \\ H_0: \mathbf{r} &= \sqrt{\text{INR}_{K+1}} b_{K+1} \mathbf{f}_{K+1} + \mathbf{n}_1, \\ \mathbf{n}_1 &= \sum_{k=1}^K \sqrt{\text{INR}_k} b_k \mathbf{f}_k + \mathbf{n}_0, \quad \mathbf{n}_0 \sim \mathcal{N}(0, \mathbf{I}_N). \end{aligned} \quad (30)$$

Equation (30) differs from Eq. (8) in the number of interferers.

Substituting Eq. (30) in Eq. (23) yields the test statistic

$$\begin{aligned} (\lambda'_{\text{mismatch}} | H_0) &= |(\text{INR}_{K+1} b_{K+1} \mathbf{f}_{K+1} + \mathbf{n}_1)^\dagger \mathbf{M}_0^{-1} \mathbf{s}|^2, \\ (\lambda'_{\text{mismatch}} | H_1) &= |(\sqrt{\text{SNR}_i} a \mathbf{s}_i + \text{INR}_{K+1} b_{K+1} \mathbf{f}_{K+1} \\ & \quad + \mathbf{n}_1)^\dagger \mathbf{M}_0^{-1} \mathbf{s}|^2. \end{aligned} \quad (31)$$

Let $x_0 = (\sqrt{\text{INR}_{K+1}} b_{K+1} \mathbf{f}_{K+1} + \mathbf{n}_1)^\dagger \mathbf{M}_0^{-1} \mathbf{s}$ and $x_1 = (\sqrt{\text{SNR}_i} a \mathbf{s}_i + \sqrt{\text{INR}_{K+1}} b_{K+1} \mathbf{f}_{K+1} + \mathbf{n}_1)^\dagger \mathbf{M}_0^{-1} \mathbf{s}$. The absolute squares of both x_0 and x_1 are chi-square random variables, with two degrees of freedom. Their probability density functions are

$$\begin{aligned} p(\lambda'_{\text{mismatch}} | H_0) &= \exp(\lambda' / D_0) / D_0, \\ p(\lambda'_{\text{mismatch}} | H_1) &= \exp(\lambda' / D_1) / D_1, \\ D_0 &= G + G_m, \quad D_1 = G + \text{SNR} * G^2 + G_m, \end{aligned} \quad (32)$$

where

$$G = \mathbf{s}^\dagger \mathbf{M}_0^{-1} \mathbf{s}, \quad G_m = \text{INR}_{K+1} |\mathbf{s}^\dagger \mathbf{M}_0^{-1} \mathbf{f}_{K+1}|. \quad (33)$$

Substituting Eqs. (32) and (33) in Eq. (25) and combining P_F and P_D yields the analytical ROC expression

$$P_{D_{\text{mismatched}}} = P_F^{1/(1 + \text{SNR} * G / G_m)}. \quad (34)$$

Equation (34) differs from Eq. (27) in that the effect of ignoring the $K+1$ th interferer on the Bayesian detection performance is captured by a degrading factor, G_m , to the SNR. From the G_m expression, we see that the higher the interference source level, and the higher the term $\mathbf{s}^\dagger \mathbf{M}_0^{-1} \mathbf{f}_{K+1}$, the

stronger degradation caused by underestimating the interferer number.

Substituting $K=0$ in Eq. (33) yields the degrading factor for the Bayesian detection algorithm that assumes diffuse noise only, while the true noise field is composed of a single interference plus diffuse noise:

$$G_m = 1 + \text{INR} |\rho|^2, \quad \rho = \mathbf{s}^\dagger \mathbf{f}. \quad (35)$$

VII. PERFORMANCE PREDICTIONS IN UNCERTAIN ENVIRONMENTS

Detection performance predictions become more difficult in the presence of interference and environmental uncertainty. Both factors can greatly limit the detection performance. Quantitative descriptions about the role of each factor on the detection performance are of practical interest. In this section, the analytical ROC expression is derived for the Bayesian detector in the presence of interference in an uncertain environment.

In Ref. 16, where the noise field is assumed to be diffuse noise only, the resultant analytical ROC expression for the Bayesian detector in uncertain environments is

$$P_D = 1 - (1 - P_F)^{(R-1)/R} (1 - (1 - (1 - P_F)^{1/R})^{1/(\text{SNR}+1)}), \quad (36)$$

where R is the rank of the signal matrix, characterizing the degree of environmental uncertainty. The SNR is the array-level signal-to-noise ratio at the receivers, assumed in the derivation to be constant over environmental uncertainty.

Here we transform the problem to the detection problem defined in Ref. 16 and exploit the result in Ref. 16. First, a prewhitening procedure is performed on the noise field. A singular value decomposition of the covariance matrix of the noise field generates $\hat{\mathbf{M}}_0 = \mathbf{U}_f \Lambda_f \mathbf{U}_f^\dagger$, where \mathbf{U}_f is a unitary matrix and Λ_f is a diagonal matrix composed of the eigenvalues of $\hat{\mathbf{M}}_0$. If $\mathbf{Q} = \Lambda_f^{-1/2} \mathbf{U}_f^\dagger$, then \mathbf{Q} is full rank. Since multiplying a full rank matrix on both sides of Eq. (8) does not change the detection performance, the detection problem becomes

$$\begin{aligned} H_1: \mathbf{r} &= \sqrt{\text{SNR}_i} a \mathbf{Q} \mathbf{s}_i + \mathbf{n}, \quad i \in 1 \cdots M, \\ H_0: \mathbf{r} &= \mathbf{n}, \quad \mathbf{n} \sim \mathcal{N}(0, \mathbf{I}_N), \end{aligned} \quad (37)$$

where the noise field \mathbf{n} is diffuse noise only.

Then the portion of the received signal, $\sqrt{\text{SNR}_i} a \mathbf{Q} \mathbf{s}_i$, is rewritten to fit into the framework of the detection problem defined in Ref. 16. The new signal wavefront vector is defined as

$$\begin{aligned} \mathbf{s}'_i &= \mathbf{Q} \mathbf{s}_i / \sqrt{(\mathbf{Q} \mathbf{s}_i)^\dagger \mathbf{Q} \mathbf{s}_i}, \\ &= \mathbf{Q} \mathbf{s}_i / \sqrt{\mathbf{s}_i^\dagger \hat{\mathbf{M}}_0^{-1} \mathbf{s}_i}, \\ &= \mathbf{Q} \mathbf{s}_i / \sqrt{G_i}. \end{aligned} \quad (38)$$

The new signal wavefront vector preserves the property $\mathbf{s}'_i{}^\dagger \mathbf{s}'_i = 1$.

Substituting Eq. (38) in Eq. (37) results in

$$\begin{aligned} H_1: \mathbf{r} &= \sqrt{\text{SNR}_i G_i} a \mathbf{s}'_i + \mathbf{n}, \quad i \in 1 \cdots M, \\ H_0: \mathbf{r} &= \mathbf{n}, \quad \mathbf{n} \sim \mathcal{N}(0, \mathbf{I}_N). \end{aligned} \quad (39)$$

Now the detection problem in the presence of interference is translated to the detection problem in diffuse noise,¹⁶ with the product of the SNR_i and G_i replacing SNR_i , and with the new signal matrix $\mathfrak{R}' = [s'_1, s'_2, \dots, s'_M]$ replacing the original signal matrix \mathfrak{R} . The SNR_i is the signal-to-noise ratio at the receivers, which is assumed constant in the derivations in Ref. 16. The parameter G_i is the signal-to-interference coefficient. An additional assumption used here is that G_i is constant over environmental uncertainty, i.e., $G_i = G$ for $i = 1 \dots M$. Since $\mathfrak{R}' = \mathbf{Q}\mathfrak{R}/\sqrt{G}$ and the transformation \mathbf{Q}/\sqrt{G} is full rank, the rank of the new signal matrix is equal to the rank of the original signal matrix, which is R .

Using similar steps as in Ref. 16, an analytical ROC expression for the Bayesian detector in the presence of interference in uncertain environments is obtained. This ROC expression differs from Eq. (36) in that the product of the SNR and G replaces the SNR:

$$P_D = 1 - (1 - P_F)^{(R-1)/R} \times (1 - (1 - (1 - P_F)^{1/R})^{1/(\text{SNR} * G + 1)}). \quad (40)$$

In real applications, the SNR and G could be replaced by the average SNR and the average G over realizations of the uncertain environmental parameters, i.e.,

$$\text{SNR} = \frac{1}{M} \sum_{i=1}^M \text{SNR}_i, \quad G = \frac{1}{M} \sum_{i=1}^M G_i. \quad (41)$$

For a short vertical array or horizontal array, the constant SNR and constant G approximation might fail because the received signal energy is sensitive to source range variation. The application of Eq. (40) for an optimal Bayesian performance prediction is limited to scenarios,¹⁶ where the received signal energy, the received interference energy, and the noise level are relatively stable.

Equation (40) is the key result in this paper. This simple analytical ROC expression captures the effects of the presence of both interference and environmental uncertainty on detection performance. The effect of the presence of interference is represented by the role of the parameter G . In Sec. V, we have shown that G is in the range of zero and one for a known environment. It can be shown that G is in the range of zero and one for an uncertain environment. This means that the presence of interferers always decreases the detection performance, in either a known or uncertain environment. However, in uncertain environments, the computation of G is affected by the presence of environmental uncertainty, through the covariance matrix $\hat{\mathbf{M}}_0$.

Figure 2 illustrates Eq. (40) by plotting P_D as a function of the key parameters: the signal-to-interference coefficient G and the environmental uncertainty scale R . Figure 2(a) plots P_D as a function of $1 - G$, assuming $P_F = 0.1$, $\text{SNR} = 10$ dB, for $R = 1, 10$, and 100 . It shows that for $R = 1$, i.e., a known environment, P_D starts at 0.81 for $G = 1$, then quickly drops to 0.1 for $G = 0$. While for $R = 100$, i.e., a greatly uncertain environment, P_D drops from 0.59 to 0.1 for the same range of G . Figure 2(a) indicates that when G is close to zero, the detection performance is primarily determined by G rather than R ; when G is close to one, the detection performance is independently determined by G and

FIG. 2. Detection performance prediction in the presence of interference in an uncertain ocean environment [Eq. (36)]. (a) P_D as a function of $1 - G$ at fixed $P_F = 0.1$, $\text{SNR} = 10$ dB for various R 's, where G is the signal-to-interference coefficient and R is the rank of the signal matrix; (b) P_D as a function of R at fixed $P_F = 0.1$, $\text{SNR} = 10$ dB for various G 's.

R . Figure 2(b) plots P_D as a function of R on a logarithmic scale, assuming $P_F = 0.1$ and for $G = 1, 0.67$, and 0.42 . It shows that the performance degradation is inversely proportional to R on the logarithmic scale for all three G conditions.

Equation (40) is a general result that is consistent with the results for special cases. For example, substituting $R = 1$ in Eq. (40) yields the ROC performance prediction expression for known environments and substituting $G = 1$ in Eq. (40) generates the results for diffuse noise only.¹⁶ Generality is an advantage of this detection performance prediction approach in addition to simplicity and computational feasibility. The developed detector statistics and the ROC performance predictions along with the expressions for special cases are summarized in Table I.

VIII. SIMULATION RESULTS

Simulation scenarios extended from the general mismatch benchmark shallow-water model ("genlmis") proposed in the May 1993 NRL Workshop on Acoustic Models in Signal Processing^{17,5,8} were used to study the effects of interference on detection performance and to check the approximate analytical ROC expressions. Figure 3 reviews a modified "genlmis" model. This model also consists of a single signal source, a single interferer, and a vertical line receiving array contains 100 hydrophones spaced 1 m apart, ranging from 1 to 100 m in depth. Table II summarizes the environmental parameters shown in Fig. 3. Three environmental configuration scenarios are used. The known ocean scenario means that the environmental parameters are configured with their mean values and are known *a priori*. The uncertain water depth scenario assumes that the water depth parameter is uncertain as defined in Table II, and other parameters take the mean values. The general uncertain scenario considers seven uncertain parameters defined in Table II: D , C_0 , C_D^- , C_D^+ , C_l , ρ , and α .

(20)	$P_D = 1 - (1 - P_F)^{R-1/R}$ $\times (1 - (1 - (1 - P_F)^{1/R})^{1/\text{SNR}^* G + 1})$ Eq. (40)
Diffuse noise only	$\lambda(\mathbf{r}) = \frac{1}{M} \sum_{i=1}^M \lambda_i,$ $\lambda_i = \frac{1}{1 + \text{SNR}_i}$ $\times \exp\left(-\frac{\text{SNR}_i \mathbf{r}^\dagger \mathbf{s}_i ^2}{1 + \text{SNR}_i}\right)$ Ref. 16	$P_D = 1 - (1 - P_F)^{R-1/R}$ $\times (1 - (1 - (1 - P_F)^{1/R})^{1/\text{SNR} + 1})$ Ref. 16

The acoustic pressure field generated by a point source at depth z_s and range r_s is computed using the normal mode theory,²²

$$p(z; r_s, z_s) = p_0 \sum_{m=1}^K \Phi_m(z_s) \Phi_m(z_i) \times \exp(-jk_m r_s) / \sqrt{k_m r_s}, \quad (42)$$

where z is the depth of the receiver and p_0 is a normalization constant. The number of propagating acoustic modes is represented by K . The terms k_m and Φ_m are the m th eigenvalue and eigenfunction of the Sturm–Liouville problem, which can be calculated using the KRAKEN²³ code.

Figure 4 illustrates the effect of the presence of a single interferer on the Bayesian detection performance using the known ocean scenario. The signal source is fixed at 5950 m range and 55 m depth. The interferer range and depth are

known *a priori*. The P_D performance is computed using Eq. (29). In Fig. 4, P_D at fixed $P_F = 0.1$ is plotted as a function of the range and depth of the interferer, for about 10 dB SNR at the receivers. In Figs. 4(a) and 4(b), the interferer levels are the same as, or 30 dB more than, the signal source level. The plots show that in the known benchmark ocean, the presence of a single interferer does not impact the detection performance, even though the interferer level is very high. This is determined by the spatial correlation property of the benchmark ocean. In the known benchmark ocean, the absolute value of the correlation coefficient between the wavefronts that come from two arbitrarily separated sources is very weak ($|\rho| < 0.2$), if the source separation is greater than 30 m in range and 4 m in depth.

The effect of mismatched *a priori* interferer number on the Bayesian detection performance is illustrated in Fig. 5 using the known ocean scenario. The scenario includes a

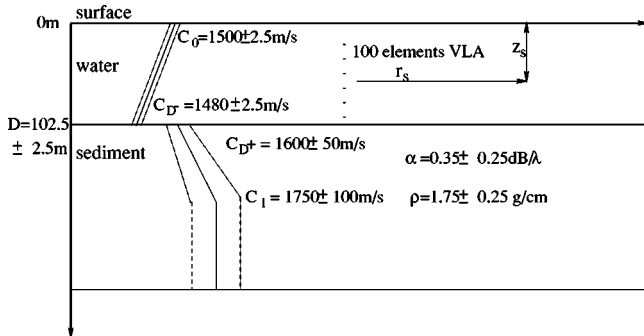

FIG. 3. NRL shallow-water environmental model.

TABLE II. Parameters of uncertain shallow-water environments.

Environmental parameter	Symbol	Value Range
Bottom depth	D	102.5 ± 2.5 m
Surface sound speed	C_0	1500 ± 2.5 m/s
Bottom sound speed	C_D^-	1480 ± 2.5 m/s
Upper sediment sound speed	C_D^+	1600 ± 50 m/s
Lower sediment sound speed	C_I	1750 ± 100 m/s
Sediment density	ρ	1.7 ± 0.25 g/cm ³
Sediment attenuation	α	0.35 ± 0.25 dB/λ
Sediment thickness	t	100 m

FIG. 4. Detection performance in the presence of a single interferer in the known benchmark ocean. The P_D image is plotted at fixed $P_F=0.1$ for SNR=10 dB at receivers. The coordinates of the image are the range and depth of the interferer. The signal source is located at 5950 m in range and 55 m in depth. (a) $\sigma_b^2 = \sigma_a^2$; (b) $\sigma_b^2 = 1000\sigma_a^2$.

single signal source fixed at 6000 m range and 50 m depth, and a single interferer fixed at 7 km range and 10 m depth. In Fig. 5, the predicted P_D performance is plotted as a function of the INR for three SNR conditions. Solid curves are P_D computed using Eq. (29), where the detector uses the correct *a priori* information about the interferer. Dashed curves are for P_D computed using Eq. (35), where the detector assumes diffuse noise only. The plots show that the degradation of the detection performance can be significant if the INR of the ignored interferer is comparable to the SNR.

The approximate analytical ROC expression for the Bayesian detector in uncertain environments is verified by comparing its prediction results with those obtained with Monte Carlo evaluations. Both the analytical approach and the Monte Carlo approach assume that the ranges of environ-

FIG. 5. Degradation of Bayesian detection performance due to underestimating the number of interferers in the known benchmark ocean. The P_D is plotted as a function of INR at fixed $P_F=0.1$ for SNR=20, 10, and 0 dB, for the Bayesian detector that uses correct (solid curve) or wrong (dashed curve) *a priori* knowledge about the interferer number.

FIG. 6. The analytical ROC performance predictions in the presence of an interferer with various INR values in uncertain environments [Eq. (36)], comparing with Monte Carlo performance evaluations of the Bayesian Detector [Eq. (21)]. (a) Uncertain ocean depth scenario; (b) general uncertain scenario.

mental uncertainties, the signal variance to diffuse noise variance ratio σ_a^2/σ_n^2 , and the interference variance to diffuse noise variance ratio σ_b^2/σ_n^2 were known *a priori*. The simulated data was generated using Monte Carlo sampling techniques over different ocean environmental, source position, diffuse noise, signal amplitude and phase, interference amplitude and phase realizations based on the data model [Eq. (8)]. In using the Monte Carlo approach, 5000 data samples were generated for each hypothesis to produce the samples of the likelihood ratio [Eq. (21)] and to compute P_F and P_D [Eq. (25)]. Before generating the likelihood ratio samples, the signal matrix and the interference matrix were generated using 500 realizations of the signal wavefronts ($M=500$, $L=500$). The SNR_{*i*}, \hat{M}_0 , and INR_{*i*} were computed using Eqs. (2), (14), and (4), respectively. In using the analytical approach, three parameters: the signal-to-noise ratio, the signal-to-interference coefficient, and the rank of the signal matrix were estimated. The rank of the signal matrix was estimated by counting the number of significant eigenvalues of the signal matrix that exceed a threshold: 5% of the maximum eigenvalue. The signal-to-interference coefficients were computed for each of the SNR and interferer level conditions using Eqs. (21), (14), and (41). The SNR was computed using Eqs. (2) and (41).

The primary cost for the Monte Carlo approach is due to generating samples of the likelihood ratio for each hypothesis, which is about $O(MNP)$, where P is the number of samples, M is the number of columns in the signal matrix, N is the number of array sensors. The primary cost for the analytical approach is due to the computation of the eigenvalues in order to estimate the rank of the signal matrix and the computation of the matrix inverse to estimate G , which is $O(N^3)$.^{24,25} Typically, M is greater than N , and P is above 1000 so that the precision of P_D and P_F reaches 0.001. P is about 10 times greater than N . Therefore, the analytical approach speeds up more than an order of magnitude.

TABLE III. Estimated signal-to-interference coefficient.

Scenario	Interferer level	SNR			
		0 dB	10 dB	20 dB	30 dB
Known	$\sigma_b^2/\sigma_a^2=1$	0.9859	0.9700	0.9662	0.9658
Environment	$\sigma_b^2/\sigma_a^2=10$	0.9700	0.9662	0.9658	0.9657
Uncertain	$\sigma_b^2/\sigma_a^2=1$	0.9667	0.8470	0.6927	0.5969
Water depth	$\sigma_b^2/\sigma_a^2=10$	0.8470	0.6927	0.5969	0.5398
General	$\sigma_b^2/\sigma_a^2=1$	0.9683	0.8316	0.5977	0.4017
Uncertain	$\sigma_b^2/\sigma_a^2=10$	0.8316	0.5977	0.4017	0.2428

Figure 6 illustrates the analytical and the Monte Carlo performance prediction results by plotting ROC curves for three interferer levels, at SNR=10 dB, using the uncertain water depth scenario and the general uncertain scenario. The plots show that the ROCs generated using the approximate analytical approach agree with those obtained using the Monte Carlo evaluation approach for both scenarios, and for various interferer levels. The results indicate that the proposed Bayesian performance prediction ROC expression captures the primary effects of the presence of interference and environmental uncertainty by the roles of the two fundamental parameters: the signal-to-interference coefficient and the rank of the signal matrix.

The effect of interference on Bayesian detection performance in uncertain environments is represented by the signal-to-interference coefficient. Table III lists the signal-to-interference coefficient values for three scenarios and various SNRs and interferer levels. It shows that G depends on the scale of environmental uncertainty. For example, for the entries of SNR=10 dB and $\sigma_b^2/\sigma_a^2=10$ (the interferer level is 10 times stronger than the target source level), G decreases from 0.9662 for the known environment scenario to 0.6927 for the uncertain water depth scenario and then to 0.5977 for the general uncertain scenario. The degrees of environmental uncertainty, i.e., the rank of the signal matrix, are 1, 5, and 13, respectively, for these three scenarios. The result shows that G decreases with increased environmental uncertainty, which means that the degradation effect of the interference on detection performance is strengthened by environmental uncertainty. This is because the rank of the interference matrix also increases with environmental uncertainty, resulting in an increase in the number of effective eigenvalues that inversely impact the computation of G . The higher the interferer level, the higher the eigenvalues for the covariance matrix, and the greater the inverse impact on the G values.

Figure 7 illustrates the combined effect of interference and environmental uncertainty on the detection performance by plotting P_D as a function of the SNR for a fixed $P_F=0.1$ for three interference levels: $\sigma_b^2/\sigma_a^2=0, 1, 10$. The uncertain water depth scenario and the general uncertain scenario were used. In each plot, the benchmark P_D performance predictions, denoted by solid lines, are computed for the known ocean scenario. Since the absolute value of the correlation coefficient between the known signal and interference wavefronts is very small, three benchmark P_D curves for three interference levels are indistinguishable. The dashed curves are analytical prediction results [Eq. (40)] and the circles are Monte Carlo evaluation results for the Baye-

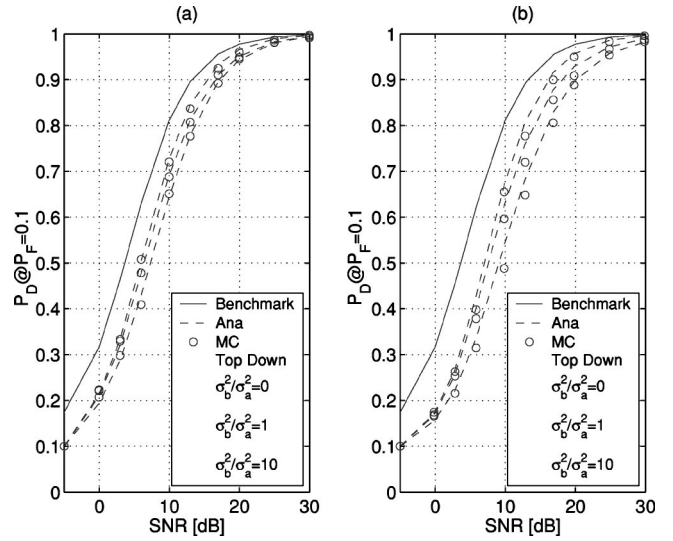

FIG. 7. Detection performance prediction P_D as a function of SNR in the presence of an interferer in uncertain environments [Eq. (36)], comparing with Monte Carlo performance evaluations of the Bayesian detector [Eq. (21)]. (a) Uncertain ocean depth scenario; (b) general uncertain scenario.

sian detector [Eq. (21)]. The degradation of the detection performance due to interference and environmental uncertainty can be illustrated by an increased SNR threshold in order to achieve a fixed P_D . For example, to achieve a fixed $P_D=0.8$, Fig. 7(a) shows that the SNR threshold is 10 dB for the known environment scenario and are about 12, 13, and 14 dB for the uncertain water depth scenario ($R=5$) for three increased interferer levels. The uncertainty of the uncertain water scenario results in a 2–4 dB SNR increase. Figure 7(b) shows that the uncertainty of the general uncertain scenario ($R=13$) results in a 2.5–7 dB SNR increase. Thus, detection performance degradation due to interference is magnified by the scale of environmental uncertainty. On the other hand, the results also indicate that the detection performance degrades much faster with an increased degree of environmental uncertainty in the presence of interference as compared to that for diffuse noise only scenarios.¹⁶

IX. CONCLUSIONS

Analytical ROC performance prediction expressions, which are computationally fast, are developed for the Bayesian detector in the presence of interference in uncertain environments. This is a significant extension to the previous detection performance prediction approach proposed for a diffuse noise only circumstance.¹⁶ The ROC expression is developed within a Bayesian decision framework that incorporates uncertainties in ocean environmental parameters and source (target and interferer) position parameters.

The analytical ROC expression is verified using several uncertain environment scenarios extended from benchmark propagation models. The results demonstrate that the ROC expression is a good approximation to the ROC obtained using Monte Carlo techniques, and can be computed much faster. The simple ROC expression captures fundamental parameters that impact sonar detection performance: the signal-to-noise ratio, the rank of the signal matrix, and the signal-to-interference coefficient. It provides a more realistic

performance prediction than the classic sonar equation that fails to incorporate the effects of interference and environmental uncertainty.

The signal-to-interference coefficient in the ROC expression characterizes the effect of interference on detection performance in uncertain environments. In computing the signal-to-interference coefficient, environmental uncertainty is incorporated through the covariance matrix of the noise field, which is obtained based on the *a priori* information of uncertain environmental parameters and uncertain interferer position parameters. The values of the signal-to-interference coefficient in different simulation scenarios show that environmental uncertainty magnifies the degrading effect of interference on the detection performance.

Concurrent inversion of geo- and bio-acoustic parameters from transmission loss measurements in the Yellow Sea

Orest Diachok^{a)} and Stephen Wales
Naval Research Laboratory, Washington, DC 20375

(Received 9 March 2003; revised 15 October 2004; accepted 25 October 2004)

This paper describes results of a simultaneous inversion of bio-acoustic parameters of fish (anchovies) and geo-acoustic parameters of the bottom from transmission loss (TL) measurements in the Yellow Sea, which were reported by Qiu *et al.* [*J. Sound Vib.* **220**, 331–342 (1999)]. This data set was selected because the bio-absorptivity at their site was extremely large, 40 dB at 1.3 kHz at 5 km, and measurements were made between multiple source and receiver depths and ranges. Measurements were made at night when anchovies are generally dispersed. Replica fields were calculated with a normal mode model, which incorporates bio-absorption layers. The inversion was based on minimizing the rms difference, Δ , between measured and calculated values of TL at all ranges and source and receiver depths, and involved a simultaneous search for bio-layer depth, bio-layer thickness, bio-alpha, geo-sound speed, and geo-alpha. The resultant small value of Δ , ± 1.7 dB, confirmed that the model, which was assumed in replica field calculations, was realistic, and that inverted parameters were meaningful. In particular, the inverted depth of the bio-absorption layer, 6.9 ± 0.3 m, was consistent with theoretical calculations of the depth, 5.8 ± 1 m, of 10-cm-long anchovies *Engraulis japonicus*, the dominant species in the Yellow Sea. © 2005 Acoustical Society of America. I. INTRODUCTION

Bio-acoustic absorptivity can have large (nominally as large as 40 dB at 5 km) frequency selective effects on transmission loss frequencies between approximately 0.5 and 5 kHz in shallow waters. In the mid-1960s Weston (1967) demonstrated that large changes in transmission loss occurred near sunrise and sunset over limited frequency bands. His experiments were conducted with several fixed sources (which operated between 0.4 and 4.4 kHz) and several fixed hydrophones on the bottom at a relatively shallow (~ 40 m) site in the Bristol Channel at ranges of 18, 22, and 120 km. Fixing the source and receiver eliminated changes in TL due to changes in the geo-acoustic properties of the bottom, minimized changes in TL versus time due to changes in oceanic sound speed, and permitted monitoring temporal changes in the magnitude of frequency selective attenuation due to fish. The latter was generally much higher at night, when fish such as sardines are dispersed near the surface. In this mode their separations are comparable to or greater than the wavelength at the resonance frequency of their swim bladders. The peak frequencies of losses at night, which occurred between 1 and 4.5 kHz, were consistent with the dimensions and depths of the swim bladders of sardines (Ching and Weston, 1971). The sardine was the dominant species in the Bristol Channel in the 1960s. However, Weston did not conduct concurrent trawling measurements of fish length distributions or echo-sounder measurements of fish layer depths. Consequently, he could not offer experimental proof of his hypothesis.

Subsequently Diachok conducted experiments, which included the following: (1) measurements of transmission loss as a function of time and frequency, (2) echo-sounder based measurements of the depths of bio-acoustic absorption layers, and (3) trawling-based measurements to determine the length distributions of the dominant species of swim-bladder-bearing fish. His experiment, which was conducted in the Gulf of Lion (Diachok, 1999), demonstrated that large, frequency-selective absorption losses occurred at the resonance frequencies of sardine and anchovy swim bladders. This experiment was conducted with a fixed broadband source and a fixed vertical receiving array. This geometrical configuration permitted inference of (1) the temporal changes in the frequencies of absorption lines (which were due to changes in the resonance frequencies of swim bladders as fish undergo vertical migrations at sunrise and sunset), (2) the average depth and thickness of absorption layers, and (3) the number densities (number per cubic meter) of fish within absorption layers. These parameters were derived by matching measured and calculated transmission loss as a function of depth and frequency. Resultant inferences were consistent with concurrent echo sounder and trawling measurements of these parameters.

In addition to absorption lines, which were associated with dispersed adult fish, these experiments also revealed the presence of absorption lines at lower and higher frequencies. A low-frequency line at a frequency equal to approximately $0.6f_0$ (where f_0 is the resonance frequency of individual sardines) during daytime in the Gulf of Lion was attributed to “bubble cloud” effects of adult sardine schools, in which average separations are approximately one fish length (Diachok, 1999). Such separations are much smaller than the wavelength at the resonance frequency. High-frequency lines

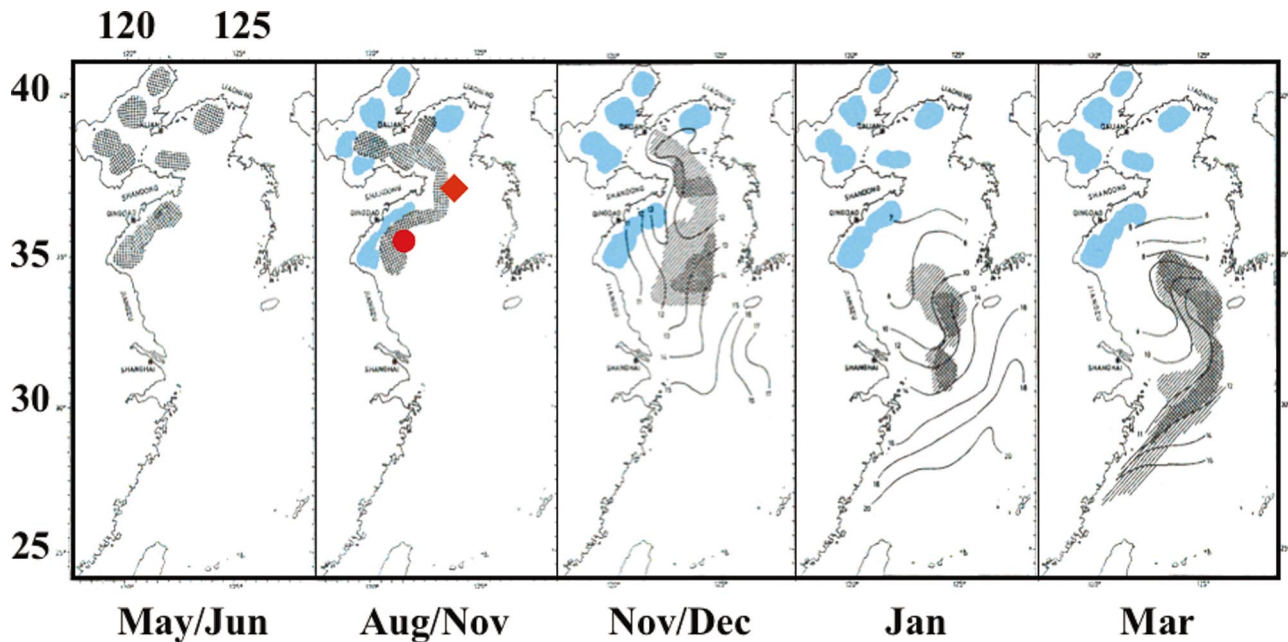

FIG. 1. Locations of transmission loss measurements by Qiu *et al.* (1999), the red dot (●), Dahl *et al.* (1998) and Rogers *et al.* (2000), the red diamond (◆) and “idealized” distributions of juvenile (blue) and adult (gray) anchovies in the Yellow Sea, based Deng and Zhao (1991) and Iverson *et al.* (1993). Adults spawn in May/June and migrate south in winter. Adults spawn *predominantly* near shore; juveniles *tend to remain* near shore.

were attributed to juvenile fish. An absorption line at 3.6 kHz in the Gulf of Lion was consistent with the presence of 6.5 cm long juvenile sardines (Diachok, 1999).

It is noteworthy that the peak frequencies of absorption lines (Diachok *et al.*, 2004) and back-scattering lines (Holliday, 1972) due to dispersed adult anchovies in the seas off California were essentially equal (at the same depth). This experimental observation is consistent with recently reported concurrent measurements of absorption and back-scattering spectra in the Yellow Sea (Qiu *et al.*, 1999), which revealed that the peak frequencies of concurrently measured absorption and back-scattering spectra at this site were nearly identical. Measured peak frequencies were consistent with calculations of the resonance frequency of swim bladders of anchovies, based on historical measurements of the average lengths and depths of this species in the Yellow Sea.

It is well known that transmission loss in shallow water is controlled by sound speed profiles in the water and the geo-acoustic parameters of the bottom. Experiments conducted by Ching and Weston (1971), Diachok, (1999), and Qiu *et al.* (1999) indicate that bio-acoustic absorptivity due to fish with swim bladders can also have a large effect on transmission loss. The objectives of this paper are to present the results of a concurrent inversion of the bio-acoustic parameters of fish (anchovies) and the geo-acoustic parameters of the bottom from Qiu *et al.*'s transmission loss data, and to demonstrate that inverted parameters are consistent with previously published values of these parameters in the Yellow Sea.

Sections II and III of this paper provide a review of the bio-acoustic properties and temporal and spatial variability of anchovies, the species of fish which is the most numerous and has the most dramatic effect on transmission loss in the Yellow Sea. Section IV provides a brief review of the geo-acoustic properties of Qiu *et al.*'s measurement site. BIO-C-

SNAP, a transmission loss model that permits simulations of the effects of bio-acoustic absorption layers, due to fish with swim bladders, and the effects of the bottom on transmission loss will be reviewed in Sec. V. This will be followed by a summary of Qiu *et al.*'s experimental procedures and their transmission loss data, and a discussion of the frequency and the Q of an apparent bio-absorption line in Sec. VI. Section VII describes the results of the concurrent inversion of the geo-acoustic parameters of the bottom and the bio-acoustic parameters of dispersed anchovies. Sections VIII and IX consist of discussions of inverted values of geo-alpha and bio-acoustic parameters, respectively. Section X provides a discussion of the uncertainty of inverted values, followed by conclusions in Sec. XI.

II. TEMPORAL AND SPATIAL DISTRIBUTIONS OF ANCHOVIES

Anchovies are the dominant fish in the Yellow Sea. According to Ohshimo (1996), about 80% of the fish, which he trawled in the northern Yellow Sea, were anchovies. Trawling is length selective: it discriminates against “small” fish, due to mesh size, and “large” fish, because they swim fast and are able to avoid capture. Consequently, his results represent an upper bound on the percentage of anchovies in this region. Anchovies are at present (Ohshimo, personal communication) and were the dominant species in this region throughout the 1990s (Ohshimo, 1996; Iverson *et al.*, 1993). Anchovies spawn near the coast of China, predominantly at sites shown in Fig. 1 (Iverson *et al.*, 1993; Deng and Zhao, 1991). Following spawning, juveniles tend to remain in the vicinity of spawning sites, whereas adults migrate south for the winter and return to their spawning sites in the spring, as

illustrated in Fig. 1. This figure should be considered an “idealized” version of this process. A significant percentage of spawnings also occurs throughout the Yellow Sea. Furthermore, currents and eddies can transport juveniles from the predominant spawning sites into the central regions of the Yellow Sea during their first year (Iverson *et al.*, 1993). Adult anchovies in this region are typically 10 ± 1 cm long (standard length) and their resonance frequencies at a depth of 7 m are nominally 1.4 kHz. The lengths of juveniles are smaller, and their resonance frequencies higher, being about 3.5 kHz at 7 m in their fourth month (Diachok, 2001). The second most common species in the Yellow Sea is jack mackerel (Deng and Zhao, 1991). These fish are typically about 20 cm long and resonate at about 0.6 kHz at 7 m (Holliday, 1972). They feed on, and to a large extent spatially coincide with, juvenile anchovies.

The concentrations of fish in the ocean are generally described in terms of spatial number densities, n_A , which may be derived by integrating volumetric number densities (number/m³) over depth. Average spatial number densities, n_A , of adult juveniles in the south-central region of the Yellow Sea and north-central region of the East China Sea in May and June are typically about 0.7/m² (top view) (Ohshimo, 1996). This value is comparable to the spatial density of sardines in the Gulf of Lion (Diachok 1999) and in the Bristol Channel (Ching and Weston, 1971), where large bioacoustic effects on transmission loss have been reported. According to Fig. 1, values of this parameter in the near-shore spawning regions are much larger than average values.

III. BIOACOUSTICS

Anchovies belong to a class of swim-bladder-bearing fish called physostomes, which have “open” swim bladders (Whitehead and Blaxter, 1989). Such fish maintain air in their swim bladders by swallowing air at the surface. The volumes of their swim bladders decrease with increasing depth, in accord with Boyle’s law. The resonance frequency, f_0 , of physostomes may be derived from an equation originally formulated to describe the resonance frequency a spherical bubble (Minnaert, 1933):

$$f_0 = (1/2\pi r)(3\gamma P/\rho)^{1/2} \quad (1)$$

where r is the radius, P is the hydrostatic pressure, ρ is the density of the surrounding fluid, and γ is the ratio of specific heats of the gas in the bubble. The presence of γ in Eq. (1) implies that the gas behaves adiabatically. This assumption is valid for relatively large bubbles (Clay and Medwin, 1977), and is therefore probably valid for fish swim bladders.

The radius of bubbles in water satisfies Boyle’s law:

$$Pr^3 = P_0r_0^3, \quad (2)$$

where P_0 and r_0 are the pressure and radius at the surface, and

$$P = P_0(1 + 0.1d/d_0), \quad (3)$$

where d is the depth in m and d_0 equals 1 m. Neglect of changes in r due to changes in temperature results in errors, which are smaller than 1%.

The resonance frequency of nonspherical bubbles is higher than the resonance frequency of spherical bubbles, which have the same volume. To account for this effect, Eq. (1) needs to be increased by a factor, ε , which is a function of the eccentricity, e , of the bubble, defined as the ratio of the major and minor axes of an ellipsoid that provides the “best” fit to the shape of the swim bladder. This correction was originally derived for prolate spheroids by Weston (1967). Subsequently Feuillade and Werby (1994) derived corrections for swim bladders modeled as cylinders with hemispherical end caps and prolate spheroids. The difference between calculations of ε based on these models is small (about 3%), which suggests that the correction is minimally affected by the shape of the swim bladder.

Substituting Eqs. (2) and (3) into Eq. (1) and inserting the correction for the eccentricity leads to

$$f_0 = \varepsilon[(1 + d/d_0)^{5/6}/(2\pi r_0)](3\gamma P_0/\rho)^{1/2}, \quad (4)$$

which can be simplified to

$$f_0 = 322\varepsilon(1 + 0.1d)^{5/6}/r_0, \quad (5)$$

where r_0 is the effective radius in cm at the surface and d is the depth in meters. The effective radius is defined as the radius of a sphere of the same volume as the swim bladder. For California anchovies e is approximately equal to 6 (Whitehead and Blaxter, 1989), which corresponds to $\varepsilon=1.14$ for prolate spheroids and 1.18 for a cylinder with hemi-spherical end caps (Feuillade and Werby, 1994). Calculations, based on this equation with $\varepsilon=1.16$, are consistent within $\pm 7\%$ of laboratory (Baltzer and Pickwell, 1970) and field measurements (Holliday, 1972) of f_0 of anchovies (Diachok, 2001). The good agreement between theory and measurements supports the “adiabatic” assumption and the applicability of the theoretical correction for eccentricity.

This equation is valid when the separation between fish, s , is comparable to or larger than the wavelength, λ_0 , at f_0 . When fish are in school and $s \ll \lambda_0$, the resonance frequency of a school is a function of s and the number of fish in the school, N , and is generally less than f_0 . See Feuillade *et al.* (1996) and Diachok (1999) for further discussion of this phenomenon.

Several theories (Andreeva, 1964; Love, 1978; McCartney and Stubbs, 1970; Feuillade and Nero, 1998) have been proposed to account for the effects of the physical properties of the swim bladder membrane on f_0 . However, the good agreement between measurements and calculations of f_0 of anchovies, based on Eq. (5), indicate that the hypothesized effects for this species are small.

The average “standard” length, SL, of anchovies in the vicinity of Qiu *et al.*’s measurements was approximately 10 cm (Ohshimo, 1996) (for anchovies SL equals 0.84 TL, where TL is the total length from nose to tail). Holliday (1978) derived empirical relationships between r_0 and SL of California anchovies from measurements on a large number of samples, which were taken in June and March. Results are summarized in Fig. 2. Measurements made on postlarval juveniles are also shown for comparison. The small difference between r_0 in March and June is probably controlled by the seasonal variation of the “lipid” (oil) content of fish flesh

FIG. 2. Effective radius, r_0 , versus standard length, L , of postlarval juvenile, and adult California anchovies (*Engraulis mordax*) in June and March (Holliday, 1978).

(Blaxter and Batty, 1990). Based on Holliday's measurements in June, which will be assumed to be representative of Qiu *et al.*'s measurements in August, the magnitudes of r_0 and e of Japanese anchovies are projected to be approximately 0.40 cm and 6, respectively. The corresponding value of ε is 1.16 ± 0.02 . Assuming these values in Eq. (5) yields f_0 equal to 1.38 kHz at 6 m.

The absorption coefficient due a large number of identical, dispersed fish with swim bladders may be calculated from the following equation (Weston, 1967),

$$\alpha \text{ (dB/m)} = 4.34n\sigma_E = n\lambda_0 r/Q[(1 - f_0^2/f^2)^2 + 1/Q^2], \quad (6)$$

where σ_E is the extinction cross section of a single bubble (due to scattering) in m^2 , n is the number density (number per m^3), $Q = f_0/\Delta f$ (where Δf is the full width at -3 dB relative to the peak of the absorption line), and λ_0 is the wavelength at f_0 . This equation has been employed successfully to derive the number densities of sardines in the Gulf of Lion (Diachok *et al.*, 2001) and the Bristol Channel (Ching and Weston, 1971).

IV. GEO-ACOUSTICS

Qiu *et al.* (1999) conducted transmission loss measurements at the site shown in Fig. 1. The depth was 40 m, the bottom boundary was flat, and the bottom consisted of a thick layer of unconsolidated sediments. Qin and Zhao's (1987) measurements of surface sediments in the Yellow Sea indicate that this site consist of "silty sand" ($\approx 58\%$ sand). Geo-acoustic parameters of this site are not known. Geo-acoustic parameters have been estimated at two nearby, unspecified sites by Zhou (1985), and at the site in the central Yellow Sea shown in Fig. 1 by Dahl *et al.* (1998) and Rogers *et al.* (2000).

Zhou inverted geo-acoustic parameters from propagation experiments at two unspecified sites (A and B) near the coast of China in the Yellow Sea. The sediments at Zhou's site A, where the water depth was 37 m, consisted of 39% sand. Sediments at site B, where the water depth was 29 m, consisted of 29% sand ("sandy silt"). Zhou concluded that the bottom at both sites may be characterized by a half-space

with c_p equal to 1584 m/s, independent of frequency between 100 and 500 Hz. Subsequently, Zhou *et al.* (1987) offered a revised geo-acoustic model that included a low sound speed (c_p equals 1560 m/s at the top), high gradient (5 m/s/m), 10-m-thick, transition layer overlying a high sound speed (1610 m/s) half-space.

Rogers *et al.* and Dahl *et al.*'s site consists of "silty sand." Rogers *et al.* concluded that the bottom at this site may be characterized as a half-space with c_p equal to 1587 m/s, independent of frequency between 100 Hz and 1.5 kHz. Dahl *et al.*, who recorded data at the same site, but on a different hydrophone array, reached a different conclusion, viz., that the bottom may be characterized by a low sound speed (1555 m/s at the top), 2-m-thick, transition layer overlying a high sound speed (1650–1700 m/s) half-space, independent of frequency between 100 and 800 Hz. Both models resulted in good matches between calculations and measurements of transmission loss.

In this paper it will be assumed that the bottom may be characterized by an interfacial sound speed, c_p , and a subsurface gradient. The measurements discussed above suggest the following upper and lower bounds on c_p for inversion calculations: 1700 and 1555 m/s. Hamilton's (1987) review suggests the following upper and lower bounds on α_p (dB/ λ): 1 and 0.02 dB/ λ . Previously reported measurements of α_p in the Yellow Sea and elsewhere will be summarized and compared with inverted values of α_p at Qiu *et al.*'s site in Sec. VIII.

V. TRANSMISSION LOSS MODEL

It will be assumed that sound propagation at the frequencies and ranges of interest may be calculated with a deterministic normal mode model, and that stochastic mode conversion due to internal waves may be ignored. This assumption seems reasonable at the frequencies and ranges of interest (Dozier and Tappert, 1978). The transmission loss model, which will be employed to model the effects of bio-acoustic absorption layers on transmission loss, is based on the coupled normal mode model, C-SNAP (Ferla *et al.*, 1993). This model can account for range-dependent sound speed profiles in the ocean, depth-dependent c_p and depth-independent α_p in the bottom, and scattering loss at boundaries. Ferla's initial modifications to C-SNAP (Diachok and Ferla, 1996) were designed to permit calculation of the effects of two bio-acoustic absorption layers. The resultant code was successfully used to model the effects of bio-acoustic absorption layers on transmission loss in the Gulf of Lion (Diachok, 1999). Subsequently, this model was refined to permit consideration of up to 100 layers. The more recent version of this code, designated BIO-C-SNAP, permits modeling the depth dependence of α_B , including Gaussian and other distributions of α_B .

The absorbing layer will be characterized by a horizontally uniform bio-absorption coefficient, α_B , a mid-layer depth, d , and a layer thickness, t . It will be assumed that the presence of fish in this layer has a negligible effect on sound speed. This is a reasonable assumption when the void fraction, β , which is defined as

FIG. 3. The postulated depth of the layer of dispersed anchovies (gray) and Qiu *et al.*'s (1999) measurements of the sound speed profile (left) and transmission loss at 5.7 km versus source and receiver depths (right).

$$\beta = (4/3)\pi r^3/s^3, \quad (7)$$

is less than approximately 10^{-6} (Commander and Prosperetti, 1989). Limited photographic data indicate that average separation between anchovies, which are dispersed near the surface at night, are about 10 fish lengths (Aoki and Inagaki, 1988). This is comparable to, but somewhat larger than, the average value of s , which will be derived through comparison of propagation model calculations with Qiu *et al.*'s data, viz., 5 L (which will be discussed in Sec. IX). Assumption of r and s equal 0.34 cm and 50 cm respectively results in β equal to 10^{-6} .

The assumption that the absorption layer is horizontally uniform is reasonable for dispersed anchovies at night. A small percentage of anchovies, however, can remain in schools at night. The presence of schools would violate the assumption of horizontal uniformity. Schools of anchovies consist of highly spatially localized "bubble clouds," which are nominally 3 m thick, 10 m wide, separated by distances on the order of 100 m, and resonate at frequencies which are less than f_0 (Diachok, 1999). The magnitude of β of some schools may be sufficiently low to affect the speed of sound. Inversion calculations, which will be presented in Sec. VII, may be affected by these phenomena, particularly at frequencies below f_0 .

The magnitude of the attenuation coefficient of compressional waves in sediments, α_P , will be assumed to be independent of depth (a limitation of the C-SNAP model). This is not a significant limitation when c_P is greater than the speed of sound in water and the shear speed, c_S , is much less than c_P . c_S will be assumed to equal zero.

VI. TRANSMISSION LOSS MEASUREMENTS

Qiu *et al.* (1999) reported transmission loss measurements at frequencies between 1 and 2 kHz in August at the site shown in Fig. 1. Their experiment was conducted at night, when anchovies are generally dispersed near the surface. Transmission loss measurements (in relative dB) were made between pairs of sources and receivers at 7 and 25 m, which were above and below the base of the mixed layer (about 15 m), as illustrated in Fig. 3. The water depth was 40 m. Pairs of explosives were deployed at these depths at

ranges between 0.4 and 6.6 km (measurements at 6.6 km were made at the beginning of twilight and were excluded from the analysis presented here). Results at a range of 5.7 km are shown in Fig. 3. This figure illustrates the main result of their experiment: (1) relative losses are greatest (~ 40 dB) when the both source and receiver are at a depth of 7 m, compared to losses when source and receiver were at 25 m, and (2) the loss is highly frequency selective, being largest at a frequency of about 1.35 kHz.

Figure 4 provides a comparison of the calculated and measured frequency dependence of the bio-acoustic component of the attenuation coefficient of the transmission channel, A_B , in dB/km. A_B is defined as the excess attenuation above cylindrical spreading. The purpose of this figure is to show that these data are consistent with theoretical calculations of the frequency dependence of bio-absorptivity due to 10 cm long anchovies. These calculations were derived from TL measurements made between source and receiver depths of 7 m. Measured values were derived from the measured rate of change of signal level with range, after correcting for cylindrical spreading, and a small frequency-independent attenuation, A_X , which is hypothetically caused by a combination of α_P and α_B . The latter is hypothetically due to schools of anchovies or a dispersed larger species which resonate at a lower frequency. The theoretical calculations, shown in Fig. 4, were based on Eq. (5). The best fit to the

FIG. 4. Measured and calculated spectra of bio-acoustic attenuation.

data was determined by searching through the following parameters: A_B at 1.35 kHz, the Q of the absorption line, and A_X . The results of fitting Qiu *et al.*'s data to this model are consistent with A_B equal to 7.5 dB/km at 1.35 kHz, Q equal to 2.7, and A_X equal to 1 dB/km. The latter is small compared to A_B at 1.35 kHz, which supports the hypothesis that bio-absorptivity due to 10-cm-long anchovies is the dominant cause of attenuation at this frequency. The absorption coefficient of the layer of anchovies, α_B , may be estimated from the calculated value of A_B by assuming that the acoustic field is uniformly distributed in the water column and the following equation (Diachok, 1999):

$$\alpha_B = A_B D / t, \quad (8)$$

where α_B is in dB/ λ , A_B is in dB/ λ , D is the ocean depth in m, and t is the thickness of the layer in m. For $A_B = 7.5 \text{ dB/km} = 0.0075 \text{ dB/m} = 0.0083 \text{ dB}/\lambda$, $D = 40 \text{ m}$, $\lambda_0 = 1.1 \text{ m}$, and $t = 0.3 \text{ m}$ (based on inversion calculations, which will be presented in Sec. VII), $\alpha_B = 1.1 \text{ dB}/\lambda$. This is approximately equal to the value of α_B , which will be derived through comparison of propagation model calculations with data, which will be presented in Sec. VII.

The magnitude of Q is determined by the values of Q_0 , the inherent Q of individual fish, Q_L , the Q associated with the distribution of lengths, and Q_Z , the Q associated with the distribution of depths through a generalized form of Weston's (1967) equation:

$$1/Q^2 = 1/Q_0^2 + 1/Q_L^2 + 1/Q_Z^2. \quad (9)$$

This equation assumes that each of these processes results in a "random" distribution of resonance frequencies. Laboratory measurements indicate that Q_0 of anchovies at 6 m equals approximately 4.5 (Baltzer and Pickwell, 1970). The magnitude of Q_L of adult anchovies in the Yellow Sea is approximately 3.5, based on measurement of the width of the 3 dB down points in Deng and Zhao's (1991) measurements of the length distributions of anchovies in the Yellow Sea, Holliday's empirical relationships between L and r_0 , and Eq. (5). Disregarding the effect of Q_Z , the calculated value of Q is 2.8. This is in excellent agreement with the measured value, 2.7, which suggests that Q_Z is large, i.e., greater than about 7. The magnitude of Q_Z , which may be estimated from Eq. (5), is approximately equal to d/t , where d is the average depth and t is the thickness of the layer. It will be shown in the next section that d at Qiu *et al.*'s site is approximately equal to 6.9 m, which implies that t is less than approximately 1 m.

The wind speed during this experiment was about 10 knots (Qiu, personal communication). Attenuation due to surface waves and subsurface bubbles at frequencies below 2 kHz at 10 knots for a water depth of 40 m is less than 0.1 dB/km (Weston and Ching, 1989). Chemical absorptivity at these frequencies and ranges is also small (Thorpe, 1965). Attenuation due to the rms roughness ($\sim 0.3 \text{ m}$) at the bottom boundary is also small at these frequencies (Zhou, 1985).

According to Holliday's empirical relationships between L and r_0 , and Eq. (5), 10-cm-long anchovies with r_0 equal to 0.4 cm and ε equal to 1.15 resonate at 1.35 kHz at a depth of 5.8 m. The uncertainty in this estimate of depth, $\pm 1 \text{ m}$, was

FIG. 5. Measured resonance frequencies due to anchovies in the Yellow Sea (Qiu *et al.*, 1999), and extrapolations from Baltzer and Pickwell's (1970) laboratory measurements.

derived from the estimated uncertainties in the measured value of the average fish length ($\pm 10\%$), the calculated value of r_0 ($\pm 5\%$), and the measured value of f_0 ($\pm 5\%$). These observations were then extrapolated to the Yellow Sea, assuming that the differences in the relationships between L and r_0 and ε of the swim bladders of Japanese and California anchovies are small. This assumption is reasonable, since the magnitude of the correction for eccentricity is small. Figure 5 provides a comparison between calculations and measurements of f_0 of 10-cm-long anchovies in the laboratory and in the Yellow Sea. The laboratory estimate was extrapolated from measurements of f_0 (1.275 kHz), which were made on 10.6-cm-long California anchovies ($r_0 = 0.43 \text{ cm}$) at 6 m. The depth of anchovies in the Yellow Sea was inverted from TL data, as discussed in Sec. VII.

VII. INVERSION OF BIO AND GEO-ACOUSTIC PARAMETERS

Additional evidence in support of the bio-acoustic paradigm will be provided by demonstrating that the depth of the absorption layer, which was derived from Eq. (5), viz., $5.8 \pm 1 \text{ m}$, is consistent with the average layer depth, which will be "inverted" from transmission loss measurements. The inversion method, which will be employed here, is similar to previously reported inversion methods for estimation of ocean and geo-acoustic parameters from sound propagation measurements (Diachok *et al.*, 1995).

TL calculations were based on incoherent addition of modes generated with the BIO-C-SNAP model. Incoherent addition of modes was assumed to result in a reasonable approximation to (0.1 kHz) frequency averaging of Qiu *et al.*'s data (Jensen and Kuperman, 1983).

It was assumed that bio-acoustic absorptivity was due to a single layer, which was modeled with a single uniform (depth independent) absorption coefficient. Incorporation of a "Gaussian" shape did not have a significant effect on calculations. It was assumed that the bottom could be characterized with an interfacial sound speed, c_p , and a subbottom gradient equal to 1.3 m/s/m (Hamilton, 1987). Assumption of other values of this parameter (up to 2 m/s/m) had no effect on inverted parameters. The rms roughness was assumed to

FIG. 6. Ambiguity surface of the rms difference, Δ (in dB), between measured and calculated transmission loss at 1.35 kHz versus bottom sound speed and attenuation coefficient, assuming that all excess attenuation is due to the bottom. The inverted sound speed is 1625 m/s and attenuation coefficient is equal to 9.5 dB/λ. Contours: ± 10 , 11, and 13 dB.

equal zero. Assumption of a small rms roughness (0.3 m) at the bottom interface did not reduce the rms difference between calculations and measurements.

Initial inversion calculations were conducted for the case of no bio-acoustic absorption layer. The search was based on minimizing the rms difference, Δ , between calculated and measured transmission losses as a function of three parameters: c_p , α_p , and the correction for source level. All of Qiu *et al.*'s TL data, which included measurement at ranges between 0.4 and 5.7 km (but excluded data at 6.6 km) and source and receiver depths of 7 and 25 m, were employed in the inversion. The search method was "comprehensive", i.e., Δ was calculated for all combinations of parameters. The resultant ambiguity surface, Fig. 6, shows that the minimum value of Δ was 9.5 dB for c_p equal to 1625 m/s and α_p equal to 3 dB/λ. The unacceptably high value of Δ indicates that the environmental model, which was assumed to generate replica fields, does not provide a good approximation to reality. It is noteworthy that the inverted value of α_p (3 dB/λ) is much larger than Hamilton's (1987) upper bound on this parameter (1 dB/λ) at high frequencies.

The correction for source level had to be included in the search, since Qiu *et al.* did not report absolute values of TL. The search was not sensitive to the magnitude of this unknown: addition of 50 dB to Qiu *et al.*'s published values of relative TL, which resulted in reasonable absolute values of TL at 1 kHz at 0.4 km, did not significantly affect calculated ambiguity surfaces.

Subsequent calculations included a search through both bio and geo parameters. This search was based on minimizing the rms difference, Δ , between calculated and measured transmission losses as a function of six parameters: α_B , d , t , c_p , α_p , and the correction for source level. The search was conducted by varying two to three parameters, while holding others constant. This procedure was repeated several times for all possible combinations of pairs of parameters until Δ approached an asymptotic value. A sufficiently large number of ambiguity surfaces were calculated to ensure that local

FIG. 7. Ambiguity surface of the rms difference, Δ (in dB), between measured and calculated transmission loss at 1.35 kHz versus layer depth and absorption coefficient within the layer. Layer thickness equals 0.3 m. The inverted layer depth is approximately equal to 6.8 m. Contours: ± 2 , 3, and 5 dB.

minima were avoided and that ambiguity surfaces for all possible combinations of parameters were self-consistent. Figures 7 and 8 show ambiguity surfaces for assumed values of the layer depth, d , layer thickness, t , and the bio-attenuation coefficient, α_B .

Figure 7 shows the magnitude of Δ vs. d and α_B at 1.35 kHz for t equal to 0.3 m and α_p equal to 0.15 dB/λ. The minimum Δ , 1.7 dB, occurs when d equals 6.9 m and α_B equals 1.1 dB/λ. This value of α_B is virtually identical to the heuristic estimate presented in Sec. VI. This figure indicates that Δ is less than 3 dB (within 1.3 dB of the minimum) when d is between 6.6 and 7.0 m, and α_B is between 0.9 and 1.4. The inverted value of d is consistent with Eq. (5) based estimate (5.8 ± 1 m).

FIG. 8. Ambiguity surface of the rms difference, Δ (in dB), between measured and calculated transmission loss at 1.35 kHz versus layer thickness, t , and "relative bio-alpha" within the layer, α_b . Bio-alpha, α_B , may be calculated from the equation, $\alpha_B = 0.3 \times \alpha_b / t$. Layer depth is 6.8 m. The inverted layer thickness is approximately equal to 0.3 m. Contours: ± 2 , 3, and 5 dB.

FIG. 9. Ambiguity surface of the rms difference, Δ (in dB), between measured and calculated transmission loss at 1.35 kHz versus bottom sound speed and attenuation coefficient. The inverted sound speed is 1645 m/s and attenuation coefficient is equal to 0.19 dB/λ. Contours: ± 2 , 3, and 5 dB.

Figure 8 shows the magnitude of Δ vs. t and α_B for a layer depth of 6.9 m and α_P equal to 0.19 dB/λ. In this case the minimum Δ , 1.8 dB, occurs when t equals 0.3 m. This figure indicates that Δ is less than 3 dB (within 1.2 dB of the minimum) when t is between 0.0 and 0.8 m. The relatively small inverted value of t is consistent with previously reported measurements of the thickness of plankton layers in the ocean. The thickness of fish layers is hypothetically driven by the thickness of plankton layers. The latter are frequently less than 1 m thick (Cowles *et al.*, 1998; Holliday, 1995). These observations are consistent with limited, previously reported echo sounder measurements of t of anchovies (Barange *et al.*, 1996; Holliday, personal communication), myctophids (Benoit-Bird and Au, 2004) and juvenile pollock (Francis and Bailey, 1983). Barange *et al.*'s measurements, which were made over several months and over hundreds of km, resulted in a time-averaged value of t of 2 m. This suggests that measurements, which were made over shorter durations, such as one night, and shorter distances, such as a few km, were less than 2 m. Benoit-Bird and Au reported that t varies with the phase of the moon and is minimum, 1 m, at night during a full moon. Holliday's unpublished measurements (personal communication) suggest that some fish (probably anchovies) aggregate at thin plankton players. Francis and Bailey (1983) reported that the layer thickness of juvenile pollock was less than 2 m when there was a strong thermocline.

Figure 9 shows the magnitude of Δ vs. c_P and α_P for fixed values of bio-acoustic parameters. This figure illustrates the low sensitivity of the data at 1.35 kHz to geo-acoustic parameters. The magnitude of Δ was less than 3 dB (within 1.3 dB of the minimum for c_P between 1580 and >1720 m/s, and α_P between 0.02 and >0.5 dB/λ; the magnitude of Δ was less than 2 dB (within 0.3 dB of the minimum) for c_P between 1580 and 1680 m/s, and α_P between 0.02 and approximately 0.36 dB/λ. The best fit occurred at c_P equal to approximately 1645 m/s and α_P equal to approximately 0.19 dB/λ, where Δ equaled 1.7 dB.

Figure 10 shows calculated magnitudes of Δ vs. α_P and

FIG. 10. Ambiguity surface of the rms difference, Δ (in dB), between measured and calculated transmission loss at 1.35 kHz versus geo alpha and bio alpha. The inverted values of α_P and α_B are equal to 0.3 and 1 dB/λ, respectively. Contours: ± 2 , 3, and 5 dB.

α_B for fixed values of c_P (1645 m/s), t (0.3 m), and d (6.9 m) at 1.35 kHz. The magnitude of Δ was less than 3 dB for α_B between 0.6 and 1.3 dB/λ, and α_P between 0.03 and 0.5 dB/λ. The magnitude of Δ was less than 2 dB for α_B between 0.8 and 0.9 dB/λ, and α_P between 0.22 and 0.32 dB/λ. The optimum values of α_P and α_B equal 0.27 and 0.9 dB/λ, consistent with results shown in Figs. 7–9.

Calculations at 2 kHz resulted in an acceptable value of Δ , 2 dB. Inversion of bio-acoustic parameters, which assumed the same values of geo-acoustic parameters that were derived at 1.35 kHz, resulted in values of d , t , and α_B , which were consistent with values derived at 1.35 kHz. The inverted value of α_B was scaled down by a factor of about 0.3, in accord with Eq. (5). Inversion of c_P , however, was not successful at this frequency. The optimum value of c_P was at the upper bound of the search space, 1720 m/s, where Δ was 2 dB, and the 3-dB bounds on c_P exceeded the search space. The low sensitivity to c_P at this frequency may have been caused by shortcomings of the geo-acoustic model, or by stochastic mode coupling due to internal waves. The latter increases with increasing range and frequency (Dozier and Tappert, 1978; Duda and Preisig, 1999). Calculations at 1 kHz resulted in an unacceptably high value of Δ , 3.5 dB, hypothetically due to shortcomings of the geo- or bio-acoustic models.

A comparison of the minimum values of Δ for inversions that assumed only geo parameters, and a combination of bio and geo-acoustic parameters, is shown in Fig. 11. These results indicate that inclusion of a bio-absorption layer results in much smaller values of Δ at all frequencies, despite the apparent shortcomings of the geo-acoustic model at 1 and 2 kHz.

VIII. GEO-ALPHA

The purpose of this section is to provide a context for comparison of the value of α_P (dB/λ) inverted from Qiu *et al.*'s data with previously reported measurements of this

FIG. 11. Minimum rms difference, Δ (in dB), between measured and calculated transmission loss, assuming attenuation is due to only geo parameters (○), and bio and geo parameters (●).

parameter. Figure 12 shows the inverted values of α_p at Qiu *et al.*'s site, Zhou's estimates at a nearby, unspecified site, Dahl *et al.* and Rogers *et al.*'s estimates at the site in the central Yellow Sea depicted in Fig. 1, and analytical calculations based on work reported by LeBlanc *et al.* (1992), Turgut *et al.* (2002), and Buckingham (2000).

LeBlanc *et al.* (1992) fit "chirp" sonar measurements at frequencies between about 3 and 10 kHz with an analytical model, which assumed that α_p was due to a relaxation mechanism. According to this model, α_p increases with frequency to the first power at frequencies below the relaxation frequency. Turgut *et al.* fit Hamilton's (1972) *in situ* measurements at frequencies between 3 and 25 kHz with theoretical calculations based on the "Biot" model. According to this model, α_p also increases with frequency to the first power at low frequencies. Buckingham's (2000) theory assumes that α_p is controlled by intergranular friction. According to his model, α_p is independent of frequency. The lines drawn in Fig. 12 assume that both mechanisms contribute, and are described by the equation

FIG. 12. Values of α_p , which were inverted from Qiu *et al.*'s data at 1.35 kHz, based on replica fields which incorporate bio- and geo-alpha (●) and only geo-alpha (○), and Zhou's (1987) (Δ), Rogers *et al.* (2000) (◇), and Dahl *et al.*'s (1998) (□) measurements of α_p in the Yellow Sea, which assume that all attenuation is due to geo-alpha, and analytical calculations in "sand" (—) and "silt" (---) from LeBlanc *et al.* (1992), and "fine sand" (—) and "clayey silt" (-.-) from Turgut *et al.* (2002).

$$\alpha_p = bf + h, \quad (10)$$

where α_p is in dB/λ, f is the frequency in kHz, h equals 0.07, and b equals 0.011 for "silt" and 0.031 for "sand" from LeBlanc *et al.*'s calculations, and 0.012 for "clayey silt" and 0.072 for "fine sand" from Turgut *et al.*'s calculations. The first term accounts for the relaxation mechanism at low frequencies. The second term is consistent with Buckingham's theory; the magnitude of h was selected to fit Dahl *et al.*'s, Rogers *et al.*'s, and Zhou's data at 200 Hz.

The inverted value of α_p at 1.35 kHz at Qiu *et al.*'s site, based on the bio and geo model, is consistent with both Turgut *et al.*'s and LeBlanc *et al.*'s extrapolations from high-frequency measurements. This is a reasonable result, since the magnitude of α_p of "silty sand" lies between "sand" and "silt" at high frequencies (Hamilton, 1972).

Values of α_p inverted from propagation measurements are sensitive to the assumed sound speed profile in the bottom. Zhou's estimates of α_p , which assumed that the bottom may be characterized by a half-space (1584 m/s), increase with frequency as shown in Fig. 12. Zhou *et al.*'s (1987) revised estimates of α_p (not shown) from Zhou's data, which assumed a low sound speed, 10-m-thick, transition layer overlying a high sound speed half-space, were about 0.6 times lower than Zhou's original estimates. Zhou *et al.* (1987) also concluded that their previously reported measurements were consistent with α_p equal to $0.45e^{-1.3z}$ dB/λ, where z is in m in the top 10 m. Dahl *et al.* inverted the following values of α_p : 0.2 dB/λ in a low sound speed, 2-m-thick, transition layer, and 0.07 dB/λ in the underlying high sound speed half-space (the average value, 0.14 dB/λ, is shown in Fig. 12). Rogers *et al.*'s estimates of α_p , which assumed that the bottom may be modeled by a half space, increased with frequency, as shown in Fig. 12.

Zhou's estimates and Dahl *et al.*'s and Rogers *et al.*'s estimates of α_p diverge at frequencies above about 500 Hz. Zhou (1985) does not offer an explanation for the abrupt increase in the apparent value of α_p at 630 Hz at his site. This anomaly may be due to α_B . Unfortunately it is not possible to investigate this hypothesis by inverting the depth of the absorbing layer from Qiu *et al.*'s data at 630 Hz, since their data is restricted to frequencies between 1 and 2 kHz, or by testing compliance of Zhou's data with Eq. (5), since the frequency resolution in his data is too low. Furthermore, the apparent values of α_p at frequencies above 1 kHz, which were derived by Rogers *et al.*, may have been biased by a finite value of α_B . According to Ohshimo (1996), the concentration of anchovies diminishes with distance from spawning grounds, and is smaller at the latter site than at Qiu *et al.*'s site (but is not equal to zero as Fig. 1 suggests).

Table I provides a comparison of inverted geo-acoustic parameters at 1.35 kHz, based on results shown in Figs. 7–10, and previously published measurements discussed above. Both 2- and 3-dB bounds are provided for consideration. The historical estimates of c_p are based on Dahl *et al.*'s and Rogers *et al.*'s measurements in "silty sand" (the bottom at Qiu *et al.*'s site consists of "silty sand"). The historical estimate of α_p is based on the analytical extrapolation between Dahl *et al.*'s and Rogers *et al.*'s measurements at

TABLE I. Comparison of inverted and other estimates of bio- and geo-acoustic parameters at 1.35 kHz. The -2 - and -3 -dB bounds on inverted values of d , t , c_p , and α_p are based on contours shown in Figs. 7–10, respectively.

	-3 dB	-2 dB	“Truth”
d (m)	6.6–7.0	6.7–6.9	5.8 ± 1 [Eq. (5)]
t (m)	0.0–0.8	0.3–0.6	< 1 m [Eq. (9)]
c_p (km/s)	1.58– >1.72	1.58–1.68	$1.56^a, 1.59^b$
α_p (dB/ λ)	0.03–0.5	0.22–0.32	$0.10 \pm 0.05^{a-d}$

low frequencies and LeBlanc *et al.*'s and Turgut *et al.*'s calculations for “sand” and “silt.” Inverted values of c_p and α_p are consistent with these estimates. Table I also provides a comparison of inverted and calculated bio-acoustic parameters, which will be discussed in the next section.

IX. BIO-ACOUSTIC PARAMETERS

The purpose of this section is to compare inverted values of bio-acoustic parameters with previously reported measurements. The depth of the absorption layer, 6.9 ± 0.3 m, was consistent with theoretical calculations of the depth (5.8 ± 1 m) of 10-cm-long anchovies, the dominant species in the Yellow Sea, and with the extrapolated value of the measured resonance frequencies of anchovies in the laboratory; the inverted layer thickness, 0.3 ± 0.2 m, was consistent with measurements of the Q of this absorption line. It is noteworthy that this value of t is also consistent with the nominal thickness of “thin” layers of phyto and zooplankton on continental shelves, which tend to occur when wind speeds are low (Cowles, 1998). The wind speed during Qiu *et al.*'s experiment was about 10 knots.

The inverted value of α_B is consistent with photographic measurements (Aoki and Inagaki, 1988) of the average separation between adult anchovies at night, viz., s equals 10 ± 2 L. Substitution of $\alpha_B = 0.1$ nepers/m, $r = 0.0034$ m, $\lambda_0 = 1.11$ m, and $Q = 2.7$ into Eq. (6) results in n equal to $9.8/\text{m}^3$. This value of n corresponds to s equal to 47 cm, which equals 4.3 L. This estimate assumes that the layer thickness was 0.3 m. If the layer thickness was actually 0.8 m (the upper 3 dB bound on t , shown in Fig. 8), then the n would have equaled $3.7/\text{m}^3$, and s would have equaled 6 L. The latter is in good agreement with Aoki and Inagaki's data.

The inverted value of α_B is significantly higher than historical measurements of the number density of anchovies in the Yellow Sea. Multiplying n by t (0.3 m) results in n_A (the spatial density) equal to $3/\text{m}^2$. The uncertainty in this estimate, approximately $\pm 1/\text{m}^2$, is driven primarily by the uncertainties in Q and α_B (both are approximately $\pm 20\%$). This estimate can be compared with Ohshimo's (1996) estimate of the *average value* of this parameter ($0.6/\text{m}^2$) in the central region of the southern Yellow Sea and the central region of the northern East China Sea in May and June. Ohshimo's measurements show that n_A increases with proximity to the spawning grounds off China, qualitatively consistent with spatial distributions shown in Fig. 1. Further-

more, n_A in the vicinity of eddy-associated “habitats” can be much larger (by a factor of about 4) than average values. Consequently, the actual number density in the vicinity of Qiu *et al.*'s site may have been significantly greater than the average value in the Yellow Sea. In addition, actual *average* number densities in the Yellow Sea may have been higher than Ohshimo's estimates by a factor of about 2, due to his neglect of the depth dependence of target strength, avoidance, and attenuation due to near surface bubbles (Diachok *et al.*, 2001).

X. UNCERTAINTY OF INVERTED PARAMETERS

We consider the inversion at 1.35 kHz as “valid,” because the inverted bio and geo-acoustic parameters were consistent with previously reported estimates. In contrast, we consider the inversion at 1 kHz “not valid,” because the value of Δ , 3.5 dB, is too high; we also consider the inversion at 2 kHz “not valid” because the inverted value of c_p is much greater than previously reported estimates.

Knobles *et al.* (2003) provide a good description of the sources of uncertainty associated with inversion of geo-acoustic parameters from transmission loss data in shallow water. The uncertainty associated with the validity of the assumed geo-acoustic model is one of the primary determinants of the uncertainty in estimated geo-acoustic parameters. Inversion methods can provide valid estimates of environmental parameters, provided that the environmental model and its associated search space provide a “sufficiently realistic” representation of the environment. The success of this method at 1.35 kHz suggests that the inversion at this frequency was conducted in the context of “sufficiently realistic” bio and geo-acoustic models. In contrast, inversion calculations at higher and lower frequencies were not successful, which suggests that the assumed geo-acoustic model was probably not “sufficiently realistic.” Hypothetically, the lower values of α_B at the higher and lower frequencies resulted in a larger amount of energy in high-order modes, which are more sensitive to the details of subbottom structure (layering, gradients, roughness at interfaces, etc.). This suggests the need for a more complex geo-acoustic model and a larger number of parameters in the search space when α_B is small.

Perhaps a thin transition layer overlying a higher sound speed, lower α_p , as postulated by Zhou *et al.* (1987) and Dahl *et al.* (1998), may have provided a more realistic geo-acoustic model. Or, there may have been two or three or n distinct layers. To preclude model-associated uncertainties, experiments designed to measure effects of bio and geo-alpha on TL should include (1) co-located geo-acoustic measurements, viz., chirp sonar, *in situ* probes and/or cores, to facilitate formulation of a realistic model of subbottom structure, and (2) coincident fisheries echo sounders and direct sampling of fish (trawling, purse seining) to facilitate formulation of a realistic geometrical model of bio-absorption layers.

The uncertainty in source levels of shots is about 2 dB; this places a lower bound on Δ . In addition, temporal and spatial fluctuations in sound speed due to internal waves result in stochastic mode coupling of propagated signals,

which affects the accuracy of predicted replica fields. Furthermore, there is an uncertainty in the depth of the measurement site, and the depths of sources and receivers. An additional small, but possibly significant, source of uncertainty is the accuracy of the propagation model. As a result of these uncertainties, there is no universally accepted formula for calculating the uncertainty of inverted parameters, even when the assumed geo-acoustic model may be considered a valid representation of the environment.

XI. CONCLUSIONS

In summary, inversion calculations at the resonance frequency of anchovies, which assumed that attenuation was due to a combination of bio and geo-alpha, resulted in acceptable values of Δ and realistic values of bio and geo-acoustic parameters, whereas calculations which assumed that all excess attenuation was due to the bottom resulted in unacceptably large values of Δ and unrealistic values of α_p . These calculations assumed relatively simple bio and geo-acoustic models, viz., a biological layer with unknown depth, thickness, and bio-alpha, and a sediment layer with unknown interfacial sound speed, subbottom gradient, and geo-alpha. Inversion at the resonance frequency, where bio-alpha was large, was successful *despite the simplicity of these models*, whereas inversions at higher and lower frequencies, where bio-alpha was small, were not fully successful, hypothetically because of shortcomings of the geo-acoustic model.

The scientifically most important result of this exercise was that we correctly inverted the depth, thickness, and number density of the bio-layer at 1.35 kHz. Inversion of layer depth offers hope of classification of bio-absorption lines based on their depth, an alternative to classification of bio-absorption lines by changes in resonance frequencies at twilight (Diachok, 1999). This is important since the juveniles of most species, and many physoclists, do not undergo significant vertical migration at twilight.

Concurrent inversion of geo-acoustic parameters was a prerequisite for establishing credibility of inverted bio-acoustic parameters. The high sensitivity of this method to uncertainties in geo-acoustic parameters, when bio-alpha is small (or zero), suggests that future bio-absorptivity experiments incorporate independent measurements of geo-acoustic parameters. To minimize effects of internal waves on stochastic mode coupling, experiments should be conducted at shorter ranges.

ACKNOWLEDGMENTS

This work was supported by the Office of Naval Research Biology and Acoustics Programs and the Naval Research Laboratory (NRL). The authors would like to thank Dr. X. Qiu, formerly of the Shanghai Acoustics Laboratory, Shanghai, China, for providing information about environmental conditions during his experiment and for his permission to reproduce two of his figures. The authors would also like to thank Dr. Tom Hayward and Dr. T. C. Yang of NRL, and Dave Harvey and Allen Lowrie of the Naval Oceanographic Office, for reviewing the manuscript, and Dr. Marshall Orr, Head of the Signal Processing Branch, Dr. Ed

Franchi, Superintendent of the Acoustics Division, and Dr. Eric Hartwig, Associate Technical Director of NRL, for their support and encouragement. O.D. would like to thank Dr. Paul Smith of the Southwest Fisheries Science Center, National Marine Fisheries Service, and Dr. Van Holliday of BAE SYSTEMS Corp. for many helpful discussions. We would also like to thank the formal reviewers, who provided insightful critiques and helpful suggestions.

(Received 22 August 2003; revised 6 August 2004; accepted 7 August 2004)

An active sonar system is used to image wide areas of the continental shelf environment by long-range echo sounding at low frequency. The bistatic system, deployed in the STRATAFORM area south of Long Island in April–May of 2001, imaged a large number of prominent clutter events over ranges spanning tens of kilometers in near real time. Roughly 3000 waveforms were transmitted into the water column. Wide-area acoustic images of the ocean environment were generated in near real time for each transmission. Between roughly 10 to more than 100 discrete and localized scatterers were registered for each image. This amounts to a total of at least 30 000 scattering events that could be confused with those from submerged vehicles over the period of the experiment. Bathymetric relief in the STRATAFORM area is extremely benign, with slopes typically less than 0.5° according to high resolution (30 m sampled) bathymetric data. Most of the clutter occurs in regions where the bathymetry is locally level and does not coregister with seafloor features. No statistically significant difference is found in the frequency of occurrence per unit area of repeatable clutter inside versus outside of areas occupied by subsurface river channels. © 2005 Acoustical Society of America. I. INTRODUCTION

A long-range bistatic sonar system was used to rapidly image wide areas of the New Jersey continental shelf environment south of Long Island in a field experiment from 27 April to 5 May 2001.¹ The system consisted of a horizontally towed receiving array and two low-frequency vertical source arrays. Source signals were transmitted over long ranges to image scatterers up to tens of kilometers away. Waveguide scattering^{2–6} and propagation⁷ determine the performance of this remote sensing technology.

The field experiment, known as the 2001 Acoustic Clutter Reconnaissance Experiment (ACRE),¹ is a part of the U.S. Office of Naval Research Shallow Water Acoustic Clutter Program. The main objectives of the Program are to (1)

determine the spatial and temporal variability of clutter in long range active sonar in continental shelf environments with generally low bathymetric relief, (2) identify the dominant sources of clutter, (3) understand the physical mechanisms that lead to these prominent returns, and (4) analyze the bistatic scattering characteristics of these dominant sources. In this context, clutter refers to scattering from objects in the environment that stand prominently above the diffuse and temporally decaying reverberation background that can camouflage or be confused with the returns from an intended target.

Another purpose of ACRE was to test the possibility of using low-frequency active sonar systems to rapidly image subseafloor geomorphology over wide areas in shallow water. In deep water, several remote sensing experiments have consistently and repeatedly observed strong and deterministic clutter return from lineated ridges and scarps on seamounts.^{8–11} It was found that the level of the clutter is

FIG. 1. Location of the East Coast STRATAFORM area off the New Jersey coast. Contours in meters.

proportional to the projected area of the scarp along the path from target to bistatic source and receiver.^{8–10} Attempting to draw an analogy with the deep water results, a number of investigators, for example in Ref. 12, proposed subseafloor geomorphology, which exists throughout the continental shelf, to be potential source for anomalous sonar returns in areas of level bathymetry in shallow water.

The New Jersey STRATAFORM¹³ site, shown in Fig. 1, was well-suited for ACRE because a number of substantial geophysical surveys^{14–16} have previously characterized seafloor and subbottom features over wide areas. Furthermore, several other acoustic experiments have been conducted in this area to investigate acoustic propagation conditions¹⁷ and to invert for seabottom properties.^{18,19} Data from the geophysical surveys are used here to identify natural features of the seafloor and subseafloor that might possibly be imaged by our remote acoustic sensing system.

During the ACRE, two research vessels were used to acquire both monostatic and bistatic scattering data. Roughly 3000 waveforms were transmitted into the water column from vertical source arrays in the 390- to 440-Hz band and received by a horizontal towed array. A wide-area acoustic intensity map (image) of the environment was generated for each transmission. On average from 10 to 100 discrete and localized scattering events were registered per transmission. From a clutter perspective, this gives a total of at least 30 000 scattering events that could be confused with that from a large submerged vehicle over the period of the experiment. Two acoustic targets,^{1,20} essentially cylindrical air-filled elastic tubes approximately 30 m long, with known scattering properties and locations were vertically deployed and used to calibrate returns and confirm theories about waveguide scattering from extended objects and long-range imaging in continental shelf environments.

In this paper, wide-area acoustic images from the ACRE are presented to illustrate the prominent and discrete scattering events measured in the New Jersey continental shelf en-

vironment. Returns that coincide with the location of the calibrated targets are evident in the images indicating our ability to accurately chart the returns in both space and time. Most of the charted clutter were found to occur in regions where the bathymetry is locally level and do not coregister with any known geologic features of the seafloor. Some of the charted clutter appears to occasionally correspond with buried river channels identified from geophysical surveys. However, statistical analysis of the clutter in regions where the subbottom geomorphology has been mapped shows that there is no significant difference between the frequency of occurrence per unit area of repeatable clutter events that chart within areas occupied by buried river channels and those that chart outside of areas occupied by channels.

In Sec. II, we provide a description of the New Jersey STRATAFORM area geology and a detailed description of the ACRE. In Sec. III, we explain how long-range acoustic data are processed to generate wide-area images. Images showing the charted clutter and returns from the calibrated targets are presented in Sec. IV. Possible mechanisms for the clutter returns are discussed in Sec. V. Oceanographic data collected during the experiment, such as sound speed structure, are presented in the appendix.

II. DESIGN AND IMPLEMENTATION OF THE ACRE

Prior to the ACRE, a number of geophysical surveys^{14–16} at the New Jersey STRATAFORM site characterized the seafloor and subbottom features over wide areas. Figure 2 shows the water depth at the STRATAFORM site where bathymetric data are available at 30 m horizontal resolution.¹⁵ Seabed and subbottom features identified from the geophysical surveys are overlain on the bathymetry. The candidate features for prominent scattering include incised or buried river channels, relict iceberg scours and surface erosional features on the seafloor, and surface or near surface outcroppings of seismically reflective subsurface strata within the seabed. Figure 3 shows an interpretation of a seismic profile from Ref. 14 of several river channels buried at different depths from the seafloor intersecting with various sub-bottom strata. Apart from these geologic features, aggregates of compact scatterers such as gravel deposits on the seafloor, gas pockets in the seabed, and large and densely populated schools of fish are also possible sources of clutter.

Figure 4 shows the directional derivative (DD) of bathymetry at the STRATAFORM area. The DD is defined in Ref. 21 as the dot product of the gradient of bathymetry with the horizontal unit vector pointing in the direction of an observation point. In Fig. 4, the DD is plotted for an observation point to the north of the STRATAFORM area. Seafloor surfaces facing the observation point have positive DD, surfaces facing away have negative DD, and level surfaces have zero DD. Inspection of Fig. 4 shows that the experiment site has mostly benign slopes of less than 0.5° with few discrete features on the seafloor. Even the seafloor features that are noticeable, such as the iceberg scours and erosion pits, have small slopes typically $<3^\circ$. Their vertical relief is typically smaller than the acoustic wavelength of roughly 4 m in this experiment.

In both Figs. 2 and 4, the subbottom features shown are based on interpretations of geophysical data acquired *prior* to the ACRE 2001. The areas where the subsurface features are shown are the only areas where the subbottom data had been acquired and analyzed prior to the ACRE 2001. There may be other subsurface features elsewhere in the figure, but the geophysical data had either not been collected in those areas or had not been analyzed prior to the experiment. The most current geophysical interpretations of the subsurface features is provided and used in our analysis of the measured clutter in Sec. IV.

The experiment was conducted using the Research Vessel (RV) *Endeavor* and the NATO Research Vessel (NRV) *Alliance* (Fig. 5). RV *Endeavor* was used mainly as a source ship for bistatic measurements. It deployed a source system used by the Multistatic ASW Capability Enhancement Program (MACE) consisting of a seven-element array of uniformly spaced XF-4 transducers, beamed to transmit at broadside during the whole experiment. RV *Endeavor* was fastened to moorings at three sites where a fixed transmission location was maintained for the bistatic measurements. NRV *Alliance* was the only ship that deployed a horizontal receiving array. It also deployed a two-element MOD40 transducer source system that was towed for quasi-monostatic measurements. A nominal tow speed of 2 m/s was maintained throughout the measurements by NRV *Alliance*. The horizontal receiving array was a 256-element line array with three nested apertures, each consisting of 128 sensor elements evenly spaced at 0.5, 1, or 2 m, respectively. Only data from 128 elements at 1-m spacing are analyzed in this paper. For a sound speed of 1500 m/s, this subaperture corresponds to an array cut for 750 Hz. Each of the two calibrated targets,^{1,20} deployed at a selected site, were moored to the bottom in waters approximately 80 m deep, 18 m off the seafloor. They stood vertically in the water column spanning roughly 32- to 62-m depth from their own buoyancy.

The tracks traversed by NRV *Alliance*, mooring locations of RV *Endeavor*, and locations of the two calibrated targets and subbottom features are also plotted in Fig. 4. Acoustic transmissions were centered about three distinct sites of the STRATAFORM area identified as sites 1, 2, and 3. The water depth at the three sites ranged from approximately 70 to 130 m. At site 1, the tracks of NRV *Alliance* and the source location for RV *Endeavor* were designed to image the buried river channels and shallow subsurface reflectors truncated at the seafloor.^{14,15} At site 2, the erosion pits on the seafloor and the subsurface reflectors, as well as the calibrated targets, were the focus of the measurement. The tracks at site 3 were designed to image the iceberg scours and more subsurface reflectors and to obtain scattered returns from the Hudson Canyon walls. The large number of tracks at each site was necessary to study the range and azimuth dependence of the scattering and to distinguish returns from the various candidate clutter targets at a variety of ranges and azimuths. The numerous tracks also served to help break the ambiguity inherent in line array measurements.

The sources transmitted both linear frequency modulated (LFM) and sinusoids or “continuous wave” (CW) signals of varying duration in the frequency range from 390 to

440 Hz.¹ For the bistatic transmissions by RV *Endeavor*, the LFM signals were shaded with a Tukey window while the CW signals were shaded with a Hann window. For the quasi-monostatic transmissions by RV *Alliance*, a rectangular window was used in all transmissions for both the LFM and CW signals. The length of each NRV *Alliance* track line is roughly 10 km and the waveforms were transmitted at every 50- or 100-s interval. With a speed of 2 m/s for the receiver ship, data from a total of roughly 50 or 100 transmissions were measured along each track.

III. WIDE-AREA IMAGES OF THE OCEAN ENVIRONMENT

A. Generating images in near-real-time

During the ACRE, a wide-area image of received sound pressure level as a function of horizontal position over tens of kilometers was generated for every transmission (ping) in near-real-time. For a given transmission, two-way travel time was used to determine the range of returns and beamforming to determine the azimuth. The process has been previously described in Refs. 8, 21, and 11. It follows the same principles used in high-frequency side-scan sonar, medical ultrasound, and radar image processing except that the present imaging process involves the complexities of multipath propagation, waveguide scattering, and dispersion.

In this paper, echo returns from mono- and bistatic LFM transmissions of varying duration measured with NRV *Alliance*'s horizontal line array with 128 elements at 1-m spacing are analyzed. The raw time series data for each hydrophone were filtered, demodulated, and decimated. This decimated array data were then converted to beam-time data by time-domain beamforming. The sharpest cross-range resolution is at broadside, where the signals arrive almost perpendicular to the array axis. The broadest cross-range resolution is near endfire, where the signals arrive almost parallel to the array axis.

A Hanning spatial window function was applied in the beamforming to reduce sidelobe levels where the first sidelobe level is down 30 dB from the main lobe. This was important for reducing sidelobe leakage from radiated noise present in beams containing the source ship which was moored near the features to be imaged. Following Eqs. (1) and (2) of Ref. 21, the 3-dB beamwidth β of the array is approximated using

$$\beta(\varphi) \approx 1.3 \frac{\lambda}{L \cos \varphi}, \quad (1)$$

for steering angles from broadside $\varphi=0$ to a transition angle φ_t near endfire, $\varphi=\pi/2$, where λ is the wavelength and L is the array length. As φ approaches φ_t , ambiguous beamwidths each reach a value approximately equal to that at endfire, and begin to merge until they completely overlap at endfire where the beamwidth is

$$\beta(\varphi = \pi/2) \approx 2.8 \sqrt{\lambda/L}. \quad (2)$$

For the array aperture of 127 m, the optimal 3-dB resolution is about 2.1° at broadside and 27° at endfire. This corresponds to a cross-range resolution $\Delta\rho=\rho\beta$ of 364 m at

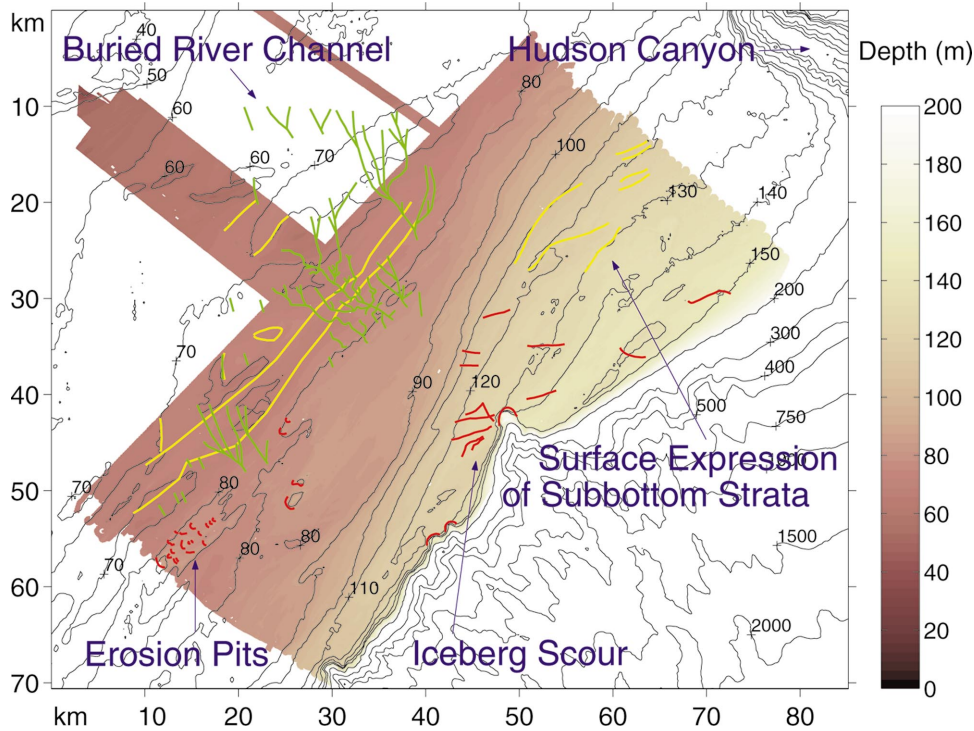

FIG. 2. Bathymetry of the STRATAFORM area with shaded region sampled at 30-m interval. Candidate features identified from previous geophysical surveys^{14,15} that might give prominent and coherent scattered returns include incised or buried river channels (green), relict iceberg scours and erosion pits on the seafloor (red), and surface or near-surface expression of seismically reflective subsurface strata within the seabed (yellow). Coordinates of x and y axis origin in the north-west corner: $39^{\circ} 31.00'N$, $73^{\circ} 17.28'W$.

FIG. 3. Interpreted seismic line, adapted from Ref. 14, showing the shallow stratigraphy within site 1. The figure shows numerous buried river channels intersected by highly reflective subbottom strata. One of these subbottom strata is called an R-reflector.

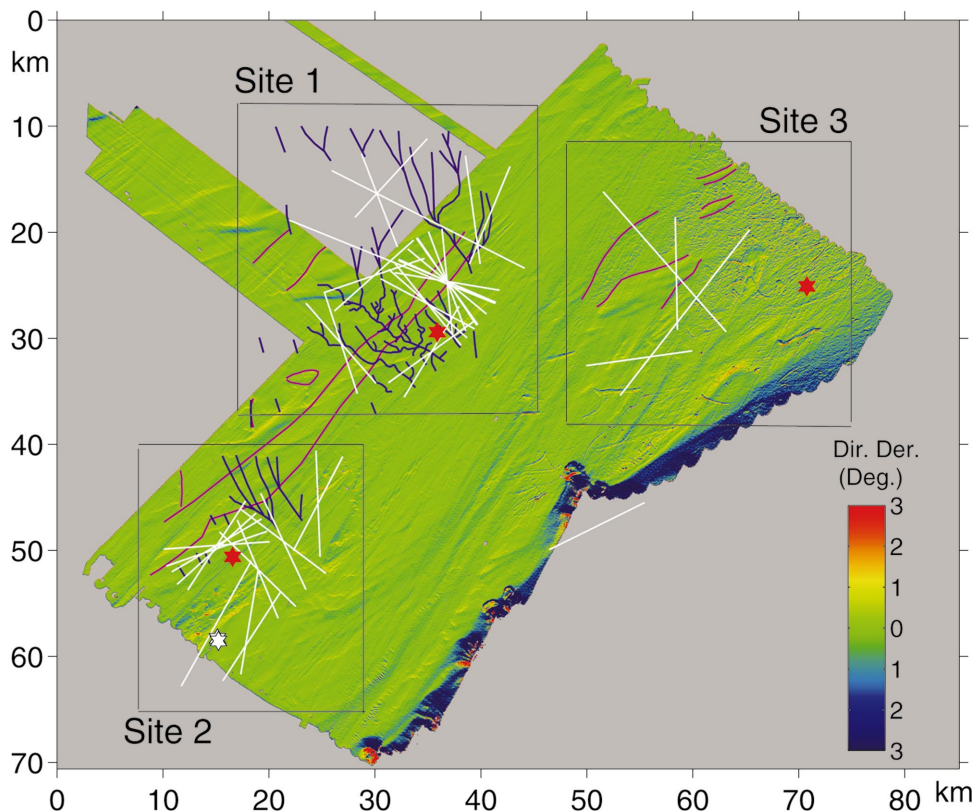

FIG. 4. Directional derivative of the 30-m sampled bathymetry at the STRATAFORM site with respect to a source far in the north. The seafloor is mostly level locally with slopes of $<1/2^{\circ}$. There are very few discrete features such as iceberg scours and erosion pits on the seafloor with slopes of at most 3° . Acoustic transmissions were centered about three distinct sites in the STRATAFORM area. Overlain are the tracks traversed by NRV Alliance (white lines), mooring locations of RV Endeavor (red stars), location of the two calibrated targets (white stars), and subbottom features (blue and pink lines). Coordinates of x and y axis origin in the north-west corner: $39^{\circ} 31.00'N$, $73^{\circ} 17.28'W$.

FIG. 5. A sketch of NRV Alliance towing a two-element vertical source array at 1.875-m spacing and a 256-element horizontal receiving array with spacing between elements of 0.5, 1, and 2 m. Only data from 128 elements of the receiving array at 1-m spacing are analyzed in this paper. The mean depth of the NRV Alliance two-element source was varied between 23 and 65 m. The mean depth of the receiver array was varied from 22 to 68 m. RV Endeavor was moored at each site where measurements were collected and it deployed the MACE source system consisting of a 7-element array spaced at 1.625 m. The mean depth of the MACE source was varied between 35 and 84 m and it was beamed to transmit at broadside throughout the experiment. The water depth at the three measurement sites ranged from approximately 70 to 130 m.

broadside and of 4.7 km at endfire at a range of $\rho=10$ km, which is a typical range for detecting the clutter events during the experiment.

The beam-time data are linearly converted to beam-range data by multiplying the total two-way travel time with half the mean sound speed c which was taken to be 1475 m/s based on measured sound speed in the water column (see Appendix A). To improve on the range resolution and signal-to-additive-noise ratio, the LFM data from 390 to 440 Hz were match filtered with a replica of the source signal to give an effective range resolution of $c/2B \approx 15$ m, where the bandwidth B is 50 Hz. The data were then averaged to 30 m resolution and then mapped to a Cartesian grid with the same 30×30 m² grid increment as the high resolution bathymetry data used. The mapping procedure accounts for beam overlap by an incoherent averaging of adjacent beams.²²

Multi-modal propagation in a shallow water waveguide leads to time spread and delay in the mean arrival time of signals. This dispersion effect is a result of the differing modes of the waveguide propagating the acoustic energy with varying group velocities, and is highly dependent upon the waveguide properties. It also varies as a function of range and depth due to modal interference which causes a change in the spatial and temporal structure of the signal. Simulations in various shallow water waveguides in Ref. 23 show that the error in charting returns from objects in the water column is about 200 m for the ranges relevant to this study after match filtering with the source signal. Charting error varies with the sound speed used to convert travel time to range. The charting error of 200 m is for a sound speed that corresponds to the minimum sound speed in the water column. This sound speed was found to provide the smallest errors in localizing a source or target in the water column.

During the experiment, fluctuations on the order of $\pm 3^\circ$ were observed in the towed array heading sensor measure-

ments. At site 2, the GPS positioning of the calibrated targets relative to the source and receiver was used to provide a more accurate mean orientation of the receiver array for each track. The corrections needed for each track, however, were small, approximately 0° to 4° . Since no calibrated targets were present at sites 1 and 3, no corrections were applied to those images.

The standard deviation of a pixel value or an average of stationary pixel values in an acoustic image is now estimated.⁸ We assume that the transmitted waveform's interaction with the seafloor scattering area completely randomizes the return such that the real and imaginary temporal components of the instantaneous scattered field are identically distributed and uncorrelated zero-mean Gaussian random variables. The instantaneous intensity of the return is then exponentially distributed and the time-averaged intensity is gamma distributed²⁴ with degrees of freedom μ corresponding to the time-bandwidth product TB of the scattered field,²⁵ where T is the measurement time. This product is an approximate measure of the number of independent and instantaneous intensity fluctuations averaged over T . If the reverberation level in dB *re* 1 μ Pa for a given pixel in the acoustic image is $R=10 \log$ (mean square pressure), the standard deviation σ of the reverberation level in dB is^{8,25}

$$\sigma(\mu) = 10(\log e) \sqrt{\zeta(2, \mu)}, \quad (3)$$

where

$$\zeta(\nu, \mu) = \sum_{k=0}^{\infty} \frac{1}{(\mu+k)^\nu}, \quad \text{for } \nu > 1, \quad \mu \neq 0, -1, -2, -3, \dots, \quad (4)$$

is the Riemann's zeta function. For an instantaneous intensity measurement, $\mu=1$ and $\sigma(1) \approx 5.6$ dB. To reduce the standard deviation to 3 dB which is relatively negligible compared to the dynamic range of the levels spanned in the images produced in this experiment, an averaging time of $T=0.04$ s is used. This corresponds to $\mu=2.0$ for the $B=50$ Hz bandwidth LFM transmissions analyzed in this paper. Stationary averaging of adjacent pixels would lead to a smaller standard deviation according to Eqs. (3) and (4), but will also reduce the spatial resolution. (We ignore averaging of overlapping beams because the measurements are not independent.) The prominent returns typically stand above the background reverberation by tens of decibels (many standard deviations) and are therefore considered to be deterministic.

B. Interpreting images generated with low frequency and long range towed array sonar

Figure 6 shows a wide-area image of the ocean environment at site 2 obtained from a single bistatic transmission with the receiver ship NRV Alliance oriented along track 17. The origin of the range axis along the x and y directions in the figure is at $39^\circ 31.00'N$, $73^\circ 17.28'W$. This origin is at the north-west corner of the images in Figs. 2 and 4. This fixed location for the range origin will be used for all acoustic intensity images presented in this paper. The array heading is measured with respect to true north increasing in a clockwise direction. The image shows both the diffuse back-

FIG. 6. A single-ping bistatic wide-area image along track 17 at site 2. Travel time to range conversions are done by multiplying the two-way travel time with half the mean sound speed of 1475 m/s. All returns are mirrored about the array axis (71° with respect to true north) due to left-right ambiguity. Two prominent and discrete scattering events >20 dB above the background co-register well with the location of the calibrated targets approximately 8.5 km to the south. Numerous other prominent scattering events (clutter features) that can be confused with returns from the calibrated targets are present in the image. Comparison with Fig. 8 breaks the receiver line array's left-right ambiguity and places the true location of these clutter features to the south within the dotted white trapezoid. (Date: 1 May, ping time: 13:04:30Z, transmission: 1-s duration LFM from 390 to 440 Hz, mean source depth: 55 m, mean receiver depth: 42 m, array heading: 71° .)

FIG. 7. Hotspot consistency chart from 49 bistatic LFM transmissions along track 17. The figure displays the number of images that register a strong scattering event >10 dB above the local average within 1.8×1.8 km² area of a given pixel location. Scattering events within the trapezoid as well as those from the calibrated targets are consistently prominent in most of the wide-area single ping images along track 17. Events within the trapezoid can either be confused with or camouflage those from the calibrated targets. (Date: 1 May, time: 12:37:00Z to 14:01:00Z, mean source depth: 55 m, mean receiver depth: 42 m, array heading: 71° .)

ground reverberation level in decibels from the ocean environment as well as strong scattered returns from the calibrated targets and other submerged objects or features. For each transmission, the signal first measured by the receiving array is that arriving directly from the source. This direct arrival is strong and gives rise to the blast-out region which appears as a red ellipse surrounding the source and the receiver in Fig. 6. The diffuse background reverberation scattered from random rough patches of the ocean environment, as well as the returns from the calibrated targets and other submerged objects or features arrive after the direct signal has passed. This environmental reverberation has a mean intensity that decays with range due to spreading and absorption loss in the waveguide. The rate of decay depends on the properties of the waveguide, such as the sound speed structure, attenuation in the water column and bottom, and surface and bottom inhomogeneities, as well as the measurement geometry. The decay in the reverberation provides vital information about the environment needed to model propagation and diffuse scattering. In Fig. 6, we do not average out the trend in the data since it would eliminate this vital information.

A horizontal line array has left–right ambiguity about the array axis that is expressed differently in monostatic and bistatic charts. Prominent returns are ambiguously charted nearly symmetrically about the receiving array axis in monostatic geometries. For bistatic geometry, ambiguity occurs on an ellipse with a major axis that passes through the source and receiver. A diagram illustrating the two-way travel time ellipse for bistatic measurements is provided in Ref. 9, where it is shown that distortion in the image may occur as the ambiguous returns are charted to either a smaller or broader spatial extent. The methods used in this paper to resolve the left–right ambiguity in the measurements are discussed further in Sec. III D. In Fig. 6, the left–right ambiguity is mapped onto ellipses at close ranges to the bistatic source and receiving array. At ranges larger than the source–receiver separation, the ambiguity about the array axis approaches circular symmetry.

During the ACRE, few monostatic measurements were made in comparison to the bistatic measurements because the monostatic source was weaker. As a result, we were not able to image very far out in range with the monostatic source. The rough maximum range before the acoustic imaging system became noise limited was on the order of 10 km for the monostatic source. For the bistatic source, this range was more than 50 km away from the source. Most of the images illustrated in this paper are from bistatic measurements.

C. Hotspot repeatability chart

In order to measure the frequency of occurrence of a strong scattering event from a target or feature along a given track, we generate a hotspot consistency chart for each track. First, a moving local peak detector is applied to a single wide-area image to detect pixels where the reverberation level stands more than 10 dB above the average for a $1.8 \times 1.8 \text{ km}^2$ subimage. These pixels are assigned a value of 1 and all others 0. Pixels in the blast-out region are assigned a

value of 0, since we are only interested in detecting targets and features in the environment. This binary matrix from each reverberation image is then summed for all the images along a track to form the hotspot consistency chart for each track. The hotspot repeatability chart for track 17 is shown in Fig. 7. A total of 49 bistatic acoustic images are combined to form this composite. In Fig. 7, a given pixel shows the number of images that register a strong scattering event $>10 \text{ dB}$ above the local average within $1.8 \times 1.8 \text{ km}^2$ area of the pixel. The maximum of the legend in each hotspot repeatability chart is the maximum clutter repeatability in the given image.

The standard deviation²⁵ for the time-averaged diffuse reverberation is 3 dB as shown in Sec. III A. The local peak detector algorithm thus picks out pixels with levels that are about three standard deviations above the local mean within each subimage. Both scattered returns from fixed targets and diffuse background reverberation decay with range due to spreading and absorption loss. A globally fixed threshold detector is only useful if the decaying trend of the reverberation can be accurately removed before the detector is applied. It is usually difficult to detrend measured data accurately given the lack of *a priori* environmental information needed to model the trend. Our local peak detector takes the range decay into account empirically. It is also independent of the strength of the source, making it versatile and easy to implement.

We combine information contained in wide-area images acquired along a single track to form the hotspot consistency chart for the given track. This chart is found to be extremely useful in picking out strong and persistent echos as well as in resolving ambiguity in measurements along a single track as will be discussed in Secs. III D and IV. A hotspot consistency chart combining information from multiple track lines should be used with caution. Our attempts at combining data from all the tracks at a given site by forming an overall hotspot chart for the site were found to lead to confusion in identifying actual returns. This is because the many tracks at a given site have varying array headings and the same scatterers often do not appear on different tracks, making it impossible to resolve ambiguity by such a combination. Even when the same scatterers do appear on differing tracks the combination does not significantly reduce ambiguity but rather leads to multiple ambiguities that often mask true features as noted in Ref. 22.

D. Ambiguity resolution

Two methods are employed in the present analysis to resolve the left–right ambiguity in the returns from the horizontal line array. The first method involves comparing events from images obtained on tracks that have approximately similar location but where the array orientation differs.⁸ In these tracks, the true returns will be consistently charted to the same location, while the ambiguous ones will be charted to different locations.

The second method resolves the ambiguity for measurements made along a single track with the use of the hotspot consistency chart for the track. This method is applicable in bistatic scenarios when the range to the feature is not much

larger than the source–receiver separation. It exploits the elliptical shape of the travel time locus to break the ambiguity in the line array measurement.

These two methods for ambiguity resolution will be pointed out in the images in Sec. IV.

IV. LONG RANGE ACOUSTIC IMAGING RESULTS

In this section we present the major experimental findings of the ACRE 2001. Roughly 3000 waveforms were transmitted into the water column and wide-area image of the reverberation from the ocean environment was generated in near-real-time for each transmission. From 10 to more than 100 discrete and localized clutter events (10 dB above the background) were registered for each image. This gives a total of at least 30 000 scattering events that could be confused with that from a large submerged vehicle over the period of the experiment. The vast majority of prominent and discrete scattering events appear in areas where the bathymetry is locally flat or with slopes less than 0.5° . This implies that these returns most probably do not originate from the seafloor and that they could be due to objects in the water column or possibly features in the subbottom.

In the following three subsections, individual ping and hotspot consistency images from various tracks at the three sites are shown. The clutter in these images is representative of the scattering events measured at each site. We begin our discussion with site 2 where the calibrated targets were deployed.

A. Site 2 with calibrated targets

In this section, we present wide-area images showing strong and discrete returns from the calibrated targets deployed in the waveguide at site 2. These images, which were acquired during the middle of the experiment, also show an organized pattern of prominent scattering events in a region of effectively flat bathymetry (slopes less than 0.5°), with water depths from 80 to 100 m, where the subbottom had not been well profiled. Subsequent geophysical surveys, specifically designed to explore the subbottom in the vicinity of these prominent scattering events at site 2, discovered a network of buried river channels.^{26,27} Most of the prominent scattering events, however, did not coregister with the newly discovered river channels. The measurements at site 2 were repeated about 4 days later at the end of the experiment along tracks with nearly similar range and bistatic location for the track center, but with varying orientation. These measurements found the clutter events at site 2 to be highly variable across the tracks, all of which had differing headings. Since there was a 2-h time period for the data collection on each track, the clutter could also have evolved with time. A statistical analysis of the spatial distribution of repeatable clutter is given in Sec. IV A 2 to determine if the repeatable clutter favors any particular spatial location.

In Fig. 6, which shows a wide-area image from track 17 at site 2, we observe two prominent scattering events approximately 8.5 km away to the south of the source and receiving array that register well with the calibrated targets. These events stand out by more than 20 dB above the reverberation in surrounding areas. This difference is much larger

than the received level standard deviation of 3 dB (shown in Sec. III A). The receiving line array has left–right ambiguity about the array axis. We therefore see the ambiguous returns from the calibrated targets charted to the west in Fig. 6.

We observe numerous other prominent and discrete scattering events in the image shown in Fig. 6. Many of these features are just as prominent as the calibrated targets, standing out by more than 20 dB above the reverberation in surrounding areas. These features can be confused with or camouflage the calibrated targets if the precise location of the targets are unknown.

To identify where the clutter originates, we break the receiving array's ambiguity by comparing Fig. 6 with Fig. 8, a bistatic transmission along track 14 which is at a similar range but slightly different orientation than track 17. In both Figs. 6 and 8, we observe consistently strong and prominent events within the trapezoid to the south of the source and receiving array. This shows that the region with the trapezoid is the true location of the clutter. The ambiguous events are charted to the west in both figures and are not in the same location. The differing array orientation in tracks 14 and 17 causes the false returns of the features to be charted to different regions.

To examine the repeatability of the prominent scattering events within the trapezoid as well as those from the calibrated targets, a hotspot consistency chart, as described in Sec. III C, is derived for track 17 and shown in Fig. 7. From Fig. 7, we observe that scattering events from the calibrated targets are repeatedly prominent as the receiver ship moves along the track. They appear as a local maxima in most of the 49 images along the track. The scattering events within the trapezoid in Fig. 7 are also prominent and repeatable. They appear in most of the charts with levels >10 dB above the local average.

In Fig. 9, we overlay the prominent events from Fig. 7 on the color directional derivative of bathymetry. Only events with levels that are 10 dB above the local average and are consistent in at least ten transmissions along the track are overlain. From Fig. 9, we infer that the prominent and consistent scattering events within the trapezoid do not originate from the seafloor surface because the seafloor in this region is level. The prominent events could have been caused by other objects submerged in the water column or features in the subbottom. Features in the subbottom may not be detectable using a conventional bathymetric depth-sounder, but can be found by subbottom profiling.

During the ACRE 2001, RV *Endeavor* explored the bottom with a hull-mounted chirp subbottom profiler in the vicinity of the prominent scattering events within the trapezoid in Figs. 6 and 7. More detailed geophysical surveys were carried out in this region using both deep-tow and hull-mounted subbottom profiling systems in August 2001^{26,27} and May 2002 under the Acoustic Clutter Program. All three surveys found a network of buried river channels with flanks that shoal close to the seafloor in the vicinity of the scattering events. An interpretation²⁷ of the morphology of these buried river channels from the geologic data are shown in Fig. 10. Figure 11 shows a deep-tow chirp profile of several buried

FIG. 8. Single-ping bistatic wide area image from track 14. Left–right ambiguity of the prominent scattering events from the features of interest can be resolved by comparing this figure with Fig. 6. (Date: 1 May, ping time: 11:35:00Z, transmission: 2-s duration LFM from 390 to 440 Hz, mean source depth: 55 m, mean receiver depth: 22 m, array heading: 226°.)

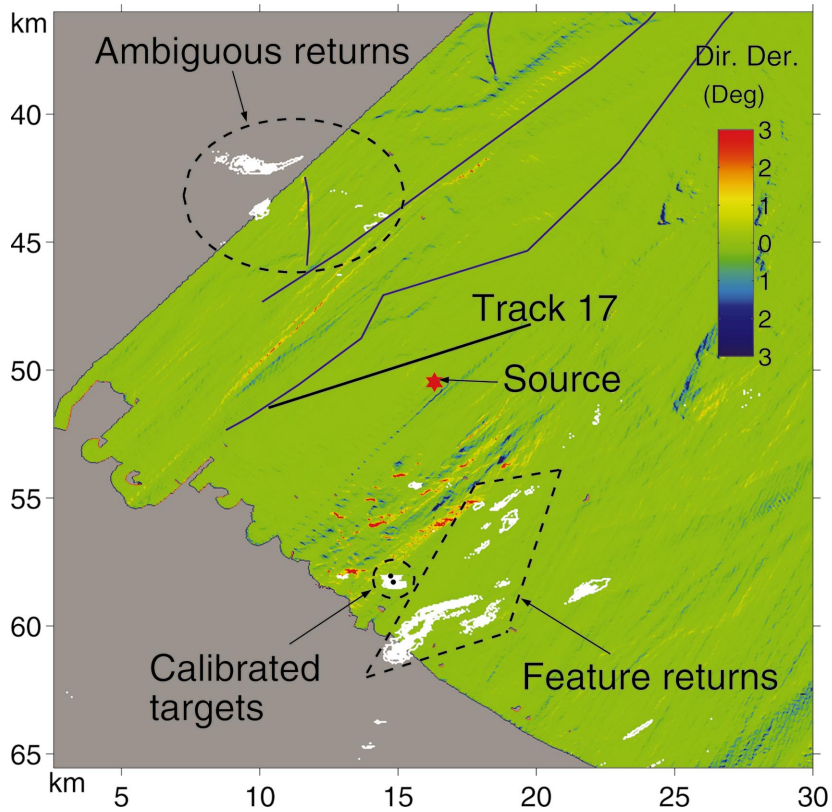

FIG. 9. Prominent events from the LFM transmissions on track 17, as shown in Fig. 7, are overlain in white on the directional derivative of the bathymetry calculated with respect to the site 2 bistatic source location and the receiver location in the middle of track 17. Only prominent (>10 dB above local average) and repeatable events that occur in at least 10 charts out of 49 are overlain. Scattering events of interest within the trapezoid do not originate from the seafloor because the seafloor in this region is level. The returns are probably due to other scatterers in the water column or in the subbottom.

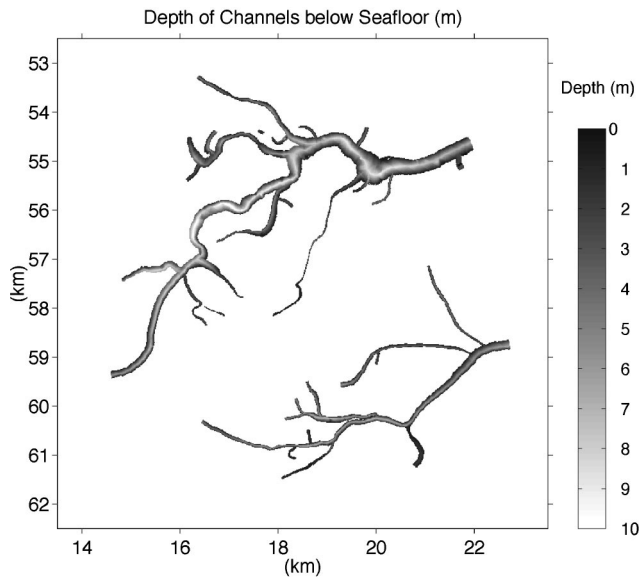

FIG. 10. Most recent interpretation²⁷ of the depth of the buried river channels at site 2 below the water–sediment interface. This interpretation is based on geophysical survey of August 2001²⁶ at site 2.

river channels found in this area from the geophysical survey in August 2001.

The trace of the buried river channels from Fig. 10 is overlain on the hotspot consistency chart for track 17 in Fig. 12. From Fig. 12, we observe that some of the prominent scattering events appear to coincide with the location of the newly discovered buried river channels. But the rest, especially the clutter in the south of the trapezoid, do not coregister. Possible source of scattering for these unidentified clutter events are discussed in Sec. V.

FIG. 11. Deep-tow subbottom chirp profile from the geophysical survey of August 2001^{26,27} at site 2 showing three buried river channels discovered in the vicinity of the prominent and discrete scattering events observed at this site as shown in Fig. 7. Some of these channels at site 2 shoal close to the water–sediment interface and are less deeply buried than those at site 1. These river channels are located between 39° 1.3684'N, 73° 2.9619'W and 39° 2.2878'N, 73° 2.9624'W.

1. Temporal and spatial variability of clutter

The trapezoidal region in Figs. 6–8 that registered strong scattering events on tracks 17 and 14 also registered many clutter events with significant temporal and spatial variability over the course of the experiment. In general, these clutter events were found to be consistently observable over hours, but not longer than a day.

Apart from tracks 14 and 17, scattering events in the region within the trapezoid were also registered on track 23x where the data were collected on the same day as tracks 14 and 17. Figure 13 shows the hotspot consistency image composed of bistatic LFM transmissions along track 23x. We observe scattering events within the trapezoid, as well as returns from the calibrated targets. Fewer bistatic signals were transmitted along track 23x than in tracks 17 or 14, as noted in the figure.

No high-level clutter is observed within the trapezoid during track 18, a day before track 17, as shown by the hotspot consistency chart for track 18 in Fig. 14. Track 18 has the same source depth of 55 m and same mean receiver array depth of 42 m, but a different location and orientation from track 17. The scattering events originating from the calibrated targets are prominent in Fig. 14. Only sidelobe leakage from the calibrated targets in the endfire direction appears within the trapezoid.

Figures 15(a)–(d) show data from four tracks with similar centers, but different orientation from tracks 17 and 14. (Note that Fig. 15 is displayed after Fig. 16.) These data were collected within a half-day period 4 days after tracks 17 and 14 were run. Several prominent clutter events occur in the trapezoidal region in Figs. 15(a) and (c). However, little or no clutter is observed in that region in Figs. 15(b) and (d). This figure shows that clutter events in and out of the trapezoid are highly variable functions of array orientation, time, or both. Since none of the individual tracks were repeated, the purely temporal variability cannot be isolated in this experiment. No returns can be seen from the calibrated targets in the later measurements because they deflated within days and were no longer functional.

2. Statistical analysis of clutter repeatability inside and outside of areas occupied by buried river channels at site 2

Clutter data from all site 2 tracks over the region where the subbottom has been profiled are analyzed statistically. The goal of this analysis is to compare the frequency of occurrence of repeatable clutter inside and outside of regions occupied by buried river channels. For each track, a hotspot consistency subimage covering a box of dimension 9.5×10.5 km² containing the buried river channels is used in the analysis. This region is the area within the yellow box in Fig. 12. The area occupied by the buried river channels within this box is approximately 5.8% of the total area of the box. An area surrounding the targets of width 1.7×2.2 km² is excluded from the analysis. For each track with index n , the number of pixels $T_n(10\%)$ with hotspots that are repeatable in at least 10% of the total number of images N_n along the track is computed for the box. The number of these pixels $C_n(10\%)$ that chart within buried river channels is next com-

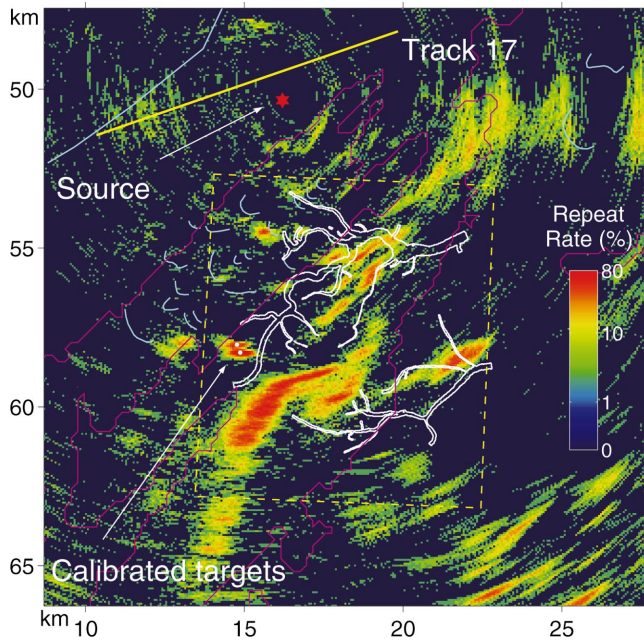

FIG. 12. Hotspot consistency chart for track 17 with white overlay showing the trace²⁷ of buried river channels discovered at site 2. This interpretation of the river channel is based on data from the August 2001 geophysical survey^{26,27} within the yellow dashed box, acquired using chirp subbottom profiling systems. Some of the prominent scattering events appear to correspond with the newly discovered river channels. Some of the events to the south, however, do not correlate with any known geologic feature in this region. This indicates that some of the prominent acoustic returns measured at site 2 are probably caused by other objects in the water column. Large and densely populated schools of fish were measured^{34,35} around the 80-m water depth contour (shown in pink line) of the STRATAFORM area and are a possible cause of some of the prominent clutter returns at this site.

FIG. 13. Hotspot consistency chart for 15 bistatic transmissions along track 23x. Data for track 23x were collected on the same day as track 17. Prominent events >20 dB above the background are registered from the two calibrated targets approximately 8.5 km to the south of the source. Scattering events located within the trapezoid (yellow-dashed line) can be observed for track 23x, similar to that on tracks 17 in Fig. 7. The 80-m bathymetric contour is shown in pink. (Date: 1 May, time: 21:45:00Z to 23:10:00Z, mean source depth: 55 m, mean receiver depth: 43 m, array heading: 209° .)

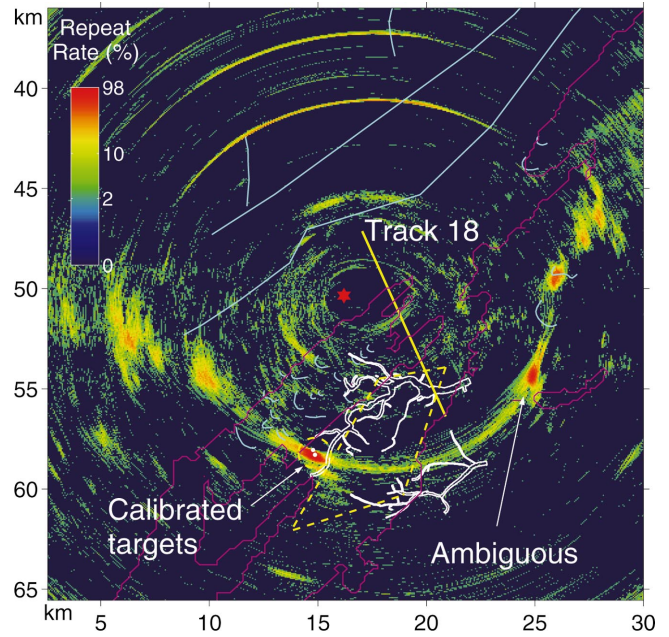

FIG. 14. Hotspot consistency chart for 47 bistatic transmissions along track 18. Data for track 18 were collected a day before that on track 17. Prominent events >20 dB above the background are registered from the two calibrated targets approximately 8.5 km to the south of the source. No high level scattering event can be detected within the trapezoid (yellow-dashed line) in this figure. The 80-m bathymetric contour is shown in pink. (Date: 30 April, time: 15:30:00Z to 16:45:00Z, mean source depth: 55 m, mean receiver depth: 42 m, array heading: 340° .)

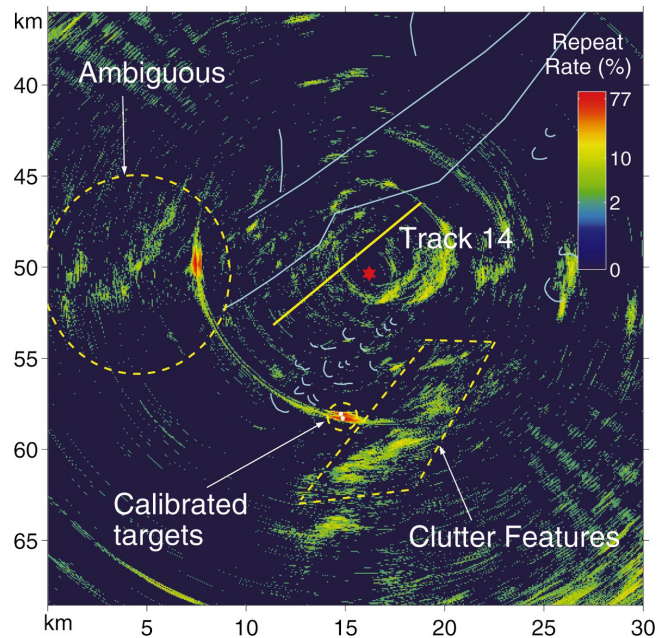

FIG. 16. Hotspot consistency image for 46 bistatic transmissions along track 14. Prominent scattering events with levels 10 dB above the background co-register with the location of the calibrated targets in most of the images. Scattering events originating from clutter features within the trapezoid are not registered as consistently along track 14. It should be noted that track 14 had a shallower receiver depth than track 17 in Fig. 7. This hotspot image shows that measurement of clutter varies with time and may also depend on receiver depth. (Date: 1 May, time: 10:30:00Z to 11:52:00Z, mean source depth: 55 m, mean receiver depth: 22 m, array heading: 226° .)

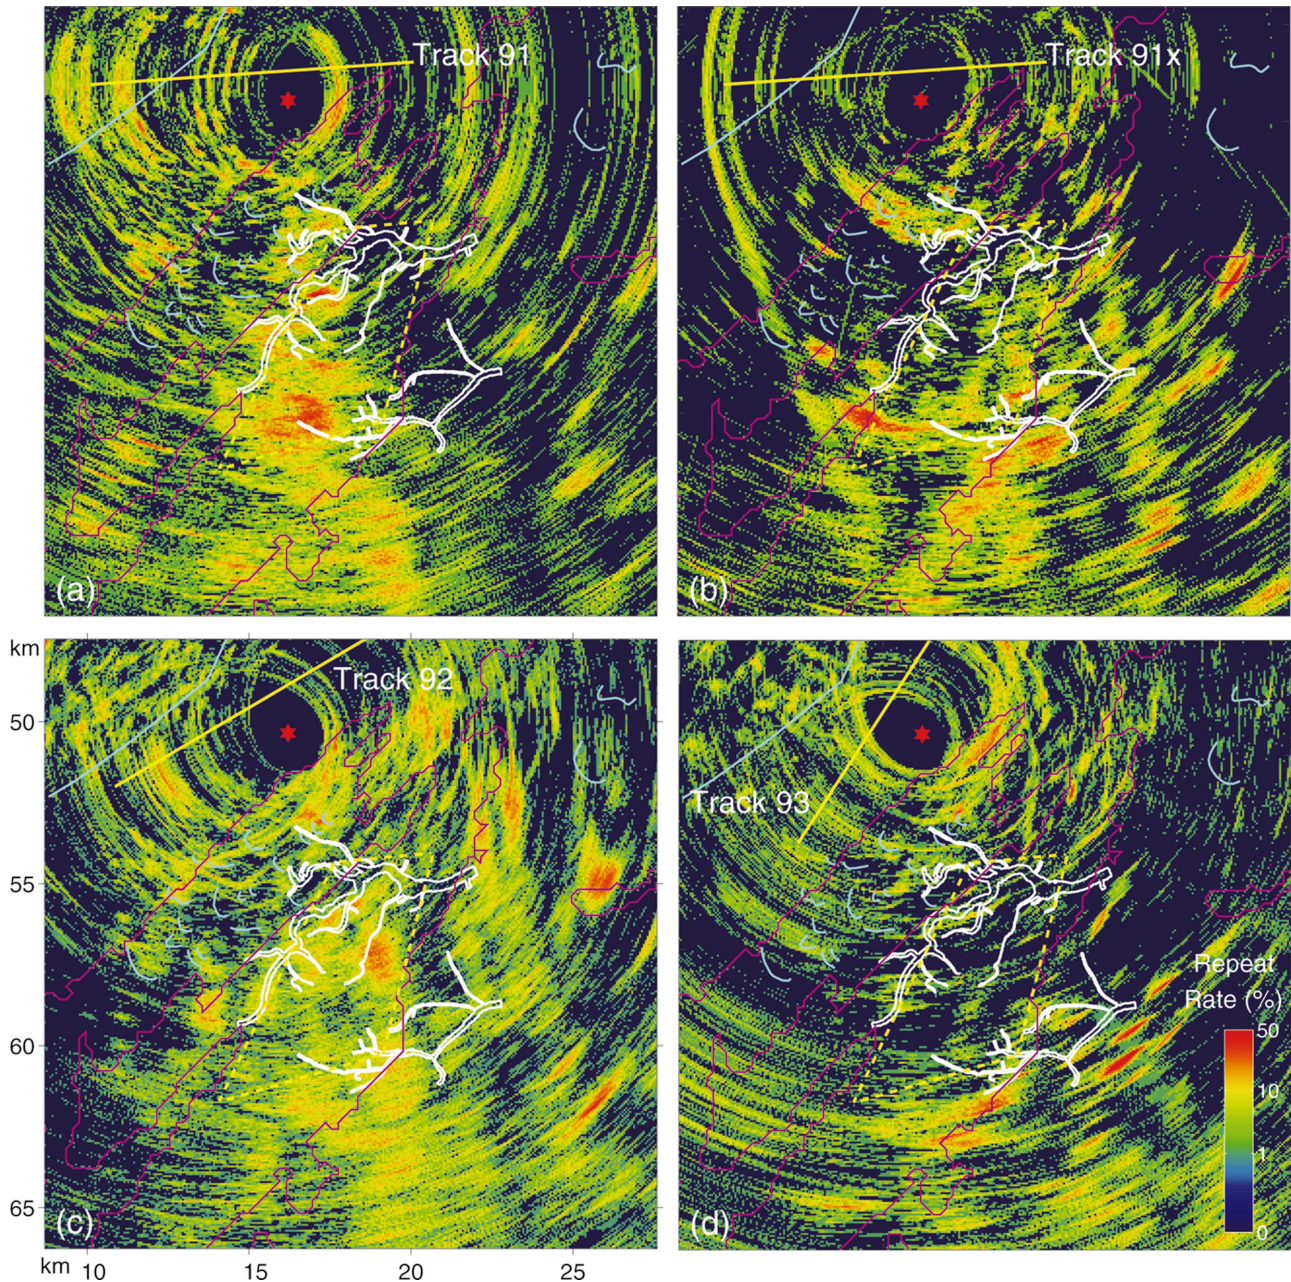

FIG. 15. Hotspot consistency charts for (a) 60 bistatic transmissions along track 91 with array heading 268.5°, (b) 42 bistatic transmissions along track 91x with array heading 270°, (c) 94 bistatic transmissions along track 92 with array heading 49°, and (d) 74 bistatic transmissions along track 93 with array heading 208.5°. Data for these tracks were collected on the same day. We observe that the scattering events within the trapezoid (yellow-dashed line) show temporal and spatial variability. The calibrated targets at site 2 had deflated during this measurement and are hence not detectable. The 80-m bathymetric contour is shown in pink. [(a)–(d) Date: 5 May, mean source depth: 35 m, mean receiver depth: 36 m.]

puted. The ratio of these quantities defined by $[C_n(10\%)/T_n(10\%)] \times 100\%$ gives the percentage $P_n(10\%)$ of repeatable clutter at 10% repeatability or more within the buried river channels. The percentage $P_n(20\%)$ is also calculated for clutter that is repeatable in at least 20% of the total number of images along the track. The results are shown in Table I. The frequency of occurrence of repeatable clutter within buried river channels has a mean from 2.3% to 4.9% and standard deviation from 1.8% to 4.3%. This frequency of occurrence of clutter within the buried river channels differs by less than a standard deviation from the area occupied by the channels in the subimage of 5.8%. This im-

plies that to within the errors of the statistical analysis, there is no evidence that the repeatable clutter favors buried river channel locations over the nonchannel locations.

3. Possible variation of clutter with receiver depth

Figure 16 shows the hotspot consistency chart for the 46 bistatic transmissions along track 14. Prominent and discrete events register at the locations of the calibrated targets in 41, or 89%, of the images. Scattering events from features within the trapezoid, however, are prominent with levels of more than 10 dB above the background in at most 7, or 15%, of

TABLE I. Frequency of occurrence of repeatable clutter within the yellow box at site 2 shown in Fig. 12. Buried river channels occupy 5.8% of the area of this box. The $M = 11$ tracks listed below are the only ones that transmitted bistatic LFM signals at site 2. Column 2 indicates N_n , the total number of images along track n , used to form the hotspot consistency chart over the box area. Columns 3 and 4 indicate $P_n(10\%)$ and $P_n(20\%)$ which are the percentages of repeatable clutter with at least 10% and 20% repeatability, respectively, that are charted within the buried river channels for each track. The unweighted mean percentages of repeatable clutter with at least 10% and 20% repeatability charted within buried river channels are calculated by taking the average of $P_n(10\%)$ and $P_n(20\%)$ respectively over all M tracks. The unweighted mean and standard deviation do not take into account the variation in the total number of images along each track. The weighted mean and standard deviation account for variations in the total number of images along each track.

Track index, n	Track name	N_n	$P_n(10\%)$ (%)	$P_n(20\%)$ (%)
1	13	46	3.2	12.0
2	14	46	2.0	0.0
3	17	49	4.4	3.2
4	18	47	4.9	10.8
5	19	9	9.3	8.2
6	20	9	4.9	3.4
7	23x	15	8.5	10.1
8	91	60	4.2	2.6
9	91x	42	3.2	3.3
10	92	94	4.5	0.0
11	93	74	1.2	0.5
Unweighted mean			4.6	4.9
Unweighted standard deviation	$\bar{P} = \frac{1}{M} \sum_{n=1}^M P_n$		3.7	3.7
	$\sigma = \sqrt{\frac{1}{M} \sum_{n=1}^M (P_n - \bar{P})^2}$			
Weighted mean			2.3	4.3
	$\bar{P}' = \frac{1}{\sum_{n=1}^M N_n} \sum_{n=1}^M N_n P_n$			
Weighted standard deviation			1.8	4.3
	$\sigma' = \sqrt{\frac{1}{\sum_{n=1}^M N_n} \sum_{n=1}^M N_n (P_n - \bar{P}')^2}$			

the images along track 14. These images were acquired when NRV *Alliance* was located towards the south-western end of the track. Clutter events measured while the NRV *Alliance* was in the north-eastern part of track 14 were less prominent within the trapezoid. Tracks 17 (shown in Fig. 7) and 14 are located at roughly the same range from the calibrated targets and the objects located within the trapezoid, but they differ in their orientation by approximately 10° . Data for these two tracks were collected on the same day, approximately 2 h apart. The receiver array was at a shallower depth in the water column of about 22 m on track 14, while it was deeper at 42 m depth on track 17. The bistatic source depth of 55 m and location did not change. These images show that variation of receiver depth may have caused substantial differences in our ability to image the clutter events within the trapezoid. Imaging of the calibrated targets is more stable with respect to changes in receiver depth. It is also highly-likely that the scatterers causing clutter may have evolved over this time leading to the observed differences in our ability to image them.

Note that the sound speed in the water column close to the location of the clutter features and calibrated targets has a maximum around 40- to 50-m depth due to a protruding filament of warm Gulf stream water as discussed in the appendix. This profile is downward refracting for a source depth of 55 m. Better detection can be obtained of scatterers located near the bottom for a deep receiver than a shallow

receiver The two calibrated targets are tall cylindrical tubes that span close to half the water column from 32- to 62-m depth which allows them to be detected much more readily regardless of the sound speed profile or receiver depth.

B. Site 3

At this site, patches of returns stretching over 35 km in range are imaged near the 100-m water depth contour on tracks 61 and 62 as seen in Figs. 17(a) and (b) respectively. Comparing Figs. 17(a) and (b) enables ambiguity about the line array to be resolved. The true location of the returns is to the south-west in both charts. It is noteworthy that the shelf break front in this region where the warmer slope water intersects the seafloor also occurs along bathymetric contour with similar water depth (see the appendix). The significance of the shelf break front to acoustic scattering is discussed further in Sec. V.

Two seafloor features are also imaged at site 3. Figures 18(a) and (b) show the hotspot consistency images formed from data acquired along tracks 61 and 62, respectively. For these particular images, levels 10 dB above the local average over an area $2.7 \times 2.7 \text{ km}^2$ are selected as peaks. The iceberg scour on the seafloor about 5 km away from the source is imaged on both tracks repeatedly. This particular iceberg scour is the only one imaged in the experiment. Scattering from the wall of the Hudson Canyon more than 30 km away from the source and receiving array is also registered as seen

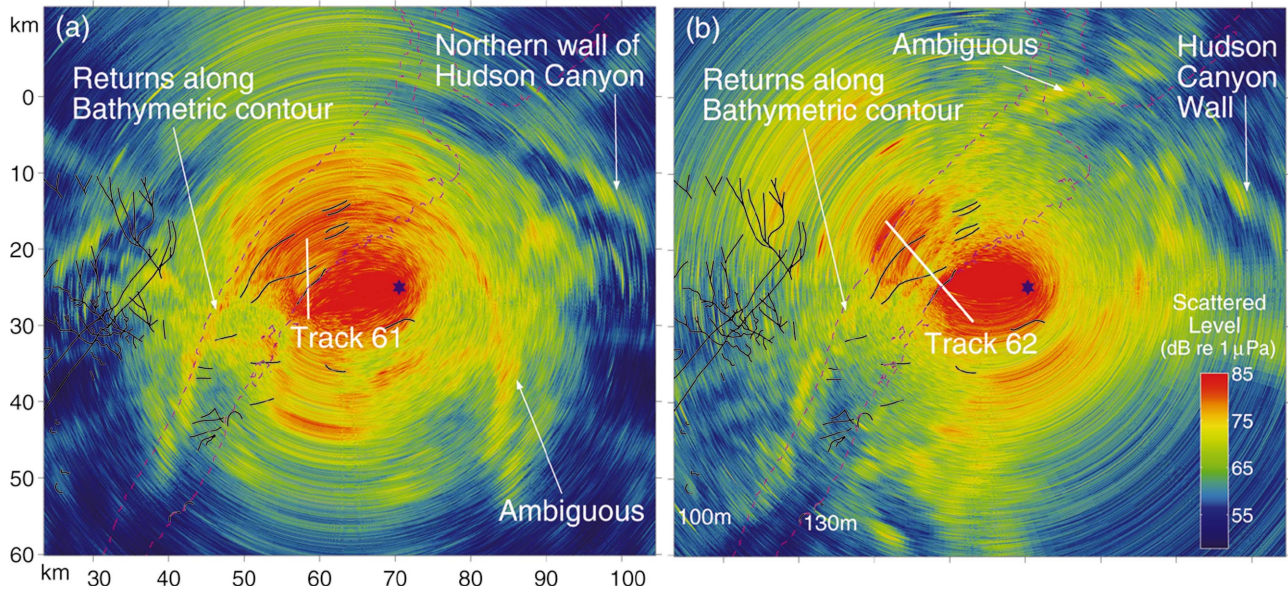

FIG. 17. Single-ping bistatic wide-area images from tracks 61 and 62 at site 3. Patches of scattered returns stretching over 30-km range and that line up with the 100-m water depth contour were imaged in this region. Comparing (a) and (b) allows the receiver line array's left-right ambiguity to be resolved. [(a): Track 61, date: 2 May, ping time: 12:11:40Z, transmission: 2-s duration LFM from 390 to 440 Hz, mean source depth: 84 m, mean receiver depth: 60 m, array heading: 358°. (b) Track 62, date: 2 May, ping time: 16:08:20, transmission: 2-s duration LFM from 390 to 440 Hz, mean source depth: 84 m, mean receiver depth: 34 m, array heading: 133°.]

in Figs. 17 and 18. Some of the patches of returns along the bathymetric contour are also visible in the hotspot consistency image in Fig. 18.

C. Site 1 with statistical analysis of clutter repeatability in and out of buried river channels

Site 1 was the focus of previous geophysical surveys where extensive networks of buried river channels were

mapped and characterized prior to the ACRE.^{14,15} Additional geophysical surveys were conducted after the ACRE to provide better characterization of the channel morphology.^{26,28}

During the first few days of the ACRE, a large number of tracks were traversed by RV *Alliance* at various ranges and azimuths from the buried river channels at site 1 shown in Fig. 19, to explore possible scattering and hence imaging of these channels. Prominent clutter events were observed

FIG. 18. Hotspot consistency charts from (a) 15 bistatic LFM transmissions along track 61, and (b) 21 bistatic transmissions along track 62 and at site 3. The figure displays the number of images that register a strong scattering event >10 dB above the local average within 2.7×2.7 km² area of a given pixel location. Comparing (a) and (b) breaks the receiver line array's right-left ambiguity. It registers prominent scattering from the walls of the Hudson Canyon located to the west in both figures, as well as scattering from the iceberg scour close to the location of the bistatic source. [(a) Track 61, date: 2 May, mean source depth: 84 m, mean receiver depth: 60 m, array heading: 358°. (b) Track 62, date: 2 May, mean source depth: 83.8 m, mean receiver depth: 34 m, array axis: 358°.]

FIG. 19. Most recent interpretation²⁸ of the depth of the buried river channels at site 1 below the water–sediment interface. This interpretation is based on geophysical surveys at site 1.

throughout the region. Some of the clutter events intersect with the buried river channels. However, the registration of the clutter with the channels could not be maintained from one track to the next.

Towards the end of the ACRE, a more controlled data collection procedure was adopted where higher temporal and spatial sampling were employed to study clutter repeatability. Bistatic sonar data were collected along six tracks numbered tracks 81 to 86, located within 5-km range of the buried river channels. These tracks had the same track center but with orientations that differed by 15° from one track to the next. Rapid transmissions were made of the same LFM waveform for all these tracks. This allowed a large number of acoustic images to be captured over small variations in receiver azimuths of approximately 1°. (This angular variation is within a scatter function lobe for objects smaller than 200 m.)

Figures 20(a)–(f) show the hotspot consistency images from tracks 81–86, respectively. Figures 21(a)–(f) provide a zoomed version of Figs. 20(a)–(f) in the vicinity of the channels where the subbottom data have been collected and analyzed. In these figures, the traces of the most recent interpretation²⁸ of the river channel morphology at site 1, shown in Fig. 19, are overlain as white lines. Some prominent hotspots occur within the buried river channels, as in Figs. 21(e) and (f), while many other prominent hotspots occur outside of the channels, as in Fig. 21(c).

From Figs. 20(a)–(f), we do observe many more extended hotspots to the east and south-east in these images. These hotspots are consistently observable in several tracks and seem to occur along a bathymetric contour that is deeper but parallel to the 100-m water depth contour. These images should be compared with Fig. 17 where the returns line-up close to the 100-m water depth contour.

Several other prominent and discrete scattering events close to the 100-m water depth region were also imaged at site 1 as shown in Figs. 22(a) and (b). These images also show how a hotspot consistency chart can be used to resolve ambiguity. In the single ping image of Fig. 22(a) from track 73, a set of prominent and discrete scattering events are

charted to the north-west and another set of more elongated events to the south-east. Only one of these is the true set of scattered returns while the other is ambiguous. From Fig. 22(b), which shows the hotspot consistency chart for the track, the events from the south-east are consistently charted to the same area, leading to a strong reinforcement of these events in the hotspot chart. The events to the north-west are distributed over a wide area in the hotspot chart with little repeatability, showing that these events are the ambiguous ones. The true scattered returns therefore originate from the south-east in the region with water depth of between 80 to 100 m. Geophysical surveys at the location of these extended clutter returns did not find any subbottom features.²⁶

The measured clutter on all the tracks at site 1 is also statistically analyzed to compare the frequency of occurrence of repeatable clutter inside and outside of buried river channels. The analysis is similar to that done at site 2 and discussed in Sec. IV A 2. The area used in the analysis is the full region shown in Fig. 19 of $17.2 \times 13.3 \text{ km}^2$, which is the same as that in Figs. 21(a)–(f). The area occupied by the buried river channels within this box is approximately 9% of the total area of the box. The results are shown in Table II. The means of between 13% to 15% and standard deviations of between 7% to 14% show that there is no statistically significant difference between the frequency of occurrence of repeatable clutter charted within areas occupied by buried river channels and that charted outside of areas occupied by channels. This finding is similar to that at site 2.

V. SUMMARY AND DISCUSSION

At all the three sites investigated in the New Jersey Strataform area, a large number of clutter events were imaged throughout the experiment. Many often persisted along a track. These events were imaged in near-real-time over wide areas extending roughly 40 km in range from the bistatic sonar. Most of the clutter events were measured in areas where the bathymetry is locally level with slopes $< 0.5^\circ$. At site 2, these scattering events are sometimes as prominent and consistent as those from the calibrated targets deployed at a similar range from the bistatic sonar. Without prior knowledge, it would be impossible to distinguish the targets from these features.

Some of the high-level clutter events intersected buried river channels at sites 1 and 2. In general, the registration of clutter events with the buried river channels at a given location could not be maintained over variations in track orientation. Since none of the tracks were repeated, it is unknown whether or not the registration of the clutter for a given track with the channels is repeatable over time.

We consider two plausible causes for the variability in measured clutter with changes in track orientation. If the measured clutter is caused by scattering from geologic features of the subbottom such as buried river channels, its variability shows that the scattering process is highly dependent on the bistatic location and orientation of the source and receiver array relative to the geologic features. An analogy can be drawn with the “glints” observed on a spoon. Due to the curved surface of the spoon, the glints on a spoon migrate when the bistatic orientation of the observer or light

FIG. 20. Hotspot consistency chart for (a) 89 bistatic transmissions along track 81 with array heading 350° , (b) 78 bistatic transmissions along track 82 with array heading 154° , (c) 94 bistatic transmissions along track 83 with array heading 327° , (d) 73 bistatic transmissions along track 84 with array heading 122° , (e) 87 bistatic transmissions along track 85 with array heading 293° , and (f) 79 bistatic transmissions along track 86 with array heading 97° . The 100-m bathymetric contour is shown in pink. The most prominent and repeatable clutter, consistently observable in several of the tracks, occur in waters that is a little deeper than 100 m. The region where the buried river channels are shown is the only region where subbottom data have been collected and analyzed. There may be subbottom features in other regions shown in this figure, but the subbottom geologic data have either not been collected or not analyzed. [(a)–(d) Date: 4 May, mean source depth: 41 m, mean receiver depth: 35 m.]

FIG. 21. (a)–(f) are similar to Fig. 20 but are zoomed in around the channels at site 1. The clutter registration with the channels changes with the orientation of the tracks which were done at different times of the day.

source changes.²⁹ The projected area of the imaged feature within the cross-range resolution of the measurement system changes with the bistatic orientation of the system relative to the feature. Bistatic aspects that lead to large projected areas would produce the strongest returns. In deep water, this is the case with deterministic reverberation from scarps on the Mid-Atlantic Ridge. The scattering strength of the scarp was found to be proportional to the projected area of the scarp

along the path from target to the bistatic source and receiver.^{8–10} Another possibility is that the clutter arises from objects moving around in the water column. This could account for the highly spatial and temporal variability observed in the measured clutter. Regardless of the origin of the clutter, returns in a waveguide also fluctuate as a result of propagation effects due to interference between the modes. The strength and consistency of the clutter measured at site 2 was

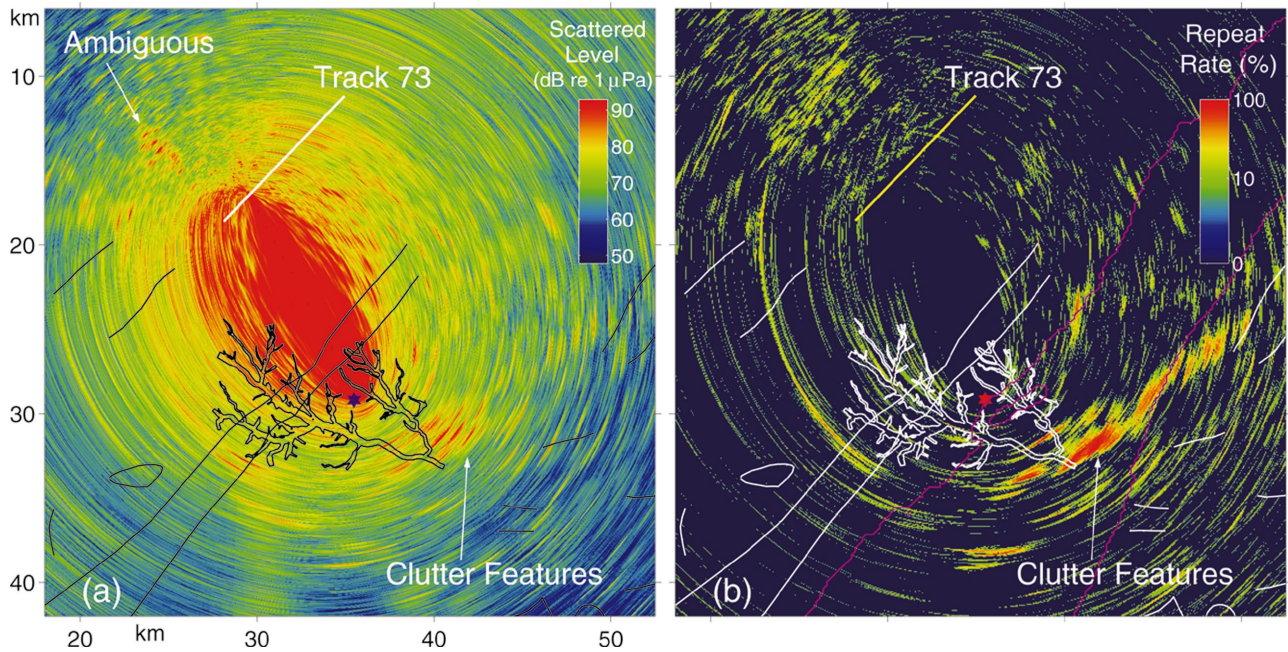

FIG. 22. (a) Single-ping bistatic wide-area image from track 73 at site 1. (b) Hotspot consistency chart for 12 bistatic transmissions along track 73 at site 1. In (a), a set of prominent and discrete scattering events has been charted to the north-west and another set of more elongated events have been charted to south-east. Only one of these is the true scattered return from the features while the other is ambiguous. Comparing (a) and (b) shows that the events to the south-west are the true returns. These returns do not coincide with any known geologic features, but are contained within the 80- to 100-m bathymetric contour (pink lines) of the STRATAFORM area at site 1. [Date: 3 May, (a) ping time: 16:28:35Z, transmission: 2 s duration LFM from 390 to 440 Hz. (a) and (b) Mean source depth: 41 m, mean receiver depth: 38 m, array heading: 220°.]

also found to vary with receiver depth and could be due to effects of the sound speed profile in the water column.

It should be noted that statistical analysis of the measured clutter at sites 1 and 2 in regions where the buried river channels have been mapped show that there is no significant difference between the rate of repeatable clutter per unit area charted within areas occupied by buried river channels and that charted outside of areas occupied by channels.

Seafloor features, such as the one iceberg scour and the large wall of the Hudson Canyon, are the only geologic features consistently imaged in the acoustic experiment. The one iceberg scour was detected at approximately 5-km range while the Canyon wall was imaged at about 30 km from the bistatic sonar at site 3. The returns from the Canyon wall are strong, but extended and not target-like in appearance.

Many of the prominent clutter events at all three sites occurred in the region along bathymetric contour between 80- and 120-m water depth. This is roughly the region where the warmer slope water mixes with the cooler shelf water in the New Jersey Strataform area as discussed in Appendix A.

One possibility for the source of unidentified clutter measured at sites 1–3 is scattering from fish.^{30–33} Fish are known to exist in tight schools about 5 m off the bottom in the STRATAFORM area with 80- to 120-m water depth.^{34,35} This is where the shelf break front exists which contains nutrients and is a source of food that attracts the fish schools. This possibility of fish schools causing clutter in long range sonar has been shown to be theoretically plausible^{30–33} and has also been observed experimentally.³⁶ When fish congregate together to form large and densely populated schools, they can scatter either coherently or incoherently, leading to returns that stand significantly above the diffuse reverbera-

tion background.^{32,33} This has been observed experimentally where such fish schools were found to be distributed in fan-shaped patterns.³⁶

Another possible origin for the unidentified clutter is

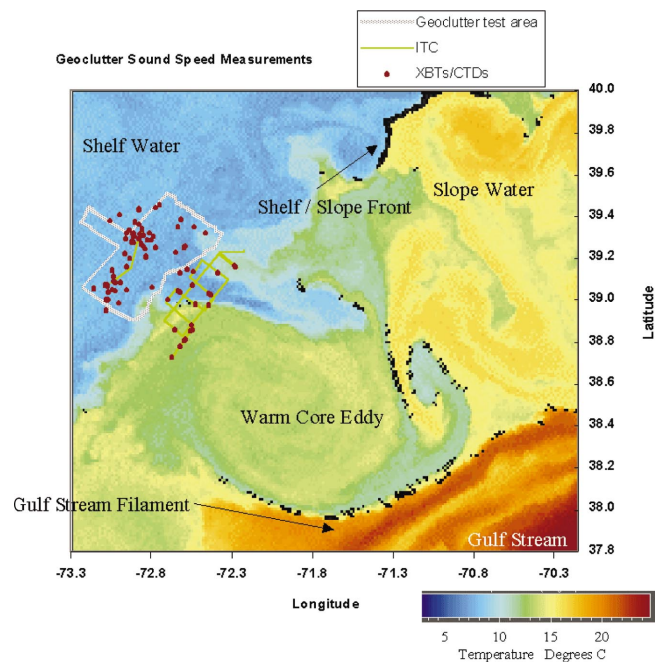

FIG. 23. Satellite image of the sea surface temperature off the New Jersey Coast on 30 April 2001. The oceanography in the region is governed by the interaction between the cooler shelf water (in blue), the warmer slope water (in yellow), and much warmer water from the gulf stream (in brown). Also visible is a warm core eddy (in green). Oceanographic data were collected using XBTs, CTDs, and an instrumented tow cable (TC) that allows almost continuous measurement of temperature along a tow cable.

TABLE II. Same as Table I but calculated for the tracks and the box with the full area in Fig. 19 at site 1. Buried river channels occupy 9.0% of the area of this box. There are a total of $M=21$ tracks at site 1 that transmitted bistatic LFM signals.

Track Index, n	Track name	N_n	$P_n(10\%)$ (%)	$P_n(20\%)$ (%)
1	1c	9	15.9	17.6

scattering from gas entrapments (pockets) within the sediment that have significant acoustic impedance contrast with the neighboring sedimentation.³⁷ There is, however, much debate over whether these pockets of gases can exist in the East Coast STRATAFORM area. None of the geophysical surveys found any evidence of gas pockets in this region. Gas pockets are therefore less likely to be the source of the measured clutter in comparison to fish schools that have been proven to exist in abundance in this region.

The temporal and spatial variability of the clutter events, along with resonance characteristic of the clutter, provide important clues regarding the identity of the scatterers and the physical mechanisms associated with the scattering process. Scattering from geologic features is expected to be repeatable at a given location as a function of time. Clutter from fish schools, on the other hand, is expected to evolve and change with both space and time as the fish congregate and disperse. Detailed theoretical analysis of the scattering from fish schools, buried river channels, the R-reflector, and reverberation from the sea bottom on the New Jersey Continental Shelf will be presented in a separate paper.

In order to condense the information contained in data from large numbers of transmissions along a track-line of the receiver ship, a “hotspot” consistency chart was derived from the images of individual transmissions along each

track. The hotspot consistency chart displays the location and persistence of strong echo returns for transmissions along a track. In many instances, the hotspot charts provide significantly improved imaging of the clutter features. They are also useful for resolving the left–right ambiguity inherent in horizontal line array data when the bistatic range to the target is not much larger than the source–receiver separation. The hotspot charts also reduce charting errors due to waveguide dispersion since they combine information from a large number of transmissions.

The results of this experiment show that a low-frequency active sonar system can be used to remotely image the underwater environment over wide areas, at ranges spanning tens of kilometers, in continental shelf waters in near-real-time.

ACKNOWLEDGMENTS

The authors would like to thank Jefferey Simmen and Ellen Livingston who supported and sponsored the Acoustic Clutter Program at the U.S. Office of Naval Research. We would also like to thank NATO’s SACLANT Center for support of the experiment. We thank the scientists and crew of NRV *Alliance* and RV *Endeavor* for their effort in making the Acoustic Clutter Reconnaissance Experiment 2001 a suc-

cess. We would also like to thank Tommy Goldsberry for allowing us to use the MACE source and the engineering staff of the MACE Program for operation of the source during the experiment. We would like to acknowledge our colleagues at the University of Texas at Austin for providing us with geophysical support of the Program.

APPENDIX: STRATAFORM OCEANOGRAPHY

The East Coast STRATAFORM area has been fairly well characterized in general physical oceanography.³⁸⁻⁴⁰ The dominant water masses consist of seasonally dependent shelf water, the surface mixed layer, and continental slope water (Fig. 23). The boundary between shelf and slope water is known as the shelf break front, and consists of a strong salinity gradient with seasonally dependent temperature gradients. Its shape and location are variable at different times of the year. Its surface expression is usually near the 200- to 1000-m bathymetric contour, while its intersection with the bottom frequently manifests up onto the outer continental slope, as shallow as the 70-m contour. Thus the shelf break front and slope waters influence the lowermost part of the water column in the test area. The upper part during the experiment was dominated by surface warming, the mixed layer, and a thermocline down to the mid-water-column shelf water.⁴¹

The oceanographic measurements during the experiment consisted of XBTs from both the RV *Endeavor* and NRV *Alliance*, 27 Seabird CTD casts from the RV *Endeavor*, and five deployments of the Instrumented Tow Cable,⁴² a nearly

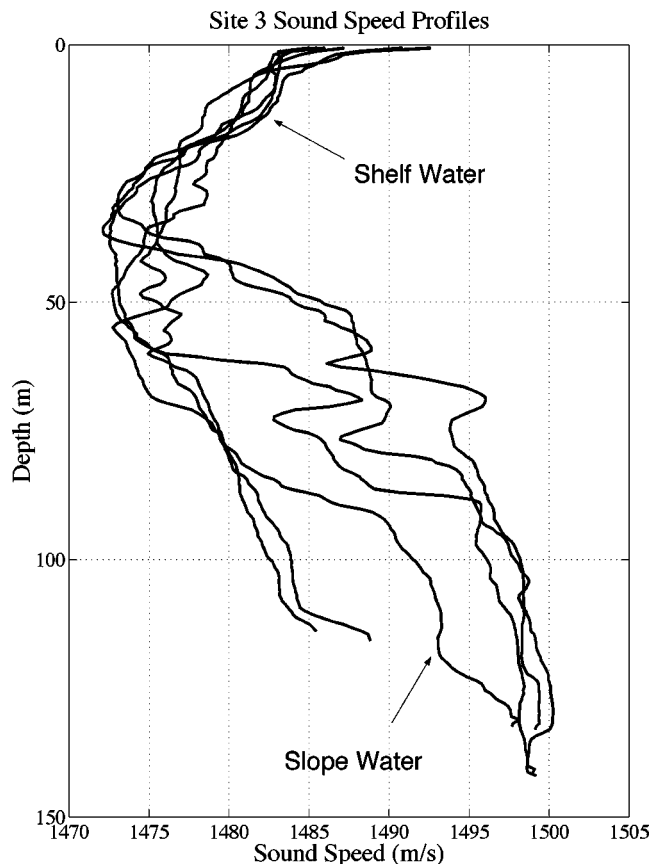

FIG. 26. Measured sound speed profiles of the water column at site 3.

continuous measurement device for temperature along a tow cable. In general, the measurements showed a sound speed profile with a moderately thin surface mixed layer (10 m or less), a thermocline of moderate gradient, to a temperature and sound speed minimum near 30- to 50-m depth (depending on the location) containing the “cold pool” of shelf water, below which was an increase in salinity and temperature associated with the shelf break front zone of mixing. The conditions have a tendency to channel the sound energy away from both the surface and bottom of the water column in the deeper portions of the area, and to allow better sound interaction with the bottom in areas shallower than 80 m.

Beyond this general physical oceanographic framework were two processes having a more variable effect on the sound speed structure. One was the existence of an unusually warm air mass over the area, causing near-surface warming continuously and gradually during the experiments, with a more pronounced effect in late afternoon. The second was the presence of a major (50 km diameter) slope eddy with an anticyclonal motion sitting just east of the shelf break front directly offshore of the STRATAFORM test area (Fig. 23). These warm eddies are known to have considerable influence on cross-frontal water mass movements and enhancements of chlorophyll in the shelf region.^{43–45} This feature had a fairly important and variable influence on the waters over the shelf up to the 85-m bathymetric contour during the experiments.

Figures 24–26 show representative sound speed profiles measured at sites 1–3, respectively. At site 1, Fig. 24 shows the effect of the near surface warming, a mixed layer less than 10 m thick, a fairly equal thermocline and salinity front, with the cold pool of shelf water on the order of 10 to 20 m thick centered on 40-m water depth. The deeper water profiles show a strong influence of the shelf slope front, while the probes from 70 m and shallower show no influence at all from the slope waters, with the cold pool extending to the bottom.

At site 2, Fig. 25, three of the sound speed profiles show the presence of entrained gulf stream waters in the mid water column. These three profiles were the furthest east collected during the experiment. The warm waters from the gulf stream filament produced a high-speed sound layer in the water column for some areas deeper than the 80-m bathymetric contour. Outside the region of influence of this filament, however, there was the more normal behavior of the cold pool extending to the bottom west of the 70-m contour and the influence of the shelf break front deeper than 50 to 60 m in the water column. The thermocline moved up or down by ± 5 m, while the lower to mid part of the water column was influenced by various filaments of warm water, creating a less stable sound speed profile than at site 1.

Site 3 was further towards the shelf edge, and measurements were sampled deeper than at the other two sites. In Fig. 26, the thermocline moved up and down on the order of ± 5 m. There were cooler waters near the bottom for profiles taken shoreward of the mooring site, and a dominant presence of slope water in the near-bottom profiles further offshore. In these profiles slope waters themselves appear deeper than 95 m in the water column. This causes a fairly sharp upward refracting profile below the sound channel

axis. This caused less bottom interaction at site 3. Finally, in several profiles we observe the influence of fingers or filaments of warmer waters in the mid-water column.

The oceanographic measurements at the East Coast STRATAFORM show the interaction between the various water masses that influence the outer shelf water properties. This highlights the need for making high resolution temperature measurements, especially for understanding their effects on acoustic propagation in this region.

Time-reversal imaging for classification of submerged elastic targets via Gibbs sampling and the Relevance Vector Machine

Nilanjan Dasgupta and Lawrence Carin^{a)}

Department of Electrical and Computer Engineering, Duke University, Durham, North Carolina 27708-0291

(Received 19 April 2004; revised 15 December 2004; accepted 8 January 2005)

Time-reversal imaging (TRI) is analogous to matched-field processing, although TRI is typically very wideband and is appropriate for subsequent target classification (in addition to localization). Time-reversal techniques, as applied to acoustic target classification, are highly sensitive to channel mismatch. Hence, it is crucial to estimate the channel parameters before time-reversal imaging is performed. The channel-parameter statistics are estimated here by applying a geoacoustic inversion technique based on Gibbs sampling. The maximum *a posteriori* (MAP) estimate of the channel parameters are then used to perform time-reversal imaging. Time-reversal implementation requires a fast forward model, implemented here by a normal-mode framework. In addition to imaging, extraction of features from the time-reversed images is explored, with these applied to subsequent target classification. The classification of time-reversed signatures is performed by the relevance vector machine (RVM). The efficacy of the technique is analyzed on simulated in-channel data generated by a free-field finite element method (FEM) code, in conjunction with a channel propagation model, wherein the final classification performance is demonstrated to be relatively insensitive to the associated channel parameters. The underlying theory of Gibbs sampling and TRI are presented along with the feature extraction and target classification via the RVM. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1862592]

I. INTRODUCTION

The problem of imaging and classifying a target situated in a shallow-water (sound) channel is complicated by multipath, due to multiple reflections within the sound channel. Such multipath is dependent on parameters such as the target and receiver location, the channel depth, the sound-speed profile within the channel, and the geoacoustic parameters of the channel bottom.¹ The impact of the channel on the measured target signature may be significant. Therefore, it is often important to account for channel effects on the target signature² when performing classification. Our objective is to remove the channel effects from the in-channel target response such that a channel-independent classifier can be designed for classification of submerged in-channel targets.

Pioneering work on classification of underwater targets was detailed by Gorman and Sejnowski,³ where they used spectral features to distinguish cylindrical targets based on a neural-network classifier. Goo *et al.*⁴ have developed the “G-Transform” which, in conjugation with a neural-network-based classifier, worked successfully to detect and identify targets in shallow water. These techniques try to learn the target response in the sound channel; hence, the classifier performance is severely degraded when the anticipated and actual parameters are mismatched. Consequently, an important issue in sensing underwater targets involves removing the effects of the channel. This is motivated by the flexibility of using a single classifier, trained on free-field target signatures, for classifying the scattered responses from the same target(s) situated in different acoustic environments—by

contrast, it is prohibitive to require a different classifier for each channel environment. The deterministic deconvolution method for extracting the scattered signature is very sensitive to channel Green’s function mismatch. Other researchers have employed statistical techniques, like higher order statistics⁵ and minimum entropy deconvolution (MED).⁶ For the case of a shallow water channel with long observation distances (for which many modes are excited), one requires a large array of receivers for the channel Green’s function to satisfy the requirements of these methods. In addition to work on channel deconvolution, Runkle *et al.*⁷ have demonstrated that classification accuracy may be greatly improved by fusing scattering data from multiple orientations around a target, via a hidden Markov model (HMM).

In the work reported here time-reversal imaging is applied to simulated data, from which features are extracted; these features are processed subsequently to make a classification decision. Time reversal is manifested by taking the time-domain scattered fields received on an array, reversing them in time, and then propagating them back into the domain. One must distinguish active time-reversal from time-reversal imaging (TRI). In active time-reversal⁸ the signals are *physically* radiated into the domain via a transducer, and the spatio-temporal focusing at the source may be used for covert communication and/or to direct a large amount of energy at the source. In TRI the time-reversed signals are radiated into the domain *computationally*, yielding a space-time image, with temporal and spatial focusing at the scatterer. The main distinction between TRI and conventional matched-field processing⁹ is that TRI is typically wideband^{10,11} and implemented in the time domain (i.e., the frequencies are processed coherently). Jackson and

^{a)}Electronic mail: lcarin@ee.duke.edu

Dowling¹² have established a theoretical understanding of the time-reversal technique applied to underwater imaging, considering a simulated medium. The time-reversal image yields a four-dimensional signal (three spatial dimensions, and time), and the time dependence of each scattering center is also recovered approximately. The spatio-temporal focusing achieved by time-reversal imaging is strongly dependent on the similarity between the true and simulated acoustic channel (the former is characteristic of the scattering data in the measurements, and the latter is employed computationally in the TRI procedure).⁸

There have been several manifestations of time-reversal imaging in the literature. For example, Fink and colleagues¹³ have performed an eigen-decomposition of the time-reversal operator, and each eigenmode may be linked to a specific target or subtarget. These eigenmodes may be radiated actively or numerically into the domain, to achieve selective focusing. These eigenmodes are closely related to the modes in a MUSIC algorithm¹⁴ and authors have also considered¹⁵ time-reversal imaging in a modified MUSIC framework. Carin *et al.*^{1,16} have employed direct space-time time-reversal imaging to measured underwater scattering data, including estimation of the unknown channel parameters via a genetic-algorithm optimization applied to the time-reversal image.

As discussed by Carin *et al.*,^{1,16} the quality of the time-reversal imagery is dependent on the accuracy with which the channel Green's function is estimated. This is closely related to previous research in matched-field processing. Dosso^{17,18} has demonstrated that the quality of focusing in acoustic matched-field processing is a strong function of the mismatch between the numerical and actual channel parameters. This dependence of quality on channel-parameter mismatch has been exploited to invert for the channel parameters using a Gibbs-sampling approach (GS).¹⁹ Gibbs sampling is used in a Bayesian framework to generate the *a posteriori* distribution of the channel parameters, based on the observed data and a statistical prior distribution over the channel parameters (if available). In this paper time-reversal imaging²⁰ of underwater targets is performed based on channel-parameter statistics estimated via GS.

After performing Gibbs sampling to estimate channel parameters, performing time-reversal imaging, and then extracting features from the time-reversal imagery, the features are utilized to make a classification decision. A nonlinear classifier called the relevance vector machine (RVM) is employed to classify targets from (non-targets) in feature space. The RVM was first proposed by Tipping²¹ as a Bayesian generalization of the support vector machine (SVM).²² The RVM is an algorithm for finding the best Gaussian prior distribution for a logistic regression (LR)²³ classifier, by using evidence maximization²¹ (also called the type-II maximum likelihood). The objective is to estimate a robust and generalized classification in the feature space.

This paper therefore represents an integration of several state-of-the-art tools in imaging, statistics, and classifier design. The space-time image is manifested via TRI, and the features from the TRI image are processed to yield a classification decision, based on the RVM. Finally, the quality of

the TRI algorithm and associated features employed within the RVM is dependent upon the accuracy with which the channel Green's function is estimated. Rather than simply performing a maximum-likelihood estimate of the channel parameters (point estimate), Gibbs sampling is used to estimate the full posterior distribution of the model parameters, the results from which are integrated into the TRI algorithm.

The remainder of the text is organized as follows. In Sec. II we briefly address the theory of time-reversal imaging, and in Sec. III Gibbs sampling is explained in the context of channel-parameter estimation. Feature extraction and classifier design based on the RVM are discussed in Sec. IV. Target classification performance is analyzed in Sec. V, followed by conclusions in Sec. VI.

II. TIME-REVERSAL THEORY

The phenomenon of time-reversal has been studied by several scientists^{8,11,24-26} in actual channel environments and for simulated acoustic medium. Previous researchers^{12,26} have presented the physics of time-reversal; hence the phenomenon is briefly described here, concentrating on the specifics of our problem. For an acoustic waveguide, scattering center localization can be achieved by spanning the channel by a vertical array of transceivers (say, L_r receivers, at locations \mathbf{r}_{rl} , $l \in \{1, \dots, L_r\}$) with maximum interelement distance of $\lambda/2$ with λ being the minimum wavelength of the transmitted signal. Let \mathbf{r}' and \mathbf{r}_{sk} represent respectively the source and k th scattering center location. For a transmitted signal $S(\omega)$ from the source, the backscattered signal received by the l th receiver located at \mathbf{r}_{rl} is given by

$$R(\omega, \mathbf{r}_{rl}) = \sum_k S(\omega) \Gamma_k(\omega) G(\omega, \mathbf{r}_{sk}, \mathbf{r}') G(\omega, \mathbf{r}_{rl}, \mathbf{r}_{sk}), \quad (1)$$

where Γ_k represents the reflectivity of the k th scattering center, $G(\omega, \mathbf{r}, \mathbf{r}')$ represents wave propagation from location \mathbf{r} to \mathbf{r}' , and the summation is over all scattering center locations. The target scattering is represented in terms of diffraction from isolated scattering centers; a more-general analysis has been performed by Carin *et al.*¹ Launching the time-reversed signal into the waveguide is equivalent to phase conjugation in the frequency domain. The phase-conjugated signal observed after propagating from \mathbf{r}_{rl} to any observation point \mathbf{r} is expressed as

$$S_{TR}(\omega, \mathbf{r}) = R^*(\omega, \mathbf{r}_{rl}) \hat{G}(\omega, \mathbf{r}, \mathbf{r}_{rl}), \quad (2)$$

where $\hat{G}(\omega, \mathbf{r}, \mathbf{r}')$ represents the numerically computed Green's function between \mathbf{r} and \mathbf{r}' . Assuming perfect knowledge about the channel, one can express $\hat{G}(\omega, \mathbf{r}, \mathbf{r}') = G(\omega, \mathbf{r}, \mathbf{r}')$, and due to reciprocity $G(\omega, \mathbf{r}_{rl}, \mathbf{r}_{sk}) = G(\omega, \mathbf{r}_{sk}, \mathbf{r}_{rl})$. Therefore constructive interference (focusing) is obtained at $\mathbf{r} = \mathbf{r}_{sk}$, with the wrong time dependence due to the effects of the initial propagation through the channel, from the source to the respective scattering center. To eliminate the effects of this propagation, one needs to run the forward model again to approximate $G(\omega, \mathbf{r}_{sk}, \mathbf{r}')$, which finally yields the time-dependent reflection coefficient, con-

volved with the incident pulse, at the point of the scattering center as

$$S_{TRM}(\omega, \mathbf{r}) = R^*(\omega, \mathbf{r}_{r_l}) \hat{G}(\omega, \mathbf{r}, \mathbf{r}_{r_l}) \hat{G}(\omega, \mathbf{r}', \mathbf{r}). \quad (3)$$

Repeating this same process for all the receivers and summing yields

$$S_{TRM}^{array}(\omega, \mathbf{r}) = \sum_{l=1}^{L_r} R^*(\omega, \mathbf{r}_{r_l}) \hat{G}(\omega, \mathbf{r}, \mathbf{r}_{r_l}) \hat{G}(\omega, \mathbf{r}', \mathbf{r}). \quad (4)$$

Performing an inverse Fourier transform of (4) yields a four-dimensional (space-time) image. This localizes the scattering centers in three-dimensional space while also approximately recovering the time dependence of each scattering center.

The above theoretical discussion assumes that the Green's function of the channel is known exactly. Typically, when performing TRI the Green's function is not known precisely *a priori*. Hence, one must perform geoacoustic inversion in order to estimate the channel parameters. In this paper a Gibbs sampling¹⁹ approach is employed to estimate these parameters.

III. CHANNEL INVERSION BY GIBBS SAMPLING

Dosso¹⁷ has developed a new Bayesian approach for estimating the geoacoustic parameters of a channel. Given prior knowledge of the model parameters, the proposed method estimates the posterior distribution based on Gibbs sampling.¹⁹ Since GS is explained in detail by Dosso,¹⁷ a brief summary is provided here in the context of our problem.

Let the vectors \mathbf{m} and \mathbf{d}^{obs} represent respectively the channel model parameters and observed scattering data at the array of receivers. Our objective is to estimate the underlying channel parameter vector \mathbf{m} given \mathbf{d}^{obs} . The *a posteriori* probability of the channel parameters $p(\mathbf{m}|\mathbf{d}^{\text{obs}})$ is of the form

$$p(\mathbf{m}|\mathbf{d}^{\text{obs}}) = \exp[-E(\mathbf{m})] p(\mathbf{m}) / \int_{\mathbf{m}'} \exp[-E(\mathbf{m}')] p(\mathbf{m}') d\mathbf{m}', \quad (5)$$

where $p(\mathbf{m})$ represents the prior distribution on the channel model parameters, and $E(\mathbf{m})$ is an energy function defined by Dosso¹⁷ as

$$E(\mathbf{m}) = \sum_{f=1}^F B_f(\mathbf{m}) |\mathbf{d}_f^{\text{obs}}|^2 / \eta, \quad (6)$$

where $B_f(\mathbf{m})$ represents the normalized Bartlett mismatch function $B_f(\mathbf{m}) = 1 - |\boldsymbol{\rho}_f^H(\mathbf{m}) \mathbf{d}_f^{\text{obs}}| / |\boldsymbol{\rho}_f(\mathbf{m})|^2 |\mathbf{d}_f^{\text{obs}}|^2$, with H being the complex conjugate transpose operator. The vector $\mathbf{d}_f^{\text{obs}}$ represents the backscattered signal at the receiver array for frequency f , and the parameter η represents the noise variance (frequency invariant, in our case). The vector $\boldsymbol{\rho}_f(\mathbf{m})$ is the simulated channel response as viewed by the array of receivers, for model parameters \mathbf{m} , due to a point source located at the position of the target.

Our objective is to approximate the integral in the denominator of (5) in terms of a sum, using a finite set of "important" examples of \mathbf{m} . This is executed by using a

TABLE I. The channel parameters estimated via the Gibbs sampling approach.

	True value	Estimated value	Search range
Channel depth (m)	6	6.01	(5.0–10.0)
SS in water (m/s)	1520	1523.2	(1470–1550)
SS in bottom (m/s)	1800	1807.8	(1750–1850)
Density of bottom (g/cm ³)	1.5	1.63	(1.0–2.0)
Attenuation of bottom (dB/kmHz)	0.28	0.295	(0.25–0.35)

variation of the Metropolis^{27,28} algorithm (MA). Assume that \mathbf{m}_i are the model parameters considered for iteration i , with associated energy $E(\mathbf{m}_i)$. Model parameters \mathbf{m}_{i+1} are deemed important if $\exp\{-[E(\mathbf{m}_{i+1}) - E(\mathbf{m}_i)]/T\} > \delta$, for temperature T , where δ is a random variable drawn from a uniform distribution over zero to one. Therefore, if $E(\mathbf{m}_{i+1}) < E(\mathbf{m}_i)$, then model parameter vector \mathbf{m}_{i+1} is always deemed important, and if $E(\mathbf{m}_{i+1}) > E(\mathbf{m}_i)$, the probability that \mathbf{m}_{i+1} is important is $\exp\{-[E(\mathbf{m}_{i+1}) - E(\mathbf{m}_i)]/T\}$. Therefore, with decreasing T , the probability of accepting parameters \mathbf{m}_{i+1} that increase the energy becomes very small.

In our problem, the channel model parameters \mathbf{m} are drawn randomly from the channel parameter search space using a uniform probability distribution [$p(\mathbf{m})$ is uniform]. The search space is initialized based on the prior knowledge of the channel environment (see Table I for the search space used in our problem). For each sample \mathbf{m}_i drawn uniformly from the model search space, the impulse response of the corresponding channel $\boldsymbol{\rho}_f(\mathbf{m})$ is computed numerically in a normal mode framework.²⁹ Given the impulse response $\boldsymbol{\rho}_f(\mathbf{m})$, the mismatch function $B_f(\mathbf{m})$, and the corresponding energy function, $E(\mathbf{m})$ is computed as shown in Eq. (6) (η is assumed known). The sample \mathbf{m}_i is accepted (or deemed important) if $E(\mathbf{m}_i) < E(\mathbf{m}_{i-1})$ or $\exp\{-[E(\mathbf{m}_i) - E(\mathbf{m}_{i-1})]/T\} > \delta$ with $p(\delta) = 1$, $\delta \in [0, 1]$. Note that the algorithm is started at $T > 1$ (T is initialized to 10). In subsequent iterations the temperature is lowered ($T^{\text{new}} = T^{\text{old}}/2$) until the temperature reaches unity and is kept constant thereafter. This process of accepting "important" samples is repeated until the resulting channel parameter posterior distribution converges. The "cooling" procedure is employed to achieve rapid convergence of the channel-parameter posterior distribution. In addition, the channel model search space is adaptively modified after every 20 new samples are accepted (deemed important). The modified range spans between $\boldsymbol{\mu}_m - 2\boldsymbol{\sigma}_m$ to $\boldsymbol{\mu}_m + 2\boldsymbol{\sigma}_m$, where $\boldsymbol{\mu}_m$ and $\boldsymbol{\sigma}_m$ represents the mean and standard deviation of the model parameters evaluated from the last 50 "important" samples accepted by MA.

IV. FEATURE EXTRACTION AND CLASSIFIER DESIGN

In the previous section a procedure for estimating Eq. (5) (the likelihood of the channel parameters given the observed data) is summarized. Time-reversal imaging can now be performed based on these estimated channel statistics. It is observed that, for relatively high signal-to-noise ratio (SNR),

Eq. (5) is typically strongly peaked about the true value for the channel parameters, and therefore the MAP channel estimator is employed in forming a time-reversal image [rather than integrating across the likelihood in Eq. (5), as in a Bayesian setting]. Details on the dependence of channel-parameter estimation on SNR are described when presenting example results.

The data under consideration were generated as follows. An FEM^{30,31} model was used to compute the multistatic scattered fields from five elastic targets in free field. The in-channel signatures were then computed by coupling these free-field solutions to a numerical forward model for the channel. The numerical details of the FEM model have been discussed previously.^{32,33}

The underwater targets possessed bisectonal symmetry, and therefore data were computed for 180° of variation in the target-sensor orientation, in 1° increments. A vertical receiver array was employed, and the source is placed at the array center. The observed array data for a given target-sensor orientation is time-reversed to generate a three-dimensional image in range, depth, and time (no azimuthal resolution). Target classification techniques applied to the time-reversed images are discussed in the following subsections.

A. Features

It has been demonstrated^{34,35} that, for the TRI procedure discussed in Sec. II, the image at $t=0$ corresponds to focusing at the target scattering centers. Feature are therefore extracted from the time-reversal image at time $t=0$, now corresponding to a range-depth image. Finally, to simplify things further, the depth is fixed, and the time-reversed one-dimensional signal is viewed as a function of range, through the nominal target center (which may be estimated from the range-depth two-dimensional image, prior to feature extraction). In the work presented here this process is automated, based on the energy distribution in the time-reversal image. Assume that $p_j(i,n)$ represents the one-dimensional time-dependent time-reversed data for target j at orientation n , where i denotes the time index (the time-dependent signal is the range-dependent waveform divided by the sound speed at the target depth). Features based on the spectral (Fourier) properties of $p_j(i,n)$ are considered in these examples for training the classifier. In this case the Fourier transform of $p_j(i,n)$, operated along dimension i , is uniformly divided into a set of seven frequency subbands, and the features are the energy within each band. The seven-dimensional feature vector \mathbf{v}_n corresponds to the orientation n of the target with respect to the vertical array. For the sake of simplicity the subscript j that represents the underlying target is ignored in the rest of the paper. It should be emphasized that only a subset of the information available in the time-reversal data is exploited here, since the image is a four-dimensional space-time signal. Future studies are of interest to optimally exploit all information in the four-dimensional time-reversal data.

B. Relevance vector machine (RVM) regression

Tipping²¹ has proposed the relevance vector machine classifier as a Bayesian generalization of the support vector machine (SVM).³⁶ Given a feature vector \mathbf{v} , our goal is to perform classification based on the probability that \mathbf{v} is associated with hypotheses H_0 (false target) and H_1 (true target), denoted respectively by $p(H_0|\mathbf{v})$ and $p(H_1|\mathbf{v})$. RVM-based regression is discussed first, which will set the stage for designing the classifier $p(H_1|\mathbf{v})$.

Assume access to “training” data $\{\mathbf{v}_n, l_n\}_{n=1,N}$, where \mathbf{v}_n represent feature vectors and l_n represent scalar labels. In the regression problem the objective is to learn a function that predicts the label of a given feature vector. Predictor function f can be written as

$$f(\mathbf{v}, \mathbf{w}) = \sum_{n=1}^N \mathbf{w}_n g(\mathbf{v}, \mathbf{v}_n) + \mathbf{w}_0, \quad (7)$$

where $g(\mathbf{v}, \mathbf{v}_n)$ is a kernel that quantifies the similarity between feature vectors \mathbf{v} and \mathbf{v}_n . Any linear or nonlinear measure may be selected for the kernel. The radial basis function (RBF) kernel^{21,23} is used in this paper where the similarity between two feature vectors \mathbf{v} and \mathbf{v}_n is defined as $g(\mathbf{v}, \mathbf{v}_n) = \exp[-\|\mathbf{v} - \mathbf{v}_n\|/2\sigma^2]$ with $\sigma=0.5$.

It is assumed that the error ϵ_n between the regression function $f(\mathbf{v}_n, \mathbf{w})$ and true label l_n is an independent, identically distributed (iid) zero-mean Gaussian with variance σ^2 , yielding $l_n = f(\mathbf{v}_n, \mathbf{w}) + \epsilon_n$, and for the N training examples the likelihood of the label set \mathbf{l} can be represented as

$$p(\mathbf{l}|\mathbf{w}, \sigma^2) = (2\pi\sigma^2)^{-N/2} \exp\left(-\frac{\|\mathbf{l} - \Phi\mathbf{w}\|^2}{2\sigma^2}\right), \quad (8)$$

where $\mathbf{l} = \{l_1, \dots, l_N\}$, $\mathbf{w} = \{w_0, \dots, w_N\}$, and Φ is a kernel design matrix of size $N \times (N+1)$ whose i th row $\Phi_i = [1, g(\mathbf{v}_i, \mathbf{v}_1), \dots, g(\mathbf{v}_i, \mathbf{v}_N)]$. The weight w_n quantifies the importance of the training feature vector \mathbf{v}_n on the regression function $f(\mathbf{v}_n, \mathbf{w})$. The likelihood of label \mathbf{l} [see Eq. (8)] is dependent on the weights \mathbf{w} and variance σ^2 ; although not shown explicitly, the likelihood of \mathbf{l} is also dependent on the feature vectors $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_N\}$, via the kernel matrix Φ .

Our objective is to learn the weights \mathbf{w} of the regression model, based on the training data $\{\mathbf{v}_n, l_n\}_{n=1, \dots, N}$. A prior distribution is introduced over the weights \mathbf{w} , governed by a set of hyperparameters $\boldsymbol{\alpha}$, defining $p(\mathbf{w}|\boldsymbol{\alpha})$. The unknowns to be estimated are now the weights \mathbf{w} , the hyperparameters $\boldsymbol{\alpha}$, and the variance σ^2 . The introduction of hyperparameters $\boldsymbol{\alpha}$ appears counterintuitive, since the number of unknowns has essentially been doubled. However, careful design of $p(\mathbf{w}|\boldsymbol{\alpha})$ makes these additional unknowns desirable. Specifically, as discussed further below, the density function $p(\mathbf{w}|\boldsymbol{\alpha})$ and prior probability distribution on the hyperparameters $p(\boldsymbol{\alpha})$ are designed such that they constrain the properties of \mathbf{w} learned during the training phase, thereby serving as a regularization that avoids overfitting. Overfitting occurs when the weights \mathbf{w} match the training data $\{\mathbf{v}_n, l_n\}_{n=1, \dots, N}$ very well, but the regression model does not generalize well to feature vectors \mathbf{v} that are not in the training set.

The likelihood of the weights \mathbf{w} , hyperparameters $\boldsymbol{\alpha}$, and variance σ^2 given the training data is expressed as

$p(\mathbf{w}, \boldsymbol{\alpha}, \sigma^2 | \mathbf{I}) = p(\mathbf{w} | \boldsymbol{\alpha}, \sigma^2, \mathbf{I}) p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I})$. The first term on the right can be written as $p(\mathbf{w} | \boldsymbol{\alpha}, \sigma^2, \mathbf{I}) = p(\mathbf{I} | \mathbf{w}, \sigma^2) p(\mathbf{w} | \boldsymbol{\alpha}) / p(\mathbf{I} | \boldsymbol{\alpha}, \sigma^2)$. By choosing $p(\mathbf{w} | \boldsymbol{\alpha})$ as a product of Gaussians, $p(\mathbf{w} | \boldsymbol{\alpha}) = \prod_{n=0}^N N(w_n | 0, \alpha_n^{-1})$, the integral $p(\mathbf{I} | \boldsymbol{\alpha}, \sigma^2) = \int p(\mathbf{I} | \mathbf{w}, \sigma^2) p(\mathbf{w} | \boldsymbol{\alpha}) d\mathbf{w}$ can be evaluated analytically (it is a convolution of Gaussians). Now combining $p(\mathbf{I} | \boldsymbol{\alpha}, \sigma^2)$ with (8) yields

$$p(\mathbf{w} | \mathbf{I}, \boldsymbol{\alpha}, \sigma^2) = (2\pi)^{-(N+1)/2} |\boldsymbol{\Sigma}|^{-1/2} \exp\left\{-\frac{1}{2}(\mathbf{w} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1} (\mathbf{w} - \boldsymbol{\mu})\right\}, \quad (9)$$

where the mean and covariance of the posterior distribution are given by

$$\boldsymbol{\Sigma} = (\sigma^{-2} \boldsymbol{\Phi}^T \boldsymbol{\Phi} + \mathbf{A})^{-1}, \quad \boldsymbol{\mu} = \sigma^{-2} \boldsymbol{\Sigma} \boldsymbol{\Phi}^T \mathbf{I} \quad (10)$$

with $\mathbf{A} = \text{diag}\{\alpha_0, \dots, \alpha_N\}$.

The evaluation of $p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I}) \propto p(\mathbf{I} | \boldsymbol{\alpha}, \sigma^2) p(\boldsymbol{\alpha}) p(\sigma^2)$ requires introduction of prior distributions $p(\boldsymbol{\alpha})$ and $p(\sigma^2)$. Since $\boldsymbol{\alpha}$ and σ^2 are associated with the variances of Gaussian distributions, they must be purely positive. Therefore gamma priors are introduced

$$p(\boldsymbol{\alpha}) = \prod_{n=0}^N \text{Gamma}(\alpha_n | a, b), \quad p(\beta) = \text{Gamma}(\beta | c, d) \quad (11)$$

with $\beta = \sigma^{-2}$ and $\text{Gamma}(\alpha_n | a, b) = \Gamma(a)^{-1} b^a \alpha_n^{a-1} e^{-b\alpha_n}$, with $\Gamma(a) = \int_0^\infty x^{a-1} e^{-x} dx$. The parameters a, b, c , and d are set to zero, yielding a set of uniform hyperpriors (Jeffrey's prior²¹).

The expression $p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I})$ cannot be evaluated analytically, and therefore it is approximated as a delta function at its mode: $p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I}) \approx \delta(\boldsymbol{\alpha} - \boldsymbol{\alpha}_{MP}) \delta(\sigma^2 - \sigma_{MP}^2)$. The most-probable $\boldsymbol{\alpha}_{MP}$ and σ_{MP}^2 are computed by maximizing $p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I})$, which for the uniform hyperparameters reduces to maximizing

$$p(\mathbf{I} | \boldsymbol{\alpha}, \sigma^2) = \int p(\mathbf{I} | \mathbf{w}, \sigma^2) p(\mathbf{w} | \boldsymbol{\alpha}) d\mathbf{w} \\ = (2\pi)^{-N/2} |\sigma^2 \mathbf{I} + \boldsymbol{\Phi} \mathbf{A}^{-1} \boldsymbol{\Phi}^T|^{-1/2} \\ \times \exp\left\{-\frac{1}{2} \mathbf{I}^T (\sigma^2 \mathbf{I} + \boldsymbol{\Phi} \mathbf{A}^{-1} \boldsymbol{\Phi}^T)^{-1} \mathbf{I}\right\}. \quad (12)$$

The maximization yields

$$\alpha_n^{new} = \gamma_n / \mu_n^2, \quad \text{where} \quad \gamma_n \equiv 1 - \alpha_n \sum_{nn}, \quad (13)$$

and

$$(\sigma^2)^{new} = \frac{\|\mathbf{I} - \boldsymbol{\Phi} \boldsymbol{\mu}\|^2}{N - \sum_n \gamma_n}. \quad (14)$$

The learning process is therefore characterized by repeated application of (13) and (14), concurrent with updating $\boldsymbol{\Sigma}$ and $\boldsymbol{\mu}$ from (10).

The composite prior distribution on the weights, defined by $p(\mathbf{w} | \boldsymbol{\alpha}) = \prod_{n=0}^N N(w_n | 0, \alpha_n^{-1})$ and $p(\boldsymbol{\alpha}) = \prod_{n=0}^N \text{Gamma}(\alpha_n | a, b)$, yields an algorithm in which most of the α_n in (13) go to "infinity" (reaching the maximum precision of the computer), and the associated weight w_n has a likelihood highly peaked at zero. The associated feature vector \mathbf{v}_n is deemed "irrelevant" to the function $f(\mathbf{v}, \mathbf{w})$ that one wishes to learn, and the irrelevant feature vectors are

pruned via iterative update of Eqs. (13) and (14). The algorithm therefore works by seeking to maximize the likelihood $p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I})$, under the constraint imposed by the prior distributions $p(\mathbf{w} | \boldsymbol{\alpha})$ and $p(\boldsymbol{\alpha})$.

Once the most-probable parameters $\boldsymbol{\alpha}_{MP}$ and σ_{MP}^2 are estimated within the training phase, the joint posterior of model parameters is approximated as $p(\mathbf{w}, \boldsymbol{\alpha}, \sigma^2 | \mathbf{I}) = p(\mathbf{w} | \boldsymbol{\alpha}, \sigma^2, \mathbf{I}) p(\boldsymbol{\alpha}, \sigma^2 | \mathbf{I}) \approx p(\mathbf{w} | \boldsymbol{\alpha}_{MP}, \sigma_{MP}^2, \mathbf{I})$. For given weights \mathbf{w} the likelihood of label l_* being associated with a feature vector \mathbf{v}_* is expressed as, from (8), $p(l_* | \mathbf{v}_*, \mathbf{w}, \sigma_{MP}^2) = (2\pi \sigma_{MP}^2)^{-1/2} \exp(-\|l_* - \boldsymbol{\phi}(\mathbf{v}_*) \mathbf{w}\|^2 / 2\sigma_{MP}^2)$ where the vector $\boldsymbol{\phi}(\mathbf{v}_*)$ is defined as $\boldsymbol{\phi}(\mathbf{v}_*) = [1, g(\mathbf{v}_*, \mathbf{v}_1), \dots, g(\mathbf{v}_*, \mathbf{v}_N)]^T$. Given these expressions, the likelihood of target l_* for feature vector \mathbf{v}_* is expressed as

$$p(l_* | \mathbf{I}, \boldsymbol{\alpha}_{MP}, \sigma_{MP}^2) = \int p(l_* | \mathbf{v}_*, \mathbf{w}, \sigma_{MP}^2) p(\mathbf{w} | \boldsymbol{\alpha}_{MP}, \sigma_{MP}^2, \mathbf{I}) d\mathbf{w} = N(l_* | y_*, \sigma_*^2) \quad (15)$$

with

$$y_* = \boldsymbol{\mu}^T \boldsymbol{\phi}(\mathbf{v}_*), \quad \sigma_*^2 = \sigma_{MP}^2 + \boldsymbol{\phi}(\mathbf{v}_*)^T \boldsymbol{\Sigma} \boldsymbol{\phi}(\mathbf{v}_*). \quad (16)$$

The feature vector \mathbf{v}_* may therefore be mapped to $l_* = y_*$, and the uncertainty in this mapping is reflected by σ_*^2 .

C. Relevance vector machine (RVM) classifier

For the classification problem the labels l are binary, where $l=1$ corresponds to a target and $l=0$ to a nontarget (clutter). Introducing a logistic link²¹ as

$$\sigma[f(\mathbf{v}; \mathbf{w})] = 1 / \{1 + \exp[-f(\mathbf{v}; \mathbf{w})]\}, \quad (17)$$

the probability of labels \mathbf{I} (for the N training examples) may be expressed as

$$p(\mathbf{I} | \mathbf{w}) = \prod_{n=1}^N [\sigma\{f(\mathbf{v}_n; \mathbf{w})\}]^{I_n} [1 - \sigma\{f(\mathbf{v}_n; \mathbf{w})\}]^{1-I_n}. \quad (18)$$

The model-parameter posterior distribution can be written as $p(\mathbf{w}, \boldsymbol{\alpha} | \mathbf{I}) = p(\mathbf{w} | \boldsymbol{\alpha}, \mathbf{I}) p(\boldsymbol{\alpha} | \mathbf{I})$, where the regression variance σ^2 is no longer present [note that the use of the $\sigma(\cdot)$ to represent the logistic link function is widely employed within the statistics community, and this must be distinguished from the variance σ^2]. The approximation $p(\boldsymbol{\alpha} | \mathbf{I}) \approx \delta(\boldsymbol{\alpha} - \boldsymbol{\alpha}_{MP})$ is again employed, using the same sparseness prior distributions $p(\mathbf{w} | \boldsymbol{\alpha})$ and $p(\boldsymbol{\alpha})$ as employed in the regression problem. The computation of $p(\mathbf{w}, \boldsymbol{\alpha} | \mathbf{I}) = p(\mathbf{w} | \boldsymbol{\alpha}, \mathbf{I}) p(\boldsymbol{\alpha} | \mathbf{I})$ depends on the evaluation of $p(\mathbf{w} | \boldsymbol{\alpha}, \mathbf{I})$, which for the classification problem is not Gaussian (as it was for the regression problem). In the interest of obtaining a solution analogous to that found for the regression formulation, $p(\mathbf{w} | \boldsymbol{\alpha}, \mathbf{I})$ is approximated by a Gaussian distribution. The associated mean is computed as the maximum of $p(\mathbf{w} | \boldsymbol{\alpha}, \mathbf{I}) \propto p(\mathbf{I} | \mathbf{w}) p(\mathbf{w} | \boldsymbol{\alpha})$, with the covariance matrix represented by the Hessian of $p(\mathbf{w} | \boldsymbol{\alpha}, \mathbf{I}) \propto p(\mathbf{I} | \mathbf{w}) p(\mathbf{w} | \boldsymbol{\alpha})$; this yields the so-called Laplace approximation.²¹ The most-probable weights \mathbf{w}_{MP} can be computed analytically, as can the Hessian. Once the Laplace approximation is so employed, the training of the classifier is performed by an iterative algorithm, exactly as developed above for RVM regres-

sion. During this training procedure the most-probable weights \mathbf{w}_{MP} are characterized by many \mathbf{w}_n being set to zero, with only the most-relevant training examples (those with nonzero weights) used in the final classifier.

Now consider a feature vector \mathbf{v} that needs to be classified. The probability that \mathbf{v} is associated with label $l=1$ (corresponding to the probability that \mathbf{v} corresponds to a target of interest) is evaluated by computing (17) using the most-probable weights \mathbf{w}_{MP} , determined when training. This yields the desired $p(H_1|\mathbf{v})$.

V. TARGET CLASSIFICATION PERFORMANCE

A. Problem details

To consider changes in the channel parameters, the channel depth is varied between 6 and 9 m, with all other channel parameters held constant. In each test case, it is assumed that a submerged target has already been detected and our objective is to determine if it is one of the targets seen when training (or if it is a clutter item). All examples shown in this paper correspond to simulated targets where the free-field bistatic responses are computed using an FEM code³¹ and the in-channel response is computed using the free-field response and normal-mode channel model (KRAKEN²⁹). The performance of time-reversal imaging has been considered by us previously using measured data;¹ simulated data are considered here such that a range of uncertainty in the channel parameters may be examined, as well as a range of target/clutter types (the measured data in Ref. 1 is too limited to perform the classification studies of interest here). In each test case, the channel parameters are estimated via GS, before TRI is performed. Five distinct scatterers are placed within the acoustic channel. Two of the targets are deemed “targets of interest” (defined by hypothesis one, H_1), and the other three are deemed “false targets” (defined by null hypothesis, H_0). The incident fields on the target propagate through the channel from an unidirectional source, located at the center of the sensor array. The scattered fields are computed for observations in a vertical plane, this plane situated

FIG. 1. Schematic of array-based sensing of a target in an acoustic waveguide. A single isotropic source (\mathbf{r}') is located at the center of the receiver array, and \mathbf{r}_{rl} , $rl=1,\dots,L_r$, locate the array elements. The k th target scattering center is located at \mathbf{r}_{sk} . The position of the receiver array and depth of the target relative to the bottom are kept fixed, and the target is rotated relative to the array to generate multiple target-sensor orientations.

within the channel, at a fixed distance from the target center. The fields within the plane are then coupled to a modal channel model,²⁹ with which they are propagated away from the target through the channel to the receiver array. The target-receiver distance is fixed at 100 m. In addition, the center of the target is 0.12 m above the channel bottom. A 28-element linear receiver array is employed perpendicular to the bottom (see Fig. 1). The ocean bottom is treated as a smooth horizontal surface to which the array is vertical. The array is 2 m long and its center is situated 2 m below the sea surface. A two-layer geoacoustic model is considered, with sound speed in water of 1520 m/s, a bottom density of 1.5 g/cm³, a channel-bottom attenuation factor of 0.28 dB/KmHz, and sound speed in the bottom of 1800 m/s for simulating the in-channel response at the receiver array.

The two scatterers in H_1 are minelike targets (a steel and fiberglass cylinder). The three false targets are a 55-gallon drum, an oxygen tank, and a rock. The data covers the frequency band 50 Hz to 10 KHz, and the scattered waveforms received by the vertical receiver array are considered in the time domain (after Fourier synthesis), as propagated through the channel to the vertical receiver array. Each of the five targets is rotated about its axis over 180°, with 1° angular

FIG. 2. Incident pulse shape for the synthesized time-domain scattering data.

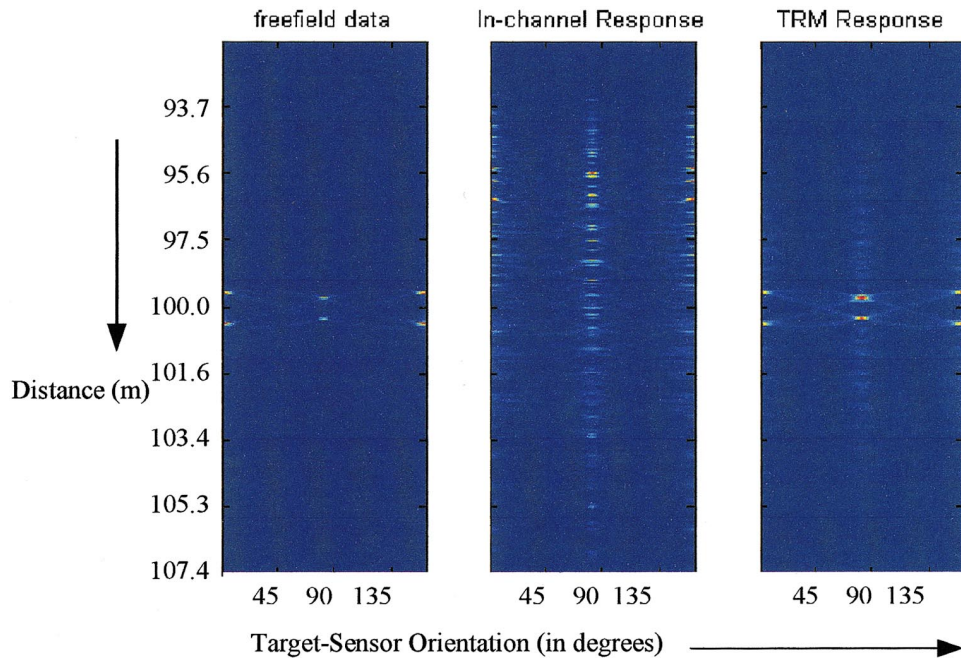

FIG. 3. Scattering data from a 55-gallon drum in the channel. The horizontal axis denotes the orientation of the target relative to the vertical sensor array (broadside or specular reflection at 90°) and the vertical axis represents target-sensor distance in meters (which may be related to time, via the sound speed). The drum is on the channel bottom, with center 0.12 m above the channel floor at a range of 100 m (6-m channel depth): (a) synthesized free-field time-domain data, (b) scattering data as received by the center element of the receiver array, and (c) time-reversed signal through the target center, using channel parameters estimated via Gibbs sampling. Each subimage is normalized such that dynamic range is between 0 and 1.

FIG. 4. Performance of the RVM classifier, trained using free-field signatures from two targets of interest (H_1). The dashed line shows the classification performance when tested on free-field responses from all targets and the dotted line shows the performance of the same classifier when tested directly on in-channel responses of all targets (at all orientations and at depths of 6, 8, and 9 m). The solid lines in different colors show the performance when time-reversed in-channel target signatures were subjected to the RVM classifier. Different colors represent different channel depths. Gibbs sampling was used to estimate the channel parameter prior to time-reversal. The data included three “false targets” not observed while training. Target-sensor distance was fixed at 100 m.

FIG. 5. The classification performance of the RVM classifier, trained on free-field response of two minelike targets and tested on multi-aspect scattering data sampled in 5° increments. The figure shows classification performance for different sequence lengths. For all sequences the angular increment between successive observations is 5° . The relative change in target-sensor orientation is assumed known, but the absolute target-sensor orientation is unknown to the classifier.

sampling, thereby constituting multiple synthesized measurements. The shape of the pulse driving the point-source transmitter is shown in Fig. 2.

B. Geoacoustic inversion via Gibbs sampling

The parameters of the geoacoustic model (e.g., depth, sound speed in the water and bottom, channel depth, etc.) are assumed unknown at the receiver array although the target location is assumed known (100 m along downrange and 0.12 m above the floor). Note that our objective is to perform target classification, and it is assumed that detection has already been achieved. The target depth and position could also be accounted within the GS procedure, as has been done in a previous genetic algorithm study.¹ The channel parameters considered for GS estimation are channel depth, sound speed in water, sound speed in the bottom, and the density and attenuation of the bottom. Since GS tries to address channel estimation in a Bayesian construct, one needs to define the model space and the *a priori* probability of the model parameters within that space. The model space is defined by channel depth varying between 5 and 10 m, sound speed in water between 1470 and 1550 m/s, sound speed of the bottom between 1750 and 1850 m/s, bottom attenuation between 0.25 and 0.35 dB/Km Hz, and density of the bottom between 1 and 2 g/cm³. In our problem a uniform *a priori* probability is assumed within the model space. GS is employed for a single frequency (the frequency that corresponds to the strongest signal at the receiver array, 2.25 KHz) although the algorithm is capable of handling multiple frequencies, as presented in (6). For noise-free data the marginal posterior distribution of individual channel parameters is observed to be approximately a delta function around the

true values; details for noisy data are given below. The comparison between the true and estimated channel parameters is shown in Table I for scattering from an oil-drum situated in a 6-m-deep channel, for noise-free data. The GS-based geoacoustic inversion is performed for each target separately and the MAP estimates are used from the *a posteriori* parameter density for subsequent time-reversal imaging.

To demonstrate the form of the data, Fig. 3(a) represents the free-field scattered response from the 55-gallon drum. The vertical axis represents time and the horizontal axis denotes the target orientation. Scattering from the same target is shown in Fig. 3(b), situated in a 6-m-deep channel and 100 m from the receiver array, as received by the center receiver element. It is important to note that the extended temporal support of the time-domain signal is reflective of the waveguide dispersion.

C. Time-reversal imaging and feature extraction

The time-reversed response of the 55-gallon drum is shown in Fig. 3(c). The vertical axis in Fig. 3(c) represents target-sensor range and the horizontal axis represents orientation of the drum relative to the receiver array. It is apparent from Fig. 3(c) that the time-reversal processing with an estimated channel model largely removes the channel-induced dispersion and recovers a signal similar to the free-field response [Fig. 3(a)]. The comparison between Figs. 3(a) and 3(c) motivates RVM design based on free-field data, with time-reversal employed to approximately remove channel effects. The time-reversed response for each target/clutter at every orientation is subjected to feature extraction and the feature vector is used for subsequent classification by the RVM.

FIG. 6. Example scattered waveforms at various SNR levels. The additive noise is formed by convolving the incident-pulse shape (Fig. 2) with white Gaussian noise. These example results correspond to a 55-gallon drum situated in a 9-m-deep channel, with center 0.12 m above the floor, at a range of 100 m. These examples correspond to data received at the center element of the vertical array. The target is oriented at 90° with respect to the vertical array, corresponding to broadside excitation (strongest target signature): (a) noise-free data, (b) 10 dB SNR, (c) 0 dB SNR, and (d) -10 dB SNR. The horizontal axis for all the subplots is time in milliseconds.

FIG. 7. As in Fig. 6, for the target-sensor orientation corresponding to weakest target-signature strength. The SNR values correspond to average target signature strength across all possible target-sensor orientations: (a) 10 dB SNR and (b) 0 dB SNR. The horizontal axis for both the subplots is time in milliseconds.

D. Classification results

As indicated above, a time-reversal signature is obtained for each orientation of the vertical array relative to the target, using the speed of sound to convert from the range-dependent time-reversal data. Features are extracted from this time-domain waveform. It is assumed that in each case the presence of a target or non-target has been detected, and our objective is to classify it. It needs to be emphasized that the RVM classifier²¹ is trained solely on free-field data from the two targets of interest (H_1), with no *a priori* knowledge assumed for the false targets (H_0) and with channel effects removed approximately via time reversal.

Figure 4 demonstrates the performance of the RVM classifier in terms of the receiver operating characteristic (ROC), quantified in terms of the probability of detection (probability that a target from H_1 is properly so classified) versus the probability of false alarm (probability that one of the three false targets is classified as being in H_1). The solid lines in three different colors depict the performances when the clas-

sifier is tested on the time-reversed responses for all targets and false targets, at channel depths of 6, 8, and 9 m. These results are based on classification at a single target-sensor orientation (with performance averaged across all orientations). The dash-dotted magenta line in Fig. 4 shows the RVM performance of the same classifier when tested directly on in-channel target data (no time-reversal), as received at the center element of the receiver array, using the same features as discussed above. The dashed red line in Fig. 4 shows the performance of the same RVM classifier when tested on the free-field response of all targets and non-targets (no channel). This represents the optimal performance that could be achieved if time-reversal removes the channel effects completely.

It has been demonstrated by several researchers^{37,38} that the performance of target classification may be enhanced by combining the information gathered from multiple target orientations (aspects). Multi-aspect classification is performed here as follows. Assume that vertical array data are collected

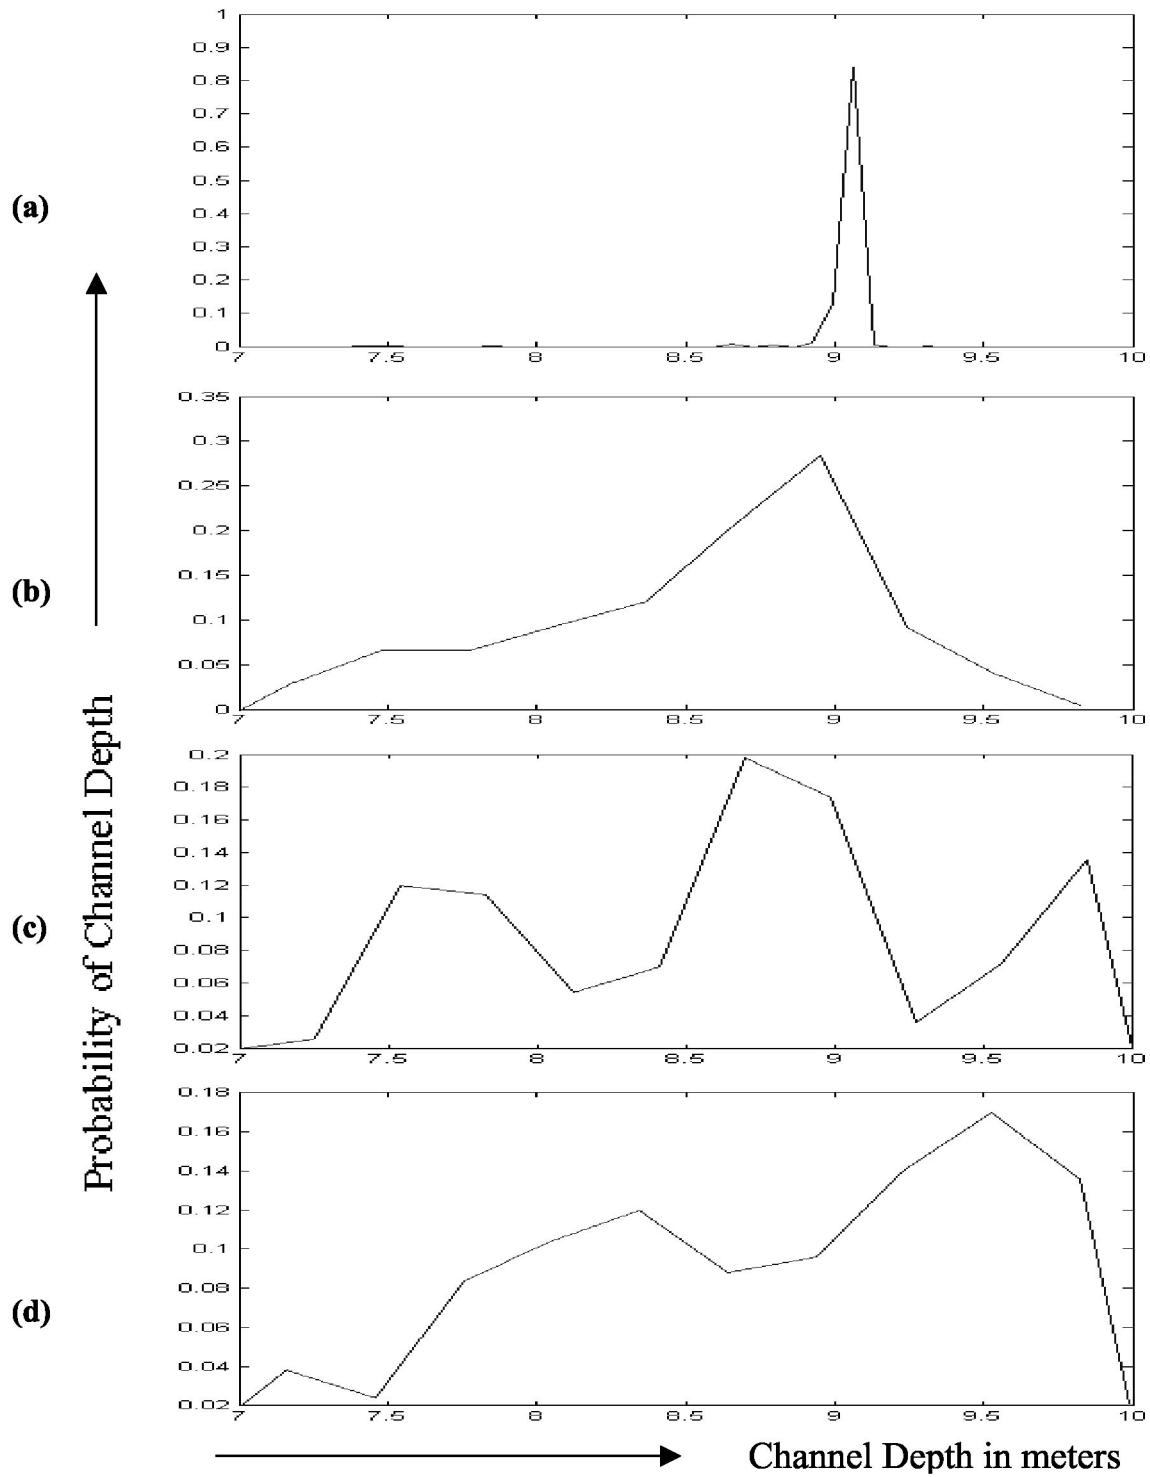

FIG. 8. The marginal posterior distribution of channel depth at different SNR levels (colored noise), over the 7–10-m search range. The true channel depth is 9 m: (a) 0 dB, (b) –5 dB, (c) –10 dB, and (d) –20 dB.

at multiple orientations (with respect to the target) along a circular path, constituting a synthetic aperture. Let \mathbf{x}_q represent the vertical-array data, for the q th position along the synthetic aperture. Given a set of backscattered responses from multiple target-sensor orientations, the response \mathbf{x}_q that corresponds to maximum signal strength is selected and the

channel parameters are estimated from \mathbf{x}_q via GS. Time-reversal imaging of \mathbf{x}_q ($\forall q=1, \dots, Q$) based on estimated channel parameters yields the associated feature vector, \mathbf{v}_q (Q feature vectors, one for each of the Q vertical-array positions, at multiple orientations about the target). Note that the

FIG. 9. Target classification performance for the case of additive colored noise. The colored noise was added to the backscattered response received by the sensor array before channel parameters were estimated.

channel parameters are estimated from the most significant backscattered response, not individually from each target-sensor orientation. The classifier in Eq. (17) quantifies the probability $p(H_1|\mathbf{v}_q)$ that the q th measurement is associated with class H_1 . For Q sensor positions along the synthetic aperture, the cumulative statistic is obtained as $P_Q = \prod_{q=1}^Q p(H_1|\mathbf{v}_q)$. Note that the multi-aspect waveforms are treated independently here for simplicity, although more-sophisticated techniques are available.³⁷ Synthetic apertures of multiple lengths are considered in Fig. 5, and, in each case, consecutive positions along the aperture correspond to changes of 5° in the target-sensor angle (angular sampling of 5°). As expected, the classification performance increases monotonically when observations from multiple aspects are fused.

E. Noisy data

All examples considered above assumed no noise at the receiver array. In the following examples noise is added at the receiver array before estimation of the channel parameters. To approximate scattering from rough channel interfaces (top and bottom), the additive colored noise was synthesized by convolving white Gaussian noise with the incident-pulse shape. The noisy time-domain waveforms at the receiver were converted to the frequency domain and subjected to channel-parameter estimation. Figure 6(a) shows the noise-free in-channel response for a 55-gallon drum situated in a 9-m-deep water channel, with center 0.12 m above the channel bottom, as received by a single receiver in the array center. The target response corresponds to a target-sensor orientation of 90° . Figures 6(b)–6(d) show the in-channel drum response at noise levels of 10, 0, and -10 dB, respectively, defined in terms of the signal energy divided by the noise energy. For a given value of SNR, the noise variance is the same for each target-sensor orientation considered. Since the signal strength is a strong function of

orientation, the SNR is in fact target-sensor-orientation dependent. The SNR values mentioned above represent average values across all orientations. Figures 7(a) and 7(b) show the noisy in-channel response at 45° orientation for the same drum, for noise variances associated with average SNR values of 10 and 0 dB, respectively. A comparison of Figs. 6 and 7 underscores that the strength of the target-signature relative to the noise is a strong function of orientation.

As discussed above, at high average SNR values (>0 dB), the marginal posterior distributions for the channel parameters are strongly peaked. Figure 8(a) shows the marginal posterior distribution of channel depth for a 55-gallon oil drum at a SNR of 0 dB. It is apparent that the posterior distribution is strongly peaked around the true channel depth of 9 m. Similar characteristics of the posterior distribution are observed for other channel parameters, such as the sound speed in the water and the bottom, not shown here for brevity.

The effect of noise on channel parameter estimation via GS is portrayed in Fig. 8. The noisy in-channel response corresponds to the same target (55-gallon oil drum situated in a 9-m-deep channel), with all results for the orientation corresponding to maximum signal strength. As expected, the posterior distribution (along with the MAP estimate of channel depth) deviates from being strongly peaked as the noise level increases. Figures 8(b)–8(d) represent the marginal posterior distribution of channel depth at three levels of SNR: -5 , -10 , and -20 dB, respectively.

RVM classification performance is now considered for the noisy data (as in Fig. 4, wherein noise-free data were considered). Figure 9 shows the performance of the same RVM classifier as in Fig. 4 (trained on noise-free, free-field data), applied to noisy time-reversed target responses at different noise levels. These results are based on a single observation (*i.e.*, observation sequence length, $K=1$). The results are averaged across all possible target-sensor orientations,

and it demonstrates the expected vitiation in performance as SNR is diminished.

VI. CONCLUSIONS

Time-reversal imaging has been employed to remove channel-induced dispersion effects, associated with backscattered signatures from targets situated in a shallow channel. The channel parameters required of the time-reversal imager have been estimated within a Bayesian framework, via Gibbs sampling. The key new development is examination of target classification, based on the time-reversed image. The objective was to use time reversal to remove channel-induced effects, such that the same classifier [trained solely on the free-field response of the target(s)] may be employed for different channel parameters (here multiple channel depths have been considered). In this study an RVM²¹ classifier is employed, and it was found that the classification performance (after time reversal) was relatively invariant to channel parameters (across a large range of channel depths).

The features employed in the RVM classifier were based on the spectral properties of a one-dimensional waveform, computed by taking a one-dimensional “cut” in the full time-reversal image. In general, the time-reversal imager yields a four-dimensional image (space-time),³⁹ and in future research it is of interest to develop features that fully exploit this information base. In addition, all of the synthesized data corresponded to the case of a perfect (flat-surface) acoustic waveguide. Colored noise was added to the data, to synthesize scattering from a rough channel surface and bottom. However, future studies are needed to explicitly assess the effects of surface roughness on time-reversal-image quality, and on the subsequent classification performance.

(Received 16 July 2004; revised 13 January 2005; accepted 20 January 2005)

Development of protocols for calibrating multibeam sonar by means of the standard-target method is documented. Particular systems used in the development work included three that provide the water-column signals, namely the SIMRAD SM2000/90- and 200-kHz sonars and RESON SeaBat 8101 sonar, with operating frequency of 240 kHz. Two facilities were instrumented specifically for the work: a sea well at the Woods Hole Oceanographic Institution and a large, indoor freshwater tank at the University of New Hampshire. Methods for measuring the transfer characteristics of each sonar, with transducers attached, are described and illustrated with measurement results. The principal results, however, are the protocols themselves. These are elaborated for positioning the target, choosing the receiver gain function, quantifying the system stability, mapping the directionality in the plane of the receiving array and in the plane normal to the central axis, measuring the directionality of individual beams, and measuring the nearfield response. General preparations for calibrating multibeam sonars and a method for measuring the receiver response electronically are outlined. Advantages of multibeam sonar calibration and outstanding problems, such as that of validation of the performance of multibeam sonars as configured for use, are mentioned. © 2005 Acoustical Society of America. I. INTRODUCTION

Multibeam sonar, with its simultaneous formation of multiple beams oriented differently in space, typically in a fan shape,¹ has a long history of application to the imaging of fixed structures. Chief among these has been imaging the seafloor to determine the bottom depth over relatively broad transects or swaths. The resulting data are typically georeferenced and displayed as maps, while substantial efforts are made to avoid echoes, also called returns, from scatterers such as fish in the intervening water column.

In other applications, particularly those relating to fisheries, specialized multibeam sonars have been adapted to allow collection of returns from the water column and display of data in real time on a screen, much like conventional sonar data.² The increased areal coverage provided by multibeam sonars without compromise of spatial resolution makes them well suited for studies of fish behavior and vessel avoidance. A number of pioneering studies have looked at the behavior of pelagic fish schools during the passage of an acoustic survey vessel including, for example, Misund and Aglen,³ using the SIMRAD SM600 sonar, with operating frequency of 34 kHz, and Gerlotto *et al.*^{4,5} and Soria *et al.*,⁶ using a RESON SeaBat 6012, with operating frequency of 455 kHz. The behavior of pelagic fish schools during trawling has also been observed with the SM600.³ The swimming speed of fish has been measured using the Doppler function of the same sonar.⁷ Migration of schools of herring (*Clupea*

harengus) in the North Sea has been observed, with concomitant measurements of swimming speed, by both the Simrad SR240 and SA950 sonars, with operating frequencies of 24 and 95 kHz, respectively.⁸ Migration behavior of schools of capelin (*Mallotus villosus*) in the Barents Sea has also been observed with the SR240.⁸ Some other applications of multibeam sonar to fish, as well as limitations in the use of the sonar, have been summarized by Reid.⁹

The three-dimensional nature of multibeam sonar data has also encouraged application of modern visualization techniques, allowing the complex behavior of mid-water targets to be explored interactively and in three dimensions.¹⁰ The advantage of using multibeam sonar for mid-water target identification is also being explored by the military.¹¹

Predator-prey interactions are being studied by means of multibeam sonar. The movements of schools of herring induced by killer whales (*Orcinus orca*) have been measured,¹² as have the interactions between juvenile herring and the Atlantic puffin (*Fratercula arctica*).¹³ In both of these studies, the RESON SeaBat 6012 sonar was used, with respective operating frequencies of 455 and 150 kHz. The behavior of Hawaiian spinner dolphins (*Stenella longirostris*) and pelagic prey has been studied with the new SIMRAD MS2000 sonar, with 200-kHz operating frequency and 128 1.5-deg beams spanning a 150-deg sector.¹⁴

The several fisheries applications mentioned here have succeeded because of the qualitative imaging capability of

the multibeam sonar in a high-signal, low-noise environment, supplemented by registration of the echo magnitude. Calibration is generally important for imaging applications, for example, to define the limits of performance *vis-à-vis* the signal-to-noise ratio and to ensure consistent, distortionless performance at high signal-to-noise ratios. In other desired applications beyond those of visualization,¹⁰ a quantitative capability, hence calibration, is essential. This is true for numerical determination of concentration densities of fish and other biological organisms. It is also true for measurement of bubble populations¹⁵ and particulate concentrations near hydrothermal vents,¹⁶ for example.

There are additional advantages to calibrating multibeam sonars. For example, sonar performance can be monitored, with the ready possibility of detecting changes in this. While a multibeam sonar may be calibrated by the manufacturer prior to shipping to a customer, the owner may want to confirm its compliance with the specifications. Also, the user needs to be able to check the state of the instrument at or near to the time of application.

There are well-established procedures for calibrating sonars. A dozen different basic approaches to measuring the frequency response function of sonar receivers were listed in 1983 by Urick.¹⁷ Given the complexity of multibeam sonar, particularly the large number of beams, use of any of these approaches must be time consuming. At the same time, these calibration procedures require measurements of parts of the sonar, with the inevitable compounding of errors, and use of secondary standards, such as hydrophones, themselves requiring calibration.

Fortunately, there is an alternative procedure available for multibeam sonar, namely that of the standard target.^{18–20} This is widely used for calibrating scientific echo sounders at ultrasonic frequencies, and has already been used for measuring certain performance measures, including the overall system directionality, of the SIMRAD SM2000/200-kHz multibeam sonar^{21,22} and SM2000/90-kHz multibeam sonar.²³

Recognizing the importance of developing simple and straightforward calibration procedures for multibeam sonar, a project has been conducted with the aim of developing convenient calibration protocols for multibeam sonars used for

water-column measurement. Development of new protocols has already been described in a series of preliminary publications.^{21,23,24} This development work is summarized, and the protocols are documented. It is believed that these are sufficiently detailed to serve as guides for the interested user. It is believed further that the protocols collectively will enable multibeam sonars configured for water-column measurement to be used as an integrated set of scientific echo sounders.

In the following, the test multibeam sonars and calibration targets are described, as are the seawater and freshwater facilities and associated instrumentation used in developing the calibration protocols. Methods involving acoustic measurements are reviewed, and results of the development work are summarized in the form of protocols. Some outstanding problems in multibeam sonar calibration are briefly discussed.

II. MULTIBEAM SONARS AND TARGETS

Essential to the development of calibration protocols for multibeam sonar was identification of appropriate sonar systems and specification of standard targets. Both subjects are addressed.

A. Sonars

Three sonar systems were selected for their routine provision of the water-column signal, which is otherwise the exception in most commercial multibeam sonar systems. In this section, details are given on the transducer array geometries. While this information is not usually regarded as being commercially confidential, it is not generally published either, not even in proprietary literature provided to owners of such sonars. The information is valuable in several ways, e.g., for use in beamforming based on individual element signals (Sec. V A) and for other processing or analytical operations, as in calculating nearfield–farfield transition characteristics (Sec. V G).

Some transducer specifications are compared in Table I. Differences in particular configurations are sufficient to require further elaboration in the text.

TABLE I. Comparison of three different multibeam sonars used in the calibration exercises.

Parameter	SM2000/90 kHz	SM2000/200 kHz	RESON Seabat 8101
Operating frequency (kHz)	90	200	240
Receiving array			
No. of channels	80	80	176
Radius (cm)	38.7	20.0	15.6
Angular span (deg)	94.8	88.16	150
Displayed beams			
No. of beams	128	128	101
Angular resolution (deg)	1.5	1.5	1.5
Displayed-beam signals			
No. of bits	8	8	8
Dynamic range (dB)	48	48	48
Individual-channel signals			
No. of bits	12	12	8
Dynamic range (dB)	72	72	48

FIG. 1. Schematic diagram of the sea well as configured for calibration. For the transducer mountings, as indicated in Fig. 2, the equatorial plane is that plane running through the arc of the receiving elements, with $\theta=0$ or equivalently $h=0$, thus coinciding with the horizontal plane. The polar planes are perpendicular to the equatorial plane and contain the rotational axis of the transducer; for the particular configuration, they are vertical planes.

Transducer-mounting convention: In all cases, the transducers were mounted with their active surfaces in the vertical plane, as indicated in Fig. 1. Thus, the acoustic axis of each was horizontally oriented.

Terminology: As indicated below, the elements of each receiving array used in this study are arranged in a single row along a circular arc. The plane of this arc is called the equatorial plane. The perpendicular planes containing the rotational axis of the transducer are called the polar planes. Each particular polar plane is distinguished by its azimuthal orientation, which may define an acoustic axis if the beam-forming is done through postprocessing.

1. SIMRAD SM2000/200-kHz multibeam sonar

The SM2000 has two separate operating modes, referred to as imaging and echo-sounding. In the imaging mode, the same transducer array is used in both signal transmission and echo reception. This array consists of 80 elements positioned with equal spacing on a circular arc (Fig. 2), thus defining the equatorial plane. Each element is rectangular, 2.54 by 19.05 mm. Two versions are fabricated. For that of nominal span 120 deg, the radius to the outer faces of the elements is 20.00 cm, and the interelement spacing is 1.12 deg, hence spanning a total angular sector of 88.16 deg as measured between the centers of the end elements. For that with nominal span 150 deg, the radius to the outer faces of the elements is 10.85 cm, and the interelement spacing is 1.13 deg, spanning a total sector of 155 deg. In the associated digital signal processor, a total of 128 receive beams are formed, each with beamwidth 1.5×20 deg in the respective horizontal and vertical planes.

In the echo-sounding mode, the described transducer array is used only in reception. Transmission is effected by an

FIG. 2. Schematic diagrams of transducer-mounting plates for the SeaBat 8101 240-kHz multibeam sonar, SM2000/200-kHz multibeam sonar, and SM2000/90-kHz multibeam sonar. The black rectangular areas designate the protective coverings of the external transmitter. The black curved areas designate the same for the receiving arrays. In the case of the SM2000 models in the imaging mode, the external transmitter is not used, and the curved arrays are used both for transmission and reception. In the case of the SM2000 models in the echo-sounding mode, the external transmitter is used.

external line array of 50 elements of total length 27.6 cm oriented along the vertical, thus in the central polar plane perpendicular to the equatorial plane of the receiving array (Fig. 2), and thence forming a Mills cross.¹⁷ Each transmitting element is a narrow band of width 2.1 mm spanning 177 deg of a circular arc of radius 44.45 mm. The entire array appears to be a half-cylinder. The elements are stacked with a center-to-center distance of 5.6 mm. They are weighted in amplitude, i.e., amplitude shaded.¹⁷ The computed nearfield distance is 11 m.²⁵ Through digital signal processing, 128 receive beams are formed for the display, with nominal beamwidths 1.5×1.5 deg. The number of beams that can be formed on an external processor is arbitrary.

The distinction between the two modes is recognized by a particular naming convention, which is adhered to in this work. For the general system, with optional use of either mode, reference is made to the SM2000 multibeam sonar. For the particular configuration in which the external transmitter is used, reference is made to the SM2000 multibeam echo sounder.

The transmitted signal in both modes is typically a finite, or pulsed, sinusoid at 200 kHz. The duration may be specified directly by the user or indirectly based on the specified range. For target ranges of order 5–25 m, which are typical in standard-target calibrations of high-frequency sonars, a pulse duration of 100 μ s was generally used. The pulse repetition frequency was determined automatically in accordance with the range, typically about 1 Hz or 1 ping/s. Notwithstanding the appearance of user control over the settings, the sonar itself is configured internally with certain constraints that cannot be exceeded. In addition, the sonar can neither accept nor generate an external trigger signal, which may be regarded as highly inconvenient in many applications.

The sonar displays echoes as received on 128 beams over the total angular sector of 120 or 150 deg. Significantly, the sonar can record either the raw complex echo signals from each of the 80 elements or the 128 beamformed signals. Beamforming performed within the sonar digital signal processor (DSP) uses a Hamming-type amplitude-weighting.²⁶ Beamforming performed through postprocessing external to the sonar DSP uses Chebyshev-type amplitude-weighting.¹⁷ Other shading schemes may be implemented when using the individual element outputs, and other apertures may also be defined.

The data are digitized with 8-bit resolution for display and with 12-bit resolution for recording purposes. The nominal dynamic range of the recorded data is thus 72 dB.

2. SIMRAD SM2000/90-kHz multibeam sonar

The architecture of this sonar, which operates at 90 kHz, is similar to that of the 200-kHz sonar described above. Similarly to the 200-kHz sonar, the 90-kHz sonar operates in both imaging and echo-sounding modes. The collocated imaging array (Fig. 2) also consists of 80 identical elements spaced at intervals of 1.20 deg along a circular arc of radius 38.74 cm measured to the outer face of the element and

spanning 94.8 deg as measured between the centers of the end elements. The dimensions of the individual rectangular elements are 5.08×64.8 mm.

The external transmitter is a linear array 86.6 cm in length oriented perpendicularly to the equatorial plane of the receiving array (Fig. 2). This consists of 12 pairs of elements. Each element is rectangular with dimensions 3.8×64.8 mm. The center-to-center distance between elements in a pair is 17.8 mm. The center-to-center distance between pairs, aligned end-on, is 65.3 mm.

The digital signal processor forms 128 beams for display. The nominal beamwidths are 1.5×20 deg in the imaging mode, without use of the external transmitter, and 1.5×1.5 deg in the echo-sounding mode, with use of the external transmitter.

Transmit signals are pulsed sinusoids with a center frequency of 90 kHz. For nominal target ranges of order 5–25 m, which are used in standard-target calibrations, a pulse duration of 300 μ s was typically selected.

As with the 200-kHz sonar, the 90-kHz sonar provides both the beamformed signals and individual element signals, but only one at a time depending on operator choice. Thus, the user can choose to perform the beamforming independently of the sonar processor.

As with the 200-kHz multibeam sonar, the digitized data are displayed with 8-bit resolution, but recorded with 12-bit resolution. Thus, the nominal dynamic range of the recorded data is 72 dB.

3. RESON SeaBat 8101 multibeam sonar at 240 kHz

This sonar consists of separate transmitting and receiving transducer arrays (Fig. 2). The transmitting array is a linear array of 36 elements conforming to a slender cylinder of radius 2.5 mm, each 5.28 mm in length and separated by a gap of 0.7 mm, hence with total length 21.46 cm. The transmitting array is oriented perpendicularly to the equatorial plane of the receiving array. A swath exceeding 150 deg is insonified. Shading is employed to reduce the on-axis transmit signal strength, as this typically corresponds to the nadir in bathymetric mapping exercises. The same shading achieves a one-way, received sidelobe level of about -20 dB, as computed.

The receiving array is composed of 176 elements evenly spaced on a circular arc of radius 15.6 cm. Each receiving element is rectangular, with height 16.88 mm and width 3.1 mm. The center-to-center distance subtends an arc of 1.5 deg. The system forms 101 1.5×1.5 -deg beams over an angular sector of 150 deg.

In contrast to the SM2000, the SeaBat 8101 operates in only one mode, with separate transmitting and receiving arrays. Thus, it functions like the SM2000 multibeam echo sounder, but is referred to in this work as a multibeam sonar, consistent with the manufacturer's own naming convention.

Although the SeaBat 8101 does not support external-trigger operation, it does accept a synchronized clock signal from another computer. The computer that transmits the synchronization signal can also accept motor-position information from the motor controller. The beamformed data are

digitized and stored with 8-bit resolution. The nominal dynamic range is thus 48 dB.

B. Standard targets

A number of standard targets were selected or devised. In every case these were based on the spherical form. Principles of optimization of the diameter for both narrow-band and broadband sonars^{18,27–29} were not applied in the present work. Rather, for reasons of convenience, a number of sub-optimal targets were chosen based on ready availability. These included spheres made of electrolytic-grade copper with diameters 23 and 60 mm, tungsten carbide with 6% cobalt binder with diameters 20 and 38.1 mm, aluminum with diameter 60 mm, and titanium with diameter 47 mm.

To achieve substantially higher target strengths, several focusing spheres^{30–33} were fabricated.³⁴ Two of these were based on spherical shells made of high-silicon bronze with external diameters 101.6 mm and shell thickness 3 mm. One was outfitted with a movable piston plug, diameter 14.22 mm, and the other with a simple shallow screw. Another focusing sphere was fabricated from a hollow rubber ball of diameter 88.9 mm, with thickness varying from 1.7 to 2.1 mm (average 1.9 mm). The three hollow spheres were vacuum-filled with the fluorocarbon liquid FS-5, also known by the tradename Fluorlube.³⁵

In some cases, the target strengths of the several spheres were either computed according to the respective theories for solid elastic spheres,^{36,37} noting corrections,¹⁸ or the appropriate limiting case as given by Goodman and Stern,³⁸ or for spherical shells,³⁸ assuming accepted values for the material properties. In other cases, the target strengths were determined according to comparative measurements. The results are shown in Table II.

III. CALIBRATION FACILITIES AND THEIR INSTRUMENTATION

Both seawater and freshwater facilities were instrumented for the work of developing calibration protocols. Earlier preliminary reports^{34,39,40} are summarized and updated.

A. Sea well

Iselin Dock at the Woods Hole Oceanographic Institution is a large dock supported by concrete pilings. Large reinforced concrete blocks have been removed from a particular area, exposing a sea well with rectangular opening $6 \times 13 \text{ m}^2$ (Fig. 1). The hard bottom beneath this opening slopes from about 15 to 20 m. Another area approximately 22–24 m from the transducer mounting apparatus is also easily accessible for mounting equipment such as calibration targets.

The sea well is within about 700 m of the Woods Hole passage. Because of its high-tidal-current velocities,⁴¹ stratification is at most weak. Because of the performance of sea-well calibrations over quite short ranges, effects of such stratification are negligible.

Interestingly, the tidal current at Iselin Dock is rectified. The flood occurs with substantial current towards the south-east, typically of the order of 1.5 knots. During the ebb, however, the water level falls or settles with very slight and variable current. The tidal range is typically of order 0.8 m. It has been possible to perform measurements during both tidal states, with those made during the flood being less variable.

The sea well was equipped with a variety of instruments and gear for deploying and rotating sonar transducers and for suspending and controlling targets at known positions in the transducer beam. Because of the wide range of uses of the sea well, all mountings were made in a provisional manner, but with drilled holes or markings for future reassembly of the facility.

A standard, 6-m-long shipping container was provided or configured as a laboratory for the electronic instruments and computers during each calibration trial. Mains power of both 110 and 220 V at 60 Hz was supplied by cable. The laboratory was placed immediately beside the sea well for operational convenience, specifically to minimize the cable distance to the transducers and rotation apparatus and to facilitate communication among the various participants.

1. Transducer-mounting system

During calibration trials, a 6-m-long steel-trussed tapered antenna tower weighing 150 kg was affixed to a mas-

TABLE II. Nominal target strength (TS) values of standard targets as computed and as inferred at 200 kHz by means of the SM2000 multibeam echo sounder. The TS values shown in the parentheses have been computed at precisely 200 kHz according to the single-frequency theory³⁶ based on tabulated values for the physical properties of the respective target and applicable conditions of temperature and salinity. The inferred TS values have been calculated relative to the average target strength of the 38.1-mm tungsten carbide sphere (WC38.1).

Target	Diameter (mm)	Relative TS (dB)	Inferred TS (dB)	Computed TS (dB)
AL60	60	96.52 ± 1.83	−35.31	−34.46
WC38.1	38.1	96.41 ± 1.02	−35.42	−34.46
		92.43 ± 0.76	−39.38	−39.36
		92.47 ± 0.87	−39.34	−39.36
WC20	20.0	88.99 ± 0.23	−42.84	−44.99
High-silicon bronze	25.4	94.87 ± 0.17	−36.96	
Focusing sphere 1	101.6	96.74 ± 0.95	−35.09	
Focusing sphere 2	88.9	93.47 ± 1.28	−38.36	
Stainless steel	50.8	93.40 ± 1.47	−38.43	
Titanium	47	84.88 ± 0.60	−46.95	

sive I-beam spanning the sea-well opening at the northwest end. The tower was held securely in place by a mechanical lock under gravity. The tower was strapped to the lower part of the I-beam mounting plate to resist the bending moment caused by the flooding tide when acting on the tower and transducer submerged at nominal 3-m depth.

An aluminum pipe is centrally mounted in the tower to serve as a shaft for holding and rotating the transducer. The shaft is guided by holes in the steel endplates and an intermediate plate added to reduce flexure. Low-friction bearings are mounted at each hole.

The shaft is held by the rotation apparatus, described in the next section. A flange with six bolts is mounted on the lower end to serve as a universal coupling joint for the transducer plate.

Given significant differences in the shape and size of each of the multibeam sonar transducers, a separate mounting plate was fabricated in aluminum to hold the respective transducer in a secure manner. Longer mounting plates for holding separate transmitting and receiving arrays were generally braced with aluminum angle-brackets for stiffness under flooding conditions. Examples of mounting plates with attached transducers are shown in Fig. 2.

In the case of separate transmitting and receiving transducer arrays, alignment of the several beams could be effected by shimming one of the arrays relative to the other. This was done for the SM2000/90-kHz multibeam echo sounder to reduce effects of parallax given the relatively short range of the target.

2. Rotation apparatus

A commercial antenna motor made by M2-Antenna Systems, the MT1000 antenna azimuth positioner, was adapted to serve as a precision rotator. The apparatus was mounted atop the central shaft of the tower, supporting both thrust and radial loads.

In the course of adapting the rotator, the central gear was replaced by one made of marine bronze. The original dc-motor was also replaced with an ac-motor with 14-bit absolute encoder and counter. The rotator can turn about a 360-deg arc, thus achieving a nominal precision of ± 0.01 deg, well within the design goal of ± 0.05 deg.

The accuracy of the rotator was established by measuring the deflection of the beam of a laser pointer mounted atop the central transducer-rotation shaft. Under commanded rotations, the position of the center of the red laser spot on the bridge platform, for example, was determined to within ± 5 mm at a nominal range of 11.7 m. This was found to be repeatable over a period of days, hence with demonstrable accuracy to within ± 0.025 deg.

The alignment of the transducer at the end of the 6.5-m shaft with the rotator was confirmed by attaching an outrigger to the rotator and dropping a plumb line from the outrigger to a corresponding outrigger affixed to the shaft immediately above the transducer plate, while the transducer tower was held vertically by a mobile crane. The distance from the shaft centerline to the plumb bob centerline was 47.1 cm. Very small adjustments could be made to the alignment by exploiting the small degree of play in the flange coupling. It

is estimated that the transducer could be aligned to within ± 0.5 mm over 4 m, or to within ± 0.007 deg.

Rotator positions were sent in ASCII format via serial link, RS232, to the SM2000 and were recorded with the SM2000 raw data files. There was a five-ping delay between the actual rotator position and the ping that recorded the position.

3. Target-suspension and -positioning systems

A number of systems were procured or assembled for suspending standard targets and controlling their positions in the transducer beam. One system was adapted from that currently used on board fisheries research vessels.^{19,20} The target was held by each of three monofilament nylon lines connected to motorized fishing reels, with outriggers mounted on barrier timbers, two on one side of the sea well and one on the opposite side. The position of the target was controlled by means of joysticks from the electronics laboratory.

In a second system, indicated schematically in Fig. 1, the target was suspended by a central monofilament line spooled on a motorized fishing reel. A second monofilament nylon line was attached to the central line and threaded through a block resting on the bottom of the sea well directly below the target to a second block. This was attached to a safety beam bordering the well, with lead weight suspended at the submerged end of the line to maintain constant tension, whatever the tidal state.

A third system was derived from the second by attaching four additional lines to the target.³⁴ Each of these was tensioned by running the respective line through a block to an attached weight. Each block was supported by the sea well bulkhead mounted along the long sides. The four blocks were arranged at the corners of a square. This additional tensioning was obliquely upwards, offering stability against lateral, tidally induced currents.

The second system was most used in the trials. The vertical suspension line was run through a block mounted on a platform bridging the sea well to a motorized fishing reel (Fig. 1). A variable voltage motor was used to control the fishing reel. The line was run directly over a meter ruler, allowing depth adjustments to within ± 0.5 mm. At a range of 11.7 m, this corresponds to an angular uncertainty of ± 0.003 deg.

B. Freshwater tank facility

The Chase Ocean Engineering Laboratory at the University of New Hampshire (UNH) has a freshwater tank that is nominally 12 by 18 m in plan view, with 6-m water depth. Modifications were made to this tank to facilitate the required acoustic measurements. These modifications fundamentally concerned the placement and control of the transducer under test in the tank. There were three fundamental issues to consider in achieving this goal: *X-Y-Z* transducer-positioning, rotation, and system integration.

1. *X-Y-Z* transducer-positioning system

The *X-Y* positioning in the plan view of the tank was accomplished through the addition of an industrial crane-rail system spanning the 12-m width of the tank, and moving

FIG. 3. Schematic diagram of the freshwater tank as configured for calibration.

along the longer, 18-m dimension (Fig. 3). The span accommodated a carriage, which moved across the 12-m span and was designed to secure the rotator. The rotator was mounted on the carriage and held the transducer under test, while controlling the incremental rotation about the vertical or Z axis. The rotator held a carbon fiber pole to which the transducer under test was attached (Fig. 4). The Z depth of the transducer was adjusted by securing the pole in the three-jaw chuck at the appropriate location.

2. Rotator

Rotation was accomplished using a Yuasa International, three-jaw chuck rotator (SUDX-320) with a programmable controller (UNDC-100). This rotator was selected due to the zero-backlash claim, and the ability to effect small increments of angular rotation, 0.1 deg. The rotator was readily mounted on the carriage. The transducer-mounting pole and rotation shaft was placed in the three-jaw chuck. A universal transducer-mounting flange was attached to the bottom of the pole. The pole was fabricated from carbon fiber, and the length was adjusted by adding sections outfitted with locally fabricated centering couplings.

FIG. 4. Configuration of the transducer and its mounting system in the freshwater tank.

The rotator performance was verified by means of a machinist dial indicator to measure the arc length traveled due to an incremental angular input. Two-degree arcs were randomly selected around the circumference. Each 2-deg arc was traversed with 0.1-deg increments in both directions. Precision control over the angle and the ability of the rotator to return to the place where it began, to within the accuracy limit of ± 0.1 deg, were both demonstrated. Details of this system development are reported in Baldwin *et al.*⁴⁰

3. System integration

System integration was achieved using LabView© software. An interpreter program was acquired which enabled LabView to communicate with the rotator controller. Subsequently other code was developed to facilitate the tasks required to perform a beam pattern measurement. Transmit signal generation, receive signal acquisition, transmit-receive-rotation coordination, and beam-pattern plotting were the basic functions. The specific linking of these functions was an artifact of the particular source-receiver-target or hydrophone configuration.

4. Target suspension and positioning

Target suspension and positioning were effected with a single line of monofilament nylon deployed through a block at the end of an outrigger. The line was attached to a motorized fishing reel, allowing fine control of the target depth, as described in more detail above in Sec. III A 3.

IV. METHODS

A number of procedures preparatory to calibrating sonars have already been described in the previous section. These include alignment of the transducer and rotator and possible shimming of separate transmitting and receiving arrays.

Another general preparatory measure is that of measuring the hydrographic state of the calibration environment. Vertical temperature and salinity profiles should be taken at intervals. Additionally, time series of temperature and salinity might be recorded at the transducer depth. During the particular calibration trials in the sea well, vertical conductivity-temperature-depth (CTD) profiles were taken, indicating that the seawater was well mixed. At other times, the CTD sensor was placed at the depth of the transducer to collect time series of temperature and salinity. The average temperature, salinity, and sound speed measured throughout one trial were 2.88 ± 0.02 °C, 31.60 ± 0.25 PSU, and 1457.5 ± 0.4 m/s, respectively.

Methods involving acoustic measurements are described in this section. Some of these are common to calibration of both scientific echo sounders and multibeam sonars; they are included here for the sake of completeness.

Implicit in the measurements for the SM2000 multibeam echo sounders are real-time storage and rapid retrieval of the echo signals from the individual receiving transducer elements and availability of operational software for beamform-

ing. Algorithms for beamforming have been described in some detail for multibeam sonar.^{21,22} These follow the general method.^{17,42}

A. Target positioning and mapping central polar beam pattern

A standard target can be placed at an essentially arbitrary position in the sonar beam by purely geometrical considerations. Not all positions are equally favorable, it must be emphasized. It is generally desirable to avoid reverberation from surfaces and possible extraneous scatterers in the water column, e.g., fish and underwater moorings. It is also desirable, if not absolutely necessary, to make measurements in the transducer farfield.

In practice it is easier to perform relative positioning of the target in the transducer beam by placing the target at the approximate depth of the centered transducer, then finding the coincident horizontal and equatorial planes of maximum sensitivity by moving the standard target systematically through a series of depths and making multiple measurements at each target depth. Beamforming is then performed, and the resulting data are fit in a least-squares sense by a quadratic or other nonlinear function. The beamformed data describe the central polar beam pattern.

Examples of resulting data derived from measurements with the SM2000/90-kHz multibeam echo sounder are shown in Fig. 5. In the first example, taken from the sea-well facility, a standard target at 23-m range was lowered, and then raised, systematically at constant increments of 10 cm or 0.25 deg. In the second example, taken from the freshwater-tank facility, the same standard target at 11.7-m range was used and the procedure was repeated, but at 2-cm increments, hence with nominal resolution of 0.10 deg.

B. Measurement of system response and choosing receiver gain function

The performance of a system is considered to be linear if a change in the amplitude of an input signal results in a linearly proportional change in the amplitude of the output signal. While there is no need for a system to perform linearly for it to be used quantitatively, given that it performs monotonically, the system response needs to be determined. Among other reasons, the sonar will be most useful if its gain function enables both weak and strong echo signals from interesting targets to be registered without loss due to inadequate sensitivity or saturation, with clipping, due to inadequate dynamic range. The general effect of clipping may be *hard*, with abrupt change in any amplitude exceeding a threshold value to the threshold value itself, or *soft*, with gradual approach to the threshold value, where the exact relationship is nonlinear. The general case has been treated under the name of band-pass limiting.⁴³ The importance of choosing the gain function is evident from practical considerations of dynamic range: the test multibeam sonars used in this study have rather limited dynamic ranges, especially relative to those of modern scientific echo sounders.⁴⁴

Multibeam sonars generally have a number of available transmit-power settings. In keeping with the aim of develop-

FIG. 5. Directionality of the SM2000/90-kHz multibeam echo sounder in the vertical plane, as determined by changing the depth of the rubber-walled focusing sphere (a) at 23-m range in 4-cm increments in the sea well and (b) at 11.7-m range in 2-cm increments in the freshwater tank. The directionality is expressed through the beam pattern in normalized intensity units. The maximum intensity value is that observed in a spatial window consisting of five contiguous beams and five range cells centered on the respective beam and range of nominal greatest sensitivity. The mean is that of all echo values within the window. A Gaussian function has been fitted to the maximum intensity values.

ing convenient and useful protocols, the transmit power of each sonar was set at that level most often used in field applications.

Measurement of the system response is performed by observing the change in echo amplitude due to changing the receiver gain function of the sonar. It is effected conveniently by observing the change in echo amplitude from a standard target under systematic changes in the receiver gain function. This is illustrated for the SM2000/90-kHz multibeam echo sounder in Fig. 6, where the full range of gain settings has been exercised. A linear function has been fit to the echo-intensity data by means of a least-squares-regression analysis.⁴⁵ On the basis of the data and their analysis, the gain function $20 \log r + 2\alpha r$ was chosen, where r is the range and $\alpha = 0.0157 \text{ dB/m}$. In the case of the SM2000/90-kHz multibeam echo sounder, the system sensitivity was expressed through a numerical value. This was determined from the equation

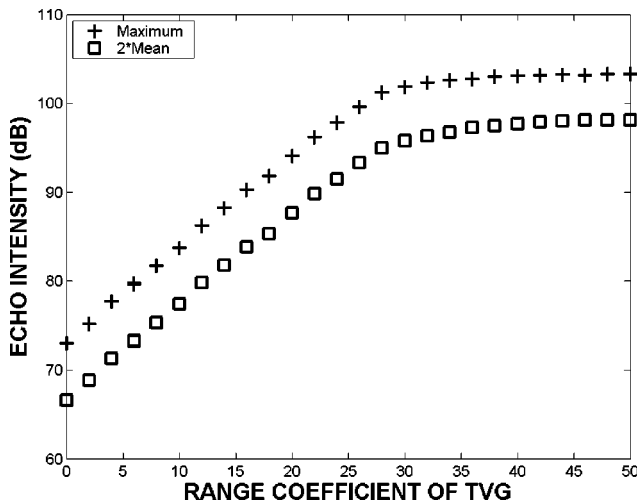

FIG. 6. Measured dependence of the echo intensity from the standard target AL60 on the gain function of the SM2000/90-kHz multibeam echo sounder. The target was measured at 11.7-m range in the sea well, with pulse duration of 300 μ s. For an explanation of maximum and mean values, see the caption to Fig. 5.

$$TS = 10 \log_{10}(G(r_0)|V_{rec}|) + 20 \log_{10}(r_0) + 2\alpha r_0, \quad (1)$$

where $TS = -34.40$ dB denotes the target strength of the 60-mm-diam aluminum sphere (Sec. II B) at 90 kHz for the particular hydrographic conditions, $r_0 = 11.7$ m, V_{rec} is a relative digitized real number that is proportional to the received voltage level, and $\alpha = 0.0157$ dB/m. It is emphasized that V_{rec} also depends on the instrument settings, including transmit power level, pulse duration, sampling rate, and assumed absorption coefficient value, which in the present case was 0.0068 dB/m. Substituting for V_{rec} and solving, the sensitivity coefficient is $G(r_0) = 3.68 \times 10^{-6}$. Multiplying the raw echo amplitude due to an arbitrary target or targets at the same 11.7-m range, with the same gain function, yields backscattering units of square meters. For other gain functions at the same range, the relationship defined in Fig. 6 may be used. Since the calibration was performed in the transducer nearfield, Eq. (1) must be modified for use at other ranges.

C. Measurement of system stability

There is little reason to suspect instabilities in performance of multibeam sonars designed for scientific use, although their possible occurrence at high pulse repetition frequencies might be entertained. Ultimately, it is only measurement that can decide the matter or quantify the degree of stability.

Measurement of the system stability is straightforward. The target is held at a fixed position in the transducer beam, and echo measurements are performed over a relatively long period of time. This might last from minutes to hours or days or weeks, the longer period corresponding to potential use on fisheries survey cruises.

An example of a measurement of system stability is presented in Fig. 7. This shows the time series of echo amplitude from the SM2000/200-kHz multibeam echo sounder due to repeated insonification of the standard target WC38.1.

FIG. 7. Echo amplitudes from an on-axis standard target, WC38.1, as measured at 11.7-m range in the freshwater tank by the SM2000/200-kHz multibeam echo sounder over a time period of 175 s.

D. Measurement of equatorial-plane sensitivity

For conventional imaging purposes, the equatorial-plane sensitivity function is very important. The value of this function for a small target at a given angle is the peak echo amplitude from among all beams where the target is detected. It is advantageous in imaging applications that the function be relatively flat over the full angular span of the sonar.

The equatorial-plane sensitivity function must vary over the angular span, for it is defined by a finite series of beams of fixed orientation. Adjacent beams meet at a level that depends on the number of beams, their total angular span, the respective aperture size, and the shading of individual elements. For the 128 displayed beams of the SM2000, this level is roughly 2 dB less than peak levels, thus defining a measure of ripple.

For scientific imaging purposes, knowing the sensitivity function and how it varies is important, for it enables compensation to be effected and distortions removed.

The equatorial-plane sensitivity function can be determined by measuring the echo response of the sonar at closely separated, discrete angles over the full angular span. This was done for the SM2000 multibeam echo sounders and the RESON SeaBat 8101 multibeam sonar. Exemplary resulting functions are shown in Fig. 8.

E. Measurement of central-region directionality in two dimensions

As mentioned in the previous section, there is particular interest in the equatorial-plane sensitivity function. This is a one-dimensional slice of the more general two-dimensional sensitivity function. Implicit in this description is a rather broad width of the beam in the transverse direction, nominally 20 deg in the vertical plane for the imaging mode of the SM2000. In the echo-sounding mode, the nominal beamwidth is 1.5 deg in the vertical plane.

Again, there is no substitute for measurement of the directionality. This has been done in two dimensions by repeat-

FIG. 8. Measured equatorial-plane sensitivity function of the (a) Seabat 8101 240-kHz multibeam sonar, (b) SM2000/200-kHz multibeam echo sounder, and (c) SM2000/90-kHz multibeam echo sounder. The target range was 11.7 m. In (b), only part of the central section of greatest sensitivity was measured.

ing the one-dimensional measurements, with the standard target moved systematically through a series of discrete vertical positions.

Exemplary results of this measurement for the SM2000/90-kHz multibeam echo sounder are shown in Fig. 9. Measurements are shown of the central region of directionality.

F. Measurement of directionality of individual beams

An envisioned major use of multibeam sonar in fisheries survey work is quantification of fish density. For measurements of resolved single fish by echo counting, this requires

FIG. 9. Measured central-region directionality in two dimensions of the SM2000/90-kHz multibeam echo sounder at (a) 23-m nominal range in the sea well and (b) 11.7-m nominal range in the freshwater tank. The dark brown color represents echo levels extending from -1 to 0 dB.

knowledge of the acoustic sampling volume,⁴⁶ which depends on the individual beam patterns, i.e., the beam patterns of individual apertures used in the quantification. For measurements of unresolved fish aggregations by means of echo integration,¹ measurement of the area backscattering coefficient requires knowledge of the equivalent beam angle. This is the integral of the product of transmit and receive beam patterns, each expressed in the intensity domain, over all angles.¹⁷ For directional beams, this angular measure can be determined with high accuracy from the characteristics of the main lobe alone.

Data collected in the measurement of the central-region directionality in two dimensions, described in the previous section, are sufficient to determine this function. Individual-aperture beam patterns can also be derived by approximation from measurement of the equatorial-plane sensitivity function, and assumption that the beamwidth in the vertical plane is that measured in the central polar beam pattern (Sec. IV A). In either case, the individual beam patterns are formed

FIG. 10. Equatorial-plane beam patterns, measured and estimated, of a single aperture of the SM2000/90-kHz multibeam echo sounder. The measured value of the beamwidth BW and the estimated value of the equivalent beam angle Ψ are attached to the respective function.

without further selection or reduction, as in the operation of selecting peak values.

Results from the second procedure are shown in Fig. 10 for a single aperture and in Fig. 11 for a set of apertures. Individual beam patterns are shown in the horizontal, equatorial plane together with fitted functions. The inferred equivalent beam angle for the central beam in Fig. 10 is $7.76 \cdot 10^{-4}$ sr or, logarithmically, -31.1 dB. The theoretical prediction based solely on the geometry of the transducer array is $6.46 \cdot 10^{-4}$ sr or -31.9 dB.

FIG. 11. Equatorial-plane beam patterns, measured and estimated, of a set of individual apertures of the SM2000/90-kHz multibeam echo sounder. Measured values of the beamwidth BW are shown.

G. Measurement of system axial sensitivity in transducer nearfield

It is often advantageous to make measurements of beam patterns in the transducer farfield. At the so-called farfield distance, the radiated field in terms of pressure or particle velocity amplitude decreases inversely as the range r . This farfield distance is conventionally defined as one-half of the square of the maximum transducer dimension divided by the wavelength.²⁵ When the maximum measurement range available for calibration is less than the farfield distance, it may be convenient or necessary to make measurements in the transducer nearfield. Such measurements can be productive if the transducer nearfield characteristics can be modeled successfully, then extrapolated to the farfield.

An illustration is provided by calibration of the SM2000/90-kHz multibeam echo sounder with external transmitting transducer in the freshwater tank. Given the standard array length, 86.6 cm, the farfield distance is about 23 m, which can be achieved without significant interference in the sea well but not in the freshwater tank. Measurements were therefore performed of the system axial response in the transducer nearfield.²³ These are documented in Fig. 12. The modeled results are superimposed, suggesting the possibility of making angular measurements at nearfield ranges as close as 6 m, then extrapolating these by means of modeling to the ordinary farfield.

V. PROTOCOLS

Protocols are developed for each of the several measurement methods, with the intention of describing how to perform these in the form of prescriptions. The protocols are preceded by a description of preparatory procedures to be

FIG. 12. Dependence of the axial response of the SM2000/90-kHz multi-beam echo sounder on range in the transducer nearfield, as measured in the freshwater tank. Superimposed on the data is the response as modeled from the transducer geometry.

carried out in advance of the acoustic measurements. Immediately following a review of the acoustic target-positioning operation, which also accomplishes mapping of the central beam pattern, measurement of the system response and stability, and choice of the receiver gain function, are described. Measurement of system directionality in each of several dimensions is then addressed. Measurement of the noise environment and system gain are also reviewed.

A. Preparations

In the case of multibeam sonars consisting of separate transmitting and receiving arrays, it may be necessary or advantageous to orient the arrays so that their acoustic axes intersect at the target range. This is particularly important for reducing effects of parallax in the case of nearfield calibration measurements to be applied in the transducer farfield. An easy method for adjusting the relative array orientations is to place shims between the bolts and mounting plate at the far end of one of the transducer arrays.

Another, essential operation in preparing for a calibration exercise is wetting the transducer faces and target to preclude formation of air bubbles on the respective surfaces.⁴⁷ This can be done by washing with a surfactant, for example, a simple household liquid detergent.

Recording the hydrographic state over the range of depths spanned by the transducer and target is essential in any calibration exercise. This is important for excluding stratification and other inhomogeneities in the water column as a cause of refractive effects during a calibration. At sufficiently near ranges, the effect of these on the propagation path between transducer and target may be entirely negligible, but they may be a limiting factor in others. In field applications over longer ranges, especially with horizontal or near-horizontal orientations, refractive effects, which are determined by the hydrography, may be substantial.

Beamforming is essential for the rapid and timely analysis of data. If desired or necessary, it may be performed digitally by software on the basis of the full set of individual

element echo signals and detailed knowledge of the receiving aperture geometry. Alternatively, the output signals from the sonar beamformer may be recorded and used directly in the data analyses.

B. Target positioning and measurement of central polar beam pattern

The basic procedure for relative positioning of the target in the transducer beam has already been outlined in Sec. IV A. It is reduced to a prescription in the following, assuming that the echo measurements are made in or close to the horizontal plane.

The standard target is suspended at a fixed distance from the centered transducer at the nominal transducer depth, specifically, the depth of the center of the transducer array or arrays. The target echo is registered. The target is now lowered by a fixed increment corresponding to some fraction of the nominal beamwidth of the transducer, say one-tenth. The echo measurement at this new position is repeated. The target is lowered again by the same fixed increment and its echo is recorded. This process is repeated until the first null is passed, which can be determined by observing a rise in the echo amplitude immediately following a steady decrease. The target is returned to the first measurement depth and the original measurement is repeated. The target is now raised by the fixed increment, and the echo is recorded. This process is repeated until the first null is again passed.

Beamforming is performed, if necessary, and the peak amplitude from the full set of beams is selected and plotted. The central equatorial plane of sensitivity is defined generally by the maximum in the plotted function. This may be determined by simple visual inspection if unambiguous, otherwise by fitting a quadratic or other nonlinear function to the data.

The exact position of the central axis can now be determined by rotating the transducer and observing the peak echo in the vicinity of the mechanically determined central axis. If the signal-to-noise ratio is sufficiently high, phase differences can be used to determine the angle of greatest sensitivity, which defines the central axis.⁴⁸ In either case, this refined determination of the central axis can reveal possible mechanical or electrical offsets in the central acoustic axis of the sonar. If the central axis deviates very much from the assumed axis, the measurements of polar directionality can be repeated to ensure their precision.

In the course of finding the central equatorial plane, the central polar beam pattern is measured. Noncentral polar beam patterns can be determined in a similar way.

C. System response, stability, and choosing receiver gain function

Having found the central plane of sensitivity, the system response can be determined for particular array orientations by observing the echo. By relating the measured output, e.g., amplitude, to the corresponding input signal and backscattering properties of the standard target, the transfer function of the system can be measured. This may involve analyzing the

frequency content of the transmitted signal and frequency dependence of the target backscattering cross section.

By repeating the measurements for the same transducer orientation and target position over a period of time, the stability of the system can be gauged. This can be quantified by a conventional time-series analysis, with observation of possible changes in the mean and variance over time.

By repeating the measurements with different receiver gain functions, the dependence of the system response on this function can be determined. By fitting a linear function to the echo intensity data, a suitable time-varied-gain function for the measurements can be determined. The system performance at the selected gain function can be related to other gain functions by means of the repeated measurements of system response.

D. Equatorial-plane sensitivity

Given knowledge of the location of the central plane of sensitivity, the equatorial-plane sensitivity function can be determined by rotating the transducer array or arrays over the angular span of interest. At each individual orientation, the several beam outputs are examined and the peak amplitude is selected. This process is repeated over the full angular span. The function defined by the peak output versus angle constitutes the equatorial-plane sensitivity.

E. Central-region directionality in two dimensions

The measurements of the equatorial-plane sensitivity function are now repeated at each of a succession of target depths. As in the target-positioning operation (Sec. V B), the target is moved systematically from the central plane past the first null below the plane, then from the central plane past the first null above the plane. Knowing the full target depth range spanning the main lobe, the measurements can also be performed in a single direction from one null to the other. By measuring the sensitivity function at each of these discrete target depths, the central-region directionality can be mapped in two dimensions.

F. Directionality of individual beams

The directionality of individual beams is measured in the central plane of sensitivity, as in Sec. V D, and over the central region of sensitivity, as in Sec. V E. The basic beamformed outputs are identical. Instead of selecting peak amplitudes from the range of beams for each transducer orientation, the amplitudes are associated with the respective individual beam. The individual beam patterns can thus be mapped. Individual beams are conveniently identified by their order in the series or by their nominal angle of peak sensitivity.

G. Nearfield response along acoustic axis

In cases where the multibeam sonar is to be used in the transducer nearfield or where the sonar is to be used in the farfield but can only be calibrated in the nearfield, the nearfield response should be measured. This is done by moving either the transducer or standard target along the acoustic

axis and measuring the echo response at discrete positions. The beamformed results are plotted against the transducer-target range.

The measurements are used for comparison against computations based on the transducer geometry and transmit frequency. Confirmation of the computational results provides support for the model, which can then be used to extrapolate either to greater or lesser ranges, depending on the intended sonar application.

H. Noise measurements

In all of the foregoing protocols, the echo from a standard target was generally measured. These measurements should be accompanied by similar measurements made in the absence of the target, hence of volume reverberation.

The reverberation measurements might be performed conveniently immediately before or immediately after a series of measurements with a standard target. While echoes from transient targets such as schools of juvenile fish passing through the sea well might not be recorded, the general level of background reverberation would be. Such measurements are important for describing the reverberation background and for quantifying the signal-to-noise ratio present during the target measurements. If the reverberation level is sufficiently high, another target with greater target strength might be chosen to ensure a better signal-to-noise ratio.

I. Electronic measurements

While purely electronic measurements are inadequate for determining the overall transmit-receive sensitivity, because of neglect of the transducer, they are nonetheless very useful for determining how signals are transferred in the receiver. The basis of the measurements is that of the time-amplitude-frequency measurement method.⁴⁹

The transducer is decoupled from the receiver. Signals of known amplitude and time delay are introduced into each channel, and the output is observed over a range of amplitudes sufficient to test the dynamic range and application of gain to each signal. The measurement sequence is repeated for each transducer element.

A complication with this simple notion is that of multiplexing of the individual transducer element signals before transmission to the beamforming processor, i.e., beamformer. Introduction of a signal of known amplitude and time delay is thus made to a multiplexer, with reception at the end of a cable. A special manufacturer-built unit can be entertained for measurement of the overall receiver sensitivity function with decoupled transducer. Such a capability would allow measurement of the electronic system to be undertaken independently of that of the combined acoustic and electronic system.

VI. DISCUSSION

By means of the calibration protocols described here, which have been developed through actual testing in nearly every instance, the performance of multibeam sonars can be defined. The general system sensitivity can be expressed through transfer characteristics and measures of directional-

ity. In addition, the stability can be quantified, and the connection between nearfield and farfield characteristics can be established.

The standard-target calibration method, which has been extended to multibeam sonar, is useful for its absolute character. Multibeam sonars calibrated in this way can be used in quantitative applications, for example, to estimate the numerical density of fish aggregations through echo-counting or echo-integration techniques. Visualization of fish aggregations by multibeam sonar, which is more often accomplished by uncalibrated systems, also benefits from a standard-target calibration, for variations in angular sensitivity can be compensated, giving a more accurate impression of the relative concentration densities.

Another practical advantage of calibration is making possible intercomparability of measurements with different multibeam sonars. Whether the several systems operate at the same or different frequencies, the measurements can be performed in an absolute sense. Given knowledge of the backscattering properties of the target, including the frequency dependence of target strength, if necessary the several acoustic measurements can be converted to biological or other physical measures of density, opening the possibility of direct comparison.

While the present work is directed to the calibration of multibeam sonars used for water-column measurements, it can also be applied to bathymetric multibeam sonars. In addition to measuring the range to the seafloor over a swath, the backscattering properties of the same can be measured and expressed in absolute units of surface scattering. Such measurements are essential for characterizing the seafloor and detecting changes in this, for example, to observe possible changes to the seafloor over time, as due to natural or man-made disturbances.

By quantifying the performance of multibeam sonar, conformity of manufactured units to their specifications can be confirmed. In addition, the performances of different sonars can be compared.

A number of outstanding problems in multibeam sonar calibration are identified. One is to generalize Eq. (1) to arbitrary operating conditions and ranges spanning the nearfield–farfield transition region of the sonar transducer. Another is to identify the causes of variability, for example, those encountered in measurements of system stability, already noted in Sec. IV C and observed in Fig. 8, as well as in Ref. 50. A third problem is to realize the electronic measurements described in Sec. VI in a rapid, automated manner. This could be done through a computer-controlled time-amplitude-frequency device. Another problem is extending the calibration protocols to multibeam sonars as configured for use, for example, as mounted within a sonar dome on the hull of a research vessel or on a fixed structure.

It is appreciated that rigorous calibration of multibeam sonars as configured for use may be difficult. In such cases, confirmation of the performance rather than measurement of the performance can be entertained. The problem of validation is thus identified. Derivative procedures, possibly with relaxed tolerances, could be very useful.

VII. SUMMARY

The goal of the project documented here was to develop convenient protocols for the calibration of multibeam sonar. The protocols that have been developed, based on the standard-target method, will enable absolute physical measurements to be made with the sonar. Addressing identified outstanding issues will enable the protocols to be extended efficiently to sonars as configured for use. It will also enable the overall accuracy of echo signal processing in the receiver to be quantified.

ACKNOWLEDGMENTS

The following are thanked for their participation in one or more of the calibration trials: B. Doherty, K. W. Doherty, S. P. Liberatore, and M. Parmenter, Woods Hole Oceanographic Institution; P. Lavoie, A. McLeod, and J. Millar, University of New Hampshire; Y. Li, formerly at the University of New Brunswick, Canada; G. D. Melvin, Department of Fish and Oceans, Canada; W. Michaels and D. A. Perry, Northeast Fisheries Science Center, Woods Hole. A. Bowen and D. R. Yoerger, Woods Hole Oceanographic Institution, are thanked for allowing their 6000-m-depth-rated SM2000/200-kHz multibeam imaging sonar to be used in an early trial. Several multibeam sonar manufacturers and their representatives are thanked for lending or arranging loans of sonars for use in developing the calibration protocols, as well as for participating in various trials. These include R. Asplin and C. Smith, Kongsberg Simrad Mesotech, Port Coquitlam, B.C., Canada; J. Condiotty, Simrad, Inc.; and S. Johnson and R. Morton, RESON, Inc. L. Bjørnø, J. Steensrup, and P. K. Eriksen are thanked for providing data on the RESON Sea-Bat 8101 sonar array. J. Doucette is thanked for assistance in preparing figures; S. Barkley, A. Norton, and M. Parmenter are thanked for assistance in assembling the manuscript. Support by the National Science Foundation through Award No. OCE-0002664, NOAA through Grant No. NA97OG0241, and the Cooperative Institute for Climate and Ocean Research (CICOR) through NOAA Contract No. NA17RJ1223 is acknowledged. This is Woods Hole Oceanographic Institution Contribution No. 11178.

Multi-mode Lamb wave tomography with arrival time sorting

Kevin R. Leonard and Mark K. Hinders

Department of Applied Science, College of William and Mary, Williamsburg, Virginia 23187-8795

(Received 22 July 2004; revised 13 January 2005; accepted 14 January 2005)

Lamb wave tomography has been shown to be an effective nondestructive evaluation technique for platelike structures. A series of pitch-catch measurements between ultrasonic transducers can be taken from different orientations across the sample to create a map of a particular feature of interest such as plate thickness. Most previous work has relied solely on the first arriving mode for the time-of-flight measurements and tomographic reconstructions. The work described here demonstrates the capability of the Lamb wave tomography system to generate accurate reconstructions from multiple modes. Because each mode has different through-thickness displacement values, each is sensitive to different types of flaws, and the information gained from a multi-mode analysis can improve understanding of the structural integrity of the inspected material. However, one of the problems with the extraction of multi-mode arrival times is that destructive interference between two modes may cause one of the modes to seemingly disappear in the signal. The goal of the sorting algorithm presented in this work is to try and counteract this problem by using multiple frequency scans—also known as frequency walking—to sort the arrival times into their correct mode series. © 2005 Acoustical Society of America.

I. INTRODUCTION

Lamb waves are useful for the inspection of a variety of platelike structures. If Lamb wave measurements are made for a large number of specific pitch-catch transducer positions surrounding a region of interest, then an image of that region can be reconstructed tomographically. The reconstruction is an easily interpretable quantitative map of a parameter of interest, e.g., thickness loss due to corrosion.

Key to any practical Lamb wave tomography (LWT) scheme is a suite of robust and reliable algorithms that automatically interprets the digitized Lamb waveforms. In bulk wave ultrasonics gating and peak-detection schemes are usually adequate. With guided waves, however, sophisticated signal processing is required in order to identify the various Lamb wave modes in the digitized waveforms and then to extract the feature(s) of interest from each mode as input for the reconstruction algorithm. Fairly small errors in this mode extraction step usually spoil the reconstruction completely. Also, for a practical nondestructive evaluation (NDE) system these algorithms must run in real time on portable hardware, and must be able to deal with millions of digitized waveforms per minute.

Early Lamb wave tomography work by Hutchins *et al.*,^{1–5} Achenbach,⁶ and Degertekin⁷ used a parallel projection geometry with the velocity and/or attenuation of Lamb waves as input for the tomographic reconstructions. McKeon and Hinders^{8–12} implemented this also, and then investigated a “crosshole” tomographic scheme similar to a preliminary pipe inspection study done by Hilderbrand *et al.*¹³ that has many practical advantages for aircraft NDE. Malyarenko and Hinders¹⁴ subsequently compared fan beam and double crosshole geometries, and found the latter to be superior. A secondary conclusion of that work is that the iterative reconstruction algorithms from the seismological literature seem

to be better suited to Lamb wave NDE applications than are the convolution-backprojection type of algorithms from the medical imaging literature. Malyarenko *et al.*^{15–17} have implemented a curved ray tracing technique that accounts for scattering or refractive media and improves the technique’s accuracy in sizing flaws.

Reconstructions that only use the time-of-flight information for the first arriving mode at a predetermined frequency may be discarding a wealth of information in the rest of the signal. The various Lamb wave modes interact with flaws differently because of their different through-thickness displacement properties, and certain modes only interact weakly with certain flaws. Therefore, delineating the different mode arrivals could significantly enhance the capabilities of the LWT system.

II. EXPERIMENTAL SETUP

In our current laboratory system we use a pair of independently scanning pitch-catch transducers that are attached to linear slider screws and are moved back and forth by computer controlled stepper motors. The data acquisition equipment and scanning system consist of a Matec TB-1000 toneburst pulser-receiver board and a Gage CS8012A 12-bit A/D board contained within a PC running Linux. The stepper motors are under computer control via a Velmex 9000 controller. Figure 1 shows a schematic of the scanning system. For the results presented in this work, a pair of 0.5-in.-diam, 1-MHz longitudinal contact transducers are used for both transmission and reception of the Lamb wave signals. The total scanned area is 20×20 cm², and the step size between scanning locations is 2 mm. As the sample is scanned, the waveforms for each projection are digitized, stacked into a data file and stored for subsequent data analysis. For each tomographic projection, the transmitting transducer steps

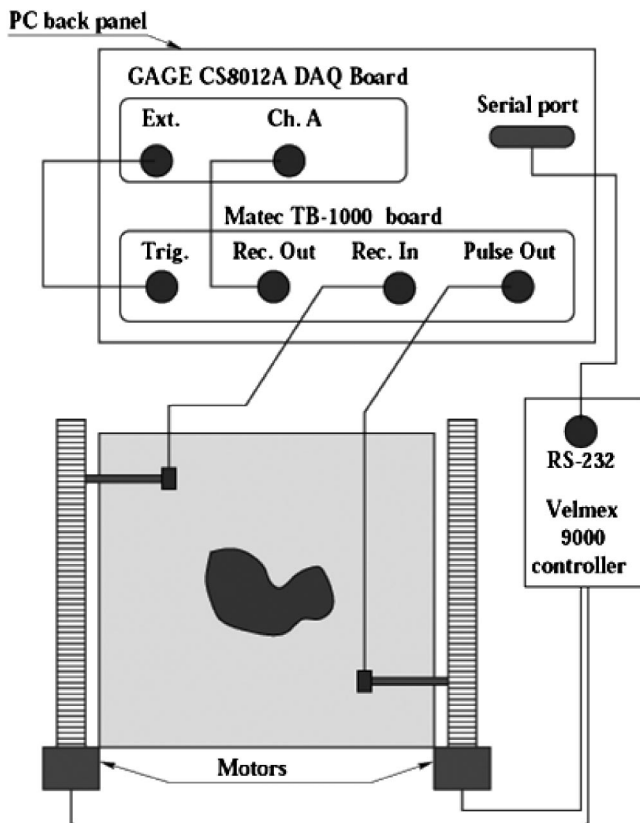

FIG. 1. Schematic of the Lamb wave tomography (LWT) scanner.

along one edge of the perimeter of a rectangular region of interest while the receiving transducer steps through all the positions on a different edge. This gives us the large number of crisscross ray paths necessary for tomographic reconstruction, and mimics a situation where a four-legged “picture-frame” array of multiplexed transducers is used to surround the area to be inspected.

In order to evaluate the effectiveness of the arrival time extraction algorithm, an intermediate representation of the tomographic data is needed. We have found that arrival time scatter plots work well for this purpose. For example, Fig. 5(a) is an arrival times scatter plot for a complete projection of a flawless aluminum plate. The x axis is called the pitch-catch, or waveform, number. In the LWT scanner, the transmit transducer remains stationary while the receive transducer steps through the 100 scan positions (the total scan area is 20×20 cm² and the step size for both the transmit and receive transducers is 2 mm). Once the receive transducer has stepped through all the positions the transmit transducer steps a single position. The receive transducer then steps through its 100 positions in reverse until it reaches its original starting position. Again, the transmit position steps once and the receive transducer then steps through all of its positions. This process is repeated until the transmit transducer has stepped through all 100 positions. Therefore, the pitch-catch number—or waveform number—is $(transmit_position - 1) * 100 + receive_position$. This also explains why the arrival times as a whole seem to decrease and then increase again in a symmetrical pattern. This occurs as the transmit transducer moves through all of its

scanning positions. For a clean plate, this pattern should be symmetrical and regular as shown. Flaws appear in these representations as deviations from the symmetrical flawless patterns. This intermediate representation allows us to make sure that the data were recorded properly and it also can serve as a measure of the performance of different time extraction algorithms since errors in the arrival times show up as extreme deviations from the expected pattern.

III. WAVELET ANALYSIS AND ARRIVAL TIME EXTRACTION

The method used previously to extract the arrival times of the fastest Lamb wave modes is based on enveloping the signal and is described in previous work.^{10–12,14–20} It is a straightforward and computationally inexpensive method, which has been shown to perform better than other more complicated and computationally expensive time-frequency methods.¹⁶ However, even though the simple thresholding arrival time extraction algorithm is effective, certain limitations still exist. For instance, if the amplitude of the mode of interest drops below the threshold level—as it often does after it interacts with a flaw—then the extraction algorithm will pick up a later mode. Furthermore, it is incapable of providing arrival time information for multiple modes.

Malyarenko¹⁶ explored various time-frequency methods to try and improve the arrival time extraction methods. However, Wigner-Ville distributions, short-time Fourier transforms (STFTs), and positive distributions did not sufficiently improve the accuracy of the arrival times. In work recently done by Hou *et al.*,^{21,22} wavelet analysis was explored as a better solution to the current arrival time extraction problem. Wavelets have become popular in many different types of signal and image processing techniques. They are particularly advantageous for both the denoising and compression of signals.²³

The continuous wavelet transform is defined as:

$$W_g(a,b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} x(t) g_{a,b}(t) dt, \quad (1)$$

where $g_{a,b}(t) = g^* \left(\frac{t-b}{a} \right)$.

$W_g(a,b)$ is the wavelet coefficient for the translation b and the scale a . $g_{a,b}$ is the scaling function which is calculated from the mother wavelet $g(t)$. By varying the translation and scale parameters, one can inspect the signal from different time and scale representations. This flexibility is a great advantage over the traditional Fourier analysis and STFT.

In our case, the signals being processed are discrete signals. The discrete wavelet transform (DWT) implements the CWT for discrete signals. Conceptually, the DWT can be viewed as a series of filters where the input signal is broken down into a low frequency approximation and a high frequency detail signal. The approximation signal can then be broken down further through the same process. The result will be an approximation signal with a number of detail signals. Each of the detail signals is a set of wavelet transform coefficients at the next finer scale. Denoising and compres-

FIG. 2. Comparison of enveloping techniques: (a) wavelength peak enveloping and (b) wavelet enveloping.

sion are accomplished by setting a threshold value for the resulting coefficients. For most signals, the majority of information is contained within only a few coefficients. Furthermore, because the details are the high frequency components, by removing these coefficients, one can also reduce the noise in the signal—which is often higher in frequency and smaller in scale. This allows one to eliminate the noise, while keeping the information that is desired.

IV. SORTING ALGORITHM

The method presented here uses a version of the DWT to generate smooth envelopes for the Lamb wave signals. The peaks of these different envelopes are then used as the arrival times of the multiple Lamb wave modes. One of the problems with the extraction of multiple arrivals is that destructive interference between two modes may cause one of the modes to seemingly disappear in the recorded signal (see Fig. 4). The goal of the sorting algorithm presented in this section is to try and counteract this problem by using the frequency walk information described below to sort the arrival times into their correct mode series.

As discussed above, the current time extraction algorithm relies on the accurate enveloping of the signal. In the past this had been done using the peak values of each wave-

FIG. 3. Arrival times for the first three peaks of a clean aluminum plate at the first 100 receiver positions (points—peak 1; triangles—peak 2; crosses—peak 3). The solid lines are the fitted mode predictions. Notice that starting at position 61, the second peak arrives closer to the expected arrival of mode 3.

length. However, when trying to track more than just the first arriving mode, the unsmooth nature of this type of envelope made it difficult to detect subsequent modes. Therefore, wavelets were used to simultaneously denoise and envelope

FIG. 4. The envelopes and waveforms of the recorded Lamb wave signals in the clean aluminum plate sample for receiver positions 55–62 (top to bottom). As the second and third wave packets interfere, the second peak disappears while the third peak increases in amplitude.

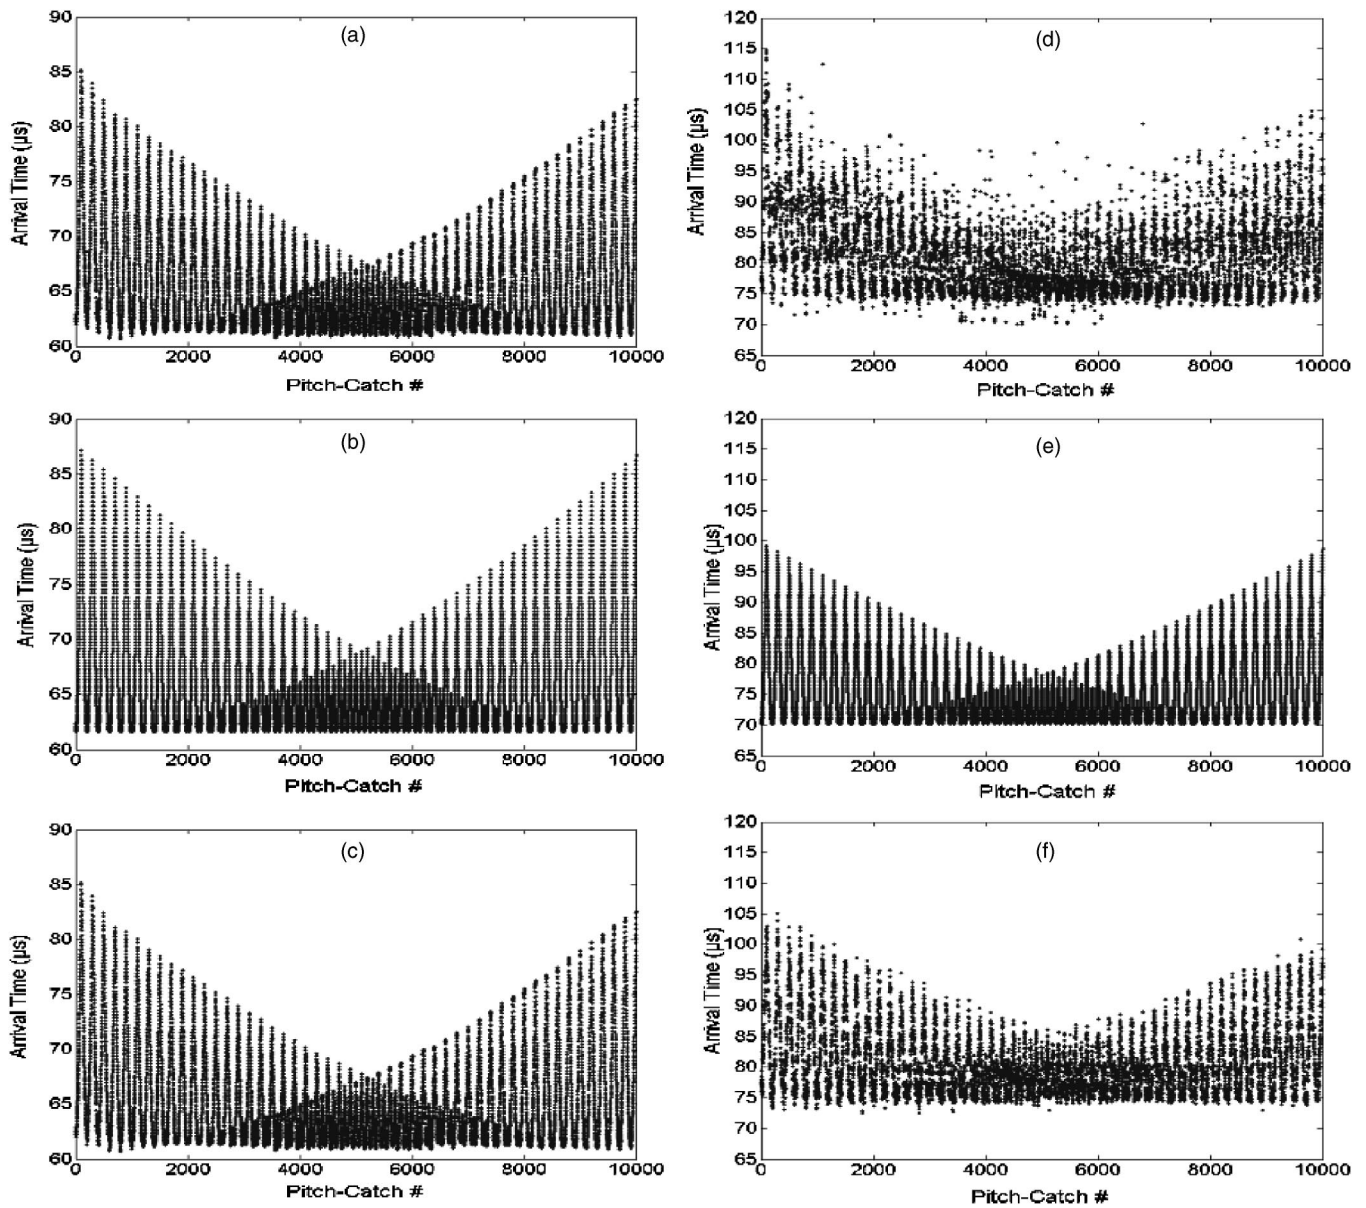

FIG. 5. Arrival time scatter plots for the A_1 and S_0 modes for a single projection of a clean aluminum plate. (a) Raw data of the first envelope peak arrival. (b) Theoretical data for first arriving mode: Group velocity of $A_1 = 3.25 \text{ mm}/\mu\text{s}$. (c) Sorted data for the first arriving mode. (d) Raw data of the third envelope peak arrival. (e) Theoretical data for third mode: Group velocity of $S_0 = 2.85 \text{ mm}/\mu\text{s}$. (f) Sorted arrival times for the third mode.

the signal with a pruning procedure²⁴ based on the discrete stationary wavelet transform.²⁵ Naturally, other methods could have been used to smooth the envelopes, but the following procedure integrates easily with the work recently performed by Hou *et al.*^{21,22} Ultimately, it is desired to combine the sorting algorithm described in this work with the wavelet detection algorithm developed by Hou *et al.* to form a robust multi-mode LWT system.

MatlabTM was used to compute the wavelet transform of the Lamb wave signals using an eight-level *coiflet3* decomposition. The *coiflet3* wavelet was chosen because it seemed to most closely resemble the wave packets we were trying to find the arrival times for. The absolute value of each signal was decomposed using the stationary wavelet transform. The first five levels of coefficients were zeroed and the remaining levels were inverse transformed to provide the envelope values. The ability of the wavelet transform to separate out the

high frequency noise and oscillations of the signal into the first five levels of detail is what makes this technique possible. Figure 2 shows a typical signal and compares the peak enveloping and wavelet enveloping techniques. It can be seen that the wavelet enveloping technique provides a smoother envelope and identifies fewer “false peaks.”

The wavelet enveloping allows us to extract the arrival times of the envelope peaks after the first arriving mode. Figure 3 shows the arrival times for the first three peaks in the recorded signal for the first transmitter position in a scan of a clean aluminum plate at 920 kHz. It can be seen that the first peak’s arrival time is extracted cleanly, but that the subsequent peak arrivals are much more scattered on the plot. The uncertainty in the arrival times of the later arriving peaks arises from constructive and destructive interference between dispersive modes. Figure 4 shows the signal envelopes and waveforms from receiver positions 55 to 62. At a

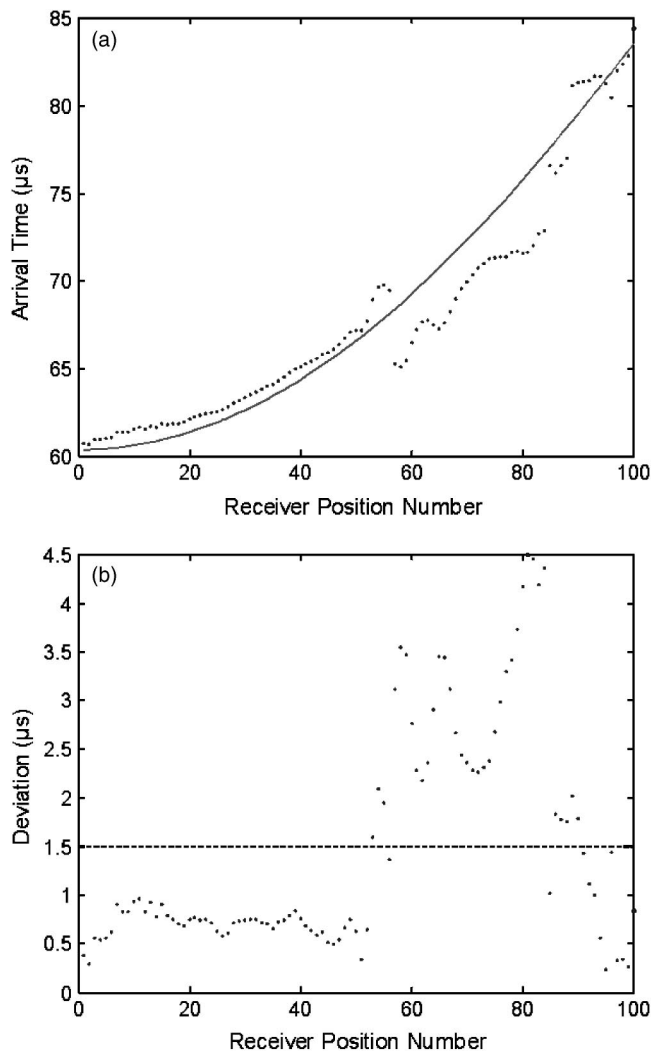

FIG. 6. (a) The first peak's arrival times for the first 100 points of projection 1 for the flat-bottomed hole sample (solid line is the polynomial fit of the arrival times for the first mode). (b) Deviations of the arrival times from the polynomial fit. Notice that a deviation threshold of $1.5 \mu\text{s}$ can be used to differentiate between the flawed and unflawed regions of the plate.

frequency thickness of $2.92 \text{ MHz}\cdot\text{mm}$, it is expected that the first arriving mode will be the A_1 mode with a group velocity of $3.24 \text{ mm}/\mu\text{s}$. It will be followed by the A_0 mode ($3.14 \text{ mm}/\mu\text{s}$) and then the S_0 mode ($2.87 \text{ mm}/\mu\text{s}$). The sequence of plots in Fig. 4 highlights how the envelope peaks combine because the individual dispersive modes are spreading as they propagate. The disappearance of the peak is less of an issue than the intermixing of the mode series. In order to generate a tomographic image from the later arriving mode arrival times, they need to be separated from each other. However, this problem becomes nontrivial because the data series jump between modes as certain modes interfere with each other. It is necessary to note that for accurate tomographic reconstructions, the measurements are designed to be taken in highly dispersive regions because the change in velocity due to thickness loss is the parameter of interest. Thus, in order to use the multi-mode information, a more robust time extraction algorithm is needed to overcome these interference problems.

For the clean plate, the arrival times can be sorted into

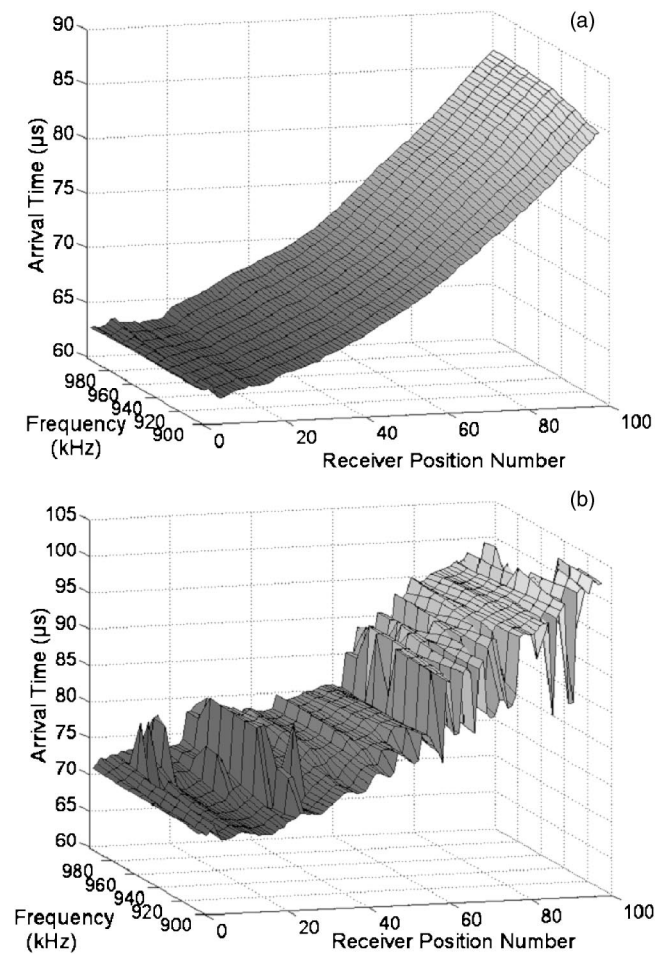

FIG. 7. Frequency walk surface plots for the arrival times of the first transmit position in a scan of a clean aluminum plate. Times recorded for ten evenly spaced frequencies between 900 and 990 kHz. (a) Arrival times for the first peak. (b) Arrival times for the second peak.

their correct series by fitting the individual series with a third-order polynomial fit. This provides a guess for where the missing points should lie and provides a measure to determine whether a mode has been missed. Figure 3 shows the arrival times for the first three envelope peaks and the polynomial fit for each data series. It can be seen that the polynomial fit effectively estimates where the mode should be and also shows how at receiver position 61, the second recorded peak arrival is actually the arrival time for the third mode.

In order to use the polynomial fit to sort the arrival times into their appropriate mode numbers, we compare the times to the fitted mode curves. For the clean plate, the arrival times are sorted into the series that corresponds to the fitted curve that they are closest to. If a particular mode is not present, we store the fitted value at that waveform number into the arrival time data as a placeholder for the tomographic reconstruction algorithms since we do not have enough information to determine when the actual arrival time is. Once the data has been sorted, the process can be iterated and we can refit the mode data and sort again to further improve the arrival times for the clean sample.

The sorting algorithm compared to both the theoretical and predicted arrival times reduced the mean square error

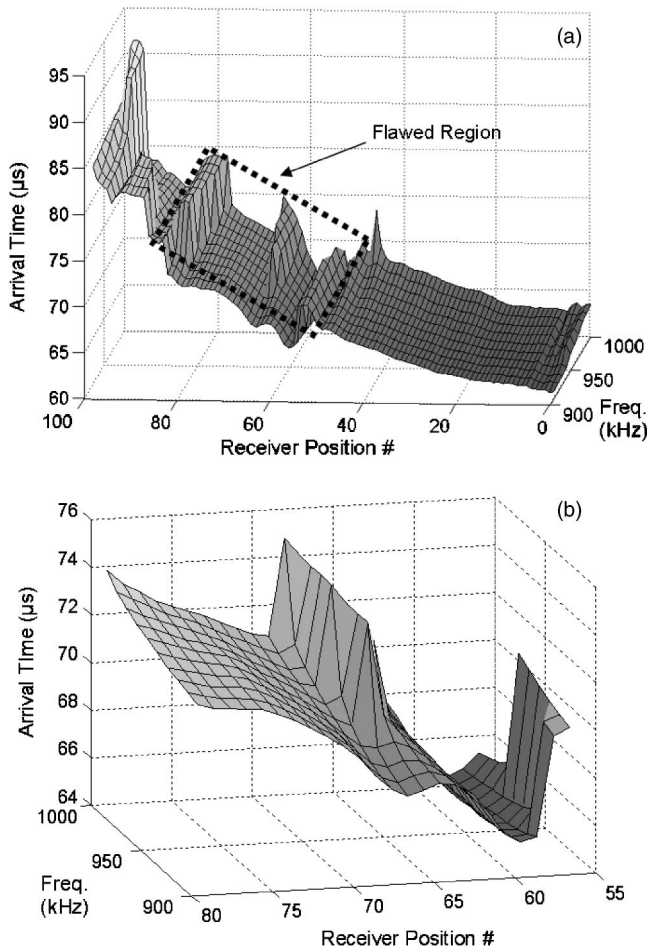

FIG. 8. (a) Frequency walk data for the first 100 arrivals of the first arriving mode in the flat-bottomed hole sample (see Fig. 5 for comparison with a clean plate). (b) Arrival times for the “flawed” region between receiver positions 55 and 80.

(MSE) of the measurement. The MSE for the unsorted arrival times compared to theoretical arrival times was 3.01, 6.32, and 8.26 μs for the first three modes, respectively. After sorting, the MSE was reduced to 3.01, 5.77, and 7.47 μs . Part of the large discrepancy between the theoretical and experimental arrival times of the modes is due to how the times were extracted. The arrival times are determined by the location of the envelope’s peak. Dispersion of the mode’s shape due to the bandwidth of the input signal can cause variations in the peak arrival. A more effective measure of arrival times has been found to be the location of the front of the envelope.¹⁶ However, for later arriving modes, this position is hard to obtain. In contrast, the MSE between the unsorted arrival times and the predicted arrivals (the fitted data) was 0.24, 2.24, and 3.48 μs for the first three modes and for the sorted times, the MSE was 0.24, 1.47, and 1.71 μs . Figure 5 shows the arrival time scatter plots before and after the sorting algorithm was applied for the A_1 and S_0 modes. As expected, the first arrival time is fairly accurate and is not affected by the sorting algorithm, but the third mode is significantly improved.

The previous algorithm works well for a clean sample, but will blur out flaws in the tomographic reconstructions because it assumes that any deviation from the predicted

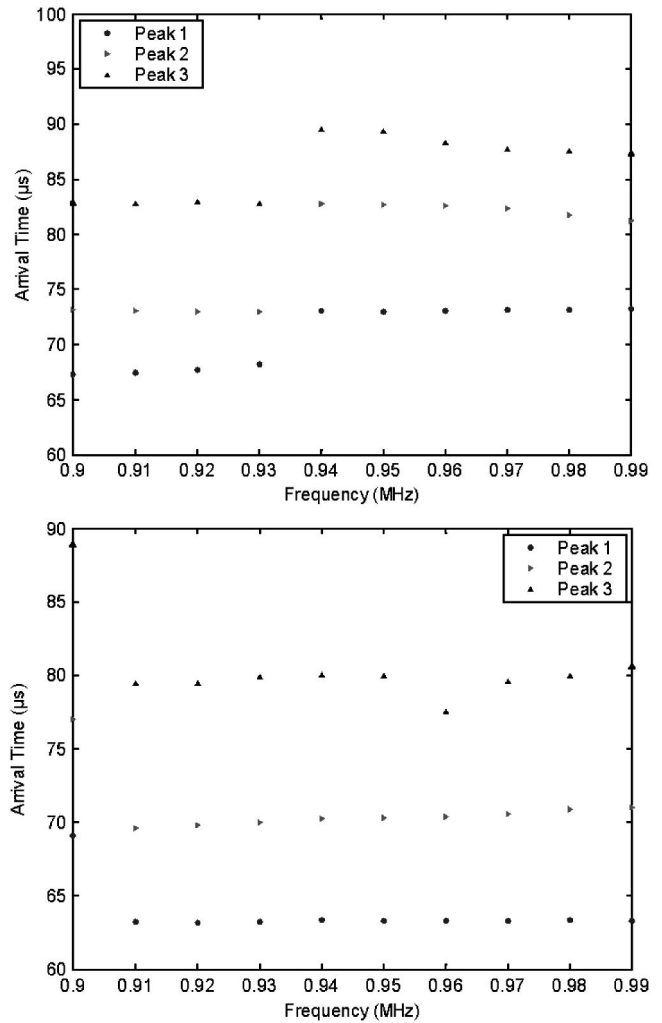

FIG. 9. (a) Arrival time versus frequency for the first three envelope peaks in signal 65. (b) Arrival time versus frequency for signal 598 where only the first frequency missed the first arriving mode.

curves is due to interference. To extend the usefulness of the sorting algorithm to flawed samples, more information is needed to determine whether the individual arrival times are due to a flaw, a missed mode, or a bad data point resulting from poor coupling or digitization. Because the first arrival is accurately detected and is not affected by the clean plate sorting algorithm, we can use the first arrival as a measure to see whether the subsequent arrivals can be seen as “clean” arrivals or need to be handled as “potential flaw” arrivals.

Figure 6(a) shows the first 100 points of a projection for a 3.17-mm-thick aluminum plate with a 2.2-in.-diam off-center flat-bottomed hole ($\sim 60\%$ thickness loss). From the geometry of this sample and the scanner, the Lamb wave data should begin to interact with the flaw around receiver position 55 for the first transmit position. The arrival time plot shows how the fastest mode arrives earlier in the flawed region because the frequency-thickness product has changed. It also should be noted that due to change in the frequency-thickness product, the second arrival also speeds up and arrives where the first mode would be located on a clean sample. This causes the sorting algorithm to choose the second arrival time as the first mode and thus discounts the actual “flaw” arrivals. In Fig. 6(b) the deviations of the ar-

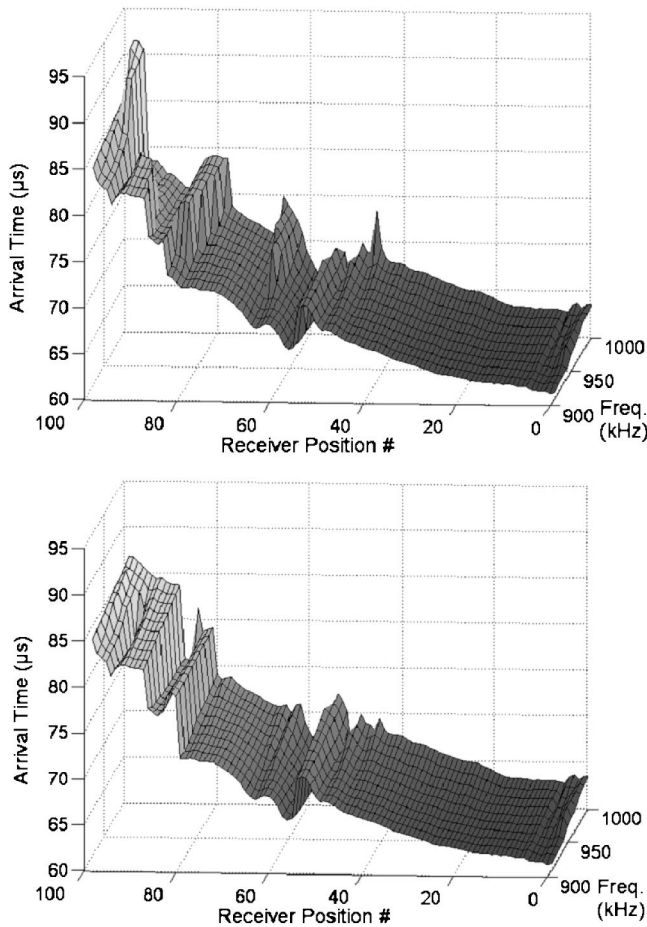

FIG. 10. Comparison of frequency walk data for the first arriving mode before sorting (top) and after sorting (bottom).

arrival times from the polynomial fit in the flawed sample are also shown. It can be seen that at position 55—where the Lamb wave data begin to interact with the flaw—the deviation in the measurement from the fitted data is greater than $1.5 \mu\text{s}$. Therefore, in order to delineate the suspected “clean” arrivals from suspected “flaw” arrivals, a deviation of $1.5 \mu\text{s}$ from the expected arrival was used as a threshold level.

Once the arrival times are able to be separated, it is still necessary to determine which mode they belong to and whether they are actual arrivals or erroneous data points. To gain more information, at each pitch-catch position the frequency was incremented at equally spaced intervals. The frequency was changed from 900 to 900 kHz at 10 kHz steps, and, for each frequency, the waveform was digitized and stacked into its corresponding data file. The frequency walking technique provides an extra dimension in order to solve the arrival time sorting problem. As the frequency is slightly varied, the arrival times of the different lamb wave modes should also change. By selecting a particular region on the group velocity dispersion curves, this can provide more information about which modes are actually being recorded. The 900- to 990-kHz region was selected because the modes’ group velocity curves were relatively well separated and because their slopes over this region were significantly different.

Figure 7 shows the same arrival times as in Fig. 3, but

FIG. 11. Tomographic reconstructions for the first three modes of a 3.17-mm-thick plate sample with a 2.2-in.-diam flat-bottomed hole. Thickness loss within the flaw was 60%. (a) S_0 , unsorted. (b) S_0 , sorted. (c) A_0 , unsorted. (d) A_0 , sorted. (e) A_1 , unsorted. (f) A_1 , sorted. The dashed line in each reconstruction represents the actual location and size of the flaw.

separates them by mode and has the additional frequency walk information. The fastest mode, A_1 , is a smooth distribution between the different frequencies. The second peak’s arrival time can again be seen to jump from a time consistent with the second arriving mode, A_0 , to one consistent with the third arriving mode, S_0 , at about receiver position 61. It can then be seen to oscillate between the two values for a period.

Figure 8(a) shows the first 100 points of the frequency walk data for the first mode’s arrival time in the same flat-bottomed hole sample as above. Some frequencies interact with the flaw before the other frequencies. Also, due to either inconsistent coupling of the moving contact transducer or mode interference as described above, in the middle of the flawed area the first arriving peak in the higher frequencies can be seen to jump from the first mode to the second mode [see Fig. 8(b)]. Thus, even within the suspected flaw regions the data needs to be sorted so that the correct arrivals are included in the correct mode series.

The frequency walk data actually provides enough information to determine which mode series the arrival times should belong to. Figure 9(a) is a plot of the first three arrival times versus frequency number for pitch-catch position 65 (where the first peak’s arrival for the higher frequencies seems to jump to the second mode). From this graph it is seen that the first arrival for the higher frequencies, along with the second arrival for the lower frequencies, forms a line. This shows that something is occurring to mask the first

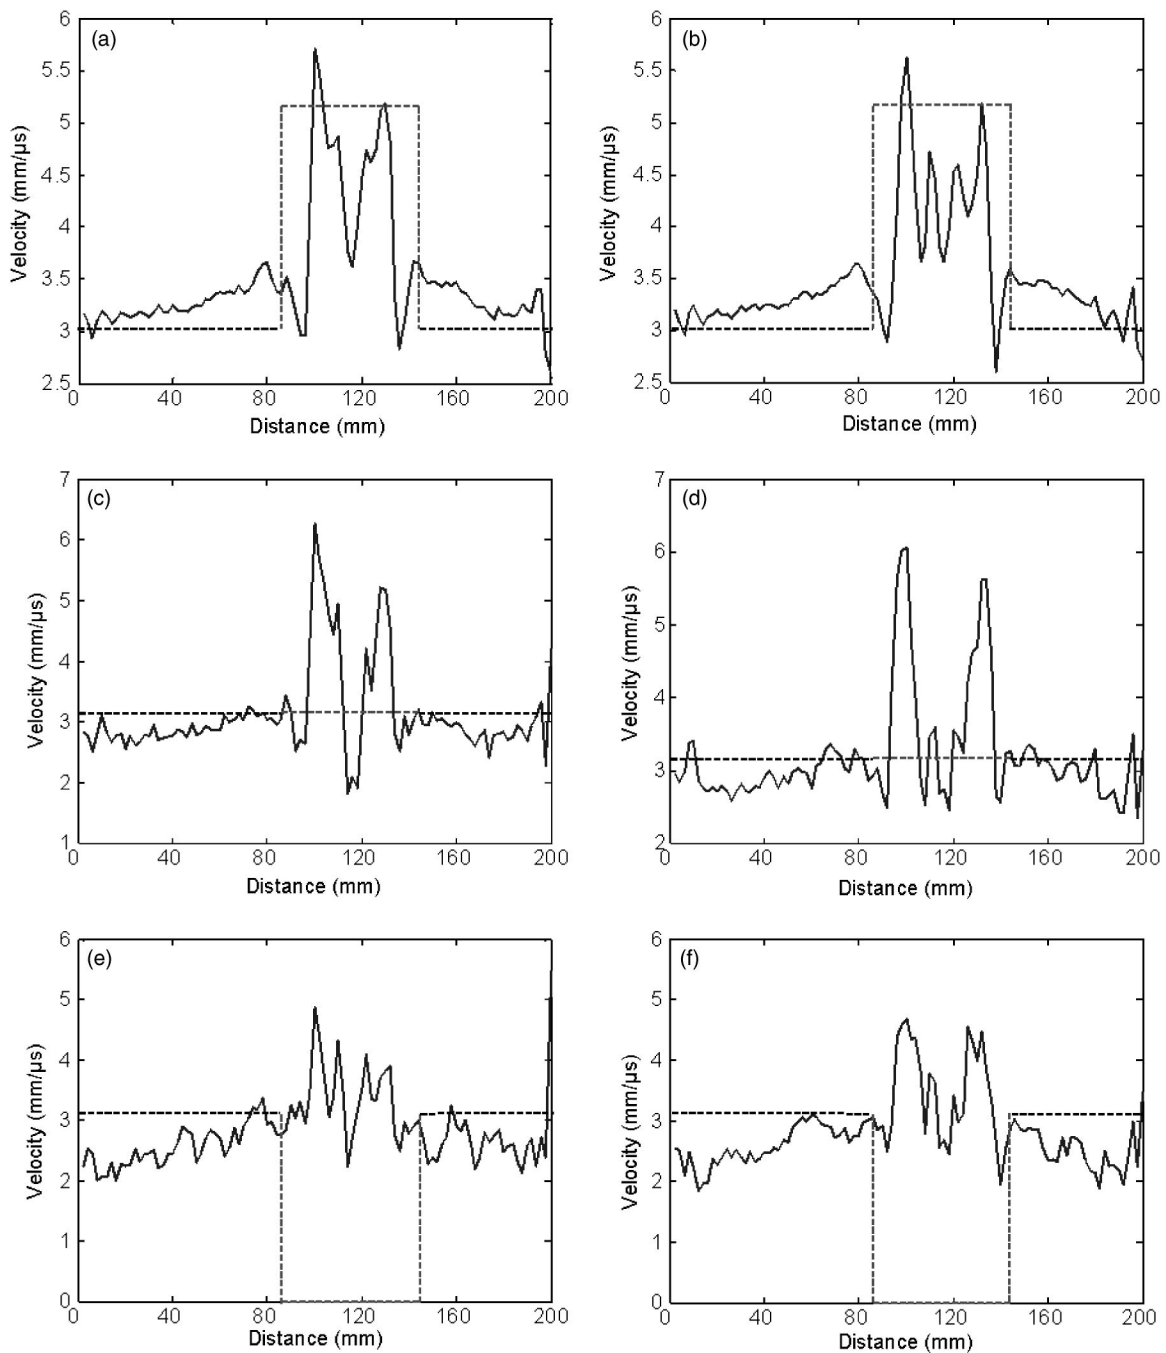

FIG. 12. Group velocity line plots for the first three modes of a vertical line through the center of the flat-bottomed hole. (d) A_0 , sorted. (e) A_1 , unsorted. (f) A_1 , sorted.

mode arrival and that the higher frequencies are actually locating the second mode as the first arriving peak. In the same way, Fig. 9(b) shows a similar plot for waveform 598 (the 98th receive position for the 5th transmitter position) in the flawed sample. In this graph, it can be seen that the first arrival for 900 kHz was missed. Therefore, the first arrival will have been marked as a potential flaw area by the sorting algorithm. However, the frequency data show that the first arrival actually belongs with the second mode and can be resorted without affecting the resulting reconstruction.

Therefore, using both the predicted mode curves and the frequency data, the multiple peak arrival times can be sorted

into the correct mode series both inside and outside a flawed region. First, each of the original peak arrival series is fitted with a third-order polynomial. Then each arrival time is compared with these expected mode arrivals. If the deviation between the actual arrival and the expected arrival is greater than $1.5 \mu\text{s}$, then the data point is marked as a potential flaw area. After all the arrivals of each frequency scan have been marked, the predicted mode values are updated by fitting only the arrivals which were not marked as a potential flaw. The nonflaw points are then sorted by the same algorithm used above to sort the clean plate arrivals. Finally, the flaw points are sorted using the frequency walk data. By sorting

FIG. 13. Tomographic reconstructions for the first three modes of a 3.17-mm-thick plate sample with a 2.2-in.-diam, successively dished-out flat-bottomed hole. Maximum thickness loss within the center of the flaw was 60%. (a) S_0 , unsorted. (b) S_0 , sorted. (c) A_0 , unsorted. (d) A_0 , sorted. (e) A_1 , unsorted. (f) A_1 , sorted. The dashed line in each reconstruction represents the actual location and size of the flaw.

the frequency data into linear series as in Fig. 9, the arrival times within a flaw region can be sorted to the correct mode series.

Figure 10 shows the results of the sorting algorithm for the frequency walk data of the first 100 pitch-catch positions on the flat-bottomed hole sample. Figure 11 also shows the effects of the sorting algorithm on the tomographic reconstructions of the flat-bottomed hole sample for the first three modes. These reconstructions are for only the two parallel crosshole projections as opposed to the full six projections in multiple crosshole tomography so there are some unavoidable artifacts in the reconstructed images. It can be seen that the flaws are more accurately sized by the sorted data than the unsorted mode data. This is also illustrated in Fig. 12 where a velocity line plot is given for a vertical line that runs through the center of the flaw. The dashed lines in Fig. 12 represent the theoretical group velocities for the measured frequency-thickness (fd) product both within and outside of the flaw. The second arriving mode, A_0 , is not very dispersive and thus its theoretical group velocity does not change much within the flaw. However, the reconstructed data show a higher velocity within the flaw. Why this occurs has not been explored yet, but it is expected that this happens because of scattering, diffraction, and energy being converted from one mode to another as the Lamb wave modes interact with the flawed region. Similarly, the fd product within the flaw is also below the cutoff frequency of the A_1 mode.

FIG. 14. Tomographic reconstructions for the first three modes of a 3.17-mm-thick plate sample with a 51-mm-diam circular flat-bottomed hole. Thickness loss was only 12% within the flaw. (a) S_0 , unsorted. (b) S_0 , sorted. (c) A_0 , unsorted. (d) A_0 , sorted. (e) A_1 , unsorted. (f) A_1 , sorted. The dashed line in each reconstruction represents the actual location and size of the flaw.

Again, the group velocity profile most likely shows a non-zero value because of the effects described above.

Similar results have been found for two other flawed samples. Figure 13 shows the reconstructions for the first three modes of a sample with a gradually dished out flat-bottomed hole the same diameter as the flat-bottomed hole sample above. The maximum thickness loss at the center of this flaw was 60%. The plate's thickness was again 3.17 mm. Finally, Fig. 14 shows a 2-in. flat-bottomed hole with a 12% thickness loss. It can be seen for this subtle flaw that the sorting algorithm improved the overall shape of the flaw for the S_0 mode.

The effects of the mode sorting algorithm on the tomographic reconstruction's quality can also be quantified with the following image quality parameters—contrast-to-noise ratio (CNR), flaw signal-to-noise ratio (FSNR), and speckle signal-to-noise ratio (SNR). These image quality parameters are similar to those defined by Behar *et al.*²⁶

$$\begin{aligned} \text{CNR} &= (\mu_s - \mu_n) / \sigma_n, \\ \text{FSNR} &= (\mu_s - \mu_n) / \sqrt{\sigma_s^2 + \sigma_n^2}, \\ \text{SNR} &= \mu_n / \sigma_n, \end{aligned} \quad (2)$$

where μ_s is the mean of the flaw data, μ_n is the mean of the noise outside of the flaw area, σ_n is the standard deviation of the noise outside of the flaw, and σ_s is the standard deviation of the flaw data. Table I summarizes their results. In order to

accurately determine the flawed region from the unflawed region for the calculation of these parameters, the location and size of the flaws were carefully measured and the corresponding pixel values were used to select the correct areas in the images. It can be seen that the sorting algorithm does improve the overall image quality of the individual modes for each sample. From this data it can be seen that the sorting algorithm improves the contrast-to-noise ratio of the flaw for the second two modes the best. This is an important result, since it enhances the capability to automatically extract the flawed region from the unflawed region computationally.

V. CONCLUSION

This work, along with Hou,²¹ has laid the groundwork for the accurate extraction of multiple mode arrival times. In addition to platelike structures, it has also been shown by Leonard and Hinders²⁷ that pipelike objects can be treated as plates wrapped around upon themselves. Therefore, the same tomographic and arrival time sorting algorithms can also be used to inspect pipelike structures. The technique developed by Hou has the capability to extract more accurate arrivals and to ignore the unwanted pipe modes that exist in the more complicated pipe signals. Combined, the two techniques have the potential to lead to even better reconstructions that accurately locate and size flaws in both pipes and plates.

The sorting algorithm was demonstrated on four different plate samples. It was seen that after sorting the arrival times, the reconstructions did a better job of sizing the flaws. Another result from these tests was that after sorting, the tomographic data better represented the actual velocity data within the flawed area for the first mode and the deeper flaws showed up better in the reconstructions. In contrast, the sorting algorithm improved the quantitative accuracy—both in size and velocity reconstruction—for the subtle flaw, but the actual reconstructed images for the A_0 and A_1 modes did not highlight the flaw as well. However, this demonstrates the validity of the statement that the individual modes will interact with the flaws differently. The A_0 is nondispersive around the frequency-thickness product that we are operating and

thus we would not expect to see the flaw in these reconstructions unless other effects such as scattering, diffraction, or mode conversion are occurring.

Future work needs to pursue the application of the sorting and frequency compounding algorithms combined with the DWFP technique to pipelike structures. In order for the helical arrivals to be obtained accurately, a systematic study needs to be conducted on pipe data in order to obtain the correct fingerprint patterns for the different arrivals. Furthermore, as suggested by Hou,²¹ different wavelets need to be studied to determine which basis is best to solve this problem.

Finally, a systematic theoretical and experimental study of a representative flaw would be extremely beneficial. Since the calculations of the theoretical arrival times of the various modes in a flawed sample are nontrivial, it is hard to provide an accurate measure of the success of the multi-mode extraction algorithms. If a systematic study was done with a simple type of flaw that was slowly enlarged, both theoretical simulations—such as FEM, BEM, FDTD, etc.—and experimental data could be collected. This would allow for a comparison of the DWFP and sorting algorithms to theoretical data and would provide a clearer understanding of how the individual guided wave modes interact with a characteristic flaw.

(Received 13 August 2003; revised 1 July 2005; accepted 31 January 2005)

The regularization method for measurement of structural intensity using nearfield acoustical holography is proposed. Spatial derivatives of normal displacement are necessary to obtain the structural intensity. The derivative operations amplify high-wave-number components of measurement noise. Therefore, the estimation of an appropriate wave-number filter is crucial for implementation of the measurement of structural intensity. In conventional methods, this wave-number filter is determined from the flexural wavelength. And the same wave-number filter is applied to obtain all spatial derivatives. As a result, structural intensity obtained from the pressure hologram, whose signal-to-noise ratio is low, is seriously contaminated by the noise. To overcome this difficulty, regularization theory is applied to determine the appropriate wave-number filter for each order of derivatives. The effectiveness of the proposed method is demonstrated by experiments. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1875652]

I. INTRODUCTION

Measurement of power flow in structures is essential for the vibration control and noise reduction. Many researchers have studied the measurement techniques of this structure-borne power flow, called structural intensity (SI). In the 1970s, Noiseux¹ and Pavic² introduced the formulation of the SI for thin beams and plates. To obtain the SI, spatial derivatives of the normal displacement of structure are necessary. This normal displacement is measured by various kinds of devices such as accelerometers,^{1,3–5} strain gauges,⁶ and laser Doppler vibrometer (LDV).^{7–10} Nearfield acoustical holography (NAH)¹¹ is also applied to obtain the normal displacement.^{12,13}

Strain gauges or accelerometers pick up the surface vibration directly to yield the local SI. However, we must attach many sensors on the structure if the SI is to be measured over the whole structure, and these attached sensors significantly affect the SI. On the contrary, noncontacting measurement methods based on LDV or NAH can yield the SI over the whole structure, and the method based on NAH enables us to obtain SI and acoustic intensity (AI) simultaneously.^{12,13} Therefore, NAH-based method is suitable to analyze the interrelationship between SI and AI.

Spatial derivatives of normal displacement are calculated by a finite difference (FD) approximation method^{1–7} or fast Fourier transform (FFT)-based method.^{8–10,12–16} The FD method is appropriate to measure local SI because of the simplicity of the FD method. However, the derivative operations of the FD method significantly magnify the noise of higher-order spatial derivatives. To avoid this noise amplification, the velocity or pressure data must be measured on a finely meshed contour.^{6,17} On the contrary, the FFT-based

method enables us to obtain spatial derivatives over the whole structure, and the amplification of noise is suppressed by applying a wave number-space (K-space) filter. In this method, the estimation of the appropriate filter is crucial. If the filter size is too large, the noise cannot be removed and the SI may be noisy. If the size is too small, useful information to locate a vibration source cannot be obtained.

In conventional FFT-based methods, the K-space filter is determined by a trial and error process,⁸ or determined from the flexural wavelength only.^{12,15,16} The same filter is used to evaluate all derivatives. Therefore, it is difficult to obtain SI by NAH from the low signal-to-noise ratio (SNR) measured pressure hologram using the K-space filter estimated by the conventional method.

In this paper, the estimation method of an appropriate k -space filter for each order of derivatives is proposed. The method utilizes the improved Tikhonov regularization filter¹⁸ (abbreviated as “Tikhonov filter” hereafter). The regularization parameter is determined by the modified generalized cross validation (GCV) method. As demonstration examples, experimental investigations are carried out to show the effectiveness of the proposed method.

II. STRUCTURAL INTENSITIES OF THIN PLATE

Before discussion of the regularization for measurement of SI, we review the basic formulas. First, let us describe the SI of thin plate below. If a plate is located on the x - y plane, the formulation for SI² is

$$I_x = D \left\langle \frac{\partial}{\partial x} (\nabla^2 w) \frac{\partial w}{\partial t} - \left(\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} \right) \frac{\partial^2 w}{\partial x \partial t} - (1 - \sigma) \frac{\partial^2 w}{\partial x \partial y} \frac{\partial^2 w}{\partial x \partial t} \right\rangle_T$$

^{a)}Electronic mail: saiyou-kenji@jcom.home.ne.jp

^{b)}Electronic mail: okawara@jda-trdi.go.jp

$$I_y = D \left\langle \frac{\partial}{\partial y} (\nabla^2 w) \frac{\partial w}{\partial t} - \left(\frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial x^2} \right) \frac{\partial^2 w}{\partial y \partial t} - (1 - \sigma) \frac{\partial^2 w}{\partial x \partial y} \frac{\partial^2 w}{\partial y \partial t} \right\rangle_T, \quad (1)$$

where outer bracket $\langle \rangle_T$ indicates time average, E is the Young's modulus, σ is the Poisson's ratio, h is the plate thickness, w is the normal displacement, and $D = Eh^3/[12(1 - \sigma^2)]$. To calculate Eq. (1), spatial derivatives of the normal displacement are necessary. These spatial derivatives are easily obtained in K-space from the following relationship:^{8,12,15}

$$\frac{\partial^m}{\partial x^m} \frac{\partial^n}{\partial y^n} [w(x, y, 0)] = \mathcal{F}^{-1} \{ (ik_x)^m (ik_y)^n \mathcal{F}[w(x, y, 0)] \}, \quad (2)$$

where \mathcal{F} and \mathcal{F}^{-1} represent the two-dimensional forward and inverse Fourier transforms in x and y , and k_x and k_y are wave numbers in the x and y direction, respectively. The normal displacement of the plate is reconstructed by NAH¹¹ from the measured pressure, and SI of thin plate is calculated by Eqs. (1) and (2).

We have not considered the influence of measurement noise in these formulations of SI described in this section. In the practical NAH experiment, the reduction of the influence of measurement noise is crucial. In the next section, the regularization method for measurement of SI is explained in detail.

III. REGULARIZATION FOR SPATIAL DERIVATIVES

The Tikhonov filter for Cartesian coordinates is described as¹⁸

$$F^{\alpha,1}(k_x, k_y, \lambda_{k_x, k_y}) = \frac{|\lambda_{k_x, k_y}|^2}{|\lambda_{k_x, k_y}|^2 + \alpha [\alpha / (\alpha + |\lambda_{k_x, k_y}|^2)]^2}, \quad (3)$$

where

$$\lambda_{k_x, k_y} = \frac{\rho c k}{i \sqrt{k_x^2 + k_y^2 - k^2}} e^{-\sqrt{k_x^2 + k_y^2 - k^2} (z_{\text{mea}} - z_0)}. \quad (4)$$

is called the propagator,¹¹ ρ is the density of medium, c is the sound velocity, $k = 2\pi f/c$, f is the frequency, and $z = z_{\text{mea}}$ and $z = z_0$ are measurement and reconstruction planes, respectively. Let $\dot{w}(\mathbf{r}_0) = \dot{w}(x, y, z_0)$ be the normal velocity of the structure surface and $p(\mathbf{r}_{\text{mea}}) = p(x, y, z_{\text{mea}})$ be the hologram pressure on the measurement plane. The harmonic time dependence $e^{i\omega t}$ is suppressed throughout this paper. The following relationship exists between them:¹¹

$$w(\mathbf{r}_0) = \dot{w}(\mathbf{r}_0)/(i\omega) = \mathcal{F}^{-1} [\mathcal{F}\{p(\mathbf{r}_{\text{mea}})\} \lambda_{k_x, k_y}^{-1}] / (i\omega). \quad (5)$$

This is the reconstruction equation. Here, λ_{k_x, k_y}^{-1} is called the inverse propagator. To suppress the amplification of noise in high-wave-number region, the Tikhonov filter is applied. Thus Eq. (5) is modified as

$$\tilde{w}(\mathbf{r}_0) = \mathcal{F}^{-1} [\mathcal{F}\{p(\mathbf{r}_{\text{mea}})\} F^{\alpha,1}(k_x, k_y, \lambda_{k_x, k_y}) \lambda_{k_x, k_y}^{-1}] / (i\omega). \quad (6)$$

Here, tilde indicates the smoothed variable. To obtain spatial derivatives of the normal displacement from the measured pressure, Eq. (6) is substituted into Eq. (2) as

$$\begin{aligned} & \frac{\partial^m}{\partial x^m} \frac{\partial^n}{\partial y^n} [\tilde{w}(\mathbf{r}_0)] \\ &= \mathcal{F}^{-1} \{ \mathcal{F}\{p(\mathbf{r}_{\text{mea}})\} F^{\alpha,1}(k_x, k_y, \lambda_{k_x, k_y}) \\ & \quad \times \lambda_{k_x, k_y}^{-1} (ik_x)^m (ik_y)^n \} / (i\omega). \end{aligned} \quad (7)$$

Equation (7) is a typical FFT-based method. Here, the filter $F^{\alpha,1}(k_x, k_y, \lambda_{k_x, k_y})$ is appropriate to obtain the normal velocity $\dot{w}(\mathbf{r}_0)$ because the inverse propagator λ_{k_x, k_y}^{-1} , which describes the relationship between the measured pressure $p(\mathbf{r}_{\text{mea}})$ and the normal velocity $\dot{w}(\mathbf{r}_0)$, is treated as the eigenvalue of the Tikhonov filter. However, this filter is not appropriate to obtain the spatial derivative of the normal displacement from the measured pressure, because $(ik_x)^m (ik_y)^n$ is multiplied to the K-space representation of the measured pressure $\mathcal{F}\{p(\mathbf{r}_{\text{mea}})\}$ and this filter does not sufficiently suppress the growth of the high-wave-number noise which contaminates the reconstructed result.

To suppress the amplification of high-wave-number noise, Morikawa¹⁵ proposed that the circ function should be applied for the k -space filter to the normal velocity as

$$\begin{aligned} & \frac{\partial^m}{\partial x^m} \frac{\partial^n}{\partial y^n} [\tilde{w}(\mathbf{r}_0)] \\ &= \mathcal{F}^{-1} \{ \mathcal{F}\{p(\mathbf{r}_{\text{mea}})\} \text{circ}(k_x, k_y, k_{\text{cut}}) \\ & \quad \times F^{\alpha,1}(k_x, k_y, \lambda_{k_x, k_y}) \lambda_{k_x, k_y}^{-1} (ik_x)^m (ik_y)^n \} / (i\omega), \end{aligned} \quad (8)$$

$$\text{circ}(k_x, k_y, k_{\text{cut}}) = \begin{cases} 1, & k_x^2 + k_y^2 < k_{\text{cut}}^2 \\ 0, & k_x^2 + k_y^2 \geq k_{\text{cut}}^2. \end{cases} \quad (9)$$

Here, the cutoff wave number satisfies the relationship as $1.5k_{\text{flex}} < k_{\text{cut}} < 1.8k_{\text{flex}}$, $k_{\text{flex}} (= [h\rho_0(2\pi f)^2/D]^{1/4})$ is the flexural wave number, and ρ_0 is the density of the plate. Nejade¹⁶ proposed that a band-pass filter should be applied for the K-space filter as the normal velocity as

$$\begin{aligned} & \frac{\partial^m}{\partial x^m} \frac{\partial^n}{\partial y^n} [\tilde{w}(\mathbf{r}_0)] \\ &= \mathcal{F}^{-1} \left\{ \mathcal{F}\{p(\mathbf{r}_{\text{mea}})\} \left[\text{circ} \left(k_x, k_y, k_{\text{flex}} + \frac{2\pi}{L} \right) \right. \right. \\ & \quad \left. \left. - \text{circ} \left(k_x, k_y, k_{\text{flex}} - \frac{2\pi}{L} \right) \right] \right. \\ & \quad \left. \times F^{\alpha,1}(k_x, k_y, \lambda_{k_x, k_y}) \lambda_{k_x, k_y}^{-1} (ik_x)^m (ik_y)^n \right\} / (i\omega). \end{aligned} \quad (10)$$

Here L is the width of the measurement aperture. However, if the cutoff wave number is too small, the useful information

cannot be obtained to calculate SI, because the resolution of the reconstructed result is degraded. The amplification by the lower-order spatial derivative is relatively small; therefore, the lighter filtration is necessary to obtain the useful information when a lower-order derivative is reconstructed. When the cutoff wave number is too large, the amplification of noise in the high-wave-number region seriously contaminates the reconstructed result. The amplification by the higher-order derivative is relatively large; therefore, the deeper filtration is necessary to suppress the amplification of noise when a higher-order derivative is reconstructed. In other words, the appropriate cutoff wave number for circ function filter and band-pass filter are different at each frequency for each derivative order, and the appropriate cutoff wave number is not uniquely determined by conventional methods. Therefore, conventional methods are not appropriate for obtaining the SI when the SNR of the measured pressure hologram is low.

Now, we introduce the modification of the Tikhonov filter for spatial derivatives. The term, which is contained in Eq. (7),

$$\lambda_{k_x, k_y, (x, m), (y, n)}^{-1} = \lambda_{k_x, k_y}^{-1} (ik_x)^m (ik_y)^n, \quad (11)$$

expresses the relationship between the measured pressure and the spatial derivative of the normal displacement. Then, we can treat Eq. (11) as an eigenvalue of the Tikhonov filter, and the effect of the spatial derivative can be included in the determination process of regularization filter. The Tikhonov filter is modified for the spatial derivative as

$$F^{\alpha, 1}(k_x, k_y, \lambda_{k_x, k_y, (x, m), (y, n)}) = \frac{|\lambda_{k_x, k_y, (x, m), (y, n)}|^2}{|\lambda_{k_x, k_y, (x, m), (y, n)}|^2 + \alpha[\alpha + |\lambda_{k_x, k_y, (x, m), (y, n)}|^2]^2}, \quad (12)$$

and the spatial derivative is obtained as

$$\begin{aligned} & \frac{\partial^m}{\partial x^m} \frac{\partial^n}{\partial y^n} [\tilde{w}(\mathbf{r}_0)] \\ &= \mathcal{F}^{-1} \{ \mathcal{F} \{ p(\mathbf{r}_{\text{mea}}) \} F^{\alpha, 1}(k_x, k_y, \lambda_{k_x, k_y, (x, m), (y, n)}) \\ & \quad \times \lambda_{k_x, k_y, (x, m), (y, n)}^{-1} \} / (i\omega). \end{aligned} \quad (13)$$

Equation (12) is a Tikhonov filter for the spatial derivative. This filter is optimized for the order of derivative and SNR of the measured pressure.

IV. MODEL EXPERIMENT

In this section, the SI in a thin plate is measured to demonstrate the effectiveness of the proposed method. In experiments, natural frequencies at which the driving point is easily localized and other frequencies at which the localization of the driving point is difficult (this frequency is called as “non-natural frequency” hereafter) are selected. An automated scanning system was developed for measurement of airborne sound. An experimental model is SUS 304 stainless steel (the side is 500 mm × 600 mm × 5 mm). A shaker (Wil-

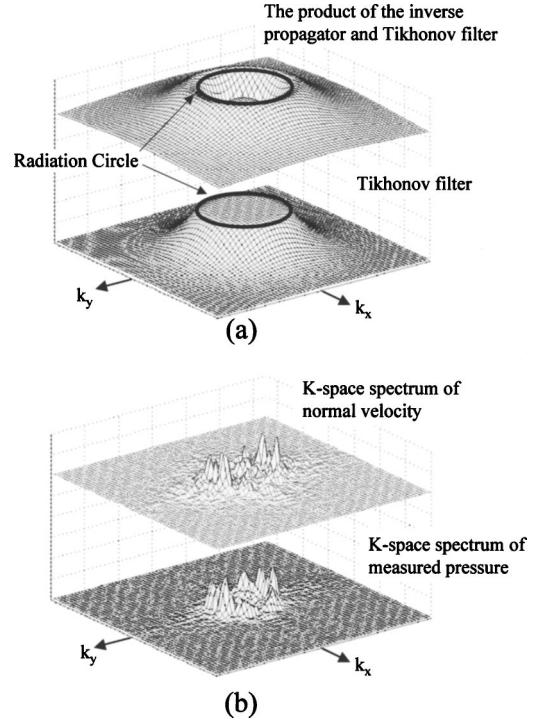

FIG. 1. K-space filter and K-space spectra. The frequency is 1144 Hz. (a) Tikhonov filter and the product of the inverse propagator and Tikhonov filter. (b) K-space spectra of measured pressure and reconstructed normal velocity.

coxon F3/Z3/F9) that vibrates the sample plate is attached at the center of the plate. The shaker is driven by a (300–6000 Hz) linear frequency modulation (LFM) signal. A Brüel & Kjaer Type 4182 microphone is placed at the prescribed position with scanners. Stepwise movement of the plate thus scans a two-dimensional measurement plane. Measured data of the measurement aperture are taken in 20-mm steps along x - and y -axis scanning. Thus, 64 × 64 points data make one hologram. The distance between the sample plate and the measurement hologram is 3 mm. The received and amplified signal from the microphone is digitized and transferred to a personal computer. Sampling inception time is accurately controlled by the computer, which acts as the reference source for holographic interference. The ends of the plate are sealed with rubber packing to approximate the simply supported boundary condition.

Figure 1 shows the K-space filter, K-space spectra of measured pressure and normal velocity. The plate is vibrated at the natural frequency of 1144 Hz at which the driving mobility shows a peak. In this paper, all data are normalized by the maximum value. The filter is the Tikhonov filter for normal velocity [Eq. (3)]. In Fig. 1(a), circles indicate radiation circles. The product of the inverse propagator and the Tikhonov filter show that (1) the amplitude inside the radiation circle is small, (2) the peak exists near the radiation circle, and (3) the amplitude outside the radiation circle is small. The K-space spectrum of the normal velocity is expressed as

$$\mathcal{F}[\tilde{w}(\mathbf{r}_0)] = \mathcal{F}[p(\mathbf{r}_{\text{mea}})] F^{\alpha, 1}(k_x, k_y, \lambda_{k_x, k_y}) \lambda_{k_x, k_y}^{-1}. \quad (14)$$

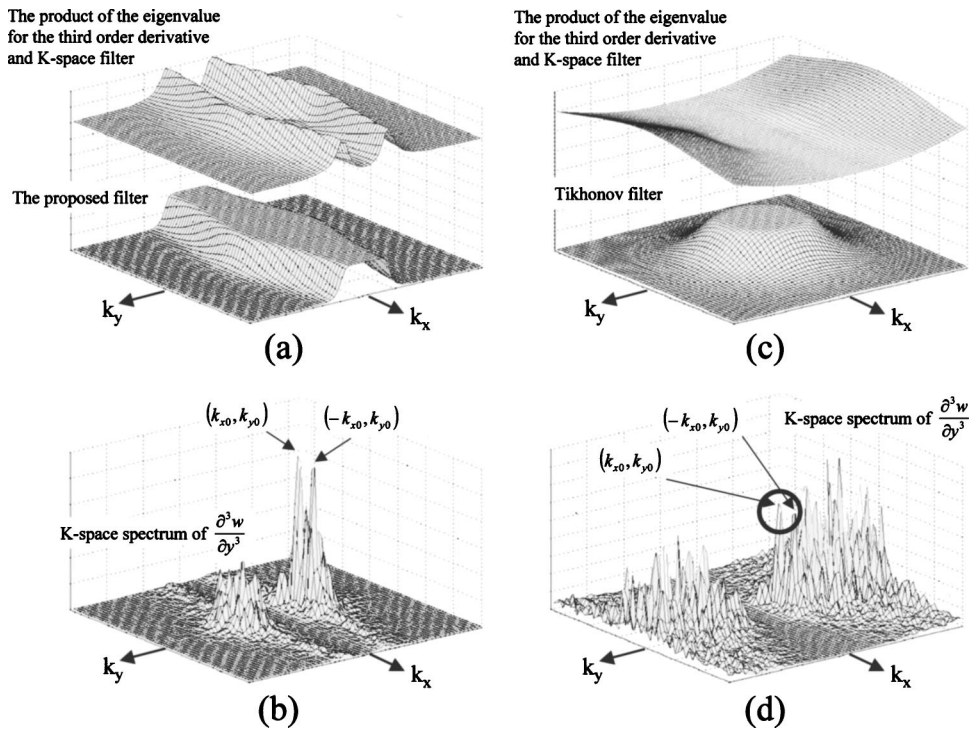

FIG. 2. K-space filter and K-space spectra. The frequency is 1144 Hz. (a) The proposed filter and the product of the eigenvalue for the third-order derivative $\lambda_{k_x, k_y, (x,0), (y,0)}^{-1}$ and the proposed filter. (b) K-space spectrum of $\partial^3 w / \partial y^3$ obtained by the proposed filter. (c) The Tikhonov filter for normal velocity and the product of eigenvalue for the third order derivative $\lambda_{k_x, k_y, (x,0), (y,0)}^{-1}$ and the Tikhonov filter. (d) K-space spectrum of $\partial^3 w / \partial y^3$ obtained by the Tikhonov filter. The circle shows local peaks that correspond to the peak of (b).

Therefore, the K-space spectrum of the normal velocity is wider than that of the measured pressure.

Figure 2 shows the K-space filter and K-space spectrum of the third-order spatial derivative of normal displacement. The frequency is 1144 Hz. Figure 2(a) shows the proposed filter for the third-order derivative and the product of the eigenvalue of the filter for the third-order derivative $\lambda_{k_x, k_y, (x,0), (y,3)}^{-1}$ [i.e., the product of the inverse propagator and $(ik_y)^3$] and the filter. The pass-band of the filter exists along the k_x axis, and the amplitude of the product of the eigenvalue and the filter is large near the k_x axis. Here, high-wave-number component is exponentially amplified in the NAH reconstruction process because of the multiplication of the inverse propagator. However, in this case, the amplification by the spatial derivative surpasses that by multiplication of the inverse propagator. In fact, the cube of the highest wave number of the y direction is $(2\pi/0.04)^3 \approx 3\,876\,000$, and the maximum amplitude of the inverse propagator is $e^{(2\pi/0.04) \cdot 0.005} \approx 345$. Therefore, the suppression of the growth of the noise due to the spatial derivative by the Tikhonov filter is appropriate to obtain the spatial derivative by Eq. (13). As the result, two peaks of the K-space spectrum of $\partial^3 w / \partial y^3$ [Fig. 2(b)] exist at $(\pm k_{x0}, k_{y0})$ ($\sqrt{k_{x0}^2 + k_{y0}^2} = k_{\text{flex}}$), and the amplitude $\partial^3 w / \partial y^3$ of the spectrum diminishes at the region which is far from the k_x axis. This result exhibits that the amplification of noise at the high-wave-number region is sufficiently suppressed by the proposed filter.

Figure 2(c) shows the Tikhonov filter and the product of the eigenvalue for third-order derivative $\lambda_{k_x, k_y, (x,0), (y,3)}^{-1}$ and the K-space filter. This Tikhonov filter is the same as that of Fig. 1(a). The Tikhonov filter cannot suppress the amplitude of the eigenvalue for third-order spatial derivatives, and the amplitude of the product of the propagator and the filter is

large at the region which is far from the k_x axis. As the result, the K-space spectrum of $\partial^3 w / \partial y^3$ [Fig. 2(d)] is seriously contaminated by noise. Two peaks in Fig. 2(d) marked with a circle corresponding to peaks in Fig. 2(b) are about to be hidden in some noise. Therefore, the Tikhonov filter for the normal velocity is not an appropriate filter for higher-order derivatives. To suppress this noise contamination, Morikawa¹⁵ and Nejade¹⁶ proposed the K-space filter whose cutoff wave number is lower. However, the size of the filter is sometimes too small, and useful information to calculate the SI may not be obtained.

To demonstrate the influence of K-space filters, the injected power calculated from the SI of the plate obtained by each K-space filter is compared. The injected power is given by¹²

$$\Pi_C = \oint_C \mathbf{I} \cdot \hat{n} \, dl, \quad (15)$$

Here, C is the contour surrounding each point, dl is the element of a square contour C , \mathbf{I} is the SI vector, and \hat{n} is the outward normal to the element of contour dl . Figure 3 shows the injected power at 1144 Hz. This frequency is the natural frequency. The SNR of the measured pressure hologram is 40 dB. The driving point is shown by a small triangle symbol, hereafter. Gray-scale plots show injected power and AI, white is positive, and black is negative, respectively. In this figure, the horizontal and vertical axes indicate x and y axes, respectively. Figure 3(a) represents the injected power reconstructed by the proposed method. The peak of the injected power corresponds to the driving point and comparison between the injected power and the AI [cf. Fig. 3(e)] shows fairly good matching at the periphery of the plate because Π_C is equal to the negative of the normal AI away from the driver.¹⁹ Figures 3(b) and (c) are the injected power recon-

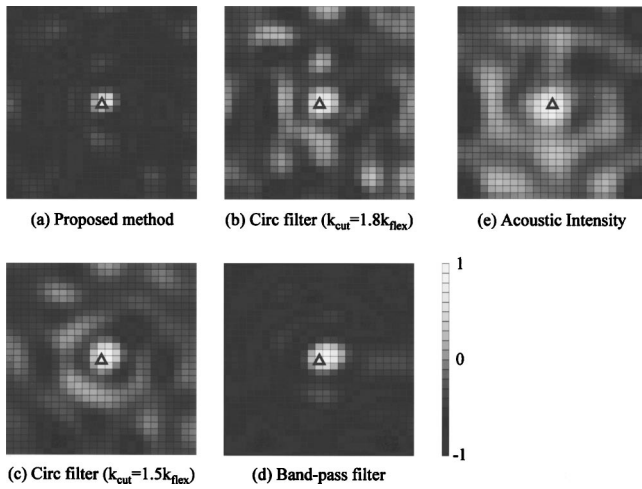

FIG. 3. The power injected to the plate. The frequency is 1144 Hz. SNR of the measured pressure is 40 dB. The triangle indicates the driving point. (a) The injected power by the proposed method. (b) The injected power by the circ function filter. The cutoff wave number is $1.8k_{flex}$. (c) The injected power by the circ function filter. The cutoff wave number is $1.5k_{flex}$. (d) The injected power by the band-pass filter. The center wave number is k_{flex} . (e) The normal component of the acoustic intensity radiated from the plate.

structed by circ function filter, which is proposed by Morikawa¹⁵ [cf. Eq. (8)], and Fig. 3(d) is that reconstructed by band-pass filter, which is proposed by Nejade¹⁶ [cf. Eq. (10)]. In Figs. 3(b)–(d), the peak of the injected power corresponds to the driving point. Comparison between the injected power and the AI shows fairly good matching away from the driver in Figs. 3(b) and (c). However, the region surrounding the driving point is contaminated by the amplification of noise in Figs. 3(b) and (c), because the cutoff filters are not selected appropriately. In Fig. 3(d), the injected power is not matched by the AI away from the driver, because the filter removes useful information.

Figure 4 shows the injected power at 1144 Hz. Random Gaussian noise was added to the measured pressure hologram with a 15-dB SNR. The (AI [Fig. 4(e)] is the same as Fig. 3(e) for comparison between reconstructed results of injected power and AI.) Differences between Figs. 3(b) and 4(b), Figs. 3(c) and 4(c), and Figs. 3(d) and 4(d) are relatively small, because the cutoff wave number is small and the influence of the noise is small. Comparison between Figs. 3(a) and 4(a) shows relatively large difference, especially in the vicinity of the driving point. However, the peak of the injected power corresponds to the driving point, and comparison between the injected power and the AI shows fairly good matching away from the driver. As a result, all methods considered here enable us to localize the driving point at 1144 Hz, because 1144 Hz is the natural frequency of the plate and the amplitude of the mode component in K-space surpasses noise components. However, the injected power reconstructed by the circ function filter shows that the region surrounding the driving point is contaminated by the amplification of noise and the injected power reconstructed by the band-pass filter is not matched by the AI away from the driver. On the contrary, the injected power reconstructed by the proposed filter shows fairly good matching with AI away from the driver.

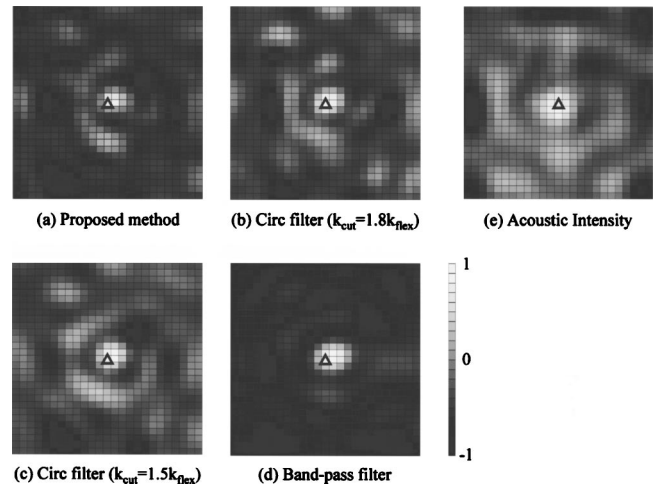

FIG. 4. The power injected to the plate. The frequency is 1144 Hz. SNR of the measured pressure is 15 dB. The triangle indicates the driving point. (a) The injected power by the proposed method. (b) The injected power by the circ function filter. The cutoff wave number is $1.8k_{flex}$. (c) The injected power by the circ function filter. The cutoff wave number is $1.5k_{flex}$. (d) The injected power by the band-pass filter. The center wave number is k_{flex} . (e) The normal component of the acoustic intensity radiated from the plate, which is reconstructed from the measured pressure without additional random Gaussian noise.

Figure 5 shows the injected power at 1923 Hz that is the non-natural frequency. The SNR of the measured pressure hologram is 40 dB. Figure 5(a) shows that the peak corresponds to the driving point and local peaks at the periphery of the plate are matched by the AI [cf. Fig. 5(e)]. Figures 5(b) and (c) show that the peak is exhibited at the upper-right corner of the plate and does not correspond to the driving point. The injected power at the driving point is negative. Figure 5(d) shows that the peak corresponds to the driving point; however, false local peaks are exhibited near the driving point and the injected power is not matched by the AI away from the driving point. As the result, the appropriate

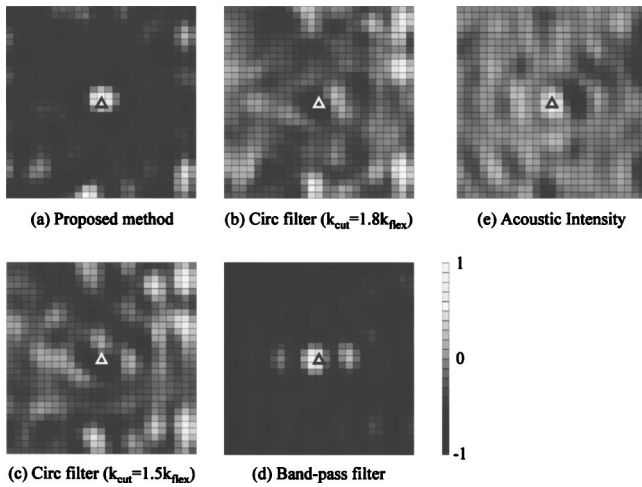

FIG. 6. The power injected to the plate. The frequency is 1923 Hz. SNR of the measured pressure is 15 dB. The triangle indicates the driving point. (a) The injected power by the proposed method. (b) The injected power by the circ function filter. The cutoff wave number is $1.8k_{flex}$. (c) The injected power by the circ function filter. The cutoff wave number is $1.5k_{flex}$. (d) The injected power by the band-pass filter. The center wave number is k_{flex} . (e) The normal component of the acoustic intensity radiated from the plate, which is reconstructed from the measured pressure without additional random Gaussian noise.

filter can only be estimated by the proposed method.

Figure 6 shows the injected power at 1923 Hz. Random Gaussian noise was added to the measured pressure hologram with a 15-dB SNR except for the AI [Fig. 6(e)]. In Fig. 6(a), the injected power shows a relatively large difference because of the noise influence. However, the peak corresponds to the driving point, and the comparison between Figs. 6(a) and (e) shows fairly good matching at the periphery of the plate. Figures 6(b) and (c) show that the peak does not correspond to the driving point. Comparison between Figs. 5(d) and 6(d) shows that the difference is relatively small, because the cutoff wave number is low. The peak corresponds to the driving point; however, false local peaks are exhibited near the driving point and the injected power is not matched by the AI away from the driving point. Here 1923 Hz is the non-natural frequency, therefore the vibration mode is not clearly shown, and the influence of the noise inside the circ filter is serious, especially in the higher-order spatial derivative [cf. Figs. 6(b) and (c)]. And the lack of the high-wavenumber component induces the false local peaks near the driving point [cf. Fig. 6(d)]. Therefore, conventional methods cannot bring us the appropriate filtration in this critical situation. On the contrary, the proposed method can localize the driving point without any false local peaks [cf. Fig. 6(a)].

V. CONCLUSIONS

A new regularization method for measurement of SI using NAH is presented. Since the K-space filter is determined from the flexural wavelength by conventional methods, it is difficult to measure SI by NAH from the low-SNR pressure hologram with the conventional filter. Therefore, the SI has not been applied to detect the vibration source in the noisy field, because the SNR of the measured pressure hologram is

low. To overcome this situation, the Tikhonov regularization filter is modified for each order of derivative. The regularization parameter for each derivative order is determined by modified GCV method using the measured pressure. Therefore, the K-space filter is optimized for low-SNR measured pressure.

The effectiveness of the proposed method is demonstrated by experiments. For comparison, the K-space filters estimated by the conventional methods are used to measure the SI. The experimental results of the SI in a thin plate are as follows:

- (1) The circ function filter proposed by Morikawa¹⁵ can localize the driving point at the natural frequency; however, the region surrounding the driving point is contaminated by the amplification of noise.
- (2) The circ function filter cannot localize the driving point at the non-natural frequency, and many false local peaks are exhibited.
- (3) The band-pass filter proposed by Najede¹⁶ can localize the driving point whether the frequency is the natural frequency or not; however, the injected power is not matched by the AI away from the driver at the natural frequency, and false local peaks are exhibited at the non-natural frequency.
- (4) The influences of noise to the reconstructed result by the conventional filter (i.e., circ function filter and band pass filter) are serious at the non-natural frequency.
- (5) On the contrary, the proposed filter can localize the driving point without any false local peaks whether the frequency is the natural frequency or not, and the influence of the noise to the reconstructed result is relatively small.

As a result, the availability of the proposed method is confirmed. This method may thus be recommended to apply the detection of the vibration source in an actual noisy field.

Smart panels with velocity feedback control systems using triangularly shaped strain actuators

Paolo Gardonio and Stephen J. Elliott

Institute of Sound and Vibration Research, University of Southampton, Highfield, Southampton SO17 1BJ, United Kingdom

(Received 28 July 2004; revised 2 December 2004; accepted 25 December 2004)

In this paper we present a theoretical study on the active structural acoustic control of a new smart panel with sixteen triangularly shaped piezoelectric patch actuators, having their base edges evenly distributed along the perimeter of the panel, and velocity sensors positioned at the vertices opposite the base edges. The performance is assessed and contrasted with that of a conventional smart panel using a 4×4 array of square piezoelectric patch actuators evenly distributed over the surface of the panel with velocity sensors at their centers. For both systems the control effectiveness and stability of MIMO decentralized or SISO direct velocity feedback control architectures have been analyzed. The two control systems are arranged to generate active damping which reduces the response and sound radiation of the panel in the lightly damped and well separated low-frequency resonances. In particular the new control system can be seen as a set of sixteen “active wedges” which absorb energy from the incident flexural waves to the borders of the panel so that the panel could be considered anechoic. This study shows that the new arrangement with triangularly shaped actuators can achieve better control than the corresponding system using square actuators. © 2005 Acoustical Society of America. I. INTRODUCTION

In general, the low-frequency broadband sound transmission through a lightly damped and lightweight panel, such that its response is characterized by well separated resonances below the critical frequency, is controlled by the response of the panel itself at the resonance frequencies and by the radiation efficiencies of the resonant modes.¹ The sensitivity to the radiation efficiencies arises from both the acoustical excitation and sound radiation mechanisms.¹ In order to control low-frequency sound transmission through a panel it is therefore necessary to either move up its first few resonance frequencies by stiffening the panel or to apply damping treatments to the panel in such a way as to reduce its response at resonance frequencies.¹ Both types of treatments require substantial variations to the structure of the panel which have several drawbacks such as, for example, the change of geometry and weight of the partition and increase of costs. Alternatively, active control techniques could be used, the most attractive of which have the actuators and sensors integrated onto the partition itself in such a way as to create a smart panel for the implementation of active structural acoustic control (ASAC).^{2–5} The control system linking these actuators to these sensors increasingly uses a feedback rather than feed-forward arrangement, because of its ability to deal with broadband random or transient disturbances without an external reference signal.⁶

During the past decade a lot of research work has been carried out to develop ASAC systems to be embedded on thin partitions in order to form compact and possibly lightweight smart panels.^{2–5} Several configurations have been studied that could be grouped into two main families: first, single input single output (SISO) classic feedback control systems^{3,7} using collocated and dual^{8,9} distributed sensor-

actuator pairs which are arranged in such a way as to control radiation modes of panels^{2,10–12} and, second, SISO or multi-input multi-output (MIMO) modern feedback control systems^{3,7} where H_2 or H_∞ optimum state regulators are designed in a LQR/LQG framework, with a state observer based on radiation filters.^{13–15} The advantage of the classic approach is given by the possibility of implementing relatively simple direct feedback control loops that produce active damping⁷ and thus reduces the response of the panel at the low resonance frequencies without sound radiation spillover effects.¹⁶ However, several problems have been encountered in the development of truly collocated and dual^{8,9} distributed sensor-actuator pairs which would guarantee unconditionally stable feedback control loops.^{7,17–24} In contrast the modern approach uses much simpler arrays of sensors and actuators but rather complicated control systems with a state observer that inherently limits the control effectiveness as well as the robustness of the controller.^{3,20,24–37} In summary the development of SISO classic feedback control systems is held back by the difficulties encountered to develop collocated and dual distributed sensor-actuator pairs whose response functions have real part positive definite so that unconditionally stable direct feedback loops could be implemented.^{3,7} In contrast the development of SISO or MIMO modern feedback control systems is held back by the necessity of developing complicated state observers which should be robust to changes of the response of the panel due, for example, to variations of temperature, pressure loading, tensioning effects, etc.

In this context Petitjean and Legrain³⁸ have considered the possibility of simplifying the architecture of a MIMO feedback controller for a smart panel with a 5×3 array of closely located piezoelectric patch sensor-actuator pairs by

implementing decentralized feedback control loops with fixed control gains. In particular they compared the control effectiveness of the decentralized control system with that of a fully coupled MIMO feedback controller and found comparable control results for the two systems. Like a number of authors Elliott *et al.*³⁹ have shown that, provided the sensors and actuators are arranged in collocated and dual pairs, unconditionally stable decentralized feedback loops with fixed gains could be implemented. They have also shown that, if the control systems are arranged to implement active damping, for example with direct velocity feedback loops, then as the control gains are raised up to an optimal value as the response of the panel at resonance frequencies is damped down so that the low-frequency broadband sound transmission is monotonically reduced. References 40 to 42 present the development study of a smart panel with a 4×4 array of decentralized MIMO direct velocity control units which are formed by a square piezoelectric patch actuator with an accelerometer sensor at its center. With this arrangement quite good damping levels have been obtained in the low-frequency resonances of the panel, which have produced reductions of the averaged vibration of the panel between 5 and 8 dB for the third octave bands up to 1 kHz. However, the feedback control gains had to be limited to relatively low values since the decentralized control systems are only conditionally stable as the accelerometer sensor and piezoelectric actuator behaves as a collocated and dual pair only at low frequencies such that the bending wavelength is larger than the dimensions of the piezoelectric patch.⁴²

In this paper, we present a new type of smart panel with sixteen decentralized active damping control units which are composed of triangularly shaped piezoelectric patch actuators, with the base edges aligned along the borders of the panel, and accelerometer sensors placed at the vertices opposite to the base edges of the actuators. The sixteen control units are evenly spaced along the four edges of the panel so that they both look like and work like “active wedges.” The triangular shape of the actuator generates bending moments along the edges plus a transverse point force at the vertex opposite to the base edge⁴³ which results to be collocated and dual with the linear velocity measured by the accelerometer sensor. This makes the sensor actuator pair able to have better collocation and duality features than the one with the square piezoelectric patch actuator. As a result, larger control gains could be implemented in a direct velocity feedback loop which should then produce larger active damping.⁷ Thus, these control units can indeed be considered to be a sort of structural active wedges whose damping effect reduces reflections of incident flexural waves to the edges of the panel which could then be considered to be anechoic. In order to better highlight the control mechanisms and control effects of this type of smart panel with triangularly shaped piezoelectric actuators, the theoretical study presented in this paper contrasts its flexural response and sound radiation with those of a smart panel with a 4×4 array of MIMO-decentralized direct velocity feedback control units evenly distributed over the panel surface which are formed by a square piezoelectric patch actuator with an accelerometer sensor at its center. Also, the effectiveness of simpler control

FIG. 1. Physical arrangement considered in a simulation study, in which the vibration of a simply supported panel is excited by a plane acoustic wave on one side and radiates sound into an anechoic half space on the other side of the panel.

configurations is considered for both types of smart panels where the sum of the sixteen velocity outputs is feedback to the sixteen actuators via a fixed gain SISO controller. The sensor-actuator response functions are studied both in frequency domain and with the Nyquist plots in order to assess the stability of the MIMO-decentralized and SISO control configurations.

The paper is structured into four parts. In Sec. II we present the analytical model used to predict the response and sound transmission through the smart panel when it is excited by a plane acoustic wave. In Sec. III the implementation of MIMO-decentralized or SISO direct velocity feedback control loops is modeled and discussed. Finally in Secs. IV and V the main control features of the two smart panels are analyzed and contrasted with reference to MIMO decentralized and SISO feedback control architectures, respectively.

II. RESPONSE AND SOUND TRANSMISSION THROUGH THE SMART PANELS

The steady state flexural response and sound radiation of smart panels which, as shown in Fig. 1, are excited by a harmonic acoustic plane wave, will be used as a model problem to illustrate the effects of the two sensor-actuator arrangements and control architectures shown in Fig. 2. The first arrangement is made by a 4×4 array of square piezoelectric patch actuators with at the centers velocity sensors evenly distributed over the surface of the panel. The second arrangement is instead made by sixteen triangularly shaped piezoelectric patch actuators, with the base edges evenly distributed along the perimeter of the panel, and velocity sensors at the vertices opposite to the base edges. The panel is made of aluminum, with dimensions $l_{xp} \times l_{yp} = 278 \times 247$ mm and thickness $h_p = 1$ mm and it is assumed to be baffled and simply supported along the perimeter. The material and geometrical properties of the panel are summarized in Table I. The far-field sound radiation is determined by the time-averaged total sound power radiated by the panel while

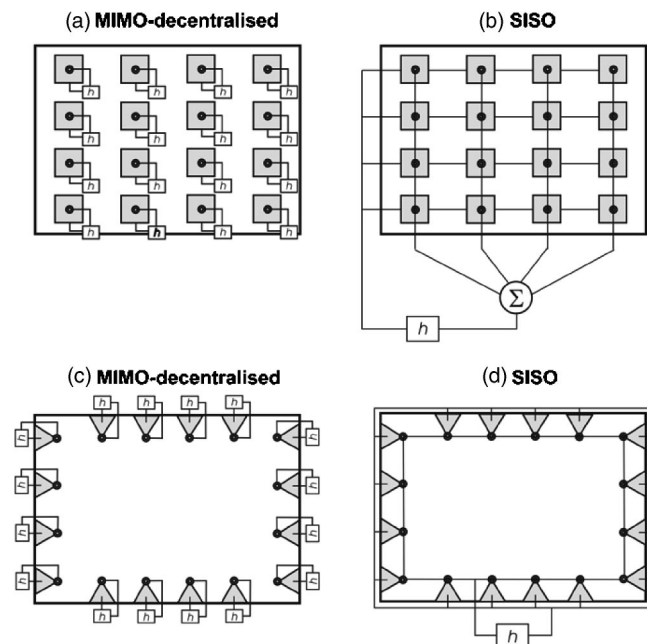

FIG. 2. Smart panels with a 4×4 grid of closely located ideal velocity sensors and square piezoelectric patch actuators or sixteen closely located ideal velocity sensors and triangular piezoelectric patch actuators with the base edges evenly aligned along the four edges of the panel which are arranged either in MIMO-decentralized (type a and c) or SISO (type b and d) direct feedback loops.

its time-averaged total kinetic energy is used to represent the near-field sound radiation which is determined by both strong and weakly radiating modes.¹⁶

The square piezoelectric patches, which have dimensions $a_x \times a_y = 25 \times 25$ mm and thickness $h_{\text{PZT}} = 0.2$ mm, are taken to be evenly distributed over the panel surface so that the distance between the centers of two adjacent patches is given by $d_{sx}, d_{sy} = l_{xp}/4, l_{yp}/4 = 69.5, 61.7$ mm and the distances of the centers of the external patches with the borders of the panel are given by $d_{sx}/2, d_{sy}/2 = 34.8, 30.9$ mm. The square piezoelectric patches, which have base and height dimensions $b, a = 40, 25$ mm and thickness $h_{\text{PZT}} = 0.2$ mm, are instead taken to be evenly distributed along the edges of the panel so that the distances between the centers of the base edges aligned along the $y = 0, l_{yp}$ borders of the panel are given by $d_{tx} = (l_{xp} - 2a)/5 = 45.6$ mm while the distances

TABLE I. Geometry and physical parameters for the panel.

Parameter	Value
Dimensions	$l_{xp} \times l_{yp} = 278 \times 247$ mm
Thickness	$h_p = 1$ mm
Mass density	$\rho_p = 2720$ Kg/m ³
Young's modulus	$E_p = 7 \times 10^{10}$ N/m ²
Poisson ratio	$\nu_p = 0.33$
Modal damping ratio	$\zeta_n = 0.02$

between the centers of the base edges aligned along the $x = 0, l_{xp}$ borders of the panel are given by $d_{ty} = (l_{yp} - 2a)/3 = 65.7$ mm. Also, the centers of the base edges of the outer patches aligned along the $y = 0, l_{yp}$ borders of the panel are located at a distance $d_{ty} + a = 70.6$ mm from the $x = 0, l_{xp}$ border while the centers of the base edges of the outer patches aligned along the $x = 0, l_{xp}$ borders of the panel are located at a distance $a = 25$ mm from the $y = 0, l_{yp}$ border. In this way, as shown in the two bottom schemes of Fig. 2, the vertices of the sixteen triangular patches define a rectangle of dimensions $(l_{xp} - 2a) \times (l_{yp} - 2a)$. The material and geometrical properties of the square and triangular piezoelectric, PZT (lead zirconate titanate), patches are summarized in Table II.

The steady state response of the panel has been derived assuming the incident acoustic plane wave to be harmonic with time dependence of the form $\text{Re}\{\exp(j\omega t)\}$ where ω is the circular frequency and $j = \sqrt{-1}$. The mechanical and electrical functions used in the model have therefore been taken to be the real part of counterclockwise rotating complex vectors, e.g., phasors, given in the form $v(\omega)e^{j\omega t}$ where $v(\omega)$ is the phasor at $t = 0$. A harmonic acoustic wave is assumed to excite the panel with azimuthal and elevation angles of $\phi = 45^\circ$ and $\theta = 45^\circ$ so that it excites all the structural modes of the panel. The sound pressure field $p_i(x, y, t)$ in the plane of the plate is therefore given by

$$p_i(x, y, t) = \text{Re}\{p_i(\omega)e^{j(\omega t - k_x x - k_y y)}\}, \quad (1)$$

where $p_i(\omega)$ is the phasor of the incident wave, $k_x = k_0 \sin(\theta)\cos(\phi)$ and $k_y = k_0 \sin(\theta)\sin(\phi)$ are the acoustic wave numbers in x - and y -directions where $k_0 = \omega/c_0$ and $c_0 = 343$ m/s are, respectively, the acoustic wave number and speed of sound in air.

TABLE II. Geometry and physical parameters for the piezoelectric, PZT (lead zirconate, titanate), patches.

Parameter	Value
Dimensions of the square patches	$a_x \times a_y = 25 \times 25$ mm
Base and height dimensions of the triangular patches	$b, a = 40, 25$ mm
Distances between the centers of two square patches	$d_{sx} = 69.5$ mm, $d_{sy} = 61.7$ mm
Distances between the centers of the base edges aligned either along the $y = 0, l_{yp}$ or $x = 0, l_{xp}$ borders of the panel	$d_{tx} = 45.6$ mm, $d_{ty} = 65.7$ mm
Thickness of the square and triangular patches	$h_{\text{PZT}} = 0.2$ mm
Density	$\rho_{\text{PZT}} = 7600$ kg/m ³
Young's modulus	$E_{\text{PZT}} = 6.3 \times 10^{10}$ N/m ²
Poisson ratio	$\nu_{\text{PZT}} = 0.29$
PZT strain/charge constants	$d_{31}^o = 166 \times 10^{-12}$ m/V $d_{32}^o = 166 \times 10^{-12}$ m/V $d_{36}^o = 0$

Both the time-averaged total kinetic energy and time-averaged total sound power radiated have been derived by dividing the panel into a grid of quadrilateral elements whose dimensions have been taken to be $l_{xe} = l_{xp}/(4N_1)$ and $l_{ye} = l_{yp}/(4N_2)$, where N_1 and N_2 are the higher modal orders used in the calculations. The phasors of the complex transverse velocities, $\dot{w}_{er}(\omega)$, at the centers of these R elements have been grouped into the following column vector:

$$\mathbf{w}_e(\omega) \equiv \begin{Bmatrix} \dot{w}_{e1}(\omega) \\ \dot{w}_{e2}(\omega) \\ \vdots \\ \dot{w}_{eR}(\omega) \end{Bmatrix}. \quad (2)$$

The flexural vibration of the smart panel under study is given by the superposition of the acoustic primary excitation generated by the incident plane wave and the structural secondary excitations generated by the control transducers bonded on the panel. Thus, assuming the system is linear, and assuming the radiated pressure has no effect on the panel vibration, then the vector with the phasors of the velocities at the centers of the elements, $\mathbf{w}_e(\omega)$, can be derived with the following matrix relation:

$$\mathbf{w}_e(\omega) = \mathbf{Y}_{ep}(\omega) p_i(\omega) + \mathbf{Y}_{ec}(\omega) \mathbf{v}_c(\omega), \quad (3)$$

where $\mathbf{v}_c(\omega)$ is a vector with the phasors of the complex input voltage signals, $v_{cs}(\omega)$, to the S control piezoelectric transducers:

$$\mathbf{v}_c(\omega) \equiv \begin{Bmatrix} v_{c1}(\omega) \\ v_{c2}(\omega) \\ \vdots \\ v_{cS}(\omega) \end{Bmatrix}. \quad (4)$$

The elements in the two matrices of Eq. (3) have been derived with a finite modal expansion so that⁴⁴

$$Y_{ep}^{r,1}(\omega) = j\omega \sum_{n=1}^N \frac{\psi_n(x_r, y_r) F_{np}(\omega)}{\rho_p h_p l_{xp} l_{yp} (\omega_n^2 - \omega^2 + j2\zeta_n \omega \omega_n)}, \quad (5)$$

$$Y_{ec}^{r,s}(\omega) = j\omega \sum_{n=1}^N \frac{\psi_n(x_r, y_r) F_{nc,s}(\omega)}{\rho_p h_p l_{xp} l_{yp} (\omega_n^2 - \omega^2 + j2\zeta_n \omega \omega_n)}, \quad (6)$$

where ρ_p and h_p are the density and the thickness of the smart panel ζ_n is the modal damping ratio, which was taken to be 0.01 for all modes in these simulations, ω_n and $\psi_n(x, y)$ are, respectively, the n -th natural frequency and natural mode, which for a simply supported panel are given by

$$\omega_n = \sqrt{\frac{D_p}{\rho_p h_p} \left[\left(\frac{n_1 \pi}{l_{xp}} \right)^2 + \left(\frac{n_2 \pi}{l_{yp}} \right)^2 \right]}, \quad (7)$$

$$\psi_n(x, y) = 2 \sin\left(\frac{n_1 \pi x}{l_{xp}}\right) \sin\left(\frac{n_2 \pi y}{l_{yp}}\right), \quad (8)$$

where $D_p = E_p h_p^3 / 12(1 - \nu_p^2)$ is the bending stiffness of the smart panel, with E_p and ν_p the Young's modulus of elasticity and Poisson's ratio, and n_1, n_2 are the two modal integers for the n -th mode. Finally $F_{np}(\omega)$ and $F_{nc,s}(\omega)$ are the two modal excitation terms which are due, respectively, to the primary acoustic excitation generated by the incident plane

wave and to the secondary flexural excitations generated by either the s -th square or s -th triangular piezoelectric patch control actuators bonded on the panel. The modal primary excitation terms, $F_{np}(\omega)$, are obtained by integrating the pressure field generated over the panel surface, that is⁴⁵

$$F_{np}(\omega) = p_i(\omega) \int_0^{l_{xp}} \int_0^{l_{yp}} \psi_n(x, y) e^{-j(k_x x + k_y y)} dx dy \\ = 4 p_i(\omega) I_{n1} I_{n2} l_{xp} l_{yp}, \quad (9)$$

where, if $n_1 \pi \neq \pm \sin \theta \cos \phi (\omega l_{xp} / c_0)$ and $n_2 \pi \neq \pm \sin \theta \sin \phi (\omega l_{yp} / c_0)$,

$$I_{n1} = \frac{n_1 \pi [1 - (-1)^{n_1} e^{-j \sin \theta \cos \phi (\omega l_{xp} / c_0)}]}{[n_1 \pi]^2 - [\sin \theta \cos \phi (\omega l_{xp} / c_0)]^2} \quad (10a)$$

and

$$I_{n2} = \frac{n_2 \pi [1 - (-1)^{n_2} e^{-j \sin \theta \sin \phi (\omega l_{yp} / c_0)}]}{[n_2 \pi]^2 - [\sin \theta \sin \phi (\omega l_{yp} / c_0)]^2}; \quad (10b)$$

and, if $n_1 \pi = \pm \sin \theta \cos \phi (\omega l_{xp} / c_0)$ and $n_2 \pi = \pm \sin \theta \sin \phi (\omega l_{yp} / c_0)$,

$$I_{n1} = (j/2) \operatorname{sgn}(\sin \theta \cos \phi) \quad (11a)$$

and

$$I_{n2} = (j/2) \operatorname{sgn}(\sin \theta \sin \phi). \quad (11b)$$

The modal secondary excitation terms, $F_{nc,s}(\omega)$, are derived by integrating the bending excitation fields generated by the control actuators over the panel surface. According to Ref. 46 and as shown in Fig. 3(a), if the principal axes x', y', z' of the piezoelectric material are aligned along the x, y, z axes of the panel, the s -th square piezoelectric patch actuator produces moment excitations,

$$m_{xs}(x_{es1,3}, y_{es1,3}, t) = \pm \frac{h_s}{2} e_{32}^0 v_{cs}(t), \quad (12a)$$

$$m_{ys}(x_{es2,4}, y_{es2,4}, t) = \pm \frac{h_s}{2} e_{31}^0 v_{cs}(t), \quad (12b)$$

respectively along the horizontal edges 1, 3, with coordinates $x_{cs} - a_x/2 \leq x_{es1,3} \leq x_{cs} + a_x/2$ and $y_{es1,3} = y_{cs} \mp a_y/2$, and along the vertical edges 2, 4, with coordinates $x_{es2,4} = x_{cs} \pm a_x/2$ and $y_{cs} - a_y/2 \leq y_{es2,4} \leq y_{cs} + a_y/2$. The indices 1 to 4 indicate the four edges in anticlockwise order starting from the bottom horizontal edge and, as given in Table II, a_x, a_y are the dimensions of the patches while x_{cs}, y_{cs} are the center coordinates of the s -th patch. Also, as shown in Fig. 3(a), point forces,

$$f_z(x_{vs2,4}, y_{vs2,4}, t) = -f_z(x_{vs1,3}, y_{vs1,3}, t) = \frac{h_s}{2} e_{36}^0 v_{cs}(t), \quad (12c)$$

are exerted at the four vertices of coordinates $(x_{vs1,3}, y_{vs1,3}) = (x_{cs} \mp a_x/2, y_{cs} \mp a_y/2)$, and $(x_{vs2,4}, y_{vs2,4}) = (x_{cs} \pm a_x/2, y_{cs} \mp a_y/2)$ of each patch. In Eqs. (12a)–(12c), h_s is the total thickness of the panel and piezoelectric patch, that is $h_s = h_p + h_{pZT}$. The piezoelectric stress/charge parameters, e_{31}^0, e_{32}^0 and e_{36}^0 , are derived from the following relation:⁴⁶

FIG. 3. Panels with square (top) or triangular (bottom) piezoelectric patches.

$$\begin{Bmatrix} e_{31}^0 \\ e_{32}^0 \\ e_{36}^0 \end{Bmatrix} = \begin{bmatrix} \frac{E_{PZT}}{(1-\nu_{PZT}^2)} & \frac{\nu_{PZT}E_{PZT}}{(1-\nu_{PZT}^2)} & 0 \\ \frac{\nu_{PZT}E_{PZT}}{(1-\nu_{PZT}^2)} & \frac{E_{PZT}}{(1-\nu_{PZT}^2)} & 0 \\ 0 & 0 & \frac{E_{PZT}}{2(1+\nu_{PZT})} \end{bmatrix} \times \begin{Bmatrix} d_{31}^0 \\ d_{32}^0 \\ d_{36}^0 \end{Bmatrix}, \quad (13)$$

where the Young's modulus of elasticity, E_{PZT} , the Poisson's ratio, ν_{PZT} , and the piezoelectric strain/charge, d_{31}^0 , d_{32}^0 and d_{36}^0 , parameters of the piezoelectric PZT (lead zirconate, titanate) material considered in this paper are given in Table II. Since the piezoelectric material considered in this paper has $e_{36}^0=0$, then there are no force excitations at the four vertices. Therefore the secondary modal excitation terms for square piezoelectric patch actuators, $F_{nc,s}(\omega)$, are given by the sum of the integrals along the four edges of the piezoelectric patch of the first derivatives of the panel natural modes in directions orthogonal to the edges, pointing outside the square surface, multiplied by the appropriate excitation coefficients given in Eqs. (12a), (12b) that is,

$$\begin{aligned} F_{nc,s}(\omega) = & \frac{h_s}{2} e_{32}^0 \left\{ + \int_{x_{vs1}}^{x_{vs2}} \frac{\partial \psi_n(x, y_{es1})}{\partial y} dx \right. \\ & - \left. \int_{x_{vs3}}^{x_{vs4}} \frac{\partial \psi_n(x, y_{vs3})}{\partial y} dx \right\} \\ & + \frac{h_s}{2} e_{31}^0 \left\{ \int_{y_{vs1}}^{y_{vs4}} \frac{\partial \psi_n(x_{es4}, y)}{\partial x} dy \right. \\ & - \left. \int_{y_{vs2}}^{y_{vs3}} \frac{\partial \psi_n(x_{es2}, y)}{\partial x} dy \right\}. \quad (14) \end{aligned}$$

The bending excitation field generated by a triangular piezoelectric patch has been derived in Ref. 43. Considering the triangular patches shown in Fig. 3(b), which are bonded in such a way as their base edges, a , are aligned with either the x - or y -borders of the panel and assuming that the principal axes x', y', z' of the piezoelectric material are aligned in such a way as x' and y' are parallel, respectively, to the height a and base b of the triangular patches, then the s -th triangular piezoelectric patch actuator produce moment excitations along the base edge of amplitude,

$$m_{bs}(x_{bs}, y_{bs}, t) = \frac{h_s}{2} e_{31}^0 v_{cs}(t), \quad (15a)$$

and moment excitations along the two lateral edges of amplitude,

$$m_{ls1,2}(x_{ls1,2}, y_{ls1,2}, t) = \frac{h_s}{2} (m^2 e_{31}^0 + e_{32}^0) v_{cs}(t). \quad (15b)$$

The positions of the triangular patches have been defined with reference to the middle points of their base edges x_{ms} and y_{ms} . Thus the coordinates of the base edge of the s -th triangular piezoelectric patch actuator are either $x_{ms} - b/2 \leq x_{bs} \leq x_{ms} + b/2$, $y_{bs} = 0, l_{yp}$ or $x_{bs} = 0, l_{xp}$, $y_{ms} - b/2 \leq y_{bs} \leq y_{ms} + b/2$ depending whether the base is aligned along the $y = 0, l_{yp}$ or $x = 0, l_{xp}$ borders of the panel. Also, the coordinates of the lateral edges of the s -th triangular piezoelectric patch actuator with the base aligned along the $y = 0, l_{yp}$ borders of the panel are, respectively, $y_{ls1,2} = \pm m[x_{ls1,2} - (x_{ms} \mp b/2)]$ and $y_{ls1,2} = \mp m[x_{ls1,2} - (x_{ms} \mp b/2)]$ with $x_{ms} - b/2 \leq x_{ls1} \leq x_{ms}$ and $x_{ms} \leq x_{ls2} \leq x_{ms} + b/2$. Finally the coordinates of the lateral edges of the s -th triangular piezoelectric patch actuator with the base aligned along the $x = 0, l_{xp}$ borders of the panel are, respectively, $x_{ls1,2} = \pm m[y_{ls1,2} - (y_{ms} \mp b/2)]$ and $x_{ls1,2} = \mp m[y_{ls1,2} - (y_{ms} \mp b/2)]$ with $y_{ms} - b/2 \leq y_{ls1} \leq y_{ms}$ and $y_{ms} \leq y_{ls2} \leq y_{ms} + b/2$. As listed in Table II, b, a are, respectively, the base and high of the triangular patch and $m = b/2a$ is the slope of the lateral edges. Finally as found for the square piezoelectric patches $h_s = h_p + h_{PZT}$. Also three point forces are generated at the vertices of the s -th triangular piezoelectric patch actuator,

$$f_z(x_{vs1,2}, y_{vs1,2}, t) = 2m \frac{h_s}{2} e_{31}^0 v_{cs}(t), \quad (15c)$$

$$f_z(x_{vs3}, y_{vs3}, t) = -4m \frac{h_s}{2} e_{31}^0 v_{cs}(t), \quad (15d)$$

where the vertices of the s -th triangular piezoelectric patch actuators with the base aligned along the $y=0, l_{yp}$ borders of the panel are, respectively, $x_{vs1,2}=x_{ms} \mp b/2$, $y_{vs1,2}=0, l_y$ and $x_{vs3}=x_{ms}$, $y_{vs3}=a, (l_y - a)$ while the vertices of the s -th triangular piezoelectric patch actuators with the base aligned along the $x=0, l_{xp}$ borders of the panel are, respectively, $x_{vs1,2}=0, l_x$, $y_{vs1,2}=y_{ms} \mp b/2$ and $x_{vs3}=a, (l_x - a)$, $y_{vs3}=y_{ms}$. In summary the secondary modal excitation terms for triangularly shaped piezoelectric patch actuators with the base edge aligned along the perimeter of the panel, $F_{nc,s}(\omega)$, are given by the sum of the integrals along the three edges of the piezoelectric patch of the first derivatives of the natural modes in directions orthogonal to the edges, pointing outside the triangular surface, plus the amplitudes of the modes at the tip vertices multiplied by the appropriate excitation coefficients given, respectively, in Eqs. (15a), (15b), (15d), that is,

$$F_{nc,s}(\omega) = \frac{h_s}{2} (m^2 e_{31}^0 + e_{32}^0) \left\{ \int_{v_{s1}}^{v_{s3}} \frac{\partial \psi_n(x,y)}{\partial \mathbf{n}_{ls1}} dl_{s1} + \int_{v_{s2}}^{v_{s3}} \frac{\partial \psi_n(x,y)}{\partial \mathbf{n}_{ls2}} dl_{s2} \right\} + \frac{h_s}{2} e_{31}^0 \int_{v_{s1}}^{v_{s2}} \frac{\partial \psi_n(x,y)}{\partial \mathbf{n}_{bs}} db_s - 4 \frac{h_s}{2} m e_{31}^0 \psi_n(x_{sv3}, y_{sv3}), \quad (16)$$

where $v_{sj}=(x_{vsj}, y_{vsj})$ indicates the coordinates of the vertices of the triangular patch as given above and $\mathbf{n}_{ls1}, \mathbf{n}_{ls2}, \mathbf{n}_{bs}$ are the normal unit vectors to the lateral and base edges pointing outside the triangular surface of the actuator. Equation (16) does not account for the two forces acting at the base vertices of the triangular patches because the panel is simply supported and therefore does not allow transverse excitations along its perimeter.

The time-averaged total kinetic energy of the panel is given by

$$E(\omega) = \frac{\rho_p h_p}{4} \int_0^{l_{xp}} \int_0^{l_{yp}} |\dot{w}(x,y,\omega)|^2 dx dy, \quad (17)$$

where $\dot{w}(x,y,\omega)$ is the phasor of the transverse velocity over the panel surface. This expression can be approximated by the summation of the kinetic energies of each element into which the panel has been subdivided so that

$$E(\omega) = \frac{M_e}{4} \mathbf{w}_e^H(\omega) \mathbf{w}_e(\omega), \quad (18)$$

where $M_e = \rho_p h_p l_{xe} l_{ye}$ is the mass of each element and H denotes the Hermitian transpose. The time-averaged total sound power radiation by a baffled panel can be derived by integrating the product of the phasor of the nearfield sound pressure, $p_0(x,y,\omega)$, on the radiating surface and the phasor of the transverse velocity of the panel, $\dot{w}(x,y,\omega)$, so that

$$W_r(\omega) = \frac{1}{2} \int_0^{l_{xp}} \int_0^{l_{yp}} \text{Re}[\dot{w}(x,y,\omega)^* p_0(x,y,\omega)] dx dy, \quad (19)$$

where $*$ denotes the complex conjugate. For the baffled flat plate considered in this paper, the acoustic pressure $p_0(x,y,\omega)$ can be written in terms of the surface velocity using the Rayleigh integral¹

$$p_0(x,y,\omega) = \frac{j\omega\rho_0}{2\pi} \int_0^{l_{xp}} \int_0^{l_{yp}} \dot{w}(x',y',\omega) \frac{e^{-jk_0 r}}{r} dx' dy', \quad (20)$$

where $r = \sqrt{(x-x')^2 + (y-y')^2}$ is the distance between the point (x,y) where the sound pressure is estimated and vibration velocity positions on the panel (x',y') and $\rho_0 = 1.21 \text{ kg/m}^3$ is the density of air. Substituting Eq. (20) in (19), the time average total sound radiation is found to be given by a quadruple integral:

$$W_r(\omega) = \frac{\omega\rho_0}{4\pi} \int_0^{l_{xp}} \int_0^{l_{yp}} \int_0^{l_{xp}} \int_0^{l_{yp}} \dot{w}(x,y,\omega)^* \dot{w}(x',y',\omega) \times \frac{\sin k_0 r}{r} dx' dy' dx dy. \quad (21)$$

The quadruple integral in Eq. (21) can also be approximated by summing the radiation contributions of all the elements into which the panel has been subdivided, so that the time-averaged total sound power radiation can be expressed as¹⁶

$$W_r(\omega) = \frac{A_e}{2} \text{Re}[\mathbf{w}_e^H(\omega) \mathbf{p}_e(\omega)], \quad (22)$$

where $A_e = l_{xe} l_{ye}$ is the area of each element and $\mathbf{p}_e(\omega)$ is the vector with the phasors of the sound pressure terms in front of the panel at the center positions of the grid of elements:

$$\mathbf{p}_e(\omega) \equiv \begin{Bmatrix} p_{e1}(\omega) \\ p_{e2}(\omega) \\ \vdots \\ p_{eR}(\omega) \end{Bmatrix}. \quad (23)$$

Following Ref. 16, Eq. (12) can also be written as

$$W_r(\omega) = \frac{A_e}{2} \text{Re}[\mathbf{w}_e^H(\omega) \mathbf{Z}(\omega) \mathbf{w}_e(\omega)] = \mathbf{w}_e^H(\omega) \mathbf{R}(\omega) \mathbf{w}_e(\omega), \quad (24)$$

where $\mathbf{Z}(\omega)$ is the matrix with the point and transfer acoustic impedance terms over the grid of points into which the panel has subdivided:¹² $Z_{ij}(\omega) = (j\omega\rho_0 A_e / 2\pi r_{ij}) e^{-jk_0 r_{ij}}$, with r_{ij} the distance between the centers of the i -th and j -th elements. The matrix \mathbf{R} is defined as the radiation matrix which is given by¹²

$$\mathbf{R}(\omega) = \frac{A_e}{2} \text{Re}[\mathbf{Z}(\omega)] = \frac{\omega^2 \rho_0 A_e^2}{4 \pi c_0} \begin{bmatrix} 1 & \frac{\sin(k_0 r_{12})}{k_0 r_{12}} & \dots & \frac{\sin(k_0 r_{1R})}{k_0 r_{1R}} \\ \frac{\sin(k_0 r_{21})}{k_0 r_{21}} & 1 & & \\ \dots & \dots & \dots & \dots \\ \frac{\sin(k_0 r_{R1})}{k_0 r_{R1}} & & & 1 \end{bmatrix}. \quad (25)$$

Since the primary excitation is an acoustic wave, the ratio of the time-averaged total sound power radiated, $W_r(\omega)$, to the time-averaged incident sound power, $W_i(\omega)$, which is termed the sound transmission ratio;

$$T(\omega) = W_r(\omega)/W_i(\omega), \quad (26)$$

has been used to describe the sound transmission phenomenon. The time-averaged incident sound power due to the plane acoustic wave is given by⁴⁵

$$W_i(\omega) = |p_i(\omega)|^2 l_{xp} l_{yp} \cos(\theta) / 2 \rho_0 c_0. \quad (27)$$

III. DIRECT VELOCITY FEEDBACK CONTROL

The phasors of the output error signal(s), $i_{ce}(\omega)$, from the E velocity error sensors can also be derived with a matrix relation of the type

$$\mathbf{i}_c(\omega) \equiv \mathbf{Y}_{cp}(\omega) p_i(\omega) + \mathbf{Y}_{cc}(\omega) \mathbf{v}_c(\omega), \quad (28)$$

where $\mathbf{i}_c(\omega)$ is the column vector with the phasors of the error sensor signal(s):

$$\mathbf{i}_c(\omega) \equiv \begin{Bmatrix} i_{c1}(\omega) \\ i_{c2}(\omega) \\ \vdots \\ i_{cE}(\omega) \end{Bmatrix}, \quad (29)$$

and $\mathbf{v}_c(\omega)$ is defined in (4). Assuming the velocity sensors used in the smart panels of Fig. 2 to be ideal transducers that measure the transverse velocity at the centers of the square patches or at the tips of the triangular patches, then the elements of the two matrices in Eq. (28) could be derived with a finite modal expansion considering the modal amplitude at the detection points $(x_e, y_e) = (x_{cs}, y_{cs})$ or, $(x_e, y_e) = (x_{vs3}, y_{vs3})$, respectively, for the square and triangular actuators, so that⁴⁴

$$Y_{cp}^r(\omega) = j\omega \sum_{n=1}^N \frac{\psi_n(x_s, y_s) F_{np}(\omega)}{\rho_p h_p l_{xp} l_{yp} (\omega_n^2 - \omega^2 + j2\zeta_n \omega \omega_n)}, \quad (30)$$

$$Y_{cc}^{r,s}(\omega) = j\omega \sum_{n=1}^N \frac{\psi_n(x_s, y_s) F_{nc,s}(\omega)}{\rho_p h_p l_{xp} l_{yp} (\omega_n^2 - \omega^2 + j2\zeta_n \omega \omega_n)}. \quad (31)$$

For the two panels types b and d in Fig. 2, where in order to implement a SISO velocity feedback loop the sensors outputs are summed up and the same control signal is feed to the control actuators, the total current output is still derived with Eq. (28) where the two mobility matrices \mathbf{Y}_{cp} and \mathbf{Y}_{cc} are pre-multiplied by a $1 \times E$ vector \mathbf{e} of unit terms and the matrix \mathbf{Y}_{cc} is also post-multiplied by an $S \times 1$ vector \mathbf{s} of unit

terms so that they become two scalar terms Y_{cp} and Y_{cc} .

The general block diagram of a multi-channel velocity feedback control system is shown in Fig. 4. If an equal number of actuators and velocity sensors is used, the matrix of plant responses, $\mathbf{Y}_{cc}(\omega)$, is square and the matrix of feedback control filters, $\mathbf{H}(j\omega)$, is also square. Provided the control system is stable, the vector with the phasors of the sensor(s) current output(s), $\mathbf{i}_c(\omega)$, is related to the phasor of the incident plane acoustic wave, $p_i(\omega)$, by the expression

$$\mathbf{i}_c(\omega) = [\mathbf{I} + \mathbf{Y}_{cc}(\omega) \mathbf{H}(\omega)]^{-1} \mathbf{Y}_{cp}(\omega) p_i(\omega). \quad (32)$$

Also the vector of control inputs to the actuators, $\mathbf{v}_c(\omega)$, is given by

$$\mathbf{v}_c(\omega) = -\mathbf{H}(\omega) [\mathbf{I} + \mathbf{Y}_{cc}(\omega) \mathbf{H}(\omega)]^{-1} \mathbf{Y}_{cp}(\omega) p_i(j\omega). \quad (33)$$

For single input single output control (SISO) the vectors and matrices reduce to scalars and thus the stability of the feedback control loop could be assessed using the classic feedback control theory.^{3,7,47} In particular, Balas⁹ has shown that, if the sensor-actuator pair is collocated and dual,⁸ then the SISO direct velocity feedback control loop is unconditionally stable. Indeed in this case the sensor-actuator frequency response function is real positive definite⁷ so that its Nyquist plot occupies the right hand side quadrants as ω varies from $-\infty$ to $+\infty$ and thus the Nyquist instability point $(-1 j0)$ is never encircled whatever is the control gain.

For multi-input multi-output (MIMO) decentralized control, $\mathbf{Y}_{cc}(\omega)$ is a fully populated matrix of input and transfer responses between the actuators and sensors on the panel and $\mathbf{H}(\omega)$ is a diagonal matrix which, for direct velocity feedback control, is assumed to have equal fixed gains so that $\mathbf{H}(\omega) = h \mathbf{I}$, where h is the feedback gain. In this case the stability

FIG. 4. Multichannel feedback control system, which for a passive plant response, $\mathbf{Y}_{cc}(j\omega)$, and a passive controller $\mathbf{H}(j\omega)$, is unconditionally stable.

FIG. 5. Total kinetic energy (left) and sound transmission ratio (right) of the panel excited by a plane acoustic wave with no control (solid line) and with a 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (type a in Fig. 3) MIMO decentralized feedback controllers with feedback gains of 10 (dashed line), 10^2 (dotted line), 10^3 (dash-dotted line) and 10^4 (faint line).

of the MIMO decentralized control system can be determined by examining whether the locus of the determinant of $[\mathbf{I} + \mathbf{Y}_{cc}(j\omega)\mathbf{H}(j\omega)]$ encloses the origin^{48,49} as ω varies from $-\infty$ to $+\infty$. Alternatively the fact that the determinant of a matrix is the product of its eigenvalues can be used to derive a series of polar plots, each of which are analogous to the single channel Nyquist criteria. As found for the SISO control case, if collocated and compatible transducers are used,⁸ then the real part of $\mathbf{Y}_{cc}(\omega)$ must be positive definite and $\mathbf{Y}_{cc}(\omega)$ can be described as being passive. If $\mathbf{H}(\omega)$ is also passive, e.g., when it is equal to $h\mathbf{I}$ and $h > 0$, then the control system is unconditionally stable.^{39,48,49}

When the SISO or MIMO decentralized velocity feedback control systems are implemented, the total kinetic energy and sound transmission ratio given in Eqs. (18) and (24) can be derived after combining Eq. (3) with Eq. (33) so that

$$\mathbf{w}_e(\omega) = \mathbf{Y}_{ep}(\omega)p_i(\omega) - \mathbf{Y}_{ec}(\omega)\mathbf{H}(\omega)[\mathbf{I} + \mathbf{Y}_{cc}(\omega)\mathbf{H}(\omega)]^{-1} \times \mathbf{Y}_{cp}(\omega)p_i(j\omega). \quad (34)$$

It is important to underline that in the following sections the stability properties of the MIMO and SISO control systems in Fig. 2 will be discussed only at a qualitative level. Therefore the control effectiveness of the studied control systems are derived without taking into account whether it would be possible or not to implement the necessary gains without generating instabilities in the control loops.

IV. DECENTRALIZED MIMO DIRECT VELOCITY FEEDBACK CONTROL

In this section the control effectiveness of the smart panels with sixteen decentralized MIMO control units type (a) and type (c) in Fig. 2, which have either sixteen square piezoelectric patch actuators or sixteen triangular piezoelectric patch actuators, is investigated. The stability of the two decentralized control systems is also analyzed to some extent by considering Bode and Nyquist plots of the sensor-actuator frequency response function of one of the sixteen decentralized control systems in the two smart panels. Although the

stability of MIMO control systems should be assessed with reference to the locus of the determinant of $[\mathbf{I} + \mathbf{Y}_{cc}(j\omega)\mathbf{H}(j\omega)]$, for decentralized control, the stability of each control unit could also be evaluated independently using the classic feedback control theory^{3,7,47} which provides an indication of whether the decentralized MIMO control system is to be only conditionally stable. Moreover, if the smart panel is sufficiently damped and the control units are well separated from each others, then an indication about the gain or phase margins for each individual controller could also be derived.

A. Control effectiveness

The two plots in Fig. 5 show, respectively, the total kinetic energy and the sound transmission ratio of the smart panel with the 4×4 array of square piezoelectric patch actuators with the center velocity sensors' MIMO decentralized control system. The solid line on the left hand side plot for the total kinetic energy highlights the typical response of a panel which is characterized by a series of resonances whose amplitudes gradually roll off as the frequency rises. In particular the peaks of the first few resonances are relatively high and sharp because of the low damping effects at lower frequencies. The solid line on the right hand side plot for the sound transmission ratio shows a similar behavior, although there are almost no peaks for the resonances due to the even-even or even-odd natural modes of the panel which have relatively low sound radiation efficiency.¹

The dashed and dotted lines in the two plots of Fig. 5 show that as the gains of the sixteen control systems are raised the resonance peaks are flattened down. This is due to the active damping effect⁵⁰ generated by the sixteen DVFB control systems that indeed increase the overall damping of the lower-frequency resonant modes of the smart panel.^{39,40} However when relatively higher control gains are implemented this trend is inverted and, as shown by the dash-dotted and faint lines in the two plots of Fig. 5, the total kinetic energy and the sound transmission ratio are once more characterized by a new set of low-frequency reso-

FIG. 6. Normalized total kinetic energy (left) and sound transmission ratio (right), integrated between 0 Hz and 1 kHz, plotted against the gain in the MIMO decentralized velocity feedback controllers, h , for the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (solid line, type a in Fig. 2) and the 16 closely located velocity sensors and triangular piezoelectric patches actuators (faint line, type c in Fig. 2).

nances whose amplitudes are similar, if not higher, than those of the panel with no control. This is a typical control spillover phenomenon where, as discussed in Ref. 51, the large control gains produces a pinning effect at the control positions so that the response of the smart panel is rearranged into that of a lightly damped panel which is pinned at the sixteen control positions.

This type of behavior is summarized by the solid lines in the two plots of Fig. 6 which show how the normalized (normalized to the total kinetic energy when there is no control) total kinetic energy and normalized (normalized to the sound transmission ratio when there is no control) sound transmission ratio, integrated from 0 Hz to 1 kHz, vary with the feedback gain. Indeed both plots indicate that as the control gains are raised from zero as the frequency-averaged response and sound radiation of the smart panel monotonically falls down and reductions of the normalized total kinetic energy and normalized sound transmission ratio, respectively, of 17 dB and 9 dB could be achieved. If the control

gains are pushed farther up then, because of the pinning effect described above, the response of the smart panel is brought back to the levels with no control while its sound radiation is even increased by about 6 dB than in the case of no control. This is due to the fact that the new resonant modes of the smart panel generated by the pinning effects at the sixteen control positions have relatively higher sound radiation efficiency than the lower order modes of the unconstrained simply supported panel.¹

The two plots in Fig. 7 show the total kinetic energy and the sound transmission ratio of the smart panel with sixteen triangularly shaped piezoelectric patch actuators with velocity sensors at the vertices opposite to the base edges MIMO decentralized control system. From a qualitative point of view these two plots indicate that the sixteen control units with triangular actuators arranged along the perimeter of the panel produces similar effects than the sixteen control systems with square actuators distributed over the surface of the panel. The most important difference is found when rela-

FIG. 7. Total kinetic energy (left) and sound transmission ratio (right) of the panel excited by a plane acoustic wave with no control (solid line) and with 16 closely located velocity sensors and 16 triangular piezoelectric patches actuators (type c in Fig. 2) MIMO decentralized feedback controllers with feedback gains of 10 (dashed line), 10^2 (dotted line), 10^3 (dash-dotted line) and 10^4 (faint line).

FIG. 8. Deflection shapes of the panel at the first six resonance frequencies with no control.

tively high control gains are implemented in which case the resonances of the new modes of the smart panel, which are generated by the pinning effect of the triangular actuators scattered along the perimeter of the panel, occur at relatively higher frequencies than those due to the pinning effect of the square actuators distributed over the surface of the panel.

Moving to a quantitative analysis the faint lines of the two plots in Fig. 6 indicates that the sixteen control systems with triangular actuators evenly distributed along the perimeter of the smart panel generates slightly larger control effects than those due to the square actuators evenly distributed over the surface of the smart panel. In fact the maximum reduction of the normalized total kinetic energy is increased from 17 dB to 19 dB while the maximum reduction of the normalized sound transmission ratio is increased from 9 dB to 11 dB. As for the smart panel with square actuators evenly distributed over the surface of the smart panel, when relatively large control gains are implemented, the pinning effects at the vertices of the triangular actuators generate a new set of lightly damped resonant modes, which, however, still produce a reduction of about 5 dB of the normalized kinetic energy since in this case the vibrating surface of the panel is reduced to virtual edges defined by the control positions at the tips of the triangular actuators arranged along the edges of the panel. The frequency-averaged sound radiation of the panel is instead brought back to the case with no control, probably because the reduction of the response of the smart panel is balanced by the increased radiation efficiencies of the new resonant modes generated by the pinning effects along the perimeter of the smart panel.

In order to analyze in detail the different behaviors of the two smart panels, the deflections shapes of the panels in correspondence to the first six resonances, which as shown in Fig. 8 are closely linked to the first four natural modes of the panel, have been considered. Figures 9 and 10 show how these six deflection shapes varies when either the optimal control gains, that give the best control effects, or when very

large control gains are implemented in the smart panels with either the sixteen decentralized control systems made by square actuators (left hand side plots) or the sixteen decentralized control systems made by triangular actuators (right hand side plots). Since the deflection shapes occur over a wide range of amplitudes, the plots in Figs. 8 to 10 have been normalized to have the same maximum deflections.

Comparing the two plots in Fig. 9 with that of Fig. 8, it is found that, when the optimal control gains are implemented, then the response of the panel at the first six resonance frequencies is generally modified in such a way that the deflection shapes of the smart panel are not anymore controlled by the co-respective natural modes of the panel. This confirms the active damping action which indeed tends to reduce the contribution of the resonant modes so that the residual response is controlled by nonresonant modes of the panel. It is important to note that the sixteen control units arranged along the perimeter of the smart panel produces the damping action exactly along the borders of the panel which, at frequencies below the critical frequency, are indeed the portions of the panel which generates the sound radiation.¹ Thus the idea of scattering the control units along the perimeter of the smart panel is not convenient just for control stability issues, as discussed in the following section, or for practical matters such as the fact that the central part of the panel is not occupied by the control systems which are instead located near the borders of the panel where it is much easier to arrange the electronics of the sixteen control systems. On the contrary the control units located along the perimeter of the panel generate active damping exactly over the portion of surface of the smart panel that primarily causes sound radiation. Thus the triangularly shaped control actuators arranged along the edges of the panel could indeed be referred as “active structural wedges” that reduce the reflection of incident flexural waves. It is therefore realistic to presume that when localized structural excitations are generated on the panel then even bigger control effects should be

FIG. 9. Deflections shapes of the panel at the first six resonance frequencies when the optimal feedback control gains are implemented in the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (left, type a in Fig. 2) and the 16 closely located velocity sensors and triangular piezoelectric patches actuators (right, type c in Fig. 2).

obtained than those found for the incident acoustic wave disturbance.

When very large control gains are implemented in the sixteen control loops then, as shown in the two plots of Fig. 10, the deflection shapes relative to the first six new resonance frequencies clearly show the pinning actions of the control units which, as shown on the left hand side plot, occurs on the 4×4 grid of control points for the system with the square piezoelectric patch actuators or, as shown on the right hand side plot, are located along the perimeter of the panel for the system with the triangular piezoelectric patch actuators. As highlighted by Fahy,¹ a periodically supported panel better radiates sound than a one bay panel since the periodic constraints generates new “edges” around which extra sound is radiated. This is why the frequency-averaged sound radiation of the smart panel constrained by the 4×4 grid of control systems with the square piezoelectric patch

actuators that implement large control gains is about 5 dB higher than that of the unconstrained one-bay panel. In contrast, the sixteen control units with triangular actuators that implement large control gains produce a pinning effect around the edges of the panel such that the deflection shapes are still characterized by a central part which is not constrained. As a result the frequency-averaged sound radiation is about the same to that of the one-bay panel. Essentially, the right hand side plot in Fig. 6, indicates that it is just a little lower probably because the radiating surface of the actively constrained smart panel is smaller than that of the unconstrained panel.

B. Control stability of a single control unit

The stability properties of the two independent control units in Figs. 2(a) and 2(c) are examined using the classic

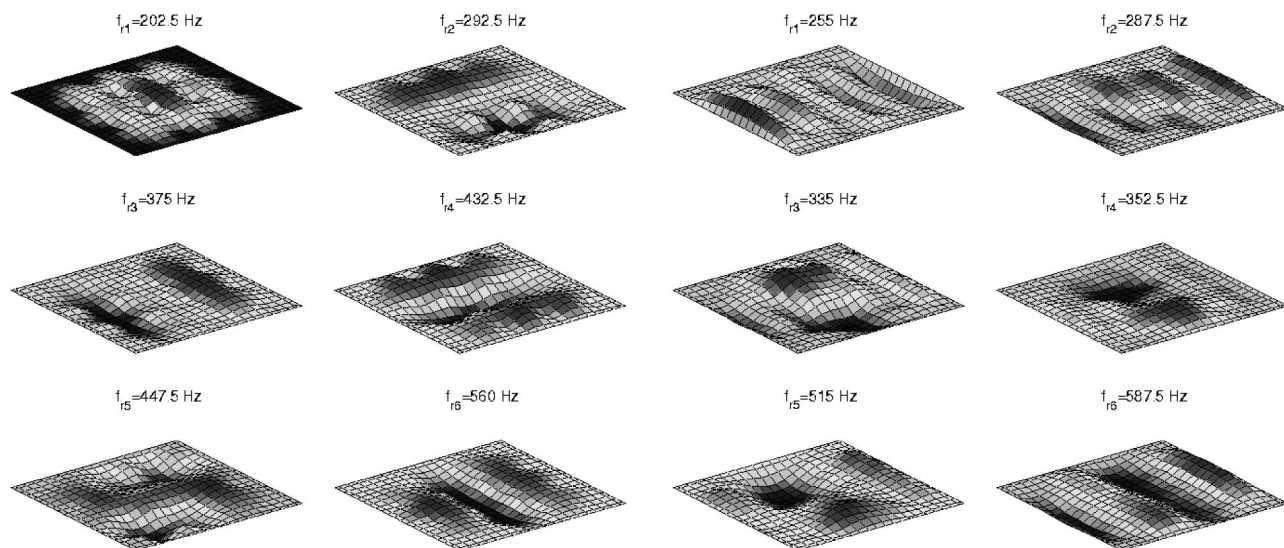

FIG. 10. Deflection shapes of the panel at the first six new resonance frequencies generated by very large feedback gains in the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (left, type a in Fig. 2) and the 16 closely located velocity sensors and triangular piezoelectric patches actuators (right, type c in Fig. 2).

FIG. 11. Frequency response functions of a closely located velocity sensor and square piezoelectric patch actuator control unit (left, type a in Fig. 2) and a closely located velocity sensor and triangular piezoelectric patch actuator (right, type c in Fig. 2).

feedback control theory for SISO feedback control systems.^{3,7,47} The Bode and Nyquist plots of one sensor-actuator feedback loop frequency response function of the two control systems are shown in Figs. 11 and 12.

The left hand side amplitude plot in Fig. 11 highlights the typical feature of square strain actuators which more efficiently excite the panel at higher frequencies so that the amplitude of the sensor-actuator frequency response function grows as the frequency rises.⁵² In contrast the right hand side amplitude plot in Fig. 11 shows that the excitation generated by a triangularly shaped piezoelectric patch is modulated in frequency. This is probably due to a cancellation effect of the moment excitations generated along the lateral edges of the triangular patch in which case the actuation principally occurs via the transverse force generated at the tip of the triangular patch.

The left hand side phase plot of Fig. 11 indicates that the frequency response function generated by the square piezoelectric patch actuator with the velocity sensor at its center is

positive definite up to about 10 kHz. Thus this control system is only conditionally stable.^{3,7,47} Indeed, the Nyquist plot on the left hand side of Fig. 12 suggests that this control system would be unstable even with small feedback control gains since the higher-frequency part of the frequency response functions, with the larger amplitude, would encircle the stability point $-1 + j0$. The right hand side phase plot of Fig. 11 indicates that the frequency response function generated by the triangular piezoelectric patch actuator with the velocity sensor at its tip is positive definite only up to about 2.5 kHz where a sudden phase drop to about -540° occurs. Therefore this control system is also only conditionally stable. However in this case the Nyquist plot on the right hand side of Fig. 12 suggests that for this control system a relatively large gain margin is available since the left hand side of the plot is about five times smaller than the loops on the right hand side. This effect is due to the modulation of the excitation in frequency which combined with the complementary phase drops generates a Nyquist plot with

FIG. 12. Nyquist plots for the frequency response functions of a closely located velocity sensor and square piezoelectric patch actuator control unit (left, type a in Fig. 2) and a closely located velocity sensor and triangular piezoelectric patch actuator (right, type c in Fig. 2).

FIG. 13. Total kinetic energy (left) and sound transmission ratio (right) of the panel excited by a plane acoustic wave with no control (solid line) and with a 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (type b in Fig. 2) SISO feedback controller with feedback gains of 10 (dashed line), 10^2 (dotted line), 10^3 (dash-dotted line) and 10^4 (faint line).

the left hand side squeezed towards the imaginary axis. The modulated excitation of the triangularly shaped actuator depends on the angle of the lateral edges. A trial and error approach has been used in this study to find that the best stability effects are generated by a triangular patch with base $b = 40$ mm and height $a = 25$ mm.

The design of the closely located sensor-actuator control units is an important issue that has been briefly introduced in this section in order to contrast the intrinsic properties of sensor-actuator pairs made with either a square or a triangular strain actuator and an ideal velocity sensor. In practice the local dynamics effects of the sensor should also be taken into consideration as well as the mass and stiffening effects of the piezoelectric patch actuator. A detailed study of these issues is presented in Refs. 41, 53, 54 for a square piezoelectric patch actuator with a velocity sensor at its center.

V. SISO DIRECT VELOCITY FEEDBACK CONTROL

In this section the control effectiveness of the smart panels with SISO control units type (b) and type (d) in Fig. 2, which have either sixteen square piezoelectric patch actuators or sixteen triangular piezoelectric patch actuators driven by a single input signal, is investigated. In this case the stability of the two SISO control systems is fully analyzed by considering Bode and Nyquist plots of the sensor-actuator frequency response function.^{3,7,47}

A. Control effectiveness

The two plots in Fig. 13 show, respectively, the total kinetic energy and the sound transmission ratio of the smart panel with the SISO control system using the 4×4 array of square piezoelectric patch actuators at the center velocity sensors. As found with the MIMO control arrangement, the dashed and dotted lines in the two plots of Fig. 13 show that as the SISO control gain is raised up to an optimal control gain as the active damping generated by the feedback loop levels down most of the resonance peaks. However, in this case the SISO control system does not damp down the resonances due to natural modes of the panel which have no

volumetric vibration component since the sum of the sixteen sensors outputs goes to zero and thus the SISO control loop becomes ineffective. For example, no damping is introduced on the second, third and fourth resonances which are related to the (2,1), (1,2) and (2,2) natural modes of the panel. Beyond the optimal control gain, this trend is inverted and, as shown by the dash-dotted and faint lines, a new set of low-frequency resonances emerge whose amplitudes are similar, if not higher, than those of the panel with no control. Also in this case this phenomenon results from the control spillover effect where a large control gain tends to pin the smart panel at the control positions so that the response of the smart panel is rearranged into that of a lightly damped panel which is pinned at the sixteen control positions.

The two plots in Fig. 14 indicate that, as the control gain is raised as the normalized total kinetic energy and normalized sound transmission ratio, integrated from 0 Hz to 1 kHz, monotonically fall down and reach maximum reductions, respectively, of 12 dB and 8 dB. Therefore the SISO control arrangement is not able to replicate the 17 dB reduction of the total kinetic energy produced by the equivalent MIMO control system. In contrast it nearly generates the 9 dB reduction of the sound transmission ratio produced by the equivalent MIMO control system. This is due to the fact that the error signal used in the SISO feedback control loop is proportional to the volumetric vibration of the smart panel which generates most of the sound radiation at low frequency.^{12,16} When relatively high control gains are implemented then the pinning effect generated at the control positions brings the response of the smart panel back to the levels with no control while its sound radiation is increased by about 2.5 dB than in the case of no control. This is due to the increased sound radiation efficiency of the new resonant modes compared to that of the lower order modes of the unconstrained simply supported panel.¹

The two plots in Fig. 15 show the total kinetic energy and the sound transmission ratio of the smart panel with the SISO control system using the sixteen triangularly shaped piezoelectric patch actuators, with the base edges evenly dis-

FIG. 14. Normalized total kinetic energy (left) and sound transmission ratio (right), integrated between 0 Hz and 1 kHz, plotted against the gain in the SISO velocity feedback controllers, h , for the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (solid line, type b in Fig. 2) and the 16 closely located velocity sensors and triangular piezoelectric patches actuators (faint line, type d in Fig. 2).

tributed along the perimeter of the panel, and velocity sensors at the vertices opposite to the base edges. Comparing the dashed lines in these two plots with those of Fig. 13 it can be noticed that this SISO control system produces at the low-frequency resonances larger damping effects than the SISO control system using the sixteen square actuators. However it still does not generate damping effects at the resonance frequencies related to the natural modes of the panel with no volumetric component. Also, when large control gains, well above the optimal one, are implemented then the SISO control system with the sixteen triangular actuators generates new resonance frequencies some of which occurs at rather different frequencies than those obtained with the SISO control system using square actuators.

This type of behavior is confirmed by the faint lines of the two plots in Fig. 14 which indicates that the SISO arrangement with sixteen triangular actuators brings the maximum reduction of the normalized kinetic energy at 14.5 dB and the maximum reduction of the normalized sound trans-

mission ratio at 10 dB in comparison to the 12 dB and 8 dB, respectively, obtained with the SISO control system using the sixteen square actuators. However, as found for the SISO system with square actuators, the SISO arrangement with sixteen triangular actuators is not able to replicate the 19 dB reduction of the normalized kinetic energy obtained with the equivalent MIMO control system. In contrast it closely generates the 11 dB reduction of the normalized sound transmission ratio produced by the equivalent MIMO control system. Again this is due to the fact that the error signal used in the SISO feedback control loop is proportional to the volumetric vibration of the smart panel which generates most of the sound radiation at low frequency.^{12,16} When relatively high control gains are implemented, then the pinning effect at the sixteen control positions close to the edges of the panel produces a response of the smart panel which is about 5 dB lower than in the case of no control since the vibrating surface has been reduced to that delimited by the sixteen control positions. The frequency-averaged sound radiation of the

FIG. 15. Total kinetic energy (left) and sound transmission ratio (right) of the panel excited by a plane acoustic wave with no control (solid line) and with 16 closely located velocity sensors and 16 triangular piezoelectric patches actuators (type b in Fig. 2) SISO feedback controller with feedback gains of 10 (dashed line), 10^2 (dotted line), 10^3 (dash-dotted line) and 10^4 (faint line).

FIG. 16. Deflection shapes of the panel at the first six resonance frequencies when the optimal feedback control gain is implemented in the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (left, type b in Fig. 2) and the 16 closely located velocity sensors and triangular piezoelectric patches actuators (right, type d in Fig. 2).

panel is instead reduced by just 2 dB, probably because the reduction of the response of the smart panel is balanced by the increased radiation efficiencies of the new resonant modes generated by the pinning effects along the perimeter of the smart panel.

Figures 16 and 17 show the deflections shapes of the panels in correspondence with the first six resonances when either the optimal control gain, that give the best control effects, or when a very large control gain is implemented in the smart panels with either the SISO control system made with sixteen square actuators (left hand side plots) or the SISO control system made with sixteen triangular actuators (right hand side plots). Also in this case, because the deflection shapes occurs over a wide range of amplitudes, the plots in Figs. 16 and 17 have been normalized to have the same

maximum deflections which are also equal to those in Figs. 8 to 10.

Comparing the two plots in Fig. 16 with that of Fig. 8 indicates that when the optimal control gains of the SISO control systems are implemented, then the response of the panel at some of the first six resonance frequencies is generally modified in such a way as the deflection shapes of the smart panel are not anymore controlled by the co-respective natural modes of the panel. This is due to the active damping action which, as seen for the MIMO control systems, tends to reduce the contribution of the resonant modes. However, as shown by the dashed lines on the left hand side plots in Figs. 13, the SISO control system with square actuators cannot damp down the resonances related to even-even or even-odd modes, such as those at 167.5 and 192.5 Hz relative to

FIG. 17. Deflection shapes of the panel at the first six new resonance frequencies generated by a very large feedback gain in the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (left, type b in Fig. 2) and the 16 closely located velocity sensors and triangular piezoelectric patches actuators (right, type d in Fig. 2).

FIG. 18. Frequency response functions of the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (left, type b in Fig. 12) and 16 closely located velocity sensors and triangular piezoelectric patches actuators (right, type d in Fig. 2).

the (2,1) and (1,2) modes, and thus the deflection shapes for these two resonance frequencies are exactly the same as those when there is no control. A similar phenomenon is found for the SISO system with triangular actuators arranged along the perimeter of the panel, even though in this case the deflection shapes relative to the resonances at 167.5 and 192.5 Hz are similar to (2,1) and (1,2) natural modes but rotated by an angle of 45° . This is probably due to the combined effects due to the azimuthal angle of the primary acoustic wave and the spacing of the error sensors along the perimeter of the panel. Finally the deflection shapes relative to the second three resonances generated by the system with square actuators and the deflection shapes relative to the first and sixth resonances generated by the system with triangular actuators do not show any type of vibration pattern. This is probably because, as shown by the dotted lines on the left hand side plots of Figs. 13 and 15, the optimal control gains tend to move up these resonance frequencies so that the plots in Fig. 16 show an off-resonance deflection shape.

As shown in the left hand side plot of Fig. 13, when very large control gains are implemented in the SISO control system with square actuators, a new set of resonance frequencies is generated. This is because, as shown on the left hand side plot of Fig. 17, the control actuators produce a 4×4 grid of pinning points that slightly modify the characteristic deflection shapes of the first six resonance frequencies of the unconstrained panel, which are shown in Fig. 8. The left hand side plot in Figs. 15 shows that when very large control gains are implemented in the SISO control system with triangular actuators the new set of resonance frequencies occurs at much higher frequencies. This is because the pinning effect generated by the control actuators generates higher order modes as one can deduce from the deflection shapes of the first six new resonances shown on the right hand side plot of Fig. 17.

B. Control stability

The stability properties of the two SISO control systems which, as shown in Figs. 2(b) and 2(d), are formed either by

a sixteen square piezoelectric patch actuator at the center velocity sensors or by sixteen triangularly shaped piezoelectric patch actuator with velocity sensors at the vertices are investigated using the classic feedback control theory for SISO feedback control systems.^{3,7,47} The Bode and Nyquist plots of the sensor-actuator open loop frequency response functions for the two control systems are therefore shown in Figs. 18 and 19. As found for a single control unit with a square actuator used in the decentralized MIMO control system, the left hand side amplitude plot in Fig. 18 highlights the typical rising trend due to the higher frequency excitation efficiency of square strain actuators⁵² although in this case there is a drop of the amplitude in the frequency range between 100 Hz and 1 kHz and the rising effect is less effective above about 10 kHz. This is probably due to the fact that between 100 Hz and 1 kHz and above 10 kHz the response of the panel is primarily controlled by structural modes with little or no volumetric vibration component so that the sum of the sensor outputs from the sixteen velocity sensors is relatively low. Also, as found for a single control unit with a triangular actuator used in the decentralized MIMO control system, the right hand side amplitude plot in Fig. 18 shows that the excitation generated by the sixteen triangularly shaped piezoelectric patches is modulated in frequency. Moreover in this case there is not an overall rising trend of the excitation so that the amplitude of the sensor-actuator frequency response function in correspondence to resonances below 1 kHz is at least equal to or much higher than those in correspondence to the higher-frequency resonances. This is probably due to a combination of effects where on one hand the excitation generated by the sixteen triangularly shaped actuators is reduced by local cancellation phenomena and on the other hand the sum of the sixteen control signals at the tips of the triangular actuators is also reduced by cancellation phenomena due to the contribution of higher order modes of the panel with a nonvolumetric vibration component.

The left hand side phase plot of Fig. 19 indicates that the frequency response function generated by the square piezoelectric patch actuators with the velocity sensor at their cen-

FIG. 19. Nyquist plots for the frequency response functions of the 4×4 grid of closely located velocity sensors and square piezoelectric patches actuators (left, type b in Fig. 2) and 16 closely located velocity sensors and triangular piezoelectric patches actuators (right, type d in Fig. 2).

ters is positive definite up to about 10 kHz so that this SISO control system is only conditionally stable.^{3,7,47} However, since above 10 kHz the amplitude of the frequency response function is about 10 dB lower than those of the first few resonant modes and that in the frequency band between 1 kHz and 10 kHz, the left hand side of the Nyquist plot on the left hand side of Fig. 19 is squeezed towards the imaginary axis so that a limited range of control gains could be implemented without the higher-frequency part of the frequency response function encircles the stability point $-1 + j0$. As found for a single control unit used in the MIMO control system, the right hand side phase plot of Fig. 18 indicates that the frequency response function generated by the sixteen triangular piezoelectric patch actuators with the velocity sensors at their tips is positive definite only up to about 2.5 kHz where a sudden phase drop to -540° occurs which also makes this SISO control system only conditionally stable. However, the fact that the amplitude of the sensor-actuator frequency response function above 1 kHz is modulated in frequency and relatively lower than at frequencies below 1 kHz gives the Nyquist plot shown on the right hand side of Fig. 19 which suggests that for this control system a relatively large gain margin is available. Indeed the left hand side of the Nyquist plot is about twenty times smaller than the loops on the right hand side so that large control gains could be implanted without generating instabilities. The small circles on the left hand side of the Nyquist plot are again due to the combination of periodic drops of the amplitude and co-respective drops of the phase of the sensor-actuator frequency response function.

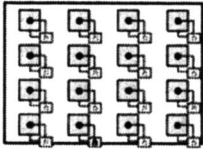

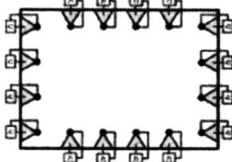

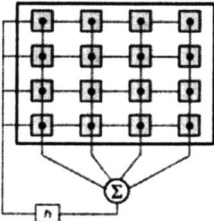

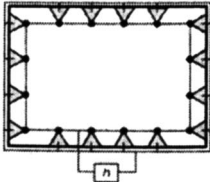

Therefore both SISO control system either with sixteen square control actuators and sixteen velocity sensors at their centers or with sixteen triangular control actuators and sixteen velocity sensors at the vertices could be used to implement direct velocity feedback control. In particular, the system with sixteen triangularly shaped actuators enables the implementation of relatively large control gains without causing instabilities.

VI. CONCLUSIONS

In this study the active structural acoustic control effectiveness of a new smart panel with sixteen triangularly shaped piezoelectric patch actuators having the base edges evenly distributed along the perimeter of the panel and velocity sensors at the vertices opposite to the base edges has been assessed and contrasted with that of a conventional smart panel made by a 4×4 array of square piezoelectric patch actuators evenly distributed over the surface of the panel at the centers velocity sensors. For both systems the control effectiveness and stability issues of MIMO decentralized or SISO velocity feedback control architectures have been analyzed.

As summarized in Table III the MIMO system with square actuators and velocity sensors at their centers relatively large reductions of the integrated kinetic energy and sound transmission ratio between 0 and 1 kHz can be achieved with a maximum value of, respectively, -17 and -9 dB. However the MIMO system with triangular actuators and velocity sensors at the tips produces even larger reductions, respectively, of -19 and -11 dB. Therefore the new system with triangular actuators and velocity sensors at the tips which are evenly distributed along the borders of the panel is not just able to replicate the results of the conventional smart panel with sixteen square piezoelectric patch actuators and velocity sensors at their centers. On the contrary it produces larger control reductions in particular with reference to the far field sound radiation. This is probably due to the fact that the active damping action is generated along the borders of the panel where indeed the sound radiation occurs at low frequencies below coincidence. The same type of behavior is obtained for the case where a SISO control architecture is implemented except that the reductions of the integrated kinetic energy and sound transmission ratio between 0 and 1 kHz go down, respectively, to -12 and -8 dB for the system with square actuators and velocity sensors at their centers and, respectively, to -14.5 and

TABLE III. Maximum frequency-averaged reductions of the total kinetic energy and sound transmission ratio with optimal feedback gains.

Smart panel	Change in kinetic energy dB	Change in sound transmission ratio dB
(a) MIMO-decentralised 	-17	-9
(c) MIMO-decentralised 	-19	-11
(b) SISO 	-12	-8
(d) SISO 	-14.5	-10

- 10 dB for the system with triangular actuators and velocity sensors at the tips. Since for both control arrangements the error sensors are evenly spaced either over the surface of the panel or along its perimeter, then no control signal is generated in correspondence to even-even or even-odd resonant modes which are therefore not controlled. Since the sound radiation efficiency of these modes is relatively low, then this phenomenon has little effect on the overall reduction of the sound radiation but, as confirmed by the data in Table III, it has relatively large effects on the vibration response of the panel and thus on its near field sound radiation.

The stability of one decentralized control unit for the two control arrangements has also been assessed by considering the Bode and Nyquist plots of the sensor-actuator frequency response function. This analysis has indicated that the triangular actuator is less effective at higher frequencies than the square actuator. Also, the triangular shaping generates a point force at the tip of the actuator where the point velocity sensor is placed so that a better collocation effect is obtained than with the square actuator. These two phenom-

ena makes the system with triangularly shaped actuators and velocity sensors at the tips to be relatively more stable so that direct velocity feedback control loops could be implemented up to relatively large control gains. Similar type of results have also been obtained for the SISO control architecture in which case the stability is even enhanced by the fact that the sensor does not measure the vibration contribution of even-even or even-odd resonant modes.

(Received 13 February 2004; revision received 2 November 2004; accepted 5 November 2004)

Transient near-field acoustical holography (NAH) formulation is derived from the Helmholtz equation least squares (HELs) method to reconstruct acoustic radiation from a spherical surface subject to transient excitations in a free field. To facilitate derivations of temporal solutions, we make use of the Laplace transform and expansion in terms of the spherical Hankel functions and spherical harmonics, with their coefficients settled by solving a system of equations obtained by matching an assumed-form solution to the measured acoustic pressure. To derive a general form of solution for a temporal kernel, we replace the spherical Hankel functions and their derivatives by polynomials, recast infinite integrals in the inverse Laplace transform as contour integrals in a complex s -plane, and evaluate it via the residue theorem. The transient acoustic quantities anywhere including the source surface are then obtained by convoluting the temporal kernels with respect to the measured acoustic pressure. Numerical examples of reconstructing transient acoustic fields from explosively expanding, impulsively accelerating, and partially accelerating spheres, and that from a sphere subject to an arbitrarily time-dependent excitation are depicted. To illustrate the effectiveness of HELs-based transient NAH formulations, all input data are collected along an arbitrarily selected line segment and used to reconstruct transient acoustic quantities everywhere. I. INTRODUCTION

Analyses of transient acoustic radiation are often encountered in engineering applications because most vibrating structures are subject to impulsive or transient force excitations. In many cases, the transient excitations are unspecified and therefore the structural vibration responses are unknown, which makes the analysis of resultant acoustic field difficult. It is worth noticing that there are available numerous papers on predicting the transient acoustic^{1–10} and electromagnetic fields^{11–15} from finite objects subject to given excitations or boundary conditions. Of particular interest is the paper by Hansen¹⁶ on predicting time-domain acoustic radiation using a spherical near-field scanning around an arbitrary object. In other words, a single set of time-domain near-field measurements on a scanning sphere that encloses an arbitrarily shaped source can yield the time-domain acoustic field everywhere outside this scanning sphere.

However, the literature on the reconstruction of a transient acoustic field is very scarce. This scarceness is due to a lack of an effective methodology to deal with an inverse acoustic radiation problem in the time domain based on the limited information of acoustic pressure measurements.

One possible way of tackling transient acoustic radiation from an arbitrary object is to use the Kirchhoff–Helmholtz integral theory,¹⁷ which correlates the field acoustic pressure to surface acoustic pressure and normal surface velocity. These surface acoustic quantities are governed by the Kirchhoff–Helmholtz integral equation and must be solved before the field acoustic pressure can be calculated. For an arbitrary surface, this Kirchhoff–Helmholtz integral theory can only be implemented numerically through the boundary element method (BEM) by discretizing the surface into elements and calculating the acoustic quantities on each of the

discrete nodes. Since the acoustic quantities on these nodes have different emission times for an observer in any fixed coordinate system, the integrals are time dependent. Accordingly, one must discretize the integrals in both time and spatial domains, thus making the numerical computations extremely time consuming.⁵

An alternative in transient NAH is to reconstruct the acoustic quantities in the frequency domain first and take an inverse Fourier transform to retrieve the time domain signals. Wang was the first to reconstruct transient acoustic radiation from a vibrating object in this manner.¹⁸ In his Ph.D. dissertation, Wang demonstrated that a transient acoustic field could be reconstructed in the frequency domain using the Helmholtz equation least squares (HELs) method,¹⁹ and then taking an inverse Fourier transform to recover the time history of the normal surface velocity response. The infinite integral in inverse Fourier transform was calculated by direct numerical integration. Needless to say, numerical computations involved in this reconstruction process were intensive. Therefore, a direct calculation of an inverse Fourier transform to reconstruct transient acoustic radiation is not advisable.

Hald showed another pioneering work on reconstruction of temporal acoustic field via the so-called nonstationary spatial transformation of sound field (NS-STSF).²⁰ NS-STSF is based on time-domain holography (TDH) that processes the acoustic pressures measured by using a two-dimensional microphone array with the neighboring microphones separated by a half-wavelength. TDH “can be seen as a sequence of snapshots of instantaneous pressure over the array area, the time separation between subsequent snapshots being equal to the sampling interval in A/D conversion. Similarly, the output of TDH is a time sequence of snapshots of a

selected acoustic quantity in a calculation plane parallel to the measurement plane.”²⁰ Therefore, what we see is an acoustic pressure or intensity distribution in the frequency domain at some fixed instants over the recorded measurement time period. This is why it is called nonstationary STSF (NS-STSF), but not transient STSF. Note that NS-STSF is subject to the same restrictions as STSF. Namely, it is valid for reconstructing acoustic quantities on a planar surface in free space only, and allows for the projection of acoustic quantities along the microphones perpendicular to a measurement plane.

The objective of this paper is to derive transient NAH formulations using the HELS method²¹ to visualize acoustic waves traveling in both space and time based on a finite number of acoustic pressure measurements in free space. It is worth mentioning that HELS is valid for a arbitrarily shaped sources²² and has been used successfully to reconstruct time-harmonic acoustic radiation from vibrating structures in both exterior^{23,24} and interior regions.^{25,26}

The difference between Hansen’s work and the present one is that the former is a forward problem in which the cause (sound source) is given and its effect (sound field) is sought. On the other hand, the reconstruction of a transient acoustic field is a backward problem in which the effect is partially known via measurements, and the cause on a source surface is sought. Mathematically, a backward problem may be ill posed because the input data may be incomplete and inaccurate. Therefore, reconstruction is much more difficult to handle than prediction. A common approach to an ill-posed reconstruction problem is to regularize it by suppressing the small singular values that tend to inflate the errors embedded in the input and distort the reconstructed acoustic image.

For simplicity, our attention is focused on a spherical surface (the extension to a nonspherical surface is shown in a separate paper). In Sec. II we present HELS formulations for reconstructing transient acoustic quantities on a sphere in a free field. In Sec. III we derive general formulations for the temporal kernels. Stability of the solutions thus obtained is discussed in Sec. IV. Also shown are transient formulations via a spherical wave expansion with its coefficients determined by the orthogonality properties of the spherical harmonics. The advantages and disadvantages of these two approaches are discussed in Sec. V. In Sec. VI we demonstrate numerical examples of reconstructing the transient acoustic quantities produced by explosively expanding, impulsively accelerating, and impulsively accelerating baffled spheres, as well as those by a sphere subject to an arbitrarily time-dependent excitation. Conclusions are drawn in Sec. VII.

II. TRANSIENT HELS FORMULATIONS

Consider transient acoustic radiation from a sphere in a free field of density ρ_0 and speed of sound c . Assume that the sphere is excited at $t=t_0$ and prior to that the acoustic pressure at any point is zero, i.e., $p(\mathbf{x};t)=0$ at $t<t_0$. Our objective is to reconstruct the transient acoustic quantities everywhere, including the source surface, based on acoustic

pressure signals measured on a conformal surface Γ around the source. To this end, let us first define the Laplace transform pair for a function $f(\mathbf{x};t)$ as

$$F(\mathbf{x};s) = \int_0^{\infty} f(\mathbf{x};t) e^{-st} dt \quad \text{and} \\ f(\mathbf{x};t) = \frac{1}{i2\pi} \int_{\epsilon-i\infty}^{\epsilon+i\infty} F(\mathbf{x};s) e^{st} ds, \quad (1)$$

where s is a complex variable in the Laplace or s domain, ϵ is a real constant that is greater than the real parts of all singularities of $F(\mathbf{x};s)$. Note that the function $f(\mathbf{x};t)$ in Eq. (1) satisfies the condition $\int_0^{\infty} |f(\mathbf{x};t)| e^{-\sigma t} dt < \infty$ for some finite real value of σ , and ϵ is strategically placed to ensure that the real parts of all singularities of $F(\mathbf{x};s)$ fall on the left-half s plane so the result is bounded as $t \rightarrow \infty$.²⁷ Accordingly, we can express the acoustic pressure in the s domain as an expansion,²¹ which can be written under the spherical coordinates as

$$P(r, \theta, \phi; s) = \sum_{n=0}^N \sum_{l=-n}^n h_n(\beta) Y_n^l(\theta, \phi) C_{nl}(s), \quad (2)$$

where $\beta = isr/c$, $h_n(\beta)$ are the spherical Hankel functions of order n of the first kind, $Y_n^l(\theta, \phi)$ represent the spherical harmonics, and $C_{nl}(s)$ stands for the expansion coefficients. To determine the values of $C_{nl}(s)$, we can take acoustic pressure measurements over an enclosure conformal to the source at $\mathbf{x}^\Gamma \equiv \{x_m^\Gamma\}^T \in \Gamma$, $m=1$ to M , where $M > J$; here $J = (1+N)^2$ indicates the total number of expansion terms in (2). In a matrix form, this can be written as

$$\mathbf{P}(\mathbf{x}^\Gamma; s) = \mathbf{\Psi}(\mathbf{x}^\Gamma; s) \mathbf{C}(s), \quad (3)$$

where $\mathbf{P}(\mathbf{x}^\Gamma; s)$ and $\mathbf{C}(s)$ represent the column vectors that contain measured acoustic pressures and expansion coefficients, respectively, and $\mathbf{\Psi}(\mathbf{x}^\Gamma; s)$ is the matrix whose elements are given by

$$\Psi_{nl}(r_m^\Gamma, \theta_m^\Gamma, \phi_m^\Gamma; s) = h_n(\beta_m^\Gamma) Y_n^l(\theta_m^\Gamma, \phi_m^\Gamma).$$

The solution to Eq. (3) can be expressed as

$$\mathbf{C}(s) = \mathbf{\Psi}(\mathbf{x}^\Gamma; s)^\dagger \mathbf{P}(\mathbf{x}^\Gamma; s); \quad (4)$$

here $\mathbf{\Psi}(\mathbf{x}^\Gamma; s)^\dagger = [\mathbf{\Psi}(\mathbf{x}^\Gamma; s)^H \mathbf{\Psi}(\mathbf{x}^\Gamma; s)]^{-1} \mathbf{\Psi}(\mathbf{x}^\Gamma; s)^H$ denotes a pseudoinversion of the transfer matrix $\mathbf{\Psi}(\mathbf{x}^\Gamma; s)$ and superscript H implies a conjugate transpose. Once the $\mathbf{C}(s)$ are specified the acoustic pressure on the source surface $\mathbf{x}_0 \in S_0$ or anywhere else can be reconstructed,

$$\mathbf{P}(\mathbf{x}_0; s) = \mathbf{G}^p(\mathbf{x}_0 | \mathbf{x}^\Gamma; s) \mathbf{P}(\mathbf{x}^\Gamma; s), \quad (5)$$

where $\mathbf{G}^p(\mathbf{x}_0 | \mathbf{x}^\Gamma; s) = \mathbf{\Psi}(\mathbf{x}_0; s) \mathbf{\Psi}(\mathbf{x}^\Gamma; s)^\dagger$ is the transfer matrix for reconstructing acoustic pressure.

The normal surface velocity of a source can then be obtained via the Euler’s equation,

$$\mathbf{V}(\mathbf{x}_0; s) = \mathbf{G}^v(\mathbf{x}_0 | \mathbf{x}^\Gamma; s) \mathbf{P}(\mathbf{x}^\Gamma; s), \quad (6)$$

where $\mathbf{G}^v(\mathbf{x}_0 | \mathbf{x}^\Gamma; s) = \mathbf{\Phi}(\mathbf{x}_0; s) \mathbf{\Psi}(\mathbf{x}^\Gamma; s)^\dagger$ is the transfer matrix for reconstructing the normal surface velocity, $\mathbf{\Phi}(\mathbf{x}_0; s)$

$= -(\rho_0 s)^{-1} \partial \Psi(\mathbf{x}_0; s) / \partial r_0$, and ρ_0 is the density of the medium. Note that since the source is a sphere, the normal derivative becomes a derivative with respect to the radius r_0 .

The time-domain acoustic pressure and normal component of velocity at the j th point on the source surface $x_0 \equiv (r_0, \theta_0, \phi_0)$ is obtained by taking an inverse Laplace transform of (5) and (6), which is expressible as a convolution in a time domain:²⁸

$$p_j(x_0; t) = \sum_{m=1}^M g_{jm}^p(x_0|x_m^\Gamma; t) \circ p_m(x_m^\Gamma; t), \quad (7)$$

$$v_j(x_0; t) = \sum_{m=1}^M g_{jm}^v(x_0|x_m^\Gamma; t) \circ p_m(x_m^\Gamma; t), \quad (8)$$

where $x_m^\Gamma \in \Gamma$, $m=1$ to M , and the temporal kernels $g_{jm}^p(x_0|x_m^\Gamma; t)$ and $g_{jm}^v(x_0|x_m^\Gamma; t)$ are given by

$$g_{jm}^p(x_0|x_m^\Gamma; t) = \frac{1}{i2\pi} \int_{\epsilon-i\infty}^{\epsilon+i\infty} G_{jm}^p(x_0|x_m^\Gamma; s) e^{st} ds, \quad (9a)$$

$$g_{jm}^v(x_0|x_m^\Gamma; t) = \frac{1}{i2\pi} \int_{\epsilon-i\infty}^{\epsilon+i\infty} G_{jm}^v(x_0|x_m^\Gamma; s) e^{st} ds. \quad (9b)$$

It is emphasized that general closed-form solutions for the temporal kernels $g_{jm}^p(x_0|x_m^\Gamma; t)$ and $g_{jm}^v(x_0|x_m^\Gamma; t)$ cannot be found since measurement and reconstruction locations are arbitrary. The reason for having a flexible measurement scheme is because it is impractical to stipulate that acoustic pressure measurements be taken on a fixed configuration, say, a spherical surface.

III. TEMPORAL KERNELS

The integrands in Eqs. (9a) and (9b) are given by $G_{jm}^p(x_0|x_m^\Gamma; s) = \Psi_j(x_0; s) \Psi_j(x_m^\Gamma; s)^\dagger$ and $G_{jm}^v(x_0|x_m^\Gamma; s) = \Phi_j(x_0; s) \Psi_j(x_m^\Gamma; s)^\dagger$, respectively, where $\Psi_j(x; s) \equiv \Psi_{nl}(r, \theta, \phi; s) = h_n(\beta) Y_n^l(\theta, \phi)$ and $\Phi_j \equiv \Phi_{nl}(x; s) = -(\rho_0 s)^{-1} h_n(\beta) Y_n^l(\theta, \phi)$; here the indices j , n , and l are related together via $j = n^2 + n + l + 1$, with n increasing from 0 to N and l from $-n$ to n .

To facilitate evaluations of the temporal kernels, we recast the infinite integrals in Eqs. (9) into contour integrals:²⁹

$$g_{jm}^p(x_0|x_m^\Gamma; t) = \frac{1}{i2\pi} \oint_l G_{jm}^p(x_0|x_m^\Gamma; s) e^{st} ds, \quad (10a)$$

$$g_{jm}^v(x_0|x_m^\Gamma; t) = \frac{1}{i2\pi} \oint_l G_{jm}^v(x_0|x_m^\Gamma; s) e^{st} ds, \quad (10b)$$

where contour l consists of a straight line from $-i \operatorname{Im}(s)$ to $+i \operatorname{Im}(s)$ and a semicircle of radius $|s|$ on the left-half s -plane in counterclockwise direction. The contribution of this integral along the semicircle is identically zero as $|s| \rightarrow \infty$. This is obvious if we notice that the integrand in Eq. (10) contains the factor e^{st} that decays exponentially as $|s| \rightarrow \infty$ and $t > 0$.

The contour integrals in (10) can be evaluated using the residue theory.³⁰ To this end, we replace the spherical Hankel functions and their derivatives in $G_{jm}^p(x_0|x_m^\Gamma; s)$ and $G_{jm}^v(x_0|x_m^\Gamma; s)$ by polynomials of s :

$$h_n\left(\frac{ir}{c} s\right) = -e^{-rs/c} \sum_{q=0}^n \frac{(n+q)!}{i^n 2^q q!(n-q)!} \left(\frac{c}{r}\right)^{q+1} \frac{1}{s^{q+1}}, \quad (11a)$$

$$h_n'\left(\frac{ir}{c} s\right) = e^{-rs/c} \sum_{q=0}^n \frac{(n+q)! [(rs/c) + (q+1)]}{i^n 2^q q!(n-q)!} \times \left(\frac{c}{r}\right)^{q+1} \frac{1}{rs^{q+1}}. \quad (11b)$$

Substitute Eq. (11) into $G_{jm}^p(x_0|x_m^\Gamma; s)$ and $G_{jm}^v(x_0|x_m^\Gamma; s)$, use partial expansion to recast the polynomial of $[s - (s_{jm}^p)_q]^{-1}$, and sum them up in terms of the distinct real and pairs of complex poles. Doing so, we obtain

$$G_{jm}^p(x_0|x_m^\Gamma; s) = e^{[t_0 + (r_m^\Gamma - r_0)/c]s} \left[\sum_{q=0}^{Q_{jm}^p - 1} \frac{\Pi_{jm}^p(s_{jm}^p)_q}{s - (s_{jm}^p)_q} + \sum_{q=0}^{\hat{Q}_{jm}^p - 1} \frac{\hat{\Pi}_{jm}^p(\hat{s}_{jm}^p)_q}{s^2 - 2 \operatorname{Re}(\hat{s}_{jm}^p)_q s + |\hat{s}_{jm}^p|_q^2} \right], \quad (12a)$$

$$G_{jm}^v(x_0|x_m^\Gamma; s) = e^{[t_0 + (r_m^\Gamma - r_0)/c]s} \left[\sum_{q=0}^{Q_{jm}^v - 1} \frac{\Pi_{jm}^v(s_{jm}^v)_q}{s - (s_{jm}^v)_q} + \sum_{q=0}^{\hat{Q}_{jm}^v - 1} \frac{\hat{\Pi}_{jm}^v(\hat{s}_{jm}^v)_q}{s^2 - 2 \operatorname{Re}(\hat{s}_{jm}^v)_q s + |\hat{s}_{jm}^v|_q^2} \right], \quad (12b)$$

where $(s_{jm}^p)_q$ and $(\hat{s}_{jm}^p)_q$ denote the q th distinct real pole and q th pair of complex poles for reconstructing the surface acoustic pressure, respectively, $\Pi_{jm}^p(s_{jm}^p)_q$ and $\hat{\Pi}_{jm}^p(\hat{s}_{jm}^p)_q$ stand for the residues that correspond to $(s_{jm}^p)_q$ and $(\hat{s}_{jm}^p)_q$, respectively, Q_{jm}^p and \hat{Q}_{jm}^p are the total numbers of distinct real and pairs of complex poles for $G_{jm}^p(x_0|x_m^\Gamma; s)$. Similarly, $(s_{jm}^v)_q$ and $(\hat{s}_{jm}^v)_q$ indicate the q th distinct real and complex poles for reconstructing the normal surface velocity, respectively, $\Pi_{jm}^v(s_{jm}^v)_q$ and $\hat{\Pi}_{jm}^v(\hat{s}_{jm}^v)_q$ are the residues that correspond to $(s_{jm}^v)_q$ and $(\hat{s}_{jm}^v)_q$, respectively, and Q_{jm}^v and \hat{Q}_{jm}^v are the total numbers of distinct poles and pairs of complex poles for $G_{jm}^v(x_0|x_m^\Gamma; s)$. The general solutions for the temporal kernels can be obtained by multiplying sums of the residues by $i2\pi$:

$$g_{jm}^p(x_0|x_m^\Gamma; t) = \left[\sum_{q=0}^{\Theta_{jm}^p-1} \Pi_{jm}^p(s_{jm}^p)_q e^{-(s_{jm}^p)_q t} + \sum_{q=0}^{\hat{\Theta}_{jm}^p-1} \frac{\sin(\omega_{jm,q}^p t + \gamma_{jm,q}^p)}{\omega_{jm,q}^p} \times \hat{\Pi}_{jm}^p(\hat{s}_{jm}^p)_q e^{-\sigma_{jm,q}^p t} \right] H\left(t - t_0 - \frac{r_m^\Gamma - r_0}{c}\right), \quad (13)$$

$$g_{jm}^v(x_0|x_m^\Gamma; t) = \left[\sum_{q=0}^{\Theta_{jm}^v-1} \Pi_{jm}^v(s_{jm}^v)_q e^{-(s_{jm}^v)_q t} + \sum_{q=0}^{\hat{\Theta}_{jm}^v-1} \frac{\sin(\omega_{jm,q}^v t + \gamma_{jm,q}^v)}{\omega_{jm,q}^v} \times \hat{\Pi}_{jm}^v(\hat{s}_{jm}^v)_q e^{-\sigma_{jm,q}^v t} \right] H\left(t - t_0 - \frac{r_m^\Gamma - r_0}{c}\right),$$

where $H(t - t_0 - r_m^\Gamma - r_0/c)$ is the Heaviside step function, and ω_{jm} , σ_{jm} , and γ_{jm} are defined as

$$\omega_{jm,q}^p = \text{Im}(\hat{s}_{jm}^p)_q, \quad (14a)$$

$$\sigma_{jm,q}^p = \text{Re}(\hat{s}_{jm}^p)_q, \quad (14b)$$

$$\gamma_{jm,q}^p = \tan^{-1}[-\text{Im}(\hat{s}_{jm}^p)_q / \text{Re}(\hat{s}_{jm}^p)_q], \quad (14c)$$

$$\omega_{jm,q}^v = \text{Im}(\hat{s}_{jm}^v)_q, \quad (14d)$$

$$\sigma_{jm,q}^v = \text{Re}(\hat{s}_{jm}^v)_q, \quad (14e)$$

$$\gamma_{jm,q}^v = \tan^{-1}[-\text{Im}(\hat{s}_{jm}^v)_q / \text{Re}(\hat{s}_{jm}^v)_q]. \quad (14f)$$

Equation (13) illustrates that the temporal kernels act like weighting functions. The first terms in the square brackets of Eq. (13) resulting from the distinct real poles $(s_{jm}^p)_q$ and $(s_{jm}^v)_q$ decay exponentially in time. The second terms in the square brackets that result from distinct complex poles $(\hat{s}_{jm}^p)_q$ and $(\hat{s}_{jm}^v)_q$ are sinusoidal; however, their amplitudes decay exponentially in time and decrease monotonically in frequency. The rates of exponential decay are dictated by the real parts $\sigma_{jm,q}^p$ and $\sigma_{jm,q}^v$, and the angular frequencies are depicted by the imaginary parts $\omega_{jm,q}^p$ and $\omega_{jm,q}^v$ of $(\hat{s}_{jm}^p)_q$ and $(\hat{s}_{jm}^v)_q$. By convoluting the temporal kernels with measured acoustic pressures, we can reconstruct the transient acoustic waves that travel in space and time.

IV. STABILITY OF SOLUTIONS

As in any inverse problem, we may face an ill-posedness difficulty in reconstructing the temporal acoustic quantities.

In time-harmonic NAH, this ill-posedness problem is dealt with via regularization that smoothes the dependence of solution on the input data.³¹ A common approach is to employ Tikhonov regularization (TR)³² with a certain parameter choice method together with singular value decomposition (SVD). The objective of TR is to strike a balance between minimal residues and minimal solution norms, while SVD enables one to expand an acoustic quantity in terms of the principal acoustic modes and eliminate the evanescent waves that may drop below the ambient noise level and cause distortions in reconstruction.³³

In transient NAH regularization can be done conveniently by eliminating the poles that stay close to the imaginary axis. Since the contour integral is carried out in the left-half s plane, the real part of a distinct pole is negative and the amplitude of the corresponding temporal kernel decays exponentially in time. This guarantees a stability of a temporal solution. However, when a pole approaches the imaginary axis, its real part diminishes and the amplitude of corresponding temporal kernel decays very slowly. Under this condition, the errors embedded in the input data may remain finite and be transferred to the reconstructed acoustic quantities.

To circumvent this difficulty, we can design a low-pass filter that eliminates all poles whose real parts are larger than a tolerance ϵ . Accordingly, we can rewrite Eq. (12) as

$$G_{jm}^p(x_0|x_m^\Gamma; s) = e^{[t_0 + (r_m^\Gamma - r_0)/c]s} \left[\sum_{q=0}^{\Theta_{jm}^p-1} \frac{\Pi_{jm}^p(s_{jm}^p)_q}{s - (s_{jm}^p)_q} + \sum_{q=0}^{\hat{\Theta}_{jm}^p-1} \frac{\hat{\Pi}_{jm}^p(\hat{s}_{jm}^p)_q}{s^2 - 2 \text{Re}(\hat{s}_{jm}^p)_q s + |\hat{s}_{jm}^p|_q^2} \right], \quad (15a)$$

$$G_{jm}^v(x_0|x_m^\Gamma; s) = e^{[t_0 + (r_m^\Gamma - r_0)/c]s} \left[\sum_{q=0}^{\Theta_{jm}^v-1} \frac{\Pi_{jm}^v(s_{jm}^v)_q}{s - (s_{jm}^v)_q} + \sum_{q=0}^{\hat{\Theta}_{jm}^v-1} \frac{\hat{\Pi}_{jm}^v(\hat{s}_{jm}^v)_q}{s^2 - 2 \text{Re}(\hat{s}_{jm}^v)_q s + |\hat{s}_{jm}^v|_q^2} \right], \quad (15b)$$

where Θ_{jm}^p and $\hat{\Theta}_{jm}^p$ are total numbers of the principal poles for reconstructing surface acoustic pressure, Θ_{jm}^v and $\hat{\Theta}_{jm}^v$ are those of the principal poles for reconstructing normal surface velocity in the time domain, and the rest poles whose real parts are larger than ϵ are eliminated. Thus, this low-pass filter effectively expands an acoustic quantity in terms of the principal acoustic modes that remain bounded in the time domain, which is equivalent to what truncated SVD does for time-harmonic NAH applications. Accordingly, the regularized temporal kernels can be written as

$$\begin{aligned}
g_{jm}^p(x_0|x_m^\Gamma;t) &= \left[\sum_{q=0}^{\Theta_{jm}^p-1} \Pi_{jm}^p(s_{jm}^p)_q e^{-(s_{jm}^p)_q t} \right. \\
&\quad + \sum_{q=0}^{\hat{\Theta}_{jm}^p-1} \frac{\sin(\omega_{jm,q}^p t + \gamma_{jm,q}^p)}{\omega_{jm,q}^p} \\
&\quad \left. \times \hat{\Pi}_{jm}^p(\hat{s}_{jm}^p)_q e^{-\sigma_{jm,q}^p t} \right] H\left(t-t_0 - \frac{r_m^\Gamma - r_0}{c}\right), \quad (16) \\
g_{jm}^v(x_0|x_m^\Gamma;t) &= \left[\sum_{q=0}^{\Theta_{jm}^v-1} \Pi_{jm}^v(s_{jm}^v)_q e^{-(s_{jm}^v)_q t} \right. \\
&\quad + \sum_{q=0}^{\hat{\Theta}_{jm}^v-1} \frac{\sin(\omega_{jm,q}^v t + \gamma_{jm,q}^v)}{\omega_{jm,q}^v} \\
&\quad \left. \times \hat{\Pi}_{jm}^v(\hat{s}_{jm}^v)_q e^{-\sigma_{jm,q}^v t} \right] H\left(t-t_0 - \frac{r_m^\Gamma - r_0}{c}\right).
\end{aligned}$$

V. SPHERICAL WAVE EXPANSION

Since in this paper we focus on a spherical surface, it is possible to reconstruct transient acoustic quantities using the spherical wave expansion theory. Assume that the transient acoustic field is radiated from a sphere of radius $r=r_0$. Then we can write the acoustic pressure as²⁹

$$P(r, \theta, \phi; s) = \sum_{n=0}^{\infty} \sum_{l=-n}^n h_n(isr/c) Y_n^l(\theta, \phi) D_{nl}(s), \quad (17)$$

where the expansion coefficients $D(s)$ can be determined by multiplying both sides of Eq. (17) by a complex conjugate of the spherical harmonics $Y_n^l(\theta, \phi)^*$, integrating the resultant equation over a sphere of radius $r=r_m$ that enclose the source and on which the acoustic pressures are measured, and then using the orthogonality properties of the spherical

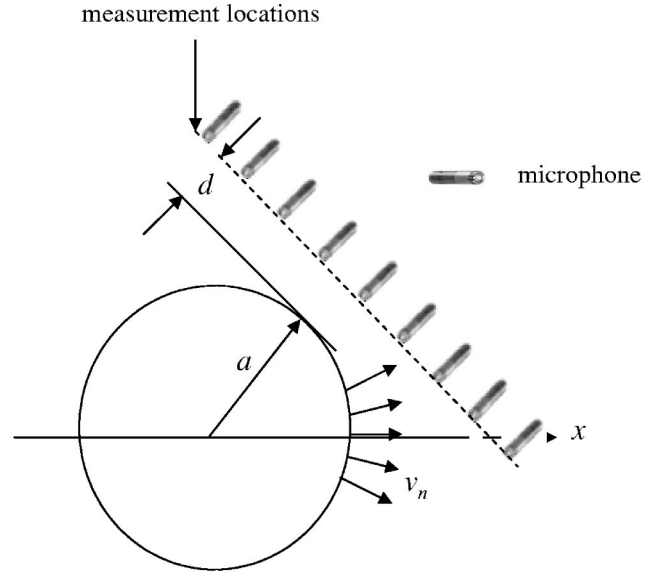

FIG. 1. Schematic of measurements of acoustic pressures from a partially accelerated sphere.

harmonics. Once $D(s)$ are specified, the surface acoustic pressure can be written as

$$\begin{aligned}
P(r_0, \theta, \phi; s) &= \sum_{n=0}^{\infty} \frac{h_n(isr_0/c)}{h_n(isr_m/c)} \sum_{l=-n}^n Y_n^l(\theta, \phi) \\
&\quad \times \int_{\Omega_m} \int P(r_m, \theta_m, \phi_m; s) \\
&\quad \times Y_n^l(\theta_m, \phi_m)^* d\Omega_m, \quad (18)
\end{aligned}$$

where a superscript $*$ implies a complex conjugate and $d\Omega_m = \sin \theta_m d\theta_m d\phi_m$ is the solid angle of integration over the measurement sphere.

The temporal surface acoustic pressure can now be obtained by taking an inverse Laplace transform of (18), which is expressible as a temporal convolution in the form of Eq. (7):

FIG. 2. A comparison of the reconstructed normal surface velocity distributions on the surface of an explosively expanding sphere and actual excitation. Solid line: excitation; \blacklozenge : reconstructed.

(3a) $t = 3.24$ (ms)

(3b) $t = 4.41$ (ms)

(3c) $t = 5.88$ (ms)

(3d) $t = 7.35$ (ms)

FIG. 3. Reconstructed 3-D transient acoustic pressure fields generated by an explosively expanding sphere.

$$p(r_0, \theta, \phi; t) = \sum_{n=0}^{\infty} A_n(r_0, r_m; t) \tilde{D}_n(r_m, \theta, \phi; t), \quad (19)$$

where A_n and \tilde{D}_n are defined, respectively, by

$$A_n(r_0, r_m; t) = \frac{1}{i2\pi} \int_{\epsilon - i\infty}^{\epsilon + i\infty} \frac{h_n(isr_0/c)}{h_n(isr_m/c)} e^{st} ds, \quad (20a)$$

$$\begin{aligned} \tilde{D}_n(r_m, \theta, \phi; t) &= \sum_{l=-n}^n Y_n^l(\theta, \phi) \\ &\times \int_{\Omega_m} p(r_m, \theta_m, \phi_m; t) \\ &\times Y_n^l(\theta_m, \phi_m)^* d\Omega_m. \end{aligned} \quad (20b)$$

The expansion coefficients A_n can be evaluated in exactly the same way as that for which the temporal kernel $g_{jm}^p(x_0|x_m^\Gamma; t)$ is obtained (see Sec. III). Thus, the spherical wave expansion is similar to HELS for a spherical surface; however, there are major differences between the two methods, as summarized below.

- (1) The spherical wave expansion is an infinite series and its solution converges uniformly in the region outside a sphere of radius $r = r_0$. HELS is a finite expansion and its solution is approximate, but nonetheless valid everywhere, even on an arbitrary source surface.²²
- (2) The spherical wave expansion uses the orthogonality property to determine its expansion coefficients, whose

FIG. 4. A comparison of the reconstructed normal surface velocity distributions on the surface of an impulsively accelerated sphere and actual excitation. Solid line: excitation; ■: reconstructed.

values are fixed and independent of the number of expansion terms. HELS determines its coefficients by matching the assumed-form solution to the measured acoustic pressures and employs the least squares to minimize the residue norms.

- (3) The spherical wave expansion requires that the acoustic pressure measurements be taken over a spherical surface. HELS has no restrictions whatsoever on measurement locations.

Note that in practice it is not easy to take acoustic pressure measurements on a spherical surface. The flexibility of HELS in accommodating any measurement configuration can make it the method of choice for NAH. In Sec. VI, we illustrate numerical examples of reconstructing transient acoustic radiation from spheres by taking 12 measurements of the acoustic pressure along a straight line. Note that there is no way of knowing how many measurements are needed, because in general there is no prior knowledge of the source characteristics. If measurements are severely insufficient, the problem will be highly ill posed and the reconstructed image be greatly distorted. On the other hand, if too many measurements are taken, the reconstruction process can be too expensive and costly. So we must strike a balance between accuracy and cost in this case.

VI. NUMERICAL EXAMPLES

In this section, we use the transient NAH formulations (7) and (8) derived in Sec. III to reconstruct the transient acoustic quantities generated by a sphere. To facilitate validations of the reconstructed field, we consider a sphere of radius $r_0 = 1$ m subject to an impulsive excitation for which the analytic solution is readily available:

$$v(r_0, \theta_0, \phi_0; t) = \hat{v}(r_0, \theta_0, \phi_0)H(t - t_0), \quad (21)$$

where $\hat{v}(r_0, \theta_0, \phi_0)$ is the amplitude of the normal velocity on the source surface.

In time-harmonic NAH it has been shown that satisfactory reconstruction can be obtained by taking acoustic pres-

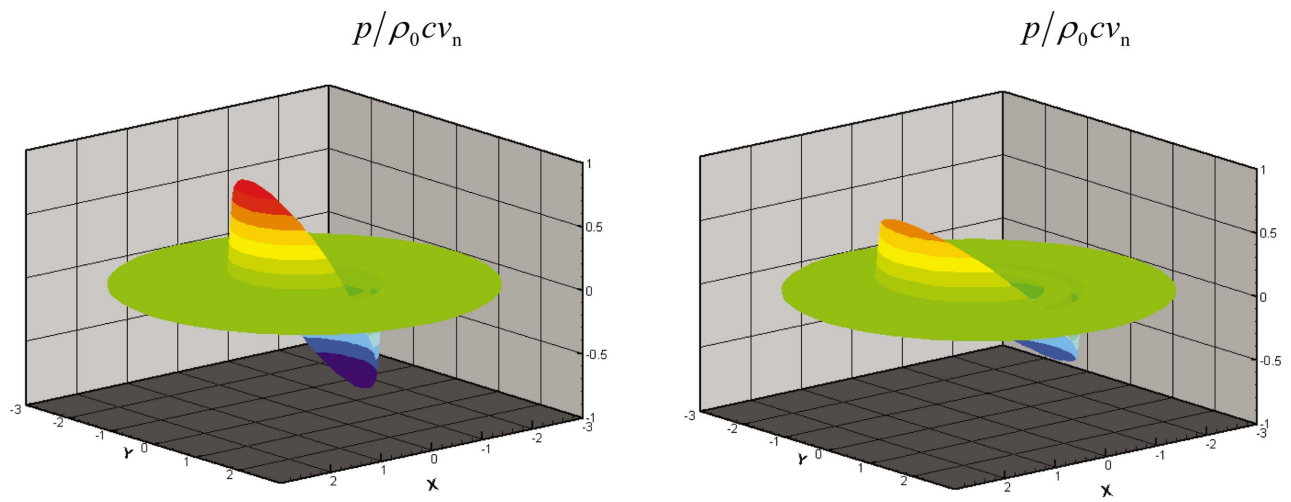

sure measurements on a surface conformal to the source geometry. This is especially true in transient NAH for the microphones can capture transient signal simultaneously. To test the effectiveness of the present formulations, we deliberately align the microphones along a line segment because this is easy to implement in practice. Figure 1 illustrates 11 measurement microphones that are placed on a straight line that intersects the x axis at 135° with a minimum distance of $d = 0.1$ m. Apparently, under such a measurement scheme, an acoustic signal cannot reach all microphones simultaneously, which makes reconstruction a challenge. Accordingly, we take a shot segment of measurements of acoustic pressures and ensure that all microphones have received the signals, although the amplitudes at these microphones may be quite different. The signals thus obtained are taken as input data to Eqs. (7) and (8) to reconstruct the entire acoustic field including the source surface in the time domain.

A. Explosively expanding sphere

The first example is concerned with reconstruction of transient acoustic radiation from an explosively expanding sphere in free space. Since the resultant field is spherically symmetric, the acoustic pressure is a function of the radial distance and time only. The analytic solution for an explosively expanding sphere is given by²⁹

$$\frac{p(r;t)}{\rho_0 c v} = \frac{r_0 e^{-(ct-(r-r_0))/r_0}}{r} H\left(t - \frac{(r-r_0)}{c}\right). \quad (22)$$

Equation (22) is used to generate transient acoustic pressures at the microphone locations. It is emphasized that the signal level at each microphone is different because the impulse cannot reach all microphones simultaneously. These acoustic pressure signals are taken as input to Eqs. (7) and (8) to reconstruct the transient acoustic field. In this case, there is only one distinct pole at $s = -c/r_0$, whose residue is r_0/r^Γ ; here r^Γ is the radial distance of a microphone to the center of the explosively expanding sphere ($r_0 < r^\Gamma$). The

FIG. 7. Reconstructed transient acoustic pressure field from an impulsively accelerated baffled sphere.

FIG. 8. A comparison of exact dimensionless acoustic pressure (solid line) and reconstructed ones (dashed line) on the surface of a partially vibrating sphere under an arbitrarily time-dependent excitation. (a) Distribution at $t = 2.529$ ms with $e = 5.875 \times 10^{-9}$; (b) time history at $\theta = 20^\circ$ with $e = 4.602 \times 10^{-8}$, where $e = \|\{p_{\text{rec}}\} - \{p_{\text{exact}}\}\|_2 / \|\{p_{\text{exact}}\}\|_2$.

test results show that solutions thus obtained converge rapidly. This is no surprise since the input data are exact. Hence perfect reconstruction of surface acoustic pressure and normal surface velocity can be obtained directly.

For brevity, we only exhibit the comparison of reconstructed normal surface velocities with the actual excitation (see Fig. 2) and three-dimensional images of acoustic pressure fields at arbitrarily selected time instances t

$t = 3.24$ (ms), 4.41 (ms), 5.88 (ms), and 7.35 (ms) (see Fig. 3).

B. Impulsively accelerated sphere

The second example is reconstruction of transient acoustic radiation from an impulsively accelerated sphere in free space, whose analytic solution is given by²⁹

FIG. 9. A comparison of the exact normal velocity history (solid line) and reconstructed one (dashed line) on the surface of a partially vibrating sphere under an arbitrarily time-dependent excitation at $\theta = 20^\circ$ with $e = 6.262 \times 10^{-3}$, where $e = \|\{v_{\text{rec}}\} - \{v_{\text{exact}}\}\|_2 / \|\{v_{\text{exact}}\}\|_2$.

(a)

(b)

$$\frac{p(r, \theta; t)}{\rho_0 c v} = \frac{r_0 \cos \theta}{r} e^{-(ct - (r - r_0))/r_0} H\left(t - \frac{(r - r_0)}{c}\right) \times \left[\cos\left(\frac{ct - (r - r_0)}{r_0}\right) - \left(1 - \frac{r_0}{r}\right) \sin\left(\frac{ct - (r - r_0)}{r_0}\right) \right], \quad (23)$$

where $\cos \theta = \mathbf{n} \cdot \mathbf{e}_R$; here \mathbf{n} is the unit normal on the source surface and \mathbf{e}_R is the unit vector in the direction of wave propagation from the source to a receiver.

Equation (23) is used to generate the field acoustic pressures in the same manner as that described in the preceding section. These signals are substituted in Eqs. (7) and (8) to reconstruct the temporal acoustic quantities. In this case, there are a pair of complex conjugate poles located at $s = (-1 \pm i)(c/r_0)$. The corresponding residues are $(r_0/2r^\Gamma)[1 \mp (r_0/r^\Gamma - 1)i]$.

Figure 4 displays the reconstructed normal component of velocity, which agrees perfectly with the actual excitation. Figure 5 depicts the reconstructed acoustic pressure distributions produced by an impulsively accelerated sphere in free space at $t = 3.24$ (ms), 4.41 (ms), 5.88 (ms), and 7.35 (ms).

C. Impulsively accelerated baffled sphere

In this example, a small portion of the surface is impulsively accelerated and the rest area is rigidly baffled. Mathematically, we can write the normal surface velocity as

$$v(r_0, \theta, t) = \hat{v}_0(r_0, \theta) [H(\theta + \theta_0) - H(\theta - \theta_0)] H(t - t_0), \quad (24a)$$

where $2\theta_0$ is the vertex angle (in this example we select $2\theta_0 = 60^\circ$) and $\hat{v}(r_0, \theta)$ is the amplitude of the normal surface velocity. The normal surface velocity can be rewritten as

$$v(r_0, \theta, t) = \sum_{j=0}^{\infty} \zeta_j(r_0, \theta_0) P_j(\cos \theta) H(t - t_0), \quad (24b)$$

where $P_j(\cos \theta_0)$ represents the Legendre functions²⁹ and $\zeta_j(r_0, \theta_0)$ are the expansion coefficients. The analytic solution of transient acoustic pressure can be written as an infinite series.³⁰

Table I compares the reconstructed expansion coefficients with the exact values. Because of a rich content of high spatial frequencies around the corners at $\theta_0 = \pm 30^\circ$, as it is indicated by the Heaviside step function in Eq. (24a), a large number of expansion functions are required to approximate a sudden rise of the normal surface velocity. Figure 6 displays a comparison of the reconstructed normal surface velocity using different numbers of expansion functions with the actual excitation. Results indicate that the reconstructed normal surface velocity converges to the actual one as the number of expansion terms increases. Theoretically, if input data are complete and error free, the reconstructed normal surface velocity may converge to the true value as the number of expansion terms approaches infinity. However, this will not happen since in reality the input data are incomplete

FIG. 10. A comparison of exact dimensionless acoustic pressure (solid line) and reconstructed ones (dashed line) in the field produced by a partially vibrating sphere under an arbitrarily time-dependent excitation. (a) Distribution at $r = 1.1$ m, $t = 2.529$ ms, and $e = 3.125 \times 10^{-8}$; (b) Time history at $r = 1.1$ m, $\theta = 20^\circ$, and $e = 1.607 \times 10^{-8}$, where $e = \|\{p_{\text{rec}}\} - \{p_{\text{exact}}\}\|_2 / \|\{p_{\text{exact}}\}\|_2$.

and inaccurate. Therefore, regularization is needed to truncate the expansion or eliminate unstable poles so that errors in input are not amplified in reconstruction.

Table II lists the distinct poles s_j , $j=1$ to 11, in this case. Once these poles are identified and the corresponding residues are obtained, the temporal acoustic pressure can be reconstructed by the temporal kernel with measured acoustic pressures. Figure 7 shows reconstructed 3-D transient acoustic pressure fields produced by an impulsively accelerated baffled sphere at $t=3.24$ (ms), 4.41 (ms), 5.88 (ms), and 7.35 (ms).

D. A partially vibrating sphere under an arbitrarily time-dependent excitation

Finally, we show reconstruction of transient acoustic radiation from a partially vibrating sphere subject to arbitrarily time-dependent excitations in a free field. Without loss of generality, we express the normal surface velocity as a sum of harmonic functions with randomly selected amplitudes, frequencies, and phases,

$$v(r_0, \theta, t) = \hat{v}_0(r_0, \theta)[H(\theta + \theta_0) - H(\theta - \theta_0)] \times \sum_{j=1}^4 A_j \sin(2\pi f_j t + \vartheta_j) H(t - t_0), \quad (25)$$

where $A_1=1$, $A_2=0.2$, $A_3=0.3$, $A_4=0.3$, $f_1=0.5$, $f_2=23$, $f_3=56$, $f_4=100$, $\vartheta_1=10^\circ$, $\vartheta_2=40^\circ$, $\vartheta_3=30^\circ$, and $\vartheta_4=40^\circ$. The input data are generated by superimposing contributions from a partially vibrating sphere under individual harmonic excitation. To test the effectiveness of the formulations derived, we insert 5% spatially uncorrelated Gaussian noise to the input data and substitute them in Eqs. (7) and (8) to reconstruct the temporal acoustic quantities. To ensure a satisfactory reconstruction, we regularize the solutions by eliminating the poles that are close to the imaginary axis of the s plane.

Note that in this case the distinct poles remain unchanged (see Table II) since they depend on source geometry and measurement configuration. However, the residues are different because they are not only source geometry and measurement configuration dependent, but also excitation dependent. Once the residues are obtained, the temporal surface acoustic pressure and normal surface velocity are obtained by convoluting the temporal kernels over input acoustic pressures. As before, excellent reconstruction is obtained. For brevity, we illustrate the comparisons of the reconstructed acoustic pressure and normal velocity on the source surface in the time domain (see Figs. 8 and 9), the reconstructed acoustic pressure on a spherical surface of radius $r=1.1$ m at $t=2.529$ (ms) versus the benchmark values [see Fig. 10(a)], and the time history of acoustic pressure at a field point $r=1.1$ m and $\theta=0^\circ$ versus the benchmark values [see Fig. 10(b)].

VII. CONCLUSIONS

HELs formulations are extended to the reconstruction of transient acoustic radiation from a spherical source subject to arbitrarily time-dependent excitations in a free field. It is

shown that HELs enables one to obtain the satisfactory reconstruction of 3-D images of transient acoustic waves as they travel in space and time based on a few measurements taken along a finite line segment. Since HELs imposes no restrictions whatsoever on measurement locations and since the nature of HELs formulations is naturally suited for transient NAH, it can become the method of choice for visualizing transient acoustic quantities.

(Received 7 April 2004; revised 14 December 2004; accepted 15 January 2005)

The acoustic attenuation performance of perforated dissipative circular expansion chambers with inlet/outlet extensions is investigated. The eigenvalues and eigenfunctions of the sound field are analytically determined in the extended inlet/outlet circular ducts, upstream/downstream end annular dissipative chambers, and the central perforated dissipative expansion chamber. Utilizing the continuity conditions of velocity/pressure at the interfaces, the transmission loss is predicted by a two-dimensional analytical approach. For a specific configuration, such predictions are compared with both experiments and a three-dimensional computational solution based on the substructure boundary element technique, showing a reasonable agreement. The analytical results for the effect of the absorbent resistivity, duct porosity, and geometry on the acoustic attenuation performance are discussed in detail. © 2005 Acoustical Society of America. I. INTRODUCTION

Due to the relative simplicity of their flow path leading to low backpressure and desirable sound attenuation performance with increasing frequency, dissipative silencers have been used increasingly in gas flows, such as heating, ventilation, air conditioning, and automotive exhaust systems. To predict their acoustic behavior, both three-dimensional (3D) finite-element (FEM)^{1–3} and boundary element methods (BEM)^{4,5} have been developed for complex geometries. For silencers of axially uniform and arbitrary cross sections, various approaches^{6–11} have been adopted to reduce the computational time associated with a 3D FEM/BEM. Including the effect of mean flow and calculating the eigenvalues by FEM, Astley and Cummings⁶ obtained the modal attenuation rate in a silencer of rectangular cross section. Cummings⁷ further predicted the sound transmission in a dissipative silencer of arbitrary cross section by using a segmented Rayleigh–Ritz method. Glav obtained the eigenvalues (wave numbers) and eigenfunctions of an infinite cylindrical dissipative silencer of arbitrary cross section by using the point-matching⁸ and null-field approaches;⁹ he further expanded¹⁰ the acoustic field in a dissipative silencer by using the eigenfunctions and adjusted to the boundary conditions at the inlet/outlet by mode matching, then derived the transfer matrix for a silencer of arbitrary cross section, while providing numerical results for a silencer with elliptical cross section. Kirby¹¹ derived the eigenvalues/eigenfunctions by employing a 2D FEM, matched the expanded acoustic pressure and velocity fields in the expansion chamber of dissipative silencer to the inlet/outlet pipes by using point collocation, and obtained the transmission loss.

For a dissipative silencer of simple cross section, such as

circular, various analytical approaches have also been developed.^{12–15} Cummings and Chang¹² obtained the transmission loss of a dissipative expansion chamber including the mean flow by a mode-matching technique. Kirby¹³ investigated the acoustic attenuation of a circular dissipative silencer and obtained the transmission loss by using a simplified approach. Xu *et al.*¹⁴ developed a 2D analytical solution to examine the acoustic performance of dissipative expansion chambers by a pressure- and velocity-matching technique.¹⁶ Selamet *et al.*¹⁵ further investigated the effect of perforated ducts on the sound attenuation in dissipative silencers.

The foregoing studies^{1–15} have demonstrated that the acoustic performance of a dissipative expansion chamber can be improved by the fibrous material, though usually at relatively high frequencies. Due to the coupling of broadband modes of a simple expansion chamber and the resonant peaks of a quarter-wave resonator, the inlet/outlet extensions can enhance the transmission loss in an expansion chamber, particularly at low frequencies.^{17–21} Utilizing the mode-matching technique, Abom¹⁷ developed a general 3D analytical approach to determine the four-pole parameters including higher order mode effects for expansion chamber mufflers with inlet/outlet extensions. Selamet and Ji¹⁸ investigated the acoustic attenuation performance of circular expansion chambers with extended inlet/outlet, and employed three approaches to determine the transmission loss: a 2D axisymmetric analytical solution, a 3D BEM, and experiments. For a circular expansion chamber with extended end inlet and side outlet, they¹⁹ also investigated the acoustic attenuation and determined the transmission loss by a 1D analytical approach, a 3D BEM, and experiments. Furthermore, Selamet *et al.*²⁰ studied the acoustic behavior of a circular dual-chamber muffler by a 2D analytical approach, FEM, and experiments, and investigated the effect of rigid baffles, the

FIG. 1. Perforated dissipative circular expansion chamber with inlet/outlet extensions.

inner radius and the axial position of the baffle, and the inlet/outlet extensions. For extended-duct and perforated-duct mufflers, Torregrosa *et al.*²¹ obtained the end corrections by a 2D FEM, and validated the predictions experimentally.

Although the dissipative silencers and the expansion chambers with inlet/outlet extensions have been investigated in detail, the combination of the two concepts—the perforated dissipative silencers with inlet/outlet extensions—remains to be explored. The objective of the present study is then to: (1) investigate the acoustic attenuation of a perforated dissipative silencer with inlet/outlet extensions by a two-dimensional analytical approach; (2) compare such predictions with the experimental and numerical results for a specific configuration; and (3) examine analytically the effect of absorbent resistivity, duct porosity, and geometry on the transmission loss. Following this Introduction, Sec. II develops a two-dimensional analytical approach for the transmission loss of the perforated dissipative silencers with extended inlet/outlet. Section III discusses the effects of absorbent resistivity, duct porosity, and geometry on the transmission loss, and compares the analytical results with the numerical predictions and experiments. The study is concluded with final remarks in Sec. IV.

II. TWO-DIMENSIONAL ANALYTICAL APPROACH

Consider a cylindrical expansion chamber of radius r_2 and total length $L = L_1 + L_C + L_2$ with solid inlet (of length L_1) and outlet (of length L_2) extensions, a perforated duct of radius r_1 , length L_C , and porosity ϕ , and a sound-absorbing material between radii r_1 and r_2 , as shown in Fig. 1. The origin of the x axis is located at the end of the solid inlet duct. The absorbing material is assumed to be homogeneous and isotropic, and characterized by the complex speed of sound \tilde{c} and density $\tilde{\rho}$ (The expressions are deferred to Appendix A.) The air in the airway is characterized by the speed of sound c_0 and density ρ_0 . The extended inlet duct, the upstream end concentric annular chamber ($-L_1 \leq x \leq 0$), the central perforated expansion chamber ($0 \leq x \leq L_C$), the downstream end concentric annular chamber ($L_C \leq x \leq L_C + L_2$), and the extended outlet duct are denoted by domains I, II, III (including the central airway III_a and the concentric outer chamber with sound-absorbing material III_b), IV, and V, respectively.

A. Wave propagation in domain I

For an axisymmetric wave propagation in the extended inlet duct (domain I in Fig. 1), the solution of the Helmholtz equation can be written as

$$P_A(r, x) = \sum_{n=0}^{\infty} (A_n^+ e^{-jk_{x,A,n}x} + A_n^- e^{jk_{x,A,n}x}) \psi_{A,n}(r), \quad (1)$$

with $j = \sqrt{-1}$, P_A being the acoustic pressure in the inlet pipe; A_n^+ and A_n^- the modal amplitudes corresponding to components traveling in the positive and negative x directions, respectively; r designates the radial direction; $k_{x,A,n}$ the wave number in the x direction with subscripts x, A, n denoting axial direction, domain I, and order of the waves, respectively;

$$\psi_{A,n}(r) = J_0(k_{r,A,n}r) \quad (2)$$

is the eigenfunction, J_0 is the zeroth-order Bessel function of the first kind, and $k_{r,A,n}$ the radial wave number satisfying the rigid wall boundary condition of

$$J_0'(k_{r,A,n}r_1) = 0, \quad (3)$$

with wave numbers $k_{x,A,n}$ and $k_{r,A,n}$ being related by

$$k_{x,A,n}^2 + k_{r,A,n}^2 = k_0^2, \quad (4)$$

where $k_0 = \omega/c_0 = 2\pi f/c_0$ is the wave number in air, ω being the angular velocity, and f the frequency. In view of the linearized momentum equation, the particle velocity in the axial direction may then be written as

$$u_{x,A}(r, x) = \frac{1}{\rho_0 \omega} \sum_{n=0}^{\infty} k_{x,A,n} (A_n^+ e^{-jk_{x,A,n}x} - A_n^- e^{jk_{x,A,n}x}) \times \psi_{A,n}(r). \quad (5)$$

B. Wave propagation in domain II

The pressure for a two-dimensional axisymmetric wave propagation in the upstream annular duct (Fig. 1: domain II of length L_1 , inner radius r_1 , outer radius r_2 , and filled with sound-absorbing material) is expressed as

$$P_B(r, x) = \sum_{n=0}^{\infty} (B_n^+ e^{-jk_{x,B,n}x} + B_n^- e^{jk_{x,B,n}x}) \psi_{B,n}(r), \quad (6)$$

with P_B being the acoustic pressure; B_n^+ and B_n^- the modal amplitudes corresponding to components traveling in the positive and negative x directions, respectively; $k_{x,B,n}$ the axial wave number with subscript B denoting domain II. The eigenfunction for such a circular, concentric annular duct is

$$\psi_{B,n}(r) = J_0(k_{r,B,n}r) - [J_1(k_{r,B,n}r_2)/Y_1(k_{r,B,n}r_2)]Y_0(k_{r,B,n}r), \quad (7)$$

with J_1 being the first-order Bessel function of the first kind; Y_0 and Y_1 being Bessel functions of the second kind of zeroth- and first order; $k_{r,B,n}$ the radial wave number satisfying

$$J_1(k_{r,B,n}r_1) - [J_1(k_{r,B,n}r_2)/Y_1(k_{r,B,n}r_2)]Y_1(k_{r,B,n}r_1) = 0. \quad (8)$$

The axial wave number of the n mode $k_{x,B,n}$ is related to $k_{r,B,n}$ by

$$k_{r,B,n}^2 + k_{x,B,n}^2 = \tilde{k}^2, \quad (9)$$

with $\tilde{k} = 2\pi f/\tilde{c}$ being the wave number in the fibrous material. From the linearized momentum equation, Eq. (6) yields the particle velocity in the axial direction as

$$u_{x,B}(r,x) = \frac{1}{\tilde{\rho}\omega} \sum_{n=0}^{\infty} k_{x,B,n} (B_n^+ e^{-jk_{x,B,n}x} - B_n^- e^{jk_{x,B,n}x}) \times \psi_{B,n}(r). \quad (10)$$

C. Wave propagation in domains III_a and III_b

Consider the central perforated dissipative expansion chamber of radius r_2 (domain III in Fig. 1) with a perforated screen of radius r_1 and porosity ϕ that separates the central airway (domain III_a), and the sound-absorbing material in the outer chamber between radii r_1 and r_2 (domain III_b). The pressure may then be expressed as

$$P_C(r,x) = \sum_{n=0}^{\infty} (C_n^+ e^{-jk_{x,C,n}x} + C_n^- e^{jk_{x,C,n}x}) \psi_{C,n,P}(r), \quad (11)$$

with

$$P_C(r,x) = \begin{cases} P_{III_a}(r,x), & 0 \leq r \leq r_1 \\ P_{III_b}(r,x), & r_1 \leq r \leq r_2 \end{cases}, \quad (12a)$$

and

$$\psi_{C,n,P}(r) = \begin{cases} \psi_{III_a,n,P}(r), & 0 \leq r \leq r_1 \\ \psi_{III_b,n,P}(r), & r_1 \leq r \leq r_2 \end{cases}, \quad (12b)$$

where subscripts C , III_a, III_b denote domains III, III_a, and III_b, respectively; C_n^+ and C_n^- the modal amplitudes; $k_{x,C,n}$ the axial wave number for both the central airway and absorbent material. The transverse modal eigenfunction for the pressure is given by

$$\psi_{C,n,P}(r) = \begin{cases} \psi_{III_a,n,P}(r) = C_1 J_0(k_{r,C,n}r) + C_2 Y_0(k_{r,C,n}r), & 0 \leq r \leq r_1 \\ \psi_{III_b,n,P}(r) = C_3 J_0(\tilde{k}_{r,C,n}r) + C_4 Y_0(\tilde{k}_{r,C,n}r), & r_1 \leq r \leq r_2 \end{cases}, \quad (13)$$

where $k_{r,C,n}$ and $\tilde{k}_{r,C,n}$ are the radial wave numbers for the air and fibrous material, respectively, which are related to $k_{x,C,n}$ by

$$k_{r,C,n}^2 + k_{x,C,n}^2 = k_0^2, \quad (14a)$$

$$\tilde{k}_{r,C,n}^2 + k_{x,C,n}^2 = \tilde{k}^2. \quad (14b)$$

The wave numbers can be obtained from the characteristic equation (derived from the boundary conditions of acoustic pressure and radial particle velocity at $r=0$, r_1 , and r_2) as¹⁵

$$\frac{\rho_0 \tilde{k}_{r,C,n}}{\tilde{\rho} k_{r,C,n}} \left[\frac{J_0(k_{r,C,n}r_1)}{J_1(k_{r,C,n}r_1)} + \frac{j\tilde{\xi}_p k_{r,C,n}}{k_0} \right] = \frac{J_0(\tilde{k}_{r,C,n}r_1)Y_1(\tilde{k}_{r,C,n}r_2) - Y_0(\tilde{k}_{r,C,n}r_1)J_1(\tilde{k}_{r,C,n}r_2)}{J_1(\tilde{k}_{r,C,n}r_1)Y_1(\tilde{k}_{r,C,n}r_2) - Y_1(\tilde{k}_{r,C,n}r_1)J_1(\tilde{k}_{r,C,n}r_2)}, \quad (15)$$

with $\tilde{\xi}_p$ (given in Appendix B) being the nondimensionalized perforate acoustic impedance, which relates the acoustic pressure in the inner duct and outer chamber through the interface. The coefficients $C_1 - C_4$ can also be expressed as

$$C_1 = 1, \quad (16a)$$

$$C_2 = 0, \quad (16b)$$

$$C_3 = \frac{k_{r,C,n}\tilde{\rho}}{\tilde{k}_{r,C,n}\rho_0} \times \frac{J_1(k_{r,C,n}r_1)Y_1(\tilde{k}_{r,C,n}r_2)}{J_1(\tilde{k}_{r,C,n}r_1)Y_1(\tilde{k}_{r,C,n}r_2) - J_1(\tilde{k}_{r,C,n}r_2)Y_1(\tilde{k}_{r,C,n}r_1)}, \quad (16c)$$

$$C_4 = -\frac{J_1(\tilde{k}_{r,C,n}r_2)}{Y_1(\tilde{k}_{r,C,n}r_2)} C_3 = -\frac{k_{r,C,n}\tilde{\rho}}{\tilde{k}_{r,C,n}\rho_0} \times \frac{J_1(k_{r,C,n}r_1)J_1(\tilde{k}_{r,C,n}r_2)}{J_1(\tilde{k}_{r,C,n}r_1)Y_1(\tilde{k}_{r,C,n}r_2) - J_1(\tilde{k}_{r,C,n}r_2)Y_1(\tilde{k}_{r,C,n}r_1)}. \quad (16d)$$

With the solution of the wave numbers from Eq. (15) and the coefficients $C_1 - C_4$ from Eq. (16), Eq. (13) yields the expression for the transverse modal eigenfunction of the pressure as

$$\psi_{C,n,p}(r) = \begin{cases} J_0(k_{r,C,n}r), & 0 \leq r \leq r_1 \\ C_5 \left[J_0(\tilde{k}_{r,C,n}r) - \frac{J_1(\tilde{k}_{r,C,n}r_2)}{Y_1(\tilde{k}_{r,C,n}r_2)} Y_0(\tilde{k}_{r,C,n}r) \right], & r_1 \leq r \leq r_2 \end{cases}, \quad (17a)$$

with

$$C_5 = \frac{Y_1(\tilde{k}_{r,C,n}r_2) \left[J_0(k_{r,C,n}r_1) + \frac{j\tilde{\xi}_p k_{r,C,n}}{k_0} J_1(k_{r,C,n}r_1) \right]}{J_0(\tilde{k}_{r,C,n}r_1) Y_1(\tilde{k}_{r,C,n}r_2) - J_1(\tilde{k}_{r,C,n}r_2) Y_0(\tilde{k}_{r,C,n}r_1)}. \quad (17b)$$

From the linearized momentum equation

$$u_{x,C}(r,x) = \begin{cases} \frac{j}{\rho_0 \omega} \frac{\partial P_{III_a}}{\partial x}, & 0 \leq r \leq r_1 \\ \frac{j}{\tilde{\rho} \omega} \frac{\partial P_{III_b}}{\partial x}, & r_1 \leq r \leq r_2 \end{cases}, \quad (18)$$

Eq. (17) yields the particle velocity in the axial direction as

$$u_{x,C}(r,x) = \frac{1}{\rho_0 \omega} \sum_{n=0}^{\infty} k_{x,C,n} (C_n^+ e^{-jk_{x,C,n}x} - C_n^- e^{jk_{x,C,n}x}) \times \psi_{C,n,u_x}(r), \quad (19)$$

with the transverse modal eigenfunction for the velocity being expressed as

$$\psi_{C,n,u_x}(r) = \begin{cases} J_0(k_{r,C,n}r), & 0 \leq r \leq r_1 \\ C_5 \frac{\rho_0}{\tilde{\rho}} \left[J_0(\tilde{k}_{r,C,n}r) - \frac{J_1(\tilde{k}_{r,C,n}r_2)}{Y_1(\tilde{k}_{r,C,n}r_2)} Y_0(\tilde{k}_{r,C,n}r) \right], & r_1 \leq r \leq r_2 \end{cases}. \quad (20)$$

D. Wave propagation in domains IV and V

The acoustic pressure and axial particle velocity in domains IV and V are similar to those in domains I and II, and can be readily expressed as

$$P_D(r,x) = \sum_{n=0}^{\infty} (D_n^+ e^{-jk_{x,D,n}(x-L_C)} + D_n^- e^{jk_{x,D,n}(x-L_C)}) \psi_{D,n}(r), \quad (21a)$$

$$P_E(r,x) = \sum_{n=0}^{\infty} (E_n^+ e^{-jk_{x,E,n}(x-L_C)} + E_n^- e^{jk_{x,E,n}(x-L_C)}) \psi_{E,n}(r), \quad (21b)$$

$$u_{x,D}(r,x) = \frac{1}{\tilde{\rho} \omega} \sum_{n=0}^{\infty} k_{x,D,n} (D_n^+ e^{-jk_{x,D,n}(x-L_C)} - D_n^- e^{jk_{x,D,n}(x-L_C)}) \psi_{D,n}(r), \quad (21c)$$

and

$$u_{x,E}(r,x) = \frac{1}{\rho_0 \omega} \sum_{n=0}^{\infty} k_{x,E,n} (E_n^+ e^{-jk_{x,E,n}(x-L_C)} - E_n^- e^{jk_{x,E,n}(x-L_C)}) \psi_{E,n}(r), \quad (21d)$$

where subscripts D and E denote domains IV and V, respectively; D_n^+ , D_n^- , E_n^+ , and E_n^- the amplitudes; with both the

eigenfunctions $\psi_{D,n}(r)$, $\psi_{E,n}(r)$ and wave numbers $k_{x,D,n}$, $k_{x,E,n}$ being similar to those of domains II and I.

E. Transmission loss prediction

With the pressure and particle velocity given by Eqs. (1), (5), (6), (10), (17), (19), and (21), transmission loss can then be obtained by solving the unknown coefficients A_n , B_n , C_n , D_n , and E_n using the boundary conditions at $x = -L_1$, 0 , L_C , and $L_C + L_2$. In view of Eqs. (10) and (21), the rigid boundary condition at the left ($x = -L_1$) and right ($x = L_C + L_2$) endplate of the chamber

$$u_{x,B} = 0, \quad \text{for } r_1 \leq r \leq r_2, \quad x = -L_1, \quad (22a)$$

and

$$u_{x,D} = 0, \quad \text{for } r_1 \leq r \leq r_2, \quad x = L_C + L_2, \quad (22b)$$

yields

$$B_n^+ = B_n^- e^{-2jk_{x,B,n}L_1}, \quad (23a)$$

$$D_n^- = D_n^+ e^{-2jk_{x,D,n}L_2}. \quad (23b)$$

At the interfaces of expansion ($x=0$) and contraction ($x=L_C$), the continuities of the acoustic pressure and axial velocity give

$$P_C = P_A, \quad \text{for } 0 \leq r \leq r_1, \quad x=0, \quad (24a)$$

$$P_C = P_B, \quad \text{for } r_1 \leq r \leq r_2, \quad x=0, \quad (24b)$$

$$u_{x,C} = \begin{cases} u_{x,A}, & \text{for } 0 \leq r \leq r_1, x=0 \\ u_{x,B}, & \text{for } r_1 \leq r \leq r_2, x=0 \end{cases} \quad (24c)$$

and

$$P_C = P_E, \quad \text{for } 0 \leq r \leq r_1, x=L_C, \quad (25a)$$

$$P_C = P_D, \quad \text{for } r_1 \leq r \leq r_2, x=L_C, \quad (25b)$$

$$u_{x,C} = \begin{cases} u_{x,E}, & \text{for } 0 \leq r \leq r_1, x=L_C \\ u_{x,D}, & \text{for } r_1 \leq r \leq r_2, x=L_C \end{cases} \quad (25c)$$

In view of the expressions of the pressure and velocity as infinite series of unknown amplitudes in Eqs. (1), (5), (6), (10), (17), (20), and (21), Eqs. (24) and (25) yield

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ + C_n^-) \psi_{C,n,P}(r) \\ &= \sum_{n=0}^{\infty} (A_n^+ + A_n^-) \psi_{A,n}(r), \quad \text{for } 0 \leq r \leq r_1, \end{aligned} \quad (26a)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ + C_n^-) \psi_{C,n,P}(r) \\ &= \sum_{n=0}^{\infty} (B_n^+ + B_n^-) \psi_{B,n}(r), \quad \text{for } r_1 \leq r \leq r_2, \end{aligned} \quad (26b)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} k_{x,C,n} (C_n^+ - C_n^-) \psi_{C,n,u_x}(r) \\ &= \begin{cases} \sum_{n=0}^{\infty} k_{x,A,n} (A_n^+ - A_n^-) \psi_{A,n}(r), & \text{for } 0 \leq r \leq r_1 \\ \frac{\rho_0}{\bar{\rho}} \sum_{n=0}^{\infty} k_{x,B,n} (B_n^+ - B_n^-) \psi_{B,n}(r), & \text{for } r_1 \leq r \leq r_2 \end{cases}, \end{aligned} \quad (26c)$$

and

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ e^{-jk_{x,C,n}L_C} + C_n^- e^{jk_{x,C,n}L_C}) \psi_{C,n,P}(r) \\ &= \sum_{n=0}^{\infty} (E_n^+ + E_n^-) \psi_{E,n}(r), \quad \text{for } 0 \leq r \leq r_1, \end{aligned} \quad (27a)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ e^{-jk_{x,C,n}L_C} + C_n^- e^{jk_{x,C,n}L_C}) \psi_{C,n,P}(r) \\ &= \sum_{n=0}^{\infty} (D_n^+ + D_n^-) \psi_{D,n}(r), \quad \text{for } r_1 \leq r \leq r_2, \end{aligned} \quad (27b)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} k_{x,C,n} (C_n^+ e^{-jk_{x,C,n}L_C} - C_n^- e^{jk_{x,C,n}L_C}) \psi_{C,n,u_x}(r) \\ &= \begin{cases} \sum_{n=0}^{\infty} k_{x,E,n} (E_n^+ - E_n^-) \psi_{E,n}(r), & \text{for } 0 \leq r \leq r_1 \\ \frac{\rho_0}{\bar{\rho}} \sum_{n=0}^{\infty} k_{x,D,n} (D_n^+ - D_n^-) \psi_{D,n}(r), & \text{for } r_1 \leq r \leq r_2 \end{cases}. \end{aligned} \quad (27c)$$

In order to solve Eqs. (26) and (27), the infinite series of unknown amplitudes needs to be truncated to a suitable number. In solving a similar problem, the acoustic field across the discontinuities was matched in Refs. 14 and 15 by imposing the continuities of the acoustic pressure/velocity integral over discrete zones at the expansion/contraction. For dissipative silencers with inlet/outlet extensions, another analytical approach¹⁸ proves to be more suitable to match the acoustic field across the interfaces of expansion/contraction. For the continuities of pressure at interfaces of $x=0$ and L_C , multiplying both sides of Eqs. (26a) and (27a) by $\psi_{A,s}dS$ or $\psi_{E,s}dS$ gives

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ + C_n^-) \langle \psi_{C,n,P} \psi_{A,s} \rangle_{0 \leq r \leq r_1} \\ &= \sum_{n=0}^{\infty} (A_n^+ + A_n^-) \langle \psi_{A,n} \psi_{A,s} \rangle_{0 \leq r \leq r_1}, \quad \text{for } s=0,1,\dots,\infty, \end{aligned} \quad (28)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ e^{-jk_{x,C,n}L_C} + C_n^- e^{jk_{x,C,n}L_C}) \langle \psi_{C,n,P} \psi_{E,s} \rangle_{0 \leq r \leq r_1} \\ &= \sum_{n=0}^{\infty} (E_n^+ + E_n^-) \langle \psi_{E,n} \psi_{E,s} \rangle_{0 \leq r \leq r_1}, \quad \text{for } s=0,1,\dots,\infty, \end{aligned} \quad (29)$$

with $\langle \rangle$ being the integration over the surface. Similarly, by multiplying $\psi_{B,s}dS$ or $\psi_{D,s}dS$, Eqs. (26b) and (27b) give

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ + C_n^-) \langle \psi_{C,n,P} \psi_{B,s} \rangle_{r_1 \leq r \leq r_2} \\ &= \sum_{n=0}^{\infty} (B_n^+ + B_n^-) \langle \psi_{B,n} \psi_{B,s} \rangle_{r_1 \leq r \leq r_2}, \quad \text{for } s=0,1,\dots,\infty, \end{aligned} \quad (30)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} (C_n^+ e^{-jk_{x,C,n}L_C} + C_n^- e^{jk_{x,C,n}L_C}) \langle \psi_{C,n,P} \psi_{D,s} \rangle_{r_1 \leq r \leq r_2} \\ &= \sum_{n=0}^{\infty} (D_n^+ + D_n^-) \langle \psi_{D,n} \psi_{D,s} \rangle_{r_1 \leq r \leq r_2}, \quad \text{for } s=0,1,\dots,\infty. \end{aligned} \quad (31)$$

By multiplying both sides of Eqs. (26c) and (27c) by $\psi_{C,s,u_x}dS$, the continuities of axial velocity at interfaces of $x=0$ and L_C provide

FIG. 2. Transmission loss of a perforated dissipative silencer with inlet/outlet extensions ($r_1=2.45$ cm, $r_2=8.22$ cm, $L=L_1+L_C+L_2=25.72$ cm, $L_1=L_2=2.4$ cm, $R=4896$ Rayls/m, $\phi=8\%$, $d_h=0.249$ cm, and $t_w=0.09$ cm).

$$\begin{aligned} & \sum_{n=0}^{\infty} k_{x,C,n}(C_n^+ - C_n^-) \langle \psi_{C,n,u_x} \psi_{C,s,u_x} \rangle_{0 \leq r \leq r_2} \\ &= \sum_{n=0}^{\infty} k_{x,A,n}(A_n^+ - A_n^-) \langle \psi_{A,n} \psi_{C,s,u_x} \rangle_{0 \leq r \leq r_1} \\ &+ \frac{\rho_0}{\bar{\rho}} \sum_{n=0}^{\infty} k_{x,B,n}(B_n^+ - B_n^-) \langle \psi_{B,n} \psi_{C,s,u_x} \rangle_{r_1 \leq r \leq r_2}, \\ & \text{for } s=0,1,\dots,\infty, \end{aligned} \quad (32)$$

$$\begin{aligned} & \sum_{n=0}^{\infty} k_{x,C,n}(C_n^+ e^{-jk_{x,C,n}L_C} - C_n^- e^{jk_{x,C,n}L_C}) \\ & \times \langle \psi_{C,n,u_x} \psi_{C,s,u_x} \rangle_{0 \leq r \leq r_2} \\ &= \sum_{n=0}^{\infty} k_{x,E,n}(E_n^+ - E_n^-) \langle \psi_{E,n} \psi_{C,s,u_x} \rangle_{0 \leq r \leq r_1} \\ &+ \frac{\rho_0}{\bar{\rho}} \sum_{n=0}^{\infty} k_{x,D,n}(D_n^+ - D_n^-) \langle \psi_{D,n} \psi_{C,s,u_x} \rangle_{r_1 \leq r \leq r_2}, \\ & \text{for } s=0,1,\dots,\infty. \end{aligned} \quad (33)$$

The expressions of the integrals $\langle \rangle$ in Eqs. (28)–(33) are provided in Appendix C.

To determine the transmission loss of the perforated dissipative silencers with inlet/outlet extensions: (1) the incoming wave is assumed to be planar and its magnitude A_0^+ is chosen to be unity for convenience, and (2) an anechoic termination is imposed at the exit by setting $E_n^- = 0$. Thus, in view of Eq. (23), Eqs. (28)–(33) give a large (theoretically infinite) number of relations $6(s+1)$ for a large number of unknowns $6(n+1)$. The unknowns are the magnitudes of incident and reflected waves in domains I–V (A_n^- , B_n^- , C_n^+ , C_n^- , D_n^+ , and E_n^+). Since higher modes have a diminishing effect on the solution, s and n can be truncated to N , resulting

in $6(N+1)$ equations with $6(N+1)$ unknowns. The value of N needed for a converged solution depends on the dimensions of the chamber, and the frequency range of interest. Once Eqs. (28)–(33) are solved, the transmission loss may be determined as

$$\text{TL} = -20 \log_{10} |E_0^+|, \quad (34)$$

under the assumption that all transmitted waves in the outlet pipe are nonpropagating modes except the first mode.

III. RESULTS AND DISCUSSION

For the perforated, dissipative circular expansion chamber with inlet/outlet extensions studied here (recall Fig. 1), the following base parameters are chosen: $r_1=2.45$ cm, $r_2=8.22$ cm, $L=L_1+L_C+L_2=25.72$ cm, $R=4896$ Rayls/m (for a filling density of 100 g/l), porosity of perforated duct $\phi=8\%$, thickness of the perforated duct $t_w=0.09$ cm, and diameter of the holes $d_h=0.249$ cm. With the exception of solid inlet/outlet extensions, this choice retains consistency with the configuration of Ref. 15.

Figure 2 presents the analytical results for the transmission loss of a perforated dissipative circular expansion chamber with extensions $L_1=L_2=2.4$ cm. To examine the accuracy of the analytical approach, the results from experiments (utilizing the two-microphone technique) and computations (BEM⁵) are also provided. For the current geometry and frequency range of interest, the analytical results are sufficiently accurate for $N \geq 9$; hence, $N=9$ is used in the remainder of the study. The analytical results agree well with those of BEM, and show a reasonable comparison with the measurements. The transmission loss of this silencer has a peak value at the resonance frequency around 1200 Hz, and exceeds 30 dB at a relatively broad frequency range ($770 \text{ Hz} \leq f \leq 1650 \text{ Hz}$.) The difference between predictions and measurements is attributed to the approximations in-

volved in expressions for absorbing material properties and perforation impedance, and filling/texturization method used in the experiment.

Analytical TL predictions for perforated dissipative expansion chambers with different lengths of inlet/outlet extensions (L_1, L_2) are presented in Fig. 3, while retaining the same total length (L). Figure 3(a) shows results for silencers with $L_2=0$ and varying L_1 ; Fig. 3(b) with $L_1=L_2$ and varying lengths; Fig. 3(c) with $L_1 \neq L_2$ and varying lengths. The no-extension ($L_1=L_2=0$) base case is also included in these figures for comparison. Figures 3(a)–(c) reveal that: (1) the extensions do not influence the low-frequency behavior, as could partially be inferred from earlier empty silencer results;¹⁸ (2) increasing extension lengths reduces TL at high frequencies; and (3) relatively small extensions improve TL in midfrequency range: Note, for example, the silencer of Fig. 3(b) with $L_1=L_2=3.5$ cm with improved attenuation (40 dB at the frequency range of $980 \text{ Hz} \leq f \leq 1450 \text{ Hz}$). Further increase in extension lengths may suppress the attenuation relative to the no-extension case: Note, for example, the $L_1=L_2=7.5$ cm configuration in Fig. 3(b). The results in Figures 3(a)–(c) for filled silencers may be contrasted to their counterparts in Figs. 4(a)–(c) with the filling and perforations removed, while retaining the same geometry.

Using the same pairs of inlet/outlet extensions in Fig. 3, the attenuation performance in the absence of perforated screen is presented in Fig. 5. The effect of extensions at low- and high-frequency regions are qualitatively similar to Fig. 3, while the reduction in TL is smaller in the absence of perforations. Attenuation in midrange frequencies shows some qualitative similarity to that of Fig. 3, for example, in terms of some augmentation with shorter extensions and deterioration at longer extensions [see, for example, Fig. 5(b)]. The same midrange also exhibits the differences such as: (1) the longer extensions in the absence of perforations do not hinder the TL as much; and (2) the resonances tend to move to different frequencies and length combinations.

Analytical transmission loss for perforated dissipative silencers with different flow resistivities ($R=1000, 4896$, and $17\,378$ Rayls/m) are presented in Fig. 6, as contrasted to the limiting case of an empty chamber. The relative behavior is frequency dependent, with higher flow resistivity reducing TL at low frequencies and improving at high frequencies. The performance of the base model (with $R=4896$ Rayls/m) is better than the other three silencers at frequencies below 1400 Hz.

The effect of perforation porosity ($\phi=2\%$, 8% , and 50%) is shown in Fig. 7, in comparison with the limiting case of removed perforations. High porosity improves the attenuation at relatively high frequencies, whereas the lower porosities ($\phi=2\%$ and 8%) introduce resonances at low to midfrequency range, thereby improving TL. The behavior of the silencer with $\phi=2\%$ resembles that of a Helmholtz resonator, while the one with $\phi=50\%$ exhibits a behavior similar to that of no perforations, as expected.

IV. CONCLUDING REMARKS

The acoustic attenuation performance of a perforated single-pass, concentric cylindrical dissipative expansion

FIG. 3. Transmission loss of perforated dissipative silencers with varying lengths of inlet/outlet extensions ($r_1=2.45$ cm, $r_2=8.22$ cm, $L=25.72$ cm, $R=4896$ Rayls/m, $\phi=8\%$, $d_h=0.249$ cm, and $t_w=0.09$ cm). (a) $L_2=0$ and varying L_1 ; (b) $L_1=L_2$ and varying lengths; (c) $L_1 \neq L_2$ and varying lengths.

FIG. 4. Transmission loss of expansion chamber type silencers with varying lengths of inlet/outlet extensions ($r_1=2.45$ cm, $r_2=8.22$ cm, $L=25.72$ cm). (a) $L_2=0$ and varying L_1 ; (b) $L_1=L_2$ and varying lengths; (c) $L_1 \neq L_2$ and varying lengths.

FIG. 5. Effect of inlet/outlet extensions length on the transmission loss of dissipative silencers without perforated screen ($r_1=2.45$ cm, $r_2=8.22$ cm, $L=25.72$ cm, $R=4896$ Rayls/m). (a) $L_2=0$ and varying L_1 ; (b) $L_1=L_2$ and varying lengths; (c) $L_1 \neq L_2$ and varying lengths.

FIG. 6. Transmission loss of perforated dissipative extended silencers with different flow resistivities ($r_1 = 2.45$ cm, $r_2 = 8.22$ cm, $L = 25.72$ cm, $L_1 = L_2 = 3.5$ cm, $\phi = 8\%$, $d_h = 0.249$ cm, and $t_w = 0.09$ cm).

chamber with inlet/outlet extensions has been investigated by using a two-dimensional, closed-form analytical approach. With the expressions of the acoustic eigenvalues and eigenfunctions in various domains of the silencer, the transmission loss of the silencer is obtained analytically by utilizing the continuities of the acoustic pressure and particle velocity. The expected agreement between the analytical and BEM results has been illustrated for a specific configuration. These results, in turn, compare reasonably well with the measured TL. The acoustic attenuation of dissipative silencers with inlet/outlet extensions is also compared with their counterparts with the filling or perforations removed. The effects of length extensions, absorbent resistivity, and perforation porosity on the acoustic attenuation of the silencers have been illustrated.

APPENDIX A: ACOUSTICAL PROPERTIES OF FIBROUS MATERIAL

The acoustic properties of the fibrous material are characterized by the complex-valued characteristic impedance \tilde{Z} $= \tilde{\rho}\tilde{c}$ and wave number $\tilde{k} = 2\pi f/\tilde{c}$, expressed as

$$\frac{\tilde{Z}}{Z_0} = [1 + 0.855(f/R)^{-0.754}] + j[-0.0765(f/R)^{-0.732}], \quad (\text{A1})$$

$$\frac{\tilde{k}}{k} = [1 + 0.1472(f/R)^{-0.577}] + j[-0.1734(f/R)^{-0.595}], \quad (\text{A2})$$

FIG. 7. Transmission loss of perforated dissipative extended silencers with different perforation porosities ($r_1 = 2.45$ cm, $r_2 = 8.22$ cm, $L = 25.72$ cm, $L_1 = L_2 = 3.5$ cm, $R = 4896$ Rayls/m, $d_h = 0.249$ cm, and $t_w = 0.09$ cm).

with $Z_0 = \rho_0 c_0$ being the characteristic impedance of the air, and R [mks Rayls/m] the flow resistivity.

$$\tilde{\zeta}_p = [0.006 + jk_0(t_w + 0.75d_h)]/\phi, \quad (\text{B1})$$

APPENDIX B: ACOUSTIC IMPEDANCE OF PERFORATES

In Eq. (15), the nondimensionalized perforate acoustic impedance $\tilde{\zeta}_p$ relates the acoustic pressure in the inner duct and outer chamber through the interface. An empirical expression for the acoustic impedance of perforate holes facing air is presented as²²⁻²⁴

with ϕ being the porosity. In the presence of absorbent (for perforations facing absorbing material), Eq. (B1) has been modified as

$$\tilde{\zeta}_p = \left[0.006 + jk_0 \left\{ t_w + 0.375d_h \left(1 + \frac{\tilde{Z}}{Z_0} \frac{\tilde{k}}{k_0} \right) \right\} \right] / \phi. \quad (\text{B2})$$

APPENDIX C: INTEGRALS IN EQS. (28)–(33)

From the integral relations for Bessel functions of any kind, $B_0(k_s r)$ and $B_0(k_n r)$

$$\int r B_0(k_s r) B_0(k_n r) dr = \begin{cases} \frac{r}{k_s^2 - k_n^2} [k_s B_1(k_s r) B_0(k_n r) - k_n B_0(k_s r) B_1(k_n r)], & k_s \neq k_n \\ \frac{r^2}{2} [B_0^2(k_s r) + B_1^2(k_s r)], & k_s = k_n \end{cases}, \quad (\text{C1})$$

the integrals in Eqs. (28)–(33) can be obtained as

$$\langle \psi_{A,n} \psi_{A,s} \rangle_{0 \leq r \leq r_1} = \begin{cases} \frac{r_1^2}{2} J_0^2(k_{r,A,n} r_1) & n = s, \\ 0 & n \neq s, \end{cases} \quad (\text{C2})$$

$$\langle \psi_{B,n} \psi_{B,s} \rangle_{r_1 \leq r \leq r_2} = \begin{cases} \frac{1}{2}(r_2^2 - r_1^2) & \text{for } n = s = 0, \\ \frac{1}{2}[r_2^2 \psi_{B,s}^2(r_2) - r_1^2 \psi_{B,s}^2(r_1)] & \text{for } n = s = 1, 2, \dots, \\ 0 & \text{for } n \neq s, \end{cases} \quad (\text{C3})$$

$$\langle \psi_{C,n,u_x} \psi_{C,s,u_x} \rangle_{0 \leq r \leq r_2} = \begin{cases} \frac{r_1^2}{2} J_0^2(k_{r,C,s} r_1) + \frac{r_2^2}{2} \left(\frac{\rho_0}{\bar{\rho}} \right)^2 \{ [C_3 J_0(\tilde{k}_{r,C,s} r_2) + C_4 Y_0(\tilde{k}_{r,C,s} r_2)]^2 + [C_3 J_1(\tilde{k}_{r,C,s} r_2) + C_4 Y_1(\tilde{k}_{r,C,s} r_2)]^2 \} \\ - \frac{r_1^2}{2} \left(\frac{\rho_0}{\bar{\rho}} \right)^2 \{ [C_3 J_0(\tilde{k}_{r,C,s} r_1) + C_4 Y_0(\tilde{k}_{r,C,s} r_1)]^2 + [C_3 J_1(\tilde{k}_{r,C,s} r_1) + C_4 Y_1(\tilde{k}_{r,C,s} r_1)]^2 \} & \text{for } n = s, \\ 0 & \text{for } n \neq s, \end{cases} \quad (\text{C4})$$

$$\langle \psi_{D,n} \psi_{D,s} \rangle_{r_1 \leq r \leq r_2} = \begin{cases} \frac{1}{2}(r_2^2 - r_1^2) & \text{for } n = s = 0, \\ \frac{1}{2}[r_2^2 \psi_{D,s}^2(r_2) - r_1^2 \psi_{D,s}^2(r_1)] & \text{for } n = s = 1, 2, \dots, \\ 0 & \text{for } n \neq s, \end{cases} \quad (\text{C5})$$

$$\langle \psi_{E,n} \psi_{E,s} \rangle_{0 \leq r \leq r_1} = \begin{cases} \frac{r_1^2}{2} J_0^2(k_{r,E,n} r_1) & \text{for } n = s, \\ 0 & \text{for } n \neq s, \end{cases} \quad (\text{C6})$$

$$\langle \psi_{C,n,u_x} \psi_{A,s} \rangle_{0 \leq r \leq r_1} = \begin{cases} r_1^2 [J_0^2(k_{r,A,s} r_1) + J_1^2(k_{r,C,n} r_1)], & \text{for } k_{r,A,s} = k_{r,C,n} \\ \frac{r_1 [k_{r,C,n} J_1(k_{r,C,n} r_1) J_0(k_{r,A,s} r_1) - k_{r,A,s} J_0(k_{r,C,n} r_1) J_1(k_{r,A,s} r_1)]}{k_{r,C,n}^2 - k_{r,A,s}^2}, & \text{for } k_{r,A,s} \neq k_{r,C,n} \end{cases}, \quad (\text{C7})$$

$$\begin{aligned}
& \langle \psi_{C,n,u_x} \psi_{B,s} \rangle_{r_1 \leq r \leq r_2} \\
& = C_3 \frac{\rho_0}{\bar{\rho}} \left\{ \begin{aligned} & \frac{r_2^2}{2} \left[J_0(\bar{k}_{r,C,n} r_2) - \frac{J_1(\bar{k}_{r,C,n} r_2)}{Y_1(\bar{k}_{r,C,n} r_2)} Y_0(\bar{k}_{r,C,n} r_2) \right]^2 - \frac{r_1^2}{2} \left[J_0(\bar{k}_{r,C,n} r_1) - \frac{J_1(\bar{k}_{r,C,n} r_1)}{Y_1(\bar{k}_{r,C,n} r_1)} Y_0(\bar{k}_{r,C,n} r_1) \right]^2, \quad \bar{k}_{r,C,n} = k_{r,B,s} \\ & \frac{r_2 \bar{k}_{r,C,n}}{\bar{k}_{r,C,n}^2 - k_{r,B,s}^2} \left[J_1(\bar{k}_{r,C,n} r_2) + \frac{C_4}{C_3} Y_1(\bar{k}_{r,C,n} r_2) \right] \left[J_0(k_{r,B,s} r_2) - \frac{J_1(k_{r,B,s} r_2)}{Y_1(k_{r,B,s} r_2)} Y_0(k_{r,B,s} r_2) \right] \\ & - \frac{r_1 \bar{k}_{r,C,n}}{\bar{k}_{r,C,n}^2 - k_{r,B,s}^2} \left[J_1(\bar{k}_{r,C,n} r_1) + \frac{C_4}{C_3} Y_1(\bar{k}_{r,C,n} r_1) \right] \left[J_0(k_{r,B,s} r_1) - \frac{J_1(k_{r,B,s} r_1)}{Y_1(k_{r,B,s} r_1)} Y_0(k_{r,B,s} r_1) \right], \quad \bar{k}_{r,C,n} \neq k_{r,B,s} \\ & + \frac{r_1 k_{r,B,s}}{\bar{k}_{r,C,n}^2 - k_{r,B,s}^2} \left[J_0(\bar{k}_{r,C,n} r_1) + \frac{C_4}{C_3} Y_0(\bar{k}_{r,C,n} r_1) \right] \left[J_1(k_{r,B,s} r_1) - \frac{J_1(k_{r,B,s} r_1)}{Y_1(k_{r,B,s} r_1)} Y_0(k_{r,B,s} r_1) \right] \end{aligned} \right. \quad (C8)
\end{aligned}$$

(Received 29 February 2004; revised 8 January 2005; accepted 10 January 2005)

The classical description of porous media as a homogeneous equivalent fluid is presented, and its foundations on the homogenization method is introduced and applied to the numerical prediction model for a periodic porous medium composed by face centered cubic sphere packing on which measurements have been made. The results are compared with existing numerical results in the literature and with new and experimental data. © 2005 Acoustical Society of America.

I. INTRODUCTION

Noise reduction is currently a major issue, especially in aeronautics. One possible way to handle the problem among several others such as reducing noise production by engines or enhancing the design of gears, and other mechanical components, is to absorb sound close to where it is produced (e.g., inside the turboengines of aircraft). This approach requires the development of acoustic liners made of materials withstanding temperatures (up to 1000 K).¹

As polymers are unsuitable for those temperatures, the remaining material classes are metals and ceramics. However, these materials are rigid with very low intrinsic damping factors. Thus, the only way to absorb sound with them is to design a porous structure.

In this paper we deal with a particular choice of porous structure, face centered cubic (FCC) packing of spheres, as shown in Fig. 1. However, most of the methods presented in this paper can be applied to other rigid porous materials with an open porosity like metal foams and felts and particularly to porous media with a periodic structure for which the acoustical properties can be computed.

In this paper we begin with an introduction to the classical modeling of porous medium acoustics (Sec. II) followed by homogenization theory, which is usually presented as a rigorous derivation of the hypotheses required by the classical models (Sec. III), and is applied (Sec. IV) to predict the acoustic properties of a FCC packing of spheres via a numerical method. Comparisons are made with results available in the literature.

II. CLASSICAL APPROACH

Since the seminal paper of Kirchhoff,² the underlying physics of the phenomena of sound propagation and absorption in a porous material has been well known. It remains the

basis for the phenomenological models to which numerical calculations can be compared. The hypothesis and the methods used in the classical approach are recalled in Sec. II A. An applied review of the models available in the literature for different hypothesis on the structure of the porous media is given in Sec. II B which allows the presentation of a general model including all those existing as special cases.

A. Fundamental hypotheses and method in the classical approach

In Kirchhoff's model for the propagation of sound in a tube, the air, carrying the acoustic wave is a viscous, thermally conducting, Newtonian fluid, and its thermodynamic properties are well described as an ideal gas. The solid fraction of the porous material is assumed rigid and at a uniform, constant temperature. These hypotheses are valid for common cellular materials made of metal or ceramics for which the stiffness of the solid skeleton is much higher than the bulk modulus of the air and the heat capacity of the solid fraction is much higher than that of the air.

In the present work, consideration is restricted to the absorptive behavior of the porous material at equilibrium, i.e., at room temperature and without any main gas stream. Moreover, the acoustic waves are assumed to be of low amplitude to remain in the linear acoustics regime. It is thus easy to work in the harmonic regime by applying a Fourier time transform.
