Do the present data show evidence for loudness constancy defined in this way? The answer is clearly negative: Note that perfect constancy would mean that all of the identical-distance, identical-power sources used in the present experiment should be judged to be equally loud, i.e., the matches should fall on the 0-dB (reference) circle in Fig. 2, or on the 0-dB horizontal in Figs. 5 and 6. That, obviously, is not the case. Nevertheless, subjects might have a tendency to preserve constancy to varying degrees, thus producing different amounts of bias towards the zero line. Potentially, they could do so by using the localization and timbre cues available, as well as the fact that the loudspeakers producing the sounds are in plain view.

The constancy problem is related to that of the "listening attitude" a participant might adopt: In a pioneering investigation of loudness constancy (Mohrmann, 1939), this was operationalized as judging hidden sources at various distances while either adopting a sender attitude ("Sendereinstellung;" p. 155), or a receiver attitude ("Empfangseinstellung") which yielded appreciably different results. In modern terminology one would refer to judging the distal stimulus vs the proximal stimulus, and in the present situation that would be equivalent to judging the sound power of the loudspeaker as opposed to judging how it affects the listener. It is unclear, however, whether subjects can make that distinction in an anechoic situation, and the present authors know of no published reports implementing the instructional variations required.

Nevertheless, it may safely be said that a "bias" towards constancy can only play a minor role in accounting for the present data. The fact that knowing the individual HRTFs goes such a long way in accounting for the idiosyncrasies seen in the matches argues against constancy being a major factor in directional loudness perception, at least for the synthetic sounds and the anechoic environment studied here.

VI. CONCLUSIONS

(1) Loudness matches obtained with narrow-band noises in an anechoic environment showed that loudness is not constant over sound incidence angles. Rather, directional loudness sensitivities varied by up to 10 dB in individual, and up to 8 dB in averaged data.
(2) The directional effects on loudness showed considerable dependency on center frequency, with greater directional effects being observed at higher center frequencies, and to some extent on the overall sound-pressure level of the stimuli.
(3) Large, but highly reliable individual differences in directional loudness perception were observed.
(4) The individual patterns of directional loudness could largely be accounted for by the corresponding changes in physical stimulation, as determined by head-related transfer functions (HRTFs).
(5) These transfer functions were utilized for modeling binaural loudness based on the at-ear sound-pressure levels encountered. A 3-dB binaural loudness-summation ("power-summation") rule predicted the obtained mean data best, but sizable interindividual differences remained, even after the effect of individual HRTFs was taken into account.
(6) The results can be used for predicting loudness in any type of sound field (be it free, diffuse, or directional, resulting in diotic or dichotic at-ear signals) using a dummy head.

ACKNOWLEDGMENTS

The authors would like to thank Claus Vestergaard Skipper for his help in setting up the apparatus used in the present experiment. Henrik Møller and Dorte Hammershøi are thanked for their advice on how to carry out HRTF measurements. Pauli Minnaar helped in analyzing the HRTFs and with including them in the modeling, Florian Wickelmaier advised us with the statistical analyses. We would further like to thank Brian C.J. Moore for giving us access to and advice in utilizing his loudness model. Finally, we would like to thank the participants for their patience and devotion donated to extensive and at times exhaustive listening tests. This research was carried out as part of the "Centercontract on Sound Quality" which establishes participation in and funding of the "Sound Quality Research Unit" (SQRU) at Aalborg University. The participating companies are Bang & Olufsen, Brüel & Kjær, and DELTA Acoustics & Vibration. Further financial support comes from the Ministry for Science, Technology, and Development (VTU), and from the Danish Research Council for Technology and Production (FTP).

[1]Directional loudness sensitivities are thus defined in loose analogy to the directivity characteristics of microphones (Beranek, 1986, Chap. 6). Being the inverse of the relative sound-pressure level required to produce a loudness match, they are—despite the similarity in terms—not related to sensitivity parameters (such as d') as conceptualized in signal detection theory (Green and Swets, 1988).

[2]These predictions were made both for the individual and the mean data, essentially yielding the same conclusions. Thus, only the results for the mean data are presented here.

[3]Even though a 20-dB range may not appear sufficient to investigate the effects of overall level, note that when considering the extra headroom required for the adaptive starting values (±10 dB), and HRTF effects boosting or attenuating levels by approximately the same amount, the effective range listeners were exposed to in the experiment was quite large, covering what can be handled in a loudness-matching experiment without encountering floor ("too soft") or ceiling ("too annoying") problems.

(Received 6 September 2005; revised 20 February 2006; accepted 27 February 2006)

NoSπ thresholds for a 500-Hz tonal signal were measured with broadband and with narrowband maskers using a single-interval adaptive matrix procedure [C. Kaernbach, J Acoust. Soc. Am. **88**, 2645–2655 (1990)]. The purpose of the study was to investigate and to account for the effects on thresholds of varying the durations of the signals and maskers and the durations of forward masking fringes that preceded the occurrence of signal-plus-noise. For detection in both broadband and narrowband noise, the addition of brief forward fringes of masking noise resulted in elevations in threshold for the shortest signal durations. Longer forward fringes led to larger decreases in threshold when the masker was broadband as compared to when the masker was narrowband. The complex patterning of the data was explained by the operation of: (1) "predetection" temporal integration associated with peripheral auditory filtering; (2) duration-dependent, across-frequency influences that differentially affect broadband and narrowband NoSπ thresholds, (3) "post-detection" temporal integration associated with the central binaural mechanism, and (4) consideration of the detection thresholds in terms of changes in interaural correlation rather than in terms of signal level or signal-to-noise ratio, *per se*. © *2006 Acoustical Society of America.*

I. INTRODUCTION

In 1966, McFadden reported two important findings concerning the detection of a tonal signal masked by broadband noise when the stimuli were presented in the NoSπ configuration. The first finding was that thresholds of detection were elevated when the masking noise was pulsed on and off simultaneously with the signal, as compared to when the masking noise was presented continuously. The second finding was that thresholds lower than those measured when the masking noise was pulsed on and off simultaneously were obtained when the masking noise had a "forward fringe" that began prior to the presentation of the otherwise pulsed signal and masker. When the duration of the forward fringe of masking noise reached 600 ms, thresholds were essentially equal to those measured with continuous masking noise. We refer to the first finding as the "pulsed effect" and the second finding as the "forward fringe effect." McFadden's general results have been replicated and extended in several studies designed to reveal whether and to what degree each of the effects depends upon parameters of the signals and maskers, including their duration, spectrum, and interaural configuration (e.g., Robinson and Trahiotis, 1972; Gilkey *et al.*, 1990; Yost, 1985). The studies cited above also demonstrated that neither the pulsed effect nor the forward fringe effect was observed when both maskers and signals are presented diotically in the NoSo configuration. That is, the two effects were only observed when detection was based on binaural cues.[1]

The beneficial effects of forward fringes of masking noise on binaural signal detection notwithstanding, other studies have indicated that forward and/or backward temporal fringes of masking noise generally hamper performance. Those studies have reported that preceding and/or trailing diotic noise led to *increased* thresholds for discrimination of interaural temporal disparities (ITDs) and interaural intensitive disparities (IIDs) (e.g., Gilkey *et al.*, 1990; Bernstein *et al.*, 2001; Akeroyd and Bernstein, 2001). The results of these studies were explained by assuming that the listener effectively averages binaural information via a temporal window that exceeds the duration of the brief target. Such averaging of the target-based binaural information with the masker-based binaural information would effectively dilute the binaural information conveyed by the target, leading to increases in threshold. Similarly, assuming the operation of such a temporal window, one might expect that adding a forward fringe of diotic noise to a NoSπ stimulus would render the signal *less* detectable.

An experimental condition employed by Yost (1985) is especially pertinent. Yost inserted a temporal gap between the offset of a 500-ms-long forward fringe and the onset of a NoSπ signal plus masker. He found that progressively increasing the temporal gap progressively increased thresholds. This outcome seems *opposite* to the decreases in threshold that would be expected if the listener processed the binaural information through a temporal window. One might expect that increasing the temporal gap would result in there being

included *lesser* amounts of diotic noise within the temporal window and, therefore, *less* dilution of the signal-plus-noise-based binaural cues. This would, in turn, lead to *lower* thresholds of detection.

The purpose of this study was to investigate these issues. To that end, NoSπ thresholds were measured with both broadband and narrowband maskers while varying independently the durations of the signals and maskers and the durations of forward masking fringes. The inclusion of narrowband masking conditions was considered important because two prior "pilot studies" indicated that the forward fringe effect was minimal or absent when the masker was a narrowband of noise centered on the frequency of the signal. The durations of the stimuli were varied in a manner similar to, but with a finer "grain," than that employed by Robinson and Trahiotis (1972). Robinson and Trahiotis (1972) always gated their masking noise and signal such that the masking noise was at steady-state level during the 5-ms rise/decay of the tonal signal. Thus, even in their "no fringe" condition, there actually was 5 ms of masking noise preceding and following the steady-state portion of the signal. It occurred to us that such short "fringes" of diotic masking noise could, via an averaging process, dilute the binaural information conveyed by the NoSπ stimulus. In order to evaluate this hypothesis, it was deemed necessary to include measures of NoSπ detection thresholds in a true "no-fringe" condition, wherein signals and maskers are gated on and off simultaneously with the same rise/decay times.

It will be seen that the complex patterning of the data can be explained by the operation of: (1) a "predetection" temporal integration associated with peripheral auditory filtering; (2) duration-dependent, across-frequency influences that differentially affect broadband and narrowband NoSπ thresholds, and (3) a separate "post-detection" temporal integration associated with the central binaural mechanism.

II. EXPERIMENT 1

A. Procedure

Binaural (NoSπ) detection thresholds were measured for 500-Hz tonal signals presented against a background of broadband noise (bandwidth 100–3000 Hz) or narrowband noise (450–550 Hz). In both cases, the spectrum level of the noise was equivalent to 45 dB SPL. Data were obtained using a single-interval, "yes/no" task. This type of task was chosen for two reasons. First, as shown by McFadden (1966), the pulsed effect is larger when the task is single interval than it is when a two-interval, forced-choice task is employed. Second, studies following McFadden's that investigated the pulsed effect and the forward fringe effect and to which we wished to compare our data (e.g., Robinson and Trahiotis, 1972; Yost, 1985) also employed single-interval procedures.

In order to obtain thresholds more efficiently than could be done using "fixed" conditions (i.e., a method of constant stimuli), data were collected using the single-interval adaptive matrix (SIAM) procedure described and evaluated by Kaernbach (1990). Each trial consisted of a 500-ms warning interval and a single observation interval during which a visual display on a computer monitor marked the potential occurrence of the signal. Noise alone trials and signal-plus-noise trials were presented randomly with equal *a priori* probability. Correct-answer feedback was provided via the computer monitor for 400 ms after the listener responded followed by a 400-ms pause before the beginning of the next trial. The procedure was used to target 75% correct performance. As discussed by Kaernbach (1990, p. 2649), this required the level of the signal to be reduced by one step-size unit after each "hit," increased by one step-size unit after each "miss," increased by two step-size units after each "false alarm," and left unchanged after each "correct rejection." In order to minimize the errors of estimation of threshold, the step size was initially 2 dB and was reduced to 1 dB after the first two "reversals," a run was terminated after 16 reversals, and threshold was defined as the average level of the signal across the last 12 reversals (see Kaernbach 1990, Fig. 6, p. 2651).

Prior to the collection of formal data, detection thresholds yielded by the SIAM procedure were "validated" by comparing them to thresholds obtained with a single-interval fixed procedure in which a maximum probability correct $[p(c)_{\max}]$ of 0.75 was derived from the psychometric function relating 10 log d' to 10 log E/No (see Egan, 1965). Four young adults, two of whom were to participate in the main experiments, served as listeners. Because the two sets of thresholds proved to be, for all practical purposes, equivalent, all of the data to be reported here were collected using the more efficient SIAM procedure.

When the broadband maskers were employed, signals and maskers were each gated on and off using 5-ms $\cos^2$ ramps. The total durations of the tonal signals (including the ramps) were 10, 20, 40, 125, or 500 ms. When the narrowband maskers were employed, signals and maskers were each gated on and off using 10-ms $\cos^2$ ramps and the total durations of the tonal signals were 20, 40, 125, or 500 ms. The on/off ramp durations were increased to 10-ms $\cos^2$ when narrowband maskers were employed in order to effectively confine the spectrum of the stimuli to their nominal bandwidth of 100 Hz and thereby guard against detection of the signal on the basis of spectral "splatter" (e.g., Leshowitz and Wightman, 1971; Wightman, 1971). The spectral content of the forward fringe matched that of the masking noise in both the broadband and the narrowband conditions.

In the pulsed conditions, noise and signals were gated on and off simultaneously. In the "forward fringe" conditions, the onset of the noise preceded the onset of the signal by 2.5, 5, 10, 15, 30, 60, 125, 250, or 500 ms and the offset of the noise always occurred 5 ms after the offset of the signal. That is, in all of the forward-fringe conditions, there was also a 5-ms "backward" fringe. A condition in which the signal was masked by a continuous masker was not included as a reference condition (as has been the case in earlier studies). This decision was made for two reasons. First, the major focus of the study was to reveal and understand forward fringe effects on detection thresholds. Therefore, it was deemed necessary to measure those effects while holding constant and keeping brief, the duration of any "backward" fringe of masking noise. Second, the employment of 500-ms-

long forward fringe conditions virtually assured performance very close or equivalent to that measured in continuous noise (e.g., McFadden, 1966; Robinson and Trahiotis, 1972; Yost, 1985). All stimuli were generated digitally with a sampling rate of 20 kHz via a custom software library (MLSIG) running within MATLAB©, were converted to analog form via a TDT PD1, and were low-passed filtered at 8.5 kHz (TDT FLT1) before being presented via matched TDH-39 earphones.

The noise and signal waveforms were each selected randomly from within their own two-second-long buffers that were generated anew prior to each adaptive run. The relative levels of the stimuli and their rise-decay ramps were controlled via software and the absolute levels of the stimuli were determined by programmable attenuators (TDT PA4) in a manner that maximized the use of the 16-bit range of the digital-to-analog converters.

Four young adults (one male and three female) with audiometrically normal hearing served as listeners. Thresholds were obtained with broadband maskers before they were obtained with the narrowband maskers. Because one of the original female listeners was unavailable to participate in the experiment after the broadband masking thresholds were obtained, she was replaced with another female listener who only participated in the narrowband stimulus conditions. Thresholds were measured using blocks of conditions for which the duration of the tonal signal was held constant. When the broadband masker was employed, the durations were visited in the order of 20, 125, 500, 10, and 40 ms and the durations of the forward fringe employed within each block were chosen pseudorandomly. At the beginning of the testing for each duration, two thresholds were obtained in the pulsed (i.e., no fringe) condition and then one threshold was obtained for each forward fringe condition until all fringe durations were exhausted. Then, the forward fringe conditions were revisited in reverse order. Overall, this yielded two estimates of threshold for the pulsed and for each forward fringe condition. The same sequence of testing was repeated twice more. In this manner, a total of six estimates of threshold was obtained for the pulsed and for each forward fringe condition. The same scheme was used for the collection of thresholds when the narrowband masker was employed. For that set of thresholds the durations were visited in the order 20, 125, 40, and 500 ms.

Thresholds were calculated by first omitting the lowest and highest of the six estimates of threshold for each stimulus condition and then computing the mean of the remaining four. For about 9% of the 360 estimates of threshold (90 stimulus conditions $\times$ four listeners), the standard deviation of the four estimates exceeded 3 dB. In those instances, additional measures of threshold were obtained substituting the new measures one-for-one with the "oldest" measures until the four estimates of threshold yielded a standard deviation of less than 3 dB. This typically required the measurement of two additional thresholds. The data were scrutinized to determine whether "order effects" were present and none was found.

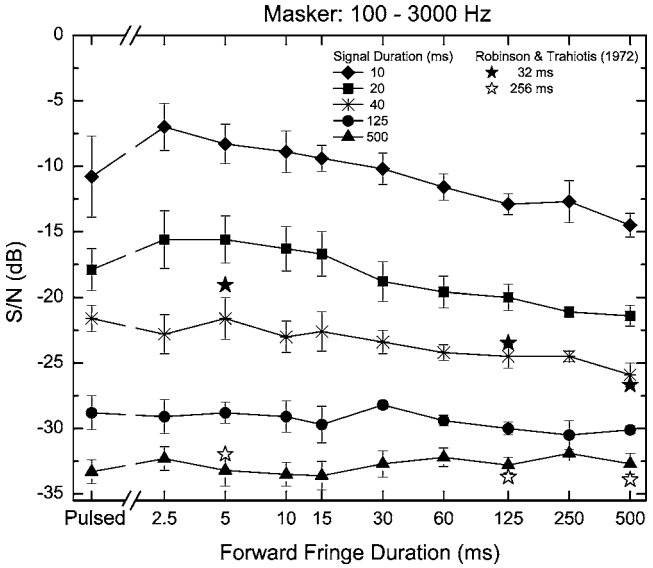

FIG. 1. NoSπ threshold signal-to-noise ratio (S/N) in decibels plotted as a function of forward fringe duration. The data represent the thresholds averaged across four listeners when the masker was broadband. Error bars represent ±1 standard error of the mean. The parameter of the plot is the duration of the signal. Data plotted as stars represent thresholds obtained by Robinson and Trahiotis (1972), after adjustment as described in the text.

B. Results

Figure 1 displays thresholds of NoSπ detection obtained with the broadband masker and averaged across the four listeners. Thresholds are reported in terms of signal-to-noise ratio (S/N) (the ratio of the total power of the signal to the total power of the noise, in decibels), calculated across the 2900-Hz bandwidth of the masker, as a function of the duration of the forward fringe of the masking noise. The error bars represent ± one standard error of the mean. The reader is reminded that all of the forward fringe conditions also had a "backward" temporal fringe of 5 ms and the pulsed condition is the one in which the signal and noise were gated on and off simultaneously. Thresholds obtained in the pulsed condition, in which there was neither a forward fringe nor a backward fringe, are plotted to the left of the break in the abscissa. The parameter of the plot is the duration of the signal.

For purposes of comparison, the thresholds obtained by Robinson and Trahiotis (1972) with signal durations of 32 and 256 ms are plotted, respectively, as closed and open stars. The Robinson and Trahiotis thresholds, which were originally reported in terms of $10\log(E/No)$, were transformed to S/N (dB) and reduced by 1 dB in order to account for the fact that their "threshold" level represented 80% correct while, in the current study, the SIAM procedure targeted 75% correct. The adjustment of 1 dB was based on the fact that the linear portion of the psychometric functions fit by Robinson and Trahiotis, like those commonly found in other studies of binaural detection (e.g., Egan, 1965) had a slope of about 5% per dB (Trahiotis, 2005). Note that the positioning and trends of the thresholds obtained by Robinson and Trahiotis (1972) are consistent with those obtained in the current study. This confirms the validity of the SIAM procedure found in our pilot studies because Robinson and Trahiotis employed "fixed" stimulus conditions.

The new data in Fig. 1 were subjected to a two-factor within-subjects repeated-measures analysis of variance [signal duration × forward fringe duration]. The error terms for the main effects and for the interaction were the interaction of the particular main effect (or the interaction) with the subject "factor" (Keppel, 1973). In addition to testing for significant effects, the proportions of variance accounted for (ω^2) were determined for each significant main effect and interaction (Hays, 1973). The main effect of signal duration was significant [$F(4,12)=707.02$, $p<0.001$] and accounted for 90% of the variance in the data. The main effect of forward fringe duration was also significant [$F(9,27)=7.50$, $p<0.001$] and accounted for 2% of the variance in the data. The interaction of signal duration and forward fringe duration was significant [$F(36,108)=4.53$, $p<0.001$] and accounted for 2% of the variance in the data. Overall, then, the physical parameters of the stimuli and their interaction accounted for 94% of the variance in the data.

Visual comparisons among the data reveal three important trends. First, when the signal duration was 10 or 20 ms, adding a short forward fringe increased thresholds by as much as 3–4 dB, as compared to those measured in the pulsed condition. This is the type of outcome that was hypothesized to occur if the listeners were monitoring the stimuli via a short temporal window that served to dilute the binaural cues produced by the addition of the Sπ signal to the masker.

Second, for signal durations below 125 ms, thresholds declined as the duration of the forward fringe was increased from 2.5 to 500 ms. In addition, the magnitudes of the declines in threshold were inversely proportional to signal duration. These trends in the data, taken together, are what led to the significance of the main effect of forward fringe duration and the significant interaction between signal duration and forward fringe duration. For the four shortest signal durations, the longest forward fringes yielded thresholds that were lower than those obtained in their corresponding pulsed conditions, thus replicating the fringe effects originally reported by McFadden (1966) and Robinson and Trahiotis (1972). An appreciation for the potency of the forward fringe in reducing masking can be gained by focusing on the data obtained when the duration of the signal was either 10 or 20 ms. For those short signals, extending the duration of the forward fringe beyond 30 ms resulted in *increases* in sensitivity that more than compensated for *decreases* in sensitivity attributable to the operation of a temporal window.

The third important trend in the data is the well-ordered, vertical separation of thresholds between differing signal durations. This is the significant main effect that accounted for 90% of the variability in the data. Further discussion and interpretation of this important aspect of the data is postponed until the presentation of the data obtained with narrowband maskers.

Figure 2 displays thresholds of NoSπ detection obtained with the narrowband masker, plotted in terms of the S/N (in decibels) calculated across the 100-Hz bandwidth of the masker. These thresholds were subjected to a two-factor within-subjects repeated-measures analysis of variance [signal duration × forward fringe duration]. Once again, the

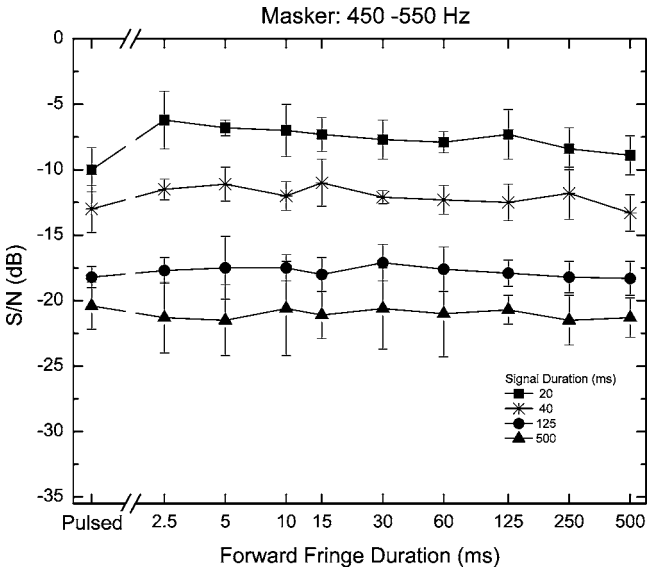

FIG. 2. Similar to Fig. 1, but for NoSπ thresholds obtained with the narrowband masker.

error terms for the main effects and for the interaction were the interaction of the particular main effect (or the interaction) with the subject "factor" (Keppel, 1973). The main effect of signal duration was significant [$F(3,9)=122.44$, $p<0.001$] and accounted for 90% of the variance in the data. The main effect of forward fringe duration was *not significant* [$F(9,27)=2.06$, $p=0.07$] and accounted for less than 1% of the variance in the data. The interaction of signal duration and forward fringe approached but did not reach significance [$F(27,81)=1.59$, $p=0.06$] and accounted for about 1% of the variance in the data. It was necessary to evaluate whether this lack of significance of the main effect of fringe duration and the lack of significance of the interaction of signal duration with fringe duration resulted from the omission of the 10-ms signal duration in the narrowband conditions. In order to do so, we reran the analysis of variance (ANOVA) on the data obtained with broadband maskers (Fig. 1) while omitting the 10-ms signal duration. Importantly, as with the original analysis, both main effects and their interaction reached significance ($p<0.001$) and, overall, about 90% of the variance in the data was attributable to these effects. Thus, the differences in the statistical outcomes between broadband and narrowband conditions appear to reflect actual differences in the patterning of the data.

Visual comparisons among the data in Fig. 2 and between the data in Figs. 2 and 1 parallel the statistical findings. First, for the 20-ms signal masked by narrowband noise, adding a short forward fringe increased thresholds by about 3 dB as compared to those measured in the pulsed condition, very much like what was found when the maskers were broadband. This is consistent with the listeners' monitoring of the stimuli via a temporal window. Second, in contrast to what was found with the broadband maskers, thresholds with narrowband maskers decreased much less as the duration of the forward fringe was increased from 2.5 to 500 ms. Thus, based on visual inspection and statistical analyses, the large forward fringe effects found here and in the literature with broadband maskers appear to be attenu-

ated or absent when the masker is narrowband (i.e.,100-Hz wide). On the other hand, the data in Fig. 2, are like those in Fig. 1 in that there is a well-ordered vertical separation of thresholds between differing signal durations.

C. Discussion and interpretations of the data

As discussed above, there are three major trends in the data: (1) effects logically attributable to the operation of a temporal window; (2) effects stemming from the presence of a forward fringe of masking noise; and (3) effects resulting from variations of signal duration. Each of these will be discussed in turn.

1. A temporal window

The data obtained with both broadband and narrowband maskers reveal that the addition of a short forward fringe of noise increases thresholds compared to those measured in the pulsed condition by amounts that are inversely proportional to the duration of the signal. Specifically, the largest increases occurred for 10-ms-long signals, a slightly smaller increase occurred for the 20-ms signals, and no increase was observed for signal durations of 40 ms and longer. Such an outcome is consistent with the assumption that the listeners process the stimuli via a short temporal window that dilutes the binaural cues produced by the addition of the $S\pi$ signal to the masker.

An attempt was made to formalize this notion in a quantitative, parsimonious, and theoretically "neutral" manner. This was done by investigating whether the relevant increases in threshold could be accounted for by considering any "temporal integration" that would occur as a consequence of the stimuli being processed via peripheral auditory filtering. That is, the temporal integration was, parsimoniously, assumed to be "predetection" and to occur within each monaural channel as a necessary consequence of peripheral filtering. A similar approach was used by Hartung and Trahiotis (2001).

The temporal integration was accomplished by passing the stimuli through a gammatone filter centered at 500 Hz and having a 3-dB down bandwidth of about 75 Hz (for details concerning the validity and implementation of such a filter, see, e.g., Glasberg and Moore, 1990; Slaney, 1993; Patterson *et al.*, 1995; Hartung and Trahiotis, 2001). The impulse response of the filter and its envelope are depicted in Fig. 3. Note that the maximum of the response is reached at about 6 ms and that the response falls to essentially zero at 25–30 ms.

In order to form a decision variable that would yield predictions of threshold, functions were generated that related input S/N to output $\Delta\rho$ (i.e., the change in interaural correlation of the waveforms produced by the addition of the $S\pi$ signal as measured at the output of the gammatone filter). This was done by averaging 100 estimates at each of several behaviorally relevant values of S/N for each of the 50 broadband stimulus conditions (five signal durations $\times$ 10 forward fringe durations) and each of the 40 narrowband stimulus conditions (four signal durations $\times$ 10 forward fringe durations). Each of the measures was made by evaluating the interaural correlation of the signal-plus-noise waveform utilizing the 30-ms epoch of the gammatone response that produced the maximal decrease in interaural correlation (from the "masker" interaural correlation of 1.0). This enabled the predictions to include any advantages in detection that would be gained by "off-time" listening.

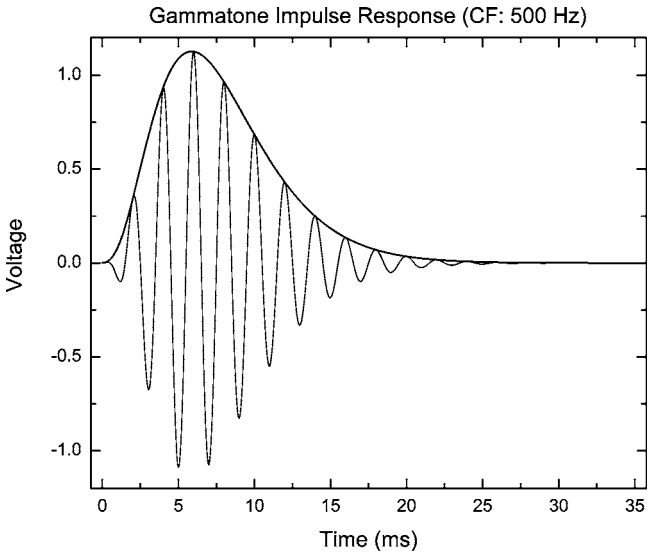

FIG. 3. The impulse response of the gammatone filter centered at 500 Hz. The solid line atop the peaks in the fine structure is the envelope of the response.

For each stimulus configuration, the paired values of S/N and $\Delta\rho$ were fit by either polynomial (broadband stimuli) or rational (narrowband stimuli) functions. This enabled accurate interpolations to be made. For each signal duration, the value of $\Delta\rho$ corresponding to the value of S/N at threshold in the pulsed condition was determined via interpolation using separate polynomial functions relating S/N and $\Delta\rho$. That value of $\Delta\rho$ was taken to be the criterion for threshold and its corresponding S/N was used as the predicted threshold for each of the forward fringe conditions, respectively.

Figure 4 contains the predictions (dotted lines) and data when the masker was broadband.[2] The predictions capture whether and to what degree increases in threshold, over those obtained in the pulsed conditions, occurred when short forward fringes of either 2.5 or 5 ms were added along with a 5-ms backward fringe of masker. The reader is reminded that the largest increase in predicted and obtained thresholds occurred when the duration of the signal was 10 ms; a somewhat smaller increase occurred when the duration of the signal was 20 ms. No increases in threshold occurred for durations of the signal equal to or greater than 40 ms. This is understandable in that signal durations of 40 ms and longer exceed the 30 ms or so duration of the impulse response of the gammatone filter centered at 500 Hz. Thus, for the longer signal durations, adding a forward and/or backward fringe of noise to the pulsed signal-plus-masker would not be expected to dilute the binaural cues and thereby affect thresholds. By the same token, the predictions, by their very nature, asymptote to the threshold predicted at the point at which the temporal window is "filled" by the signal-plus-masker-plus-fringe waveforms. Therefore, the *decreases* in

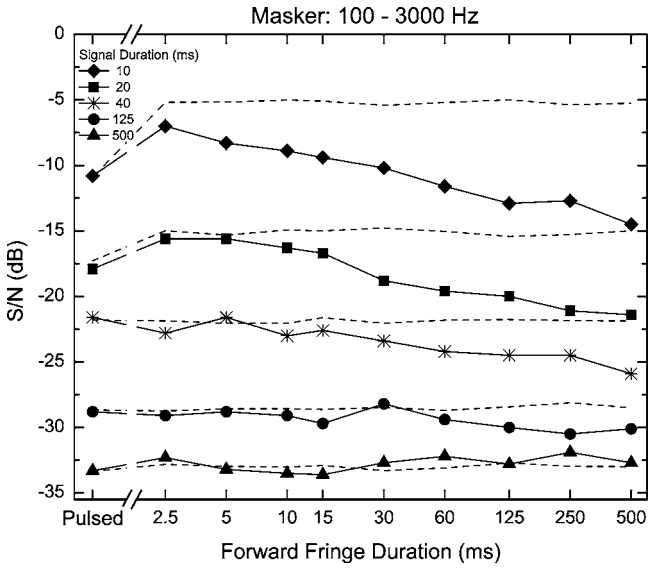

FIG. 4. Thresholds obtained with the broadband masker replotted from Fig. 1. The dashed lines represent predicted thresholds based on temporal integration arising from the peripheral auditory filter centered on 500 Hz (see the text).

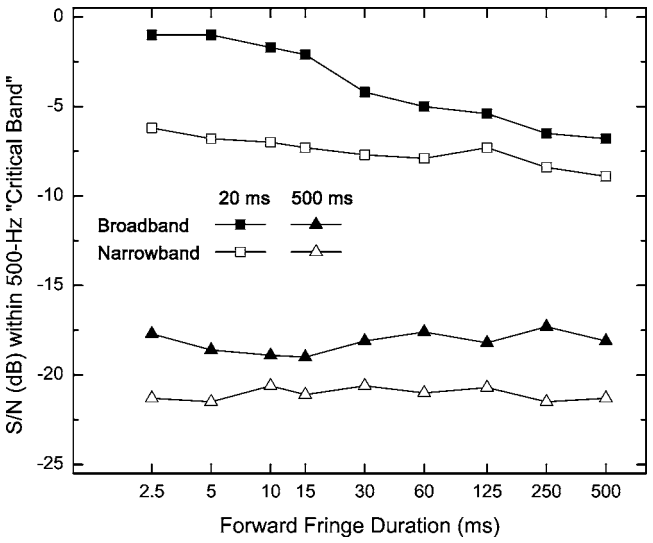

FIG. 6. Thresholds obtained with signals having durations of either 20-ms (squares) or 500-ms (triangles) in both broadband (closed symbols) and narrowband (open symbols) masking conditions plotted in terms of the S/N within the critical band. The dashed line represents predicted thresholds for the 20-ms signal masked by broadband noise. The predictions are based on a model that incorporates changes in the variation in the activity across auditory filters produced by variations in the duration of the forward fringe (see the text).

threshold that define McFadden's (1966) forward fringe effect appear to be an independent phenomenon that coexists with the increases in thresholds that arise from peripheral temporal integration. Thus, for broadband stimuli, the decreases in $N_0S\pi$ threshold produced by the addition of forward fringes of masking noise do not preclude or contradict the notion that listeners integrate binaural information via a temporal window.

The predictions and data for the narrowband conditions are shown in Fig. 5. Once again, the predictions capture quite well whether and to what degree the addition of forward and backward fringes produce increases in threshold over and above those obtained in the pulsed conditions. Note that a slight increase in threshold was observed and predicted for the 40-ms signal when the masker was narrowband. Recall that such an increase was neither observed nor predicted for this signal duration when the masker was broadband. The difference results from the fact that a rise/decay time of 10 ms was employed with the 100-Hz-wide narrowband masker and a rise/decay time of 5 ms was employed with the 2900-Hz-wide broadband masker. This resulted in the 40-ms pulsed signal-plus masker having a plateau of 20 ms when the masker was narrowband and a plateau of 30 ms when the masker was broadband. Consequently, there was a bit of "room" within the approximately 30-ms-long temporal window for the addition of a masking fringe to dilute the binaural cues. To us, considering the types and amounts of within- and across-listener variability that can occur in psychophysical experiments, it is remarkable that such subtle theoretically-expected effects can be measured empirically.

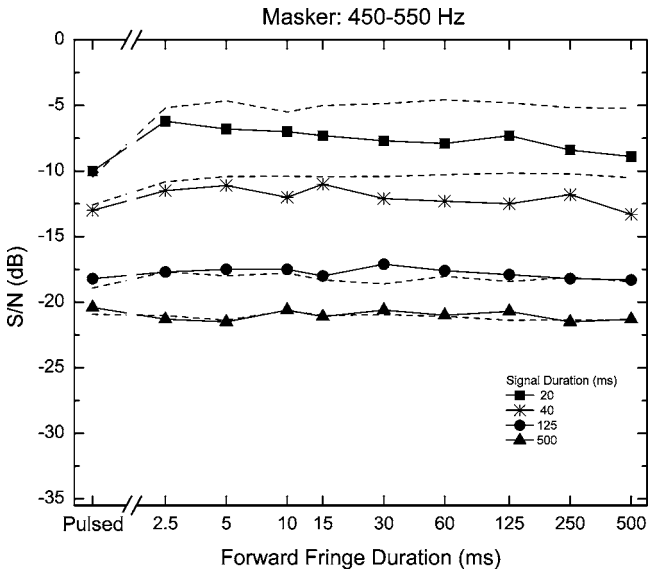

FIG. 5. Similar to Fig. 4, but for thresholds obtained with the narrowband masker.

2. The forward fringe effect

The addition of longer and longer forward fringes produced substantially greater decreases in threshold in broadband conditions, as compared to narrowband conditions. This outcome was expected on the basis of pilot studies and is especially interesting. It suggests that merely having diotic masker stimulation available for comparison to subsequent signal-plus-masker stimulation is not, in and of itself, sufficient to produce the relatively large decreases in threshold that define the forward fringe effect with broadband maskers. Therefore, explanations of the forward fringe effect wherein the fringe provides a stable diotic referent against which the addition of the signal is compared (e.g., McFadden, 1966; Robinson and Trahiotis, 1972; Yost, 1985), cannot, without further qualification, account for the data.

Figure 6 contains a subset of the data presented in a manner that helps foster an understanding of what aspects of the stimuli and their processing by the auditory system result

in forward fringe effects for broadband but not for narrowband masking conditions. The thresholds depicted are those obtained with signals having durations of either 20 ms (squares) or 500 ms (triangles) in both broadband (closed symbols) and narrowband (open symbols) masking conditions and when forward fringes were present.

In order to make direct and meaningful comparisons among the thresholds of detection obtained in those four conditions, the data are plotted in terms of the S/N in decibels within an assumed 100-Hz-wide "critical band" filter centered at 500 Hz. To this end, the threshold S/Ns obtained with the broadband masker were increased by 14.6 dB, the value representing the ratio between the 2900-Hz bandwidth of the broadband masking noise and the 100-Hz-wide critical band. The threshold S/Ns obtained with the narrowband masker required no adjustment because that masker was 100-Hz wide.

Beginning with the data obtained with the 500-ms forward fringe, note that, for both signal durations, higher values of S/N (about 2–3 dB) were required to reach threshold in the broadband conditions. This outcome is consistent with a number of previous studies indicating that detection of a $S\pi$ signal against diotic masking noise is adversely affected by noise that is present in the approximately 400-Hz-wide spectral regions surrounding the (monaural) critical band (e.g., Bourbon, 1966; Hall *et al.*, 1983; Kohlrausch, 1988; van der Heijden and Trahiotis, 1998; van der Par and Kohlrausch, 1999). This finding was, for decades, often interpreted to mean that binaural processing was constrained by there being a "binaural critical band" that was analogous to, but wider than, the monaural critical band. As discussed in the three most recent of the studies cited above, the current view is that binaural processing is constrained by the same peripheral filtering as is monaural processing, but, depending upon the spectral content of the masker, binaural processing is also influenced by a wider operational bandwidth that includes information within auditory filters adjacent to and centered on the frequency of the signal.

Overall, the figure shows that thresholds obtained with the broadband masker are always larger than their narrowband counterparts and, for 20-ms signals, the differences between the thresholds obtained with broadband versus narrowband maskers become greater and *exceed* the 2–3 dB differences attributable to the wider "operational band" as the duration of the forward fringe is reduced. These outcomes may provide important clues concerning the interpretation of the forward fringe effect. They suggest that what requires explanation is the *degradation* of detectability in broadband masking conditions produced by *shortening* the forward fringe, rather than any *enhancement* in detectability produced by *lengthening* the fringe.

Before describing our thoughts concerning what may underlie the forward fringe effect, it is helpful to first summarize van de Par and Kohlrausch's (1999) explanation of why the binaural operational bandwidth appears to be broader than the monaural critical bandwidth (auditory filter). According to van de Par and Kohlrausch (see pp. 1944–1945), in $NoS\pi$ detection conditions employing relatively high-level *narrowband* maskers, listeners maximize performance by optimally combining useful binaural information from both the auditory filter centered on the signal frequency and from adjacent auditory filters near enough in frequency to contain appreciable signal energy. An underlying assumption is that the internal noise within each of the relevant filters is independent, and, therefore, combining the binaural information across filters improves sensitivity relative to that possible using only the binaural information present in the filter centered on the signal.

In the case of a broadband masker, however, little or no useful binaural information would be present in the adjacent filters because the high levels of external diotic masking noise result in vanishingly small S/Ns in those channels. In this case, optimizing performance would entail essentially ignoring the binaural information carried by the adjacent filters while "attending" only to the binaural information carried in the on-frequency filter. Therefore, the type of benefit that stems from combining information across filters in the case of the narrowband masker is lost when the masker is broadband and the signal level required for threshold is increased.

van de Par and Kohlrausch's (1999) ideas appear to provide a framework for understanding why shortening the forward fringe degrades $NoS\pi$ detectability for short signals masked by broadband noise. Perhaps shortening the forward fringe either precludes or hampers listeners' abilities to attend primarily to the auditory filter centered on the frequency of the signal. In order to illustrate how this might come about, Fig. 7 displays the average powers at the outputs of gammatone filters for our broadband masker. The top left panel shows the outputs for each of three independent 20-ms samples of the broadband masker for auditory filters having center frequencies spanning the range 100 to 4000 Hz. The three curves reveal large variations in output both across filters and across 20-ms samples of noise. The large variations in powers at the outputs of the filters are a manifestation of the independent, Rayleigh-distributed, variations in the magnitudes of the input that occur within differing spectral regions for short samples of broadband Gaussian noise. The top right panel shows the same filter outputs, but only for filters spanning the binaural operational bandwidth of 300 to 700 Hz.

The bottom row of Fig. 7 depicts corresponding plots for 125-ms-long samples of a broadband diotic masker. Note that both within-plot and across-plot variability in the activity of the filters is substantially reduced, as compared to when the maskers were only 20-ms long. Thus, the binaural information provided by the 125-ms-long broadband forward fringe could lead to relatively increased detectability because there would be little filter-to-filter variability that would serve to hamper the listener's ability to detect the addition of the $S\pi$ signal.

In order to assess the viability of this line of reasoning, we attempted to relate the expected amounts of duration-dependent, across-frequency variability in the outputs of auditory filters to changes in threshold produced by variations in the duration of forward fringes. Measures of filter-by-filter variability were made in the following manner. The first step was to measure a "reference" output of a bank of gammatone

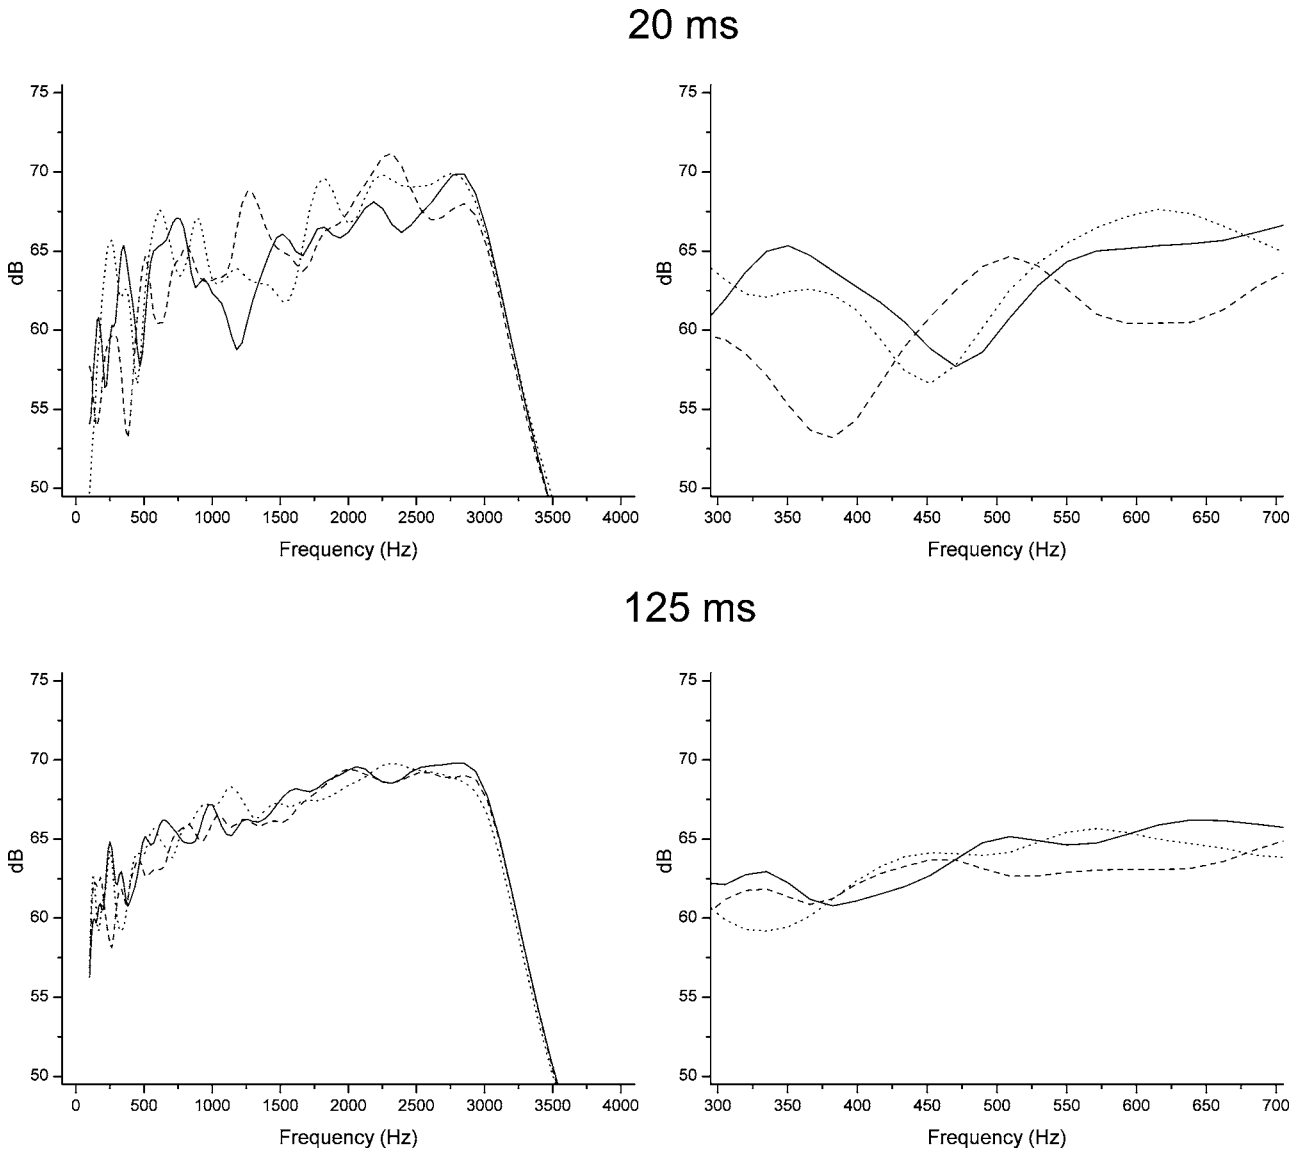

FIG. 7. Average powers at the outputs of gammatone filters for the broadband masker. Top row: outputs for each of three independent 20-ms samples of the broadband masker for filters spanning the range 100 to 4000 Hz (left) or for filters spanning the binaural operational bandwidth of 300 to 700 Hz (right). Bottom row: same as top row but for 125-ms-long tokens of broadband noise.

filters having center frequencies spanning the range 300–700 Hz, the operational binaural bandwidth discussed earlier. By "reference" output, we mean the output that would occur for an essentially steady-state input of our broadband Gaussian noise. This was done by averaging the outputs across 100 independent, 30-s-long samples of the noise. This produced a smoothly rising output of the filters as a function of frequency, commensurate with their increasing values of bandwidth. Then, the outputs of the filters were measured for each of the nine durations of the forward fringe. To each of the nine forward-fringe durations, 15, 25, 45, or 130 ms of the masking noise was appended in order to match the total durations of the maskers employed in the behavioral experiments when the signal was 10, 20, 40, or 125 ms long, respectively (i.e., our simulations included the 5-ms backward fringe that accompanied all of the forward fringe conditions). Two thousand five hundred independent tokens of diotic broadband noise were used as inputs to the filter bank and were constructed anew for each of the 36 different total durations of the masker. For each such token, the decibel difference in the outputs was computed, filter by filter, from the reference output. Then, the variance of the deviations from the reference output was computed. For each duration of the masker, the estimate of the across-filter variance was taken to be the average of the variance computed across the 2500 tokens.

The estimates of the relative variance of the decibel differences measured across filters are plotted as the dashed lines in Fig. 8 and are indexed by separate right-hand axes for each of the four signal durations. The vertical position of each line was adjusted to provide a reasonable visual fit to the detection thresholds obtained at each signal duration. The changes in the behavioral thresholds appear, line by line, to be closely paralleled by the changes in the variance of the outputs of the 300–700 Hz-wide gammatone filter bank.

After extensive deliberation, it occurred to us that several factors could underlie or be related to *how* behavioral thresholds are affected by changes in across-filter variability

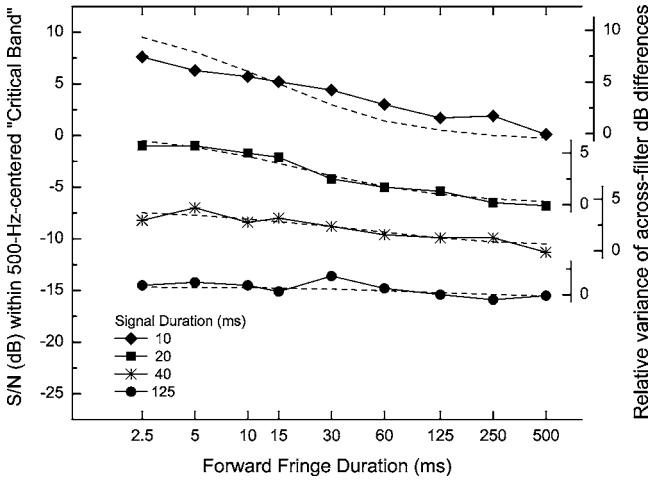

FIG. 8. Thresholds obtained with signals having durations of 10, 20, 40, or 125 ms in broadband masking conditions plotted in terms of the S/N within the critical band. The dashed lines represent estimates of the relative variance of the decibels differences measured across filters and are indexed by separate right-hand axes for each of the four signal durations.

that, in turn, stem from changes in the duration of the forward fringe. For example, we considered the effects that across-filter variations could produce when combined with the presence of a slightly positively interaurally correlated internal noise such as that typically used to explain how NoSπ thresholds are affected by the level of a diotic masker (e.g., Diercks and Jeffress, 1962; McFadden, 1968; Yost, 1988). Those papers illustrate how internal noise serves to decorrelate the perfectly interaurally correlated external masker.

In the face of across-filter variations in power that occur in response to short-duration broadband maskers, the amount of decorrelation produced by internal noise would vary across filters, both within and between brief samples of the masking noise. This is so because the decorrelation within each auditory filter would be inversely proportional to the amount of external masker energy that was momentarily present. As a result, from one brief sample of the masker to the next, the listener might have difficulty deciding which particular auditory filter contained the additional change in interaural correlation produced by the addition of the Sπ signal. Said differently, and a la van de Par and Kohlrausch (1999), performance with short signals masked by short broadband noises (including either brief or no forward fringe) could be hindered by an inability to discern and/or to attend to the auditory filter centered on the signal. Within the same rubric, and consistent with the behavioral data (Fig. 5), one would not expect strong forward fringe effects to be present when the masker is narrowband. This is so because the type of across-filter variability that occurs for broadband maskers would be lessened or would not occur, depending on the actual bandwidth of the masker.

In order for this approach to be plausible, however, psychoacoustically relevant filter-by-filter variations in *internal* interaural correlation would have to occur when short-duration, external broadband diotic noise is combined with the aforementioned internal noise. In order to investigate this issue, computer simulations were run using a model based on interaural correlation that included stages of bandpass filtering, envelope compression, and rectification (for details, see Bernstein *et al.*, 1999). The external noises that served as inputs were generated in the same fashion (and had the same characteristics) as those employed in our experiments when the signal duration was either 10 or 20 ms and the forward fringe duration was 2.5 ms. Those stimulus conditions were two for which there were large forward fringe effects and large across-filter variations in power. The additive "internal" noise had the same spectral shape, level, and interaural correlation as that described by Yost (1988).

Normalized interaural correlations were computed filter by filter assuming an integration window of 100 ms (see Bernstein and Trahiotis, 1999). The magnitudes of the interaural correlations ranged, both across samples and across filters, from about 0.98 to 1.0, with the largest values of decorrelation occurring for auditory filters at the lower portions of the 300–700 Hz operational bandwidth, where the power of the internal noise was greatest. Such values of interaural correlation are not unlike the value of about 0.95, calculated via the same model, that corresponds to thresholds obtained in the pulsed NoSπ configuration when the signals and maskers are of long-duration (i.e, 250–500 ms). It is the case, however, that for signals and maskers of *short duration* (i.e., 10–20 ms), that are of greatest interest here, the interaural correlation corresponding to threshold is much lower, being about 0.0 to 0.4. Based on this analysis, it appears that the across-filter variations in power, when combined with internal noise estimates based on Yost's (1988) analyses cannot in and of themselves be responsible for the forward fringe effect. This outcome does not negate the potential import of the close correspondence between the measures of variations in power across filters and the behavioral thresholds measured as a function of forward fringe duration for signals having durations between 10 and 125 ms (Fig. 8). It remains for future research to determine what factor(s) or mechanism(s) operate in conjunction with the variations in power across filters to produce the changes in behavioral thresholds observed under NoSπ forward fringe conditions with short-duration signals.

The general theoretical framework described here helps to explain many of the outcomes Yost (1985) reported in his comprehensive study of how forward fringes affect the NoSπ detectability of a 500-Hz, 20-ms tone under broadband masking conditions. For example, Yost (1985) found that thresholds increased and rose to the value observed in the pulsed condition when the bandwidth of the 500-ms-long forward fringe (but not that of the broadband masker) was made progressively narrower from the "operational" bandwidth of 400- to a 500-Hz tone. That is, the forward fringe effect was either attenuated greatly or was absent for narrowband forward fringes. According to our schema, the more narrow the spectrum of the forward fringe the less the opportunity for reduction of the across-filter and across-token variability arising from the short-duration broadband masker.

Yost (1985) also found that reductions in the level of the forward fringe led to proportional reductions in the magnitude of the forward fringe effect. Now, assume that the listener integrates information in the forward fringe with infor-

mation provided during the last 20 ms of the masker (when the signal could be added). Reducing the level of the forward fringe would have the effect of producing relative *increases* in the salience of internal noise (that is slightly positively interaurally correlated). Integration of the internal noise with the diotic masker would result in the effective broadband masker having, filter by filter, a "reference" interaural correlation of less than 1.0. That, in turn, would lead to poorer detectability of the Sπ signal (e.g., Robinson and Jeffress, 1963; van der Heijden and Trahiotis, 1998).

Direct support for the notion that forward fringe effects stem from some type of integration of the information in the forward fringe with information provided by the signal-plus-masker waveform is also provided by Yost (1985). Yost separated the offset of a 500-ms forward fringe from the onset of the 20-ms pulsed signal-plus masker. Greater temporal separations led to proportionately greater attenuations of the forward fringe effect. Such temporal separations would reduce the effectiveness of the integration of binaural information in the masking fringe with that provided by the signal-plus noise, thereby leading to greater across-filter variability and poorer detectability of the Sπ signal. Thus, many of the data concerning forward fringe effects are consistent with our hypothesis linking forward fringe effects with across-filter variations in binaural activity.

At this time, details concerning the exact nature of the integration of binaural information in the forward fringe with the information occurring during the time the signal could be present are unknown. For example, one may conceive of the process as being one of "running" integration that begins with the onset of the forward fringe. The addition of the Sπ signal would produce a maximal change in the interaural correlation within the auditory filter centered on the signal during that portion of the running integration that encompasses the signal. Seen in this light, detection of the signal comes about via both across-filter and across-time changes in interaural correlation.

The type of integration described above would be expected to produce the same magnitude of fringe effects independent of whether the fringe preceded or followed the signal. It is the case, however, that backward masking fringes yield enhancements of detectability for short-duration Sπ signals masked by diotic broadband noise that are smaller than those observed for forward masking fringes (e.g., Trahiotis *et al.*, 1972; Zwicker and Zwicker, 1984; Gilkey *et al.*, 1990). Perhaps, the asymmetric fringe effects stem from differential "predetection" effects arising directly from the response of the peripheral auditory filters. In the case of forward fringes, the Sπ signal is added to the noise after the hair cell/auditory filter mechanism has reached a "steady-state" response. In the case of backward fringes, the Sπ signal is added to the noise at the onset of stimulation. The internal representation of the signal-plus masker in the two cases would be expected to differ as a result of well-documented onset-related non-linearities (adaptation) in the neural responses (e.g., Meddis, 1986; Dau *et al.*, 1996a,b; Kohlrausch and Fassel, 1997). Perhaps differential effects of adaptation underlie the differences observed for NoSπ detection with forward and backward masking fringes.

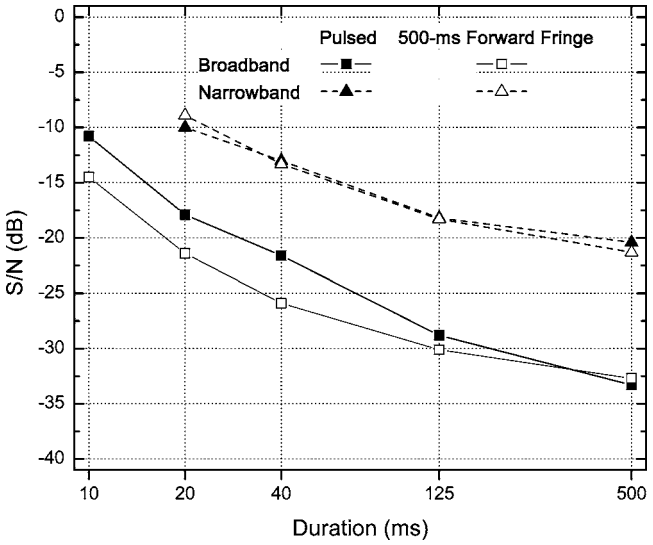

FIG. 9. Threshold signal-to-noise ratio (S/N) in decibels plotted as a function of the duration of the signal for the broadband (squares) and narrowband (triangles) masking conditions. Thresholds obtained with a 500-ms forward fringe are indicated by open symbols; thresholds obtained in the pulsed conditions are indicated by closed symbols.

3. Signal duration

The third important trend in the data that remains to be explained concerns the substantial increases in threshold found with decreasing signal durations in both broadband and narrowband masking conditions (Figs. 1 and 2). We begin with a consideration of the thresholds obtained with a 500-ms forward fringe. Those thresholds are replotted as open symbols in Fig. 9 with the abscissa being signal duration. Note that the thresholds obtained with broadband (squares) and narrowband (triangles) maskers are affected similarly by changes in duration. For both, thresholds decrease at a rate of approximately 4.5 dB per doubling of duration as duration is increased toward 125 ms and decrease at a much slower rate (about 1.5 dB per doubling) as duration is increased to 500 ms. These trends are consistent with several previous studies that are summarized and explained by Breebaart *et al.* (2001). They explain the slope of 4.5 dB per doubling as being a manifestation of two different processes. The first is the integration of binaural information within a fixed-duration "post-detection" temporal window. For durations less than the duration of the temporal window, thresholds would be expected to drop by 3 dB for each doubling of the duration of the signal. This is so because doubling the duration of the signal doubles the *effective* power of the signal as measured over the fixed (longer) duration of the "post-detection" integration. The second process is the relative reduction of an independent "decision noise" that comes about as a result of having the signal available for a longer time. Breebaart *et al.* argue that the second process produces an additional reduction in threshold of 1.5 dB per doubling which, when combined with the 3 dB per doubling reduction in threshold, yields an overall reduction of 4.5 dB per doubling for signal durations less than the duration of the "post-detection" temporal window.

Let us now consider the thresholds obtained with broadband and narrowband maskers when signals and maskers

were pulsed on and off with *no* temporal fringe (the points plotted at the far left of Figs. 1 and 2). Those thresholds are replotted as closed symbols in Fig. 9. Note that, for these "pulsed" conditions, thresholds obtained with broadband (squares) and narrowband (triangles) maskers are not affected similarly by changes in duration. Specifically, the narrowband data exhibit the same rates of change as were found with the 500-ms forward fringe. The broadband data, however, exhibit a steeper slope. That steeper slope is part and parcel of the differential elevations in thresholds at the shortest signal durations that define the forward fringe effect. Those differential elevations were explained as arising from across-filter variability. Taking all of this into account, we believe that the various sets of data collected across studies of the "pulsed" effect in broadband NoSπ masking conditions (e.g., McFadden, 1966; Robinson and Trahiotis, 1972; Yost, 1985) reflect several interacting processes: (1) temporal integration via peripheral auditory filtering; (2) duration and bandwidth-dependent variability in output across auditory filters; and (3) "post-detection" integration of binaural information via a fixed temporal window combined with reduction of noise in the decision process. The degree to which each of these processes affects measures of the pulsed effect in any particular study depends upon rise/decay and timing issues regarding the manner in which the signals and maskers are gated on and off. As an example, consider thresholds measured in studies wherein the broadband masker was gated so that it was at steady-state prior to and just after the occurrence of the Sπ tonal signal (e.g., Robinson and Trahiotis 1972). Those thresholds would reflect dilution of binaural cues via integration of short diotic masking fringes with the signal-plus-noise waveform while their counterparts measured with in true "no-fringe" conditions (such as those employed in this study) would not.

4. The integration of binaural cues

Our explanations of the changes in NoSπ thresholds entail the integration of binaural information across time. Either implicitly or explicitly, it has been assumed that a change in interaural correlation, or some measure isomorphic with it, serves as the quantity that is integrated. Historically, similar types of trading relations between the amount of stimulus power and stimulus duration required for detection have been found for both monaural (NoSo, NmSm) and binaural (NoSπ) thresholds (Blodgett *et al.*, 1958). Following Kohlrausch (1988), we too believe that it is important to make explicit that, in the case of binaural detection, it is not signal power nor energy, *per se*, that underlies performance but, rather, interaural disparity as quantified by interaural correlation. According to this point of view, the pulsed effect found under NoSπ detection of a 500-Hz tonal signal masked by diotic broadband noise should also be found if the "signal" were a narrow (i.e., critical-band-wide) change in interaural correlation. In such an experiment, there would be no added signal power to integrate over time.

We knew of no study in the literature that could provide the relevant data. While Jain *et al.* (1991) did measure correlation discrimination thresholds using a similar (spectrally) "fringed" paradigm, they did not vary duration. Consequently, we collected data in a supplementary experiment with four listeners, utilizing three listeners who had participated in the main experiment. Decreases in interaural correlation of a 100-Hz-wide band of noise centered at 500 Hz were detected against the same diotic masking noise as that employed in Experiment 1. The selection of 100 Hz as the bandwidth over which to decrease the interaural correlation was made in order to provide changes in the interaural cues over approximately one critical bandwidth centered at 500 Hz. A similar size of monaural critical bandwidth was assumed/discussed, for example, by Kohlrausch (1988) and by van der Heijden and Trahiotis (1998). By changing the interaural correlation of a 100-Hz-wide band, the same range of frequencies that putatively provide the interaural cues when a 500-Hz Sπ tone serves as the signal would be operative. All other aspects of the stimuli were the same as those described for the pulsed condition of Experiment 1.

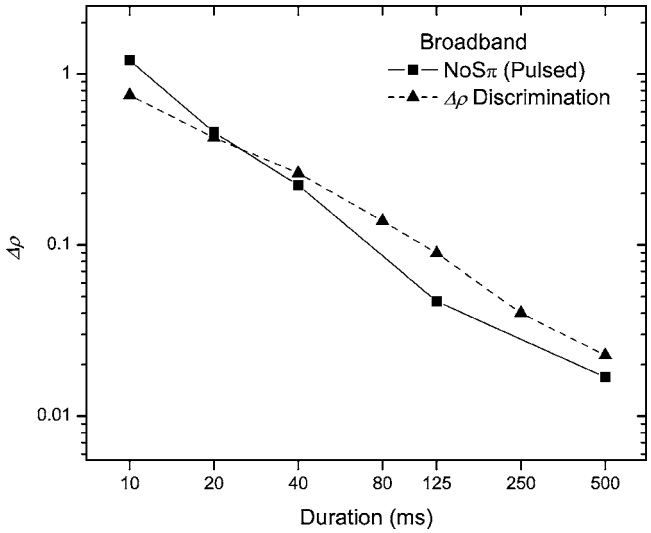

FIG. 10. Threshold change in interaural correlation ($\Delta\rho$) plotted as a function of signal duration. Squares represent pulsed NoSπ thresholds (see Fig. 1) transformed to $\Delta\rho$. Triangles represent analogous thresholds obtained using a "direct" interaural correlation discrimination paradigm.

Data were obtained using a two-cue, two-alternative, forced choice adaptive procedure targeting 71% correct (e.g., see Bernstein and Trahiotis, 1997, for details). This procedure was employed so that direct comparisons could be made in this "fringed" interaural correlation experiment with data obtained in interaural correlation-discrimination experiments conducted earlier (e.g., Bernstein and Trahiotis, 1997). The variable that was adaptively manipulated was the decrease in interaural correlation ($\Delta\rho$) from the reference interaural correlation of 1.0. Following van der Heijden and Trahiotis (1998), values of $\Delta\rho$ were generated by adjusting the ratio of two independent 100-Hz-wide bands of noise, one interaurally phase reversed (Nπ) and one diotic (No). The ratio of Nπ-to-No noise was varied adaptively in decibel steps. This produced essentially equal steps of 20 log ($\Delta\rho$) for behaviorally relevant (small) values of the ratio. The initial step size was 2 dB and it was decreased to 1 dB following two reversals.

The squares in Fig. 10 represent the NoSπ thresholds obtained in the pulsed condition of the main experiment transformed to changes in interaural correlation. The trans-

formation was done in three steps. First, the S/N thresholds obtained with the SIAM procedure were reduced by 2 dB in order to have the thresholds in that single-interval task map to the same value of d' (0.78) that defined threshold in the two-interval correlation-discrimination task. Then, the S/Ns were increased by 14.6 dB in order to reflect the threshold S/N values within a 100-Hz-wide band centered at 500 Hz (rather than the bandwidth of 2900 Hz that defined the external masker). Said differently, the value of the noise power N was taken to be the power of a 100-Hz-wide portion of the 100–3000 Hz masking noise used in Experiment 1. Finally, the adjusted values of S/N were transformed to $\Delta\rho$ via the equation (e.g., Durlach *et al.*, 1986)

$$\Delta\rho = 1 - \left[\frac{(1 - \mathrm{S/N})}{(1 + \mathrm{S/N})}\right]. \quad (1)$$

The triangles in Fig. 10 represent the data collected in the interaural correlation-discrimination task. They are the averages of 16 estimates of threshold (four estimates × four listeners) at each signal duration.

The close correspondence across the two sets of thresholds strongly supports the point of view that $\mathrm{NoS}\pi$ detection thresholds obtained in pulsed masking conditions while varying duration can be considered to be, fundamentally, manifestations of changes in interaural correlation.

D. Summary

$\mathrm{NoS}\pi$ thresholds were measured with either broadband or narrowband maskers while varying independently the durations of the signals and maskers and the durations of forward masking fringes. Comparisons among the data revealed three important trends. First, when the signal duration was 10 or 20 ms, adding a short forward fringe and backward fringe *increased* thresholds by as much as 3–4 dB, as compared to those measured in the pulsed condition. This was explained by assuming that listeners monitor the stimuli via a predetection temporal window arising from peripheral auditory processing.

Second, with a broadband masker, thresholds generally increased as the duration of the forward fringe was decreased from 500 to 2.5 ms. The magnitudes of the increase in threshold were greatest for signal durations of 10, 20, and 40 ms. These findings were accounted for by considering duration-dependent variability in activity or output that occurs across auditory filters that span the binaural operational bandwidth.

The third important trend in the data is the well-ordered, forward-fringe-duration-dependent vertical separation of thresholds between differing signal durations. These were discussed as resulting from "post-detection" integration of binaural information via a fixed temporal window combined with reduction of noise in the decision process. Further, it was argued that the degree to which each of these processes affects measures of the "pulsed effect" originally reported by McFadden (1966) depends upon details concerning exactly how signals and maskers are gated on and off.

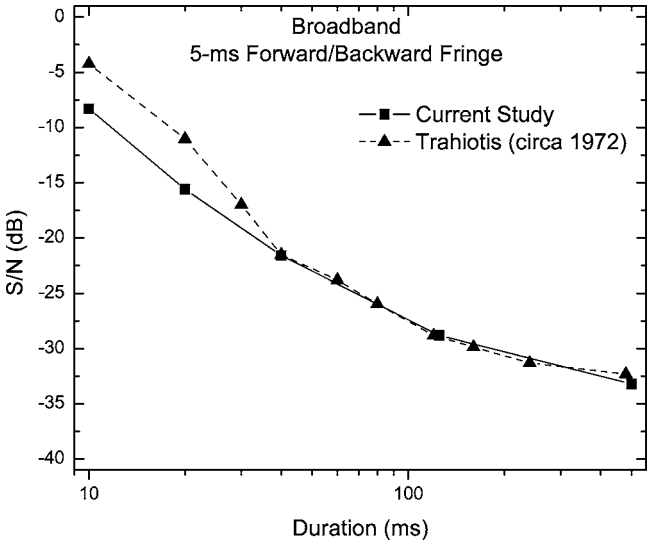

FIG. 11. Threshold signal-to-noise ratio (S/N) in decibels plotted as a function of the duration of the signal. A subset of the thresholds obtained with broadband masking in the main experiment (squares, see Fig. 1) is plotted together with thresholds (triangles) obtained in a pilot study by Trahiotis *et al.* (circa 1972). In both cases, a 5-ms forward and backward fringe of diotic noise surrounded the 500-Hz, $\mathrm{S}\pi$ signal.

ACKNOWLEDGMENTS

The authors thank Dr. Thomas N. Buell for many helpful discussions that served to both differentiate and bring focus upon the many interrelated phenomena and conceptual issues that had to be addressed. The authors also thank Dr. Armin Kohlrausch, Dr. William A. Yost, and two anonymous reviewers for their helpful comments on an earlier version of the manuscript. This research was supported by research Grants No. NIH DC-04073, No. DC-04147, and No. DC-00234 from the National Institute on Deafness and Other Communication Disorders, National Institutes of Health.

APPENDIX

The purpose of this Appendix is to provide further validation of the SIAM procedure employed in the main experiments and to demonstrate that duration-dependent changes in $\mathrm{NoS}\pi$ thresholds are robust, repeatable, and relatively free of interindividual differences. To that end, a subset of the thresholds obtained with broadband masking in the main experiment is plotted together (Fig. 11) with thresholds obtained in a pilot study by Trahiotis *et al.* (circa 1972). In both cases, a 5-ms forward and backward fringe of diotic noise surrounded the 500-Hz, $\mathrm{S}\pi$ signal. The earlier study employed four normal-hearing young adults [by now, probably American Association of Retired Persons (AARP) members]. As was common then, fixed psychometric procedures were employed and 400-trial-per-point psychometric functions were generated in order to estimate the S/N required for a value of $p(c)_{\max}=0.80$. The earlier experiment also employed a broadband masker extending from 100 to 3000 Hz having a spectrum level equivalent to 50 dB SPL. A single-interval, "yes/no" task, like the one used in the current study was employed. The thresholds obtained in the earlier study

were adjusted as described in Sec. II B of this paper in order to approximate the performance level of 75% that was targeted by the SIAM procedure.

The close correspondence between the two sets of thresholds that were measured 33 years apart attests not only to the validity of the SIAM procedure employed in the main experiments but also demonstrates that duration-dependent changes in NoSπ thresholds are robust, repeatable, and relatively free of interindividual (and intergenerational) differences.

[1]In accord with comments made by a reviewer, we believe it beneficial for archival consideration to differentiate clearly these types of studies from both monaural and binaural studies that have focused on what has been termed the "overshoot" phenomenon. Overshoot is operationally defined as the relatively higher level of a brief signal that is required for detection when that signal is presented shortly after the beginning, or shortly before the end, of a (longer) masker (e.g., McFadden, 1988). A major difference is that the studies of interest here manipulated the duration of the forward fringes of masking noise but included very short or no backward fringes of masking noise. In contrast, studies of overshoot, typically manipulate simultaneously, and in a complementary fashion, the duration of both forward and backward fringes of masking noise. Specifically, the relative amounts of forward and backward masking fringes change as the onset of the signal is delayed with respect to the onset of a (longer) masker of constant duration. Perhaps more to the point for our purposes, McFadden (1988) found no changes in NoSπ thresholds that could be attributable to overshoot.

[2]The predicted values of threshold do not coincide perfectly with the obtained values in the pulsed condition from which they were derived. This is so because the functions relating S/N to $\Delta\rho$ which were used to determine the criterion value of $\Delta\rho$ in the pulsed conditions were not *perfect* mirror images of the functions relating $\Delta\rho$ to S/N.

Effect of electrode configuration on psychophysical forward masking in cochlear implant listeners[a)]

Bom Jun Kwon[b)] and Chris van den Honert
Cochlear Americas, 400 Inverness Parkway, Suite 400, Englewood, Colorado 80112

(Received 11 July 2005; revised 7 February 2006; accepted 8 February 2006)

Bipolar stimulation has been thought to be more beneficial than monopolar stimulation for speech coding in cochlear implants, on the basis of its more restricted current flow. The present study examined whether bipolar stimulation would indeed lead to reduced channel interaction in a behavioral forward masking experiment tested in four Nucleus® 24 users. The masker was fixed on one channel and three masker levels that were balanced for loudness between the configurations were chosen. As expected, masking was maximal when the masker and probe channels were spatially close and decreased as they were separated. However, overall masking patterns did not consistently demonstrate sharper tuning with bipolar stimulation than monopolar. This implies that the spatial extent of a bipolar current field is not consistently narrower than that of an equally loud monopolar stimulus; therefore, it should not be assumed that bipolar stimulation leads to reduced channel interaction. Notably, bipolar masking patterns appeared to display more variations across channels, possibly influenced more by anatomical and neural irregularities near electrode contacts than monopolar masking patterns. The present psychophysical results provide a theoretical basis regarding the widespread use (and success) of monopolar configurations by implant users. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184128]

I. INTRODUCTION

Since multiple-electrode arrays were first introduced in cochlear implant (CI) systems, channel interactions have emerged as a limiting factor in increasing the number of electrodes. With simultaneous stimulation, channel interactions result from summation of current fields. While such summation is avoided with nonsimultaneous stimulation, channel interactions nevertheless exist due to (1) summation of charge accumulation at the neural membrane, (2) refractoriness of neurons previously excited by an adjacent channel, or (3) central interactions. Speech coding strategies that utilize simultaneous stimulation, such as the compressed analog (CA) strategy, are susceptible to current field summation. Sequential pulsatile stimulation, as used in the continuous interleaved sampling (CIS; Wilson *et al.*, 1991), eliminates current field summation, as multiple current fields do not occur simultaneously. By reducing the current field interactions, the CIS strategy has been shown to provide better speech recognition for CI patients, compared with the CA strategy (Wilson *et al.*, 1991).

With nonsimultaneous stimulation of channels, neural interactions might occur at both the peripheral and central stages of the auditory system, as observed in psychophysical tasks such as loudness summation (e.g., Shannon, 1983) or gap detection (Hanekom and Shannon, 1998). Forward masking is another psychophysical task used to study channel interactions in CIs (Shannon, 1983; Tong and Clark, 1986; Lim *et al.*, 1989; Chatterjee and Shannon, 1998; Cohen *et al.*, 1996, 2001; Boëx *et al.*, 2003). The threshold of a probe stimulus could be elevated by a preceding masker stimulus, if the electrodes carrying the masker and probe stimuli are close in space. The threshold shift, or the amount of masking, might be an indicator of channel interaction between the masker and probe, as we would expect a large threshold shift if the masker and probe channels activate a large population of common neurons. Therefore, the amount of masking as a function of the intracochlear spatial distance between the masker and probe channels would reveal the "width" of channel interactions.

In bipolar stimulation, current flows between an active and a return electrode located within the cochlea. The bipolar stimulation "mode" for Nucleus® devices indicates the distance between the active and return electrodes (in terms of electrode separation): current flows between adjacent electrodes in BP mode, current flows between electrodes that are separated by one electrode in BP+1 mode, and so on. In monopolar stimulation, current flows between an active intracochlear electrode and one or two extracochlear return electrodes (a ball electrode placed under the temporalis muscle for MP1 mode; a plate electrode on the casing of the internal receiver for MP2 mode; and both electrodes for MP1+2 mode). Monopolar stimulation generally requires much less current to evoke a hearing sensation, and therefore provides an advantage in terms of power consumption. Physiological measures have shown that "narrow" bipolar configurations produce spatially restricted current fields (Kral *et al.*, 1998), providing more "focused" stimulation of neural populations (van den Honert and Stypulkowski, 1987;

[a)]A portion of this study was presented in poster sessions at the 33rd Neural Prosthesis Workshop, October 2002 (Bethesda, MD), and at the 26th Mid-Winter Research Meeting Association for Research in Otolaryngology, February 2003 (Daytona Beach, FL).

[b)]Electronic mail: bjkwon@gmail.com

 0001-4966/2006/119(5)/2994/9/$22.50

Bierer and Middlebrooks, 2002). Monopolar configurations, on the other hand, produce broader current fields (van den Honert and Stypulkowski, 1987; Bierer and Middlebrooks, 2002). One could presume that bipolar stimulation, with its narrow current fields, would produce less channel interaction than monopolar stimulation. However, the presumed advantages of bipolar stimulation have not been shown in patient performance. Speech recognition with monopolar stimulation has been equal to or better than that with bipolar stimulation and many patients have expressed a preference for monopolar rather than bipolar stimulation modes (Lehnardt *et al.*, 1992; von Wallenberg *et al.*, 1994; Zwolan *et al.*, 1996; Pfingst *et al.*, 1997, 2001; Kileny *et al.*, 1998). Thus, monopolar electrode configurations are most commonly used in many CI speech processors.

Previous studies have shown mixed results regarding the effects of electrode configuration on forward masking. Shannon (1983) observed broader forward masking patterns with the monopolar configuration than with the bipolar configuration, consistent with physiological predictions (van den Honert and Stypulkowski, 1987; Bierer and Middlebrooks, 2002). A recent study by Boëx *et al.* (2003) reiterated Shannon's observation, with Clarion® patients implanted with the HiFocus-I™ array. With Nucleus® 22 CI patients, "pseudo-monopolar" forward masking patterns were measured by Cohen *et al.* (1996, 2001), in which the most basal intracochlear electrode was used as the return electrode in a bipolar pair (monopolar stimulation is not possible with the Nucleus® 22 device, as all electrodes are located inside of the cochlea). Cohen *et al.* (1996, 2001) found that the masking patterns for pseudo-monopolar maskers were not consistently broader than those of bipolar maskers. A similar observation was made by Lim *et al.* (1989), who varied the distance between the active and return electrodes in bipolar maskers (or the "spatial extent"). They found that the masking patterns initially became broader as the spatial extent of the masker was increased; when the spatial extent was sufficiently wide, the masking patterns often exhibited two peaks, rather than one broad peak. Beyond very narrow bipolar configurations, the width of the peak(s) did not increase with wider bipolar configurations. Thus, these previous studies present somewhat conflicting views regarding the effects of electrode configuration.

While these previous studies have shown some effects of electrode configuration on forward masking patterns, it is unclear, as yet, how the *relative* spread of excitation differs between monopolar and bipolar stimulation modes. Another consideration is the effect of stimulation level on forward masking patterns, which have been shown to broaden as the masker level is increased, in both acoustic (e.g., Nelson and Fortune, 1991) and electric hearing (e.g., Chatterjee and Shannon, 1998). It is unclear how the spread of excitation differs with stimulation level, or whether this interacts with the masker electrode configuration. To address these issues, forward-masked excitation patterns were measured as functions of masker stimulation mode and level in Nucleus® 24 CI users. The masker stimulation mode was varied between either bipolar or monopolar. Maskers were presented at loudness-balanced levels corresponding to soft, soft-medium, and medium listening levels.

TABLE I. Subjects' demographic information, etiology of deafness, and CNC word recognition scores in quiet.

ID	Gender	Age (years)	CI use (years)	Etiology	CNC word score
S1	Female	28	5	Unknown	78%
S3	Male	72	5	Noise exposure	46%
S4	Male	55	2	Otosclerosis	63%
S5	Male	74	3	Familial	54%

II. METHODS

A. Subjects and equipment

Four adult postlingually deafened CI patients participated in the present study. All subjects were implanted with the Nucleus® CI24M device (straight electrode array) and each had least 2 years' experience with his/her implant prior to testing. Table I contains relevant subject information, including CNC word recognition scores in quiet (Peterson and Lehiste, 1962), measured prior to the present study with their clinical MAP (MP1+2 mode). The use of human subjects in this study was reviewed and approved by the Western Institutional Review Board.

All stimuli were presented via the Nucleus® Implant Communicator™ (NIC™), a dynamic link library interface between a computer and the SPrint™ speech processor connected to the clinical fitting interface (Programming Control Interface). The computer generated the stimuli and the SPrint™ processor transmitted the encoded radio frequency (RF) pulses to the subject's internal receiver/stimulator.

The forward masking experiments were conducted using custom software written in C. During testing, one computer was dedicated to stimulus generation and test procedure, while another computer was dedicated as subject interface (e.g., subject response, test instructions, feedback, etc.). The two computers were linked via TCP/IP-based custom software.

B. Stimuli

In the Nucleus® 24 implant system, stimulation current intensity is specified in logarithmic units of "current levels (CLs)." The relationship between intensity represented in CLs and the corresponding linear current I in μA is given by

$$I = 10I_o^{\mathrm{CL}/255}, \tag{1}$$

where CL is an integer ranging from 0 to 255 and I_o has a nominal value of 175 μA, which is one tenth of the maximum current of the device (the actual calibration data for individual devices are displayed in Table II). One CL corresponds to 0.176 dB. Increasing the current by 34 CLs is approximately equivalent to doubling it (or a 6-dB increase).

Figure 1 shows the stimulus timing (a) and the masker and probe electrode locations (b) used in the forward masking experiments. All stimuli were biphasic, charge-balanced

TABLE II. Factory-calibrated currents (see text), per channel stimulation rates and modes used in clinical speech processing MAP, and the experimental stimulation rates and modes used for experiments.

Subject	I_o in Eq. (1) (μA)	Stimulation rate, mode (clinically) assigned MAP)	Stimulation rate for experiments	
			Monopolar	Bipolar (mode)
S1	190	1800 Hz, MP1+2	1800 Hz	1800 Hz (BP+1)
S3	175	900 Hz, MP1+2	900 Hz	2400 Hz (BP+2)
S4	178	900 Hz, MP1+2	1800 Hz	2400 Hz (BP+2)
S5	188	250 Hz,MP1+2	2400 Hz	2400 Hz (BP+2)

pulse trains. The masker duration was 500 ms, and the probe duration was 20 ms; the masker-probe delay was 20 ms. The pulse phase width was 25 μs and the interphase gap was 8 μs. The same phase width was used for both monopolar and bipolar conditions, so that equal currents indicate equal amounts of charge. For each monopolar and bipolar condition, masker and probe were presented in the same mode. For the bipolar conditions, due to the relatively high current requirement, the narrowest bipolar spacing (BP mode) could not be used. The stimulation mode was varied across subjects to ensure that sufficient loudness could be achieved for as narrow a bipolar configuration as possible. For S1, sufficient loudness was achieved with BP+1 mode; for the rest of the subjects, BP+2 mode was necessary. Furthermore, relatively high stimulation rates were used with bipolar conditions for each subject, to alleviate the high current level requirement in bipolar stimulation. The exact stimulation rates used for bipolar and monopolar stimulation in each subject are shown in Table II, with corresponding values from their clinical MAPs. Originally, it was intended that the same stimulation rate would be used for both monopolar and bipolar conditions. However, a somewhat lower monopolar rate was chosen for two subjects who did not prefer the high stimulation rate (S3 and S4). The masker was always presented to electrode 7; probe stimuli were presented to electrode 2, 4, 6, 8, 10, 12, 14, 16, or 18. [For brevity, the stimulation channel is denoted by the active electrode with the mode specification—e.g., when the stimulation is at (active) electrode 7, the actual electrode pair is (7,9), (7,10), or (7, *extracochlear electrodes*) with BP+1, BP+2, or MP1+2 mode, respectively.]

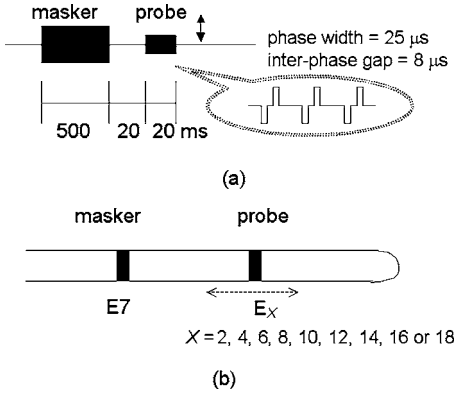

FIG. 1. Schematic diagram of the temporal (a) and spatial (b) properties of the masker and probe stimuli. Note that only the active electrode is denoted in this paper to specify a stimulation channel. For example, electrode 7 with BP+1 mode refers to the current field between the electrode pair (7,9).

Forward masking was measured at three presentation levels, corresponding to soft, soft-medium, and medium loudness levels, which are shown in Table III. Loudness at each presentation level was approximately matched across stimulation modes. First, three levels were established with monopolar stimulation. Then, for each presentation level, the experimenter adjusted the level of the bipolar masker until the subject reported that the monopolar and bipolar maskers were equally loud.

C. Procedure

Forward masking was measured using an adaptive, three-alternative forced-choice procedure (two-down/one-up). The masker was present in all three intervals; the probe existed in only one interval following the masker. The subject's task was to identify the interval containing the probe. The level of the probe was adjusted according to subject response, ultimately converging on 70.7% correct (Levitt, 1971). The adjustment step size was initially 0.88 dB (5 CLs) and was reduced to 0.35 dB (2 CLs) after six reversals. Each run contained 14 reversals, and the mean of the final eight reversals was calculated as the threshold. Each condition was repeated three times and the measurements were averaged. In addition, absolute detection thresholds without the masker were measured for all probe stimuli through the same procedure. For each probe, the threshold shift was calculated as the difference between the masked threshold and the detection threshold without the masker.

III. RESULTS

Figure 2 shows the detection thresholds with and without the masker for each electrode and stimulation configura-

TABLE III. Masker levels, in CL units (min: 0, max: 255), used for the soft, soft-medium, and medium presentation levels. The loudness was balanced between stimulation modes for each level.

Subject	Monopolar			Bipolar		
	Soft	Soft-Med	Medium	Soft	Soft-Med	Medium
S1	129	150	170	182	230	245
S3	160	180	190	200	235	245
S4	148	160	180	205	220	243
S5	155	170	190	217	234	250

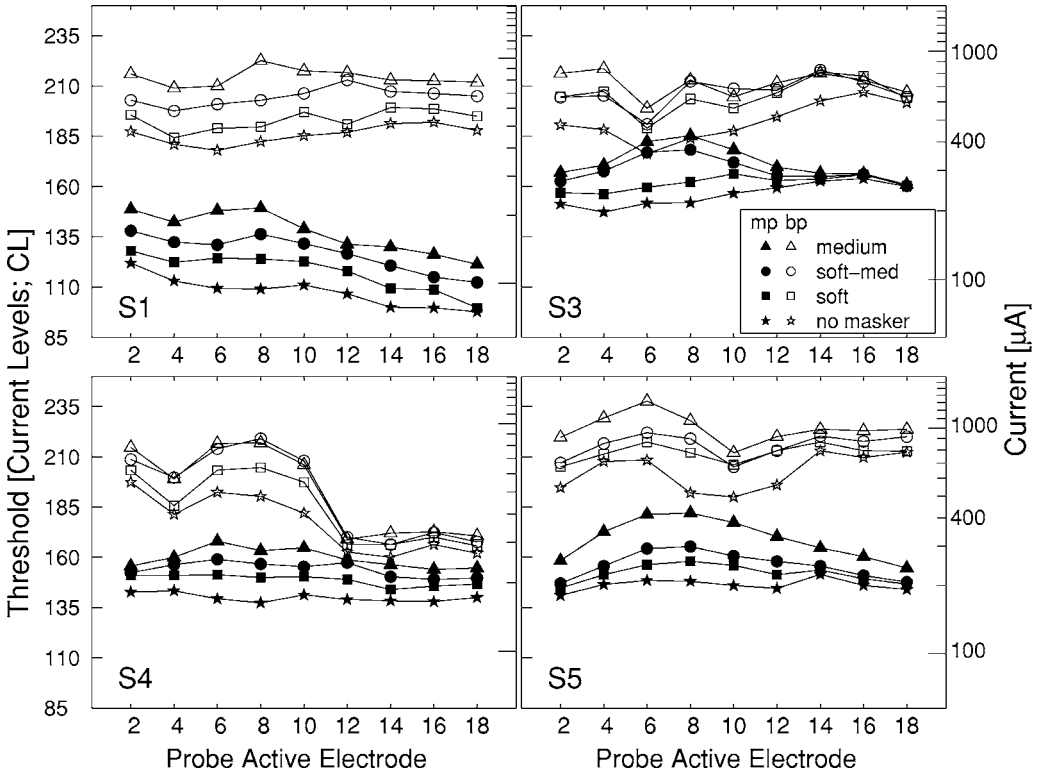

FIG. 2. Detection thresholds with the monopolar and bipolar configurations for each subject. The *x* axis shows the probe location (active electrode). The filled and open symbols indicate masked thresholds at three masker levels for monopolar and bipolar stimulations, respectively.

tion. Thresholds are plotted against the CL scale on the left axis, and log μA on the right for reference. Figure 3 displays threshold shifts, calculated from the masked threshold subtracted by the unmasked threshold in the CL scale. The different symbols represent different masker presentation levels. There was large intersubject variability in terms of the shape of the masking patterns. However, the results are generally consistent with those of previous studies (Cohen *et al.*, 1996; Chatterjee and Shannon, 1998), in that the peak in the forward masking pattern was found near the masker location, and the amount of masking is reduced as the masker and probe become more spatially remote. Masked thresholds

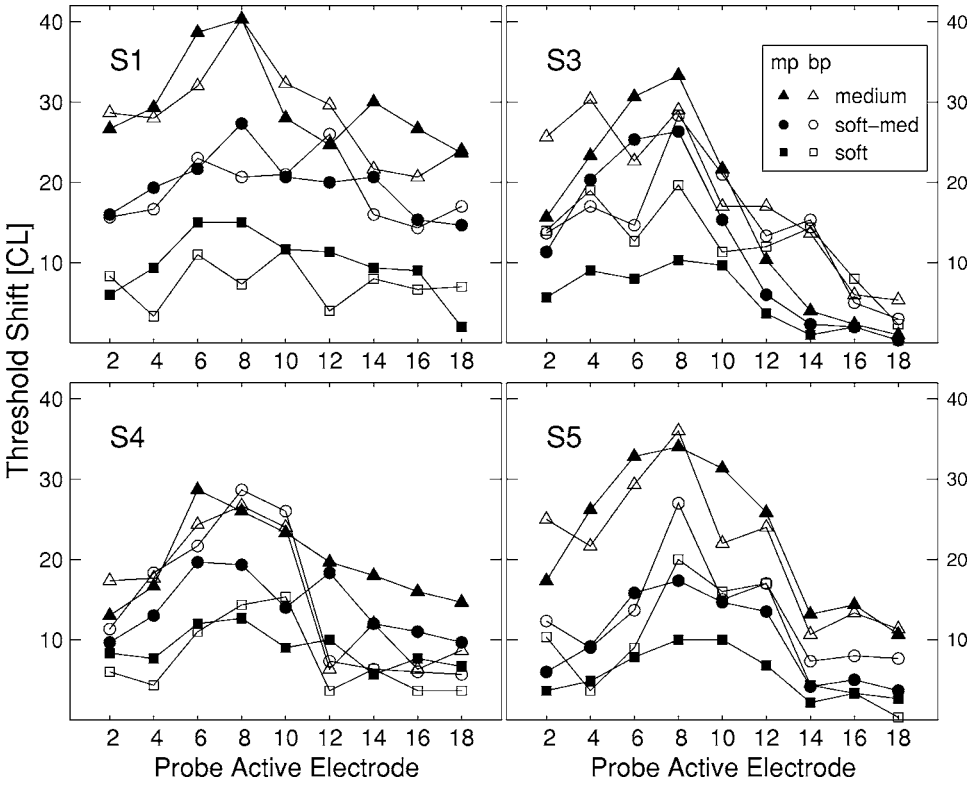

FIG. 3. Threshold shifts (difference between masked and unmasked thresholds) in CLs, plotted as a function of the active electrode of the probe channel. The *x* axis shows the probe location (active electrode). The filled and open symbols indicate masked thresholds at three masker levels for monopolar and bipolar stimulations, respectively.

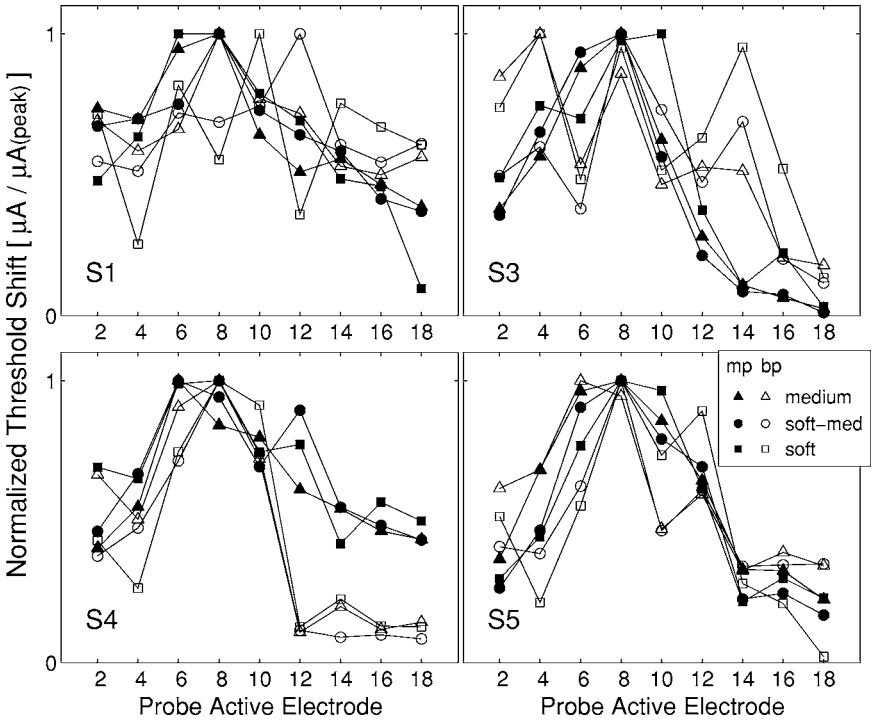

FIG. 4. Normalized threshold shifts for each subject. For each masking pattern, threshold shift was normalized to the peak threshold shift (in μA). Figure format is the same as Fig. 3.

generally increased with masker level. As seen in Fig. 3, the maximum amount of masking at each masker level is comparable between monopolar and bipolar modes in most cases, implying that the loudness balance between stimulation modes was properly done. In terms of absolute detection thresholds (cf. Fig. 2), there was a greater variability in bipolar thresholds across the electrode array, compared with monopolar thresholds, consistent with the results found by Pfingst and Xu (2004). Statistical significance was assessed using a three-way, repeated measures ANOVA to test the effects of the following within-subject factors on threshold shifts: stimulation mode (two levels: monopolar, bipolar), probe electrode location (nine levels), and masker level [three levels: soft (S), soft/medium (SM), medium (M)]. Most importantly, the effect of stimulation mode was not significant ($F_{1,3}=0.32, p=0.61$), and none of interaction terms with stimulation mode was significant (all the p values were greater than 0.2). While both the effects of probe location ($F_{8,24}=16.24, p<0.01$) and masker level ($F_{2,6}=18.64, p<0.01$) were significant, the interaction between them was also significant ($F_{16,48}=7.08, p<0.01$); therefore, a *posthoc* analysis was necessary to assess the effects of interaction. The monopolar and bipolar data were grouped together for each condition and three paired t tests (S-SM, SM-M, and S-M) for the masker level were done at each probe location. With a 95% confidence interval, the effect of masker level was the most significant at probe electrode 6 (all three t-test pairs significantly different), two pairs were significant at probe electrodes 2, 4, 8, and 10, and one or no pair was significant from electrode 12 and the rest. In other words, the interaction term indicated that threshold shifts depended on masker level only for probe locations near active electrode 7 and there was no effect of masker level for remote locations.

As an alternative analysis, threshold shifts were also calculated as the difference in linear μA. Due to the substantial difference in the absolute magnitudes of the stimuli, it would be difficult to plot and compare the result patterns for monopolar and bipolar stimulations in the same graph panel. Therefore, threshold shifts were normalized to the peak masking (in linear μA) in each level and plotted in Fig. 4, similar to the analysis done by Shannon (1983, 1990; see the Appendix). Once normalized, the masking patterns are quite similar across stimulation level within each stimulation mode. There are some deviations in this trend, notably for the bipolar masking patterns in subjects S1 and S3. At the soft and soft-medium presentation levels, the normalized masking patterns are more diffused. Only at the medium presentation level does a clear peak emerge near the masker location. Across stimulation mode, the patterns are also similar, in that the peak of the masking patterns is generally found near the masker location. However, there are also noticeable differences in the masking patterns between the stimulation modes. For subject S4, there was relatively little masking for the apical probe electrodes with bipolar stimulation; with monopolar stimulation, there was relatively more masking across the electrode array. Conversely, for subject S3, there was relatively more masking with bipolar stimulation for the apical probe electrodes at the soft masker level, and more masking for the basal electrodes at the medium level. This trend created double-peaked masking patterns. Local irregularities in neural survival and the geometric relation between implanted electrodes and healthy neural populations most likely contributed to the variance in the threshold patterns measured with bipolar stimulation, as previously described by Pfingst *et al.* (2004). With monopolar

stimulation, threshold patterns were less variable, most likely because of the presumed broader current spread within the cochlea.

IV. DISCUSSION

A. Comparison with previous studies

The peak threshold shifts measured in the present study, 4.7 to 7 dB (or 27 to 40 CLs), are comparable to the 7–11-dB range reported by Chatterjee and Shannon (1998; from their Fig. 1, converted to dB), and the 2–10-dB range reported by Cohen *et al.* (1996). The difference in these measurements could reflect methodological differences and parameter choices (e.g., masker and probe durations, interstimulus delay, etc). Considering that it is not uncommon to observe a substantial variability in forward masking data with cochlear implants in the literature [e.g., a wide range of the time constants for recovery from masking reported by Shannon (1990), Chatterjee and Shannon (1998), and Nelson and Donaldson (2002)], the discrepancy between the present and previous measurements is rather modest. In fact, some qualitative similarities across studies are noteworthy. For example, the peak of the masking pattern was generally located closest to the masker and the amount of masking increased with masker level. The across-site threshold variability was greater for bipolar stimulation than for monopolar stimulation, consistent with the findings of Pfingst and Xu (2004). However, the spread of excitation, as represented by forward masking patterns, was not significantly greater for monopolar stimulation than for bipolar stimulation in the present study. This observation is consistent with the results from Cohen *et al.* (1996, 2001), but somewhat in conflict with previous results from Shannon (1983) and Boëx *et al.* (2003). We note that the argument for broader monopolar masking patterns in those studies is relatively weak, as the observation was made with only one subject (out of two) in both studies. The results from the present study indicate that the difference in masking patterns between stimulation configurations often clearly exists. As seen in the present study, the difference could lead to either broader monopolar masking (e.g., S4) or broader bipolar masking (e.g., S3), depending on the subject and the masker level. Therefore, with the data from the present and previous studies at hand, we cannot conclude that convincing and consistent evidence exists for broader monopolar masking.

To rephrase the findings of the present study, at suprathreshold levels, the relative spread of masking is overall not significantly different between monopolar and bipolar stimulation, while an intersubject variability might exist. As such, the degree of channel interaction is most likely similar between these stimulation modes. The discrepancy between the present psychophysical and previous physiological data (e.g., Bierer and Middlebrooks, 2004) still needs to be reconciled. According to the spike-count model of loudness, the loudness of a stimulus is determined by the number of neurons responding to electrical stimulation. Spatially compact stimulation (e.g., narrow bipolar electrode configurations) is disadvantageous in terms of neural recruitment (Pfingst *et al.*, 1997): relatively high current levels are required to evoke comparable loudness with broader stimulation modes (e.g., wide bipolar or monopolar electrode configurations). It is plausible that the elevated current requirement for sensation (due to the very nature of narrow stimulation) causes the spatial extent to be broadened, ironically compromising its benefit. In physiological studies, the levels of stimuli are determined mainly by the observed neural responses, possibly lower than practically required for behavioral testing; therefore, it would be easier to maintain a focused spatial extent with bipolar stimulation. While loudness growth could differ between bipolar and monopolar stimulation, these stimulation modes should be compared at similar loudness levels, which is difficult to do in physiological studies. Moreover, in Bierer and Middlebrooks (2004), the different degrees of channel interaction observed with different electrode configurations occurred primarily with simultaneous stimulation. The difference in channel interaction was much smaller with nonsimultaneous stimulation.

B. Growth of masking

Another way to characterize the differences between bipolar and monopolar stimulation is to compare the growth of masking (GOM), i.e., threshold shift as a function of masker level. For each subject and at each probe location, the slope of GOM was calculated from the linear regression fit. Figure 5 shows the slope of GOM for each probe location condition, also illustrating a typical example of GOM function in the small figure insert. The slope of GOM, in $\mu A/\mu A$, is related to the effectiveness of a masker: the unity slope indicates that the increase of masker intensity leads to the increase in threshold shift to the same degree. For each stimulation mode, the maximum slope (steepest GOM) generally occurred near the masker location, ranging from 0.44 to 0.75 for monopolar and 0.15 to 0.51 for bipolar. These maximum slopes are comparable to the data range (0.38–0.72) reported by Chatterjee and Shannon (1998). The slopes decreased as the probe became spatially remote from the masker. A two-way repeated measures ANOVA on the GOM slopes, with factors stimulation mode (monopolar, bipolar) and probe electrode location (nine levels), indicated a significant effect of both factors (mode: $F_{1,3}=19.224$, $p=0.022$; electrode: $F_{8,24}=12.517$, $p<0.01$). The interaction between these factors was not significant ($F_{8,24}=2.209, p=0.064$). This indicates that the GOM slopes were generally steeper with monopolar stimulation than bipolar stimulation. The slopes in the bipolar condition were particularly small for S3 and S4, reflecting that as the masker level increased, the threshold shifts were relatively unchanged with bipolar stimulation. These shallow slopes might have in part resulted from irregularities in neural survival (which are also reflected in the previous figures of thresholds and threshold shifts). Possibly, uneven and poor neural survival at the sites of excitation (in the proximity of electrode contacts) compromised the spread of excitation associated with the increase of the masker level. Therefore, this phenomenon is a complex interaction between the profile of surviving neurons and current spread of the stimulation configuration. It is also possible that most surviving neurons in the region, where the neural survival is

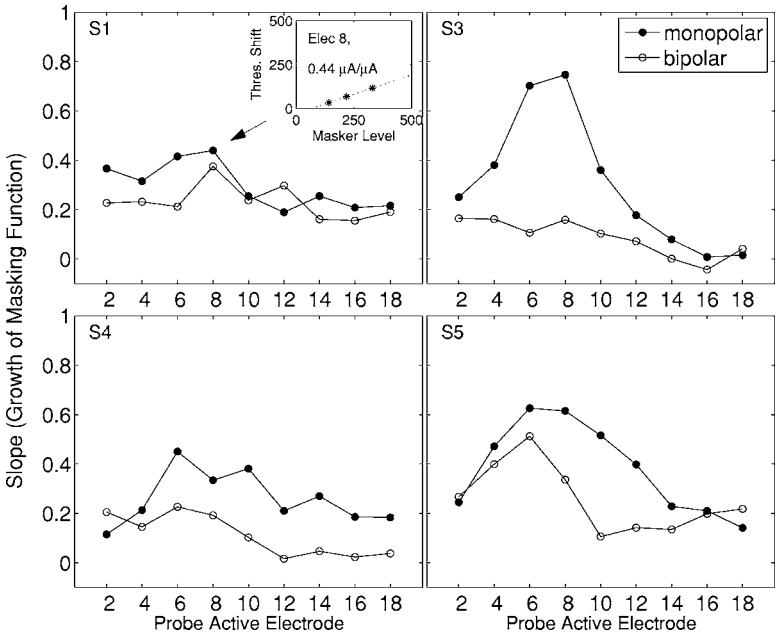

FIG. 5. Slope of linear fits to growth of masking at each probe location. Linear regressions were applied to masked threshold shifts (in μA) as function of masker level (in μA), at each probe location. The filled and open symbols shows the slope values for monopolar and bipolar stimulations, respectively. The small figure insert shows a typical example of growth of masking from S1's monopolar data at electrode 8.

uneven, have relatively high neural thresholds, thus making the increase of masker level less effective in recruiting more neurons in the spread region. At any rate, it is likely that local irregularities such as uneven or poor neural population exist for these two subjects, and they were reflected in the GOM slopes with the bipolar configuration. With monopolar stimulation, because the current spreads more broadly in the cochlea, there is less variance in the detection thresholds, thereby producing a more predictable growth of masking across the probe locations, relative to the masker location.

C. Implications for speech coding

The comparable forward masking patterns between monopolar and bipolar stimulation modes might explain why speech recognition results are generally similar between the two stimulation modes. The presumed better spatial selectivity with bipolar stimulation has not provided consistently better speech recognition results. The smaller power consumption and relative uniformity in thresholds and comfort levels can provide a substantial advantage for monopolar stimulation with current clinical speech processors. Pfingst *et al.* (2004) recently demonstrated a negative correlation between across-site variation in thresholds and speech recognition scores (correlation coefficients ranging from -0.7 to -0.47, depending on testing materials, with statistical significance, $p<0.05$). That would be an additional reason why monopolar stimulation, with its smaller across-site threshold variability, could be preferable to bipolar stimulation. This implies that stimulations that further restrict the current flow (e.g., tripolar stimulation) would presumably produce even more across-site threshold variability, and might not provide a noticeable advantage in speech recognition, as long as the coding strategy employs pulsatile sequential stimulation, such as CIS (Wilson *et al.*, 1991). Of course, regardless of stimulation mode, any speech processing strategy will be limited by the health of the neural populations and their proximity to the implanted electrodes. Finally, narrow electrode configurations might provide some advantages, if the strategy demands increased channel independence to permit simultaneous stimulation across channels (e.g., Clopton *et al.*, 2003). However, such an advantage has yet to be shown.

ACKNOWLEDGMENTS

The authors thank Wendy Parkinson for assisting data collection and her contribution to the project. The first author thanks John J. Galvin III for his critically valuable review and editorial assistance during the manuscript preparation, Robert Shannon and Monita Chatterjee for constructive discussion in the early stages of the study, and also two anonymous reviewers as well as John Grose for helpful comments. Finally, many thanks go to the NIC development team (Bret Swanson, Colin Irwin, and Michael Goorevich) in Cochlear Ltd., Australia.

APPENDIX: LINEAR VERSUS LOGARITHMIC SCALE TO REPRESENT CURRENT THRESHOLDS

It has long been debated as to how current threshold values in CI should be scaled. Some researchers have used a linear current scale, in μA (e.g., Chatterjee and Shannon, 1998; Nelson and Donaldson, 2001, 2002). Others have used a logarithmic current scale, in dB (e.g., Cohen *et al.*, 1996; Lim *et al.*, 1989). In the present study, currents were shown both in terms of CLs (Figs. 2 and 3) and μA (Figs. 4 and 5). Linear current scales may be appropriate because (1) loudness growth has been shown to be linearly related between acoustic sound pressure level (in dB SPL) and electric current (in μA) with patients who had a substantial residual hearing contralateral to the implanted ear (e.g., Eddington *et al.*, 1978; Zeng and Shannon, 1993; Dorman *et al.*, 1993), and (2) the loudness theory of electrical stimulation proposed by Zeng and Shannon (1994) would be better suited with a linear current scale. However, the demonstration of linearity between dB SPL and μA is not as definitive as it appears in

TABLE IV. The ranges of electric currents used for the previous loudness matching studies between acoustic and electric stimuli and the r values of regression for linear and logarithmic fit. The data of ABI 14 from Zeng and Shannon are represented in mV.

	Current range (μA)		r	
Study reference	min	max	Linear	Log

the literature. The authors in the above studies (Eddington *et al.*, 1978; Zeng and Shannon, 1993; Dorman *et al.*, 1993) emphasized the successful linear fitting, but did not present a comparative fitting with a logarithmic scale. Due to the narrow dynamic range of electrical stimulation, the maximum current was less than twice the minimum current in these studies (cf. Table IV) and regression fitting of the data on both linear and log scales would have been equally good. We attempted a logarithmic fitting of the data and present the R values in Table IV, demonstrating that either fitting is indeed equally successful. Nevertheless, the successful demonstration of linear fitting in those studies might have led subsequent researchers to the inference that a linear scale is more proper.

When the range of amplitude under consideration is small, the choice of scale (linear or logarithmic) is of little consequence. However, if the range is sufficiently large, it can affect interpretation of the data. Threshold shifts in μA would have been difficult to compare without the normalization, as done in Fig. 4, because the maximum threshold shift with each mode differs substantially. A large change in amplitude is often necessary for bipolar stimulation to match the perceptual change in small amplitude with monopolar stimulation. Perhaps a logarithmic scale is particularly useful if the range of comparison is large, as the use of a logarithmic scale would mitigate this mismatch of scaling. Thus, a linear scale should be used only when current values have similar absolute magnitudes (e.g., as with a fixed stimulation mode). Of course, normalizing linear threshold shifts to the peak shift (as in Fig. 4) also allows direct comparison of stimuli with large differences in current values. This is essentially the same approach in a log (dB) scale, in that the ratio (rather than the absolute difference) between physical measurements is analyzed.

(Received 30 December 2004; revised 16 February 2006; accepted 20 February 2006)

Vocal fold geometry plays an important role in human phonation. A wide range of inferior and superior vocal fold surface angles has been shown to be present during phonation [Nanayakkara, Master's thesis, Bowling Green State University, Bowling Green, OH (2005)]. This study explored how these angles affect pressure distributions on the vocal folds, and thus how they may affect phonation. The computational code FLUENT was used to obtain pressure distributions for laminar, incompressible flow. Eighteen inferior vocal fold surface angles and nineteen superior vocal fold surface angles were selected for three specific glottal angles, uniform 0°, convergent 10°, and divergent 10°. Minimal glottal diameter (0.01 cm), transglottal pressure (8 cm H_2O), and glottal entrance radius (0.15 cm) were held constant, and the glottal exit radius was constant for each glottal angle. Results suggest that the vocal fold surface pressures are independent of the inferior and superior vocal fold surface angles realistic for human phonation. These results suggest that, in contrast to the important effects of glottal entrance and exit radii, minimal diameter, and angle on intraglottal pressures, the inferior and superior vocal fold surface angles (excluding possible interactive effects with the false vocal folds) do not have an influence on the intraglottal pressures. I. INTRODUCTION

The vocal fold surface is essentially three-sided. One side is the medial glottal surface that changes its orientation during phonation from convergent during glottal opening to divergent during glottal closing. A second side is the inferior surface of the vocal fold that leads from the tracheal wall upward and medially to the glottal entrance. The third side is the superior vocal fold surface that leads from the glottal exit to the lateral wall of the ventricle between the true and false vocal folds. Much has been said about the medial surfaces of the vocal folds and their shape change, but few studies have examined the inferior and superior vocal fold surfaces.

Recent studies by Agarwal *et al.* (2003) and Nanayakkara (2005) indicate that the inferior and superior vocal fold surfaces can take on a wide range of angles during phonation. These authors made measurements on laminagram x-ray tracings from studies by Hollien and Colton (1969) and Wilson (1972, 1976) to come to this conclusion. The laminagraphic images were obtained during phonation, and represent "averages" of the vocal fold contours over short intervals of time during the phonations. The Nanayakkara results suggested that when the data were combined across men and women, modal register and falsetto, louder and softer phonation, and singers and nonsingers, the average inferior vocal fold surface angle was 30.3°, with a two standard deviation range of 13.1° to 47.6°. The average for the superior vocal fold surface angle for similarly combined data was 10.2°, with a two-standard deviation range of −7.4° to 27.7°, where a positive angle refers to the superior vocal fold surface shaped downward laterally. Relative to physical and computer models of phonation, however, the inferior vocal fold surface angle usually has been fixed at some intermediate angle and the superior vocal fold surface angle fixed at some nominal small positive angle or zero degrees (e.g., Gauffin *et al.*, 1983; Pelorson *et al.*, 1994; Alipour *et al.*, 1996). Relative to changes of the inferior and superior angle during phonation, radiographic stroboscopy with excised canine larynxes (Saito *et al.*, 1981; Fukuda *et al.*, 1983) and particle tracking with excised canine larynxes (Baer, 1981) suggest considerable change of the superior vocal fold surface angle near the medial portion of the vocal fold (the lateral portion of the superior surfaces were not shown). This is similar to the results with distributed mass models (Titze,

[a]Electronic mail: mxwan@mail.xjtu.edu.cn

1981) and finite-element models (Alipour *et al.*, 2000), which also show motion of the superior (as well as inferior) vocal fold surface throughout the vibratory cycle. Prior studies suggest, therefore, that there are individual differences in the average phonatory superior and inferior vocal fold surface angles, as well as some change of these angles during the phonatory cycle.

Nevertheless, the relation between inferior and superior vocal fold surface angles and the pressures on the vocal folds for phonation apparently has not been studied empirically or computationally. If variation of the inferior and superior angles creates substantial changes to the pressure distributions on the vocal folds, the subsequent motion of the vocal folds and the shape and size of the glottal volume velocity signal may be significantly affected. Furthermore, physical and computer models for vocal fold motion would need to be extended to include these effects. Thus, the purpose of this study was to examine the effects on the intraglottal vocal fold surface pressures when the inferior and superior vocal fold surface angles were parametrically varied.

II. METHODS

The commercially available computational fluid dynamics package FLUENT (Fluent, Inc., Lebanon, NH) was used to obtain estimates of the normal pressures along the vocal fold surfaces as a function of the inferior and superior vocal fold surface angles. The code has been shown to produce pressure distributions for constant flows in laryngeal ducts that were highly similar to those found empirically using Plexiglas models of the larynx (Scherer *et al.*, 2001a, 2001b; Li *et al.*, 2006). The code is based on the control-volume technique and was used to solve the Navier-Stokes equations for laminar, incompressible airflow physics occurring inside two-dimensional symmetric laryngeal geometries. This use of FLUENT, then, is for constant shapes, not for vibrating vocal folds. Furthermore, the code as used does not produce turbulence. The fluid material was defined as air (density of 1.225 kg/m^3 and viscosity of 1.7894×10^{-5} kg/m s). The grids used in the present simulation contained both structured and unstructured meshes. The mesh size varied from 77×10^3 to 320×10^3 nodes and was made finer in regions where high gradients in pressure or velocity were expected. The boundary conditions of the model included an inlet pressure of 8 cm H_2O and outlet pressure of 0 cm H_2O. All computational runs were performed unsteady to obtain second-order solutions for momentum and pressure that had residuals of less than 10^{-4}. The flow field was assumed to be symmetric across the midline of the glottis in this study, and therefore only the half flow field was modeled.

In this study, three glottal angles, 10° divergent, 0° uniform, and −10° convergent, were used, as they represent the three basic glottal shapes typically expected in phonation, and the angle values are typically expected for most phonation in modal register (as suggested by normal videostroboscopy (Hirano and Bless, 1993) and schematics of vocal fold vibration (Schönhärl, 1960; Stevens and Klatt, 1974; Baer, 1975; Hirano, 1977; Cranen and de Jong, 2000), which show maximum diverging glottis angles from 17° to 67° and convergent glottal angles from 8° to 67°). The 18 inferior vocal fold angles (measured between a horizontal line and the inferior vocal fold surface line) were 87.5°, 85°, 82.5°, 80°, 75°, 70°, 65°, 60°, ***45***°, ***40***°, ***35***°, ***25***°, ***15***°, 10°, 5°, 0°, −5°, and −10°, where the bold and italicized values are within ±2 SDs in the work of Nanayakkara (2005). These were used for each glottal angle. The superior vocal fold surface angle was kept constant at 0° for these runs because this angle is not atypical (see below). These inferior vocal fold surface angles for the divergent glottal angle are shown in Fig. 1(a) and 2(a). Similarly, 19 superior vocal fold surface angles (measured between a horizontal line and the superior vocal fold surface line) were −85°, −80°, −75°, −70°, −65°, −60°, −45°, −35°, −25°, −15°, −10°, ***−5***°, ***0***°, ***5***°, ***10***°, ***15***°, ***25***°, 35°, and 45°, where again the bold and italicized values are within ±2 SDs in the work of Nanayakkara (2005). These also were used for each glottal angle. The inferior vocal fold surface angle was kept constant at 40° for these runs because the value is within the expected range for phonation (see above). A subset of the superior vocal fold surface angles for the convergent glottal angle is shown in Fig. 3(a). It also can be seen from Figs. 1(a), 2(a), and 3(a) that altering the inferior and superior angles changes the size and shape of the vocal fold.

The glottal exit radii were set at 0.108, 0.0987, and 0.0908 cm for the divergent 10°, uniform 0°, and convergent −10°, respectively, consistent with the design for the empirical model M5 (Scherer *et al.*, 2001b). The false vocal folds were not included. Held constant for all cases were the glottal entrance radius (0.15 cm), the minimal glottal diameter (0.01 cm), the anterior-posterior glottal length (1.2 cm), the inlet domain axial length (0.2 cm), the outlet domain axial length (0.5 cm) (see Fig. 4), and the transglottal pressure (8 cm H_2O). The axial glottal length was set at 0.30 cm for all cases, where this length was determined by the projection to the centerline of the center of the entrance radius circle and the projection to the centerline of a line tangent to the exit radius when pointing downstream (see Figs. 1–4).

The angles beyond the range expected for human phonation mentioned above may be unrealistic, but are important because of the suspicion that the intraglottal pressure effects may not be large for the normal range; thus, it would be important to determine when the pressure effects actually come into play. Also, using a wider than normal range of angles permits inquiry into atypical laryngeal geometric conditions.

III. RESULTS

A. Effects of changing the inferior vocal fold surface angle

Figure 1(b) shows the pressure distribution results for the inferior vocal fold surface angles for the 10° divergent glottal angle. The decrease in cross-sectional area leading up to the glottis caused most of the pressure drop due to the flow acceleration (Bernoulli). Near the glottal entrance, along the glottal entrance curvature, viscous and additional flow acceleration effects would decrease the pressures further. The minimum pressure and largest velocity occurred

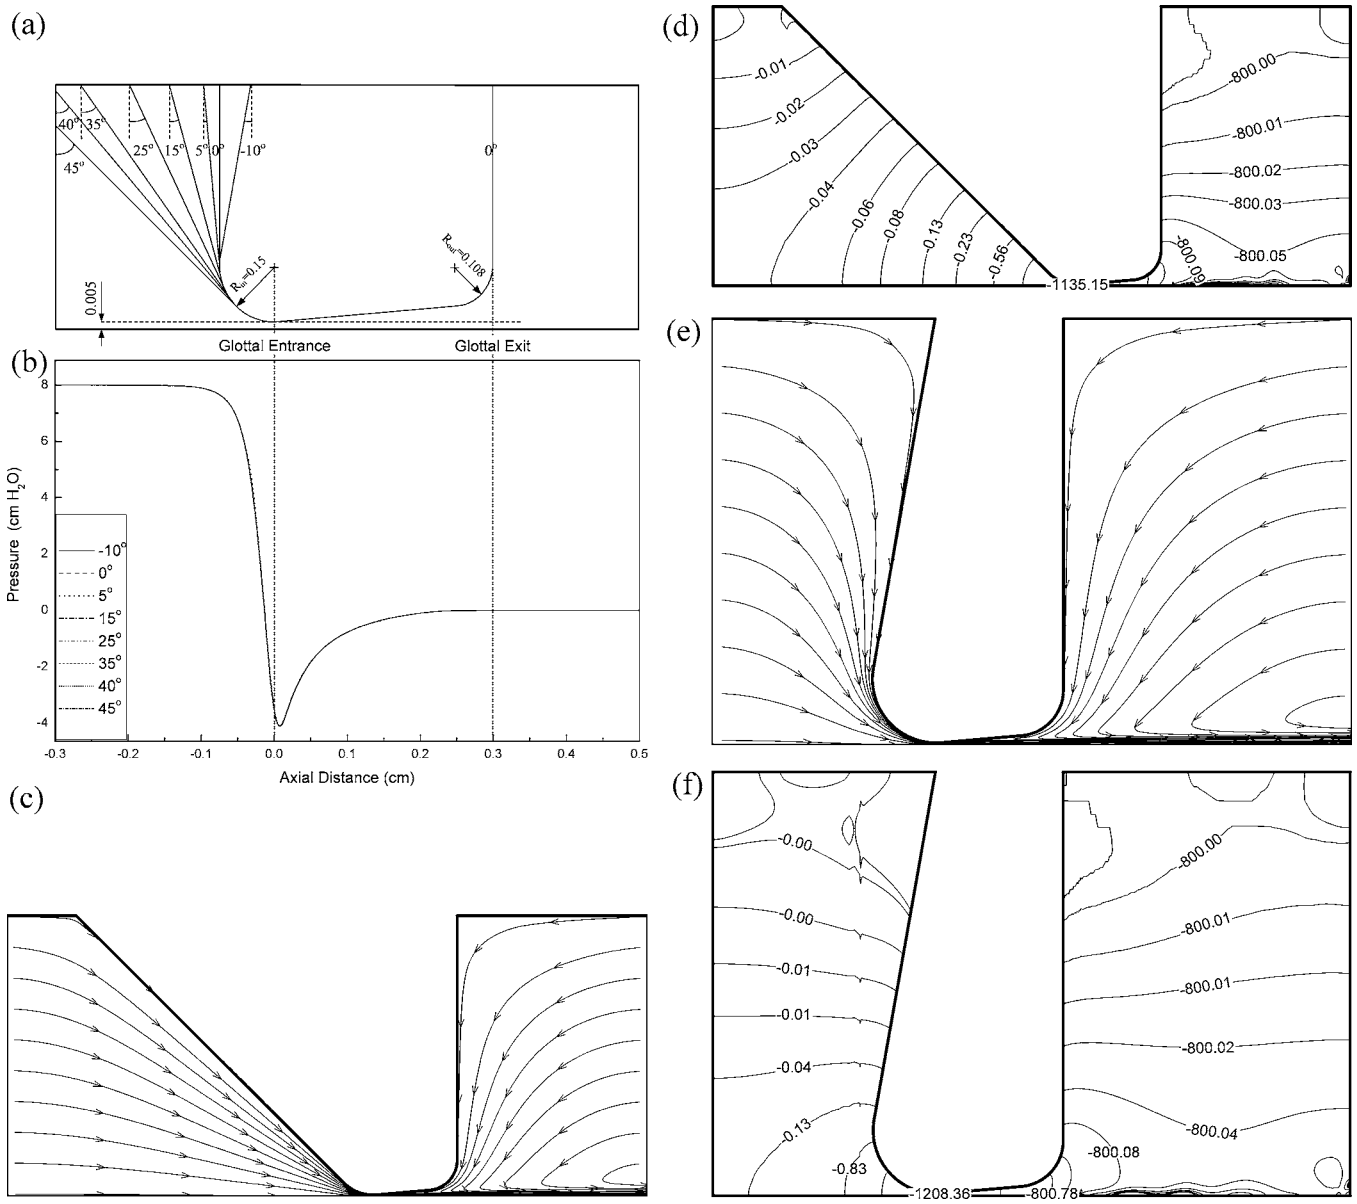

FIG. 1. Schematic of eight inferior vocal fold surface angles for the 10° divergent glottal angle, 0.01 cm minimal glottal diameter, and 8 cm H_2O transglottal pressure drop, and the corresponding pressure distributions (using FLUENT) on the vocal fold surfaces. (a) Outlines of the glottal configurations corresponding to the eight inferior vocal fold surface angles, with the superior vocal fold surface angle held constant at 0° (the entire vocal fold is not shown). (b) Corresponding pressure distributions, which overlap. (c) Streamlines for the 45° condition. (d) Pressure contours for the 45° condition. (e) Streamlines for the −10° condition. (f) Pressure contours for the −10° condition. Distances are in centimeters.

just past the minimum diameter cross section. Downstream of this location the pressure recovered (that is, increased to the prevailing supraglottal pressure, zero or atmospheric) due to the cross-sectional area increase.

The pressure distributions for the inferior vocal fold surface angles shown in Fig. 1(b) suggest that for angles considered realistic for human phonation, the vocal fold surface pressures are essentially identical (for the chosen entrance radius). How large must this angle be, assuming a constant glottal entrance radius, before significant changes to the pressure distributions appear? Figure 2(b) shows the results for inferior vocal fold surface angles between 60° and 87.5°. Differences appeared only for angles greater than 70°: the locations of the minimal diameters remained the same, the minimum pressures became less negative, and the pressure distribution on the inferior vocal fold surface decreased. The increase in minimal pressure for the largest angle shown was 13% of the transglottal pressure. These results suggest, then, that the pressure distributions on the vocal fold surfaces (inferior surface, glottal entrance, and intraglottal surface) for a constant glottal entrance radius for 10° divergent glottal angle remained approximately the same for inferior vocal fold surface angles between −10° and 70°.

It may appear curious that, as Fig. 1(b) indicates, the normal surface pressures are essentially identical for inferior vocal fold surface angles between 45° and −10°. Figures 1(c)–1(f) show the streamlines and pressure contours for the 45° and −10° geometries, respectively. These figures indicate that normal pressures are indeed almost identical because of the size of the entrance radius chosen for this study. A much

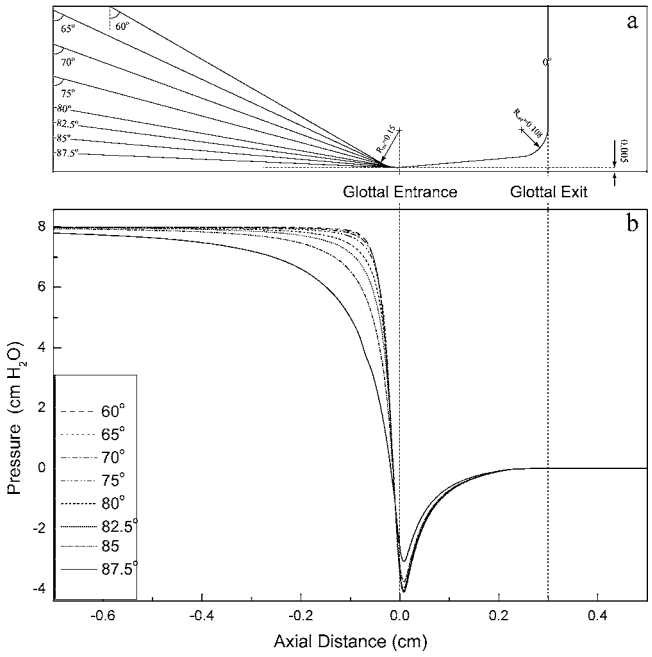

FIG. 2. Schematic of eight larger inferior vocal fold surface angles for the 10° divergent glottal angle, 0.01 cm minimal glottal diameter, and 8 cm H_2O transglottal pressure drop, and the corresponding pressure distributions (using FLUENT) on the vocal fold surfaces. (a) Outlines of the glottal configurations corresponding to the eight inferior vocal fold surface angles, with the superior vocal fold surface angle held constant at 0° (the entire vocal fold is not shown). (b) Corresponding pressure distributions. Distances are in centimeters.

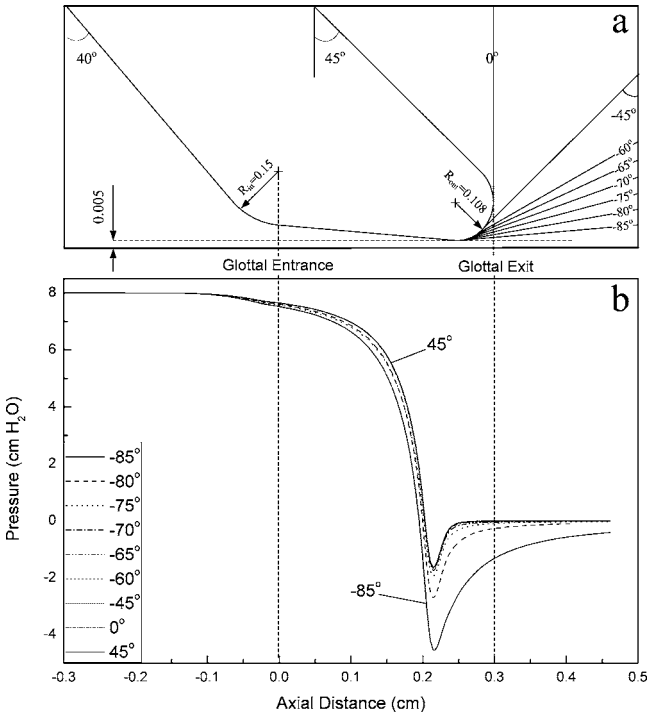

FIG. 3. Schematic of nine superior vocal fold surface angles for the 10° convergent glottal angle, 0.01 cm minimal glottal diameter, and 8 cm H_2O transglottal pressure drop, and the corresponding pressure distributions (using FLUENT) on the vocal fold surfaces. (a) Outlines of the glottal configurations corresponding to the nine superior vocal fold surface angles, with the inferior vocal fold surface angle held constant at 40° (the entire vocal fold is not shown). (b) Corresponding pressure distributions. Distances are in centimeters.

smaller glottal entrance radius might show more sensitivity to the inferior vocal fold surface angle near glottal entrance, but entrance radius was not considered as a parameter in this study (it was in the study by Li *et al.* (submitted), which shows that intraglottal pressures are highly sensitive to the entrance radius for divergent glottal angles).

Similar results for the pressures on the vocal fold surfaces were found for each of the other two glottal shapes, the uniform and 10° convergent glottal angles, for the constant glottal entrance and exit radii. That is, the minimal glottal pressures and the pressure distributions on the vocal fold surfaces were not altered until the inferior vocal fold surface angle was greater than 70°. The axial location of greatest pressure drop for both the uniform and the convergent glottis was near the exit of the glottis (as will be shown below for the convergent glottis).

B. Effects of changing the superior vocal fold surface angle

The superior vocal fold surface angle also appears not to influence the vocal fold surface pressures except for angles beyond those expected for human phonation. Figure 3(b) shows the results for the 10° convergent glottal angle for a constant glottal exit radius (the convergent angle was chosen for display because the large pressure changes near the glottal exit were thought to be potentially especially sensitive to changes in the superior vocal fold surface angle. The surface pressures for all positive angles were nearly identical, meaning that the vocal fold surface pressures were independent of positive superior vocal fold surface angles, until the superior vocal fold surface angle exceeded approximately −65°. The axial location of greatest pressure drop for each of the superior angles was constant (at approximately 0.21 cm axial distance in Fig. 3). As the superior vocal fold surface angle increased negatively beyond −65°, the minimum pressure became more negative and the pressure increase past that point became more gradual (because the superior surface acted like a diffuser, not an abrupt area enlargement), with slight influence on the intraglottal pressures (reduction in the pressure distribution).

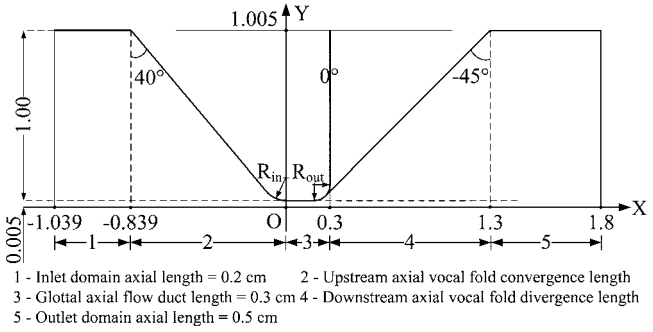

FIG. 4. Schematic of the glottal parameters and their dimensions for the 40° inferior vocal fold surface angle and −45° superior vocal fold surface angle. R_{in} was set at 0.15 cm, and R_{out} was set at 0.108, 0.0987, and 0.0908 cm for the divergent 10°, uniform 0°, and convergent −10°, respectively. The 0.005 cm shows only half of the minimum glottal diameter.

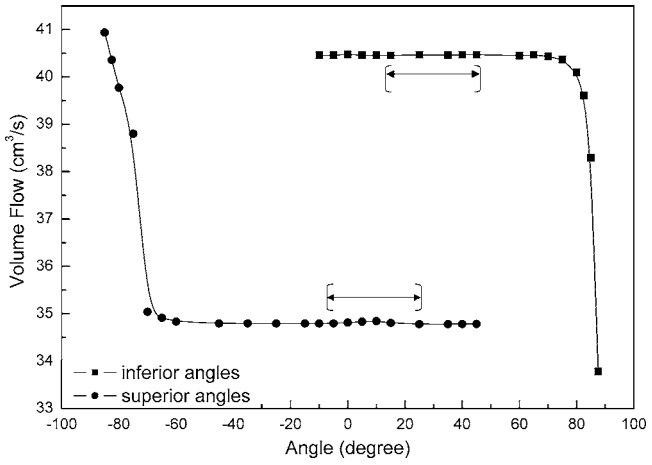

FIG. 5. Flow rates for all of the inferior and superior vocal fold surface angles used in this study. The glottal angle for the inferior angles was 10° divergent, and 10° convergent for the superior angles (0.01 cm minimal glottal diameter, 8 cm H_2O transglottal pressure drop). The brackets indicate the ±2 SDs for phonation given in Nanayakkara (2005).

Again, the trends for the results for the superior vocal fold surface angle were similar for the other two glottal angles, the uniform and 10° divergence. That is, the pressure distributions on the vocal fold were essentially identical for the range of 45° to −65° for all of the uniform and divergent glottis cases, and began to change slightly as the superior vocal fold surface angle increased negatively beyond −65°. The pressure distribution lowered along the supraglottal vocal fold walls as the negative superior angle increased negatively beyond −65°, the larger the negative superior angle, the larger this change. Because the changes were consistent, there is no need to show the figures for the uniform and divergent glottal conditions.

C. Effects of changing the superior and inferior vocal fold surface angles on glottal flow

The effect of the inferior and superior vocal fold surface angles on glottal flow can be seen in Fig. 5. The flow values are given for changes in both inferior and superior vocal fold surface angles, where the divergent 10° glottis was used for the inferior angle values, and the convergent 10° glottis for the superior angle values (the divergent glottis offers less flow resistance yielding higher flows in the bracketed angle regions). The changes in the flow for each series of values correspond to the angle values when changes in surface pressures are seen in the preceding figures. For the inferior vocal fold surface angle, the flow is constant within the region of the ±2 SDs expected for phonation noted earlier (shown by the double-headed arrows), decreasing only when the angle is above approximately 65°. Above this angle the flow resistance increases as the effective length of the inferior vocal fold surface increases. The opposite effect occurs for the superior vocal fold surface angle. The flow is unaffected within the range of ±2 SDs expected in phonation, but for angles more negative than approximately −65° the flow increases, indicating less flow resistance. This is due to the diffuser effect of the expanding supraglottal surfaces allowing pressure rise along them, and therefore less flow resistance for the same transglottal pressure condition.

D. Comparison of computational results to lossless Bernoulli equation

It is of some importance to explore the differences between the computational approach of FLUENT, which includes viscous effects, and the lossless Bernoulli equation. That is, it may be that portions of the pressure distributions are sufficiently identical to the predictions from the Bernoulli equation that the extra cost and sophistication of a computational approach such as FLUENT are not warranted.

For the steady, laminar, incompressible, and lossless airflow, Bernoulli's equation for any two cross sections in the model can be expressed as

$$P_1 + \frac{1}{2}\rho\frac{Q_1^2}{A_1^2} = P_2 + \frac{1}{2}\rho\frac{Q_2^2}{A_2^2}, \tag{1}$$

where P is pressure, ρ is the volume density of air (1.225×10^{-3} g/cm^3), and $(1/2)\rho(Q^2/A^2)$ is the kinetic energy per unit volume (or dynamic pressure). The flow rate, Q, is given by $Q=AV$, where A is the cross-sectional area in the model, and V is the average velocity.

For the models in this study, mass balance gives

$$Q_1 = A_1V_1 = Q_2 = A_2V_2.$$

The values of Bernoulli static pressure drops are therefore

$$P_{\text{static Bernoulli}} = \frac{1}{2}\rho(V_2^2 - V_1^2) = \frac{1}{2}\rho Q^2\left(\frac{1}{A_2^2} - \frac{1}{A_1^2}\right). \tag{2}$$

And, the Bernoulli dynamic pressure values are

$$P_{\text{dynamic Bernoulli}} = \frac{1}{2}\rho\frac{Q^2}{A_2^2}. \tag{3}$$

Four vocal fold surface angle conditions were used for divergent and convergent glottal angles to calculate the lossless Bernoulli pressure distributions, namely, 45° and 87.5° inferior surface angles for the 10° divergent glottal angle, and −45° and −85° superior surface angles for the 10° convergent glottal angle. These conditions were used with FLUENT in Fig. 1(a), Fig. 2(a), Fig. 3(a), and Fig. 4, with the transglottal pressure held constant at 8 cm H_2O and minimal glottal diameter of 0.01 cm. The corresponding volume flows for these four surface angles obtained using FLUENT were used in the Bernoulli equation. These were 40.47 and 33.78 cm^3/s for the 45° and 87.5° inferior surface angles, and 34.78 and 40.93 cm^3/s for the −45° and −85° superior surface angles, respectively (the flows are shown in Fig. 5).

Figures 6 and 7 show the static and dynamic pressure distributions for these four vocal fold surface angles. The figures show that there are large differences between the results of FLUENT and the lossless Bernoulli equation. It can be seen from Fig. 6(a) and Fig. 7(a) that (a) the FLUENT static pressure is lower than the corresponding Bernoulli static pressure; (b) the smaller the cross-sectional area in the model, the larger the pressure difference; and (c) more down-

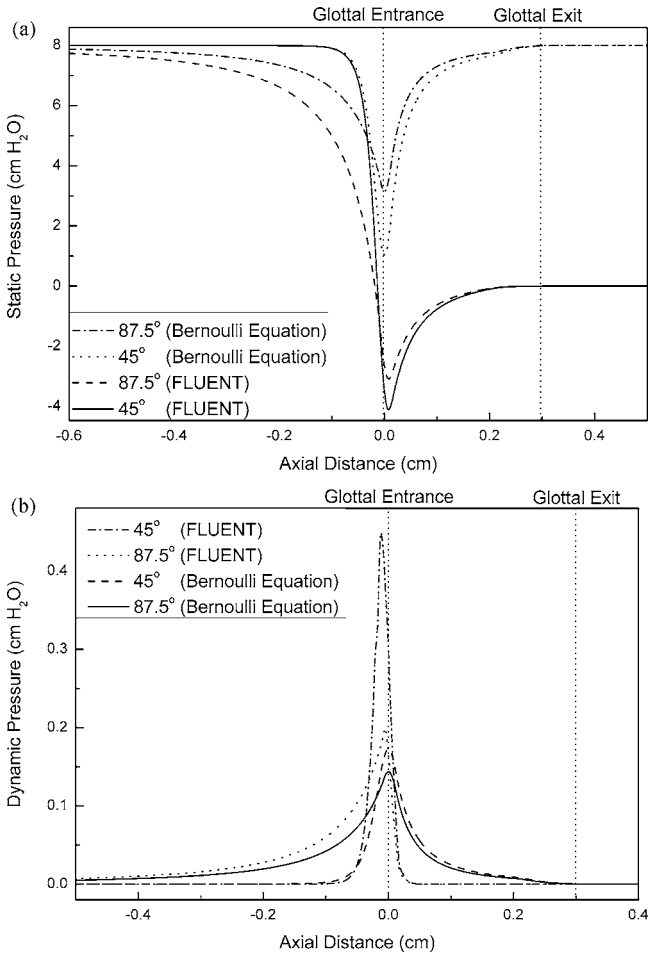

FIG. 6. Static and dynamic pressure distributions on the vocal fold surfaces for 45° and 87.5° inferior glottal angle for the 10° divergent glottal angle, 0.01 cm minimal glottal diameter, and 8 cm H_2O transglottal pressure drop. The data computed by both FLUENT and Bernoulli equation. (a) Static pressure distributions. (b) Dynamic pressure distributions.

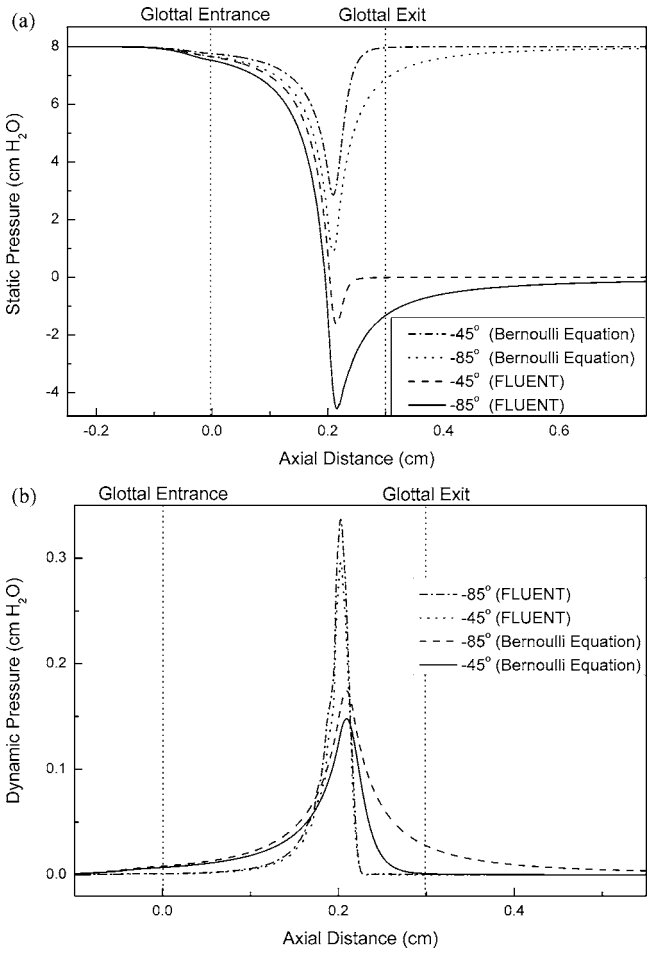

FIG. 7. Static and dynamic pressure distributions on the vocal fold surfaces for −45° and −85° superior glottal angle for the 10° convergent glottal angle, 0.01 cm minimal glottal diameter, and 8 cm H_2O transglottal pressure drop. The data computed by both FLUENT and Bernoulli equation. (a) Static pressure distributions. (b) Dynamic pressure distributions.

stream sections have larger pressure differences. For example, for the 45° inferior surface angle for the divergent case, the pressures begin to differ in an obvious manner upstream of the narrowest point. The difference is about 5 cm H_2O at the minimal diameter, and then, due to the lossless characteristic of the Bernoulli equation, differs by 8 cm H_2O at the exit. The Bernoulli equation does not predict drag losses.

The dynamic pressure distributions, which are shown in Fig. 6(b) and Fig. 7(b), suggest that the dynamic pressure values are relatively quite small compared to the static pressures. For example, for the 45° inferior surface angle case (divergent glottis) for FLUENT, the mean range of static pressure is from 8 cm H_2O to approximately −4 cm H_2O, whereas the dynamic pressure range is from approximately 0.44 cm H_2O to 0 cm H_2O. The peak dynamic pressure according to the Bernoulli equation is about one-third as much. The figures also suggest that the dynamic pressure is more sensitive to the minimal diameter region in FLUENT than for the Bernoulli equation because the former creates not only a higher peak dynamic pressure near the minimal diameter, but also lower values just away from the minimal diameter location.

IV. DISCUSSION

The results of this computational modeling study suggest that, for any specific glottal angle with specified glottal entrance radius, glottal exit radius, and minimal glottal diameter, the pressures on the vocal fold surfaces for a constant transglottal pressure are essentially nearly identical over a wide range of inferior and superior vocal fold surface angles that includes the angles which are realistic for human phonation. Therefore, whereas intraglottal pressures may be highly sensitive to the radius of the glottal contours at entry (for the divergent glottis) and exit (for the convergent glottis) (Scherer *et al.*, 2001a; Li *et al.*, submitted), as well as the glottal angle and minimal glottal diameter, these pressures are not sensitive to the steepness of either the inferior or the superior vocal fold surfaces. This may help "explain" the wide range of angles encountered in human phonation data for the inferior vocal fold surface angle. That is, a variable that has little sensitivity to the all-important vocal fold driving forces may vary over a wide range, as appears to be the case for the inferior vocal fold surface angle. Indeed, the results of Nanayakkara (2005) suggest that the inferior vocal fold surface angle in particular is highly person specific.

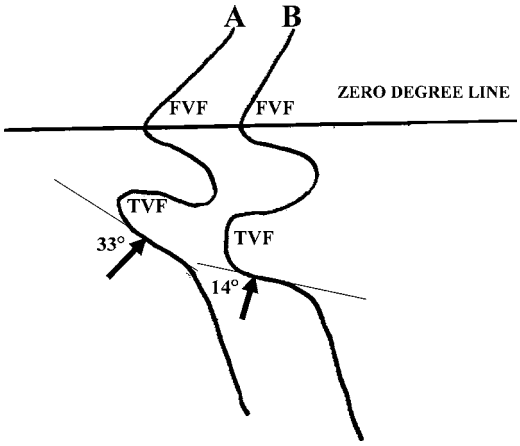

FIG. 8. (A) and (B) each represent an outline of one side of a larynx airway. The two outlines are from different subjects from the corpus of x-ray laminagram tracings of phonation by humans in Nanayakkara (2005). The outlines suggest the potentially wide range of inferior vocal fold surface angles, and therefore their corresponding resultant force vectors to move the vocal folds upward and laterally. The "FVF" and "TVF" in the figure mean "false vocal fold" and "true vocal fold," respectively.

The potential interaction of the superior vocal fold surface angle with the false vocal folds and the possible resonance utility of the ventricles (Agarwal, 2004; Zhang *et al.*, 2004), and the exit glottal jet flow behavior not given by the FLUENT approach, may make the superior vocal fold surface more sensitive to phonatory aerodynamics and acoustics not pursued in this study, although as shown here perhaps not sensitive *itself* to altering pressures on the vocal fold surfaces.

There may well be anatomical and surgical cases where the inferior and superior vocal fold surfaces take on the larger angles studied here, whereby the pressures would be altered from normal expectation. These should be taken into consideration for their potential effects on phonation.

As the figures of this report (except Figs. 5–7) suggest, when the inferior and superior vocal fold surface angles take on different values, the size and shape of the vocal fold itself changes. Thus, even though the surface pressures may not differ, the biomechanical vocal fold tissue characteristics, mass and shape in particular, will alter. With pressures that do not change when inferior and superior vocal fold surface angles change, the altered vocal fold may nonetheless take on different two-dimensional oscillatory behaviors. In particular, one might expect a greater vertical force on the vocal fold when the inferior vocal fold surface angle is smaller (more horizontal), as suggested in Fig. 8, where two x-ray laminagraphic tracings [from the corpus used in the Nanayakkara (2005) study] are shown, one having an inferior vocal fold surface angle of 14°, the other 33°. Future research modeling should alter the inferior and superior vocal fold surface angles to determine their effects on vocal fold oscillation and the resultant volume velocity signal.

The viscous and kinetic pressure losses are more realistically evident from the FLUENT computational approach than from the lossless Bernoulli equation. The Bernoulli equation underpredicts intraglottal pressure changes and should be used with great caution in phonatory modeling.

The modeling here was of the half-field type, forcing symmetry of the laryngeal duct, flows, and pressures. Assuming that the inferior vocal fold surface angle does not change appreciably during a cycle of phonation, the results appear to suggest that if there were asymmetries (right vocal fold, left vocal fold differences) in the inferior vocal fold surface angle, there most likely would *not* be significant intraglottal pressure changes due to that asymmetry *per se*, leaving asymmetries of the glottal shape (oblique glottal angles, contour differences due to lesions) more responsible for intraglottal pressure differences (Scherer *et al.*, 2001b, 2002). However, if the asymmetries were extreme enough, arising for example from edema, webbing, or lesions on the inferior surface of the vocal folds, the geometric alterations may be severe enough to alter the driving pressures along the vocal folds, and should be studied for this effect; the change in biomechanical characteristics, if involved with the tissue in motion, still may have a more profound effect on vocal fold oscillation. Because the superior vocal fold surface angle is part of the ventricle, it is more difficult to reach the same conclusion that the resulting vocal fold surface pressures are independent of the superior vocal fold surface angle throughout a phonatory cycle; the results here only suggest that if the false vocal folds were not present, the superior angle itself would not affect the vocal fold surface pressures.

V. CONCLUSIONS

A wide variety of inferior and superior vocal fold surface angles for uniform, 10° convergent, and 10° divergent glottal angles was explored separately in this study by using the computational fluid dynamics code FLUENT. The results suggest that the intraglottal pressures are essentially independent of realistic inferior and superior vocal fold surface angles for each of the glottal angle cases. However, the effects on vocal fold motion as a result of altering vocal fold biomechanical characteristics because of changes in the inferior and superior vocal fold surface angles needs study. For inferior vocal fold surface angles greater than approximately 70°, and for superior vocal fold surface angles lower negatively than about −65°, the pressures on the vocal fold surfaces began to alter, suggesting that these effects would be of importance to vocal fold kinematics and aerodynamics for a variety of abnormal and medical/surgical considerations.

Although the results of this study appear broadly applicable to aerodynamic and modeling concerns of the vocal folds and phonation, the limitations of the modeling here (laminar not turbulent or transitional code, the lack of the presence and effects of the false vocal folds, the assumption of symmetry, the use of a limited range of intraglottal angles, and only one minimal diameter and transglottal pressure) suggest a conservative acceptance of the results. Further study of a more complete model would more accurately elucidate the phonatory effects of the inferior and superior vocal fold surfaces.

(Received 25 July 2005; revised 17 February 2006; accepted 17 February 2006)

The production of voice is related to the flow of air through the glottis, whose time-dependent shape is defined by the motion of the vocal folds and the translaryngeal pressure. A scaled dynamically similar experimental apparatus that mimics the motion of the vocal folds was designed and built, such that both the glottal diameter and glottal angle change during a motion cycle. This motion is more realistic than in other reported dynamic models. The motion of the folds can be driven at different frequencies. The glottal flow takes place at a constant inlet pressure, mimicking the lung pressure. The transglottal pressure difference and flow rate were measured over the motion cycle. Satisfactory agreement was obtained for identical cases by numerically solving the two-dimensional, incompressible Navier-Stokes equations. Both experimental and numerical data showed that the glottal flow rate and transglottal pressure were affected by the oscillation frequency of the vocal folds. Flow visualization showed that the glottal flow patterns, which are a potential source of aero-acoustic sound, are influenced by the oscillation frequency. However, glottal flow resistance depended to a lesser extent on vocal fold oscillation frequency for the portion of the cycle when the glottis was divergent. [DOI: 10.1121/1.2186429]

I. INTRODUCTION

The production of voice, or phonation, is closely related to the oscillation of the vocal folds that induces a modulation of the glottal air flow. The oscillation of the folds is a quasi-periodic process, the characteristics of which (i.e., range of motion and frequency) depend on the interaction between fluid and structure (i.e., vocal folds). The average oscillation frequency is approximately 125 Hz for males and 200 Hz for female speakers (Titze, 1994).

The relationship between the transglottal pressure drop and volumetric flow rate is important relative to the oscillation of the vocal folds. A significant number of studies, both theoretical and experimental, have been dedicated to the investigation of the relationship between pressure and flow equations for situations relevant to speech production. Some theoretical models were shown to predict satisfactorily the flow-induced oscillations of the vocal folds. Relatively simple theoretical mechanical models, coupled with simplified flows, namely the two-mass (e.g., Ishizaka and Flanagan, 1972) and the three-mass model (Story and Titze, 1995), are to be listed in this category, although the current trend is to employ more complex tissue models (e.g., Alipour and Scherer, 2000; Alipour *et al.*, 2000). However, the complexity of the motion of the vocal folds has deterred the use of moving experimental models. Static models were used instead, with shapes that correspond to different position stages of oscillation of the folds (e.g., van den Berg *et al.*, 1957; Gauffin *et al.*, 1983; Scherer *et al.*, 1983; Alipour *et al.*, 1996a). The experimental data obtained with these physical models were used to validate computational models of glottal flow (e.g., Guo and Scherer, 1993). Important pressure-flow equations were thus determined for a multitude of significant static cases. Most of the static studies were performed for symmetric glottal configurations, although asymmetric configurations have also been investigated (Scherer *et al.*, 2001). The pressure and velocity profiles were investigated for the case of a hemilarynx by Alipour and Scherer (2002).

There is a limited amount of reported experimental work investigating the unsteady phenomena that occur during phonation. The work of Pelorson *et al.* (1994, 1995) investigated both experimentally and theoretically the unsteady flow through static models of the glottis when the flow was driven by an abrupt pressure variation. They used the measured glottal pressures and velocities to validate a flow model based on the unsteady Bernoulli equation and boundary layer equations. The theoretical model showed good agreement with the experimental data for the transient period. The flow model was coupled with a modified two-mass model (Pelorson *et al.*, 1994), and the predicted time derivative of glottal volume velocity was in good agreement with the experimental data (obtained by inverse filtering for real speech). There are few studies reported that utilize dynamic vocal fold models. Deverge *et al.* (2003) reported a dynamic vocal fold model which is composed of a set of rigid vocal fold replicas, one of which was given an oscillatory motion; the model allows for the collision of the vocal folds. The experimental results were compared against the theoretical predictions of

simplified flow models (steady Bernoulli equation corrected for friction, boundary layer solution for steady flows, and Reynolds equation). It was found that the effects of flow unsteadiness are not important for the studied case, such that the steady theoretical models could satisfactorily predict the pressure at a certain location inside the glottis. The unsteady Reynolds equation was found to be useful only close to collision, when the viscous effects dominate the flow. This model does not consider the vocal tract length, and the overall pressure was not kept constant. A dynamic model that uses a set of elastic replicas has been reported by Zhang *et al.* (2002), for which the acoustic pressure of waves radiated upstream and downstream of the orifice was measured. The acoustic source was modeled based on the steady Bernoulli equation, thus neglecting the unsteady phenomena. It was found that the experimental data were well predicted by using the quasi-steady approximation (i.e., assuming that the flow through the time-varying orifice can be regarded as a sequence of steady flows through stationary orifices of identical configuration). The dipole sources were identified as the dominant sound sources for pulsating flows at frequencies typical for phonation. A simple mechanical, real-life size model of the vocal folds has also been reported by Barney *et al.* (1999). In this model a pair of shutters, driven by a vibration generator, mimicked the vocal folds. The flow in the apparatus was provided by a constant flow source. The acoustic signal at the exit of the vocal tract was monitored by a pair of microphones and was used to estimate the pressure wave amplitudes in the shutter plane. The velocity at certain points in the duct was measured by hot-wire anemometry. The experimental results were compared with the predictions of the plane-wave classic acoustic theory of speech production. It was revealed that the plane wave acoustic theory failed to correctly predict the radiated sound field and that there was an additional acoustic source associated with the vortices generated at the shutter exit. This indicates that the flow patterns downstream of the vocal folds may be relevant to sound production. Recently, Thomson *et al.* (2005) reported a dynamic self-oscillating model that does not include the vocal tract, and a complementary numerical model in order to investigate the energy transferred from the flow to the vocal folds during one oscillation cycle. The motion of the folds is dependent on the properties of the material used to fabricate the model vocal folds, which was assumed to be reasonably similar to human tissue. It was found that greater pressures occur inside the glottis during the time of positive energy flow to the solid rather than during the time of negative energy flow. This asymmetry in the energy flow maintained the self-sustained oscillations of the vocal folds.

Prompted by the lack of a dynamic mechanical model that is able to realistically mimic the time-dependent glottal shape, a more realistic mechanical model was built. The oscillation of the vocal folds was forced [a similar approach was used by Alipour *et al.* (1996b), in their numerical study of the glottal flow]. The motion of the vocal folds is approximated by a plan-parallel motion, composed of translations and rotations. The generated motion is compatible with two of the lower order eigenmodes of the vocal folds. Titze and Strong (1975) analyzed the vocal folds as an elastic, compressible medium and obtained the lowest-order vibration modes that are excited in most cases of phonation. Berry and Titze (1996) obtained the three lowest order eigenmodes for the vocal folds considered as both a compressible and, more realistically, an incompressible tissue. The z-10-like (vertical) mode does not play a critical role in vocal fold dynamics. The other two modes, however, can be used to describe the vocal fold motion: x-11, which was shown to produce divergent-convergent shapes during oscillation, and x-10, which describes the medial-lateral movement of the folds. The surface of the vocal folds, between the upper and the lower curved margins, is approximately straight. It was also shown that the eigenfrequencies for these two modes are similar, which facilitates a 1:1 entrainment of the modes during oscillation. These considerations justify the design of a dynamic model, which mimics the motion of the vocal folds with a straight surface, and changes both the glottal diameter and glottal angle to obtain divergent-convergent configurations. The glottal angle can be controlled and synchronized with the glottal diameter. The flow is driven by a constant overall pressure that mimics the lung pressure, which is reported to be relatively constant during phonation. The dynamic model allows for the measurement of the time-dependent flow rate and transglottal pressure for a range of overall (lung) pressures and driving frequencies. The walls of the apparatus are transparent, such that flow visualization inside the glottis can be performed (to be more extensively reported in a future paper). Flow visualization is necessary to establish the character of the flow inside and downstream of the glottis.

The measured values of flow rates and transglottal pressures are compared with the results of numerical simulations performed using the CFD code FLUENT, which allows solution of the Navier-Stokes equations governing the flow through the moving glottis. The results of the numerical simulations are regarded as more reliable than those that can be obtained using simplified flow models based on the Bernoulli equation or boundary-layer approximation.

II. EXPERIMENTAL APPARATUS

A schematic of the experimental apparatus used to obtain the experimental results presented in this paper is shown in Fig. 1. The apparatus is a dynamic mechanical model of the vocal folds, which can replicate the time-dependent shape of the glottis. The replicas of the vocal fold surfaces were made of a deformable material (latex). The latex folds are made of strips of Thera-Band exercise band (Thera-Band Gmbh), with an initial thickness of 0.79 mm $\left(\frac{1}{32}\text{ in.}\right)$. Compared to the real-life dimensions, the model is scaled up by a factor of 7.5.

The difference between the dimensions of the real-life vocal folds and those of the model involves a difference between the parameters related to the flow. The relationship between different quantities in the real-life vocal folds and the model is established using dynamic similitude. Dynamic similitude is used to experimentally study the physical phenomena occurring in a system in which it is too difficult to use the real-life geometry for measurements due to either the

magnitudes of the flow variables or the geometric size. It is also used in cases where the governing equations (i.e., continuity, Navier-Stokes, and energy equations) cannot be solved for the original system. This concept also involves geometric similitude, where all geometric dimensions are scaled. The important dimensionless groups are obtained by using the dimensionless Navier-Stokes equations along with the dimensionless boundary and initial conditions (Batchelor, 1967). All the important dimensionless groups (Reynolds number, pressure coefficients, Strouhal number) must have the same value in the real system and the model system. Dynamic and geometric similitude ensure that the same dimensionless pressure and velocity distributions will occur in each system. For the system of concern in this study, geometrical similarity, the Reynolds number, the dimensionless pressure, and the Strouhal number must be kept the same. The choice of a scale factor of 7.5 was made in order that the apparatus could be accurately constructed. The larger dimensions also helped to insert the driving mechanism of the vocal folds, as well as to perform flow visualizations. Since enlarging the geometry causes a reduction in magnitude in model velocities and pressures, it is necessary to ensure that the flow variables can be accurately measured in the scaled system. Scaling ratios from 5 to 7.5 could have been used in the present work.

The Reynolds number is defined as $\mathrm{Re}=D_g U/\nu$, where D_g is the minimal glottal diameter, $U=Q/D_g W$ is the average flow velocity in the cross section of minimum diameter, Q is the volumetric flow rate at inlet, W is the anterior-posterior dimension of the vocal fold, 1.33 cm real-life (corresponding to a width of 10 cm in the physical model), and $\nu=15\times10^{-6}$ m^2/s is the kinematic viscosity of air. The range of Reynolds numbers for the reported experiments is 400–1800. The equality of the Reynolds number between the real-life case and the model requires that the velocities in the model must be 7.5 times smaller than in real-life, while the volume flow rates are 7.5 times larger. The equality of pressure coefficients leads to the pressures in the model being 7.5^2 times smaller than in real-life, where the pressure coefficient is defined as $\Delta p/(0.5\rho u^2)$; here p is the pressure, ρ is the density of air, and u is the fluid velocity. The Strouhal number is defined as $\mathrm{St}=fD_g/u$, where f is the oscillation frequency of the vocal folds (on average around 100 Hz for males and 200 Hz for females). Equality of the Strouhal number requires that the model frequency be 7.5^2 times smaller than the real-life frequency. In order to avoid confusion, all of the quantities reported in the following sections will be expressed in real-life units.

The total length of the experimental device is similar to that of the human vocal tract, which allows for the presence of the inertance effects of the air in the sub- and supra-glottal segments in the vocal tract. The length of the vocal tract downstream of the vocal folds (i.e., between the vocal folds and the exit reservoir) is 14.8 cm real-life, while the length of the trachea, between the entry reservoir (corresponding to the lungs) and the vocal folds, is 3.9 cm real-life.

The motion of the vocal folds is driven by a computer-controlled mechanism. The driving mechanism is composed of two identical lever mechanisms, each powered by a stepper motor (450SM-B3-HM, Aerotech Inc.). The motion of the two motors is coupled by software, allowing for flexibility in prescribing the glottal motion. Each lever mechanism drives a set of cylinders (see Fig. 2), which helps shape the elastic (deformable) material into a controlled configuration. The thickness of the deformable material (i.e., 0.79 mm) was taken into account to determine the geometrical configuration of the glottis. Repeated tests showed that the variation of thickness along a motion cycle led only to negligible alterations of the glottal configuration, as compared to an ideal material whose thickness is constant.

Both the upper and lower sets of cylinders are moved symmetrically with the centerline. The symmetry of the mechanism was verified on zoomed-in pictures with a camera mounted above the apparatus (a graded plate of Plexiglas

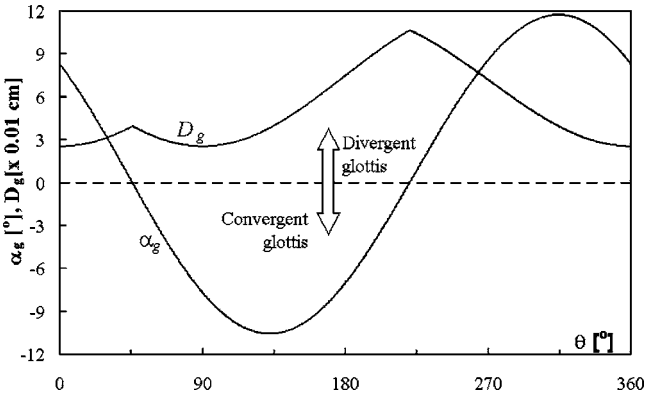

FIG. 5. Glottal diameter and glottal angle during an oscillation cycle.

was installed on top of the mechanism, with a clearly marked centerline). Due to the high stiffness of the mechanism, spring preloaded action levers, and low forces induced by the latex band, the measured double-sided uncertainty of the minimum diameter (measured at 0, 90, 180 and 270°) was less than 0.076 mm (0.003 in.). The top-view close-up of the vocal folds is presented in Fig. 3. The radii shown here include the contribution of the thickness of the deformable material. For this experiment, the mechanism was set such that the motion of the downstream set of cylindrical deformers lags the upstream set by 90°. This value is consistent with the phase delay between two flesh points located at the upper and lower margins of the vocal folds, measured by Titze *et al.* (1993) on excised canine larynges. Also, Berry *et al.* (1994) showed that a 90° phase difference exists between the two dominant eigenmodes of the vocal folds, i.e., an x-11-like mode, responsible for the alternately divergent-convergent shapes, and an x-10-like mode, responsible for the lateral motion of the vocal folds. The resulting motion mimics the motion of the vocal folds during an oscillation cycle (Hirano, 1977; Hofmans and Groot, 2003). For reasons dependent on the design of the driving mechanism, the beginning of a cycle corresponded to the upstream set of deformers being in the closest position (i.e., smallest glottal gap), with the glottis in a divergent posture. Conventionally, the start of the oscillation cycle is usually depicted when the folds are located in the closest position (normally in contact, i.e., minimum gap is zero) just before glottal opening, and the glottal angle is convergent, which means that there is a 90° difference in the reference (driving) angle between the mechanism and the real-life vocal folds. Figure 4 presents certain positions of the vocal folds versus the driving angle, θ, which is the angle of rotation of the motor driving the upstream set of deforming cylinders. The resulting motion cycle is similar to the schematic presented by Hirano (1977). The positive glottal angles correspond to the divergent shapes, while the negative ones represent convergent shapes. One restriction of the current layout of the apparatus is that it does not allow for the contact of the latex vocal folds, since the collision may result in damage to the mechanism. Thus, the minimum glottal gap was set to a positive value. The values of the minimal glottal gap (in cm real-life) are also given in Fig. 4. The smallest glottal gap was 0.025 cm, and the largest 0.104 cm, throughout the cycle. The variation of glottal gap and glottal angle during one cycle of oscillation is shown in Fig. 5. It is noted that the minimal glottal gap is the same concept as the projected glottal diameter or area in human phonation.

The variables of control are the amplitude of motion of the vocal folds (by setting up the amplitude of motion of the cylinders 3′ and 3″ in Fig. 2), the phase between the upstream and downstream margins of the vocal folds, the frequency of oscillation, and the overall driving pressure (corresponding to lung pressure). One important feature of the flow through the model is that it is driven by a constant pressure source, which models the quasi-constant lung pressure during phonation. The alternate condition, namely constant flow rate through the model, is more convenient to impose from a design standpoint, but it does not reflect physical reality as well. The apparatus was designed such that the flow resistance of the glottis is much larger than the

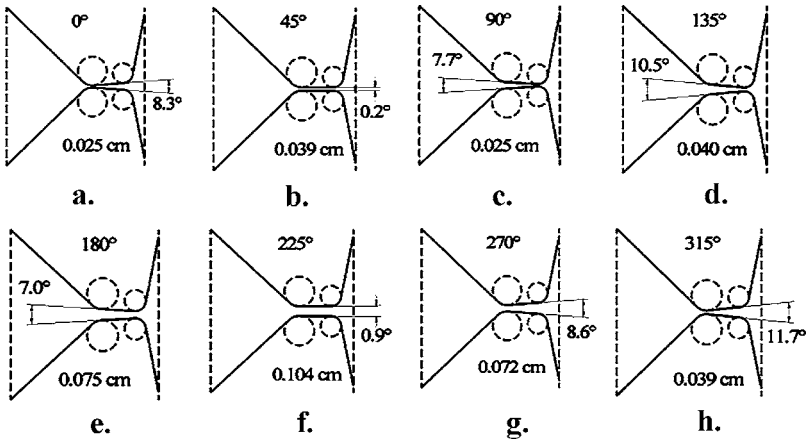

FIG. 4. Glottal shape for certain values of the driving angle, θ.

flow resistance anywhere else in the system. Another particularity of the apparatus is that the air is drawn by a lower pressure created downstream, as this was found more convenient from a design standpoint. The experiments were performed for a set of three lung pressures, i.e., 4, 8, and 12 cm H_2O real-life. Because the pressures in the model are smaller by a factor of 7.5^2 than real-life, the driving pressures used in the model were 7, 14, and 21 Pa. The measurement of such small pressures necessitates the use of extremely accurate pressure sensors (Validyne DP103-10, Validyne Engineering) for the transglottal pressure difference. The frequencies used for the experimental tests were 0.5, 1, 1.5, and 2 Hz, corresponding to real-life frequencies of 28.1, 56.2, 84.4, and 112.5 Hz, respectively. Also, tests were performed for static configurations in the cycle of glottal motion. The volume flow rate was measured via a custom-made pneumotach. Thus, the pressure drop over a metallic net (see Fig. 1) was measured by a Validyne DP103-08 pressure sensor, which is more sensitive than the DP103-10 sensor. The flow resistance of the metallic net was extremely low, about one order of magnitude less than that of the vocal folds. Thus, the pressure drop in the model over the net was oscillating in the vicinity of 0.5, 1, and 1.5 Pa, for driving pressures of 7, 14, and 21 Pa, respectively. As the Validyne pressure transducers have a poor frequency response even at low frequency, special corrections for amplitude and phase were used in order to obtain reliable results. The signal acquired from the pressure sensors was decomposed by means of discrete Fourier transform into harmonic components, whose amplitude and phase were corrected depending on the frequency. The signal was subsequently recomposed in order to obtain the correct measurement pressure. This technique required the construction of an auxiliary experimental device that permitted the comparison of the output signal of the sensor with a reference variable pressure of known amplitude and frequency, such that appropriate correction coefficients could be determined. The auxiliary device consisted of a cam (mounted on the axle of a computer-controlled stepper motor running at prescribed rotational velocities) that drove a piston in order to generate a known, time-variable pressure in a reservoir (considered as a reference pressure). The pressure in the reservoir was measured by using the Validyne sensors, and subsequently compared against the reference pressure, such that the attenuation and lag were calculated at each frequency, and appropriate correction factors were established. This method was applied, using two appropriate cams, for both DP103-10 and DP103-08 pressure sensors [for details about the procedure, see Kucinschi (2004)].

Flow visualization with glycol-based smoke was performed by using a second acquisition system. Two laser sheets were shed from both upstream and downstream of the folds, such that the glottal region could be observed regardless of the glottal angle. A specific glottal position was investigated by synchronizing the pulse of the laser by means of a position signal provided by the apparatus.

III. NUMERICAL SIMULATIONS

In order to obtain the pressure and velocity distributions in the glottis, the Navier-Stokes equations have to be solved numerically. Since the velocities present low values, leading to a small Mach number, $\mathrm{Ma} < 0.1$, the flow can be considered to be that of an incompressible fluid. The large ratio of the width of the model (1.33 cm real-life) to the glottal gap (0.025–0.104 cm real-life) allows the flow through the glottis to be considered two-dimensional. Also, the viscosity can be assumed constant, in which case the form of the Navier-Stokes equations to be solved is

$$\rho \frac{D\mathbf{u}}{Dt} = -\nabla p + \mu \nabla^2 \mathbf{u} \tag{1}$$

where $\mathbf{u} = (u_x, u_y)$ and μ is the dynamic viscosity of the air.

The numerical simulations related to the moving vocal folds were performed using the commercial CFD code FLUENT, which is an unstructured, finite-volume-based solver that incorporates a dynamic mesh capability. FLUENT has been successfully used to study the glottal flow (Scherer *et al.*, 2001). Flows can be modeled where the shape of the domain boundaries is time dependent. The flow during the present set of simulations was considered laminar everywhere in the flow domain. The decision to adopt this model was based on the experimental evidence. Flow visualizations showed that the flow inside the glottis (the zone where the velocity gradients present the highest values) is laminar for most of the range of the driving angle, θ, for transglottal pressures of up to 15 cm H_2O real-life. Also, for static cases analyzed in a previous study (Scherer *et al.*, 2001), the results obtained with the laminar model were in excellent agreement with experimental results in terms of flow rate and wall pressures, which is not unexpected since the maximum value of the Reynolds number was around 2500.

A two-dimensional computational domain was used and represented as a hatched area, Fig. 6(a), where the dimensions are provided in cm real-life, although the mesh was generated in terms of the actual dimensions of the experimental apparatus. The boundary conditions were imposed in

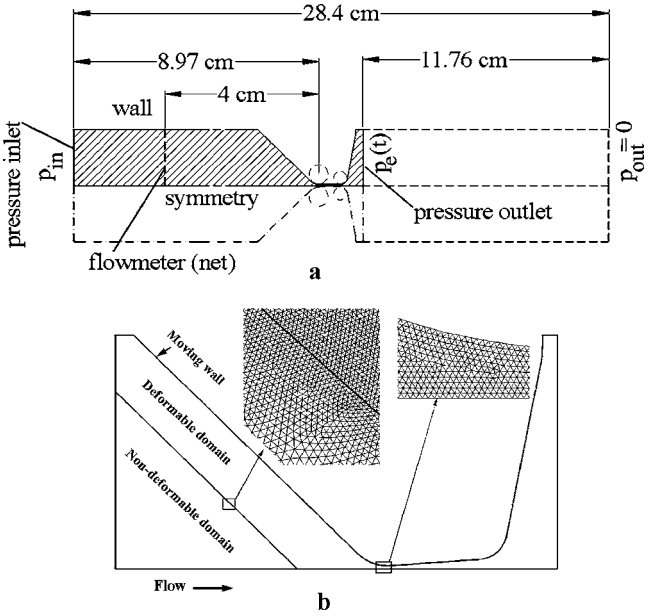

FIG. 6. Computational domain and boundary conditions: (a) computational domain and (b) computational grid.

terms of spatially constant pressures at both inlet and exit. The inlet pressure was taken as constant, while the exit pressure was time dependent, i.e., $p_e = p_e(t)$. In order to further decrease the computational effort, the area downstream of the vocal folds was excluded from the computational domain and the time-dependent exit pressure was estimated as

$$p_e(t) \approx p_{\text{out}} + I(dQ_e/dt), \tag{2}$$

where I is the inertance of the fluid downstream of the vocal folds, $I = \rho l/A$, ρ is the density of the air, and l and A are the length and the cross-sectional area of the downstream section, respectively. This equation is similar to that used by Titze and Story (1997) for the case when the transglottal pressure does not require modeling since it is solved numerically, while the flow resistance of the model vocal tract, which is a constant cross-sectional tunnel, is negligible. The inertive pressures in the model are correctly scaled (i.e., they are 7.5^2 times smaller than the ones in real-life, since the time scale in the model is 7.5^2 times larger than in real-life). The flow rate at the exit of the glottis, Q_e, was related to the inlet flow rate, Q_{in}, and the time rate of change of the glottal volume, V_g:

$$Q_e = Q_{\text{in}} - 2\pi f(dV_g/d\theta). \tag{3}$$

This equation is derived from the equation of continuity for an incompressible fluid, $Q_e = Q_{\text{in}} - (dV_g/dt)$, where $dV_g/dt = (d\theta/dt)(dV_g/d\theta)$ and $d\theta/dt = \omega$, $\omega = 2\pi f$, f being the oscillation frequency. The derivative of the glottal volume, V_g, with respect to the driving angle, θ, was calculated as the glottal volume is known from the kinematics of the mechanism. One restriction for this kind of lumped approach is that the transversal dimension of the model should be smaller than $\lambda/4$, where λ is the wavelength of the acoustic signal (Hall, 1987). As $\lambda = c/f$, $c = 340$ m/s, and f is of the order of 2 Hz (corresponding to a real-life frequency of 112.5 Hz), this condition is fulfilled for the cases approached here. The time derivative dQ_c/dt at the current iteration was calculated based on the values of the flow rate at previous iterations. Since slight numerical oscillations were present that may lead to important errors in estimating the time derivative of the flow rate, it was calculated as the slope of the linear regression of the previous four time steps. This procedure is successful provided the time step is sufficiently small.

The computational grid used for the numerical simulations contained approximately 328,000 triangular cells and, using the symmetry, represents only half of the analyzed geometric configuration. It was thus assumed that the jet was symmetric, although a certain asymmetry of the jet occurs for divergent angles (as revealed by flow visualizations). However, the relatively small divergent angles that occur in the case under scrutiny allow the consideration of the assumption of a symmetric jet for the numerical simulations. A large number of cells were necessary in order to assure a correct numerical representation of the gradient in the glottal region. The mesh is updated automatically by the code at each time step, based on the new shape of the moving boundary (i.e., vocal fold wall). The motion of a boundary is imposed by specifying the position of each node on the boundary through an equation of the type $z = z(x, y, t)$, known from the kinematics analysis of the driving mechanism of the experimental model. A starting mesh needs to be provided to the code, and the domain geometry at subsequent time steps is generated based on the equation of the boundary. An image of the initial computational domain, with details of the grid, is shown in Fig. 6(b). A particularity of the code is that it uses unstructured mesh (triangular cells) for the deformable zones. The mesh density has to be uniform in the deformable zone, even in the convergent entry region. In order to decrease the computational effort, part of the entry region was modeled as a non-deformable domain, where variable mesh density was used, which allowed for a decrease of the number of computational cells.

Ten grids were created and tested on the 8 cm H_2O, 1 Hz case, in order to insure that the results are grid independent. The final selected computational grid led to both good accuracy and a reasonable computational time and was used for the remainder of the cases. A time step of $\Delta t = 10^{-4}$ s (corresponding to a real-life time step of 1.7×10^{-6} s) was used for most of the simulations, leading to a number of time steps per cycle in the range of 5,000–20,000. A first-order implicit time marching algorithm was used, which provides good accuracy for the time step used in the simulations. The accuracy was also assured by imposing small values for the scaled residuals for continuity and momentum (10^{-4}) as convergence criteria per time step. A number of 50 to 100 iterations per time step were necessary for convergence. Details of the numerical algorithms implemented in FLUENT, as well as the methods employed for dynamic mesh handling, are documented elsewhere (FLUENT, 2005). It was observed that the process was cyclical and reached the steady-periodic state after about two complete cycles, regardless of the driven oscillation frequency. Generally, the results from the fourth cycle were retained as reliable results for a typical oscillation cycle.

IV. RESULTS AND DISCUSSION

Flow rates and transglottal pressures were measured over a complete vocal fold motion cycle, both for the static case and for dynamic cases at different frequencies. Two overall pressures were used for the measurements, namely 4 and 8 cm H_2O real-life. The overall pressure, which was constant during the experiments, corresponded to the lung pressure. For the static case, the measurements were performed for static configurations corresponding to fixed driving angles θ. The values of θ cover a complete motion cycle, i.e., from 0° to 360°, with a step of 10°.

The inlet flow rate, Q_{in}, is represented over an oscillation cycle in Fig. 7 for 4 cm H_2O and Fig. 8 for 8 cm H_2O, for the four oscillation frequencies (28.1, 56.2, 84.4, and 112.5 Hz). The experimental values, both for static and dynamic cases, were plotted together with the values obtained from the numerical simulations. For the dynamic cases, the driving angle was related to the oscillation frequency, f, and the current time of measurement/simulation, t, through the equation

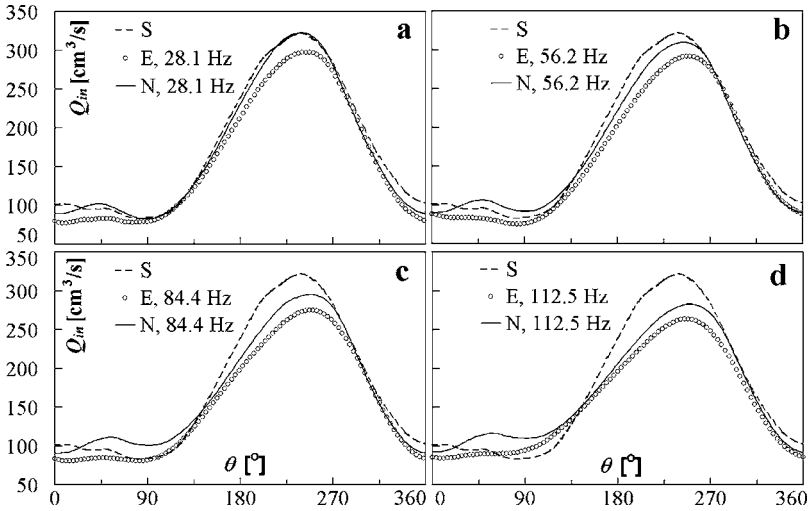

FIG. 7. Inlet flow rate over a cycle for a nominal (lung) pressure of 4 cm H_2O: (S)=static experimental, (E)=experimental, and (N)=numeric.

$$\theta = 360\,^\circ tf, \quad t \in [0, \ldots, T], \quad T = 1/f. \tag{4}$$

The experimental values are in general lower than the numerical predictions for the driving angles 0°–120° and 135°–270°, where for the latter range the flow rate strongly increases and then decreases. The difference between the numerical results and the experimental data was caused by the simplified flow model and geometry used in the numerical simulations (see Sec. III).

As the glottal diameter and the glottal angle are coupled through the geometry of the mechanism, their variation depends on the configuration of the apparatus. Thus, for θ from 0° to 90°, the glottal diameter, D_g, is roughly constant (around 0.025 cm real-life, which is the minimum value along the cycle, with a local maximum of 0.039 cm at 45°), while the glottal angle is changing continuously from 8.3° divergent to 7.7° convergent (see Fig. 5). As a general observation, the input flow rate for θ=0°–90° presents the smallest values along the cycle, regardless of the frequency of the folds and of the overall pressure. For the static case, the minimum flow rate was obtained at one-fourth of the cycle (θ=90°), when the glottal angle was convergent. Slightly higher values were measured for θ=0°, when the glottal angle had a divergent angle of roughly the same magnitude and the glottal diameter had the same value. This difference in flow was due to the larger friction drag that occurs for convergent glottal configurations and small diameters, when viscous effects are important compared to the divergent configuration of small angle. One can conclude that for the static case, when the lung pressure was constant, the smallest value of the flow rate occurred for a convergent angle and smallest glottal diameter. The dynamic results show the flow rate slightly smaller in magnitude than the static results, although the decrease in flow rate with increasing angle is still evident except for the 4 cm H_2O, 112.5 Hz case in Fig. 7(d) and the oscillatory behavior in Fig. 8(a) where the flow rate increases.

For driving angles, θ, in the 90°–180° range, the folds remain convergent, changing the converging angle from 7.7° to 10.5° to 7°, while the glottal diameter increases from 0.025 to 0.040 to 0.075 cm. The tendency of the inlet flow rate was to increase with the glottal diameter, valid for both static and dynamic cases. For driving angles, θ, in the 180°–270° range, the glottal angle changes from a convergent (7°) to a divergent configuration (8.6°), while the glottal diameter changed slightly, in the range from 0.075 to 0.104 to 0.072 cm real-life. The configurations for both θ=180° and θ=270° had nearly the same glottal diameter, but for θ=270°, where the glottal angle was divergent, the flow rate

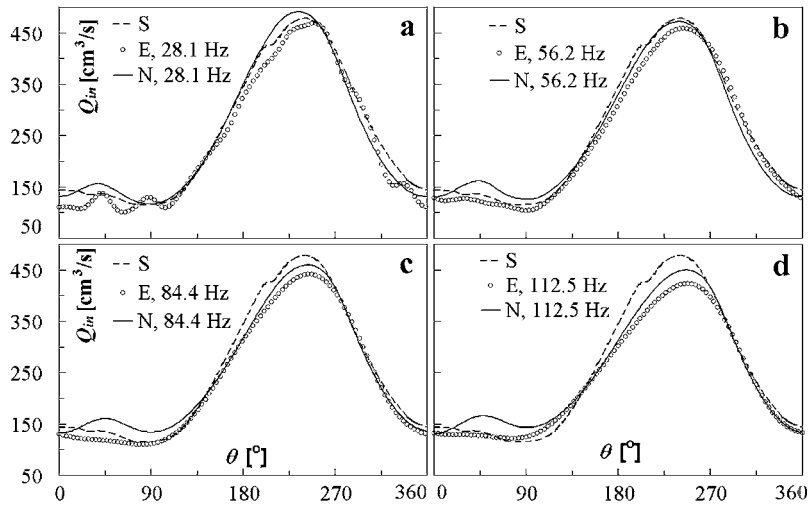

FIG. 8. Inlet flow rate over a cycle for a nominal (lung) pressure of 8 cm H_2O: (S)=static experimental, (E)=experimental, and (N)=numeric.

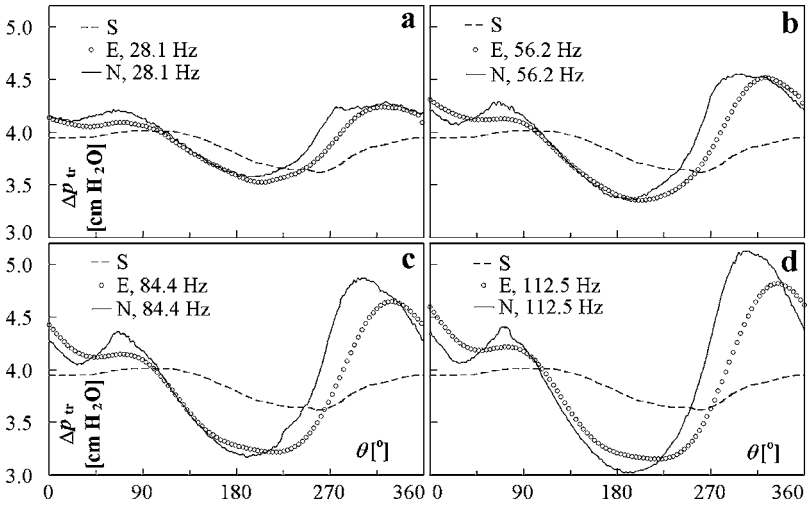

FIG. 9. Transglottal pressure for a nominal (lung) pressure of 4 cm H_2O: (S)=static experimental, (E)=experimental, and (N)=numeric.

was larger. This observation is valid for both the static and dynamic cases. Thus, a divergent glottal angle produces a larger flow rate for the same diameter, consistent with the same trend observed for θ in the 0°–90° range for the static case. The largest static flow rates occurred at θ=240° for both 4 and 8 cm H_2O, having values of 322 and 479 cm^3/s, respectively. For the last quarter of the cycle (θ =270°–360°) the glottis remained divergent (the glottal angle changing slightly in the range from 8.6° to 11.7° to 8.3°), while the glottal diameter returned to the minimal value of 0.025 cm real-life. As expected, the flow rate decreased in this portion of the cycle for both static and dynamic cases. In general, the static flow rates over the range from 135° to 270° were higher than the dynamic values.

For the dynamic cases, a decrease of the maximum flow rate was observed with an increase of the oscillation frequency of the vocal folds as shown in Figs. 7 and 8. This tendency was revealed by both the measurement data and the numerical results. The change in flow rate with frequency was due to the inertive effects of the fluid in the region upstream (corresponding to the trachea), downstream of the vocal folds (corresponding to the vocal tract), and within the glottis. However, as the mass of the air in the glottis is much smaller than that in the rest of the apparatus (less than 0.2%), one can infer that its effect was negligible. The inertance of the air upstream and downstream of the vocal folds created a time-changing pressure at the glottal inlet and exit, respectively, which opposes the variation of the flow rate. The magnitude of this effect increases with the frequency, since $dQ/dt=2\pi f(dQ/d\theta)$. One can remark here that the inertive effects could not have been revealed if the fluid were driven by a constant flow rate or if the regions of the apparatus corresponding to the trachea and vocal tract were removed. In fact, the inertive effects are probably larger in reality, since the average male vocal tract length is 17.5 cm (Titze, 1994), while the vocal tract length in the current apparatus was about 12 cm. The general shape of the variation of the reported flow rate over a cycle is consistent with the real glottal flow pulse shape (Rothenberg, 1981). The effect of inertia of the air column is to skew the waveform to the right (Titze, 1994), i.e., the glottal flow presents a slow rise followed by an abrupt fall. Obviously, if the vocal folds collide and the flow rate were temporarily zero, the time derivative of the flow rate would subsequently have large values, and hence large inertive effects would be expected. For the cases reported here, the glottal flow never reached zero, such that a strong waveform skewing was not obtained.

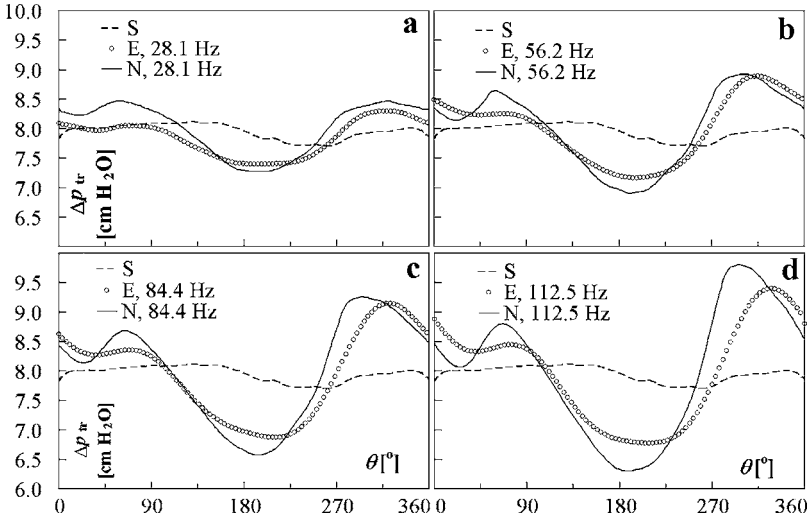

FIG. 10. Transglottal pressure for a nominal (lung) pressure of 8 cm H_2O: (S)=static experimental, (E)=experimental, and (N)=numeric.

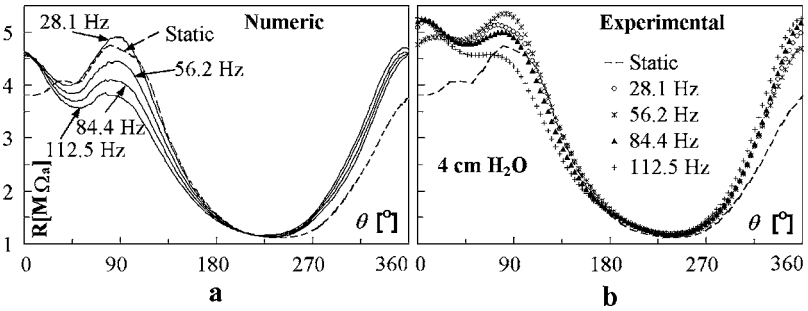

FIG. 11. Glottal flow resistance for a nominal (lung) pressure of 4 cm H_2O.

The trends of the transglottal pressure difference, Δp_{tr}, are represented in Fig. 9 for 4 cm H_2O and Fig. 10 for 8 cm H_2O, for the same frequencies (i.e., 28.1, 56.2, 84.4, and 112.5 Hz). For the static case, a larger Δp_{tr} occurs at $\theta=90°$ (convergent glottis) than at $\theta=0°$ (divergent glottis), for the same (minimum) glottal diameter, because of the higher resistive viscous effects. The minimum static transglottal pressure occurs near $\theta=255°$, which is just after the location corresponding to the maximum glottal diameter ($\theta=225°$). The static pressures show a smaller variation with phase angle than do the dynamic experimental and numerical values.

The difference between the measured and the calculated dynamic transglottal pressures is caused by the simplifying assumptions used in the numerical simulations. Small numerical oscillations are observed for the numerical pressure curves, caused by the estimation of exit boundary pressures based on the flow rate derivatives [see Eq. (2)]. The numerical model predictions show similar variations with driving angle as the experimental values, although there is a magnitude difference which increases with frequency at the higher driving angles. For the numerical 4 cm H_2O case, there is an overprediction for $30° < \theta < 90°$ and $225° < \theta < 315°$ for the lowest frequency. Higher frequencies show the numerical predictions leading the experimental values for $\theta > 225°$. For 8 cm H_2O the overprediction also exists for $\theta > 225°$, as well as an underprediction for $90° < \theta < 225°$ for the higher frequencies.

The magnitude (maximum to minimum) of the experimental Δp_{tr} is strongly dependent on the oscillation frequency, due to the inertive effects of the air columns upstream and downstream of the vocal folds. This difference increases with the frequency, from 0.8 cm H_2O at 28.1 Hz for 4 cm H_2O to 1.5 cm H_2O at 112.5 Hz, and for 8 cm H_2O, 0.9 cm H_2O at 28.1 Hz to 2.6 cm H_2O at 112.5 Hz. The most typical phonatory condition is the 112.5-Hz case, for which the percentage extent relative to the average subglottal pressure was 37.5% for 4 cm H_2O and 32.5% for 8 cm H_2O, consistent with data obtained in humans with regard primarily to subglottal pressure fluctuations because of the foreshortened subglottal tract (Kitzing and Löfqvist, 1975). It is noted that the transglottal pressure waveform is slightly displaced to the right with the increase in oscillation frequency.

The instantaneous flow resistance, R, defined as the ratio of the transglottal pressure difference, Δp_{tr}, to the inlet flow rate Q_{in}, is represented in Fig. 11 for 4 cm H_2O and Fig. 12 for 8 cm H_2O, for both the static and dynamic cases. R is expressed in $M\Omega_a$ ($\Omega_a = \text{kg m}^{-4}\,\text{s}^{-1}$). Both the numerical [Figs. 11(a) and 12(a)] and experimental [Figs. 11(b) and 12(b)] are shown and there is reasonable agreement between them. Although both the flow rate and the transglottal pressure depend on the whole system composed of fluid in the trachea, glottis, and vocal tract, their ratio defines the aerodynamic behavior of the vocal folds. Using the experimental values, Figs. 11(b) and 12(b) illustrate that the glottal flow resistance changes with glottal angle (glottal shape) and also shows a dependence on the vocal fold oscillation frequency over certain parts of the cycle of driving angles. For a driving angle range of $225° < \theta < 270°$, which corresponds to a uniform glottis at 225° becoming 8.6° divergent at 270° (Fig. 4), the resistance is at its lowest value at 240° and then increases at 270°, but does not show any dependence on the oscillation frequency. As the glottal divergence angle increases to 11.7° at 315°, and then decreases to 8.3° at 360° or 0° in the cycle, the flow resistance continues to increase and shows a decreasing magnitude with increasing vocal fold frequency. The resistance continues to increase and oscillate from the 360° or 0° divergent position through the glottal angles of 45° (glottis slightly divergent) and 90° (glottis convergent). The resistance reaches its maximum value at 90° at the lowest frequency and shows a rather large decrease in magnitude with increasing frequency. Even though the pressure at that position (90°) is higher for higher frequencies,

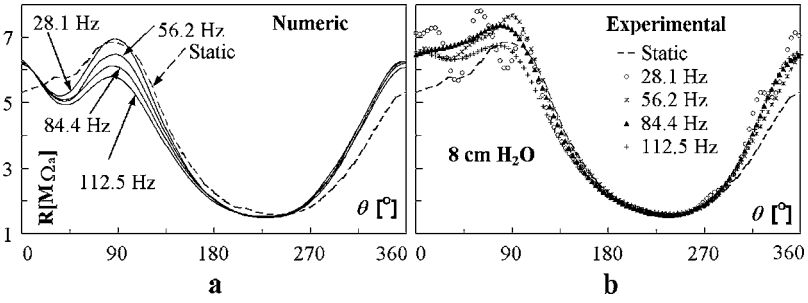

FIG. 12. Glottal flow resistance for a nominal (lung) pressure of 8 cm H_2O.

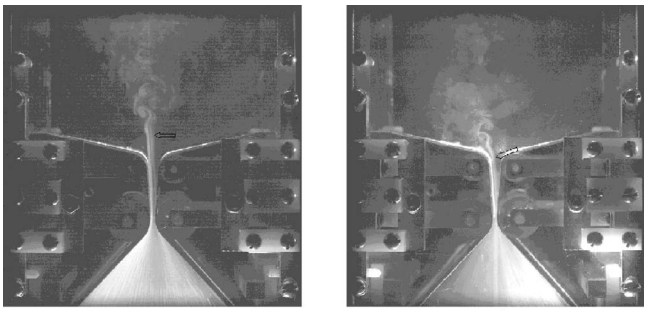

FIG. 13. Glottal flow visualization, 8 cm H_2O, position 0°, static versus dynamic (56.2 Hz). The arrow indicates the transition point.

the flow rate increases at a greater rate, leading to a decrease in the flow resistance. These changes should not be interpreted as a consequence only of the inertia of the air within the glottis, but also as the effect of the increase of the time rate of change of the volume of the glottis [see Eq. (3)]. At this position the glottal diameter is at its minimum value (0.025 cm) for a convergent angle, and the viscous effects are the most important over the cycle. Continuing the cycle to 135°, 180°, and back to 225°, the glottis is convergent, the overall resistance falls, and the dependence on frequency decreases back to being negligible for this set of convergent angles. The minimum resistance, which occurs at $\theta=240°$ (where the glottal diameter is larger and thus the viscous effects are less important) is 1.2 $M\Omega_a$ for 4 cm H_2O and 1.6 $M\Omega_a$ for 8 cm H_2O.

The trends of the flow resistance discussed above show that the aerodynamic behavior of the vocal folds, for any glottal shape, is mainly governed by viscous effects and depends to a lesser extent on the oscillation frequency except for $45° < \theta < 135°$. The flow patterns inside and downstream of the vocal folds, however, are dependent upon the oscillation frequency of the vocal folds, especially when the glottal angle is divergent and the minimum throat thickness is decreasing ($\theta=225°-0°$). For these configurations, flow visualization showed that the Kelvin-Helmholtz shear layer instabilities occur closer to the glottal exit once the frequencies were increased. A static flow visualization picture is shown in Fig. 13(a), for $\theta=0°$ (i.e., glottal angle 8.3° divergent) and a lung pressure of 8 cm H_2O, while Fig. 13(b) presents the visualization obtained at 56.2 Hz at the same moment in the oscillation cycle. For the static case, a laminar jet occurred that separated about one-third of the way upstream in the glottis from the glottal exit on the nonflow (right) wall. The jet was not symmetric, but adhered to one of the walls, and was bi-stable (i.e., the jet could switch sides, triggered by a disturbance in the flow). The jet remained laminar until transition (Kelvin-Helmholtz instability) vortices occurred, followed by turbulent dissipation. For the dynamic case [Fig. 13(b)], a bi-stable, laminar, glottal jet can be observed, but the transition occurred inside the glottis. The same behavior of the flow could be observed for a large number of oscillation frequencies over this range of glottal angles, and, interestingly, the transition points tended to move more upstream with an increase in frequency. The effect of this change in flow patterns can be seen at 0° as a decrease in the flow rate (Figs. 7 and 8) and an increase in the transglottal pressure at 0° (Figs. 9 and 10). The vortex shedding close to solid boundaries can provide a secondary source of acoustic energy. Barney *et al.* (1999) showed that, for a shutter-type dynamic mechanical model, the vortices in the shutter area provide significant acoustic sources. The relationship between the flow patterns and the acoustic field was not within the scope of the present paper, but will be examined in a separate report.

V. CONCLUSIONS

The purpose of the present study was to investigate both experimentally and numerically the relationship between the flow rate and transglottal pressure difference for the moving vocal folds. A complex experimental apparatus was designed for this purpose, which mimics with acceptable realism the oscillation of the human vocal folds.

It was also sought to determine, at least in the framework of the present experimental conditions (i.e., glottal configurations and lung pressures), to what extent the flow rates and transglottal pressure are dependent upon the oscillation frequencies of the vocal folds. Flow visualizations were performed (although not fully reported here) in order to determine the character of the glottal flow (i.e., laminar, transitional, or turbulent). The visualizations showed the existence of a laminar jet in the glottis, except near the exit of the glottis for certain diverging glottal angles and frequencies. The jet was always laminar in the throat region where the viscous effects are important.

For the static configurations, it was observed that the flow rates were lower for the convergent than for divergent glottal angles for roughly the same small glottal diameter, due to the viscous drag. As expected, the flow rate also increased with glottal diameter when the glottal angle was kept roughly constant.

The measurements showed that both the flow rate and transglottal pressure are affected by the frequency of the vocal folds. The inertia of air in the trachea and vocal tract, together with the unsteady flow rate, produced a time-changing pressure both downstream and upstream of the glottis, which was reflected in frequency-dependent flow rates and transglottal pressure differences. Although the collision of the modeled vocal folds was not permitted, the flow waveform was consistent with the shape of the glottal pulse reported in the literature (e.g., Rothenberg, 1981). The increase in oscillation frequency was reflected by a decrease in flow amplitude. Skewing (i.e., shift to the right) of the waveform relative to the static flow waveform existed for all frequencies.

The glottal flow resistance was calculated as the ratio of the transglottal pressure difference to the flow rate. A sizeable decrease of the flow resistance with increase in frequency was observed at about one-quarter of the oscillation cycle, where the glottal diameter was small and a large change in glottal volume takes place. For the remainder of the oscillation cycle, the flow resistance was practically independent of the frequency for $135° < \theta < 270°$ and showed a smaller decrease in resistance with increasing frequency for

$270° < \theta < 360°$. Also, the flow resistance changed very little with the lung pressure in the part of the cycle where the glottal diameters were large. However, it changes significantly with lung pressure for small glottal diameters, where viscous effects are important.

A satisfactory agreement of the results of the numerical simulations with the experimental data was obtained. The differences were caused by the limitations of the flow model used in the simulations, i.e., laminar flow model, glottal jet assumed symmetric, and simplified model of inertia for the vocal tract. However, the conclusion is that the CFD code FLUENT can provide reasonable predictions of the flow parameters.

Flow visualization was not the scope of the present paper, and a detailed analysis of the glottal flow patterns is not presented here. Nevertheless, the flow pictures showed that the flow patterns were altered between the static and dynamic regimes for divergent angle cases ($\theta = 225° - 0°$) where shear-layer instabilities and consequently vortex structures can occur inside the glottis for the dynamic case. Since vortex shedding can become a sizeable source of sound, it can be inferred that the oscillation frequency of the vocal folds may also be related to the generation of aero-acoustic sound. An additional study is necessary to investigate this aspect.

Enhanced contrast for vowels in utterance focus: A cross-language study

Jessica F. Hay, Momoko Sato, Amy E. Coren, Cheryl L. Moran, and Randy L. Diehl
Department of Psychology and Center for Perceptual Systems, University of Texas at Austin, 1 University Station A8000, Austin, Texas 78712-0187

(Received 3 May 2005; revised 10 February 2006; accepted 10 February 2006)

The present study examined several potential distinctiveness-enhancing correlates of vowels produced in utterance focus by talkers of American English, French, and German. These correlates included possible increases in vowel space size, in formant movement within individual vowels, and in duration variance among vowels. Each language group enhanced the distinctiveness of vowels in [+focus] context but used somewhat differing means to achieve this. All three groups used spectral differences, but only German talkers used durational differences, to enhance distinctiveness. The results suggest that the amount of distinctiveness enhancement of a vowel property in [+focus] context is positively related to the between-category variation of that property in [−focus] context. Thus, consistent with the theory of adaptive dispersion, utterance clarity appears to vary directly with information content. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184226]

I. INTRODUCTION

In this study, we examined several possible distinctiveness-enhancing correlates of focally prominent syllables in American English, French, and German. The aim was to assess cross-language commonalities and differences in how phonological distinctiveness of vowels is increased in [+focus] contexts.

Jakobson *et al.* (1963) famously remarked that "we speak to be heard in order to be understood" (p. 13). In his theory of adaptive dispersion, Lindblom (1986, 1990) elaborated this point as follows: the aim of talkers is to produce utterances that are intelligible to listeners, but to do so with as little effort as necessary. In other words, talkers try to achieve sufficient, rather than maximal, distinctiveness in articulating vowels and consonants, and they thus tend to vary their utterances from reduced (hypospeech) forms to clear (hyperspeech) forms according to the communication conditions that apply.

A variety of findings are consistent with Lindblom's account. Communication conditions that have been shown to influence how clearly talkers articulate speech sounds include factors pertaining to the communication channel, the listener, and the information content of the message.

Communication channel and listener factors: An early study by Lombard (1911) demonstrated that talkers produce clearer and louder speech in the presence of background noise, a result that has since been replicated and extended (Lane *et al.*, 1970; Lane and Tranel, 1971). As the distance to the listener increases, talkers increase their vocal effort, although not enough to compensate fully for the distance effect on signal intensity (Traunmüller and Eriksson, 2000). In conversational speech, talkers tend to speak more clearly when the line of sight between talker and listener is obstructed, and the listener is thus deprived of visual speech reading cues, than when the talker and listener are able to see each other (Anderson *et al.*, 1997). Picheny *et al.* (1985, 1986) instructed talkers to produce either ordinary conversational speech or clear speech as if "trying to communicate in a noisy environment or to an impaired listener" (Picheny *et al.*, 1985, p. 97). The clear speech was produced at a slower rate, a higher intensity, and with less vowel and consonant reduction than the conversational speech. As expected, the clear speech was more intelligible to hearing impaired listeners than the conversational speech.[1] Talkers tend to produce more widely dispersed vowel categories, yielding less acoustic overlap among categories, when speaking to non-native speaking listeners than when speaking to native speaking listeners (Knoll and Uther, 2004). Such results suggest that talkers modulate their speech clarity according to demands imposed by the communication channel and by the listener.

Information content of the message: Perhaps the strongest evidence that talkers aim for sufficient—rather than maximal—distinctiveness is pervasive findings that utterance clarity tends to vary positively with information content: (a) Words produced in isolation are more accurately identified than the same words excised from running speech (Pollack and Pickett, 1963). The excised word tokens are more reduced, presumably because of their greater predictability (i.e., lower information content) in the original contexts. (b) Words excised from stereotyped phrases or adages (e.g., "A stitch in time saves [*nine*]") are less intelligible than the same words excised from less redundant contexts (e.g., "The number that you will hear is [*nine*]") (Lieberman, 1963; see Hunnicutt, 1985, for a partial replication and qualification of this result). (c) Words produced for the first time in the course of a monolog are more intelligible when excised from their contexts than words produced for the second time (Fowler and Housum, 1987). (d) Vowels are more clearly articulated in words that occupy dense lexical neighborhoods and that are low in frequency of occurrence relative to their nearest phonological neighbors (Wright, 2003). Higher neighborhood density and lower frequency of occurrence yield higher information content, and both are associated

 0001-4966/2006/119(5)/3022/12/$22.50

with lower word recognition accuracy (Luce, 1986). (e) Vowels are more reduced in closed class function words (e.g., the auxiliary verb "can") than in open class content words (e.g., the noun "candy") (van Bergem, 1993). (f) Vowels in lexically unstressed syllables are more reduced (i.e., shorter in duration and less distant from schwa) than vowels in lexically stressed syllables (van Bergem, 1993). Cross-linguistically, vowels in stressed syllables tend to carry more information because of the greater variety of vowels permitted in stressed contexts (Altman and Carter, 1989). (g) Consonants at the beginning of prosodic domains such as words or phrases are more clearly articulated and less confusable than later-occurring consonants, which are generally more predictable (Jun, 1993; Byrd, 1994; Browman and Goldstein, 1995; Redford and Diehl, 1999; Keating *et al.*, 1999; Cho and Keating, 2001). (h) Vowels in [+focus] context (i.e., in portions of an utterance that contain *new*, as opposed to *given*, information) are produced with greater separation between vowel categories than those in [−focus] context (van Bergem, 1993). (i) In languages with vowel length distinctions, duration differences between short and long vowels tend to be enhanced in [+focus] context. Such enhancement has been observed in Swedish (Heldner and Strangert, 2001), Arabic (de Jong and Zawaydeh, 2002), and Serbian (Smiljanic, 2004). (j) Phonetic correlates of [voice] contrasts show enhanced acoustic distinctiveness in [+focus] context (Cho and McQueen, 2005).

In examples (a)–(j), information content was varied and/or assessed qualitatively, that is, in the form of ordinal comparisons. Taking a more quantitative approach, van Son and Pols (2003) used a large sample of spoken Dutch to estimate the information (in bits) carried by individual phonemes in word and sentence context. Across several speaking styles, they found positive correlations between information content and two measures of speech clarity—duration and spectral distinctiveness. Although these correlations were highly significant statistically, the *R* values were fairly small (<0.3), owing perhaps to the many other sources of durational and spectral variance in natural productions.

As this last study suggests, talker compensation for varying communication conditions is far from perfect. In some cases (e.g., varying background noise, varying distance separating talker and listener, and varying degrees of hearing loss), there may be physical or perceptual limits to maintaining uniform levels of intelligibility. Moreover, in cases of varying information content, talkers may lack the cognitive means to estimate accurately the information available to listeners on a segment-by-segment basis, and thus articulatory compensation may be rather crude. For example, Billerey-Mosier (2000) reported no systematic difference in vowel duration as a function of whether the vowel occurred at the carrier word's uniqueness point (i.e., the earliest point at which the word differs from all lexical neighbors sharing the same initial sequence of phonemes) or after the uniqueness point, where the vowel carries no information. Also, in the study by Anderson *et al.* (1997) cited earlier, the reduction in talker clarity that occurred with an unobstructed line of sight between talker and listener was not closely linked to the moment-to-moment looking behavior of the listener. Finally, talkers may sometimes have difficulty distinguishing what is given information for themselves and what is given information for the listener. For example, Bard *et al.* (2000) reported that when talkers named map landmarks in spontaneous speech to two successive listeners, the key words were produced less clearly on repetition even though the second listener had not heard the original version. Despite such findings, however, it is evident that Lindblom's notion of sufficient contrast accounts at least qualitatively for an impressive range of data.

The present study examines how production of vowels is affected by whether or not they occur in utterance focus, a variable associated with differences in information content. Declarative sentences can typically be analyzed into two kinds of grammatical constituents: those carrying information already known to the listener (given information) and those carrying information not previously known to the listener (new information). The feature [+focus] applies to the latter kind of constituent, whereas [−focus] applies to the former.[2] In general, [+focus] corresponds to the constituent occupying the location of a wh-phrase in the answer to a wh-question:

Q: Who stole the money?

A: $[\text{Bob}]_{\text{F}}$stole the money. (1)

The grammatical constituent marked as [+focus] usually includes the syllable that is intonationally most prominent in the utterance. Linguists have offered varying accounts of how focal prominence is assigned within the focused constituent (Chomsky and Halle, 1968; Ladd, 1980, 1996; Gussenhoven, 1983; Selkirk, 1984; Baart, 1987; Bolinger 1989). Typically, it is assumed to be assigned to the primary stressed syllable of the head (i.e., most important lexical item) of the focused constituent.

Phonetic investigations of various languages have described several correlates of focal prominence. Relative to stressed syllables in [−focus] context, stressed syllables in [+focus] context tend to be longer (Nooteboom, 1972; Cooper *et al.*, 1985; Eefting, 1991; Sluijter and van Heuven, 1995; Turk and Sawusch, 1997; Strangert and Heldner, 1998; Heldner and Strangert, 2001), to be more intense (Campbell, 1995; Sluijter and van Heuven, 1996a; Heldner *et al.*, 1999; Heldner, 2003), to have more high-frequency emphasis (Campbell, 1995; Sluijter and van Heuven, 1996b; Heldner *et al.*, 1999; Heldner, 2003), and to have a greater and more rapid change in fundamental frequency (O'Shaughnessy, 1979; Lyberg, 1979; 't Hart *et al.*, 1990). All of these correlates of focus are likely to contribute to intonational prominence and thus to draw the listener's attention to the most informative portion of an utterance (Ladd and Cutler, 1983).

Consistent with Lindblom's notion of sufficient contrast, other correlates of focal prominence may have a distinctiveness-enhancing role, in addition to any attention-directing function they serve. One such correlate is size of the vowel space: [+focus] syllables tend to show a greater separation of vowel categories within a formant frequency ($F1 \times F2$) space (van Bergem, 1993). It is also possible that [+focus] syllables are associated with greater formant move-

ment within each vowel and/or greater duration variance across vowel categories. Several investigators (e.g., Nearey and Assmann, 1986; Hillenbrand *et al.*, 1995; Hillenbrand and Nearey, 1999) have reported that American English vowels tend to exhibit "vowel-inherent spectral change" (VISC), whereby formant frequencies change from a relatively steady-state region near the onset of the vowel to a different set of values near the offset of the vowel. As the label implies, the frequency changes are assumed to be characteristic of the vowel itself and not merely a by-product of coarticulation with initial and final consonants. Including VISC in the design of synthetic American English vowel stimuli significantly improves their identifiability by listeners (Hillenbrand and Nearey, 1999), and including it in the parametric description of natural American English vowels significantly improves categorization performance by statistical pattern recognition models (Nearey and Assmann, 1986). Similar pattern recognition results have been reported for monophthongs of Australian English (Watson and Harrington, 1999). Because VISC contributes to vowel identity in at least one language, it may be subject to enhancement in [+focus] context, yielding greater acoustic distinctiveness among vowels. Apart from spectral differences, vowel categories tend to vary in duration, and in many languages, vowel length is phonemic (Lehiste, 1970). It was noted earlier that such vowel length distinctions have been shown to be enhanced in [+focus] context for several languages (Heldner and Strangert, 2001; de Jong and Zawaydeh, 2002; Smiljanic, 2004).

In the present study, we examined vowel space size, amount of formant movement, and duration variance as possible distinctiveness-enhancing correlates of [+focus] syllables in American English, French, and German. The aim was to assess cross-language commonalities and differences in how phonological distinctiveness of vowels is increased in [+focus] context. The requirement of sufficient (rather than maximal) contrast allows for the possibility that different languages may exploit varying means of distinctiveness enhancement. Such variation may, of course, reflect differences across languages in the phonological contrasts used, but it may also reflect different weights assigned to the various correlates of a given contrast. For example, a feature correlate that carries more information in language A than in language B may be more heavily exploited for distinctiveness enhancement in language A.

II. METHOD

A. Talkers

American English talkers were 12 undergraduates (six male and six female) from the University of Texas at Austin, all of whom spoke with a Central Texas dialect. They ranged in age from 18 to 22 years old. French talkers were 12 undergraduates (six male and six female) from the Université René Descartes, Paris, France. All spoke with a standard Parisian dialect, and they ranged in age from 18 to 29 years old. German talkers were 14 adults (seven male and seven female) who were currently living in or visiting the central Texas area and who ranged in age from 15 to 38. They were from various dialect regions in Germany, with five speaking the Franconian dialect, three speaking other regional dialects, and six speaking only standard German. However, all of the talkers reported being proficient in standard German. American English talkers were recruited from the introductory psychology subject pool at the University of Texas at Austin, and were given credit towards partial fulfillment of course requirements. French and German talkers were paid $12/hour for their participation.

B. Speech materials

The three groups of talkers produced native-language vowels in a word or nonsense word context embedded in a language-appropriate sentence frame. Eleven American English vowels (/æ, ɛ, ɪ, $e^{ɪ}$, i, ɑ, ʌ, ʊ, $o^{ʊ}$, u, ɜ˞/) were produced in /b_t/ context within the sentence frame, "The large /*b*V̲*t*/ is green." Nine French vowels (/i, ɛ, a, ɑ, o, y, ɔ, œ, u/) were spoken in /p_t/ context within the sentence frame, "La grande /*p*V̲*t*/ est bleue," which translates as "The large /*p*V̲*t*/ is blue." Fifteen German vowels (7 short, /ɑ, ɛ, ɪ, ɔ, œ, ʊ, ʏ/ and eight long, /ɑː, ɛː, eː, iː, oː, øː, uː, ʏː/) were spoken in /b_tə/ context within the sentence frame "Matthias sagt /bVtən/," which translates as "Matthias says /bVtɔn/." Whereas the German vowel set corresponded to the entire German vowel inventory, excluding diphthongs, the American English and French sets were subsets of their respective inventories. The English set lacked the vowel /ɔ/ (which is usually not distinguished from /ɑ/ in Central Texas dialect) and the diphthongs /$ɑ^{ɪ}$/, /$ɑ^{ʊ}$/, and /$ɔ^{ɪ}$/; the French set lacked the close mid vowels /e/ and /ø/ (which are similar to their open mid counterparts) and all nasalized vowels.

C. Elicitation and recording procedure

Talkers were given an orthographic version of each sentence they were to produce (see the Appendix for orthographic representations of test words). They were then presented with a written question about the sentence that was designed to encourage them to place the focus on either the target word (i.e., the word containing the target vowel), or on the final adjective in the sentence. In English, for example, when talkers read the question, "The large WHAT is blue?," the target word represented new information for the hypothetical person who had asked the question (i.e., the target word was marked [+focus]). When talkers read the question, "The large /*b*V̲*t*/ is WHAT?," the target word represented given information for the hypothetical question asker (i.e., the target word was marked [−focus]). Talkers were instructed to produce the entire sentence when responding to the question, and their responses were recorded. They were also instructed to answer the questions at a normal rate of speech.[3] For a given vowel, talkers produced each focus condition before moving on to the next vowel. The order of focus condition was randomized between vowels, and the order of vowels was randomized between talkers. Productions by English and German speakers were digitally recorded at a sample rate of 22 050 Hz using a Shure SM48 microphone and a locally developed signal processing program (WAVAX) implemented on a PC. Utterances of French speakers were recorded using a Shure HW501 headworn dy-

namic microphone and a Sony Mini Disc MZ-R70 recorder and were then imported into WAVAX at the same sampling rate. All recordings were made either in a sound-attenuated booth or in a quiet room.

D. Acoustic measurements

Vowel tokens were analyzed acoustically using the Multi-Speech Signal Analysis Workstation, Model 3700, Version 2.4 (Copyright© 2001 Kay Elemetrics Corp). Temporal measurements were made from inspection of wave forms and wideband spectrograms (323 Hz bandwidth). Vowel durations were measured as the interval between the first and last significant glottal pulses of a given token. As noted earlier, one possible means of distinctiveness enhancement of vowels in [+focus] context is to increase systematic variation in vowel duration (e.g., between tense and lax vowels in English or between long and short vowels in German). Accordingly, for all three languages examined in this study, we calculated the variance in vowel durations for each talker and condition.

Frequencies of the first two formants (F1 and F2) were measured using pitch synchronous LPC (18 coefficients) with a 20 ms Blackman analysis window centered at each of three relative temporal locations—25%, 50%, and 75% of vowel duration. LPC derived formant tracks were superimposed on the spectrograms. In cases where the formant tracks reflected spurious peaks or where actual formants were missed, formant frequencies were marked manually using visual inspection of the spectrograms and of 512-point FFT spectra. The F1 and F2 measurements were used to determine the size of the vowel space and the amount of VISC for each talker.

E. Auditory modeling and measurements

Formant frequency measurements are very useful for making comparisons with other studies of vowels. However, the motivating idea of this study—sufficient contrast—must ultimately be evaluated in auditory, rather than purely acoustic, terms. Accordingly, an auditory model was used to produce auditory spectra of each vowel token at the 25%, 50%, and 75% relative time locations. These spectral data were analyzed using principal components analysis (PCA), and the first two extracted components (PC1 and PC2) served to define a two-dimensional space (analogous to an $F1 \times F2$ space) within which vowel space size and amount of VISC could be calculated.

The auditory spectra were plotted in units of loudness (Sones) at each 0.2 Bark step, for English and French, and at each 0.1 Bark step for German, between 0 and 16 Bark (corresponding to the frequency range between 0 and 3200 Hz). (The use of a smaller Bark step for German, corresponding to a smaller analysis bin, was necessitated by the relatively low fundamental frequency values of several male talkers, which would otherwise have produced more than one harmonic per analysis bin.) These auditory spectra were derived using a modified version of the auditory model described by Bladon and Lindblom (1981), which was itself adapted from Schroeder *et al.* (1979). This model was judged to be suitable for our purposes because it was based on human psychophysical measurements rather than on physical or electrophysiological data from animal listeners. Although the Bark frequency scale of the model was retained in the present application, we replaced the Bark-based auditory filters with filters having somewhat narrower equivalent rectangular bandwidth (ERB) values as described by Moore and Glasberg (1983) and Glasberg and Moore (1990).

The Bladon and Lindblom (1981) model operates on schematic vowel spectra each consisting of a list of harmonic frequencies and amplitudes. In order to apply the model to actual vowel signals, it is necessary to preprocess the signals, converting actual spectra into schematic spectra. This was done as follows: A Hanning window was applied to a selected temporal region of the vowel consisting of at least three glottal periods, and an FFT was calculated. (Hanning windowing results in a spectrum consisting of triangular shaped harmonics.) A set of frequency-domain template functions were created each consisting of a series of triangular pulses of unit height and spaced at equal frequency intervals, with the size of the frequency interval varying in very small steps across the template set. A given FFT spectrum was multiplied by each template function of the set, and the template yielding the highest product was used to estimate the harmonic frequencies of the FFT spectrum. The corresponding harmonic amplitudes were then determined directly from the FFT spectrum. Visual inspection of sample cases confirmed that this procedure yielded highly accurate results.

F. Calculating vowel space size and amount of VISC

For both the acoustic ($F1 \times F2$) and auditory ($PC1 \times PC2$) spaces, two methods were used to calculate the size of the vowel space. These methods are described here in terms that apply equally to the acoustic and auditory spaces. The first method was to calculate the area of the triangle (using Heron's formula) defined by the vowels /i/, /ɑ/, and /u/, with the analysis window centered at the 50% time point of each vowel trajectory. An advantage of this quantity is that it corresponds to a typical graphic representation of vowel space size in two dimensions. The second method was to calculate the average Euclidean distance between every pair of vowels in the entire vowel set. Relative to the first method, this one yields a more comprehensive measure of vowel dispersion. The quantities calculated by these methods are referred to here as size (area) and size (dispersion), respectively.

Two methods were also used to calculate the amount of VISC according to both the acoustic and auditory measures. The first was to sum the Euclidean distances traversed by a given vowel (in the $F1 \times F2$ space or the $PC1 \times PC2$ space) between the 25% and 50% time points and between the 50% and 75% time points and then to average these sums across the entire vowel set. This quantity, which is referred to as VISC (magnitude), approximates the degree of spectral change across the vowel nucleus while limiting somewhat the contribution of the initial and final consonants to spectral dynamics. It can reasonably be viewed as a valid measure of

the amount of VISC. However, by itself this quantity does not provide for an adequate test of the notion of sufficient contrast. The reason is that there is no guarantee that a greater amount of VISC, defined in this way, will correspond to greater acoustic or auditory distinctiveness among vowels.

The second method for calculating the amount of VISC was an attempt to remedy this limitation. It was analogous to the size (dispersion) method for calculating vowel space size. For each stimulus, the signed differences in F1 and F2 (or PC1 and PC2) were calculated between the 25% and 50% time points and between the 50% and 75% time points. For each of the two time intervals, every vowel token was represented in a space whose dimensions corresponded to these signed differences (i.e., $F1_{diff} \times F2_{diff}$, or $PC1_{diff} \times PC2_{diff}$), and the average Euclidean distance between every pair of vowel tokens was determined. Finally, these two averages were themselves averaged across the two time intervals. This quantity, which is referred to as VISC (dispersion), yields a measure of vowel distinctiveness that is independent of size (dispersion).

III. RESULTS

For each language and for each measure, a 2 (focus condition) $\times 2$ (sex of talker) repeated-measures ANOVA was performed. In the case of German, ANOVAs for size (area) were performed on the short vowel and long vowel sets separately, whereas those for size (dispersion) and all other measures were performed on the entire vowel set.

A. Vowel space size

1. Acoustic space: F1 × F2

a. Size (area): For all three languages, there was a significant effect of focus condition (English: $[F(1,10)=10.70,\ p<0.01,\ \eta_p^2=0.517]$, French: $[F(1,10)=15.86,\ p<0.005,\ \eta_p^2=0.613]$, German long: $[F(1,12)=13.46,\ p<0.005,\ \eta_p^2=0.529]$ and German short: $[F(1,12)=15.79,\ p<0.005,\ \eta_p^2=0.568]$), with [+focus] vowels having a larger size (area) than [−focus] vowels. Sex of talker was not significant in either English or French but was significant for both German long $[F(1,12)=48.58,\ p<0.001,\ \eta_p^2=0.802]$ and short $[F(1,12)=21.04,\ p<0.005,\ \eta_p^2=0.637]$ vowels. Figures 1–4 show the effects of focus condition and sex of talker on the size of the acoustically defined vowel space for each of the three languages.

b. Size (dispersion): Figure 5(a) shows the effect of focus condition on the acoustically defined measure of size (dispersion). This effect was significant for English $[F(1,10)=33.10,\ p<0.001,\ \eta_p^2=0.768]$, French $[F(1,10)=41.61,\ p<0.001,\ \eta_p^2=0.806]$, and German $[F(1,12)=37.14,\ p<0.001,\ \eta_p^2=0.756]$, with [+focus] vowels having greater size (dispersion) than [−focus] vowels. The effect of sex of talker was significant only in German ($[F(1,12)=19.12,\ p<0.005,\ \eta_p^2=0.614]$), with German females having greater size (dispersion) than German males.

2. Auditory space: PC1 × PC2

a. Size (area): For English and French, there was a significant effect of focus condition on the size of the auditorily defined vowel space ($[F(1,10)=10.37,\ p<0.01,\ \eta_p^2=0.509]$ and $[F(1,10)=9.78,\ p<0.05,\ \eta_p^2=0.499]$, respectively), with the [+focus] vowels having a larger vowel space than [−focus] vowels. German short $[F(1,12)=19.91,\ p<0.005,\ \eta_p^2=0.624]$, but not long vowels ($p=0.072$), were produced with significantly more auditory separation in the [+focus] condition. Sex of talker was not a significant variable in any of the three languages. The results patterned very similarly for the acoustically and auditorily defined vowel spaces. Table I displays correlations, for each of the three languages, between the first and second principal components of the auditorily defined space and F1 and F2.

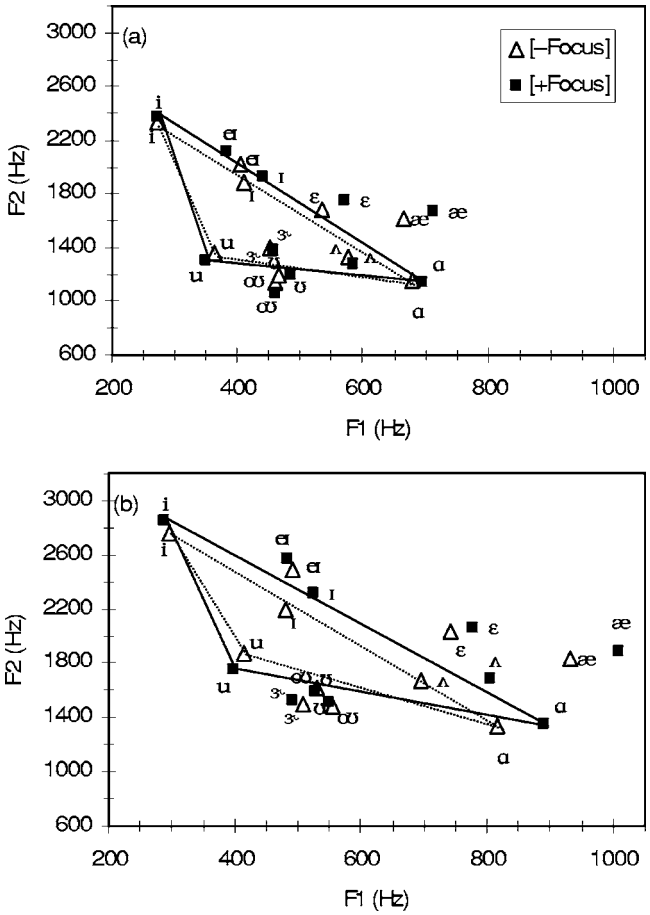

FIG. 1. Effect of focus condition on size (area) for English vowels: (a) males, (b) females. Dotted and solid lines represent the /i/-/ɑ/-/u/ vowel triangles for the [−focus] and [+focus] conditions, respectively.

b. Size (dispersion): Figure 5(b) displays the effect of focus condition on the auditorily defined measure of size (dispersion). For all three languages, [+focus] vowels showed greater size (dispersion) than [−focus] vowels (English: $[F(1,10)=49.76,\ p<0.001,\ \eta_p^2=0.833]$, French $[F(1,10)=15.04,\ p<0.005,\ \eta_p^2=0.601]$, German $[F(1,12)=15.14,\ p<0.005,\ \eta_p^2=0.558]$. As in the case of the auditorily defined size (area) measure, sex of talker was not a significant variable for any of the three languages.

B. VISC

1. Acoustic space: F1 × F2 for VISC (magnitude); $F1_{diff} \times F2_{diff}$ for VISC (dispersion)

a. VISC (magnitude): Figure 6(a) shows the effect of focus condition on VISC (magnitude) for the three languages. Focus condition was a significant variable only for

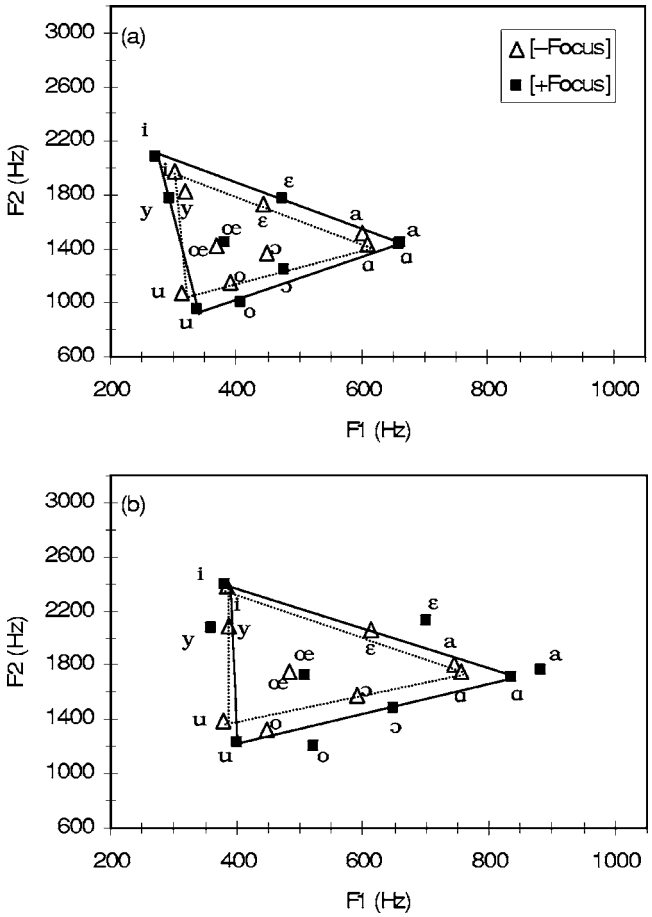

FIG. 2. Effect of focus condition on size (area) for French vowels: (a) males, (b) females. Dotted and solid lines represent the /i/-/ɑ/-/u/ vowel triangles for the [−focus] and [+focus] conditions, respectively.

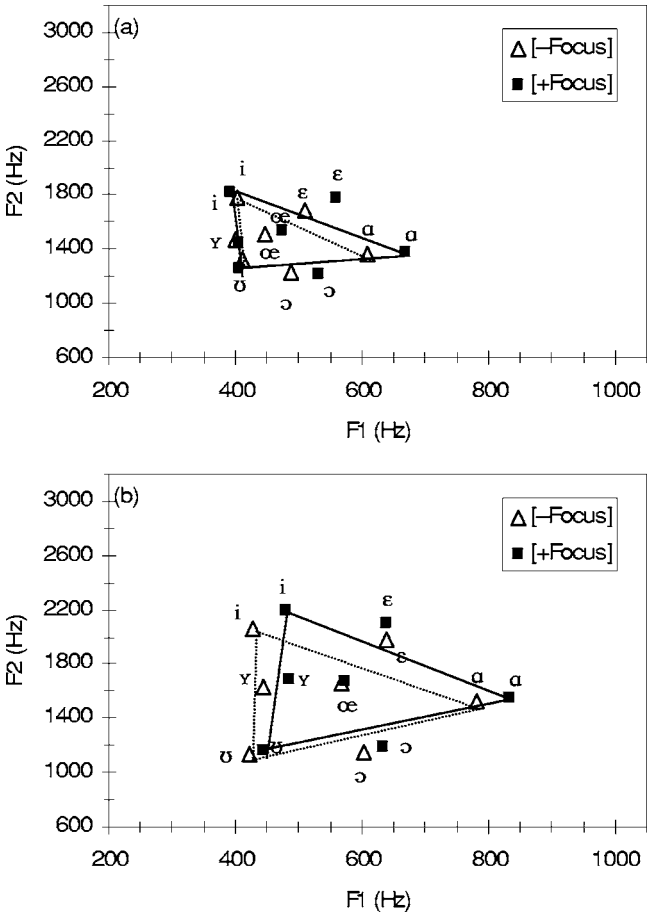

FIG. 3. Effect of focus condition on size (area) for German short vowels: (a) males, (b) females. Dotted and solid lines represent the /i/-/ɑ/-/u/ vowel triangles for the [−focus] and [+focus] conditions, respectively.

German [$F(1,12)=14.54$, $p<0.005$, $\eta_p^2=0.548$], with [+focus] vowels showing greater VISC (magnitude) than [−focus] vowels. For all three languages, female talkers showed significantly greater VISC (magnitude) than male talkers (English: [$F(1,10)=13.57$, $p<0.005$, $\eta_p^2=0.576$], French: [$F(1,10)=14.87$, $p<0.005$, $\eta_p^2=0.598$], and German: [$F(1,12)=24.76$, $p<0.001$, $\eta_p^2=0.674$]). There were no significant interactions between focus condition and sex of talker for any of the three languages.

b. VISC (dispersion): Figure 6(b) exhibits the effect of focus condition on VISC (dispersion) for the three languages. As in the case of VISC (magnitude), German was the only language to show significantly greater VISC (dispersion) for [+focus] vowels than [−focus] vowels [$F(1,12)=11.87$, $p<0.01$, $\eta_p^2=0.497$]. For each of the three languages, there was a significant effect of sex of talker on the measure of VISC (dispersion) (English: [$F(1,10)=26.12$, $p<0.001$, $\eta_p^2=0.723$], French: [$F(1,10)=10.36$, $p<0.01$, $\eta_p^2=0.509$], and German: [$F(1,12)=33.64$, $p<0.001$, $\eta_p^2=0.737$]), with females showing greater acoustic separation than males. There were no significant interactions between focus condition and sex of talker for any of the languages.

2. Auditory space: PC1×PC2 *for VISC (magnitude);* $PC1_{diff}\times PC2_{diff}$ *for VISC (dispersion)*

a. VISC (magnitude): The effect of focus condition on the auditorily defined measure of VISC (magnitude) is shown in Fig. 6(c). English, French, and German all showed greater VISC for [+focus] vowels than [−focus] vowels ([$F(1,10)=111.11$, $p<0.001$, $\eta_p^2=0.917$], [$F(1,10)=16.41$, $p<0.005$, $\eta_p^2=0.621$], and [$F(1,12)=15.09$, $p<0.005$, $\eta_p^2=0.557$], respectively). None of the languages showed an effect of sex of talker.

As was true for size (area), correlations between the first two principal components of the auditorily defined space and F1 and F2 were generally significant. These are shown in Table I.

b. VISC (dispersion): Figure 6(d) displays the effect of focus condition on the auditorily defined measure of VISC (dispersion). All three languages showed a significant effect of focus condition (English [$F(1,10)=77.05$, $p<0.001$, $\eta_p^2=0.885$], French [$F(1,10)=9.18$, $p<0.05$, $\eta_p^2=0.478$], and German [$F(1,12)=14.10$, $p<0.005$, $\eta_p^2=0.540$]), with [+focus] vowels showing greater separation than [−focus] vowels. There was no significant effect of sex of talker for any of the languages.

Note that for both VISC (magnitude) and VISC (dispersion), the auditorily defined measures yielded more cross-linguistically consistent effects of focus condition than the acoustically defined measures.

In contrast, the auditorily defined measures of both vowel space size and VISC showed, if anything, less sensitivity to the sex of talker variable. This can perhaps be attributed to the use of the Bark scale in the auditory represen-

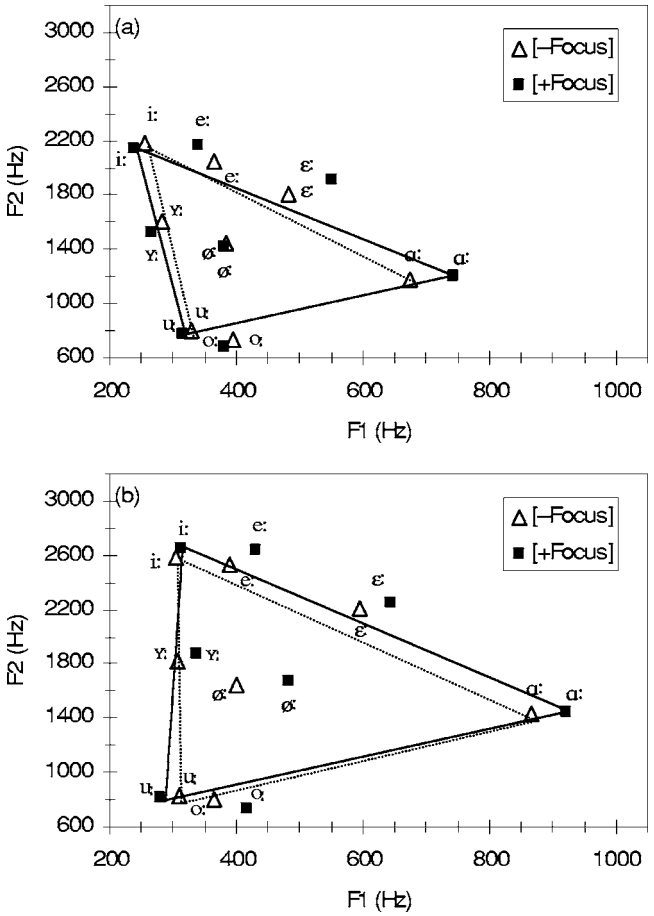

FIG. 4. Effect of focus condition on size (area) for German long vowels: (a) males, (b) females. Dotted and solid lines represent the /i:/-/ɑ:/-/u:/ vowel triangles for the [–focus] and [+focus] conditions, respectively.

tations of vowels, the effect of which is partly to normalize frequency differences between male and female talkers (Syrdal and Gopal, 1986).

Although the measures of VISC (magnitude) and VISC (dispersion) are logically independent, they should be highly correlated provided that vowel tokens are widely distributed in the $F1_{diff} \times F2_{diff}$ space or the $PC1_{diff} \times PC2_{diff}$ space. Table II shows these correlations for each language and for both the acoustic and auditory measures.

C. Duration variance

Neither English nor French showed significant effects of focus condition on vowel duration variance. However, in German there was more duration variance for [+focus] vowels than for [–focus] vowels [$F(1,12)=17.01$, $p<0.005$, $\eta_p^2=0.586$]. There was no significant effect of sex of talker on duration variance in any of the languages. Figure 7 shows the effects of focus condition on duration variance for each of the three languages.

TABLE I. Correlations between auditory principal components and formant frequencies. The asterisks represent that correlation is significant at the 0.01 level (2-tailed).

		Vowel space		VISC	
		PC1	PC2	PC1	PC2
English	F1	0.046	0.471*	0.446*	0.018
English	F2	0.184*	−0.450*	−0.472*	0.171*
French	F1	0.662*	0.289*	0.651*	0.275*
French	F2	−0.359*	0.422*	−0.386*	0.401*
German	F1	0.627*	0.159*	0.623*	0.129*
German	F2	−0.261*	0.452*	−0.295*	0.438*

D. Comparing the English tense/lax distinction and the German long/short distinction

In the analyses described above, each language was treated separately owing to differences among English, French, and German in the size and character of the vowel inventories. However, for a subset of the measurements, it is instructive to perform additional analyses in which language is a factor. This subset includes data for all seven long/short pairs of vowels in German (/ɑ:, ɑ/, /e:, ɛ/, /i:, ɪ/, /o:, ɔ/, /ø:, œ;/, /u:, ʊ/, /ʏ:, ʏ/) as well as for four tense/lax vowel pairs in America English (/ɑ, ʌ/, /e^{ɪ}, ɛ/, /i, ɪ/, /u, ʊ/). The members of each of these vowel pairs are potentially confusable because they occupy similar or adjacent regions in F1×F2 space, although in both languages (and especially in German) this problem is mitigated because of durational differences.

Three sets of measurements were analyzed using 2 (focus conditions)×2 (language) repeated-measures ANOVAs. (For the purpose of these analyses, the data were collapsed over the sex of talker variable.) The first two sets of measurements were equivalent to the auditory versions of size (dispersion) and VISC (dispersion), respectively, except that the stimulus tokens being compared did not comprise the entire vowel set but instead were restricted to the two mem-

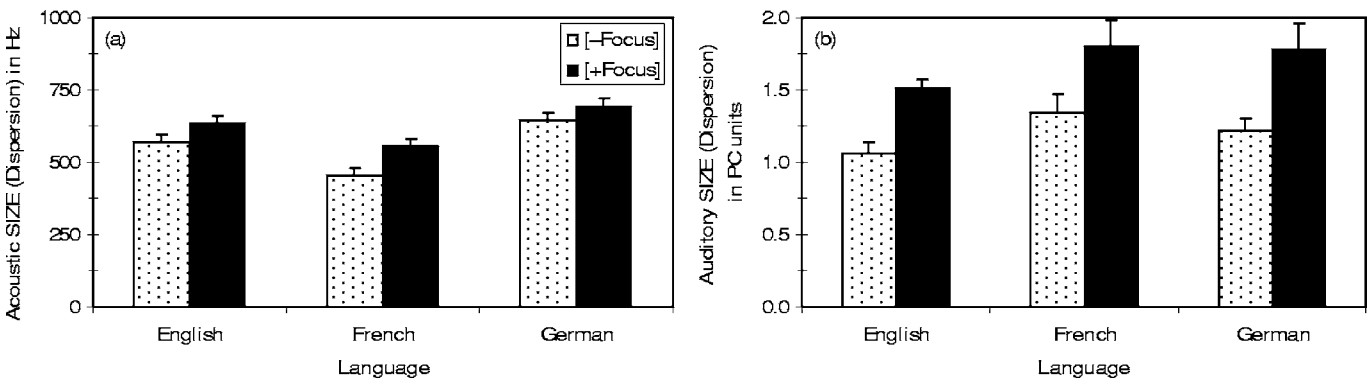

FIG. 5. Effect of focus condition on the (a) acoustically defined and (b) auditorily defined measures of size (dispersion) for English, French, and German. PC units refer to unit distances in the PC1×PC2 space. Error bars represent the standard error of the mean.

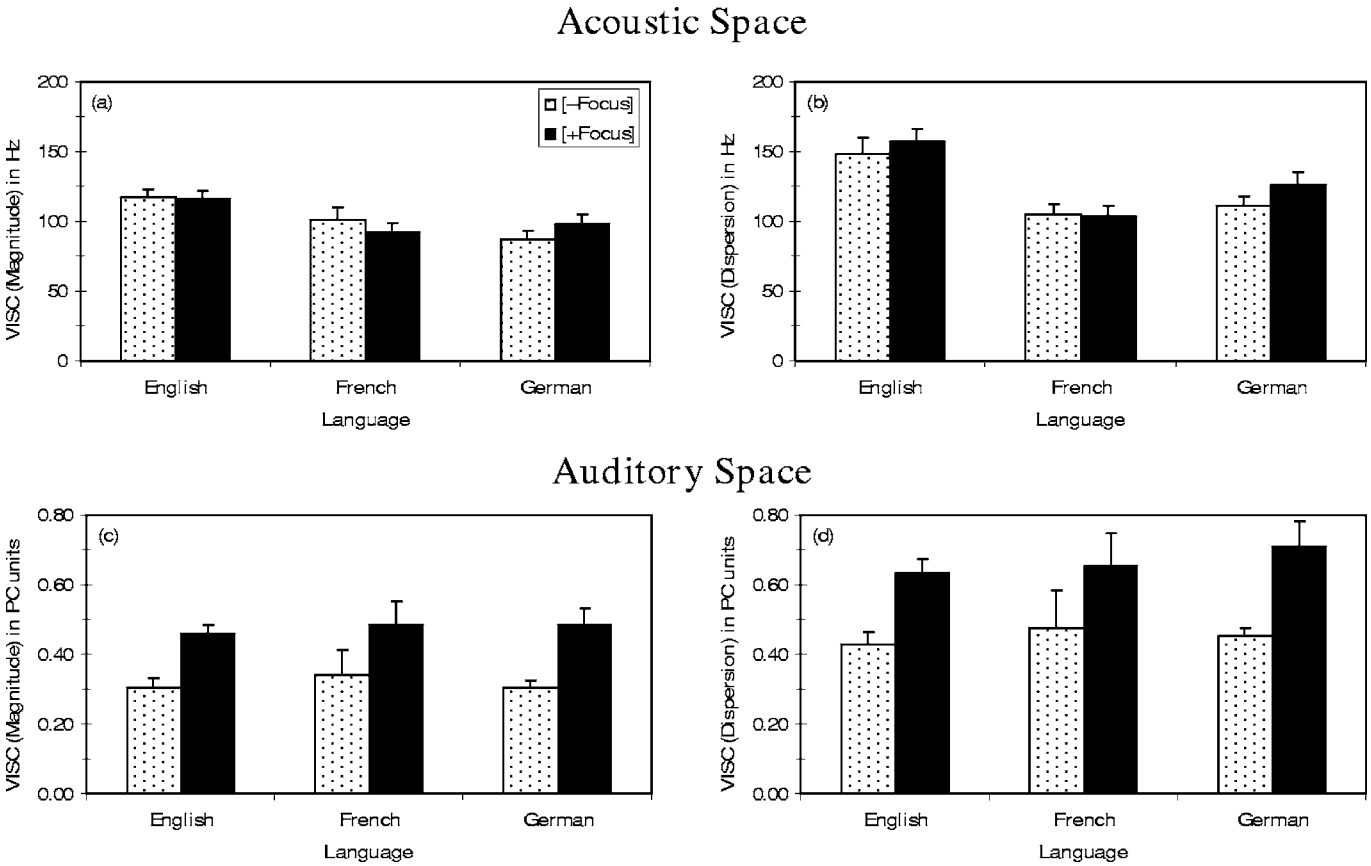

FIG. 6. Effect of focus condition on the acoustically defined measures of (a) VISC (magnitude) and (b) VISC (dispersion) and on the auditorily defined measures of (c) VISC (magnitude) and (d) VISC (dispersion), for English, French, and German. For the size (dispersion) measure, PC units refer to unit distances in the PC1 × PC2 space; for the VISC (dispersion) measure, PC units refer to unit distances in the $PC1_{diff} \times PC2_{diff}$ space. Error bars represent the standard error of the mean.

bers of each long/short or tense/lax pair. The third set of measurements consisted of the duration ratios between long/short or tense/lax pair members.

Table III shows the mean values of size (dispersion), VISC (dispersion), and duration ratio between English tense/lax and German long/short vowel pair members in [+focus] and [−focus] conditions. There were significant effects of focus condition for the modified size (dispersion) [$F(1,24)=31.89$, $p<0.001$, $\eta_p^2=0.571$] and VISC (dispersion) [$F(1,24)=27.13$, $p<0.001$, $\eta_p^2=0.531$] measures, with both yielding larger values in [+focus] condition. For neither measure was there a significant effect of language or a significant focus condition × language interaction.

For the duration ratio measure, there were significant main effects of focus condition [$F(1,24)=4.81$, $p<0.05$, $\eta_p^2=0.167$] and language [$F(1,24)=102.43$, $p<0.001$, $\eta_p^2=0.810$], with vowel pairs in [+focus] condition and in German showing greater duration ratios, but there was no interaction between these variables. Analyses of simple effects showed that focus condition was a significant variable in German [$F(1,13)=8.04$, $p<0.05$, $\eta_p^2=0.382$], but not in English ($p=0.497$). The larger duration ratios for [+focus] vowels in German help to account for the increased overall duration variance reported earlier for German vowels in [+focus] condition. Although the tense/lax duration ratios in English were much smaller than the long/short duration ratios in German, the former were nevertheless significantly greater than 1.0 ($p<0.001$) in both [+focus] and [−focus] conditions.

It is noteworthy that the relative effect of focus condition was considerably greater for the two dispersion measures than for the duration ratio measure. This was no less true in German than in English.

TABLE II. Correlations between VISC (magnitude) and VISC (dispersion) in $F1_{diff} \times F2_{diff}$ and $PC1_{diff} \times PC2_{diff}$ spaces for English, French, and German. The asterisks represent that correlation is significant at the 0.01 level (2-tailed).

	Acoustic ($F1_{diff} \times F2_{diff}$ Space)	Auditory ($PC1_{diff} \times PC2_{diff}$ Space)
English	0.908*	0.964*
French	0.859*	0.990*
German	0.966*	0.994*

IV. DISCUSSION

The present study examined several possible acoustic and auditory correlates of vowels in [+focus] context produced by talkers of American English, French, and German. Consistent with Lindblom's theory of adaptive dispersion, each language group enhanced the distinctiveness of vowels in the portion of an utterance used to signal new (as opposed to given) information, and, as allowed by the principle of sufficient contrast, the three language groups used varying

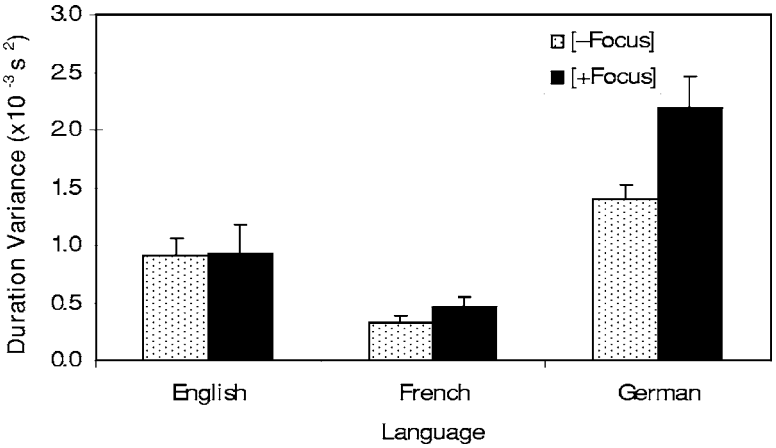

FIG. 7. Effect of focus condition on duration variance in English, French, and German. Error bars represent the standard error of the mean.

means of enhancing distinctiveness. In producing vowels in [+focus] context, all three language groups increased spectral differences among vowels, but only the German talkers increased vowel duration differences. Table IV lists the measures for which the effect of focus condition was significant in each language.

The acoustic and auditory versions of the spectral measures generally yielded similar patterns of results; however, the auditory versions yielded a higher number of significant effects of focus condition on the measures of VISC. We interpret these results as a validation of our auditory measures of spectral distance. Although the vowel space is most commonly defined acoustically, namely, in terms of the frequencies of the first several formants, there are several advantages in using an auditorily defined space. First, as noted earlier, the notion of sufficient contrast is more directly evaluated in terms of auditory rather than acoustic distance. Second, automatic formant tracking procedures are error-prone and often need to be supplemented with manual editing. In contrast, the auditory space used in the present study is derived entirely by algorithmic means. Third, there is little reason to believe that, unlike artificial systems, the human auditory system some how manages to circumvent the inherent difficulties in extracting formant frequencies reliably. It seems more plausible to assume that the auditory system extracts parameters that are rich in phonetic information but that can be computed algorithmically from the speech signal. Among possible candidates for such parameters, we would include stimulus values within a PCA-defined auditory space such as that used in the present study.[4] Previous factor analyses of auditory spectra have yielded principal components that account well for the variance among vowel sounds (Plomp *et al.*, 1967; Klein *et al.*, 1970) and that are reasonably highly correlated with formant frequencies (Nearey and Kiefte, 2003). Such correlations were also found in this study. Factor analytic approaches in these cases may thus be described as yielding implicit information about formant values without requiring actual formant tracking.

Finally, we return to the topic of cross-language variation in the means by which vowel distinctiveness is enhanced in [+focus] contexts. One possible account of this variation is based on the distinction between phonologically contrastive and noncontrastive, or secondary, properties. Consider, for example, the case of vowel duration differences. In German, such differences are used to signal phonological contrasts between long and short vowels of similar quality (e.g., /ɑː/ versus /ɑ/). However, in English, vowel duration differences are generally viewed as a type of noncontrastive variation that is correlated with and conditioned by some primary phonological contrast (e.g., tense versus lax vowels and nonlow versus low vowels). As in other languages that make contrastive use of vowel length (Heldner and Strangert, 2001; de Jong and Zawaydeh, 2002; Smiljanic, 2004), duration ratios of German long/short vowel pairs were significantly increased in [+focus] context. However, no such change occurred for English tense/lax vowel pairs. This pat-

TABLE III. Mean auditory size (dispersion), VISC (dispersion), and duration ratio for English tense/lax and German long/short vowel pairs. For the size (dispersion) measure, PC units refer to unit distances in the PC1 × PC2 space; for the VISC (dispersion) measure, PC units refer to unit distances in the $PC1_{diff} \times PC2_{diff}$ space.

	English		German	
	[+Focus]	[–Focus]	[+Focus]	[–Focus]
Size (dispersion) in PC units	1.056	0.761	1.266	0.719
VISC (dispersion) in PC units	0.578	0.396	0.688	0.396
Duration ratio	1.238	1.183	2.126	1.981

TABLE IV. Significant effects of focus condition on distinctiveness enhancement in vowels. * represents significant at the 0.05 level; ** significant at the 0.01 level; *** significant at the 0.001 level.

tern of results might suggest that in [+focus] context talkers exaggerate only those vowel differences that are phonologically contrastive.

However, this account of cross-language differences in vowel contrast enhancement faces several difficulties. First, some noncontrastive properties of phonemes do appear to be subject to enhancement in [+focus] contexts. In modern theories of distinctive features (for a review, see Diehl and Lindblom, 2004), VISC has not generally been recognized as being phonologically contrastive. It is more likely to be viewed as a secondary correlate of certain primary vowel features (e.g., tenseness or height). Yet, in the present study, talkers from all three language groups exhibited increased VISC (magnitude) or increased VISC (dispersion) in [+focus] context, by either the acoustic measure, the auditory measure, or both. Analogously, it has been reported that duration differences of English stressed vowels before [+voice] and [−voice] stop consonants are enhanced in [+focus] context (de Jong, 2004), even though such differences have typically been viewed as a secondary correlate of the syllable-final [voice] distinction. Thus, status as a phonologically contrastive feature of a language does not appear to be a necessary condition for enhanced distinctiveness in utterance focus.

Another difficulty in appealing to the contrastive/noncontrastive distinction to account for cross-language differences in vowel contrast enhancement is that the distinction itself is difficult to apply in practice and may be theoretically problematic. For example, German vowels differing in length have been variously described by linguists as tense/lax contrasts or as long/short contrasts (Hawkins, 1992). Phonetically, the members of these vowel pairs differ both in spectral properties and in duration (Fischer-Jørgensen, 1990), and it is unclear which of these differences should be viewed as contrastive and which as noncontrastive (or secondary). Because phonological features may be quite abstract, mapping onto diverse phonetic correlates each having perceptual relevance (Kingston and Diehl, 1994), the assignment of contrastive status to one correlate and secondary status to others may be quite arbitrary.

An alternative hypothesis is that the amount of contrast enhancement of a vowel property in [+focus] context is positively related to the between-category variation of that property in [−focus] context. Although the spectral measures did not provide evidence for or against this hypothesis (because the language groups did not differ very much according to these measures in either the [−focus] or the [+focus] conditions), the duration variance and duration ratio measures did yield results consistent with the hypothesis. Duration variance among [−focus] vowels was much larger in German than in English and French, and significant enhancement of duration variance in [+focus] context occurred only for German.[5] Similarly, duration ratios between German long/short vowel pairs were much larger than those between English tense/lax vowel pairs in [−focus] condition, and only German vowels exhibited significant enhancement of duration ratios in [+focus] condition. Some previous cross-language results also appear to be consistent with the above hypothesis. For example, de Jong and Zawaydeh (2002) and de Jong (2004) found that vowel duration differences conditioned by a following [voice] distinction are greater in English than in Arabic (see also Port *et al.*, 1980, and Flege and Port, 1981), and that [+focus] contexts yield a reliable enhancement of these differences only in English. A tendency to enhance properties of phonemes that show greater between-category variance may be viewed as yet another instance of the positive relationship, predicted by the theory of adaptive dispersion, between utterance clarity and information content.

ACKNOWLEDGMENTS

This work was supported by research grants Nos. R01 DC00427-13, -14, -15 from the National Institute of Health, National Institute on Deafness and Other Communication Disorders, to the fifth author (R.L.D.) Special thanks to Juan Segui and Ludovic Ferrand of the CNRS and Université René Descartes, Laboratoire de Psychologie Expérimental, Paris, France, for providing facilities to conduct the French portion of the study. Some of these findings were reported at the 143rd Meeting of the Acoustical Society of America, Pittsburgh, June 4, 2002 and at the 146th Meeting of the Acoustical Society of America, Austin, November 11, 2003. The authors thank Ann Bradlow for very helpful comments on earlier versions of this paper.

APPENDIX

The following orthographic representations of test words were used:

English material

bat bæt	*bet* bɛt	*bit* bɪt	*bait* beˈt	*beet* bit
baht bat **	*butt* bʌt	*bout* bʊt rhymes w/'put' **	*boat* boᵘt	*boot* but
bert bɜˑt **				

French material

pites pit **	*pète* pɛt 'to break' (present tense)	*patte* pat 'paw'	*pâte* pɑt 'pasta'	*peaute* pot **
pute pyt 'hooker'	*pote* pɔt 'friend' (colloquial)	*peute* pœt **	*poute* put **	

German material

Batten bɑtən **	*Betten* bɛtən 'beds'	*Bitten* bɪtən 'to ask'	*Botten* bɔtən **	*Bötten* bœtən **
Butten bʊtən **	*Bütten* bʏtən 'tubs'	*Baten* bɑːtən 'asked'	*Bäten* bɛːtən 'asked' (subj)	*Beten* beːtən 'pray'
Bieten biːtən 'to offer'	*Boten* boːtən 'boats'	*Böten* bøːtən **	*Buten* buːtən **	*Büten* bʏːtən **

**Nonsense words.

[1]Under noisy conditions, clear speech has also been found to be more intelligible than reduced speech, other things being equal, for normal hearing adults (Tolhurst, 1957) and children with learning disabilities (Bradlow *et al.*, 2003).

[2]Apart from signaling new information, [+focus] may also be used to highlight thematic relations between a constituent and its context (Nooteboom and Kruyt, 1987).

[3]For the American English and French groups but not the German group, the same questions were also answered using fast and slow rates of utterance. For a given vowel, talkers produced each focus condition at every rate before moving on to the next vowel. The order of focus condition and utterance rate was randomized between vowels. Because focus condition was the key variable of interest in the present study and because the German group produced utterances only at the normal rate, we include here only results for the normal utterance rate. In general, the pattern of results obtained for the normal utterance rate was very similar to the patterns for the other two utterance rates.

[4]The demand for efficient neural coding of signals suggests that some form of factor analysis (e.g., PCA or independent components analysis) may be implicit in the design of sensory/perceptual systems (Field, 1987; Simoncelli and Olshausen, 2001; Lewicki, 2002).

[5]A potential concern with the participant selection in the present study is that, unlike the American English and French groups, the German group was currently visiting or residing in Autsin, Texas, rather than living in their native language community. However, if exposure to English affected the German vowel productions, this was clearly not sufficient to eliminate differences between English and German modes of contrast enhancement.

Comparing the rhythm and melody of speech and music: The case of British English and French

Aniruddh D. Patel,[a] John R. Iversen, and Jason C. Rosenberg
The Neurosciences Institute, 10640 John Jay Hopkins Drive, San Diego, California 92121

(Received 8 September 2005; revised 1 February 2006; accepted 2 February 2006)

For over half a century, musicologists and linguists have suggested that the prosody of a culture's native language is reflected in the rhythms and melodies of its instrumental music. Testing this idea requires quantitative methods for comparing musical and spoken rhythm and melody. This study applies such methods to the speech and music of England and France. The results reveal that music reflects patterns of durational contrast between successive vowels in spoken sentences, as well as patterns of pitch interval variability in speech. The methods presented here are suitable for studying speech-music relations in a broad range of cultures. © *2006 Acoustical Society of America.*

I. INTRODUCTION

A. Aims

Humans produce organized rhythmic and melodic patterns in two forms: prosody and music. While these patterns are typically studied by different research communities, their relationship has long interested scholars from both fields. For example, linguists have borrowed musicological concepts in building prosodic theories (Liberman, 1975; Selkirk, 1984), and musicologists have used tools from linguistic theory to describe musical structure (Lerdahl and Jackendoff, 1983). Despite this contact at the theoretical level, there has been remarkably little empirical work comparing rhythmic or melodic structure across domains. There are reasons to believe such work is warranted. One such reason, which motivates the current study, is the claim that a composer's music reflects prosodic patterns in his or her native language. This idea has been voiced repeatedly by scholars over the past half century. For example, the English musicologist Gerald Abraham explored this topic at length (1974), citing as one example Ralph Kirkpatrick's comment on French keyboard music:

"Both Couperin and Rameau, like Fauré and Debussy, are thoroughly conditioned by the nuances and inflections of spoken French. On no Western music has the influence of language been stronger." (p. 83)

Kirkpatrick (a harpsichordist and music scholar) was claiming that French keyboard music sounded like the French language. Similar claims have been made about the instrumental music of other cultures. The linguist Hall, for example, suggested a resemblance between Elgar's music and the intonation of British speech (Hall, 1953). What makes these claims interesting is that they concern *instrumental* music. It might not be surprising if vocal music reflected speech prosody; after all, such music must adapt itself to the rhythmic and melodic properties of a text. In contrast, the notion that speech patterns are mirrored in instrumental music is much more controversial.

While provocative, until recently this idea had not been systematically tested, likely due to a lack of methods for quantifying prosody in a way that could be directly compared to music. Patel and Daniele (2003) sought to overcome this problem (with regard to rhythm) by using a recently-developed measure of temporal patterning in speech, the normalized pairwise variability index or nPVI. The nPVI measures the degree of durational contrast between successive elements in a sequence, and was developed to explore rhythmic differences between "stress-timed" and "syllable-timed" languages (Low, 1998; Low *et al.*, 2000). Empirical work in phonetics has revealed that the nPVI of vowel durations in sentences is significantly higher in stress-timed languages such as British English than in syllable-timed languages such as French (Grabe and Low, 2002; Ramus, 2002). The reason for this is thought to be the greater degree of vowel reduction in the former languages (Dauer, 1983, 1987; Nespor, 1990). Patel and Daniele applied the nPVI to the durations of notes in instrumental classical themes from England and France, and found that English music had a significantly higher nPVI than French music. This earlier work illustrates a cross-cultural approach to comparing prosodic and musical structure which is extended in the current study. This approach is based on determining whether quantitative prosodic differences between languages are reflected in music (cf. Wenk, 1987).

While Patel and Daniele (2003) focused on composers from the turn of the 20th century (a time of musical nationalism), subsequent work showed that their finding generalized to a much broader historical sample of composers from England and France (Huron and Ollen, 2003). Furthermore, it appears that other European cultures with stress-timed languages tend to have higher musical nPVI values than cultures with syllable-time languages (Huron and Ollen, 2003), though interesting exceptions exist (Patel and Daniele, 2003b; Daniele and Patel, 2004). These studies indicate that prosody and instrumental music can be meaningfully compared using quantitative methods. They also raise two key

questions which are the focus of the current study, as detailed in Secs. I A 1 and I A 2 below. As in the previous work, the current study focuses on British English and continental French (henceforth English and French). One of the principal goals, however, is to address issues and develop methods of broad applicability to speech-music research.

1. Are differences in durational contrast a byproduct of variability differences?

Although the nPVI's name refers to a "variability index," it is in fact a measure of durational contrast. This is evident from the nPVI equation,

$$\mathrm{nPVI} = \frac{100}{m-1} \times \sum_{k=1}^{m-1} \left| \frac{d_k - d_{k+1}}{\frac{d_k + d_{k+1}}{2}} \right|, \quad (1)$$

where m is the number of durational elements in a sequence d_k is the duration of the kth element. The nPVI computes the absolute difference between each successive pair of durations in a sequence, normalized by the mean duration of the pair. This converts a sequence of m durations (e.g., vowel durations in a sentence) to a sequence of $m-1$ contrastiveness scores. Each of these scores ranges between 0 (when the two durations are identical) and 2 (for maximum durational contrast, i.e., when one of the durations approaches 0). The mean of these scores, multiplied by 100, yields the nPVI of the sequence. The nPVI is thus a contrastiveness index and is quite distinct from measures of overall variability (such as the standard deviation) which are insensitive to the order of observations in a sequence. Indeed, one cannot compute the nPVI of a given sequence from its standard deviation or vice versa. Nevertheless, at the population level differences in overall variability of two sets of sequences will inevitably drive some degree of nPVI difference between the sets, simply because sequences with greater variability are likely to contain neighbors of greater durational contrast (cf. Sadakata and Desain, submitted).

This point is relevant to the comparison of English and French because there are reasons to expect that vowels in English sentences should exhibit higher overall durational variability than vowels in French sentences. One such reason is that vowel duration in English is substantially modulated by stress and vowel reduction, factors which play much less of a role in modulating vowel duration in French (Delattre, 1966; 1969). Hence it is important to know if linguistic nPVI differences between the languages are simply a by-product of variability differences. A similar question applies to music. Should this be the case, then music may simply reflect differences in linguistic temporal variability, with the nPVI difference being a by-product of such differences.

To examine these issues, a measure of overall variability for each sentence and musical theme is computed in this study in order to examine the relationship between variability and nPVI. Specifically, a Monte Carlo method is used to quantify the likelihood of observing an nPVI difference of a given magnitude between two languages (or two musics) given existing differences in variability.

2. Is speech melody reflected in music?

The original intuition of a link between prosody and instrumental music was not confined to rhythm, but encompassed melody as well (e.g., Hall, 1953). The current study addresses this issue via a quantitative comparison of intonation and musical melody. Earlier comparative work on rhythm had the benefit of an empirical measure which could readily be applied to music (the nPVI). In the case of intonation, no such measure was available. To overcome this problem, this study employs a recent computational model of speech intonation perception known as the "prosogram" (Mertens, 2004a, 2004b). The prosogram converts a sentence's fundamental frequency (Fo) contour into a sequence of discrete tonal segments, producing a representation which is meant to capture the perceived pitch pattern of a speech melody. This representation allows a quantitative comparison of pitch variability in speech and music. Further details on the prosogram and measures of variability are given in the next section.

B. Background

1. Rhythm

Speech rhythm refers to the way languages are organized in time. Linguists have long held that certain languages (such as English and French) have decidedly different rhythms, though the physical basis of this difference has been hard to define. Early ideas that the difference lay in the unit produced isochronously (either stresses or syllables) have not been supported by empirical research (e.g., Roach, 1982, Dauer, 1983). Some linguists have nevertheless retained the "stress-timed" vs "syllable-timed" terminology, likely reflecting an intuition that languages placed in these categories do have salient rhythmic differences (Beckman, 1992). Examples of languages placed in these categories are British English, Dutch, and Thai (stress-timed) vs French, Spanish, and Singapore English (syllable timed) (Grabe and Low, 2002).

Recent years have seen the discovery of systematic temporal differences between stress-timed and syllable-timed languages (e.g. Ramus *et al.*, 1999; Low *et al.*, 2000). These discoveries illustrate the fact that "rhythm" in speech should not be equated with isochrony. That is, while isochrony defines one kind of rhythm, the absence of isochrony is not the same as the absence of rhythm. Rhythm is the systematic temporal and accentual patterning of sound. Languages can have rhythmic differences which have nothing to do with isochrony. For example, Ramus and co-workers (1999) demonstrated that sentences in stress-timed (vs syllable-timed) languages had greater durational variability in "consonantal intervals" (consonants or sequences of abutting consonants, regardless of syllable or word boundaries) and a lower overall percentage of sentence duration devoted to vowels. (They termed these two measures ΔC and $\%V$, respectively). These differences likely reflect phonological factors such as the greater variety of syllable types and the greater degree of vowel reduction in stress-timed languages (Dauer, 1983). Another difference between stress-timed and syllable-timed languages, noted previously, is that the durational contrast

between adjacent vowels in sentences is higher in the former types of languages (as measured by the nPVI), probably also due to the greater degree of vowel reduction in these languages (Low *et al.*, 2000; Grabe and Low, 2002; Ramus, 2002).[1] An interesting point raised by these recent empirical studies is that languages may fall along a rhythmic continuum rather than forming discrete rhythm classes (cf. Nespor, 1990; Grabe and Low, 2002). This "category vs continuum" debate in speech rhythm research has yet to be resolved, and is largely orthogonal to the issues addressed here.

Of the different temporal measures described above, vowel-based measures of rhythm are the most easily transferred to music research. This is because musical notes can roughly be compared to syllables, and vowels form the core of syllables. It therefore seems plausible to compare vowel-based rhythmic measures of speech to note-based rhythmic measures of music. Of the two vowel-based measures discussed above (*%V* and nPVI), the latter can be sensibly applied to music by measuring the durational contrast between successive notes in a sequence. This approach is taken in the current work.

Since the focus here is on English and French, it is worth asking about the robustness of the nPVI difference between these two languages. Significant nPVI differences between English and French have been reported by four published studies, one based on vowel durations in spontaneous speech (Grabe *et al.*, 1999), and three based on vocalic interval durations in read speech (Grabe and Low, 2002; Ramus, 2002; Lee and Todd, 2004). (A vocalic interval is defined as the temporal interval between a vowel onset and the onset of the next consonant in the sentence; a vocalic interval may thus contain more than one vowel and can span a syllable or word boundary, cf. Ramus *et al.*, 1999; Grabe and Low, 2002. The choice of vowels vs vocalic intervals makes little difference when comparing the nPVI of English and French, cf. Secs. II A and II B.) One notable finding is that nPVI values for English and French vary considerably from study to study. For example, Ramus (2002) reported values of 67.0 and 49.3 for English and French, respectively, while Lee and Todd (2004) reported values of 83.9 and 54.3. Both studies measured vocalic intervals in read speech. Possible sources of this discrepancy include differences in speech materials, speech rate, and the criteria for the placement of boundaries between vowels and consonants (cf. Dellwo *et al.*, 2006). Further research is needed to clarify this issue. What one can say confidently, however, is that the finding that English has a significantly higher nPVI than French (within a given study) appears highly robust.[2]

2. Melody

A central issue for comparing melody in speech and music is how to represent speech melodies. Several choices exist. One choice is to use the raw Fo contours of sentences. Another choice is to use sequences of abstract phonological tones, such as high (*H*) and low (*L*) tones in autosegmental-metrical theories of intonation (e.g., Pierrehumbert, 1980; Ladd 1996). This study opts for a representation that is neither as detailed as raw Fo contours nor as abstract as autosegmental-metrical approaches. This is the "prosogram" representation of intonation (Mertens, 2004a, 2004b; cf. d'Alessandro and Mertens, 1995).

The prosogram aims to provide a representation of intonation as perceived by human listeners, and thus follows in the tradition of Fo stylization based on perceptual principles (Rossi, 1971; Rossi, 1978a; Rossi, 1978b; 'tHart *et al.*, 1990). It is based on empirical research which suggests that pitch perception in speech is subject to four perceptual transformations. The first is the segregation of the Fo contour into syllable-sized units due to the rapid spectral and amplitude fluctuations in the speech signal (House, 1990). The second is a threshold for the detection of pitch movement within a syllable (the "glissando threshold"). The third, which applies when pitch movement is detected, is a threshold for detection of a change in the slope of a pitch movement within a syllable (the "differential glissando threshold"). The fourth, which applies when the pitch movement is subliminal, is temporal integration of Fo within a syllable (d'Alessandro and Castellengo, 1994; d'Alessandro and Mertens, 1995). The prosogram instantiates the latter three transformations via an algorithm which operates on the vocalic nuclei of syllables (phonetic segmentation is provided by the user). As a result of these transforms, the original Fo contour of a sentence is converted to a sequence of discrete tonal segments. An example of the model's output is given in Fig. 1, which shows the original Fo contour (top) and the prosogram (bottom) for the English sentence "Having a big car is not something I would recommend in this city." Figure 1 reveals why the prosogram is useful to those interested in comparing speech and music. The representation produced by the prosogram is quite musiclike, consisting mostly of level pitches. (Some syllables are assigned pitch glides if the amount of Fo change is large enough to exceed a perceptual threshold.) On a cognitive level, this is interesting because it implies that the auditory image of speech intonation in a listener's brain has more in common with music than has been generally appreciated. On a practical level, the dominance of level pitches means that intonation patterns in different languages can be compared using tools that can also be applied to music, e.g., statistical measurements of pitch height or pitch interval patterns.[3]

The current study uses the prosogram to examine a simple aspect of the statistical patterning of spoken intonation, namely pitch variability. Specifically, pitch variability in English and French speech is quantified from prosograms and compared to pitch variability in English and French musical themes. Prior studies of pitch variability in the two languages have produced contradictory results. Maidment (1976) computed running Fo from a laryngograph while speakers ($n=16$) read a $2\frac{1}{2}$ min passage of prose. He reported the mean and standard deviation of the Fo contours produced by each speaker. When converted into the coefficient of variation (standard deviation/mean), a significantly higher degree of variability is found for the English than for the French speakers. In contrast, Lee and Todd (2004) reported no significant difference in Fo variability in English and French speech. However, rather than measure raw Fo contours they extracted the Fo at the onset of each vocalic

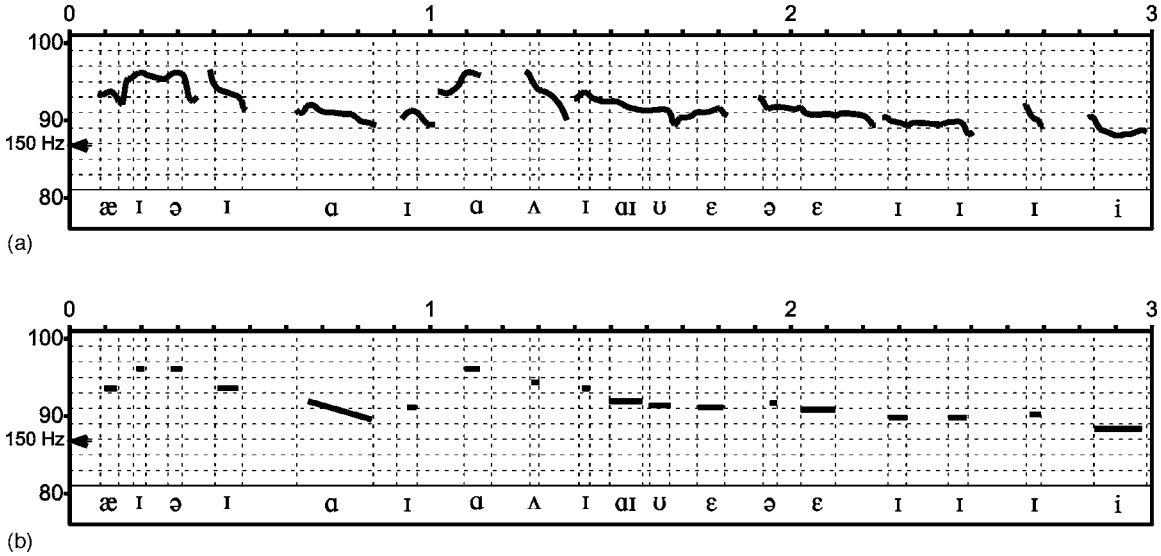

FIG. 1. Illustration of the prosogram, using the British English Sentence "Having a big car is not something I would recommend in this city" as uttered by a female speaker. In both graphs, the horizontal axis along the top shows time in seconds, the vertical axis shows semitones re 1 Hz (an arrow is placed at 150 Hz for reference), and the bottom shows IPA symbols for the vowels in this sentence. The onset and offset of each vowel is indicated by vertical dashed lines above the vowels' IPA symbol. (a) Shows the original Fo contour, while (b) shows the prosogram. In this case, the prosogram has assigned level tones to all vowels save for the vowel in "car," which was assigned a glide. Note that the pitches of the prosogram do not conform to any musical scale.

interval in a sentence and studied the variability of these values across a sentence. (They expressed each value as a semitone distance from the mean vocalic-onset Fo in the utterance, and then computed the standard deviation of this sequence of pitch values.)

These two studies illustrate the fact that pitch variability in speech can be measured in different ways. Whether or not one obtains differences between languages may depend on the method one chooses. For those interested in perception, the prosogram offers a motivated way to study the variability of pitch patterns in speech. Furthermore, it offers two ways to quantify variability, i.e., in terms of pitch height and pitch intervals. The former measures the spread of pitches about a mean pitch (as in Lee and Todd's, 2004 study). The latter measures whether steps between successive pitches tend to be more uniform or more variable in size. Both types of measures were computed in this study in order to compare speech to music.

II. METHODS

A. Corpora

The materials were the same as those in Patel and Daniele (2003). For speech, 20 English and 20 French sentences were taken from the database of Nazzi *et al.* (1998), consisting of four female speakers per language reading five unique sentences each. The sentences had been recorded in a quiet room and digitized at 16 000 Hz. They are short newslike utterances, and have been used in a number of studies of speech rhythm by other researchers (e.g., Nazzi *et al.*, 1998; Ramus *et al.*, 1999; Ramus, 2002). They range from 15 to 20 syllables in length and are approximately 3 s long (see Appendix A for a full list). Table I gives some basic data on sentence characteristics. Sentences contained about 16 vowels on average, most of which were singletons (i.e., a vowel not abutting another vowel). Thus durational computations based on vowels vs vocalic intervals are likely to yield similar results. The original motivation for studying vocalic intervals in studies of speech rhythm was an interest in infant speech perception, under the assumption that infants perform a crude segmentation of the speech stream which only distinguishes between vocalic and nonvocalic (i.e., consonantal) portions (Mehler *et al.*, 1996; Ramus *et al.*, 1999). Since the current work focuses on adult perception of speech, and since vowels are well-established phonological units in language while vocalic intervals are not, this study examines vowels rather than vocalic intervals.

The musical data are themes from turn-of-the 20th century English and French composers, drawn from a musicological sourcebook for instrumental music (*A Dictionary of Musical Themes*, Barlow and Morgenstern, 1983). Themes were analyzed for all English and French composers in the

TABLE I. Some basic statistics on the sentences studied.

	Duration (s) Mean (sd)	Speech rate (syll/s) Mean (sd)	No. Vowels / sentence Mean (sd)	Avg Fo (Hz) Mean (sd)	Total vowels	Singleton vowels
English (n=20)	2.8 (0.2)	5.8 (0.3)	15.7 (1.7)	222.2 (14.1)	314	296
French (n=20)	2.8 (0.2)	6.1 (0.5)	17.3 (1.6)	219.4 (25.7)	346	310

dictionary who were born in the 1800s and died in the 1900s. This era is recognized by musicologists as being a time of musical nationalism, when music is thought to be especially reflective of culture (Grout and Palisca, 2000). It is also not too distant in the past, which is desirable since measurements of speech are based on living speakers and since languages can change phonologically over time. To be included, composers had to have at least five usable themes, i.e., themes that met a number of criteria designed to minimize the influence of language or other external influences on musical structure. For example, themes were excluded if they came from works whose titles suggested a vocal conception or the purposeful evocation of another culture (see Patel and Daniele, 2003 for the full list of criteria). Furthermore, themes were required to have at least 12 notes (to provide a good sample for rhythm measures), and no internal rests, grace notes, or fermatas, which introduced durational uncertainties. These criteria yielded six English composers (137 themes) and ten French composers (181 themes). In reviewing the themes used in the previous study, a few inadvertent errors of inclusion or exclusion were found and corrected, resulting in 136 English and 180 French themes in the current work (see Appendix B for a complete list of composers and themes).

B. Phonetic segmentation

To analyze linguistic nPVI, vowel boundaries were marked in English and French sentences using wide-band speech spectrograms generated with SIGNAL (Engineering Design) running on a modified personal computer (frequency resolution=125 Hz, time resolution=8 ms, one FFT every 3 ms, Hanning window). Vowel onset and offset were defined using standard criteria (Peterson and Lehiste, 1960). Vowel boundaries in this study were marked independently of the boundaries defined by Ramus (2002) for the same set of sentences. Those earlier boundaries, which served as the basis of the nPVI values reported in Patel and Daniele (2003), came from a phonetic segmentation based on a waveform display with interactive playback. In the current study segmentation of the sentences was based on a display showing both the waveform and spectrogram, plus interactive playback. Availability of a spectrogram often resulted in boundary locations which differed from those marked by Ramus.

As noted above, this study focuses on vowels rather than vocalic intervals. However, both quantities were measured and yielded very similar results in the rhythmic analyses. This is not surprising since the great majority of vowels in both languages were singletons (Table I). The results report vowel measurements only (data based on vocalic intervals are available upon request).

C. Duration coding of musical themes

As in earlier work, measurement of duration in musical themes was made directly from music notation. This stands in contrast to the speech measurements, which were (necessarily) based on acoustic signals. Initially this may seem problematic, but as noted in Patel and Daniele (2003) the analysis of acoustic recordings of music raises its own problems, such as which performance of each theme to analyze and how to defend this performance against other available recordings, all of which will differ in the fine nuances of timing. Music notation is thus a reasonable choice since it at least affords an unambiguous record of the composer's intentions. That being said, it is important for future work to study timing patterns in human performances because such performances deviate from the idealized durations of music notation in systematic ways (Repp, 1992; Palmer, 1997). It will be interesting to determine what influence such deviations have on the results of a study like this one.

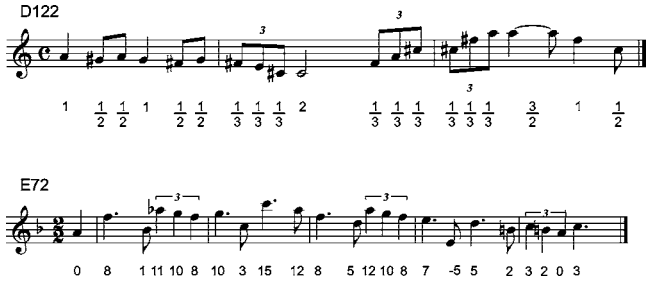

FIG. 2. Examples of duration and pitch coding of musical themes. (D122: Debussy's *Quartet in G minor for Strings, 1st movement, 2nd theme.* E72: Elgar's *Symphony No. 1, in A Flat, Opus 55, 4th movement, 2nd theme.*) D122 illustrates duration coding: the relative duration of each note is shown below the musical staff (see text for details). E72 illustrates pitch coding: each note is assigned a pitch value based on its semitone distance from A4 (440 Hz). The nPVI of note durations in D122 is 42.2. The coefficient of variation (CV) of pitch intervals in E72 is 0.79.

An example of durational coding of a musical theme is shown in Fig. 2 (top). Notes were assigned durations according to the time signature, with the basic beat assigned a duration of 1 (e.g. a quarter note in 4/4 or an eighth note in 3/8), and other notes assigned their relative durations according to standard music notation conventions. Durations were thus quantified in fractions of a beat. Because the nPVI is a relative measure, any scheme which preserves the relative duration of notes will result in the same nPVI for a given sequence. For example, the first note of a theme could always be assigned a duration of 1 and other note durations could be expressed as a fraction or multiple of this value.

D. Computation of rhythmic measures and Monte Carlo analyses

Two rhythmic measures were computed for each sentence and musical theme: the nPVI and the coefficient of variation (CV), the latter defined as the standard deviation divided by the mean. Like the standard deviation, the CV is a measure of overall variability which is insensitive to the order of elements in the sequence. Yet like the nPVI, it is a dimensionless quantity since the same units appear in both the numerator and denominator. It is thus well suited for comparing temporal patterns in speech and music when speech is measured in seconds and music is measured in fractions of a beat. Furthermore, the CV (like the nPVI) is only sensitive to the relative duration of events; scaling these durations up or down by a constant factor does not change its

value. Hence any durational coding scheme for musical themes will produce the same CV as long as the relative durations of events are preserved.

The relationship between nPVI and CV was studied in two ways. First, within each domain (speech or music) linear regressions were performed with CV as the independent variable and nPVI as the dependent variable. This showed the extent to which nPVI was predicted by CV. Next, within each domain a Monte Carlo technique was used to estimate the probability of the observed English-French nPVI difference given existing variability differences. The technique was based on scrambling the order of durations in each sequence, which destroys its temporal structure while retaining its overall variability. For example, if focusing on speech, the sequence of vowel durations in each English and French sentence was randomly scrambled and the nPVI of these scrambled sequences was computed. The difference between the mean nPVI values for the scrambled-English and scrambled-French sentences was recorded. This procedure was repeated 1000 times. The proportion of times that this "scrambled nPVI" difference was equal to or greater than the original nPVI difference was taken as a *p*-value indicating the probability of obtaining an nPVI equal to or greater than the observed nPVI difference between the languages. The same procedure was used for musical themes.

E. Melodic analyses

To quantify pitch patterns in speech, prosograms were computed for all English and French sentences using prosogram version 1.3.6 as instantiated in Praat (Mertens, 2004a; 2004b).[4] As part of the algorithm, an Fo contour was computed for each sentence using the autocorrelation algorithm of Boersma (1993). (Default parameters were used with the exception of frame rate, minimum pitch, and maximum pitch, which were set to 200 Hz, 60 Hz, and 450 Hz, respectively.) Prosogram analysis is based on the vocalic nuclei of syllables. To determine whether a given vowel should be assigned a level tone or a glide, a glide threshold of $0.32/T^2$ semitones/s was used, where T is the duration of a vowel in s. If the rate of pitch change was greater than this threshold, the vowel was assigned a frequency glide (or two abutting glides if the differential glissando threshold was exceeded). The choice of $0.32/T^2$ semitones/s as the glissando threshold is based on perceptual research on the threshold for detecting pitch movement in speech, combined with experiments in which prosogram output is compared to human transcriptions of intonation ('tHart 1976; Mertens, 2004b). Vowels with pitch change below the glide threshold were assigned a level tone equal to their median pitch value. This served as an estimate of the perceived pitch of the syllable, as formerly computed from a time-weighted average of the vowel's Fo contour in earlier versions of the prosogram (e.g., d'Alessandro and Mertens, 1995; Mertens and d'Alessandro, 1995; Mertens *et al.*, 1997).

For maximum comparability to music, only level tones were used in the quantification of pitch variability in speech. Such tones represented 97% of tones assigned to vowels in the current corpus. Occasionally the prosogram did not assign a tonal element to a vowel, e.g., if the intensity of the vowel was too low, the vowel was devoiced (e.g., an unstressed "to" in English being pronounced as an aspirated /t/), or if Praat produced a clearly erroneous Fo value. However, such omissions were rare: 90% of English vowels were assigned level tones and 4% were assigned glides, while 96% of French vowels were assigned level tones and 2% were assigned glides. A typical sentence had about 15 level tones and 1 glide.

Variability in pitch height and of pitch intervals within a sentence was computed via the coefficient of variation (CV). To study pitch height variation, each level tone was assigned a semitone distance from the mean pitch of all level-tones in the sentence, and then the CV of these pitch distances was computed. To study interval variability, adjacent level tones in a sentence were assigned a pitch interval in semitones,

$$\mathrm{st} = 12 \log_2(f2/f1), \tag{2}$$

where $f1$ and $f2$ represent the initial and final tone of the pair, respectively. (Intervals were computed between immediately adjacent level tones only, not between tones separated by a glide.) The CV of these intervals was then quantified. Because the mean appears in the denominator of the CV, measurements of pitch distances and pitch intervals used absolute values in order to avoid cases where mean distance size or mean interval size was equal to or near 0, which would yield mathematically ill-defined CVs. The choice of semitones as units of measurement is based on recent research on the perceptual scaling of intonation (Nolan, 2003). Earlier work by Hermes and Van Gestel (1991) had suggested ERBs should be used in measuring pitch distances in speech. Since the CV is dimensionless, one could measure pitch in speech and music in different units (ERBs vs semitones) and still compare pitch variability across domains using the CV as a common metric. The precise choice of units for speech is unlikely to influence the results reported here.

To quantify melodic patterns in music, musical themes were coded as sequences of pitch values where each value represented a given pitch's semitone distance from A440 (Fig. 2, bottom). This permitted straightforward computation of each tone's semitone distance from the mean pitch of the sequence and of pitch interval patterns (the latter simply being the first-order difference of the pitch values). Measures of pitch height and interval variability were then computed in precisely the same manner as for speech. (Note that the choice of A440 as a referent pitch makes no difference to the measures of variability computed here. Any scheme which preserves the relative position of tones along a semitone scale would yield the same results. For example, one could code each pitch in a musical theme as its distance in semitones from the lowest pitch of the theme, or from the mean pitch of the theme.)

III. RESULTS

A. Rhythm

Table II shows nPVI and CV values for speech and music. Reported *p*-values in this and following tables were computed using the Mann-Whitney U-test, except for *p*-values

TABLE II. nPVI and CV for speech and music (mean and s.e.). The rightmost column gives the probability that the observed nPVI difference is due to the difference in CV.

	English nPVI	French nPVI	p	English CV	French CV	p	$p(\Delta\text{nPVI}\vert\Delta\text{CV})$
Speech (vowels)	55.0 (3.0)	35.9 (1.8)	<0.001	0.55 (0.03)	0.36 (0.02)	<0.001	0.01
Music (notes)	47.1 (1.8)	40.2 (1.9)	<0.01	0.61 (0.02)	0.58 (0.02)	0.34	0.001

associated with Monte Carlo analyses, which were computed as described in Sec. II D. Table II reveals that English and French sentences show a highly significant difference in durational contrastiveness (nPVI) as well as in durational variability (CV). English and French music, on the other hand, show a significant difference in contrastiveness but not in variability.

Regressions of CV on nPVI in each domain are shown in Fig. 3. The linear regressions reveal that within each domain, higher CV is predictive of higher nPVI, though the relationship appears to be stronger in speech than in music (see Fig. 3 captions for regression slopes, r^2 values, and p values).

To assess whether CV differences between the two languages are responsible for linguistic nPVI differences, a Monte Carlo analysis was conducted as described in Sec. II D. The result of this analysis is shown in Fig. 4, which plots the distribution of nPVI differences between English and French speech when the order of vowel durations in each sentence is scrambled and the nPVI difference between the two languages is computed (1000 iterations). The actual nPVI difference (19.1 points) is shown by an arrow. Based on this frequency distribution, the probability of an nPVI difference of 19.1 points or greater is quite small ($p=0.01$). This value is listed in the right-most column of Table II as $p(\Delta\text{nPVI}\vert\Delta\text{CV})$, i.e., the probability of the observed difference in nPVI given the observed difference in variability. A similar analysis was conducted for music, with the resulting p-value being 0.001. Thus it is highly unlikely that variability differences account for nPVI differences in either domain.

B. Melody

Table III shows the results of pitch variability measurements for speech and music. Table III reveals that English and French speech do not differ in the variability of pitch height within utterances, but do show a significant difference in pitch interval size variability, with French having lower

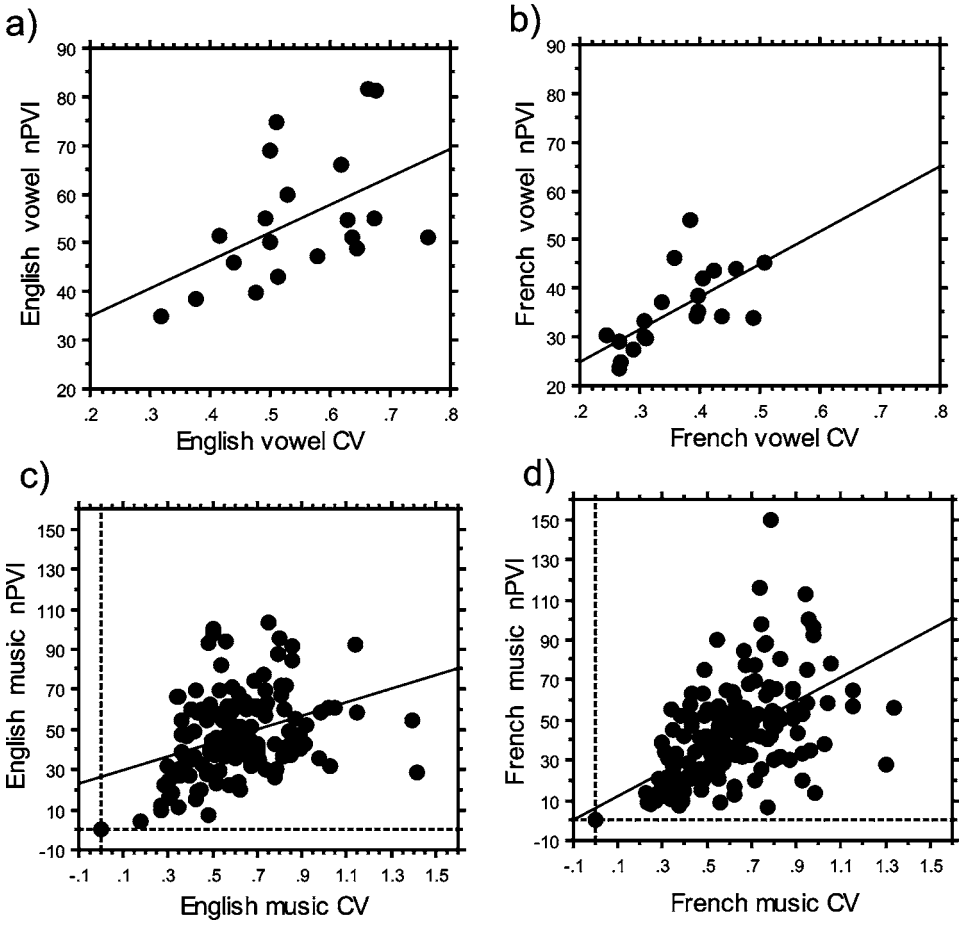

FIG. 3. The relationship between CV and nPVI for speech (a, b) and music (c, d). For speech each dot represents one sentence; for music each dot represents one theme. The best fitting regression line for each panel is also shown. English speech: nPVI=23.5 +57.3×CV, $\mathbf{r^2=0.34}$, df=18, $\mathbf{p=0.03}$; French speech: nPVI=11.7 +66.5×CV, $\mathbf{r^2=0.43}$, df=18, $\mathbf{p<0.01}$; English music: nPVI=26.6 +33.9×CV, $\mathbf{r^2=0.14}$, df=134, $\mathbf{p<0.001}$; French music: nPVI=6.2 +59.1×CV, $\mathbf{r^2=0.36}$, df=178, $\mathbf{p<0.001}$. For the musical data, hatched lines show the lower possible limit of the nPVI and CV at 0 on each axis: the axes range into negative numbers for display purposes only, so that the points at (0,0) can be clearly seen. Themes with a score of 0 for nPVI and CV have notes of a single duration. There were two such English themes and eight such French themes.

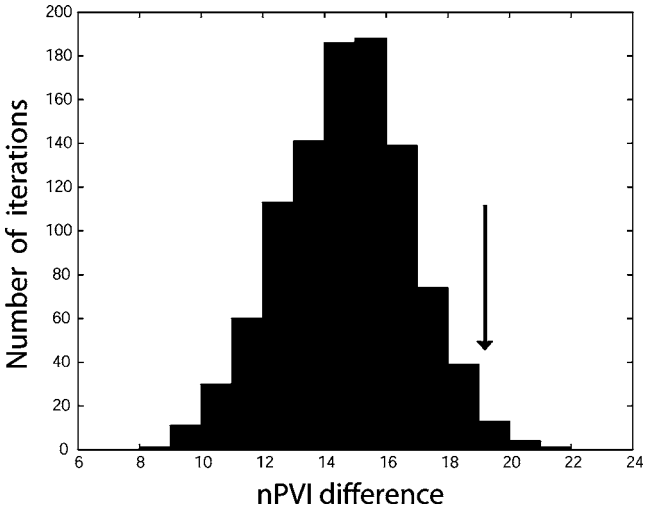

FIG. 4. Result of Monte Carlo analysis for English vs French speech. The actual nPVI difference between the two languages in this study (19.1 points) is shown by an arrow. See text for details.

interval variability than English. With regard to the latter point, it is interesting to note that the average absolute interval size is virtually identical in the two languages (2.1 vs 2.2 st for French vs English, respectively), yet French speech shows significantly lower interval variability than English. In other words, as the voice moves from one vowel to the next the size of the pitch change is more uniform in French than in English speech.

Turning to music, a similar picture emerges: differences in pitch height variability are not significant, but French music has significantly lower pitch interval variability than English music. In other words, as the melody moves from one note to the next the size of the pitch change is more uniform in French than in English music. Once again, this difference exists despite the fact that the average absolute interval size is nearly identical (2.7 vs 2.6 st for French and English music, respectively). Figure 5 shows the data for pitch interval variability in speech and music. Figure 5 shows that the linguistic difference in pitch interval variability between English and French speech is much more pronounced than is the musical difference, a finding reminiscent of earlier work

TABLE III. Pitch variability in speech and music, measured in terms of pitch height (the CV of pitch distances from the mean pitch of a sequence) or pitch intervals (the CV of pitch interval size within a sequence). Mean and s.e. are shown.

	English Pitch CV	French Pitch CV	p
Speech			
Pitch height	0.71 (0.04)	0.75 (0.04)	0.32
Pitch intervals	0.88 (0.05)	0.68 (0.03)	<0.01
Music			
Pitch height	0.69 (0.01)	0.71 (0.01)	0.14
Pitch intervals	0.76 (0.02)	0.71 (0.02)	0.03

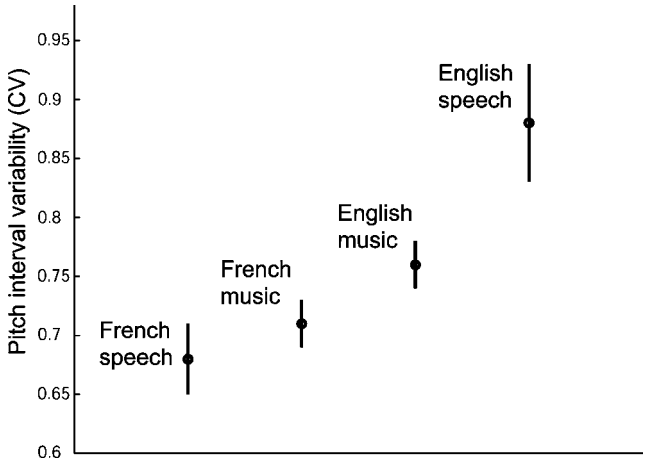

FIG. 5. Pitch interval variability in English and French speech and music. Pitch interval variability is defined as the CV of absolute interval size between pitches in a sequence. Error bars show standard errors.

on the nPVI. This should not be surprising, since music is an artistic endeavor with substantial intracultural variation and (unlike speech) no *a priori* reason to follow melodic norms. What is remarkable is that despite this variation, a significant cultural difference emerges in the same direction as the linguistic difference.

C. Rhythm and melody combined

Having analyzed rhythm and melody independently, it is interesting to combine the results in a single graph showing English and French speech and music in two-dimensional space with rhythm and melody on orthogonal axes. This representation can be referred to as an RM-space plot. Figure 6 shows such a plot, with nPVI being the measure of rhythm and melodic interval variability (MIV) being the measure of melody. MIV is defined as $100 \times$CV of pitch interval variability. Scaling the CV by 100 serves to put MIV in the same general range of values as nPVI. One aspect of this figure deserves immediate comment. Recall from Sec. I B 1 that the value of a given language's nPVI can differ widely from one study to the next, likely due to differences in corpora, speech

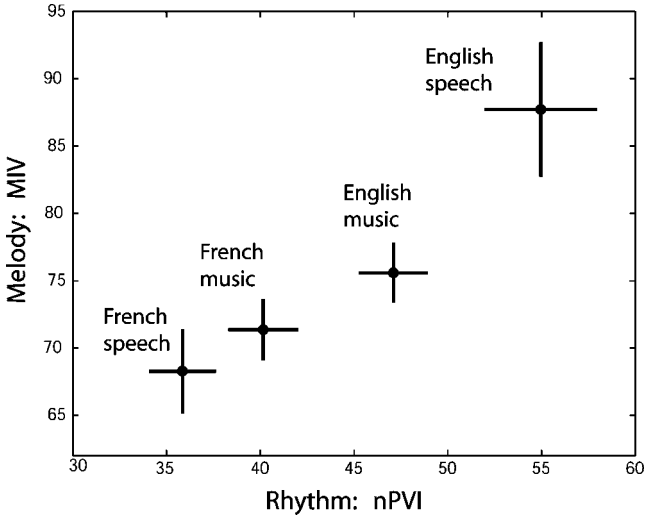

FIG. 6. Rhythm-melody (RM) space for speech and music. Axes are nPVI and MIV. Error bars show standard errors.

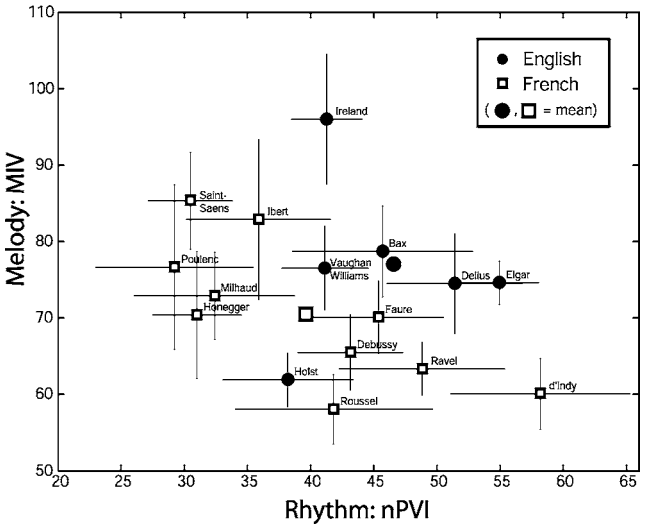

FIG. 7. nPVI and MIV values for individual composers. Error bars show standard errors. Note the almost complete separation of English and French composers in RM space, despite large overlap between the nationalities along either single dimension.

rate, and phonetic segmentation criteria. The same may be true of MIV values. Thus the position of a given language in RM space will likely vary from study to study. What is relevant is the *distance* between languages *within* a given study, where corpora and other criteria are more tightly controlled. The same point applies to music.

Using RM space, the "prosodic distance" (pd) between two languages can be defined as the Euclidean distance between the points representing the mean nPVI and MIV of the languages. For English and French speech (Es, Fs), this distance is

$$\mathrm{pd(Es,Fs)} = \sqrt{(\mathrm{nPVI_{Es}} - \mathrm{nPVI_{Fs}})^2 + (\mathrm{MIV_{Es}} - \mathrm{MIV_{Fs}})^2}. \quad (3)$$

In the current data the distance between English and French speech is 27.7 RM units. Applying the same equation to the musical data (i.e., replacing Es and Fs with Em and Fm), yields a distance between English and French music of 8.5 RM units. Thus the musical distance is about 30% of the linguistic difference.

Another aspect of Fig. 6 worth noting is that a line connecting English and French speech in RM space would lie at a very similar angle to a line connecting English and French music. In fact, if one defines vectors between the two languages and the two musics, using standard trigonometric formulas one can show that the angle between these vectors is only 14.2°. Thus a move from French to English speech in RM space involves going in a very similar direction as a move from French to English music.

Focusing now on the musical data, it is interesting to examine the position of individual composers in RM space, as shown in Fig. 7. Figure 7 reveals that English and French composers occupy distinct regions of RM space, despite large variation along any single dimension (Holst is the one exception, and is discussed later). This suggests that the *joint* properties of melody and rhythm, not either one alone, are involved in defining national characteristics of music.

IV. DISCUSSION

A. Aspects of speech prosody reflected in music

New tools from phonetics permit the confirmation of an old intuition shared by musicologists and linguists, namely that the instrumental music of a culture can reflect the prosody of its native language. These tools (the nPVI and the prosogram) are noteworthy because they allow quantitative comparisons of rhythm and melody in speech and music.

An exploration of the relationship between durational contrastiveness (nPVI) and durational variability reveals that nPVI differences between English and French speech are not a by-product of variability differences, even though the two languages do have significant differences in the variability of vowel durations in sentences. Variability differences also cannot account for musical nPVI differences between English and French (in fact, the two musics do not show a significant variability difference). It is thus clear that music reflects durational contrastiveness in speech, not durational variability. This finding is interesting in light of claims by linguists that part of the characteristic rhythm of English is a tendency for full and reduced vowels to alternate in spoken sentences (e.g., Bolinger, 1981). It appears that this tendency (or its absence) may be reflected in music.

Turning to melody, measures of pitch variability reveal that a specific aspect of speech melody is reflected in music, namely the variability of interval size between successive pitches in an utterance. English speech shows greater interval variability than French speech, even though the average pitch interval size in the two languages is nearly identical. This same pattern is reflected in music. Initially it may seem odd that pitch *intervals* in speech are reflected in music. While the human perceptual system is quite sensitive to interval patterns in music (where for example a melody can be recognized in transposition as long as its interval pattern is preserved), music features well-defined interval categories such as the minor second and perfect fifth while speech does not. Might the perceptual system attend to interval patterns in speech despite the lack of stable interval structure? Recent theoretical and empirical work in intonational phonology suggests that spoken pitch intervals may in fact be important in the mental representation of intonation, even if they do not adhere to fixed frequency ratios (Dilley, 2005). If this is the case, then one can understand why the perceptual system might attend to interval patterns in speech as part of learning the native language. It remains to be explained, though, why English speech should have a greater degree of interval variability than French. One idea is that British English may have three phonologically distinct pitch levels in its intonation system, while French may only have two (cf. Willems, 1982; Ladd and Morton, 1997; Jun and Fougeron, 2000; Jun, 2005). A compelling explanation, however, awaits future research.

While the current study focuses on just two cultures, it is worth noting that the techniques presented here are quite general. They can be applied to any culture where a sufficient sample of spoken and musical patterns can be collected. It would be quite interesting, for example, to use them to study relations between speech and instrumental music in

tone languages. Thai and Mandarin may be a good choice for such a comparison, since the languages have very different nPVI values (Grabe and Low, 2002) and different tone patterns, and since both languages come from cultures with well-developed instrumental music traditions.

B. A possible mechanism

By what route might speech patterns find their way into music? One oft-heard proposal is that composers borrow tunes from folk music, and that these tunes bear the stamp of linguistic prosody because they were written with words. This might be termed the "indirect route" from speech to music. The current study proposes a different hypothesis based on the idea of a "direct route" between the two domains. One advantage of the direct-route hypothesis is that it can account for the reflection of speech in music not thought to be particularly influenced by folk music (e.g., much of Elgar's and Debussy's work, cf. Grout and Palisca, 2000). The direct-route hypothesis centers on the notion of statistical learning of prosodic patterns in the native language. Statistical learning refers to tracking patterns in the environment and acquiring implicit knowledge of their statistical properties, without any direct feedback. Statistical learning of prosodic patterns in one's native language likely begins early in development. Research on language development has shown that infants are adept at statistical learning of phonetic/syllabic patterns in speech and of pitch patterns in nonlinguistic tone sequences (Saffran *et al.*, 1996; 1999) Thus it seems plausible that statistical learning of rhythmic and tonal patterns in speech would also begin in infancy, especially since infants are known to be quite sensitive to the prosodic patterns of language (Jusczyk, 1997; Nazzi *et al.*, 1998; Ramus 2002b).

Statistical learning of tone patterns need not be confined to infancy. Adult listeners show sensitivity to the distribution of different pitches and to interval patterns (Oram and Cuddy, 1995; Saffran *et al.*, 1999; Krumhansl, 2000; Krumhansl *et al.*, 2000). Importantly, statistical learning in music can occur with atonal or culturally unfamiliar materials, meaning that it is not confined to tone patterns that follow familiar musical conventions. Synthesizing these findings with the comments in the preceding paragraph leads to the hypothesis that statistical learning of the prosodic patterns of speech creates implicit knowledge of rhythmic and melodic patterns in language, which can in turn influence the creation of rhythmic and tonal patterns in music. Importantly, there is no claim that this influence is obligatory. Rather, linguistic patterns are seen as one resource available to a composer (either consciously or subconsciously) when they set out to compose music that is "of their culture" (cf. Patel and Daniele, 2003). Future work should consider what sort of evidence would support a causal link of this kind between speech and music.

C. Rhythm-melody relations: A domain for future investigation

Figure 7 suggested that joint properties of melody and rhythm may be particularly important for distinguishing between the music of different nations. While this study has examined rhythm and melody independently, it would be worth examining relations between rhythmic and melodic patterns in future work. Such relations may distinguish between languages and be reflected in music. One motivation for pursuing this issue is research in music perception suggesting that listeners are sensitive to such relations, e.g., the temporal alignment (or misalignment) of peaks in pitch and in duration (Jones, 1987; 1993). A second motivation is research on prosody which has revealed language-specific relations in the form of stable patterns of alignment of pitch peaks and valleys relative to the segmental string (Arvaniti *et al.*, 1998; Ladd *et al.*, 1999; Atterer and Ladd, 2004). This suggests that part of the characteristic "music" of a language is the temporal alignment between rhythmic and melodic patterns.

The key practical issue for future studies of rhythm-melody relations is how to represent pitch and temporal patterns in a manner that facilitates cross-domain comparison. Figure 8 illustrates one idea based on a vowel-based analysis of pitch and timing in speech. Panel (a) shows the pitch pattern of a French sentence ("Les mères sortent de plus en plus rapidement de la maternité") as a sequence of vowel

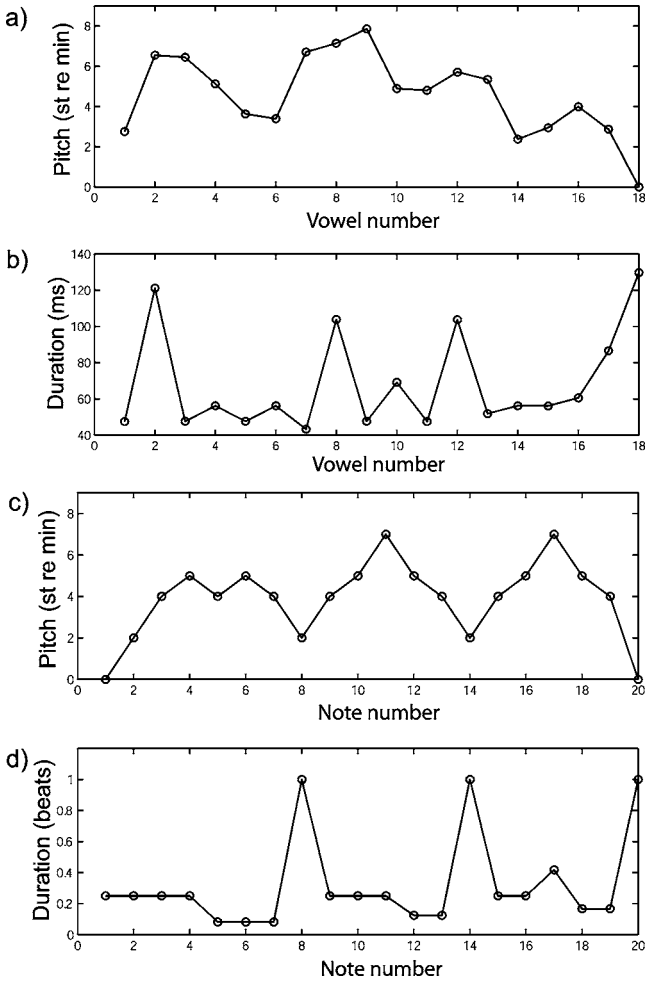

FIG. 8. (a, b) Pitch and duration patterns for the French sentence "Les mères sortent de plus en plus rapidement de la maternité" as uttered by a female speaker. (c, d) Pitch and duration patterns for a French musical theme from Debussy's *Les Parfums de la Nuit*. See text for details.

pitches, with each number representing the semitone distance of each vowel from the lowest vowel pitch in the sequence. Panel (b) shows the corresponding sequence of vowel durations (in ms). Panel (c) shows the pitch pattern of a French musical theme (4th theme of the 2nd movement of *Les Parfums de la Nuit*, theme D57 in Barlow and Morgenstern, 1983), using the same convention as panel (a), while panel (d) shows the duration pattern of the musical theme in fractions of a beat. The pitches in panel (a) are taken from the prosogram of the French sentence, but a reasonable estimate of these pitches can be made by simply taking the median Fo of each vowel (cf. Sec. IV D below).

When viewed in this way, it is easy to see how equivalent measurements of rhythm-melody relations can be made in speech and music. For example, one can ask whether there is a different pattern of alignment between pitch and duration peaks in language A than in language B, and if this difference is reflected in music. (This particular example is of interest to comparisons of British English and French, since phonologists have long noted that French sentences tend to be organized into phrases with pitch peaks and durational lengthening on the last syllable of each nonfinal phrase, e.g., Delattre, 1963; Jun and Fougeron, 2000; Di Cristo, 1998). Of course, one need not always look from speech to music; the direction of analysis can be reversed. In this case, one would first examine music for culturally-distinctive rhythm-melody relations, and then ask if these relations are reflected in speech. For example, the British composer Gustav Holst is unusual in being located in the "French" region of RM space in Fig. 6. Yet intuitively there is nothing French sounding about Holst's music (Indeed, the tune of "I Vow to Thee my Country," based on a theme from the *Jupiter* movement of *The Planets*, has often been suggested as an alternative national anthem for Britain). While Holst's anomalous position in RM space could simply be a sampling issue (i.e., it could change if more themes were added) it could also be that some as-yet unidentified relationship between rhythm and melody identifies his music as distinctively English. If so, it would be quite interesting to use this relationship to define a third dimension in RM space to see if it also separates English and French speech.

D. A possible application of RM space to quantifying non-native prosody

Learning to speak a second language with fluency requires acquisition of both segmental and prosodic patterns. Difficulty with L2 prosody is recognized as a challenge for language learners, particularly when L1 and L2 are rhythmically or melodically quite distinct (Pike, 1945; Chela-Flores, 1994). Yet there are very few quantitative methods for assessing non-native prosody. Such methods could prove useful for providing quantitative feedback to language learners in computer-based accent training programs (i.e., when practicing without the benefit of feedback from a human teacher), as well as for basic research on prosodic acquisition. RM space may have some useful qualities in this regard. As discussed in Sec. III C, it is possible to compute the prosodic distance between any two points in RM space [see Fig. 6 and Eq. (3)]. This means RM space could be used to quantify a speaker's prosodic distance from a target language which he or she is trying to acquire. For example, imagine that French and English represent $L1$ and $L2$ for a hypothetical language learner X. Further imagine that X is asked to read a set of sentences in $L2$, and nPVI and MIV measurements are made of these sentences based on the techniques used in the current study. X's mean nPVI and MIV values would define a point in RM space, whose prosodic distance from native English values, pd(X,Es), could be quantified using Eq. (3). This number could serve as the basis for a quantitative prosodic score indicating how close a given speaker was to native $L2$ prosody.

Should such an approach be taken, it will be important to determine how prosodic distance relates to perceptual judgments of foreign accent. For example, there may be a nonlinear relationship between these quantities. Only empirical research can resolve this issue. Fortunately, research relating quantitative measures of prosody to judgments of non-native accent has recently begun, motivated by the desire to test the perceptual relevance of different proposed rhythm measures. For example, White and Mattys (2005b) have studied the rhythm of non-native English as spoken by native Dutch and Spanish speakers. They examined a number of rhythm measures (such as ΔC, $\%V$, nPVI, etc.) and found that the best predictor of native-accent rating was a measure based on the coefficient of variation of vowel duration in sentences This measure, "VarcoV" (cf. Dellwo, 2006) showed an inverse linear relationship with degree of perceived foreign accent.[5] The methods of White and Mattys could be adapted to study the relationship between foreign accent judgments and measures of prosodic distance in RM space.

One notable feature of RM space is that it can easily be generalized to higher dimensions. Since RM space represents duration and pitch, an obvious candidate for an additional dimension is amplitude. In fact, a vowel-based amplitude measure has been shown to differentiate English and French speech. As part of a study comparing the variability of syllabic prominence in the two languages, Lee and Todd (2004) measured the intensity (rms) variation among vowels in a sentence, computing a value ΔI for each sentence, representing the standard deviation of the intensity values. ΔI was significantly larger for English than for French. Inspired by this work, the current study measured the RMS of each vowel in the current corpus (after first normalizing each sentence to 1 V rms). The CV of vowel rms was then computed within each sentence. Consistent with Lee and Todd's (2004) findings, English had a significantly higher vowel rms variability than French (mean and s.e. were 0.53 (0.02) and 0.40 (0.02) for English and French respectively, $p < 0.001$). Thus English and French are distinct in a three-dimensional RM space with nPVI, MIV, and rms variation as orthogonal axes. Prosodic distances can be computed in $3d$ RM space via a generalization of Eq. (3) to three dimensions, and can be used to measure a non-native speaker's prosodic distance from a target language in three dimensions.

Whether using two or three dimensions, the major practical challenge in using RM space is phonetic segmentation of sentences, a time-consuming endeavor when done by hu-

mans. This problem can be alleviated by having speakers read a fixed set of sentences whose texts are known. In this case vowel boundaries can be marked in speech signals using the procedure of forced alignment, in which a speech recognizer is given the list of segments in the order in which they appear in the signal. Dellwo (personal communication) has used this technique with the HTK speech recognition software and found very high agreement with human labeling for speech at a normal rate.

Once vowel boundaries are placed within utterances, then nPVI and MIV measurements can be made based on existing algorithms. It is even possible to compute an accurate estimate of MIV without computing prosograms, by simply assigning each vowel a level pitch based on its median Fo and computing intervals from these pitches. (To illustrate the accuracy of this approach, the resulting mean and s.e. of MIV for English and French in the current corpus were 87 (4) and 68 (3), respectively, compared to 88 (5) and 68 (3) for prosogram-based measures, cf. Table III.) In this case, all that is needed to create RM-space plots such as Fig. 6 are sentences with vowel boundaries marked and Fo contours extracted, together with software that can compute the median Fo of each vowel based on this information. The remaining nPVI and MIV computations can be done via simple equations in a spreadsheet.

V. CONCLUSION

The rhythms and melodies of speech and instrumental music can be quantitatively compared using tools from modern phonetics. Using these tools, an investigation of language and music from England and France confirms the intuition that music reflects the prosody of a composer's native language. The approaches developed here can be applied to the study of language-music relations in other cultures, and may prove useful in quantifying non-native prosody.

ACKNOWLEDGMENTS

We thank Franck Ramus for providing the English and French sentences (audio files and phonetic transcriptions), Piet Mertens for help with prosograms, Peter Ladefoged for help with IPA transcription of the English sentences, Laura Dilley and D. Robert Ladd for helpful comments on this manuscript, and Philip Ball for drawing our attention to "I vow to thee my country." This work was supported by the Neurosciences Research Foundation as part of its research program on music and the brain at The Neurosciences Institute, where A.D.P. is the Esther J. Burnham Fellow and J.R.I. is the Karp Foundation Fellow, and by a grant from the H.A. and Mary K. Chapman Charitable Trust.

APPENDIX A: ENGLISH AND FRENCH SENTENCES

A hurricane was announced this afternoon on the TV.

My grandparent's neighbor's the most charming person I know.

Much more money will be needed to make this project succeed.

The local train left the station more than 5 minutes ago.

The committee will meet this afternoon for a special debate.

The parents quietly crossed the dark room and approached the boy's bed.

[1]In the case of Thai and other languages with phonemic vowel length contrast, a high nPVI value may be driven by these length contrasts in addition to (or rather than) vowel reduction.

[2]It should be noted that all published nPVI studies comparing English and French have focused on speakers of the standard dialect of each language. Research on dialectal variation in English speech rhythm suggests that within-language variation in nPVI is smaller than the nPVI difference between English and French (E. Ferragne, unpublished data; White and Mattys, 2005a), but dialectical rhythm studies in both languages are needed to establish whether within-language variation is smaller than between-language variation.

[3]As with the better-known autosegmental-metrical approach, the prosogram is an abstraction of an Fo curve. The current study prefers the prosogram to the autosegmental-metrical abstraction because it is explicitly concerned with the psychoacoustics of intonation perception, and thus seems better suited to comparing speech and music as patterns of perceived pitches. That being said, it should be noted that the prosogram is based on research on native listeners of intonation languages, and hence its applicability to pitch patterns in tone languages is uncertain.

[4]The prosogram is freely available from http://bach.arts.kuleuven.be/pmertens/prosogram/, and runs under Praat, which is freely available from http://www.fon.hum.uva.nl/praat/

[5]It should be noted that VarcoV was only slightly better than nPVI as a predictor of accent ratings in this study. Furthermore, a concern about this research is that segmental and suprasegmental cues are probably both contributing to foreign accent ratings. Thus some method is needed to remove interspeaker variability in segmental cues, such as speech resynthesis. In fact, White and Mattys (personal communication) are pursuing such an approach.

Language redundancy predicts syllabic duration and the spectral characteristics of vocalic syllable nuclei

Matthew Aylett[a)]

(Received 24 November 2004; revised 19 February 2006; accepted 21 February 2006)

The language redundancy of a syllable, measured by its predictability given its context and inherent frequency, has been shown to have a strong inverse relationship with syllabic duration. This relationship is predicted by the smooth signal redundancy hypothesis, which proposes that robust communication in a noisy environment can be achieved with an inverse relationship between language redundancy and the predictability given acoustic observations (acoustic redundancy). A general version of the hypothesis predicts similar relationships between the spectral characteristics of speech and language redundancy. However, investigating this claim is hampered by difficulties in measuring the spectral characteristics of speech within large conversational corpora, and difficulties in forming models of acoustic redundancy based on these spectral characteristics. This paper addresses these difficulties by testing the smooth signal redundancy hypothesis with a very high-quality corpus collected for speech synthesis, and presents both durational and spectral data from vowel nuclei on a vowel-by-vowel basis. Results confirm the duration/ language redundancy results achieved in previous work, and show a significant relationship between language redundancy factors and the first two formants, although these results vary considerably by vowel. In general, however, vowels show increased centralization with increased language redundancy. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188331]

I. INTRODUCTION

Much of speech research has been devoted to the explanation and description of within-speaker variation in the production of the same phoneme in different contexts. One fairly consistent observation made by researchers going back to the 1960's (Bolinger, 1963; Lieberman, 1963; Sharp, 1960) is that the more predictable a section of speech, either because of context or inherent frequency, the shorter, or more reduced, it tends to be.

This predictability due to language structure can be termed language redundancy. Its correlation with duration is predicted by the hypothesis that the greater the language redundancy of a word, syllable or phoneme, the lower its acoustic redundancy is likely to be, where acoustic redundancy refers to its likelihood of recognition based on acoustic properties alone. On this view, duration reflects acoustic redundancy since longer segments are arguably more salient and recognizable, all other things being equal. Recent work has confirmed these earlier findings for duration (e.g., Aylett, 2000; Bybee, 2000; Bell *et al.*, 2003; Wright, 2003; Munson and Soloman, 2004).

Spectral characteristics (e.g., formant frequencies in the central portion of a vowel, among other things) can also be considered as measures of acoustic redundancy, since these are known to relate to vowel distinctiveness and thus probability of recognition. However, although spectral differences have clearly been shown to occur due to differences in speaking style (Picheny *et al.*, 1986; Lindblom, 1990; Moon and Lindblom, 1994; Bradlow *et al.*, 1996), prosodic variation (Summers, 1987; van Bergem, 1993) and also lexical neighborhood density (Wright, 2003; Munson and Soloman, 2004), evidence showing a language redundancy relationship with spectral measurements has been more elusive. Wright (2003), Munson and Soloman (2004), and Bybee (2000) all showed a relationship between word frequency and spectral measures, with vowel centralization more prevalent in more frequent words. Because these studies used a relatively small set of laboratory data, it is difficult to know whether these findings extend to a more general context. Relevant corpus studies include Aylett (2000, 2001), which show only a weak correlation between language redundancy and vocalic spectral change, and Jurafsky, Bell, and others (Jurafsky *et al.*, 2001, 2003; Bell *et al.*, 2003), which show a more robust result, but for vowel spectral reduction of function words only.

The relationship between language redundancy and acoustic redundancy has important implications for theories of speech production and perception because it offers a framework for predicting variation in articulation and, more crucially, a framework for explaining this variation in terms of speech perception. The idea of relating production to perception is by no means new. Lindblom (1990) in his H&H

theory explicitly presents the idea that articulation varies in order to reduce effort while at the same time producing a signal which shows sufficient acoustic distinctiveness for the listener to correctly identify the linguistic content of the message. Language redundancy offers a means of quantitatively modeling differences in acoustic distinctiveness because the more predictable a section of speech, given its context, the less acoustic distinctiveness (or acoustic redundancy) is required for the listener to successfully identify the contents. Thus, the relationship between language redundancy and acoustic redundancy should implicitly mirror Lindblom's findings. In addition, by offering a quantitative framework for measuring what is sufficiently acoustically distinct, it allows the investigation of these phenomena across large corpora and thus many more contexts, speakers, and speech styles than is possible in an experimental setting. Indeed, studies such as Jurafsky (2001), van Son and Pols (2003), Aylett (2000), and Aylett and Turk (2004) have all tested the relationship between language and acoustic redundancy for natural speech corpora. These authors share Lindblom's view that the more predictable a section of speech the more articulatory reduction/centralization we expect to see (Moon and Lindblom, 1994; implicit in Lindblom, 1990). This view is referred to as the probabilistic reduction hypothesis (Jurafsky, 2001), speech efficiency (van Son and Pols, 2003), and is included as a fundamental element of Aylett and Turk's (2004) smooth signal redundancy hypothesis.

The probabilistic reduction hypothesis (Jurafsky *et al.*, 2001) states that word forms are reduced when they have higher probability, and is thus more general than theories concerned only with word frequency (e.g., Zipf, 1949) and predictability (Fowler and Housum, 1987) because, "The probability of a word is conditioned on many aspects of its context, including neighboring words, syntactic and lexical structure, semantic expectations, and discourse factors" (Jurafsky *et al.*, 2001, p. 229). van Son and Pols (1999) support the relationship between language redundancy and acoustic characteristics with phonemic data, and propose that the underlying reason for this language/acoustic redundancy relationship is to make speech an efficient communication channel. Aylett and Turk's (2004) smooth signal redundancy hypothesis also proposes that word forms are reduced when they are associated with a higher probability of recognition, and agrees with van Son and Pols' claim that this relationship between language redundancy and acoustic characteristics is governed by the drive to make the speech signal more efficient. However, it makes a wider claim, first that this efficiency is gained in order to make speech robust in a noisy environment, and second that acoustic differences are linguistically implemented through prosodic prominence structure. In contrast to this view, the probabilistic reduction hypothesis argues that "probabilistic relations between words are represented in the mind of the speaker" (Jurafsky *et al.*, 2001), and thus relate directly to their acoustic correlates without the intermediary of prosodic prominence structure.

In this paper an analysis of a large speech corpus (approximately 500 000 syllables) was carried out with the following goals: (1) to test for the expected relationship between language redundancy and syllabic duration; (2) to determine the relationship between language redundancy and measures of the first and second formants; and (3) to determine the degree to which prosodic prominence and language redundancy predict the same variation in each of these measures, as predicted by the smooth signal redundancy hypothesis.

A. The smooth signal redundancy hypothesis

The smooth signal redundancy hypothesis claims that the acoustic consequences of differences in redundancy can be explained functionally within an information theoretical framework, by the drive for speakers to achieve robust information transfer in a potentially noisy environment while conserving effort. These pressures encourage speakers to produce utterances whose elements have similar probabilities of recognition, that is, utterances with a smooth signal redundancy profile. In Aylett and Turk (2004) we presented evidence showing that phrase-medial syllables with high language redundancy (i.e., they are highly predictable from lexical, syntactic, semantic, and pragmatic factors) were shorter than less predictable elements.

To take a concrete example, in the utterance "I'm going to the beach," the word "to" is more likely to occur than the word "beach" since "to" is a relatively high-frequency closed class word, and often occurs immediately after the word "going," whereas "beach" is a lower frequency word that is not predictable from its preceding context. Consequently, the amount of acoustic information both in terms of duration and in terms of spectral distinctiveness is lower in "to" than in "beach," which contains a full vowel, and is likely to bear phrasal stress. If we regard the overall probability of recognizing the lexical item as the probability of recognition given a language model multiplied by the probability of recognition given an acoustic model, we can see that the overall signal probability is smoothed by this inverse relationship. This smoothness adds robustness to communication because information content is spread evenly across the signal.

Because prosodic prominence appears to largely shadow redundancy effects (e.g., the highly language redundant word *to* is unstressed in the above example while the less predictable *beach* bears a nuclear pitch accent (phrasal stress), and because it is arguably unrealistic for articulation to adjust itself to reflect minor changes in redundancy, the smooth signal redundancy hypothesis proposes that language redundancy is implemented through prosodic prominence structure, which itself has its own language-specific conventions and rules. Aylett and Turk's (2004) present supporting evidence of a large shared influence of language redundancy and prosodic prominence structure on duration, with a small, expected, unique influence of prosodic prominence structure. In addition, a small unexpected unique influence of language redundancy factors was observed.

In this paper, we use spectral data to test a more general version of the smooth signal redundancy hypothesis that claims that any acoustic feature used to recognize the identity of a syllable could be used to smooth signal redundancy by covarying inversely with language redundancy. The measures used to test this version of the hypothesis were $F1/F2$

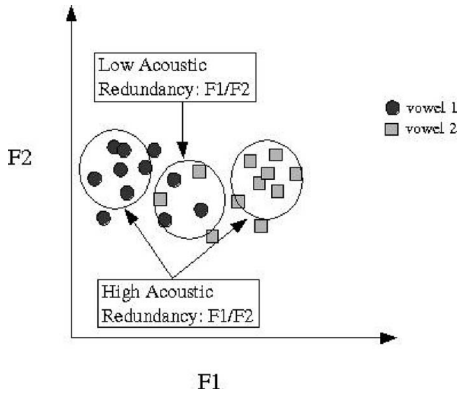

FIG. 1. Illustration of acoustic redundancy differences in an $F1/F2$ vowel space.

formant values at the temporal midpoint of vowel nuclei. These measures were chosen because relationships between vowel centralization (as measured by $F1/F2$) and intelligibility are well documented (see Sec. I B), and like syllable duration, variation in $F1/F2$ values relates straightforwardly to acoustic redundancy. For example, the probability of identifying a particular vowel is higher if its formant values are unambiguously associated with a single vowel category, and not simultaneously associated with multiple vowel categories (see Fig. 1).

B. The vowel space

The $F1/F2$ formant values for vowels can be measured by reference to the acoustic vowel space, a two-dimensional space defined by vocalic $F1/F2$ formant values. The smaller the vowel space the more bunched and centralized the vowels; the larger the vowel space the more distinctive and peripheral the vowels. It has been shown that expanded vowel spaces (associated with hyperspeech) are correlated with speech intelligibility, and thus increased acoustic redundancy (Bradlow *et al.*, 1996; Bond and Moore, 1994). In contrast, casual or reduced speech (hypospeech) is characterized by centralization (Picheny *et al.*, 1986; Lindblom, 1990; Moon and Lindblom, 1994; Bradlow *et al.*, 1996), a reduced vowel space, and arguably lower acoustic redundancy. A reasonable prediction would therefore be, that as language redundancy increases, average formant values would shift towards the neutral, centralized position, leading to lower acoustic redundancy and, smoother signal redundancy overall. For example, in the case of /i/ (as in "lease"), as language redundancy increases, $F1$ would be expected to rise and $F2$ to fall while for /ɑ/ (as in "father") $F1$ would be expected to fall and $F2$ to rise.

Different specific predictions for formants of vowels with different height and backness specifications raise the issue of how to compare centralization results across vowels. Previous work has often measured the size of the vowel space and argued that if the size increases the vowels are less reduced (e.g., Bradlow *et al.*, 1996; Wright, 2003; Munson and Soloman, 2004). This method works quite well for a constrained set of laboratory stimuli, but has the disadvantage of masking the way results vary by vowel and by formant. Similar problems occur using distance or "clarity" measurements, whereby all vowels are related to a model of a citation "clear" version of the vowel space, using a value that reflects how distinctive or clear each vowel token is given this model. The advantage of this approach is that a single comparable measurement can then be used for analysis. In previous work, a number of alternative vowel space models were applied to a single dataset in an attempt to produce a clarity score that would show a systematic relationship with language redundancy. These included a citation vowel space model to measure degrees of hyperarticulation (Aylett, 2000), hidden Markov models (HMMs) (Aylett, 2001), as well as a simple Euclidean distance to the center of the vowel space in terms of mean $F1/F2$ (1) across all vowels Aylett (2000) and (2) from a speaker's citation speech (prepublished versions of Aylett and Turk, 2004). Results for all techniques were disappointing, arguably because any modeling technique introduces articulatory and perceptual assumptions about degree of distinctiveness or clarity that obscure spectral effects that are subtle by nature and potentially vary across vowels.

Having said this, the importance of modeling the vowel space should not be discounted, for much progress has been made in developing perceptual scales and by-vowel normalization schemes (see Rosner and Pickering, 1994, for a review). However, for analyses relating language redundancy to spectral measures, the advantage of a single model-derived measure applied to all vowels is heavily outweighed by the potential noise such a model might introduce. For this reason, absolute $F1/F2$ measurements in hertz were used in the current study. By doing so, theoretical assumptions concerning the relationship between human vowel perception and production were intentionally avoided. By avoiding the pitfalls of these previous studies, the current study was able to show (1) that raw $F1/F2$ values do vary significantly with language redundancy factors; (2) that the direction of this change is one that can be interpreted as reduction, and (3) the extent of the overlap between redundancy and prosodic factors in terms of predictive power.

II. METHODOLOGY

A very large corpus of citation speech (the Rhetorical Corpus detailed in Sec. II A) was used to test the smooth signal redundancy hypothesis. This corpus was chosen because its recording quality and carefully articulated speech allowed reliable automatic formant tracking and segmentation. Each syllable of the corpus was scored on the basis of (1) a simple language redundancy model based on syllable n-gram probability; and (2) a traditional prosodic model (detailed in Sec. II B), and was represented in terms of its acoustic redundancy, i.e., in terms of (1) its $F1/F2$ values at the temporal midpoint of its vocalic nucleus; and (2) in terms of its duration. ANOVAs with posthoc tests, as well as regression analyses, were applied to investigate the relationship between language redundancy and prosodic prominence and these two types of acoustic redundancy measures. (See Sec. II D for details of the statistical analyses.)

A. Materials

1. The Rhetorical Corpus

The Rhetorical Corpus was collected by Rhetorical Systems Ltd. as a database for speech synthesis. It contains data from eight general American speakers, three female and five male, with approximately 50 000 syllables recorded for each speaker. The speakers were all professional voice talents. The material was read in a recording studio environment and contained sentences of varying lengths taken from different genres (e.g., travel directions, financial news). Disfluencies and mispronunciations were avoided by requiring speakers to repeat errorful utterances. The resulting corpus, as compared to spontaneous speech corpora such as the Map Task (Anderson *et al.*, 1991) or switchboard (Godfrey *et al.*, 1992), lends itself to spectral analysis due to the high quality of the recording, the relatively slow rate of speech (lower than typical spontaneous speech), the quality of the speakers who were chosen for their ability to produce clear natural citation speech, and the filtering out of disfluency.

2. Vowels

Results presented in Sec. III are for a limited set of possible vowels within our corpus: /ɑ/ (father), /æ/ (tap), /ɛ/ (less), /i/ (lease), /u/ (goose). /ə, ɪ, ʊ, ʌ/ were avoided since these vowels were often too short for accurate automatic spectral analysis. In addition, diphthongs were avoided due to their moving spectral targets which would require more than a single measurement. And finally, the /ɒ/ vowel (as in "lawn") was avoided because of the extensive pronunciation variation of this vowel within the general American accent (Wells, 1982).

3. Segmentation and spectral analysis

As part of rhetorical systems' synthesis process, the corpus was phonemically segmented using a mixture of proprietal automatic segmentation and hand correction. Results are similar, although superior, to automatic segmentation using HTK (Young *et al.* (1996)), which was used as a basis for word medial segmentation in Aylett and Turk (2004). Using this segmentation, log duration in milliseconds was calculated for each syllable in the corpus, and $F1$ and $F2$ values (Hz) at the temporal midpoint of each vowel were estimated using the ESPS formant tracker (Talkin, 1987).

B. Redundancy and prosodic models

1. The acoustic redundancy model

In these analyses, vowel nucleus first and second formant values were taken as measures of a syllable's spectral quality, and centralization in terms of $F1/F2$ was interpreted as reduced acoustic redundancy. Due to the possibility of centralization behavior differing markedly between vowels, $F1/F2$ results are presented separately for each vowel. In addition, syllable duration was used as another measure of acoustic redundancy, and allowed for comparison with results in the literature, e.g., Aylett and Turk (2004).

TABLE I. Contribution from the original n-gram log likelihoods to wide and narrow factors. Values for the wide and narrow factors were produced by normalizing unigram, bigram, and trigram values using mean and standard deviation values and by multiplying them by the factor analysis components.

	Factor analysis component			
	Wide	Narrow	Mean	Standard deviation
Unigram	0.315	1.090	−6.924	1.956
Bigram	0.421	−0.314	−5.480	2.931
Trigram	0.407	−0.520	−5.063	3.411

2. The language redundancy model

A wide variety of possible measurements can be used to represent language redundancy. Examples in previous work have included word frequency, syllabic trigram models, accessibility (Aylett, 2000), joint probability, and conditional probability (Bell *et al.*, 2003), and Bayesian probability given phonemic identity (van Son and Pols, 1999). All of these measurements tended to support the hypothesis that there is a relationship between language redundancy and acoustic realization.

Syllabic probabilities were determined over unigram, bigram, and trigram contexts, i.e., the likelihood of a syllable without context, given the previous syllable, and given the previous two syllables. A log transformation was applied to these likelihoods in order to relate the values more closely to information content (Pierce, 1961) and to normalize the distributions. In order to calculate these likelihoods, the CMU language toolkit (Clarkson and Rosenfeld, 1997) was used to compute n-gram statistics based on the syllabic transcriptions of 187 million words found in news resources on the Internet. Transcriptions were automatically generated using the Rhetorical Systems speech synthesizer.

To make analyses of variance possible, and to help determine the direction of language redundancy effects, factor analysis was carried out on these likelihoods. Factor analysis has the effect of reducing the number of variables and, uses a linear transformation to create new factors which have no correlation with each other. The analysis produced two factors which we called wide context and narrow context measures of redundancy, where wide context was roughly an average of all three likelihoods, and narrow context was the unigram likelihood with bigram and trigram likelihoods subtracted (see Table I).

The resulting factors had the following normalized distributions: wide factor mean 0.0, median 0.132, s.d. 1.00; narrow factor mean 0.0, median 0.1130, s.d. 1.00. These distributions explained 96.8% of the variance in unigram/bigram/trigram likelihoods. Data points were then grouped into three redundancy groups on the basis of these distributions, for use in analyses of variance where language redundancy grouping was the independent variable of interest. The groups were constructed as follows:

(1) High language redundancy group: Data points for which both narrow and wide redundancy factors were higher than the median value (+, +);

TABLE II. Example syllables from each language redundancy group (in capitals). Example syllables are shown along with the two preceding syllables used to compute the target syllable's language redundancy.

Language Redundancy		
High	Medium	Low
to town **OF**	*pause* from **O**maha	flag is **NAILED**
alternative **IN**	tanza**NI**a	unper **TURBED**
fathers such **A**	medi**NA**	radioactive gas **GUSHED**
andy **TO**	*pause* in **PO**tentially	alba**TROSS**
kind of **THE**	flights from **MA**laysia	lab lo**CUSTS**

(2) Medium language redundancy group: Data points for which either (1) narrow redundancy was higher than the median and wide redundancy was lower than the median or (2) narrow redundancy was lower than the median and wide redundancy was higher than the median. (+,−) or (−,+); and
(3) Low language redundancy group: Data points for which both narrow and wide redundancy factors were lower than the median value (−,−).

See Table II for an example of syllables that fell into each of these three groups.

3. The prosodic model

The smooth redundancy hypothesis argues that an important function of prosodic prominence is as a linguistic means for increasing smooth signal redundancy (see Aylett, 2000 and Aylett and Turk, 2004 for supporting durational data). The prosodic model used to test this hypothesis in the current study is a simple one that consists of three levels of prosodic prominence and three levels of boundary. It is identical to the one Aylett and Turk (2004) used for their automatically coded data, apart from the full/reduced vowel distinction that does not apply to the current, full-vowel only, dataset. It can be summarized as follows:

Prominence:
- None
- Primary lexical stress
- High probability of having a phrasal stress (primary lexical stress+open class)

Boundaries:
- No following prosodic boundary
- Followed by a word boundary
- High probability of a following phrase boundary (followed by a pause >100 ms)

For practical reasons phrasal stress and phrasal boundaries were not hand-labeled, but were instead predicted on the basis of primary lexical stress on open-class words (for phrasal stress), and on the basis of following pauses (for phrasal boundaries). It should be noted that the occurrence of phrasal stress has probably been overpredicted, and the occurrence of phrasal boundaries has probably been underpredicted.

In addition, due to practical limitations, several known distinctions were not taken into account. These include accent type, boundary tone type, phrase type (e.g., full vs intermediate), and distinctions between unstressed syllables and those that could bear secondary lexical stress (e.g., /i/ in "city" and /i/ in "reply"). Despite these obvious limitations, this prosodic model represents a reasonable number of factors known to affect duration and segmental phonetic characteristics, and as such, is a rough approximation of current prosodic phonological theory. For our purposes, it made it possible to automatically code the half million syllables in the Rhetorical Corpus in terms of prosodic factors.

C. Data summary

To summarize, each syllable in our corpus was coded for language redundancy, prosodic prominence, and position relative to prosodic boundaries, according to the two models presented above. Syllable durations were determined on the basis of segmentation already present in the Rhetorical Corpus, and spectral measures ($F1/F2$) at the temporal midpoint of each vowel were determined using the ESPS formant tracker (Talkin, 1987).

D. Data analyses

1. Control for prosodic boundary location and speaker sex

The weak form of the smooth signal redundancy hypothesis accepts that the expected language/acoustic redundancy relationship may be confounded by prosodic boundary markers, which, among other things, act to increase the duration of phrase-final syllables. In order to address this concern, in the data presented here boundaries are controlled by discarding any syllables (1) before a phrase boundary; and (2) with no word boundary following them, i.e., all syllables are discarded not followed by a break index of 1. This approach differs from both Aylett (2000) and Aylett and Turk (2004), where only syllables from monosyllabic words were used. This change was necessary because of differences between the two corpora. The Map Task Corpus (Anderson *et al.*, 1991) used in the earlier work had a high preponderance of monosyllabic words (around 75%), whereas the Rhetorical Corpus had a much higher incidence of polysyllabic words (only 40% were monosyllabic). Whereas the monosyllabic words in the Map Task Corpus arguably provided a fair representation of the overall behavior of data within the corpus, this was not the case for the Rhetorical Corpus. In addition, given the requirement of by-vowel analysis, where data sparsity becomes a significant problem, it was decided to relax the boundary control requirements.

As well as controlling for prosodic boundaries, spectral measure results for male and female speakers were analyzed separately. An alternative approach would have been to manipulate the underlying values using a speaker normalization scheme (e.g., Nearey, 1992). However, there are problems with these techniques (see Adank, 2003 for a review) which would be further compounded by artifacts caused by formant tracking as high female $f0$ can lead to significant formant tracking errors. Separate by-sex spectral analyses have pre-

vented any normalization errors, and have made it possible to evaluate results which may have been compromised by formant tracking errors.

2. Statistical analyses

The smooth signal redundancy hypothesis predicts a strong inverse relationship between language redundancy, and acoustic redundancy, and a positive relationship between prosodic prominence and acoustic redundancy. In addition, it predicts that the predictive power of the language redundancy model and the prosodic prominence model will be substantially shared, while acknowledging that the conventions and rules of English prosodic prominence may yield a unique prediction of variation due to prosodic prominence over and above the shared effects. The significance and direction of these relationships for our two types of dependent variables, syllable duration and vowel $F1/F2$ frequency, were addressed by way of a univariate ANOVA followed by *posthoc* t-tests with Bonferroni correction. The size of the relationships and the shared proportion of the two models predictive power were analyzed by way of multiple linear regression together with a likelihood ratio test (Neter *et al.*, 1990).

a. ANOVA and posthoc t-tests. The prosodic variables in our study were categorical and therefore ideal for an ANOVA model with either syllabic duration or $F1/F2$ formant value as a dependent variable. Continuous language redundancy values were coded in terms of the categorical redundancy grouping variable described in Sec. II B 2 to make ANOVA possible. All *posthoc* t-tests were carried out for effects that were significant at $p<0.05$ in the ANOVA. There is some debate concerning when a Bonferroni correction should be made in these circumstances. A conservative approach to the data was taken here, whereby the correction was used for all tests carried out within the same analysis. To give a concrete example, a comparison of three redundancy groups across five vowels would result in a correction factor of 15, which would then be multiplied by the p value generated by each t-test. Thus, with a correction factor of 15, if a *posthoc* t-test returned a significance of 0.01, the p value would be recomputed as a nonsignificant 0.15.

b. Linear regression and likelihood ratio tests. The main goal of the linear regressions was to show how much the prosodic and redundancy models could predict the dependent variable and to what extent the two models overlapped. To this end, multiple regression analyses with fixed factor ordering were carried out with syllabic duration and $F1/F2$ formant values as dependent variables, and with language redundancy and prosodic factors as independent variables. The result of the regression analysis revealed the size of the relationship between dependent and independent variables in terms of predicted variance. Likelihood ratio tests were then performed to reveal the unique contributions of each type of independent variable to the regression model. This was accomplished by carrying out the linear regression (1) with all factors; (2) without language redundancy factors; and (3) without prosodic factors. The extent the r-squared value decreased when factors were removed was used to represent the unique contribution of these factors. We calculated the shared contribution of the independent factors by subtracting all unique contributions from the predicted variance of the entire model.

Because $F1/F2$ analyses were conducted on a by-vowel basis, a table is included which shows the prosodic prominence and redundancy characteristics for each vowel type (see Sec. III A 2). In some cases a dependency exists between vowel identity and the variance of these factors. For example, for the /ɛ/ vowel (as in "set"), in our data 90% of all tokens were lexically stressed and 84% were open class. Such homogeneity must be taken into account when interpreting the relative contribution of prosodic and redundancy models to predicting the dependent variables by vowel.

III. RESULTS

A. Syllabic duration

1. Do the results for syllabic duration found for spontaneous speech apply to the citation speech in this database?

In Aylett and Turk (2004), the evidence supporting the smooth redundancy hypothesis was taken from a spontaneous spoken dialogue. It was by no means clear that the citation speech in the Rhetorical Corpus would show the same relationship. It could be argued that the natural patterns of redundancy would persist, despite the unnatural nature of the recording environment. Alternatively, significant differences might be expected between the duration results in the Rhetorical Corpus and those for a spontaneous speech corpus such as the Map Task Corpus. To investigate this question the analysis carried out on the Rhetorical Corpus was matched as closely as possible to the Map Task Corpus analysis reported in Aylett and Turk (2004).

Univariate ANOVAs testing effects of (1) language redundancy group; and (2) prominence group both showed highly significant effects (language redundancy group—high, medium, low, $F(2,313\,941)=67\,726$, $p<0.001$; prominence Group—no stress, lexical stress, phrasal stress, $F(2,313\,941)=72\,118$, $p<0.001$). Figure 2 shows the mean values of each group; all were significantly different from each other (*posthoc* t-tests with Bonferroni correction, all with $p<0.001$). Syllables were shorter for higher values of language redundancy and, conversely, syllables were longer for higher levels of prosodic prominence.

Linear regression analysis, with boundaries controlled, found that regression models using these factors predicted a significant proportion of the Rhetorical Corpus data ($r=0.7219, r^2=0.5211-52\%$ of the variance). The independent contribution of the redundancy and prosodic model and the shared predictive power of both models is shown in Fig. 3. Close to 20% of the predictive power was shared. These results were similar to the Map Task Corpus results reported in Aylett and Turk, 2004, where a comparable proportion of predictive power was shared. The results support the view that the smooth signal redundancy hypothesis holds for this citation speech corpus, and raise the possibility that other smooth signal redundancy effects might be found for this corpus, e.g., in the spectral domain. Because spectral effects were to be analyzed on a by-vowel basis, we analyzed the

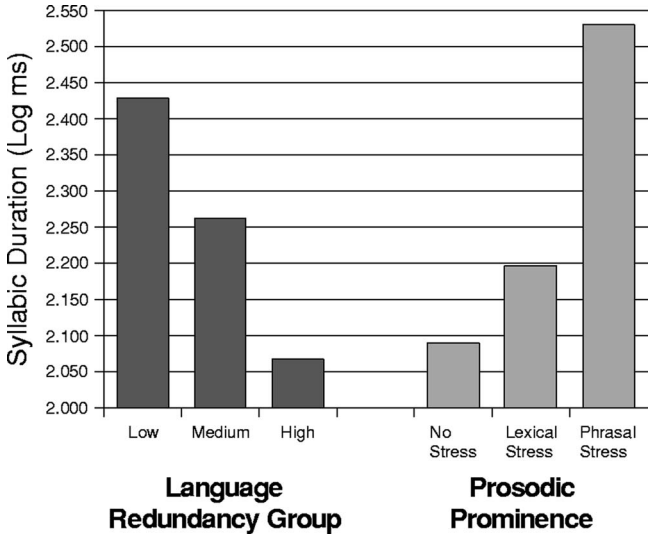

FIG. 2. Syllabic duration means (log ms), presented by redundancy group and by prosodic prominence, with prosodic boundaries controlled as specified in Sec. II D. All differences in means are significant. As a reference: 2.00 log ms=100 ms, 2.20 log ms=158.5 ms, 2.40 log ms=251.2 ms, 2.60 log ms=398.1 ms.

syllabic duration results on a by-vowel basis as well, in order to see if smooth signal redundancy effects were more reliable for some vowels as compared to others.

2. By-vowel durational evidence for smooth signal redundancy

Durational results analyzed separately for each vowel showed general support for the smooth signal redundancy hypothesis, both in terms of the direction of the language redundancy effects, and in terms of the shared predictive power of language redundancy and prosodic prominence. Figure 4 shows that vowels in the low language redundancy group were generally longer than vowels in the high redundancy group. However, there were differences across vowels in the relationship between the durations associated with the medium language redundancy group vs those associated with the high redundancy group. For example, for /i/ there was a smooth decrease across redundancy groups, but for /u/ the result was not as easy to interpret given that durations associated with the medium redundancy group were actually shorter than durations in the high redundancy group. All differences were significant at $p<0.001$ (*posthoc* t-test with Bonferroni correction).

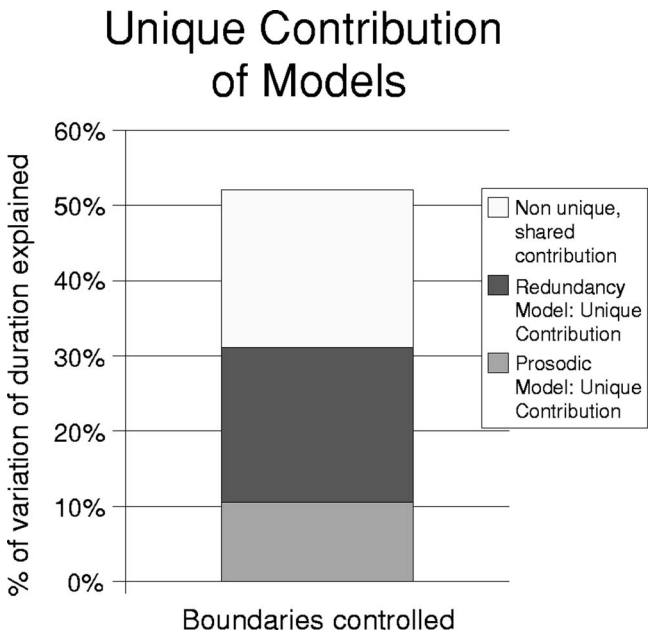

FIG. 3. Unique contributions of prosodic prominence and redundancy factors to the linear regression model.

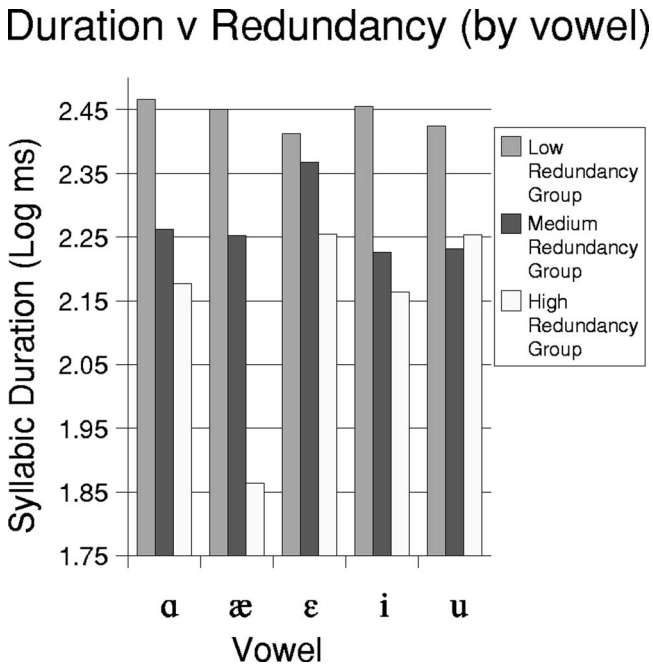

FIG. 4. Syllabic duration means (log ms), by redundancy group and by vowel. All differences in means are significant. As a reference: 2.00 log ms=100 ms, 2.20 log ms=158.5 ms, 2.40 log ms=251.2 ms, 2.60 log ms=398.1 ms.

Figure 5 shows how much of the variance in syllabic duration (log ms) for each vowel was predicted by full regression models containing both prosodic prominence and language redundancy factors. The combined regression/prosody model significantly predicted ($p<0.001$) between 18%–57% of the syllabic duration variation across vowels. Much of the predictive power was shared between language redundancy and prosodic prominence, although the extent of this shared contribution varied for different vowels. Some vowels, such as /i/, behave similarly to the pooled results, while others, for example /ɛ/, seem to exhibit a very different relationship between the prosodic model and the redundancy factors. One complication is that neither the prosodic factors nor the redundancy factors have similar variances across different vowels (see Table III). For example, /i/ is a common vowel which is often used in unstressed contexts (such as the last syllable of the word "spongy"), as well as in stressed syllables. In contrast, /ɛ/ has lower variance and a low mean in the wide redundancy category which suggests this vowel rarely if ever occurs in a very predictable syllable in any context. In addition, with boundaries controlled, nearly all the /ɛ/ tokens are stressed and in open-class words. This lack of variance available to both prominence and redundancy

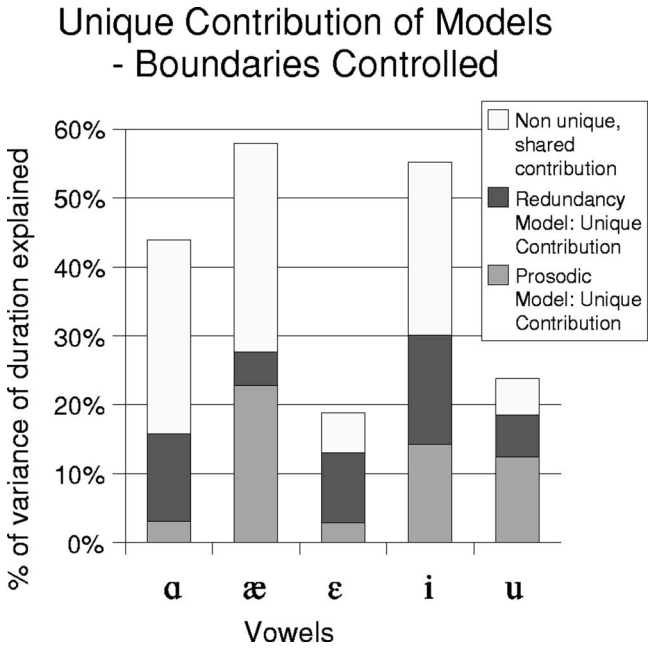

FIG. 5. Unique contributions of prosodic prominence and redundancy factors to linear regression models for each vowel.

models can thus explain the low overall performance of the models in the /ɛ/ context (less than 20% of total variance explained).

B. Spectral results

1. Spectral results: t-tests

Our hypothesis as far as $F1/F2$ effects are concerned was that vowels should show increased centralization with increased language redundancy, and that the direction of $F1/F2$ differences would be different for each vowel type (See Table IV for predicted effects for each analyzed vowel). Separate data for males vs females were analyzed for each vowel, with prosodic boundaries controlled (see Sec. II D 1).

Results show that language redundancy did indeed have a significant effect on $F1/F2$, but the significance and the direction of the effect varied by vowel. The extent to which our predictions were met can be seen in Table V, in which effects that clearly run counter to our predictions are shown in bold face. Overall, the results were reasonably consistent with a simple centralization hypothesis except for /u/, where $F1$ drops and /ɑ/ for female speakers, where $F2$ rises. Note that cases where no difference in formant value was predicted were not evaluated in this way, on the assumption that small differences could easily be accommodated by the centralization model.

TABLE IV. $F1/F2$ predictions for each vowel as acoustic redundancy drops due to centralization.

	$F1/F2$ Prediction from a centralization model of acoustic redundancy	
Vowel	$F1$ change	$F2$ change
ɑ	minus	plus
æ	minus	same
ɛ	minus	same
i	plus	minus
u	plus	plus

Figures 6 and 7 show these changes across the vowel space presented separately for male and female speakers. Groups 1 (high language redundancy) and 3 (low language redundancy) differed in a direction consistent with the hypothesis that language redundancy correlates with centralization, with /i/ showing a particularly good match to prediction. That is, average values for group 1 tended to be more central than average values for group 3. However, for many of the vowels, the difference between groups is reflected primarily in differences in $F1$, with little contribution from $F2$. Group 2, formed from a less homogeneous mixture of high/low and low/high items (see Sec. II B 2) did not show the same relationship with groups 1 and 3 across vowels.

2. Spectral results: Linear regression

Linear regression analysis showed that the redundancy and prosodic models could together predict between 0.5%–7.9% of variation in $F1$ ($p<0.001$), and 0.2%–5.9% of the variation in $F2$ ($p<0.001$), as shown in Table VI. The smaller percentage of explained variance for female speakers may be due in large part to poor performance of the formant tracker for these speakers. Given this concern about formant tracker reliability for the female speakers, relationships between prosodic and redundancy models were compared for male speakers only. Figure 8 shows that for many of the vowel formants, redundancy factors and prosodic prominence factors predicted a large proportion of shared variance. But, in contrast to results for syllable duration, this pattern did not hold for all cases: the shared contribution was quite small or nonexistent for e.g., /u/**–f1** and /æ/**–f2**. In addition, the unique contributions of redundancy and prosodic prominence factors seemed to vary considerably across vow-

TABLE III. Variation in prosodic prominence and language redundancy by vowel (prosodic boundaries controlled).

	Prominence		Wide redundancy		Narrow redundancy	
	Lexical stress	High prob phrasal stress	Mean	SD	Mean	SD
a	91%	63%	−0.58	0.98	−0.19	1.01
æ	95%	54%	−0.85	0.78	−0.24	0.87
ɛ	92%	76%	−0.53	0.89	−0.33	0.92
i	52%	37%	0.4	0.94	0.02	0.89
u	89%	54%	−0.03	0.83	0.46	0.98

TABLE V. Changes in $F1/F2$ mean values from low to high redundancy.

$F1/F2$ change from low to high redundancy prediction/result low redundancy group $F1/F2$ - high redundancy group $F1/F2$(*Hz*)		
Male Speakers (n=3)		
Vowel	$F1$ change	$F2$ change
ɑ	minus/−42.0	plus/+22.2
æ	minus/−21.0	same/+15.1
ɛ	minus/−72.2	same/−36.3
i	plus/ 8.4	minus/−48.8
u	**plus/−18.43**	plus/ 31.72
Female speakers (n=5)		
Vowel	$F1$ change	$F2$ change
ɑ	minus/−188.6	plus/−13.2
æ	minus/−44.1	same/ 37.65
ɛ	minus/−119.06	same/ 12.93
i	plus/ 8.76	minus/−37.0
u	**plus/−5.0**	plus/ 82.2

els: /u/**−f1** had a strong redundancy component orthogonal to the prosodic components of the model, whereas /i/ had a very low unique contribution from the redundancy model. However, in all cases except /ɛ/**−f2** and /u/**−f2**, both redundancy and prosodic prominence factors showed significant unique contributions to the regression model ($p<0.001$).

IV. CONCLUSIONS

The primary aim of this paper was to test whether the predictions of the probabilistic reduction hypothesis, speech efficiency, and the smooth signal redundancy hypothesis could be generalized to spectral dimensions. General support for these views was found in the form of significant effects of language redundancy on $F1/F2$ formant values: vowels with higher language redundancy and less prominence showed more centralization. Evidence for the smooth signal redundancy hypothesis in particular was found in terms of considerable overlap in effects of redundancy and prosodic prominence, supporting the view that prosodic prominence is a functional structure for achieving smooth signal redundancy and thus making the speech signal more robust in a noisy environment.

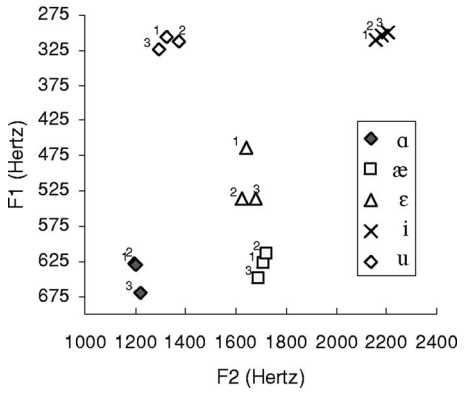

FIG. 6. Male spectral results by vowel (n=3). 1=high language redundancy, 2=medium language redundancy, 3=low language redundancy. All differences between 1 & 2, 2 & 3, 1 & 3 are significant ($p<0.005$) for both $F1$ and $F2$ (unless noted) on the basis of a *posthoc* t-test with Bonferroni correction. Nonsignificant group differences: /ɑ/ $F1$ 1 & 2, ɑ F2 1 & 2 & 3, /ɛ/ $F1$ 2 & 3, /ɛ/ $F2$ 1 & 2.

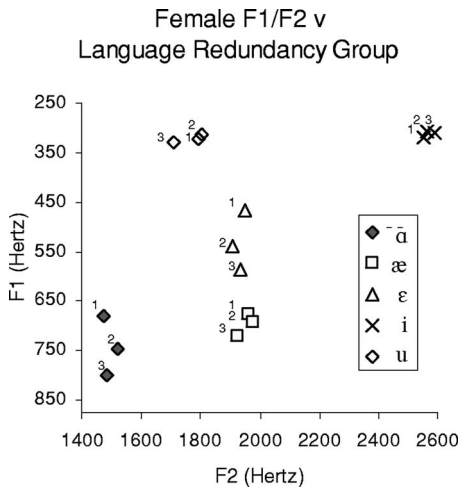

FIG. 7. Female spectral results by vowel (n=5). 1=high language redundancy, 2=medium language redundancy, 3=low language redundancy. All differences between 1 & 2, 2 & 3, 1 & 3 are significant ($p<0.005$) for both $F1$ and $F2$ (unless noted) on the basis of a *posthoc* t-test with Bonferroni correction. Nonsignificant group differences: æ/ $F1$ 1 & 2, /æ/ $F2$ 1 & 2, /i/ F1 2 & 3, /u/ $F2$ 1 & 2.

Nevertheless, these general effects were complicated by considerable by-vowel variation, some of which may be ascribed to inherent differences in the range of prosodic and language redundancy variation for these vowels in the lexicon. This was touched upon in Sec. III A 2, where differences in the redundancy profiles between /ɛ/ and /i/ in the Rhetorical Corpus were highlighted. However, limitations of our prosodic, redundancy, and acoustic models could also contribute to this variation between vowels. Indeed, many possible improvements could be made to the prosodic model. For example, the prosodic model used here does not include secondary lexical stress, degrees of variation in phrasal stress, accent type differentiation based on $f0$ contours, nor any interaction between prominence and prosodic boundaries. Refining the model along these lines might well lead to

TABLE VI. $F1/F2$ linear regression results for combined redundancy and prosodic prominence models, split by vowel and by speaker sex.

Male F1/F2	$F1$		$F2$	
	r	r^2	r	r^2
ɑ	0.261	0.068	0.113	0.013
æ	0.215	0.046	0.190	0.036

æ	0.071	0.005	0.189	0.036
ɛ	0.266	0.071	0.040	0.002
i	0.115	0.013	0.223	0.050
u	0.075	0.006	0.096	0.009

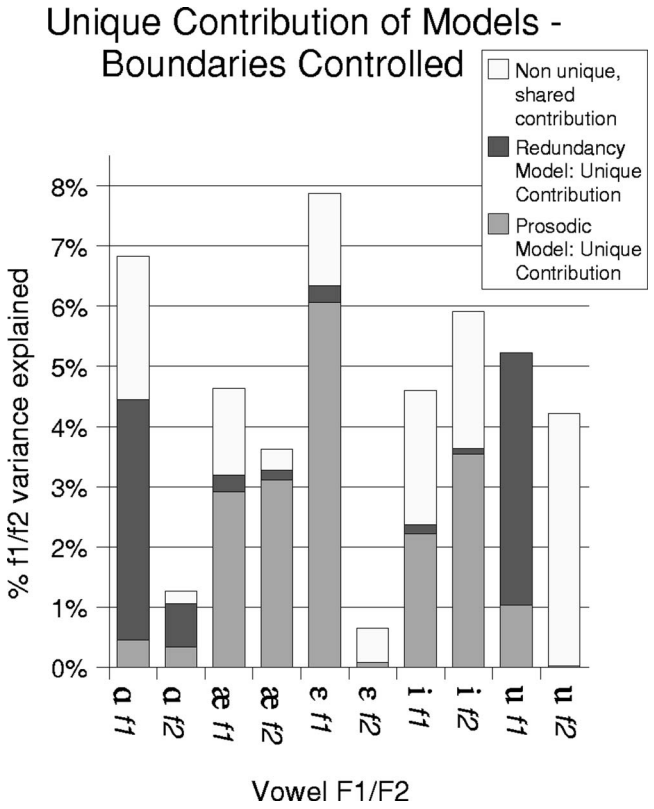

FIG. 8. The relationship between the predictive power of redundancy and prosodic prominence linear regression models, for male speakers only.

a greater overlap between the prosodic and the redundancy models. And, similarly, the redundancy model could be improved with additional specifications such as word frequency phone sequence likelihood, a neighborhood density metric, the probability of the syntactic category given a probabilistic syntax, and, at a discourse level, factors such as whether a referent has been mentioned previously. Using factor analysis as described in Sec. II B 2, any number of factors could be distilled to a smaller orthogonal set and added to the redundancy model.

Nevertheless, it may be unwise to complicate either the redundancy or the prosodic model until limitations in our acoustic modeling are addressed. In particular, syllables in the current study were represented by single $F1$ and $F2$ values taken at the temporal midpoint of each syllable in spite of the fact that formant trajectories are known to be dynamic, conditioned by the identity of surrounding consonants as well as the vowel. In fact, coarticulation with consonants, which may cause vowel centralization, may also add information concerning the surrounding segments. For example, nasalization in a vowel means it is easier to predict the subsequent segment is nasal, thus increasing acoustic redundancy. Such coarticulation, even while centralizing the middle portion of the vowel, can also add to acoustic redundancy by adding dynamic cues to the vowels' identity. Such cues at the onset and offset of a vowel have been shown to have a fundamental effect on speech perception (e.g., Strange, 1989).

In addition, the characterization of the vowel space we have used could also be improved. $F1/F2$ values could be modified by different types of vowel space normalization. There is a strong argument for the use of a perceptual frequency scaling metric, such as bark or jnd's, which we avoided in this paper to aid transparency. Finally, a more complex model than centralization may do much better at modeling this change in acoustic redundancy, for example, one that takes into account vowel distinctiveness at different points in the vowel space.

Finally, it is far from clear which underlying perceptual model is most appropriate for building a model of acoustic redundancy. Unlike duration alone, where longer segments are generally agreed to be more intelligible, little is known about how factors such as $F1/F2$, amplitude, $f0$ change, and spectral tilt combine both with dynamic and static cues to increase or decrease intelligibility. Investigating these factors and their relationship to perception is an ongoing task, but a language redundancy framework can clearly offer a solid quantitative approach for their examination.

The ability to integrate and weight information across dimensions is central to perception and is particularly important for speech categorization. The present experiments investigate cue weighting by training participants to categorize sounds drawn from a two-dimensional acoustic space defined by the center frequency (CF) and modulation frequency (MF) of frequency-modulated sine waves. These dimensions were psychophysically matched to be equally discriminable and, in the first experiment, were equally informative for accurate categorization. Nevertheless, listeners' category responses reflected a bias for use of CF. This bias remained even when the informativeness of CF was decreased by shifting distributions to create more overlap in CF. A reversal of weighting (MF over CF) was obtained when distribution variance was increased for CF. These results demonstrate that even when equally informative and discriminable, acoustic cues are not necessarily equally weighted in categorization; listeners exhibit biases when integrating multiple acoustic dimensions. Moreover, changes in weighting strategies can be affected by changes in input distribution parameters. This methodology provides potential insights into acquisition of speech sound categories, particularly second language categories. One implication is that ineffective cue weighting strategies for phonetic categories may be alleviated by manipulating variance of uninformative dimensions in training stimuli. I. INTRODUCTION

Outside of the acoustic researcher's laboratory, few sound categories are distinguished by a single acoustic dimension. In the natural world, auditory categories more typically are defined along multiple dimensions. Integration of information across acoustic dimensions, then, must be a central characteristic of auditory processing.

Speech categories provide an excellent illustration of both the complexity with which multiple acoustic dimensions define auditory categories and of the adeptness of the auditory system at integrating information across multiple dimensions. For speech categories, rarely is a single acoustic dimension necessary or sufficient to define category membership; this is the essence of the classic "lack of invariance" issue (Liberman, 1996; Liberman *et al.*, 1967). For example, there are many acoustic dimensions that contribute to voicing, as in the difference between English /ba/ and /pa/; Lisker (1986) cataloged as many as 16 acoustic dimensions that may characterize the English voicing distinction.

Nevertheless, for speech and other auditory categories the existence of multiple acoustic dimensions does not imply their perceptual equivalence. Simply put, some acoustic dimensions play a greater role in determining the perceptual identity of a sound than do others. The fact that acoustic dimensions need not contribute equivalently to category identity has been referred to as *cue weighting*. Acoustic dimensions appear to be perceptually weighted in the sense that some are strongly correlated to categorization responses whereas others, although present, weakly determine perceived category membership. As an example, both spectral and temporal acoustic cues differentiate English tense and lax vowels like /i/ versus /I/. Adult native American-English listeners, however, rely much more on the spectral dimension (formant frequency) than the temporal dimension (vowel duration) in categorizing /i/ and /I/ (e.g., Hillenbrand *et al.*, 2000). Likewise, Francis and colleagues (2000) have demonstrated that although burst cues and formant transition cues co-vary for American English stop consonant categories, listeners rely on the formant cue significantly more than the burst cue in categorization responses (see also, Walley and Carrell, 1983). Even with explicit training with feedback to use the burst cue, the listeners continue to rely on the formant transition (Francis *et al.*, 2000).

What determines the relative weighting of different sources of acoustic information? An adaptive listener would weight dimensions based on experience over time with the acoustic environment. For example, we might be able to pre-

[a)]Portions of this work were presented at the 148th Meeting of the Acoustical Society of America, San Diego, CA, November, 2004 and at the 28th Mid-Winter Meeting of the Association for Research in Otolaryngology, New Orleans, LA, February, 2005.

dict weighting functions for speech perception if we knew how acoustic dimensions co-varied with phonetic contrasts in a listener's experience. In principle, the regularity of information along different dimensions could be fully characterized if it were possible to make exhaustive acoustic measurements of the full range of speech productions for a language, an idiolect, an accent, a speaker, or group of speakers. In practice, this has been approached much more modestly by examining regularities in the realization of speech productions of small samples of speakers (e.g., Lisker and Abramson, 1964; Lotto *et al.*, 2004). Nevertheless, even with this more limited approach, it is possible to estimate the distributions of phonetic categories across a subset of acoustic dimensions. Adaptive listeners will tune their weighting of the dimensions based on the characteristics of these distributions to maximize accuracy. However, there are a number of constraints related to sensory processing, cognitive processing, and previous experience that may prevent listeners from achieving ideal performance on any particular categorization task.

Examining this at a finer grain, cue weighting can be thought of as a function of at least four variables. The first two relate to the distributional characteristics of acoustic information and are language specific. First, acoustic dimensions vary in their *informativeness* for category identity; that is, there is a difference in the distinctiveness of the distributions for competing categories along each dimension. For example, voice onset time (VOT) is a robust acoustic signal for voicing across languages. Lisker and Abramson and others (Keating, 1984; Lisker and Abramson, 1964) have examined the distribution of VOT across speech categories in several languages. In American English, for example, VOT values produced by speakers are quite reliably differentiated across speech categories. This is to say that the distributions of the voicing categories do not overlap much along the VOT dimension. As a result, VOT is highly informative for the American English voicing distinction. Because of this informativeness, VOT is likely to be a heavily weighted cue in the perception of voicing categories by American English listeners. Note, as well, that implicit in this description is the hypothesis that listeners are sensitive, not just to the absolute value on an acoustic dimension for a particular stimulus presentation, but also to the distributional characteristics of that cue as it occurs across speech instances within a language.

A second parameter of auditory distributions that could affect perceptual cue weighting is distribution *variance*. Information is carried by variance in the signal and the auditory system seems to be especially sensitive to dimensions that are varying. Studies of nonspeech pattern analysis have established that components with greater relative variance receive greater perceptual weight (Lutfi, 1993; Lutfi and Doherty, 1994). From these findings, one may predict that dimensions on which speech distributions vary the most will receive higher perceptual weights. But in categorization tasks, such as phonetic categorization, the relationship between variance and cue weighting is likely to be more complex. The relationship between within-category and between-category variance is probably an important determinant of perceptual weight. Whereas large overall variance (disregarding category) is indicative of an informative acoustic dimension, large within-category variance can decrease the informativeness of a dimension by creating distribution overlap (in the same way that variance can decrease d' in signal-detection theory). In addition, increased within-category variance across a dimension could mean that the dimension is not robustly related to the category or that there is a great deal of noise in the transmission of this dimension. In either case, the reliability of the dimension is questionable and, correspondingly, the dimension may be weighted less.

It is important to note that each of these distributional aspects of cue weighting must be considered to be language specific, dialect specific, and perhaps even speaker specific. Although the same acoustic dimensions may exist across languages or dialects, the phonetic distributions are clearly not equivalent. For example, across the voiced-voiceless distinction in American English stops, aspiration is correlated with voicing. Voiceless consonants (with longer VOTs) are typically aspirated whereas voiced consonants are much less likely to be produced with aspiration (e.g., Stevens, 1998). Aspiration is thus likely to be a relatively strong cue to voicing in American English. Aspiration also exists for Hindi stop consonant categories, but it does not carry weight as a cue for voicing because it is strongly correlated with an orthogonal category dimension (aspirated versus unaspirated, Benguerel and Bhatia, 1980). As another example, consider the relationship of vowel length to syllable-final consonant voicing. Adult native listeners of languages that do not have syllable-final obstruents or that fail to make a vowel-length distinction as a function of the voicing of the final consonant do not weight vowel duration as a cue to the final-consonant's category identity as much as listeners of languages that make vowel-length distinctions as a function of final-consonant voicing (Crowther and Mann, 1992, 1994; Flege and Wang, 1989). Listeners' weighting of acoustic dimensions, then, arises from experience with the regularities of acoustic realization in the native patterns of speech production, although the learning mechanisms remain, as yet, relatively poorly understood. At a somewhat finer level, perceptual weighting may have speaker-specific characteristics. Weighting of acoustic dimensions across individual speakers may vary somewhat and listeners' familiarity with this variation may contribute to voice recognition.

Two other variables that can influence cue weighting can be thought to be non-distributional and not language specific or speaker specific. First, the basic auditory representation of an acoustic dimension can influence its perceptual weight. Some acoustic dimensions are more robustly encoded by the auditory system than others. For example, there may be discontinuities in auditory processing along particular acoustic dimensions such that equal physical steps do not produce equivalent changes in percept (e.g., Kuhl and Miller, 1975; Stevens, 1989). VOT, again, serves as a fine example because its perception is thought to be influenced by a general auditory discontinuity in processing the onsets of simultaneous acoustic events (Kuhl and Miller, 1975; Pisoni, 1977). The acoustic dimension distinguishing VOT can be thought of as a relative onset asynchrony between two component frequencies, one higher and one lower in frequency. The

lower-frequency component may either lead or lag the higher-frequency component, or it may occur simultaneously with it. Research from human adult, infant, and animal behavior as well as electrophysiology from these populations has suggested that the mammalian auditory system is poor at resolving onset asynchrony differences less than about 20 ms, whether they are speech or nonspeech stimuli (e.g., Jusczyk *et al.*, 1980; Kuhl and Miller, 1975; Pisoni, 1977; Simos and Molfese, 1997; Simos *et al.*, 1998: Sinex *et al.*, 1991; Steinschneider *et al.*, 1999). Sinex and colleagues, for example, relate this auditory discontinuity to changes in the variance of the neural representation at the auditory nerve; there appears to be a relatively more robust neural code in the representation of stimuli with onset asynchronies greater than about 20 ms (Sinex and McDonald, 1989; Sinex *et al.*, 1991). It has been suggested that languages may exploit this discontinuity in auditory processing by developing voicing categories that straddle this sensitivity and thus exaggerate the perceived difference between categories (e.g., Pisoni, 1977). Recent research has indicated that in addition to the perceptual benefit of exaggerated discriminability, such placement may also facilitate category learning (Holt *et al.*, 2004). By these means, the relatively quantal representation for VOT (and consequent high discriminability of the category distinction) may contribute to a stronger cue weight. Of course, the opposite circumstances may also influence perceptual weighting; acoustic dimensions may be less heavily weighted as a consequence of a weak auditory representation, for example, if they are more susceptible to noise or are represented with more variability by the auditory system than other acoustic dimensions. Moreover, if the auditory system does not have sufficient resolving power or if there is too much noise in the representation of an acoustic dimension then the covariance between the dimension and the category label may be underestimated by the perceiver. In general, more discriminable acoustic dimensions will tend to be more informative for a listener and, correspondingly, should be expected to have a greater perceptual weight.

Cue weighting may also be influenced by task. The acoustic dimensions heavily weighted for phonetic categorization may be much less informative in making a lexical decision, identifying a talker, evaluating the emotional content of speech, or making other perceptual decisions. The same acoustic dimension present in the same signal may be heavily weighted for one perceptual task, but less heavily weighted for a different task. Likewise, changes in the task that affect the auditory representation (for example, the addition of low-frequency noise that selectively masks a particular acoustic dimension) or the informativeness of a cue (for example, manipulation of the distribution characteristics on an acoustic dimension in the laboratory) would also be expected to bring about shifts in listeners' perceptual cue weighting. This expectation of adaptive plasticity is particularly important for our understanding of how to alter cue weighting in aid of acquiring new categories, for example in the acquisition of second-language (L2) phonetic categories. The present experiments exploit these possibilities.

To summarize the above, not all available information is equivalent in perceptual processing and the differential contribution of acoustic dimensions to categorization arises as a result of experience with regularities in the input, the robustness or variability of the perceptual coding of an acoustic dimension, and its informativeness to category identity as a function of task. Cue weighting is a quantitative description of how auditory information (and information from other modalities as well) is integrated in perceptual categorization. An appreciation of perceptual cue weighting leads to the perspective that speech categorization is not just a matter of detecting available auditory cues along various acoustic dimensions, but also applying some weighting function that is, at least in part, dependent on experience with phonetic distributions.

This hypothesis has important implications for language acquisition. There has been considerable interest in the perceptual difficulties of L2 learners in acquiring second-language speech categories. One underlying cause of these difficulties may be that well-established native-language weighting functions are inappropriate for the L2. The language-specific nature of cue weighting may create perceptual difficulties in integrating acoustic information for nonnative speech categories. Understanding the mechanisms of cue weighting and investigating the means by which it may be possible to change these functions are therefore of considerable importance for understanding L2 category acquisition. As an example, take the classic case of English syllable-initial /l/ versus /r/ perception by native Japanese listeners (Miyawaki *et al.*, 1975). For native American English listeners, the starting frequency of the third formant (F3) carries most of the perceptual weight, but Japanese listeners appear to heavily weight F2 starting frequency in categorizing English /l/ and /r/ (Iverson *et al.*, 2003; Yamada and Tohkura, 1990). This weighting is nonoptimal as F2 is not varied contrastively for syllable-initial liquids by English speakers (Lotto *et al.*, 2004). An understanding of the basic processes by which acoustic dimensions are perceptually weighted and determination of the means by which these weights may be altered therefore are likely to have straightforward applications to understanding this classic L2 learning problem, and others.

Cue weighting also appears to be important for a full understanding of first language (L1) acquisition. Although infants begin to become perceptually tuned to the characteristics of L1 already in the first year (Jusczyk, 1997; Kuhl *et al.*, 1992; Werker and Tees, 1984), this process ultimately takes significant time to develop to adultlike perception (e.g., Morrongiello *et al.*, 1984; Nittrouer *et al.*, 1998; Nittrouer *et al.*, 2000; Nittrouer, 2004; Parnell and Amerman, 1978). Specifically, children appear to apply different weightings to acoustic dimensions in perceiving L1 speech categories (Hazan and Barrett, 2000; Mayo and Turk, 2004; Nittrouer, 2004). For example, in languages in which adults weight vowel duration as a strong cue in categorization of following final stop consonants, children tend to favor the consonant-influenced vowel-formant transitions over vowel duration (Nittrouer, 2004).

The purpose of the present experiments is to address issues of cue weighting in an effort to begin to understand the means by which the auditory system weights acoustic

dimensions and, also, to investigate methods by which listeners' cue weighting might be shifted. This latter aim is of particular importance in understanding the link between cue weighting and speech category acquisition in L1 and L2. It is presumed that cue weighting functions are determined in large part by the characteristics of distributions of experienced sounds. However, uncovering the role of experience in shaping speech categorization is quite difficult because it is impossible to know the precise history of speech experience that a listener brings to the laboratory. Therefore, as a starting point, we have taken the approach of investigating novel nonspeech auditory category learning. This allows us to maintain total control over listeners' histories of experience with the acoustic exemplars, thus ensuring that we have a precise characterization of the distributional characteristics. We can then describe the mapping between the informativeness of each dimension and the correlation of that dimension with categorization responses (i.e., its weighting). In the experiments that follow, we examine how changing the characteristics of these acoustic distributions or the manner of presentation can affect weighting functions. In each experiment, listeners are trained with feedback to categorize nonspeech sounds as coming from one of two predefined distributions. These microgenetic experiments were designed to examine auditory category formation with application to phonetic category acquisition. In fact, the characteristics of the distributions that were used were very similar to previous studies examining speech sound categorization in human adults, infants and non-human animals (Grieser and Kuhl, 1989; Kluender *et al.*, 1998; Kuhl, 1991).

II. EXPERIMENT 1

In Experiment 1, listeners were trained to categorize unfamiliar sounds drawn from two distributions situated in a two-dimensional acoustic space. The two acoustic dimensions were equated for perceptual discriminability in pilot psychophysical experiments and possessed no known *a priori* relationship. Moreover, the input distributions were created so that the two dimensions were equally informative for the categorization task. The questions under investigation were whether listeners would integrate information from both dimensions in making category decisions and, if so, whether the resulting cue weighting functions were predictable from the (in this case equal) informativeness of the dimensions.

A. Methods

1. Participants

Fourteen volunteers recruited from Carnegie Mellon University, Pittsburgh, PA, participated for course credit or a small payment. All listeners reported normal hearing.

2. Stimuli

The experiment used methods from auditory category-learning experiments (e.g., Holt *et al.*, 2004; Mirman *et al.*, 2004) whereby distributions of sounds drawn from a two-dimensional acoustic space were sampled in stimulus presentation. Listeners labeled the sound and received feedback to learn to assign category labels during training. In a subsequent test, novel stimuli drawn from the same two-dimensional acoustic space were presented to assess the relative weighting of the two acoustic dimensions as a consequence of categorization training. This design allows response patterns to be directly compared to distribution characteristics (e.g., means, variances, overlap).

The nonspeech stimuli used in all four experiments were frequency-modulated tones. The two-dimensional acoustic space from which stimuli were sampled was defined by center, or carrier, frequency (CF) and modulation frequency (MF). Within this acoustic space, two distributions corresponding to the to-be-learned auditory categories were created; they are illustrated in Fig. 1(a) as open symbols. Forty-eight unique stimulus exemplars defined each of the categories; each category exemplar is represented by an open symbol in Fig. 1(a), with circles marking one category and diamonds the other. Each stimulus was created from a sine wave tone with a particular CF modulated with a depth of 100 Hz at the corresponding MF. For example, if the CF was 760 Hz and the MF was 203 Hz, the tone was modulated from 710 to 810 Hz at a rate of 203 Hz. Each stimulus was 300 ms long and was sampled at 10 kHz with 16-bit resolution. Stimuli were created using the Cool Edit (Syntrillium, Inc., Phoenix, AZ) software.

It was desirable that sampling of the distributions along the two acoustic dimensions produce perceptual changes that were roughly equivalent. To this end, estimates of the just-noticeable-difference along the CF and MF dimensions were determined by pilot psychophysical studies in which one dimension (CF or MF) was varied while the other was held constant at an intermediate value. Based on informal listening, these tests began with minimum steps of 15 Hz along the CF dimension and 3 Hz along the MF dimension. Young, normal-hearing listeners ($N=20$) recruited from the same population as those participating in the reported categorization studies responded to pairs of stimuli varying in either CF or MF in an AX discrimination test with stimulus pairs separated by 1, 2, 3, 4, or 5 steps. This series of pilot discrimination studies revealed that the CF and MF dimensions were approximately equally discriminable (70% accuracy) when step size was adjusted to be 30 Hz along the CF dimension and 18 Hz along the MF dimension. The results of these studies also confirmed that discrimination was flat across each of the dimensions, indicating that there were no auditory discontinuities in discriminability across the region of the two-dimensional stimulus space under observation.

For Experiment 1, the positioning of the input distributions in the acoustic space resulted in the CF and MF acoustic cues being equally informative for the categorization task. Distribution overlap was equal on both dimensions. One way to quantify "informativeness" is to calculate the relative increase in accuracy over chance performance that an ideal observer could attain by using the dimension. For the current study, we used a simple criterion-bound model in which the ideal observer would place a criterion at the optimal (in terms of accuracy) position along the dimension. All stimuli on one side of the criterion are designated as category "A" and all on the other side are designated category "B." Any

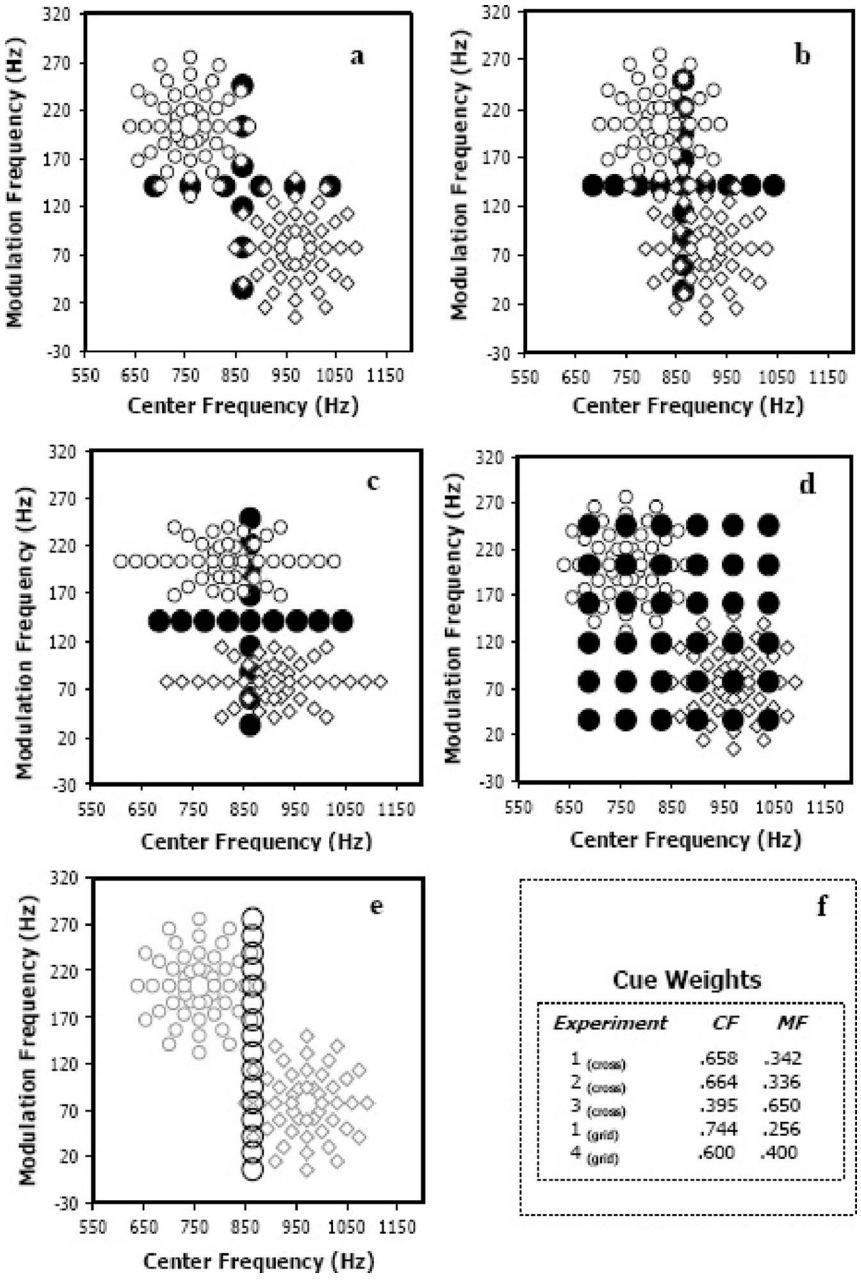

FIG. 1. Schematic representations of the stimulus input distributions in the center frequency (CF) by modulation frequency (MF) acoustic space. Open circles and open diamonds illustrate the individual stimuli from the two categories, respectively. The large filled circles show novel stimuli withheld from training from which cue weights were calculated. (a) Stimulus distributions for Experiment 1. (b) Stimulus distributions for Experiment 2. (c) Stimulus distributions for Experiment 3. (d) Stimulus distributions for Experiment 4. (e) Training distributions for Experiment 4 are shown as small light symbols for reference; they are identical to those of Experiment 1. The large open circles illustrate the stimuli presented during passive listening prior to categorization training. (f) Summary of the relative cue weights for the CF and MF dimensions across experiments.

stimuli landing on the criterion are considered "A" 50% of the time. Unlike more sophisticated ideal observer models, there is no noise in the encoding of the value on the dimension and the response is not probabilistic. With this decision model, one can calculate the informativeness of a dimension as

$$I_{\text{dimension}} = (\%\,\text{Correct Ideal Observer} - \text{Chance})/(\text{Perfect Performance} - \text{Chance}). \quad (1)$$

Equation (1) gives informativeness as the increase in accuracy over chance due to information in a dimension relative to the total amount of possible improvement. This function is equal to 1 when perfect performance can be achieved using that dimension and 0 when the dimension provides no information above chance. For Experiment 1, there are two possible responses and the prior probabilities of each response are equal; therefore, perfect performance is 100% and chance is 50%. By using either acoustic dimension alone, a perceiver could attain 95.8% correct with an optimal linear boundary [as can be seen in Fig. 1(a), the two categories are nearly perfectly linearly separable along either acoustic dimension with optimal boundaries at CF=865 Hz and MF =140 Hz]. Since the use of either acoustic dimension yields the same optimal percent correct, these acoustic dimensions are equally informative to the categorization task $I_{\text{CF}}=I_{\text{MF}}(95.8-50/100-50)=0.916$. However, integrating information across the two acoustic dimensions is more informative to the categorization response than either dimension individually; the categorization task can be performed perfectly if an ideal observer integrates across both acoustic dimensions (i.e., $I_{\text{CF+MF}}=1.0$).

In addition to the 96 stimulus exemplars (open symbols) comprising the categorization training stimuli, 12 novel test

stimuli (filled circles) were created to probe listeners' use of the CF and MF dimensions following training. These novel stimuli were reserved from categorization training to be used in generalization tests. They varied orthogonally in the acoustic space such that the value along one acoustic dimension was held constant at an intermediate value (CF = 865 Hz or MF = 140 Hz) while the values along the other acoustic dimension varied.[1]

Acoustic presentation was controlled by TDT System II hardware (Tucker-Davis Technologies, Alachua, FL). Stimuli were converted from digital to analog, low-pass filtered at 4.8 kHz, amplified and presented diotically over linear headphones (Beyer DT-150) at approximately 70 dB SPL(A).

3. Procedure

a. Categorization training. Listeners were tested individually in sound-attenuating booths. On each trial, listeners heard a single stimulus, pressed one of two unlabeled buttons to record a categorization response and received feedback as to the correct response via illumination of a light above the correct response button.

Listeners were instructed that the task was to determine whether each sound belonged to the left-most or the right-most response button. The experimenter also informed listeners that, although they would need-to guess at first, they should attempt to use the feedback given on each trial to guide later responses. Participants were encouraged to attempt to get as many responses correct as possible. Feedback assignment followed the symbols of Fig. 1; stimuli represented as open circles were assigned to one category (one response button) whereas those illustrated as open diamonds were assigned to the opposite category (and button). Left versus right button assignment to stimulus distributions was counterbalanced across participants.

Each block of training included a single presentation of each of the 96 training stimuli. There were ten blocks of training overall and the order of stimulus presentation was randomized within each block. After each block, listeners were able to take a brief break.

b. Test. Following training, listeners completed five more blocks of the categorization task. Within a block, stimulus presentation was randomized. These blocks were identical to the previous training blocks, except that in addition to the original 96 training stimuli, novel generalization stimuli were introduced. On these trials, listeners did not receive informative feedback; lights above all of the buttons lit following the response. This approach was chosen so that listeners' categorization of the generalization stimuli could be observed without encouraging participants to learn labels for the generalization stimuli across the course of testing. Listeners continued to receive feedback on trials for which familiar training stimuli were presented to assure that they continued to assign category labels in a manner that respected the distribution characteristics and feedback assignments present in training. This model of feedback assignment and mixing of novel and familiar stimuli is identical to paradigms successfully used in studying nonhuman animal category learning (see, e.g., Kluender *et al.*, 1998). Continuing to provide feedback for familiar stimuli, but not for novel stimuli, provides a safeguard against responses that drift away from learned categories as a consequence of the distribution differences that novel generalization stimuli introduce in the input. It also encourages participants to remain engaged in the task.

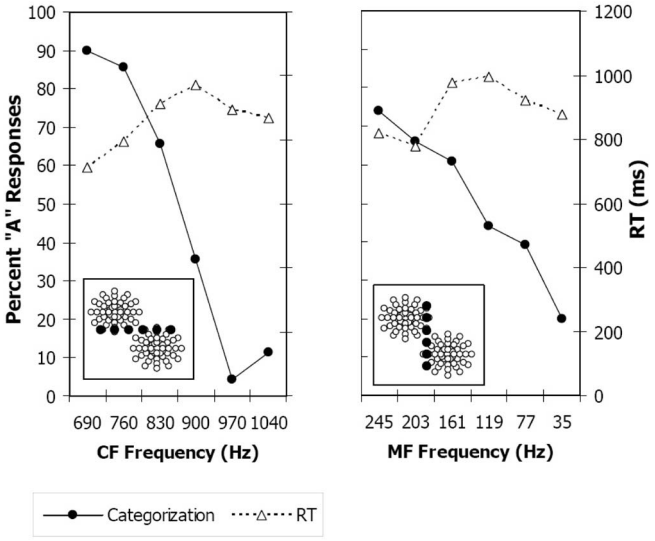

FIG. 2. Experiment 1 categorization responses and reaction time for generalization stimuli. Filled circles in the inset indicate the stimuli for which responses are plotted.

Participants completed both training and testing in a single experimental session lasting approximately 2 h.

B. Results and conclusions

The percent of "A" categorization responses was calculated whereby category "A" was arbitrarily assigned to be the category in the upper left corner of the two-dimensional acoustic space, indicated by open circles in Fig. 1(a). Overall, listeners performed fairly well in learning to categorize these unfamiliar sounds. Across the ten categorization training blocks, listeners' mean accuracy (i.e., responses consistent with feedback assignments) was $M = 87.25\%$, $SE = 0.016$. The orthogonal arrangement of the novel stimuli presented in the test blocks made it possible to assess categorization across one cue while the other was held constant. Figure 2 illustrates listeners' categorization responses and reaction times to the 12 generalization stimuli. The categorization functions averaged across listeners' responses to these novel stimuli hint that CF may have been more effective in cueing category identity because listeners were more adept at categorizing along the CF dimension than the MF dimension. An analysis of variance (ANOVA) of the percent "A" categorization responses as a function of the two orthogonal acoustic cues reveals that there was a statistically reliable Dimension × Stimulus Step interaction for both categorization response, $F(5,65) = 8.45$, $p < 0.0001$, $\eta_p^2 = 0.394$, and the reaction times, $F(5,65) = 2.77$, $p = 0.025$, $\eta_p^2 = 0.175$.

Cue weights were computed for each subject as the correlation between dimension values and percentage "A" responses across generalization stimuli. The absolute values of the correlation coefficients were normalized to sum to one.[2] These relative weights confirm the impression from the cat-

egorization functions of the dominance of the CF cue. The average weights were 0.658 for the CF cue and 0.342 for MF. The CF weight was significantly different from 0.5, meaning that listeners did not weight the two cues equivalently as may be expected given the match on informativeness.[3]

Two major conclusions may be made from the present study. First, listeners were able to learn to categorize novel acoustic stimuli effectively and did integrate information across the two dimensions (weights were above 0 for both dimensions). As such, this paradigm provides a useful means for examining cue weighting for categorization in a two-dimensional acoustic space. Second, despite the fact that the discriminability of the exemplars was psychophysically matched across the acoustic dimensions and despite the equivalent informativeness of the acoustic dimensions to the categorization task, listeners weighted CF more heavily than MF.

Of the 14 subjects, only one weighted MF higher than CF. Two participants used CF almost exclusively whereas the majority relied on both cues to some extent but weighted CF higher than MF. The reason for the dominance of CF is not immediately clear; we suggest some possibilities in the Sec. VI. However, it provides us with an opportunity to examine how changes in the training distribution characteristics may encourage listeners to shift their weighting functions.

III. EXPERIMENT 2

The aim of Experiment 2 was to determine whether listeners would make greater use of the MF cue in categorization under circumstances in which CF was rendered less informative. To accomplish this, the input distributions employed for Experiment 1 were shifted toward one another along the CF dimension, which resulted in greater overlap of the distributions on this dimension.

A. Methods

1. Participants

Fifteen volunteers recruited from Carnegie Mellon University participated for course credit or a small payment. All listeners reported normal hearing.

2. Stimuli

The two-dimensional stimulus space constructed for Experiment 1 was used again in Experiment 2, but the input distributions defining the two categories were moved closer to one another along the CF dimension. The centroids of the training distributions in Experiment 1 had CF values of 760 and 970 Hz (differentiated by seven stimulus steps or 210 Hz), respectively. In Experiment 2, these values were 820 and 910 Hz (three stimulus steps, 90 Hz). As a result of this stimulus manipulation, the category input distributions overlapped more along the CF dimension than the MF dimension. In other words, the CF dimension became less informative. By the informativeness metric introduced in Experiment 1, $I_{CF}=0.5$ (75% correct with optimal boundary). All other distribution characteristics were identical to those of Experiment 1. Therefore, the informativeness of the MF dimension was unchanged from Experiment 1 ($I_{MF}=0.916$).

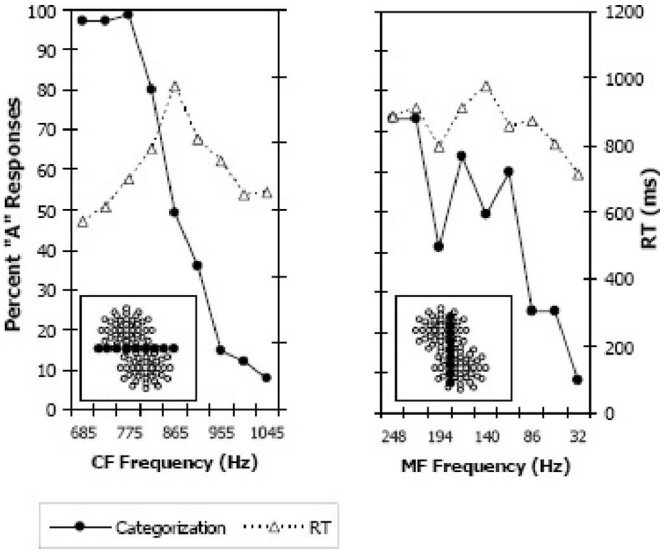

FIG. 3. Experiment 2 categorization responses and reaction time for generalization stimuli. Filled circles in the inset indicate the stimuli for which responses are plotted.

The new input distributions are illustrated as open symbols in Fig. 1(b). The generalization stimuli, which were identical to the stimuli from Experiment 1, are illustrated as filled circles in Fig. 1(b). To provide a finer sampling of categorization across the two cues, several additional stimuli were added to the novel stimulus set of Experiment 2; whereas there were 12 novel stimuli in Experiment 1, there were 17 in Experiment 2.

3. Procedure

The apparatus and procedures were identical to those used in Experiment 1.

B. Results and conclusions

Overall, listeners learned the categories very well, exhibiting a mean of 90.42% correct, $SE=1.46$, across the ten training blocks. Figure 3 illustrates listeners' categorization responses to the 17 generalization stimuli. Again, listeners' responses to the novel stimuli were more categorical along the CF dimension than the MF dimension. Supporting this conclusion, there was a significant Dimension × Stimulus Step interaction for both categorization responses, $F(8,112)=31.83$, $p<0.0001$, $\eta_p^2=0.695$ and reaction times, $F(1,112)=2.818$, $p=0.007$, $\eta_p^2=0.168$.

The average cue weights for the two dimensions were 0.664 and 0.336 for CF and MF, respectively. The relative weighting for CF was statistically equivalent to that obtained for Experiment 1, $t(27)=0.10$, $p=0.92$. Despite the reduced informativeness of CF for the task, listeners continued to rely on it in categorization judgments. Only two of the 15 subjects-gave greater weighting to the more informative cue (MF) and even in these cases the weights for CF and MF were approximately equal. Shifting the informativeness of the CF cue by moving the distribution means closer therefore was not effective in altering listeners' cue weighting.

IV. EXPERIMENT 3

The continued reliance on CF in Experiment 2 is surprising given that the observed pattern of cue weighting was a relatively inefficient weighting function for the training distributions. An obvious question is whether listeners' weighting functions are malleable at all. The goal of Experiment 3 was to present a categorization task that penalized a CF-dominant weighting function more than did the tasks of the previous two experiments. To accomplish this, we changed the variance of the training distributions in addition to changing the position of the centroids, as in Experiment 2.

A. Methods

1. Participants

Fourteen volunteers recruited from Carnegie Mellon University participated for course credit or a small payment. All listeners reported normal hearing.

2. Stimuli

The training distributions for Experiment 3 are shown in Fig. 1(c). The distribution centroids were identical to those of Experiment 2. In Experiments 1 and 2 the distributions spanned nine stimulus steps along each dimension. In Experiment 3, the variability along the CF dimension was increased (distributions spanned 15 stimulus steps) whereas the variability along the MF dimension was reduced (distributions spanned approximately five stimulus steps). The combined changes rendered MF a maximally informative cue for the categorization ($I_{MF}=1.0$) and CF a marginally informative cue ($I_{CF}=0.442$). The training distributions were composed of 86 unique stimuli. The generalization stimuli are illustrated as filled circles in Fig. 1(c) and are identical to those of Experiment 2.

3. Procedure

The procedure and apparatus were identical to previous experiments.

B. Results and conclusions

Across the ten training blocks, listeners exhibited a mean categorization accuracy of $M=78.1\%$, $SE=3.38$. Figure 4 illustrates listeners' categorization of the generalization stimuli by acoustic dimension. Unlike the previous experiments, there was no statistically significant dimension (CF versus MF) by stimulus step interaction in listeners' categorization responses, $F(8,104)=1.36$, $p=0.222$, $\eta_p^2=0.095$, or reaction times, $F(8,104)=1.73$, $p=0.10$, $\eta_p^2=0.117$. There was, however, a significant difference in overall reaction time, $F(1,13)=4.69$, $p=0.05$, $\eta_p^2=0.265$, with stimuli varying along the MF dimension categorized somewhat faster ($M=667.63$, $SE=43.01$) than stimuli varying along the CF dimension ($M=738.21$, $SE=68.5$).

The changes in distribution variances were effective in changing the preferred weighting of the dimensions. The average weight for CF was 0.395 with a corresponding MF weight of 0.65. The change in CF weight from Experiment 2 was significant, $t(27)=4.41$, $p<0.0005$. Eleven of the 14 subjects weighted MF greater than CF.

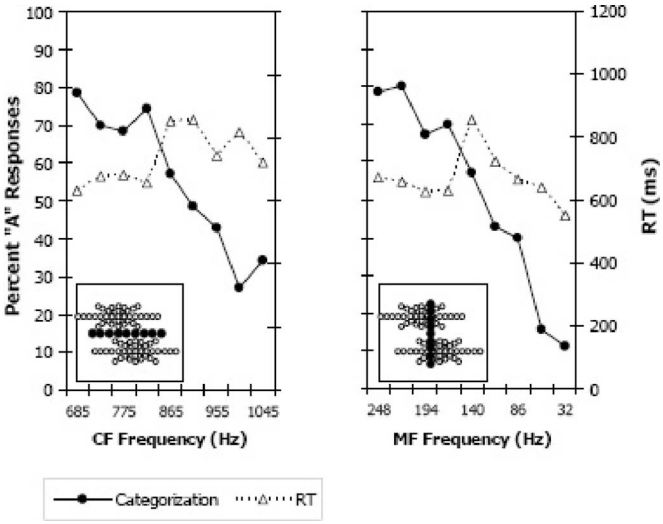

FIG. 4. Experiment 3 categorization responses and reaction time of categorization responses to novel generalization stimuli. Filled circles in the inset indicate the stimuli for which responses are plotted.

The results of Experiment 3 make it clear that weighting functions *can* be changed by the characteristics of the training distributions during a short learning session. Of theoretical and practical interest is the determination of which distributional characteristics can effect change in weighting functions. Distribution variance appears to be a better predictor of relative weighting than are measures of central tendency or our measure of informativeness. Whereas the shift in distribution centroids in Experiment 2 resulted in no change in weighting functions despite a large change in informativeness of the CF cue, the manipulations of variability in Experiment 3 led to a reversal of relative weighting with a smaller change in informativeness of the cues.

From the classic perspective that variability is the essence of information in perception, the lower weighting of the cue with greater within-category variability appears to be counterintuitive. For example, in experiments on sample discrimination in which listeners are asked to listen and respond to tones in a target frequency region, irrelevant tones in distant non-target frequency regions have little effect if they are fixed in frequency. However, when these distracter tones are allowed to vary in frequency, listeners' performance on the target task suffers dramatically (Lutfi, 1992; Neff and Odgaard, 2004). This effect can be thought of as a capture of selective attention by the variability of the irrelevant tones or it can be conceptualized as a greater weighting of highly variable components in the task, as in Lutfi's (1993) CoRE model. In the current experiment, the listeners seemed to be sensitive to increased variability across the CF dimension, as it led to a significant change in weighting functions. However, it was the lower-variance MF dimension that received the greater perceptual weight.

The details of sampling discrimination experiments and the current categorization experiments are too different to make direct comparisons that may illuminate the reason for

these different outcomes. However, the idea that the auditory system would be particularly sensitive to highly variable dimensions, *ceteris paribus*, is intuitively appealing. One may predict that exposure to variance along a dimension, with no attendant feedback, will result in this dimension becoming more heavily weighted. In Experiment 4 we investigated whether an acoustic dimension becomes more heavily weighted perceptually following exposure to its range of variability.

V. EXPERIMENT 4

Prior to categorization training in Experiment 4, listeners were exposed (without feedback) to stimuli varying along the MF dimension while CF was held constant at an intermediate value. It is predicted that this exposure independent of feedback for category membership will lead to a greater weighting of the MF dimension.

A. Methods

1. Participants

Fourteen volunteers recruited from Carnegie Mellon University participated for course credit or a small payment. All listeners reported normal hearing.

2. Stimuli

The distributions defining the categories were identical to those of Experiment 1. In addition, a set of generalization stimuli was created to more finely assess cue weighting across the acoustic space. The grid of filled symbols illustrated in Fig. 1(d) shows the position of these stimuli in acoustic space. This grid of novel stimuli, along with the cross of novel stimuli shown in Fig. 1(a), was presented to listeners in both Experiments 1 and 4.

In addition, another set of stimuli was created especially for Experiment 4. These stimuli were created as described for the previous experiments. They possessed a constant, intermediate CF frequency of 865 Hz and varied in MF from 5 to 275 Hz in 18-Hz steps. They are illustrated in Fig. 1(e) by the large open circle symbols.

3. Procedure

The apparatus and procedure were identical to those of Experiment 1. However, Experiment 4 participants completed a brief passive-listening segment before entering into categorization training. This segment lasted approximately 15 min. In that time, listeners heard the 16 stimuli illustrated in Fig. 1(e) as large open symbols 20 times each in random order. Listeners were instructed to simply listen to the sounds. Immediately after this passive exposure, listeners completed categorization training and generalization tests identical to those of Experiment 1. Thus, Experiments 1 and 4 differed only in the precategorization-training exposure.

B. Results and conclusions

A comparison of categorization accuracy during training across Experiments 1 and 4 reveals that the pretraining exposure to variability along the MF dimension had a significant influence on accuracy, $t(13)=2.19$, $p<0.05$. Across the ten training blocks, Experiment 4 listeners were significantly more accurate ($M=92.74\%$, $SE=0.02$) than Experiment 1 listeners ($M=87.25\%$, $SE=0.02$). Figure 5 illustrates listeners' categorization of the generalization stimuli cross stimuli [see Fig. 1(a)] by acoustic dimension.

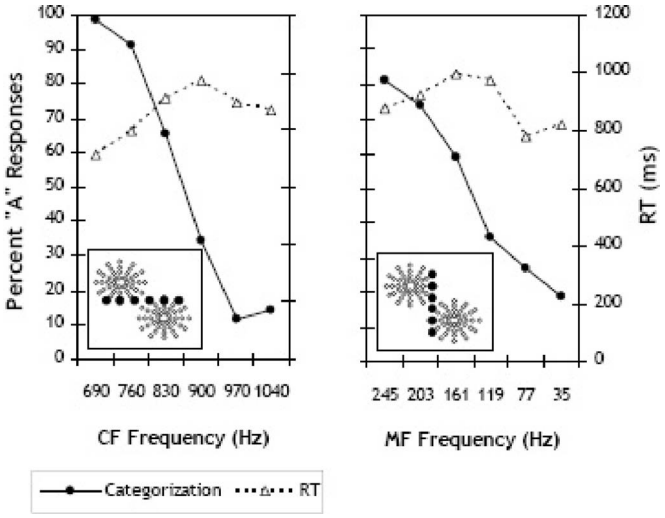

FIG. 5. Experiment 4 categorization responses and reaction time of categorization responses to novel generalization stimuli. Filled circles in the inset indicate the stimuli for which responses are plotted.

Calculations of cue weights also demonstrated that the passive exposure had an effect on categorization. Recall that Experiments 1 and 4 listeners also heard the grid of stimuli illustrated in Fig. 1(d). A contour plot illustrating listeners' categorization responses to the grid of novel generalization stimuli is shown in Fig. 6. When relative cue weights are calculated from responses to this grid of stimuli, Experiment 1 listeners exhibited a greater reliance on the CF dimension (0.744) than they did on MF (0.256). As predicted, the rela-

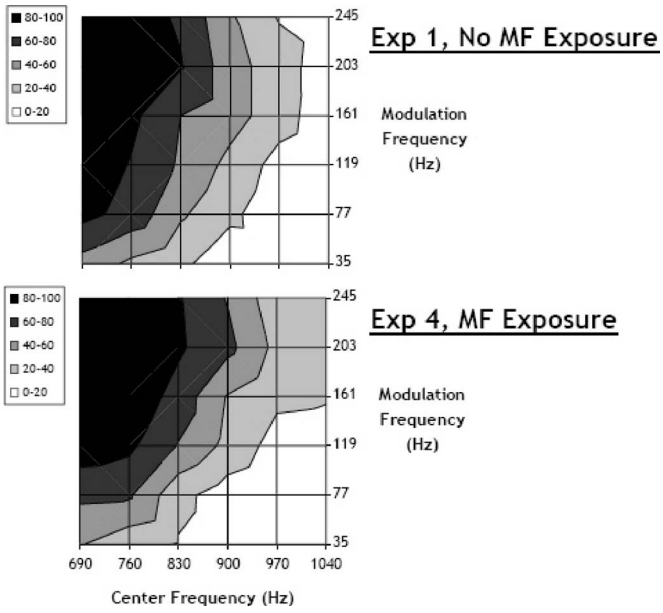

FIG. 6. Experiment 1 (no exposure to MF dimension) and Experiment 4 (exposure to MF dimension) categorization responses to generalization grid stimuli, as shown in Fig. 1(d), plotted as percent "A" category responses.

tive cue weight for CF was significantly lower for Experiment 4 (0.600) than for Experiment 1 (0.744), [$t(26)=1.75$, $p<0.05$, one tailed]. That is, preexposure to variability along the MF dimension with no feedback led listeners to rely upon MF in categorization responses moderately more than listeners who did not experience the preexposure (0.256 versus 0.400). These results suggest that the listeners were sensitive to the range of the MF dimension present in preexposure and treated it as a potential source of information. Note that this was a very conservative estimate of the effect of exposure to cue variability on cue weighting because the dependent variable was the categorization response to generalization stimuli presented at the end of categorization training. Still, a very short period of preexposure had an influence on cue weighting. It is quite possible that the categorization responses at the beginning of categorization training were more heavily weighted toward MF but that the preference for CF rebounded during training. The design of the current experiment makes it difficult to test this explicitly. However, the current evidence is suggestive of a role for unsupervised exposure with cue variability in determining weighting functions.

VI. GENERAL DISCUSSION

Although multiple cues define most auditory categories, including speech categories, how the auditory system integrates multiple acoustic dimensions in perceptual categorization is not yet well understood. The present work investigated cue weighting in auditory categorization, approaching the issue from the perspective that the perceptual system does not merely perceive acoustic dimensions and apply them as evidence for a particular category, but rather weights these dimensions as a function of characteristics of distributions of experienced sounds.

In the Introduction, we listed four variables that may affect the weighting functions for a categorization task. We summarize here the results of the experiments as they relate to these factors. The first of these potential factors was the informativeness of the cue for categorization. If the listener is weighting cues optimally then relative weightings should be predictable from relative informativeness (at least in terms of the rank ordering of the cues). The data from our experiments do not reveal such a direct relationship. In Experiment 1, CF received a much greater weighting despite the fact that the two cues were equal on our informativeness metric. CF continued to receive a higher weighting even when it was decreased in its informativeness to the categorization task in Experiment 2 by shifting the centroids of the distributions closer together on the CF dimension. We refer to a cue receiving a higher weight than dictated by its informativeness for the current task as having greater *salience* (cue *preference* or *bias* are other possible terms). Christensen and Humes (1996) also examined the categorization of nonspeech sounds differing on several dimensions and found that one of the cues tended to be weighted more despite equal informativeness for the task. However, their dimensions were not equated psychophysically for auditory step size. As a result, the weighting functions could have been reliably reflecting the informativeness of the psychoacoustic cues as opposed to the physical acoustic cues. In our experiments, the cue-weights were computed across equated psychoacoustic scales and thus reflect perceptual cue weighting.

What accounts for this salience? One possibility is that in the natural acoustic environment, CF is a more informative cue to auditory category identity than is MF. That is, in identifying a sound, the carrier frequency may provide more information or may be more reliably related to the distal source than is the rate at which the sound is modulated. Whereas we have no direct evidence that this is the case, it does have intuitive appeal. If this is the case, then listeners may come into the experiment with experience that is relevant to the task. A default higher weighting for CF could be a result of an innate predisposition (because the informativeness of CF has led to a fixed adaptation) or learned through experience. Similar patterns of differences in cue salience have been witnessed in studies of cross-modal integration. Battaglia, Jacobs, and Aslin (2003) report that visual cues are weighted more than auditory cues for spatial location even when the visual cues are not as reliably related to spatial location (see also Ernst and Banks, 2002, for an example of visual cue salience over haptic cues). Battaglia *et al.*. were able to model this influence by proposing that perceivers had *a priori* expectations of the reliability of visual information for spatial location (defined as a prior probability distribution for visual cue variance). Thus, perceivers appear to be weighting suboptimally within the context of the information in an experiment, but they may perceive optimally within the larger context of overall perceptual experience. The interaction of short-term (or local) informativeness and long-term (or global) informativeness will be an important area for future investigation.

A second factor that may affect cue weighting is distributional variance. Because our definition of informativeness is based on a criterion-based decision, variance and informativeness are not equivalent. In Experiment 3, we took the distributions from Experiment 2 and increased the within-category distribution variance along CF and decreased it along MF. The result was a small change in relative informativeness but a large change in the relative within-distribution variance for the two dimensions. Whereas the change in informativeness from Experiments 1 to 2 resulted in no change in perceptual cue weighting, the manipulation of within-category distribution variances led to a substantial change in weighting, with MF now the dominant perceptual cue. Because of the design of the experiments, it is not possible to establish exactly what caused the change in perceptual weighting from Experiment 2 to 3. The change in within-distribution variances resulted in changes in informativeness, the ratios of within- to between-distribution variance and correlations with the feedback for each cue. Further studies will be necessary to manipulate these factors independently. What is clear from these experiments is that changes in the central tendencies of the distributions (with concomitant changes in informativeness) do not appear to be effective in changing perceptual weighting functions, whereas changes in within-category variance can lead to significant perceptual change. Another open question is the influence of the pres-

ence of feedback on perceptual weighting. In Experiment 3, the CF dimension with greater within-category variance during training with feedback received the lower perceptual weighting. In Experiment 4, we presented the range of variability in MF with no feedback prior to the categorization training. This exposure resulted in a moderate increase in the relative weighting of the varied cue.[4] The present experiments do not allow us to fully dissociate the possible roles of variability along an acoustic cue with versus without explicit feedback for categorization; further studies will be necessary to investigate these manipulations independently. However, the present data are interesting in that they indicate that manipulation of distribution characteristics of acoustic categories plays a role in listeners' perceptual cue weighting.

A third factor that can affect cue weighting is how each dimension is represented by the auditory system. We attempted to account for some of the effects of auditory encoding by scaling our dimensions to equivalent auditory step sizes based on pilot testing of the stimuli. Whereas it is true that CF and MF are not independent in frequency modulation detection across a large range of values, we saw no evidence of interaction in our constrained ranges; we avoided very low MF values and created stimuli within a MF range where these dimensions are relatively independent (Demany and Semal, 1989). We did not model the effects of internal noise on the representation of our cue values. We correlated responses with the step size values of our stimuli as though these values are represented perfectly by the auditory system. The General Recognition Theory (GRT, Ashby and Townsend, 1986), a model of categorization developed mainly from visual categorization experiments, represents stimuli as multivariate probability distributions in perceptual space as opposed to points. Likewise, the COSS (conditioned-on-a-single-stimulus) analysis of perceptual weights developed for multicomponent psychoacoustic tasks (Berg, 1989) internal noise is an explicit parameter. It is likely that models of cue weighting in phonetic and other auditory categorization tasks will require a more detailed estimate of the auditory representation of the stimuli than we have used here.

The fourth potential factor affecting cue weighting is task. All of the experiments presented here were categorization tasks in which subjects were asked to maximize accuracy, so the present data do not speak to manipulating cue weighting through task adjustments. Nevertheless, task manipulations could be easily implemented in the present paradigm and would be particularly interesting to investigate in future research. In speech perception research, it is common to examine speech categories with categorization or discrimination paradigms. If one presumes that both paradigms access the same category representation, then they can provide converging evidence about auditory categories. However, if listeners modify their weighting functions to maximize performance given particular task constraints then discrimination and categorization data may not always coincide (e.g., Mirman *et al.*, 2004).

A. Implications for L2 phonetic acquisition

In the Introduction, we discussed the proposal that one of the obstacles to acquiring L2 phonetic categories could be a mismatch between weighting functions appropriate for L1 and L2. For example, Lotto *et al.* (2004) estimated the phonetic distributions for syllable-initial /r/ and /l/ from native-English productions and determined that the optimal weighting strategy for categorization was a very heavy perceptual weight on F3-onset frequency and a much lower weight on F2-onset frequency. In a follow up, Lotto *et al.* demonstrated that the optimal weighting pattern for the Japanese distinction between /w/ and /r/ (a distinction often considered to interfere with acquisition of the English liquid contrast) was just the opposite, with a higher weighting of F2-onset frequency. Thus, one may predict that Japanese listeners would have difficulty with the English contrast (and vice versa) because of the mismatch in learned weighting functions. In fact, perception and production studies both indicate that native Japanese listeners weight F2-onset higher than F3-onset for the English contrast (Yamada and Tohkura, 1990; Iverson *et al.*, 2003, 2005; Lotto *et al.*, 2004). This inappropriate weighting of F2 resembles the salience of CF in the current studies. Given the similarity, our results detailing effective and ineffective means of shifting weighting functions may have relevance for training L2 learners. In particular, the lack of weighting shift between Experiments 1 and 2 suggests that changing the informativeness of cues by shifting the average cue values (e.g., enhancing the difference in F3-onset values or decreasing the differences in F2-onset for /l/-/r/ stimuli presented to Japanese listeners) may not result in a significant change in categorization. On the other hand, the reversal of the perceptually dominant cue from Experiments 2 to 3 demonstrates that adding variance to an over-utilized cue (e.g., allowing F2 onset to vary independent of whether the sound is /l/ or /r/) may be an effective strategy to change listeners' weighting functions. In addition, the effect of preexposure to cue variance in Experiment 4, emphasizes the notion that the proper manipulation of variance may be essential to appropriate category acquisition.

In some earlier attempts to train adults on non-native contrasts the training sets did not contain much variance (e.g., Strange and Jenkins, 1978). As a result, the trainees were able to learn to discriminate the training stimuli but were not able to transfer this learning to new stimuli and contexts. In more recent attempts at L2 training, it has become clear that added variance in the training set (e.g., more speakers, more phonetic contexts) aids learning and generalization (Bradlow *et al.*, 1997; Jamieson and Morosan, 1989; Lively *et al.*, 1993). It is quite possible that a major benefit of high-variability training is that less informative cues will vary more within a category across multiple exemplars while more informative cues will be relatively more stable. As in Experiment 3, these changes in relative variance may be most effective at changing weighting functions. The importance of variance for category learning may even be seen in L1 acquisition. The speech that adults direct to their children ("motherese" or infant-directed speech) is actually *more* acoustically variable than speech directed to other adults

(Kuhl *et al.*, 1997). This seems counter intuitive unless one appreciates that infants must use the variance in speech input to determine which features are phonetically-relevant and which are not.

VII. SUMMARY

Of course, it is important to keep in mind that the categories of the present experiments were formed on the basis of an hour or so of experience whereas phonetic categories have the benefit of much greater experience, even among the youngest listeners. Nevertheless, we believe there is much to be gained for an understanding of phonetic cue weighting from laboratory studies that investigate cue weighting in general auditory (nonspeech) categorization. The purpose of the experiments presented here was to examine cue weighting in auditory categorization with well-defined training distributions for which experience could be entirely controlled. This allowed us to define the informativeness of each cue for the task and examine how changes in training distributions affect weighting functions. The long-term goals of this project are to establish a framework for testing models of cue weighting in phonetic categorization. It should be noted that there have been many models of perception, in general, and speech perception, in particular that have included cue weighting explicitly or implicitly. For example, Massaro's (1987; 1998) fuzzy logic model of perception (FLMP), Nosofsky's (1992) generalized context model (GCM), and connectionist models (e.g., TRACE, McClelland and Elman, 1986; Damper and Harnad, 2000) inherently weight cues in coming to a category decision. In order to provide a strong test of these models as a basis of speech perception, one needs good estimates of the distributions of phonetic category exemplars across the various dimensions. In addition to auditory cues, any full specification of phonetic categories would include visual cues, which can also be weighted in a categorization decision (Massaro, 1998). These kinds of estimates are rare.

We believe that nonspeech category tasks such as the ones presented here will play an important role in the development of models of auditory cue weighting. Whereas they do not have the ecological advantages of speech perception tasks, nonspeech tasks allow a level of stimulus and distribution control that allows one to investigate the constraints of the categorization process in detail.

ACKNOWLEDGMENTS

This work was supported by a National Science Foundation grant (NSF BCS-0078768) to L.L.H. and A.J.L. and by a James S. McDonnell Foundation award for Bridging Mind, Brain, and Behavior, to L.L.H. The authors thank Christi Adams for her essential role in conducting the experiments.

[1]An additional grid of 36 novel stimuli [pictured as filled circles in Fig. 1(d)] was also presented to Experiment 1 listeners for comparison with Experiment 4. Responses to these stimuli are discussed with the results of Experiment 4.

[2]It is typical in cue-weighting experiments in psychoacoustics and speech perception to normalize the weights (e.g., Berg, 1989; Christensen and Humes, 1996; Doherty and Turner, 1996; Lutfi, 1992). The result provides a comparison of the relative weighting of cues. Because this normalization scheme does not take into account the accuracy of listeners' categorizations, it can lead to problems with interpretation. For example, guessing randomly in Experiment 1 or responding perfectly with a rational weighting strategy would both result in equal normalized weights of 0.5. Given the high level of accuracy attained by listeners in the experiments presented here, we believe that this ambiguity is less of an issue than it may be for more complex tasks.

[3]All statistical tests for cue weights were performed only on the CF weights, as the MF weights are simply 1 minus the CF weight.

[4]These results may relate to an issue that we have avoided for the most part. There has been a tendency in the literature to equate cue weighting with selective attention. Some models of categorization explicitly equate weighting with attention (e.g., Nosofsky, 1986). The sensitivity of the auditory system to variability as demonstrated in psychoacoustic tasks (e.g., Lutfi, 2003; Neff and Odgaard, 2004) can be interpreted as variability capturing selective attention. The results of Experiment 4 also fit this interpretation. The change in weighting with variance manipulations between Experiments 2 and 3 demonstrate a possible dissociation between weighting and attention. Francis and Nusbaum (2002) have also called into question the viability of simple attentional models in phonetic category learning.

Early learners' discrimination of second-language vowels

Anders Højen[a] and James E. Flege[b]
Speech and Hearing Sciences Division, University of Alabama, Birmingham, Alabama 35294-2041

(Received 21 March 2005; revised 7 February 2006; accepted 14 February 2006)

It is uncertain from previous research to what extent the perceptual system retains plasticity after attunement to the native language (L1) sound system. This study evaluated second-language (L2) vowel discrimination by individuals who began learning the L2 as children ("early learners"). Experiment 1 identified procedures that lowered discrimination scores for foreign vowel contrasts in an AXB test (with three physically different stimuli per trial, where "X" was drawn from the same vowel category as "A" or "B"). Experiment 2 examined the AXB discrimination of English vowels by native Spanish early learners and monolingual speakers of Spanish and English (20 per group) at interstimulus intervals (ISIs) of 1000 and 0 ms. The Spanish monolinguals obtained near-chance scores for three difficult vowel contrasts, presumably because they did not perceive the vowels as distinct phonemes and because the experimental design hindered low-level encoding strategies. Like the English monolinguals, the early learners obtained high scores, indicating they had shown considerable perceptual learning. However, statistically significant differences between early learners and English monolinguals for two of three difficult contrasts at the 0-ms ISI suggested that their underlying perceptual systems were not identical. Implications for claims regarding perceptual plasticity following L1 attunement are discussed. © *2006 Acoustical Society of America.*

I. INTRODUCTION

It is well established that the age at which a second language (L2) is learned will exert a long-term effect on segmental phonetic perception. "Early learners" first exposed to their L2 as children resemble native speakers to a greater extent than do "late learners" whose first exposure to the L2 occurred in late adolescence or early adulthood (Flege *et al.*, 1999; Flege and MacKay, 2004; Yamada, 1995). It is uncertain, however, whether early learners will in time come to perceive L2 vowels and consonants just like native speakers of the target L2. Some studies have provided evidence of substantial differences between early learners and L2 native speakers whereas others have shown evidence of little or no difference. These divergent findings raise questions regarding the extent to which the speech perception system remains plastic following attunement to the native language (L1) sound system. The aim of this study, therefore, was to further evaluate early learners' perceptual abilities. It did so by examining the discrimination of English vowels by native Spanish speakers who had learned English as an L2 in childhood.

A. Previous research

Infants begin to perceive speech in a language-specific way during the first year of life (e.g., Kuhl *et al.*, 1992; Werker and Tees, 1984). As they develop perceptual processes specialized for perceiving phonemic contrasts used to contrast meaning (words) in the ambient language, infants' sensitivity to contrasts not serving such a function declines. The influence of this attunement to the L1 sound system is evident in the difficulties that adult L2 learners may have in distinguishing certain nonnative phonemic contrasts (e.g., in native Japanese speakers' difficulty in distinguishing English /ɹ/ and /l/).

It has been proposed that as people grow older, L2 learning is hindered by a loss of neuroplasticity that accompanies normal neural maturation (e.g., Long, 1990; Scovel, 2000). More recently, a loss of plasticity for speech perception has been discussed in the context of the effects of L1 perceptual attunement on subsequent perceptual learning rather than, or in addition to, a maturationally defined decrease of neuroplasticity that affects basic aspects of sensory coding, storage, and retrieval associated with speech learning. More specifically, it has been argued that L2 speech acquisition is impeded by the acquisition of the L1 phonological system (e.g., Flege, 1995; Iverson *et al.*, 2003; Kuhl, 2000; McClelland, 2001; Pallier *et al.*, 1997, 2003; Sebastián-Gallés and Soto-Faraco, 1999).

One influential account of the effect of L1 perceptual attunement on L2 perception is the native language magnet (NLM) theory (e.g., Kuhl *et al.*, 1992; Kuhl and Iverson, 1995). According to the NLM, during the first year of life L1 phonetic prototypes begin to act as perceptual "magnets" that "warp" auditory input. This would be expected, for example, to reduce the discriminability of L1 vowel tokens near the category center (the prototype) whereas equally distant tokens from the category boundary region, or from two different categories, would be expected to remain highly discriminable.

The NLM predicts that as an L1-specific "perceptual map" is developed, the identification of L1 speech sounds will become more robust whereas learning to perceive instances of new, L2 categories may become difficult. This might hold true, for example, if tokens of two distinct L2 vowel categories straddle the center of a vowel category in the L1 of a learner. Tokens of both L2 vowels would tend to be "attracted" by the same L1 prototype, effectively reducing perceptual distance between the L2 vowel tokens. For a native speaker of the L2, on the other hand, the perceived distances between the two tokens would be augmented by the perceptual magnet effect given that the tokens would be differentially categorized, and thus attracted by two different prototypes (see also Flege *et al.*, 1994).

Iverson *et al.* (2003) suggested that an L1-conditioned warping of the auditory properties of incoming speech occurs at an early phonetic or late auditory level of processing and may be difficult to reverse later in life. This view was supported by the results of five studies examining the perception of Catalan vowels by young native Spanish adults who had begun learning Catalan in Barcelona by the age of 6 years. Using different testing techniques, all assessed the perception of Catalan /e/ and /ɛ/, which straddle the category center of Spanish /e/. In each study, the Spanish early learners of Catalan differed from native speakers of Catalan in perceiving Catalan /e/ and /ɛ/ (Bosch *et al.*, 2000; Pallier *et al.*, 1997, 2001; Sebastián-Gallés and Soto-Faraco, 1999). Most recently, Sebastián-Gallés *et al.* (2005) presented Catalan words and nonwords (created by changing /e/ to /ɛ/ and /ɛ/ to /e/) for lexical decision. The early learners obtained significantly lower scores than Catalan native speakers did, and also showed a wider range of scores.

The research on early native Spanish learners of Catalan suggested a number of important conclusions. One was that the speech perception system "does not seem able to easily develop new phonemic categories" after perceptual attunement to the L1 phonological system (Bosch *et al.*, 2000, p. 193). Another was that early learners exhibit a "lack of behavioral plasticity" (Pallier *et al.*, 1997, p. B9) with respect to learning to perceive contrastive phonemes of an L2. Still another was that "there are severe limitations to the malleability of the initially acquired L1 phonemic categories even under conditions of early and extensive exposure" (Sebastián-Gallés and Soto-Faraco, 1999, p. 120).

The results of two studies examining the perception of English vowels by native Italian immigrants to Canada suggested a different conclusion regarding the perceptual ability of early learners. Both of these studies used a triadic categorial discrimination test (CDT) in which the task was to identify the serial position of an odd item out (in change trials) or to indicate that all three tokens were instances of a single category (in no-change trials). Flege *et al.* (1999) tested early native Italian learners of English who reported using Italian relatively often ("high-L1-use" group) or seldom ("low-L1-use" group). The low-L1-use group did not differ from native English (NE) monolinguals in discriminating English vowels whereas the high-L1-use group was found to differ marginally from the NE group. A similar result was obtained by Flege and MacKay (2004), who observed a significant vowel discrimination difference between NE speakers and an early high-L1-use group but not an early low-L1-use group. The authors interpreted this finding to mean that early exposure to the L2 does not guarantee the formation of new phonetic categories for L2 vowels, but that category formation will be more likely for individuals who use their L1 infrequently.

The research with Spanish learners of Catalan suggested that early learners are unlikely to perceive L2 vowels in a nativelike way whereas the research with Italian learners of English suggested that early learners may closely resemble L2 native speakers, at least those who use the L1 infrequently. The basis for the apparent divergence in findings obtained for early L2 learners in Canada and Spain (Barcelona) is uncertain. It was not reported how often the early learners in Barcelona used their L1 (Spanish). Perhaps they differed from native speakers because they used their L1 as frequently as the "high-L1-use" participants in the Canadian research (*viz.* an approximately equal L1-L2 use). Other possible explanations for the differing results obtained in Canada and Spain include differences in the perceived relation between the L1 and L2 vowels examined, use of diverse testing techniques that might have induced different levels of processing, the age of the participants, and the amount of foreign-accented L2 input the participants might have received.

Obtaining a better understanding of early learners' perception of L2 vowels is important because it is relates to the more general issue of perceptual plasticity in human speech. Native-nonnative differences might be attributed to a loss of plasticity arising either from a reduced capacity to use one or more processes needed to develop language-specific, long-term memory representations for vowels and consonants, or from the persistent influence of prior learning on subsequent learning [e.g., the early-level "warping" of input due to the effect of L1 "magnets;" see Iverson *et al.* (2003)]. Alternatively, native-nonnative differences might be attributed to differences in attention and/or input, or to the inability to sustain an optimal representation of more than one linguistic system (Grosjean, 1989).

Even assuming that the speech perception system remains fully plastic after the L1 sound system has been established, it is probably unreasonable to suppose that early learners' perception of L2 vowels could ever be identical to that of L2 native speakers. This is because perceptual maps are presumably based on the statistical properties of individuals' linguistic input (e.g., Kuhl, 2000; Kluender *et al.*, 1998), which can never have been the same for individuals with different L1s. That being the case, identical perception by groups of early learners and L2 native speakers should probably not be used as a litmus test for whether the speech perception system does or does not remain plastic following L1 perceptual attunement.

B. The present study

The aim of most previous L2 vowel perception research evaluating perceptual plasticity has been to determine if groups of early learners did or did not differ significantly from a control group of L2 native speakers. A more informa-

tive way to assess perceptual learning by early learners may be to compare their performance to that of two control groups, *viz.* L2 native speakers (as in past research) and monolingual native speakers of the early learners' L1. The present study compared the English vowel discrimination of early native Spanish learners of English to that of English monolinguals and Spanish monolinguals. Comparing the early learners' performance to that of English monolinguals provided a way to determine if their perceptual learning was complete. Comparing their performance to that of Spanish monolinguals provided a way to determine how much the early learners had learned, even in the absence of complete learning.

Including Spanish monolinguals ruled out the use of testing techniques that presupposed, even indirectly, a knowledge of English, e.g., forced choice identification or goodness rating. Although the CDT used in the research on Italian learners of English has certain advantages, it does not control response bias as effectively as another discrimination test widely used in cross-language and L2 research, the categorial AXB test (e.g., Best *et al.*, 1996, 2001; Harnsberger, 2001; Polka, 1995; Polka and Bohn, 1996).

A problem for the categorial AXB test, on the other hand, is that it has often yielded near-ceiling discrimination scores (90%–100% correct) for pairs of foreign vowels likely to have been perceived as instances of a single L1 category (Best *et al.*, 1996; Polka, 1995; Polka and Bohn, 1996). This suggests that the AXB paradigm may not constitute a "phonetically sensitive" test of L2 vowel discrimination in the sense that pairs of L2 vowels showing a 2-to-1 cross-language mapping pattern might be successfully discriminated on the basis of low-level (perhaps auditory) memory codes rather than different language-specific phonetic codes. Such a response would present a problem for the present study, given the plan to use the Spanish monolingual control group as a baseline to assess how much perceptual learning the early learners had shown. The Spanish monolingual reference group could not serve this function if it obtained near-ceiling scores due to the use of nonphonetic encoding strategies. Thus, for purposes of this study, an ideal ("phonetically sensitive") AXB test would be one that yielded near-ceiling scores for English monolinguals but near-chance scores for Spanish monolinguals for English vowels heard as instances of a single Spanish vowel category.

The decision was made to use the categorial AXB paradigm here, but to carry out preliminary research (experiment 1) to find a variant that would reduce scores to near-chance levels for contrasting foreign vowels heard as instances of a single L1 category. This ambitious goal was not fully met in experiment 1, but this experiment did nonetheless reveal a way to make the AXB test more phonetically sensitive. The procedures developed in experiment 1 were therefore used in experiment 2 to assess the discrimination of English vowels by native Spanish early learners, English monolinguals, and Spanish monolinguals.

II. EXPERIMENT 1

The aim of this experiment was to identify a phonetically sensitive variant of the categorial AXB discrimination test, which would yield near-ceiling scores for listeners who perceive contrasting vowels as distinct phonemes, but near-chance scores for listeners who perceive contrasting foreign vowels as instances of a single L1 category. Such a pattern of scores for Spanish and English monolinguals in experiment 2 would make it possible to assess the extent of perceptual learning by native Spanish early learners. It was not possible to recruit a sufficient number of Spanish monolinguals for this preliminary experiment as well as experiment 2. Therefore, the decision was made to test English adults on vowels drawn from a language they had never heard before, *viz.* Danish.

Previous cross-language research using the AXB discrimination test has often yielded near-ceiling scores for vowels even when tokens drawn from contrasting foreign vowel categories were classified as instances of a single L1 category (Best *et al.*, 1996; Polka, 1995; Polka and Bohn, 1996). This evidence of successful within-category vowel discrimination indicates that listeners are able to base their judgments in an AXB test on more than just language-specific phonetic codes.

Hessen and Schouten (1992) discussed the nature of processes that might be applied in the discrimination of speech sounds that are perceived as either within-category or between-category contrasts. Combining elements from dual processes theory (Fujisaki and Kawashima, 1970) and trace-context theory applied to speech (Macmillan *et al.*, 1988), Hessen and Schouten's (1992) phoneme perception theory (PPT) posits three processes for the encoding of stimuli drawn from a speech sound continuum: trace coding, context (or position) coding, and labeling. In *labeling*, the trace is mapped onto the permanent context (the language-specific sound system) and is given a phonetic label (Hessen and Schouten term it a "phoneme label"). In *context coding*, the trace is mapped onto the experimental context. The listener positions each stimulus in relation to the full range of stimuli presented and gives it a temporary sublabel, possibly relating it to "anchors" among the stimuli in the form of extreme or best category members. The sensory *trace* is stored with all acoustic information intact (except for sensory noise) but decays rapidly after a few hundred milliseconds. Seen from the perspective of the PPT, foreign vowel tokens given different phonetic labels (between-category contrasts) would be discriminated based on the labels, whereas tokens given the same label (within-category contrasts) must be discriminated using context codes or the sensory trace.

Above-chance categorial AXB discrimination of foreign vowels given the same phonetic label might be based on context codes. (Discrimination is less likely to be based on the sensory traces when all stimuli in a trial are physically different.) For example, native English speakers might label (covertly or overtly) the German vowels in an [y]-[y]-[u] trial as "two foreign-sounding u-vowels" followed by "one overly clear English u-vowel" (or some other *ad hoc* label). The use of such a strategy would be unfortunate in experi-

ment 2, where we wished to determine if Spanish early learners manage to discriminate English vowels like native English speakers by generating contrasting phonetic labels (which, of course, implies the establishment of new perceptual English vowel categories).

Accordingly, procedures that might hinder trace or context-coding strategies were evaluated. According to the PPT (Hessen and Schouten, 1992), increased "context variance"—obtained by increasing the range of stimuli presented—limits listeners' ability to hold context codes in memory. This motivated our decision to evaluate the influence of block structure. In previous applications of the AXB test, the trials testing various contrasts of interest have been presented in separate blocks. This experiment compared the discrimination of four Danish vowel contrasts when presented in separate blocks (small stimulus range) and when presented in one large randomized block (large stimulus range).

A second modification of the standard AXB format evaluated in this experiment was suggested by the results obtained in a study that focused on discrimination of stress placement (Dupoux *et al.*, 2001). The vowel stimuli were produced with either a relatively high or low fundamental frequency ($F0$). The $F0$ variations that occurred within trials were clearly audible, but were independent of category identity. We reasoned that noncriterial $F0$ variation would make context codes less useful for discrimination by diverting attention away from the dimensions that signaled vowel category identity. In addition, even if categorically relevant acoustic information became part of the context code for a stimulus, uncorrelated or misleading $F0$ information might place demands on memory that could negatively affect performance. Finally, $F0$ variation would likely also hamper the use of sensory traces.

The questions raised by this methodological experiment were as follows. First, would English monolinguals obtain lower scores in a nonblocked than blocked condition? Second, would the introduction of $F0$ variation serve to reduce scores? Third, would the two manipulations just mentioned affect performance on vowels perceived as within-category contrasts but not between-category contrasts (for which discrimination could be based on phonetic labels)?

A. Methods

1. Participants

Most of the 45 English monolinguals ("E-monolinguals") recruited for this experiment came from the southeastern portion of the U.S. (28 were from Alabama). None of the E-monolinguals reported being able to speak a language other than English, and none had previous exposure to Danish. Fifteen participants each (12 females) were randomly assigned to one of three conditions: "blocked" (the traditional approach in AXB tests), "mixed" (in which trials testing four contrasts were randomly presented in one large block), or "mixed/$F0$" (one large block, $F0$ variation introduced within trials).

Participants assigned to the three conditions differed little in mean age (blocked=27 years; mixed=28 years, mixed/$F0$=27 years). Three native speakers of Danish (mean age=34 years, 2 females) served as a reference group and took the test in the mixed/$F0$ condition. One Dane had been living in the U.S. for two months when tested, the other two for less than 2 weeks. All 48 participants were paid, and all passed a pure tone hearing screening at octave frequencies from 250 to 4000 Hz (25 dB).

2. Stimuli

Nonwords were used as stimuli because, in L1 development at least, correct discrimination rates may differ between real words and nonwords (e.g., Stager and Werker, 1997). Had real Danish words been used in the present experiment, the Danes might have enjoyed a lexical advantage not shared by the E-monolinguals.

The first author, a native Danish speaker then living in the United States, selected the four vowel contrasts to be examined based on published descriptions of Danish and English vowels (Grønnum, 1998; Steinlen, 2005) and his own intuitions about which Danish vowels might be difficult for E-monolinguals to discriminate. The inference that E-monolinguals will tend to hear Danish [uːˀ] and [ɔ̝ːˀ]) as two distinct English vowels (/u/ and /o/, respectively) was confirmed by a preliminary cross-language classification test in which ten Native English speakers classified the tokens of the eight Danish target vowels used to form the four contrasts. This Danish contrast ([uːˀ]-[ɔ̝ːˀ]) was therefore designated the "easy" contrast. Three other Danish contrasts were designated the "difficult contrasts" (D1, D2, D3) because, as expected, the two vowels in each contrast tended to be classified as a single English vowel: [e̞] and [e] 85% of the time, usually as English /ɪ/; [iːˀ] and [e̞ːˀ] 99% of the time, usually as English /i/; [y] and [ø] 88% of the time, usually as English /u/.

Different flanking consonants were used for the four Danish contrasts: /gl_s/ for the easy [uːˀ]-[ɔ̝ːˀ] contrast, /fl_s/ for the [e̞]-[e] contrast (D1), /kl_s/ for the [iːˀ]-[e̞ːˀ] contrast (D2), and /tj_s/ for the [y]-[ø] contrast (D3). These consonant sequences are legal in English. One might object that the initial /tj/ context for D3 is "foreign" for English speakers; however, its typical phonetic realization ([tᶜ]) closely resembles English [tʃ] (Grønnum, 1998).

The stimuli were produced by a native Danish male and recorded (Shure SM81 microphone, Tascam DA-302 DAT) in a sound booth. All stimuli used in the blocked and mixed conditions, and half of those used in the mixed/$F0$ condition, were produced in a declarative carrier sentence (*Det hed virkelig*_____*engang*, approximately "It really was _____ once"). The remaining half of the stimuli used in the mixed/$F0$ condition were produced in an interrogative sentence (*Hed det virkelig*_____*engang*?, "Was it really _____once?"), which yielded a relatively high $F0$ in the variable target words.

After the digitization (22.05 kHz, 16 bit), the CCVC stimuli were edited out and normalized for rms amplitude. Eight tokens for each of the eight Danish target vowels were selected. The intent was to select tokens that minimized acoustic phonetic variation within the eight tokens of each vowel category. The exception, of course, was $F0$ for tokens

selected for the mixed/$F0$ condition. For this condition, the four tokens per vowel category produced in the declarative frame had a mean $F0$ of 108 Hz at the vowel midpoint (range=102–117), and the four tokens per vowel produced in the interrogative frame had a mean $F0$ of 139 Hz (range =134–146 Hz).

3. Procedure

All 48 participants were tested on 256 AXB trials. Each of the four contrasts was tested by 64 trials with all possible AB combinations of the eight tokens of each vowel presented with an equal number of each trial type (AAB, ABB, BAA, and BBA). There was a complete and balanced rotation of the stimuli in the three positions in the triad; the three stimuli in each trial were always physically different. Participants in the blocked condition heard trials testing the four contrasts in separate, counterbalanced blocks (Latin square). For participants in the mixed condition, trials testing the four contrasts were presented in a single randomized block (with appropriate breaks). The same held true for the mixed/$F0$ condition which, in addition, introduced variation in $F0$.[1]

The stimuli were presented via headphones at a self-selected comfortable level to the participants, who were tested individually in a sound booth. The participants were told to push a button labeled "1-2" if they heard a match between the first and the second stimuli (i.e., A and X), and the "2-3" button if the second and third stimuli (X and B) matched. The interstimulus interval (ISI) for all trials was 1000 ms. A 1200-ms interval occurred between each response and the following trial.

To ensure that participants understood the task, the test was preceded by a practice block with 20 easy trials consisting of stimuli not used in the experiment. Feedback was provided during this block, but not during the experiment. Also unlike the experiment, trials could be replayed. All participants were required to respond correctly to at least 18/20 practice trials before proceeding to the experiment. All did so within four attempts.

The same 256 trials were presented in the blocked and the mixed conditions. In the mixed/$F0$ condition, half of tokens had relatively high (H) $F0$ and half had a relatively low (L) $F0$. Each trial in this condition manifested one of the following types of $F0$ pattern. In "no $F0$ change" trials, all three tokens had either H or L $F0$. In "neutral" trials, $F0$ could not influence responses because the $F0$ of the X stimulus differed from both A and B (HLH or LHL). In "congruent" $F0$ trials, $F0$ similarities "suggested" the correct response because the $F0$ level of the X stimulus was the same as that of the categorically same vowel. Conversely, in "incongruent" trials, the $F0$ suggested the wrong response, i.e., participants would always go wrong if they based their responses solely on $F0$ similarities among the three stimuli in a trial (e.g., HHL $F0$ in an [y]-[ø]-[ø] trial).

B. Results

As expected, the three Danes obtained high scores for the "easy" contrast ($M=100\%$) and also the three difficult contrasts (D1 $M=99\%$, D2 $M=96\%$, D3 $M=94\%$). The

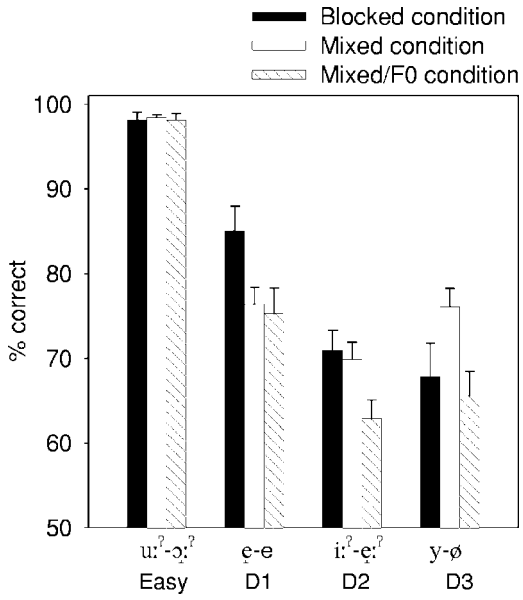

FIG. 1. Mean percent correct AXB discrimination of one "easy" and three "difficult" (D1, D2, D3) Danish vowel contrasts by three groups of English monolinguals assigned to one condition each. Error bars bracket 1 standard error.

E-monolinguals obtained high scores for the easy contrast ($M=98\%$) but, as shown in Fig. 1, substantially lower scores for the three difficult contrasts. Their scores for the difficult contrasts ranged from 63% correct for [iː?]-[e̞ː?], in the mixed/$F0$ condition, to 85% correct for [e̞]-[e], in the blocked condition. Single sample t tests showed that the E-monolinguals' scores for all three difficult contrasts significantly exceeded the chance level of 50% correct in all three testing conditions [$t(14)=4.4$ to 13.5, $p<0.001$].

The E-monolinguals' scores were submitted to an ANOVA in which condition (blocked, mixed, mixed/$F0$) served as a between-subjects factor and vowel contrast (four levels) was a repeated measure. The ANOVA yielded a significant interaction [$F(6,126)=4.2$, $p<0.001$], which was explored through tests of simple effects. The simple effect of condition was nonsignificant for the easy contrast [$F(2,42)=0.1$, $p=0.95$] but significant or marginally significant for the three difficult contrasts [D1 $F(2,42)=3.9$, $p=0.027$; D2 $F(2,42)=3.9$, $p=0.029$; D3 $F(2,42)=3.2$, $p=0.051$]. Tukey tests revealed that lower scores were obtained for D1 and D2 in the mixed/$F0$ condition than in the blocked condition ($p<0.03$). No other differences between conditions reached significance.[2] The lack of a significant difference between the blocked and mixed conditions indicated that simply combining the trials testing the four contrasts in a single randomized block was not sufficient to lower discrimination scores. This suggested that the difference between the blocked and mixed/$F0$ conditions was largely due to the manipulation of $F0$. The effect of $F0$ differences in the mixed/$F0$ condition was therefore explored further.

The E-monolinguals' scores for the easy contrast were at ceiling (98% to 99%) regardless of the $F0$ type of trial. However, for all three difficult contrasts, scores were higher in trials manifesting a "congruent" $F0$ type (D1 89%, D2 80%, D3 81%) than an "incongruent" $F0$ type (D1 63%, D2 50%,

D2 55%). Put another way, higher scores were obtained when reliance on *F*0 similarities would yield a correct response than when reliance on *F*0 would yield an incorrect response. Intermediate scores were obtained for trials with no *F*0 change (D1 80%, D2 67%, D3 68%) and trials with a "neutral" *F*0 type, which suggested neither the correct nor the incorrect response (D1 80%, D2 66%, D3 69%).

C. Discussion

This experiment aimed to develop AXB testing procedures that would yield near-ceiling scores for vowels heard as distinct phonemes (and thus given different labels) but near-chance discrimination scores for foreign vowels heard as instances of a single L1 category (and thus given the same label). This goal was only partially met.

As intended, the E-monolinguals assigned to all three conditions (testing formats) obtained near-ceiling scores for the easy Danish contrast (as did the native Danish reference group for the easy contrast and all three difficult contrasts). It is likely that the E-monolinguals obtained near-ceiling scores for the easy contrast by generating two different phonetic label codes when hearing the Danish vowels making up this contrast. Also as intended, the E-monolinguals obtained much lower scores for three difficult Danish contrasts.

Contrary to our intent, however, the E-monolinguals' scores for all three difficult contrasts were significantly above chance in all conditions. Importantly, though, significantly lower scores were obtained for two contrasts when the effect of both manipulations examined here (i.e., mixed block structure and *F*0 variation) were combined (mixed/*F*0 condition) than when standard AXB testing procedures were used (blocked condition). Assuming that the E-monolinguals based discrimination of the three difficult contrasts on context codes (Hessen and Schouten, 1992), the results suggested that the modifications hindered but did not completely prevent the use of such codes.

The effect of increasing the range of stimuli by presenting four contrasts randomly in a single block (mixed condition) rather than blocked by contrast (blocked condition) was nonsignificant. This suggested that the participants in this experiment did not generate context codes by positioning the stimuli in relation to other stimuli in the experimental context, but rather in relation to phonetic categories stored in long-term memory, a possibility also envisaged by Hessen and Schouten (1992). Context variance has previously been shown to be range dependent in experiments using synthetic stimuli (e.g., Macmillan *et al.*, 1988). The absence of a range effect in the present study, using natural rather than synthetic stimuli, raises the possibility that neither between-category nor within-category discrimination is range dependent for natural stimuli.

The significant differences between the blocked and mixed/*F*0 condition, but the lack of differences between the blocked and mixed conditions, suggested that differences between blocked and mixed/*F*0 were due largely to the *F*0 manipulation. Additional consideration of scores in the four *F*0 types in the mixed/*F*0 condition suggested that *F*0 variation might have been more effective in lowering scores had only the incongruent *F*0 type been used. The scores for the incongruent *F*0 type averaged just slightly above chance (56% correct) for the three difficult contrasts. The decision was made, therefore, to apply the procedures of the mixed/*F*0 condition in experiment 2 but only to use the incongruent and the neutral *F*0 types.

III. EXPERIMENT 2

This experiment compared the discrimination of English vowels by native Spanish adults who had begun learning English in the U.S. as children ("early learners") to that of monolingual native speakers of English ("E-monolinguals") and Spanish ("S-monolinguals"). One of the English vowel contrasts examined here was expected to be easy for the S-monolinguals to discriminate because the two vowels in it were likely to be heard as distinct Spanish vowels. However, the other three contrasts (designated D1, D2, D3) were expected to be difficult because the contrasting vowels were likely to be heard as instances of a single Spanish vowel category. Pilot tests with late learners (native Spanish speakers who had begun learning English as adults) on a range of English vowel contrasts suggested that the difficult contrasts examined here were the three most difficult English vowel contrasts for native Spanish speakers, at least for vowels spoken by the native English speaker who provided the stimuli.

In experiment 1, E-monolinguals with no prior exposure to Danish obtained significantly above-chance discrimination scores for Danish vowels that were heard as instances of a single English vowel category. This suggested that even the most difficult condition (i.e., the mixed/*F*0 condition, in which trials testing four contrasts were mixed together and *F*0 variation was added to the stimuli) did not prevent completely the use of low-level or context codes. Two additional steps were therefore taken in this experiment to further reduce percent correct scores. This was considered important to do given the nature of the question addressed by this experiment: Would the early learners' discrimination of English vowels more nearly resemble that of S-monolinguals or E-monolinguals?

One step involved the *F*0 manipulation. In experiment 1, the *F*0 manipulation lowered E-monolinguals' scores for difficult contrasts mainly when the *F*0 difference among the three stimuli in a trial was of the "incongruent" *F*0 type. Therefore, only the incongruent *F*0 type was included here, along with the "neutral" *F*0 type, to maintain some variability.

The second step was motivated by the evidence (Cowan and Morse, 1986) that vowel discrimination is poorer at an ISI of 0 ms than 250, 500,1000, or 2000 ms (both for within- and between-category trials).[3] We therefore included a 0-ms ISI as well as the 1000-ms ISI used in experiment 1. As described earlier, the PPT of Hessen and Schouten (1992) posits that label codes are generated rapidly, whereas context codes—essentially refinements of the phonetic code—are generated more slowly. If the ISI between items to be discriminated is too short, context codes might be stored in an incomplete and inaccurate form. This should render them less reliable for correct discrimination, thereby lowering

TABLE I. Mean characteristics of the three groups of participants in experiment 2. Ranges are in parentheses.

	Early learners	E-monolinguals	S-monolinguals
Gender	13 f, 7 m	11 f, 9 m	8 f, 12 m
Chronological ages	31 (20–53)	31 (21–45)	29 (19–46)
Years of education	16 (13–22)	17 (13–21)	10 (3–20)
Age of exposure to E[a]	6 (2–10)	…	…
Years of exposure to E[a]	25 (9–45)	…	…
Self-rated S ability[b]	6.0 (3–7)	…	…
Self-rated E ability[b]	6.6 (4–7)	…	…

[a]English.
[b]Self-rated Spanish (S) or English (E) ability, 1=poor, 7=good.

scores in cases where a label code is insufficient. Such interruption of the generation of context memory codes can probably be understood as informational backward recognition masking (see Watson, 2005). For ISI=0 ms, the second and third stimuli in the AXB triads will serve as masks for preceding stimuli. Subsequent masks have been shown to interrupt auditory processing of a stimulus. For example, Massaro (1970) found that identification of a test tone was impeded by an immediately following masking tone but improved with increasing ISI.

A. Methods

1. Participants

The 60 participants were recruited in Birmingham, AL. All were required to be between the ages of 19 and 55 years, to report normal hearing, and to pass a pure-tone hearing screening. Twenty participants each were assigned to one of three groups: "S-monolinguals" (Spanish monolinguals), "E-monolinguals" (English monolinguals), and "early-learners" (native Spanish adults who had begun learning English as an L2 in childhood). As shown in Table I, the three groups did not differ significantly in chronological age [$F(2,57)=0.51$, $p=0.6$], but did differ in years of formal education [$F(2,57)=30.5$, $p<0.001$]. A Tukey test indicated that the S-monolinguals had received less education than the E-monolinguals and early learners ($p<0.001$), who did not differ from one another.

E-monolinguals were required to be native speakers of American English, to have NE-speaking parents, to have never lived outside the U.S., and to be unable to speak a language other than English proficiently. The S-monolinguals were required to have been born and raised in a predominantly Spanish-speaking country (Mexico—16, Guatemala—1, Venezuela—1, Argentina—1, Colombia—1). Despite the fact that the S-monolinguals were living in Birmingham when tested (mean residence in the U.S.=3.8 years, s.d.=4.6), they had either very limited or no proficiency in English according to self-report. To verify this, the experimenter vocally asked candidates for inclusion in the S-monolingual group eight simple questions in English (e.g., *What day was it yesterday*? or *What kind of food do you like to eat*?). The S-monolinguals were able to provide a response—often just a single word—to an average of just 2.7 of the 8 questions (range=0–6).

The early learners were required to have learned Spanish as an L1 from native Spanish-speaking parents and to have learned English as an L2 in childhood. Sixteen early learners were born in a predominantly Spanish-speaking country and had immigrated to the U.S. in childhood. One was born in the U.S. but moved soon thereafter to Mexico before returning to the U.S. later in childhood. The remaining three were born and raised in a predominantly Spanish-speaking community in the U.S.; they reported being unable to understand English upon entering preschool or elementary school.

Participant characteristics are shown in Table I. The age at which the early learners had begun learning English was indexed by self-reported age of first exposure ("AOE") to English. Their English-language experience was indexed by self-reported years of exposure ("YOE") to English. All participants were paid.

2. Stimuli

A total of 64 English vowel stimuli were obtained in the following way. A list of nonwords was created by inserting eight English vowels ([i u ɪ eᴵ ɑ ʌ ʊ oʊ]) into a CC_C frame. A native English male produced the nonwords in declarative and interrogative sentence frames (*I say_____now again*; *Can you say_____now again*?). As in experiment 1, different consonants flanked the vowel pairs of interest: /gl_s/ for vowels forming the [i]-[u] contrast, /kl_s/ for the [ɪ]-[eᴵ] contrast, /tʃ_s/ for the [ɑ]-[ʌ], and /fl_s/ for [ʊ]-[oʊ] contrast. All of the consonant sequences are legal in both Spanish and English.

The sentences were recorded and the CCVC nonword stimuli edited as in experiment 1. For each vowel category, four tokens were taken from the declarative sentence frame and four from the interrogative sentence frame. $F0$ values were measured using an autocorrelation technique by placing a 40-ms window at the vowel midpoint. As shown in Table II, the $F0$ values were higher for stimuli taken from the interrogative than the declarative frame, and so the two sets of stimuli were designated the "high-$F0$" (or H) and "low-$F0$" (L) stimuli.

The frequencies of the first two vowel formants ($F1$, $F2$) of the English stimuli at the vowel midpoint have been plotted in Fig. 2 along with mean $F1$ and $F2$ values for the five vowels of Spanish [as spoken in a /b_t/ context by adult males, from Bradlow (1995)]. The perceived phonetic distance of vowels drawn from two languages cannot be accurately determined by means of distances in an $F1$-$F2$ space. However, the distances evident in Fig. 2 suggest that S-monolinguals might tend to classify the English [ɪ] and [eᴵ] tokens as instances of Spanish /e/, the [ɑ] and [ʌ] tokens as Spanish /a/, and the [ʊ] and [oʊ] tokens as Spanish /o/. The [i] and [u] tokens might be classified as instances of Spanish

TABLE II. Mean vowel duration and fundamental frequency ($F0$) values at vowel midpoint for stimuli produced in interrogative and declarative sentence frames. Ranges are in parentheses.

	$F0$ (Hz)		Duration (ms)	
	Interrogative	Declarative	Interrogative	Declarative
[i]	170 (164–178)	116 (110–120)	149 (143–158)	113 (109–117)
[u]	176 (170–182)	110 (107–111)	128 (122–133)	107 (97–121)
[ɪ]	168 (160–177)	117 (113–123)	110 (101–116)	94 (93–95)
[e^{ɪ}]	169 (163–174)	114 (113–114)	157 (153–161)	132 (121–140)
[ɑ]	163 (153–170)	121 (119–122)	173 (160–188)	151 (132–163)
[ʌ]	167 (160–170)	121 (113–132)	118 (110–124)	114 (110–121)
[ʊ]	172 (166–176)	136 (118–148)	133 (129–134)	113 (91–126)
[o^{ʊ}]	163 (158–172)	129 (124–139)	178 (170–l85)	162 (148–171)

/i/ and /u/, respectively, at least if the fronting of the English [u] did not cause Spanish speakers to perceive tokens of this category as being instances of Spanish /i/.[4]

Inferences based on formant values were formally evaluated following the discrimination experiment described below. The 64 English stimuli from the discrimination test were aurally presented a single time in quasi-random order to the S-monolinguals. Their task was to classify each token as being most like one of the five vowels of Spanish, "i", "e", "a", "o", or "u". (Data for one S-monolingual were lost due to equipment malfunction.) In agreement with the acoustic data, the English [ɪ] and [e^{ɪ}] tokens were usually classified as Spanish /e/ (128 and 124 judgments, respectively, out of a maximum 152); the [ɑ] and [ʌ] tokens were usually classified as Spanish /a/ (in 152 and 118 judgments); and the [ʊ] and [o^{ʊ}] tokens were usually classified as Spanish /o/ (116 and 134 judgments). The [i] and [u] tokens were classified as different vowels, Spanish /i/ (151 judgments) and /u/ (134 judgments).

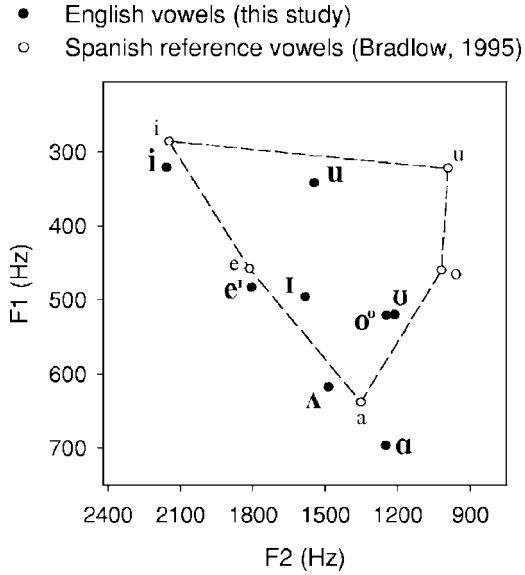

FIG. 2. Vowel chart showing first formant ($F1$) and second formant ($F2$) mean values at vowel midpoint of each of the eight English vowels used in experiment 2 (in bold). The mean values for Spanish are from Bradlow (1995).

3. Procedure

All 60 participants were tested individually in a sound booth where stimuli were presented via headphones at a self-selected level. The 64 trials testing each of the four contrasts were presented in one block of 256 trials. Half of the trials had the neutral $F0$ type (which suggested neither the correct nor the incorrect response), and the remaining trials had the incongruent $F0$ type, which suggested an incorrect response (e.g., LLH $F0$ in an [ɑ]-[ʌ]-[ʌ] trial). The block containing all 256 trials was presented two times in counterbalanced order with an ISI of either 0 or 1000 ms. In both ISI conditions, a 1200-ms interval occurred between each response and the following trial. A separate randomization was used for each participant, but was maintained across the two ISI conditions.

The 256 trials presented in both ISI conditions were preceded by 32 extra trials. Instructions, practice, and admission criterion were similar to those described in experiment 1. All test materials and instructions were translated and given in Spanish to the S-monolinguals. During the interval between blocks, participants responded to a language background questionnaire and produced sentences used for another study.

B. Results and discussion

1. Preliminary analysis

Lower scores were again expected for trials with the incongruent than the neutral $F0$ type. This expectation was tested by a (3) group × (4) vowel contrast × (2) ISI × (2)$F0$ type ANOVA examining the 16 mean scores obtained for each participant. Scores were indeed significantly lower

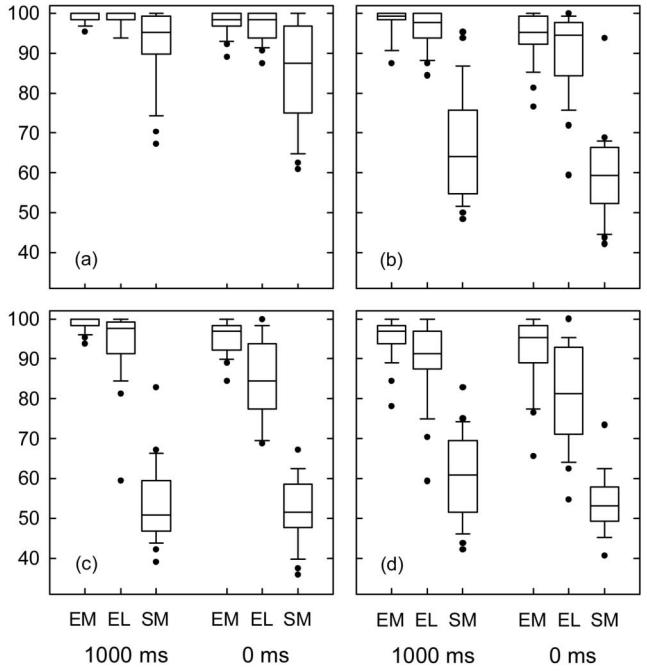

FIG. 3. Boxplots showing percent correct AXB discrimination obtained by English monolinguals (EM), early learners (EL), and Spanish monolinguals (SM). The four panels each display the results for one of the four vowel contrasts, i-u (a), ɑ-ʌ (b), ɪ-eɪ (c), and ʊ-oʊ (d), obtained by the three groups at a 1000 and a 0-ms ISI. Filled circles indicate individual outliers.

overall for trials with an incongruent than neutral *F*0 type [$F(1,57)=34.2$, $p<0.001$]. However, the lack of a group $\times$vowel contrast$\times F0$ type interaction [$F(6,171)=0.9$, $p=0.53$] suggested that the relative effect of *F*0 type on the four contrasts was similar across the three groups. In all subsequent analyses, therefore, scores were averaged over the two *F*0 types.

2. Between-group differences

As shown in Fig. 3, the mean percent correct scores were higher overall for the easy contrast ([i]-[u], $M=95\%$ correct) than for the three difficult contrasts ([ɪ]-[eɪ] 80%, [ɑ]-[ʌ] 84%, [ʊ]-[oʊ] 79%). The early learners' scores were slightly lower ($M=91\%$) than the E-monolinguals' ($M=96\%$), but substantially higher than the S-monolinguals' ($M=65\%$). Lower scores were obtained, on average, for ISI=0 ms than ISI=1000 ms ($M=82$ vs. 87%). Of greatest interest, the S-monolinguals' scores for the three difficult contrasts at ISI=0 ms were all near chance (<60% correct). A series of single sample *t* tests indicated that S-monolinguals' scores for one difficult contrast, [ɪ]-[eɪ], did not significantly exceed the chance level of 50% at ISI =0 ms [$t(19)=1.2$, $p=0.24$] or ISI=1000 ms [$t(19)=1.6$, $p=0.12$].

The eight scores obtained for each participant (4 contrasts $\times$2 ISIs) were examined in a mixed-design (3) group $\times$(2) ISI$\times$(4) vowel contrast ANOVA. All three main effects reached significance [group $F(2,57)=175.3$, $p<0.001$; ISI $F(1,57)=53.6$, $p<0.001$; vowel contrast $F(3,171)=95.8$, $p<0.001$] as did the three-way interaction [$F(3,171)=2.4$, $p=0.033$], which was explored through simple effects tests. As seen in Fig. 3, an important source of the interaction was a differing pattern of between-group differences in the two ISI conditions. The group effect was significant for all four vowel contrasts at both ISI =1000 ms [$F(2,57)=9.7$ to 180.3, $p<0.001$] and ISI =0 ms [$F(2,57)=15.4$ to 158.6, $p<0.001$]. Tukey tests ($\alpha=0.05$) revealed that at ISI=1000 ms, the S-monolinguals' scores were significantly lower for all four contrasts than those obtained by the E-monolinguals and early learners, who did not differ significantly. For ISI=0 ms, the S-monolinguals' scores were lower for all four contrasts than the E-monolinguals'. Importantly, the early learners' scores were lower than the E-monolinguals' for two difficult contrasts, [ɪ]-[eɪ] and [ʊ]-[oʊ]. Although the early learners' scores for difficult contrasts were closer to the E-monolinguals' than to the S-monolinguals' (see Fig. 3), these differences suggested that the early learners' perception of English vowels was not "functionally equivalent" (see Flege and MacKay, 2004) to that of the E-monolinguals.

The lower scores obtained for the easy contrast by the S-monolinguals than by the early learners and E-monolinguals might seem surprising given that all but one S-monolingual classified the English /i/ and /u/ stimuli as instances of two different Spanish vowels (*viz.* Spanish /i/ and /u/). The S-monolinguals' lower scores might be attributed to acoustic phonetic differences between the /i/s and /u/s found in Spanish and English (see Fig. 2).[5] Note, however, that a much smaller difference existed between the E-monolinguals and S-monolinguals for the easy contrast ($\Delta=7\%$) than for the three difficult contrasts ($\Delta=31\%-45\%$).

The simple effect of contrast was significant for all six group$\times$ISI combinations [$F(3,57)=4.3$ to 65.5, $p<0.01$], but the pattern of between-contrast differences varied as a function of group and ISI. The E-monolinguals obtained lower scores for [ʊ]-[oʊ] than [i]-[u] and [ɪ]-[eɪ] at ISI =1000, but [ʊ]-[oʊ] and [ɪ]-[eɪ] did not differ at ISI=0. The S-monolinguals obtained higher scores for [i]-[u] than for all three difficult contrasts at both ISI=0 and ISI=1000, and higher scores for [ɑ]-[ʌ] than [ɪ]-[eɪ] at ISI=1000 ms. For early learners, higher scores were obtained for [i]-[u] than all three difficult contrasts at ISI=0, for [i]-[u] than [ɪ]-[eɪ] and [ʊ]−[oʊ] at ISI=1000 ms, and for [ɑ]-[ʌ] than [ʊ]−[oʊ] at both ISIs.

Tests of the simple effect of ISI revealed that significantly lower scores were obtained at ISI=0 than ISI =1000 ms for 10 of the 12 contrast$\times$group combinations [$t(19)=2.1$ to 4.8, $p<0.05$]. The two exceptions were the highest and the lowest scores obtained, *viz.* the score obtained for the easy contrast by the E-monolinguals, and for the [ɪ]-[eɪ] contrast by the S-monolinguals. The first exception might well have been a ceiling effect (with mean values in the two ISI conditions of 98% and 99% correct), the second a floor effect ($M=52\%$ and 54%).

The effect of ISI for the E-monolinguals—for whom all trials were presumably between-category trials—was unexpected. This finding suggests that ISI influences both the between- and within-category discrimination of natural vowels [as has previously been found for synthetic vowels, see Cowan and Morse (1986)]. Perhaps between-category dis-

TABLE III. Mean characteristics of the four early learners who obtained the highest discrimination scores, and the four obtaining the lowest scores. Ranges are in parentheses.

[d]Self-rated ability (1=poor, 7=good).

crimination was based to some extent on the ISI-sensitive context codes in addition to phonetic label codes.

3. Individual differences

The large difference in scores obtained by the E-monolinguals and S-monolinguals suggests that the AXB test used here was phonetically sensitive, perhaps by virtue of hindering use of context codes (Hessen and Schouten, 1992). In the ISI=0 ms condition, the scores obtained by individual E-monolinguals and S-monolinguals were virtually nonoverlapping for the three difficult contrasts. (The exception was a single S-monolingual outlier for [ɑ]-[ʌ][6] and [ʊ]-[oʊ].) Likewise, the scores obtained for individual early learners and S-monolinguals showed virtually no overlap at ISI=0 ms (the exceptions being one outlier in each group for [ɑ]-[ʌ] and [ʊ]-[oʊ]), which provided direct evidence of perceptual learning by nearly all early learners.

Given the theoretical importance of this finding, it is worth considering in greater detail the scores obtained by individual early learners at ISI=0 ms. Averaged over all three difficult contrasts, the scores obtained for the 20 E-monolinguals ranged from 81% to 99% correct, as compared to a range of 64% to 98% for the early learners. The four lowest scores obtained for early learners fell below the E-monolinguals' range (but were nonetheless higher than those obtained for all but one S-monolingual), whereas the four highest-scoring early learners all exceeded the mean score obtained for the E-monolingual group.

Examination of the participants' questionnaires revealed, not surprisingly, that all four of the lowest-scoring early learners reported less proficiency in English than all four of the highest-scoring early learners. In fact, of all 20 early learners, only the four learners who scored below the native English range did not assign themselves the maximum value of "7" when self-rating their ability to speak English.

What enabled some early learners to discriminate English vowels so much better than others? As summarized in Table III, three of the lowest-scoring early learners were exposed to English later in life (i.e., had a later AOE) than all four highest-scoring early learners. Three of the highest-scoring learners reported using English more with friends in the past 5 years than all four of the lowest-scoring learners. And all four highest-scoring learners reported more use of English during their first 5 years of exposure to English than all four of the lowest-scoring learners. Finally, three of the four highest-scoring learners reported having attended school in the U.S. longer than all four of the lowest-scoring early learners. Although these data are only suggestive given the small number of participants (four per subgroup), the pattern seen here suggests that differences in the age of first exposure and amount of L2 use (especially during the first 5 years of L2 exposure) were responsible for important individual differences among the early learners.

IV. GENERAL DISCUSSION

This study evaluated the discrimination of English vowels by native Spanish adults who were first exposed to English in childhood (early learners). The study used a variant of the categorial AXB discrimination test that appeared to hinder vowel discrimination based on low-level or context memory codes (as opposed to language-specific phonetic codes, see experiment 1). The findings relate to the more general question of the extent to which the speech perception system remains plastic following attunement to the L1 sound system in early childhood.

The two English vowels in each of three "difficult" contrasts were both heard by Spanish monolinguals (S-monolinguals) as instances of a single Spanish vowel category. These contrasts were expected to be difficult to discriminate for the S-monolinguals and also for the early

learners unless they had developed new long-term memory representations (phonetic categories) for one or both vowels in the contrasts. The two vowels making up a fourth contrast were heard by S-monolinguals as distinct Spanish vowels. This contrast was expected to be easy to discriminate for Spanish speakers with or without perceptual learning of English vowels.

The AXB test was administered at two ISIs, 1000 vs. 0 ms, and was highly phonetically sensitive in the ISI =0 ms condition in that listeners with English-specific phonetic categories (the E-monolinguals) obtained scores near ceiling for the difficult English contrasts whereas listeners without such categories (the S-monolinguals) obtained scores that were at or near chance. Given this characteristic of the discrimination test, it was well suited to reveal perceptual learning by the early learners. The early learners obtained significantly higher scores than the S-monolinguals at both ISIs and did not differ from the E-monolinguals for any contrast at ISI=1000 ms. However, the early learners obtained lower scores than the E-monolinguals for two difficult contrasts at ISI=0 ms, suggesting that their long-term memory representations for English vowels were not identical to the E-monolinguals'.

Significant differences between early learners and L2 native speakers have often been interpreted as evidence for a loss of perceptual plasticity following attunement to the L1 sound system (e.g., Bosch *et al.*, 2000; Pallier *et al.*, 1997; Sebastián-Gallés and Soto-Faraco, 1999). However, as mentioned in the Introduction, there are *a priori* reasons to expect the perceptual systems of early learners to differ from those of L2 native speakers, and thus to expect differences in performance in sensitive tests such as the one used here. It is for this reason that including the S-monolingual group was important for considering whether the early learners' perceptual system remained plastic. Except for one outlier in each group, the scores obtained for individual early learners and S-monolinguals for the three difficult contrasts were nonoverlapping at ISI=0 ms. In our opinion, this finding provides evidence of extensive perceptual learning in early learners and is inconsistent with the view that the speech perception system loses plasticity (e.g., Pallier *et al.*, 1997; Sebastián-Gallés and Soto-Faraco, 1999), and that new phonetic categories become unlikely (Bosch *et al.*, 2000) following attunement to the L1 sound system.

Research with early learners has tended to focus on between-group differences with a view to determining whether the speech perception system does, or does not, remain plastic. However, as usually holds true in L2 perception research (e.g., Sebastián-Gallés *et al.*, 2005), we observed important individual differences among the early learners tested here. This suggests that an important question to ask in future research is: "What factors influence early learners' L2 speech perception?" A detailed analysis of the scores obtained by individual early learners identified several factors that will need to be examined in greater detail in future research. Just four (of 20) early learners obtained average scores for the three difficult contrasts that fell below the E-monolingual range at ISI=0 ms. These four early learners differed from the four highest-scoring early learners in several potentially important ways: The lowest scoring early learners reported using English less often, especially during their first years of English use, than the highest scoring early learners. This raises the question of how much L2 input early learners must receive, and when, if they are to show a nativelike perception of L2 phonetic segments.

A related question is whether the *kind* L2 input early learners receive affects their performance. For example, in a study examining Spanish speakers who had begun learning their L2 (Catalan) in Barcelona by the age of 4 years, Sebastián-Gallés *et al.* (2005) obtained scores ranging from chance level to values well above the native speaker mean for a vowel contrast not found in the L1 (Spanish). The authors noted that the numerous native Spanish speakers in Barcelona tend to realize both Catalan /e/ and /ɛ/ as an [e]-quality vowel, raising the possibility that the intersubject variability might be explained by how often the early learners had heard their L2 spoken by fellow native speakers of Spanish who neutralize the Catalan contrast.

Language use patterns, of course, are related to language dominance. The Spanish-Catalan bilinguals examined by Sebastián-Gallés and Soto-Faraco (1999) reported higher proficiency in their L1 Spanish than their L2 Catalan. This might explain why they differed from Catalan native speakers in perceiving Catalan speech sounds. It is noteworthy that L2 perception by clearly L2-dominant early learners examined by Flege and MacKay (2004) did not differ from that of L2 native speakers. If the L1 phonetic subsystem in bilinguals becomes weak through lack of use, the possibility exists that effects of cross-language phonetic interference will be minimized, and performance in the L2 will eventually become nativelike.

Indirect support for this hypothesis comes from recent research on Korean adults adopted by French families between the ages of 2 and 9 years, which suggested that early attunement to the L1 sound system may disappear following years of disuse (Pallier *et al.*, 2003; Ventureyra *et al.*, 2004). This interesting research raises the possibility that the L2 performance of early bilinguals with little or no continued L1 use for many years might become indistinguishable from that of native speakers. If so, it would suggest that perceptual learning is limited by language use or dominance patterns rather than a loss of plasticity arising from maturational constraints or irreversible effects of prior learning on subsequent learning. This hypothesis would be strongly supported if clearly L2-dominant early bilinguals with little L1 use could be shown to perform like native speakers in their L2, but show below-native performance in their L1.

The highest-scoring and lowest-scoring early learners also differed in terms of age of first exposure to English in the U.S. (M=3 vs. 8 years). Prior research of "age" effects has focused on differences between early and late L2 learners. However, the differences between the highest- and lowest-scoring early learners in experiment 2 suggested that age effects might exist among participants traditionally classified as "early" learners. Given the small sample size, however, there is a need for additional research, in which factors confounded with age are controlled. If L2 discrimination is indeed better for those first exposed to the L2 at the age of 3

than 8 years, this might be due to a differing effect of L1-on-L2 phonetic interference arising from differences in the state of development of L1 phonetic categories (e.g., Flege, 2003).

In summary, support for the existence of extensive perceptual plasticity in early learners was provided by the finding that most early learners showed nativelike discrimination of three difficult English vowel contrasts which were discriminated at near-chance levels by Spanish monolinguals. A few early learners obtained scores below the native English range, indicating that early exposure to an L2 is insufficient in itself to guarantee nativelike discrimination of L2 vowels. Additional research will be needed to clarify which factors influence early learners' perception of L2 phonetic segments, and to what extent bilinguals can show nativelike performance in both of their languages.

ACKNOWLEDGMENTS

This research was supported by NIH Grant No. DC000257. Additional support was provided to the first author by the Danish Research Council for the Humanities and by the Oticon Foundation. We wish to thank A. Bradlow and three anonymous reviewers for very helpful comments on our original submission, and O.-S. Bohn and G. Morrison for comments on a previous draft.

[1]In the blocked condition, eight extra trials were presented before each 64-trial block as a "warm-up." In mixed and mixed/*F*0 conditions, the 256-trial block was preceded by 32 extra trials. All four vowel contrasts were presented in the extra trials, which were not analyzed. All participants received a different randomization of the stimuli.

[2]The simple effect of contrast was significant for all three groups (F values ranging from 43.6 to 61.5, $p<0.001$). Tukey tests showed that higher scores were obtained for the easy contrast than for all three difficult contrasts in each testing condition ($p<0.05$). For participants assigned to the blocked and mixed/*F*0 conditions, higher scores were obtained for difficult 1 than for difficult 2 and 3; in the mixed condition, higher scores were obtained for difficult 1 and 3 than for difficult 2.

[3]The effect for within-category trials might be explained by a lack of time to build up context codes in the 0-ms condition. The effect for between-category trials is surprising assuming that discrimination was based on label codes. However, because the vowel stimuli were drawn from a synthetic continuum with little acoustic difference between the steps, the participants might have relied on context codes in addition to label codes in between-category discrimination. Also, listeners may depend more on context codes for synthetic than natural stimuli (see Hessen and Schouten, 1992).

[4]The mean $F2$ of the [u] tokens in experiment 2 was 1545 Hz, which is somewhat higher (indicating fronting) than previously published $F2$ values for American English [u], e.g., 1238 Hz in a /bVt/ context (Bradlow, 1995) or 870 Hz in an /hVd/ context (Peterson and Barney, 1952). Possibly, the preceding [l] had a fronting effect on [u].

[5]Another possibility is that the S-monolinguals' scores for the easy contrast were reduced somewhat by anxiety because they were unsure about the correct response in the majority of trials (the "difficult" trials). Whatever the explanation, it is worth noting that in previous cross-language research, similar levels of AXB scores have been obtained for instances of a clear "two-category" consonant contrast (Best *et al.*, 2001, p. 787).

[6]Inspection of the classification results revealed that this S-monolingual participant—unlike the other S-monolinguals—consistently classified English [ɑ] and [ʌ] as different Spanish vowels (*viz.* [a] and [e]), which likely explains his high discrimination scores for this English contrast.

Phonological versus phonetic cues in native and non-native listening: Korean and Dutch listeners' perception of Dutch and English consonants

(Received 28 July 2005; revised 14 February 2006; accepted 1 March 2006)

We investigated how listeners of two unrelated languages, Korean and Dutch, process phonologically viable and nonviable consonants spoken in Dutch and American English. To Korean listeners, *released* final stops are nonviable because word-final stops in Korean are never released in words spoken in isolation, but to Dutch listeners, *unreleased* word-final stops are nonviable because word-final stops in Dutch are generally released in words spoken in isolation. Two phoneme monitoring experiments showed a phonological effect on both Dutch and English stimuli: Korean listeners detected the unreleased stops more rapidly whereas Dutch listeners detected the released stops more rapidly and/or more accurately. The Koreans, however, detected released stops more accurately than unreleased stops, but only in the non-native language they were familiar with (English). The results suggest that, in non-native speech perception, phonological legitimacy in the native language can be more important than the richness of phonetic information, though familiarity with phonetic detail in the non-native language can also improve listening performance. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188917]

I. INTRODUCTION

In the first months of life, infants are typically able to discriminate acoustic-phonetic differences irrespective of whether the phonetic differences are phonologically contrastive in the ambient language or not (see, e.g., Jusczyk, 1997, for a review). By the end of their first year, however, their sensitivity to speech sound contrasts is generally refined according to the phonological properties of the ambient, native language (e.g., Werker *et al.*, 1981; Werker and Lalonde, 1988; see Cutler and Broersma, 2005, for a review). Although the timing of these refinements varies (Polka *et al.*, 2001), the general developmental pattern is that sensitivity to phonetic differences which are phonologically noncontrastive in the native language becomes attenuated relative to sensitivity to contrastive phonetic differences, and that the degree of such an attenuation is typically correlated with age (e.g., Flege, 1995). Eventually, perception of speech sounds by adults is highly biased or modulated by their experience with the phonological systems of their native language (there are effects, e.g., of phoneme repertoire, phonotactics, allophonic distribution, rhythmic structure and morphophonemic alternations; see e.g., Best, 1995; Best and Strange, 1992; Broersma, 2005; Costa *et al.*, 1998; Cutler *et al.*, 1986; Cutler and Otake, 1994; Flege, 1995; Flege and Hillenbrand, 1986; Hallé *et al.*, 1999; Kuhl and Iverson, 1995; Otake *et al.*, 1993; Weber, 2001; Weber and Cutler, 2006). Adult native Japanese listeners, for example, generally perceive both contrastive English sounds /r/ and /l/ as the flap /ɾ/, which is the sound in their native language that is phonetically closest to the two sounds (e.g., Best *et al.*, 1988; Best and Strange, 1992; see also Best, 1995). This is a case in which two contrastive categories in the non-native language are "assimilated" to the same phonological (or phonetic) category in the listener's native language.

Another example of native-language influences comes from differential use of phonetic cues by native and non-native listeners in the perception of contrastive sounds. Flege and Hillenbrand (1986), for instance, showed that in identifying fricatives as /s/ or /z/ (as in *peace* and *peas*) in American English, native English listeners used two well-known phonetic cues to the syllable-final voicing contrast, that is, fricative duration (which is longer for /s/ than for /z/) and preceding vowel duration (which is shorter before /s/ than before /z/; e.g., Denes, 1955, Raphael, 1972; see Watson, 1983 for a review). Non-native listeners of English, specifically, Swedish and Finnish listeners, who have no phonemically contrastive /s/-/z/ pair in their native language, but do have contrastive long and short vowels in their native language, used only vowel length differences to differentiate /s/ from /z/. According to Flege and Hillenbrand, listeners of Swedish and Finnish might have "reinterpreted" the role of phonologically contrastive vowel duration in their native language as a cue to the voicing contrast in non-native listening. Dutch listeners, however, appear not to use vowel duration in identification of voiced versus voiceless English syllable-final fricatives (Broersma, 2005). This may be because, in Dutch, /s/ and /z/ are phonemically contrastive, but not in

[a)]Electronic mail: tcho@hanyang.ac.kr

syllable final position. Dutch listeners may therefore have learned to use cues other than vowel duration in perceiving the fricative voicing distinction.

What has emerged from these studies on native versus non-native listening is that speech perception is tuned according to language experience, resulting in a "phonological reorganization of speech sound percepts" (Cutler and Broersma, 2005), and that one of the driving forces behind this phonological reorganization is the various language-specific constraints that arise within the phonological system of the listener's native language. It is thus not surprising, as Cutler and Broersma (2005) noted, that improving performance of adult listeners in the perception of non-native sounds has been found to be very difficult although training can improve performance to some extent (e.g., Logan *et al.*, 1991; Lively *et al.*, 1993, 1994; Bradlow *et al.*, 1997).

In the present study, we further explore how listening is tuned by language experience. We investigate how listeners of two unrelated languages, Korean and Dutch, process sounds which are phonologically viable or nonviable in their native language. In Korean, stops in syllable- or word-initial position are lenis, fortis, or aspirated, and their phonetic cues are generally present in the release portion and at the beginning of the following vowel (Cho *et al.*, 2002; Kim *et al.*, 2002). In coda position, however, stops are unreleased, at least when the syllable or word is produced in isolation. Coda stops in Korean can be realized either with or without audible releases. When the coda stop is followed by a vowel-initial morpheme (due to morpheme concatenation) or by a vowel-initial word (due to prosodic grouping), it is resyllabified as the onset of the following syllable, and is released with an audible release noise. When followed by another stop, however, coda stops can be released with only an inaudible brief transient noise. Kim and Jongman (1996) reported that when underlying stem-final /t/ was followed by the velar stop /k/ in Korean, it was released with a brief transient 83% of the time. These events were difficult to perceive, but appeared in acoustic analyses. Henderson and Repp (1982) observed similar patterns for English stop sequences, and argued that what are traditionally known as "unreleased" stops are often produced with an inaudible articulatory release gesture. Korean coda stops followed by another stop thus tend, in this sense, to be "unreleased." Korean coda stops in isolated syllables (or utterance finally), however, are unreleased both auditorily and articulatorily. This means that the three-way manner contrast found in onset position in Korean is completely neutralized, without even subtle acoustic differences distinguishing among the three types of stop (Kim and Jongman, 1996). This behavior is often considered to be the outcome of an obligatory phonological rule which states that stops are unreleased when followed by a word boundary or by another obstruent within the word (e.g., Kim-Renaud, 1976; Martin, 1992).

In Dutch, however, voiceless coda stops in word-final position are generally released when words are produced in isolation (cf., Warner *et al.*, 2004; Ernestus and Baayen, in press). Like Korean, Dutch has released stops in syllable-initial (prevocalic) positions. The question we address here, therefore, is whether and how the position-specific phonological difference between the two languages influences speech perception. Released coda stops in isolated syllables are phonologically nonviable in Korean; unreleased stops in this environment are phonologically nonviable in Dutch. It is important to emphasize that we use the term "phonological" to refer to language-specific sound patterns which are driven by obligatory phonological rules. The term "phonological knowledge" is thus used to refer to the native listener's knowledge not only about the native language's phoneme system but also about sound patterns determined by phonological rules. If the way native listeners perceive non-native speech sounds is guided by their native phonological knowledge, listeners should find it harder to process non-native sounds that deviate from native language phonological constraints (phonologically nonviable sounds) than to recognize those that are in conformity with those native constraints (phonologically viable sounds). This will be referred to as the *phonological-superiority hypothesis*.

There is a competing hypothesis, however. Released stops are produced with two distinct sets of acoustic-phonetic cues (those associated with the VC formant transition and those associated with the release burst) whereas unreleased stops are cued solely by the VC formant transition information. It has widely been agreed that the release burst is one of the most important cues to the identity of a stop, such that the presence of an audible release burst (in addition to formant transitions) increases the perceptual recoverability of the stop consonant (e.g., Stevens and Blumstein, 1978; Mattingly, 1981; Silverman, 1995; Smits *et al.*, 1996; Steriade, 1997; Kochetov, 2001; Zsiga, 2003; Wright, 2004; Flemming, 2005). That is, the information available to the listener is richer with than without the release burst.

In a perceptual study on Russian stops in syllable- or word-final coda positions, for example, Kochetov (2001) has shown that the identification of plain and palatalized coronal coda stops in Russian was significantly faster in the presence than in the absence of an audible release burst. With respect to stops in syllable-onset positions, the data reported by Smits *et al.* (1996) showed that in classifications of Dutch stops (/p/ vs /t/ vs /k/), Dutch listeners relied more on the release bursts than they did on the Consonant-Vowel (CV) formant transitions, when the stimuli contained a mismatch between the release burst and the CV formant transition. Similarly, Stevens and Blumstein (1978) showed that the presence of noise bursts at stop onset enhanced overall consonant classification in English. The perceptual importance of the release burst as a cue to stop identity has also been used as phonetic grounds for cross-linguistic phonological patterns of place and laryngeal contrasts for stop consonants (e.g., Steriade, 1997; Silverman, 1995; Wright, 2004; Flemming, 2005). Across languages, phonological place and laryngeal contrasts occur far more often in positions where the release bursts are available to cue the contrasts.

There is therefore considerable phonetic and phonological evidence for the importance of the release burst as a cue to stop identity. Thus, from the perspective of the relative richness of acoustic-phonetic cues, one might expect that released stops (with bursts) are processed more efficiently than

unreleased stops (with no bursts) irrespective of the phonological system of the listener's native language. This will be called the *phonetic-superiority hypothesis*.

In this study, we tested the *phonological-superiority* hypothesis against the *phonetic-superiority* hypothesis, by conducting two phoneme monitoring experiments (Connine and Titone, 1996; Otake *et al.*, 1996). Experiment 1 measured Korean listening performance; Experiment 2 examined Dutch listeners' performance on the same materials. Both groups of listeners heard four sets of speech materials: released and unreleased stops in Dutch, and released and unreleased stops in English. Both Dutch and English speech materials were included in order to examine whether the nature of the input language influences phoneme recognition. In Experiment 1, the language factor was whether the non-native speech materials were familiar or unfamiliar (to Korean listeners). In Experiment 2, it was whether the speech materials were native or non-native (to Dutch listeners).

II. EXPERIMENT 1

Korean listeners were presented with Dutch spoken stimuli in Experiment 1a and with English spoken stimuli in Experiment 1b. The listeners were asked to detect both nasal and oral consonants, in VC syllables. The oral consonants were either released or unreleased stops. We asked how speed and accuracy in phoneme monitoring varies as a function of the phonological viability of the stimuli in the listener's native language and as a function of the phonetic richness of those stimuli. On the one hand, the phonological-superiority hypothesis predicts that Korean listeners will detect unreleased stops more easily than released stops (because word-final stops in words spoken in isolation are always unreleased in Korean). On the other hand, the phonetic-superiority hypothesis predicts that Korean listeners will detect released final stops more easily than unreleased (because released stops are phonetically richer). The nasal targets, which were identical in the released and unreleased conditions, were included partly as distractors. Their inclusion also allowed us to examine whether phoneme monitoring performance on nasal targets varied depending on whether they co-occurred with released or unreleased stops. Finally, we tested whether phoneme monitoring performance is constrained by language experience (unfamiliar versus familiar speech stimuli, i.e., Dutch versus English).

A. Method

1. Participants

Fifty-two Korean student volunteers at Korea University in Seoul were paid to take part. They were divided into four groups of 13 according to the release condition (Released versus Unreleased) and the language condition (Dutch in Experiment 1a and English in Experiment 1b).

2. Materials

Two sets of materials were constructed in each language, one consisting of VC syllables with the release intact (the released condition), and one with the release spliced out (the unreleased condition). Within each set of VC's, there were 30 experimental items with 3 oral (/p, t, k/) and 3 nasal (/m, n, ŋ/) target consonants in their codas in 5 different vowel contexts (/a,e,i,o,u/; 6 target consonants × 5 vowel contexts =30 experimental items). Lists of four-syllable sequences were then constructed for each target-bearing experimental item with the target placed in either the last or the penultimate syllable, as in [V, V, V, V*C*] or [V, V, V*C*, V]. (Note that in the unreleased condition "VC" refers to a stimulus in which the released portion was spliced out, and therefore phonetic cues to "C" were present only in the preceding vowel.) Single V fillers (non-target-bearing syllables) were used instead of VC fillers in order to control for the frequency of occurrence of the target consonants. All V's in each list were different (e.g., [e, u, ak, i]). In addition to the 30 experimental lists, 15 nonexperimental lists were constructed in which the target consonants occurred in filler syllables with a schwa context. For these items, subjects had to detect the target consonants but the responses were not analyzed. These syllables were placed in the antepenultimate syllable ([V, V*C*, V, V]) in the lists, which made the position of target-bearing syllables in lists unpredictable. In addition to these 45 lists, 45 other lists were constructed as foils which had no instances of the specified target (thus no response was required). Among these 45 foil lists, 30 lists were the same as the 30 experimental lists except that the specified targets did not match the coda consonants in the lists. Each foil list was always presented after its occurrence as an experimental (target-bearing) list. The remaining 15 foil lists contained only vowels in the list ([V, V, V, V]). Finally, 15 practice lists were made.

3. Procedures

The speech materials (V's and VC's) were spoken individually by a male native speaker of Dutch (a speaker from Brabant), and by a male native speaker of American English (a speaker from the Midwest). Both speakers were not linguists, and both were naive as to the purpose of the experiment. The materials were recorded in a sound-treated studio directly onto computer and consequently down-sampled to 22.05 kHz (16 bit precision). All V's and VC's were repeated four times in blocks in a pseudorandomized order, and tokens with deviant prosody (e.g., extreme rising or falling intonation) were excluded. Both speakers released the stops naturally in all instances, though they were not instructed to do so. Randomly selected syllables were then combined to form four-syllable stimulus lists using the Praat speech editor (http://www.praat.org). In the stimulus lists, beginnings of syllables were separated by one second from each other. Two sets of stimuli were constructed which were identical except that, in one set, the release portions of the oral consonants in the VC stimuli were intact, while in the other set the release portions were spliced out (at a zero-crossing at the end of the vowel). The duration of the release portions were measured, as will be discussed in Sec. III B. The intensity of tokens across stimuli was then equalized, so that each stimulus had the same peak intensity but the relative amplitude within a stimulus remained intact.

The task of the subjects was to detect a pre-specified target phoneme irrespective of its position within a spoken

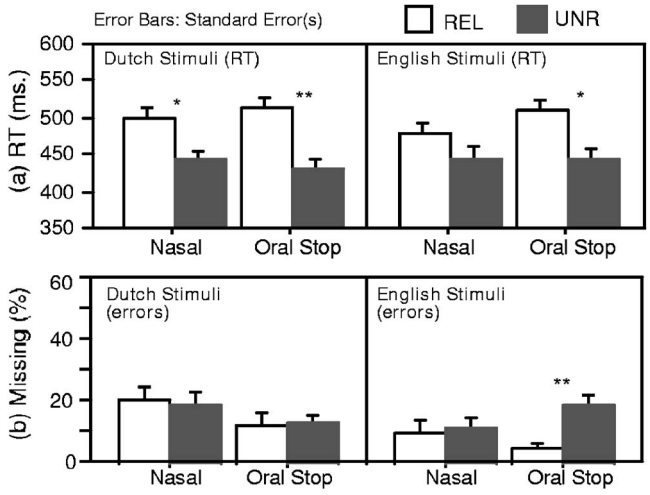

FIG. 1. Korean listeners' mean reaction Times [RTs, (a)] and errors [percent missing responses, (b)] with the spoken stimuli in Dutch (left) vs English (right). REL=released oral stops; UNR=unreleased oral stops. Note the nasal stimuli were identical in the two release conditions. *=$p<0.005$; **=$p<0.001$.

stimulus list. The targets were presented visually in lowercase letters in Roman alphabet for 1 s on a computer screen: **p**, **t**, **k**, **m**, **n**, **ng**, **l**. (/l/ was used in some filler lists.) Note that subjects were sufficiently familiar with the Roman alphabet for targets to be specified in this way. The first syllable of each stimulus list began 300 ms after the target disappeared. A new visual target was presented prior to each list. Subjects were told that they were going to hear some foreign speech (the identity of the language was not revealed) and were instructed to press a button on a response box (with their dominant hand) as fast and as accurately as possible when they detected the targets in the spoken lists.

Participants were tested individually in a quiet room. The computer clock was triggered in synchrony with the onset of the target presentation on the screen and stopped when the response button was pressed. Reaction times (RTs, relative to the offset of the vowel preceding the target phoneme) and errors were recorded. The session lasted approximately 15 min.

4. Analysis

Analyses of Variance (ANOVAs) were performed separately for each language (Dutch/English) with either subjects (F1) or items (F2) as the repeated measure. Both RT and error analyses were carried out (the errors were analyzed in terms of % missing responses). Stop release was a between-subject and within-item factor; manner (Nasal/Oral) was a within-subject and between-item factor. Planned pairwise comparisons between conditions were conducted with separate one-way ANOVAs. Reactions to both oral and nasal targets were analyzed in order to examine the effect of the presence/absence of releases on detection of nasal consonants. Remember that the nasal targets were identical in the released and unreleased conditions.

B. Results

The results are summarized in Fig. 1. Our analyses focus on the manner of articulation of the target consonants (nasals versus stops) and on whether or not the stops were released. Since our hypotheses did not concern either the place of articulation of the targets or the effects of vowel context, we collapsed over those factors. The patterns we report, however, were generally consistent over both place of articulation and vowel context, as shown in the Appendix.

1. Experiment 1a: Korean natives listening to Dutch

Korean listeners, when presented with Dutch spoken stimuli, showed a significant effect of Release ($F1[1,24]=6.969$, $p<0.025$; $F2[1,28]=28.29$, $p<0.001$), such that detection of the targets was faster by 69 ms in the unreleased than in the released condition [mean RTs, 437 vs 506 ms; s.e., 9.5 vs 10.7; see Fig. 1(a)]. Targets were therefore detected faster when they were phonologically viable, even though they were phonetically poorer. Interestingly, however, there was no significant interaction between Release and Manner ($F1[1,24]=2.04$, $p=0.166$; $F2[1,28]<1$), suggesting not only that unreleased stops were detected more rapidly than released stops, but also that nasals which were mixed with unreleased stops were processed more rapidly than those mixed with released stops (mean RTs for stops, 431 vs 513 ms; s.e., 14.4 vs 14.9; for nasals, 443 vs 499 ms; s.e., 11.2 vs 12.3). With respect to errors, neither a main effect of Release ($F1[1,24]<1$; $F2[1,28]<1$) nor an interaction between Release and Manner ($F1[1,24]<1$; $F2[1,28]<1$) was found.

2. Experiment 1b: Korean natives listening to English

In RTs with English stimuli, there was a significant main effect of Release ($F1[1,24]=9.71$, $F2[1,28]=38.72$, both $p<0.001$) and a significant Release × Manner interaction ($F1[1,24]=7.86$, $p<0.025$; $F2[1,28]=4.86$, $p<0.05$). As was the case with Dutch stimuli, Korean listeners were significantly faster by 68 ms in detecting (phonologically viable but phonetically poorer) English unreleased stops than released stops ($F1[1,24]=4.12$, $p<0.05$; $F2[1,14]=21.12$, $p<0.001$; mean RTs, 442 vs 510 ms; s.e., 16.4 vs 14.4), as shown in Fig. 1(a) (right). Detection of nasals was also faster in the unreleased than in the released condition by 36 ms, but this effect was significant only by item ($F1[1,24]=2.38$, $p>0.1$; $F2[1,14]=25.35$, $p<0.001$; mean RTs, 445 vs 480 ms; s.e., 11.2 vs 12.3).

In contrast to the RT data, however, detection of targets was more accurate for the (phonetically richer but phonologically nonviable) released stops than for the unreleased stops [see Fig. 1(b)]. There was a main effect of Release ($F1[1,24]=9.71$, $p=0.005$; $F2[1,28]=6.69$, $p<0.025$) and a significant Release × Manner interaction ($F1[1,24]=7.86$, $p=0.01$; $F2[1,28]=5.02$, $p<0.05$). Planned pairwise comparisons showed that the interaction was due to significantly higher accuracy for the released stops (5% errors; s.e., 1.6) than for the unreleased stops (19% errors; s.e., 2.7; $F1[1,24]=22.29$, $p<0.001$; $F2[1,14]=7.05$, $p<0.025$); there was no difference between the nasals in the released and unreleased conditions ($F1[1,24]<1$; $F2[1,14]<1$).

3. Combined analyses: Experiments 1a and 1b

We also asked whether Korean listeners' phoneme monitoring performance on the stops would be modulated by the language of the stimuli (Dutch versus English). This was a between-subject but within-item factor in two-way (Language × Release) ANOVAs. In RT, there was again a significant effect of Release ($F1[1,48]=11.17$, $p<0.005$; $F2[1,28]=50.53$, $p<0.001$), whereas neither a main effect of Language ($F2[1,48]<1$; $F2[1,28]<1$) nor an interaction between Language and Release ($F1[1,48]<1$; $F2[1,28]<1$) was found. The error analysis also showed a significant main effect of Release by subject ($F[1,48]=9.98$, $p<0.005$), but not by item ($F2[1,28]=2.73$, $p>0.1$) with no main effect of Language ($F1[1,48]<1$; $F2[1,28]<1$). There was also a significant interaction between the two factors by subject ($F1[1,48]=8.45$, $p<0.05$) but not by item ($F2[1,28]=2.73$, $p>0.1$). Planned pairwise comparisons suggested that this interaction was due to the fact that accuracy in detecting released stops was significantly higher with English (5% errors; s.e., 1.4) than with Dutch syllables (13% errors; s.e., 3.1) ($F1[1,24]=5.96$, $p<0.025$; $F2[1,28]=6.47$, $p<0.025$), while there was no language effect on unreleased stops ($F1[1,24]=2.81$, $p>0.1$; $F2[1,28]<1$, $p>0.5$; English versus Dutch mean errors: 19% vs 13%; s.e., 2.7 vs 2.0).

C. Discussion

The latency results showed that Korean listeners processed unreleased stops more rapidly than released stops, even though released stops carry additional phonetic cues to phoneme identity. This was true for both Dutch and English stimuli: As far as the RT data are concerned, the results thus appear to support the view that, in non-native listening, sounds which are phonologically viable in the native language are processed more efficiently than sounds which are phonologically illegitimate in the native language.

Interestingly, however, with respect to errors with English stimuli, accuracy in phoneme detection by Korean listeners improved when the targets were released. In other words, released stops (even though they are nonviable in Korean) were more accurately detected than unreleased stops (in spite of the fact that they are viable in Korean). This suggests that when the acoustic-phonetic cues in the release component of the stops were present, errors on the English spoken stimuli decreased, in spite of the illegality of released codas in Korean. This is at least in part in line with the view that the more cues to segment identity there are in the speech signal, the more efficiently the segment is processed (the phonetic-superiority hypothesis). There appears to be a language factor involved, however, since the phonetic-superiority effect in detection accuracy was observed with spoken stimuli in English—which Koreans are familiar with—but not with Dutch—a language unfamiliar to Koreans. This was further confirmed by the combined analysis which showed that the Koreans' detection accuracy was significantly higher for English than for Dutch consonants only in the released condition. We return to this issue in the General Discussion.

III. EXPERIMENT 2

Experiment 1 (the same materials and procedure) was re-run with Dutch listeners. This experiment had two goals. First, it provided a further test of the phonological-superiority hypothesis. If our interpretation of Experiment 1 is correct, such that Koreans detect unreleased stops more rapidly than released stops because unreleased coda stops are viable in Korean, then Dutch listeners should produce the opposite pattern of responses on the same stimuli. They should detect the released stops more easily than the unreleased stops because released coda stops are viable in Dutch. But they may also do so, of course, because the released stops are phonetically richer. Better performance by Dutch listeners on the released stops could thus be due to either phonological or phonetic influences. The critical analysis, therefore, is not that within the Dutch listeners' data itself, but that comparing the Dutch and Korean data (i.e., Experiment 1 versus Experiment 2). In this comparison, phonetic influences are controlled (the stimuli are the same for both groups of listeners), so if the Dutch and Korean listeners were to perform differently, this would support the phonological-superiority hypothesis. We therefore conducted an analysis in which the results of the two experiments were directly compared. Second, Experiment 2 again tested for effects of language familiarity, but now by contrasting performance on native language stimuli (Dutch) with non-native stimuli (English). This contrast provides a measure of whether non–native phoneme monitoring differs from the way the task is performed on native language materials.

A. Method

Seventy-two student volunteers from the Max Planck Institute subject pool were paid for their participation. They were all native speakers of Dutch, with no known hearing disorders. They were divided into four groups of 18, with two groups in Experiment 2a (Dutch stimuli) and two groups in Experiment 2b (English stimuli). In each sub-experiment, one group heard lists with released stops and the other heard lists with unreleased stops. The four sets of stimuli from Experiment 1 were re-used in Experiment 2. All experimental procedures were identical to those in the previous experiment.

B. Results

Ten subjects (five in each sub-experiment) were excluded from the analysis because they made errors so frequently that no scores were recorded for each of those subjects for at least one target consonant.

1. Experiment 2a: Dutch natives listening to Dutch

The RT analyses revealed that Dutch listeners showed the opposite pattern of performance on the Dutch stimuli to that of the Koreans. There was a main effect of Release on RT ($F1[1,29]=4.80$, $p<0.05$; $F2[1,28]=58.55$, $p<0.001$), which interacted with Manner ($F1[1,29]=19.32$, $p<0.001$; $F2[1,28]=23.02$, $p<0.001$). As shown in Fig. 2(a) (left), the interaction came from the fact that target stops were detected

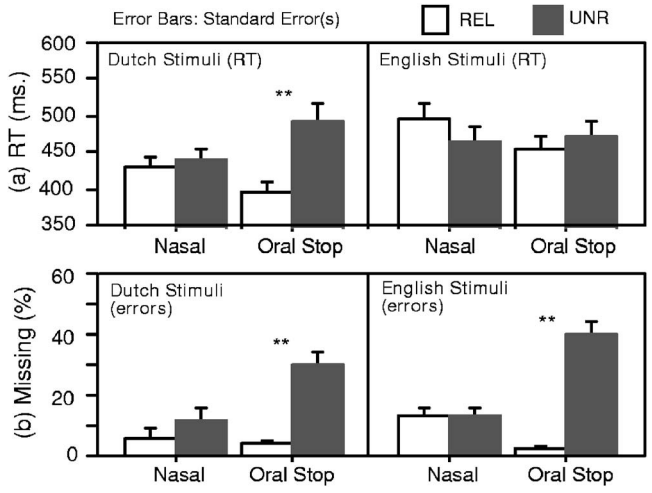

FIG. 2. Dutch listeners' mean Reaction Times [RTs, (a)] and errors [percent missing responses, (b)], with the spoken stimuli in Dutch (left) vs English (right). REL=released oral stops; UNR=unreleased oral stops. Note that the nasal stimuli were identical in the two release conditions. **=$p<0.001$.

more rapidly when released than unreleased by 97 ms ($F1[1,29]=13.09$, $p<0.001$; $F2[1,14]=87.69$, $p<0.001$; mean RTs: 400 vs 497 ms; s.e., 9.4 vs 17.9), while detection of the nasal targets was not influenced by the release condition—that is, irrespective of whether the nasals were presented in the same list as the released stops or mixed with unreleased stops ($F1[1,29]<1$; $F2[1,14]=4.65$, $p>0.07$; mean RTs for nasals: 432 vs 443 ms; s.e., 11.9 vs 11.6). Results with respect to the error rates showed a similar pattern (main effect of Release: $F1[1,29]=52.45$, $p<0.001$; $F2[1,28]=16.71$, $p<0.001$; Release × Manner interaction, $F1[1,29]=13.94$, $p<0.001$; $F2[1,28]=6.18$, $p<0.02$). Detection of stop targets was significantly more accurate when stops were released (4% errors; s.e., 1.3) than when they were unreleased (30% errors; s.e., 3.6; $F1[1,29]=54.89$, $p<0.001$; $F2[1,14]=13.60$, $p<0.005$), while there was only a nonsignificant trend for nasal targets (i.e., $F1[1,29]=3.49$, $p>0.07$; $F2[1,14]=3.11$, $p>0.09$; mean % errors for nasals: 6% vs 12%; s.e., 1.3 vs 2.9), as can be seen in Figure 2(b) (left).

2. Experiment 2b: Dutch natives listening to English

Unlike when they processed stimuli of their native language, Dutch listeners hearing English stimuli were not faster to respond to released than to unreleased stops [Fig. 2(a), right]. In the RT analysis there was no main effect of Release ($F1[1,29]<1$; $F2[1,28]<1$), but there was a significant Release × Manner interaction ($F1[1,29]=5.689$, $p<0.025$; $F2[1,28]=7.62$, $p<0.01$). This interaction was due to the fact that responses were faster for released than for unreleased stops (mean RTs: 459 vs 475 ms; s.e., 12.2 vs 17.8), while this effect reversed for the nasals (mean RTs: 499 vs 471 ms; s.e., 14.2 vs 14.4). But these simple effects were not significant by subjects ($F1[1,29]<1$, for both stops and nasals) or items ($F2[1,14]=3.38$, $p>0.08$ for stops; $F2[1,14]=4.28$, $p>0.05$ for nasals).

In errors, however, there was a significant effect of Release ($F1[1,29]=52.91$, $p<0.001$; $F2[1,28]=23.83$, $p<0.001$) and a significant Release × Manner interaction ($F[1,29]=69.51$, $p<0.001$; $F2[1,28]=20.59$, $p<0.001$). The interaction arose because Dutch listeners' detection of English oral stops was far more accurate for released than unreleased stops ($F1[1,29]=116.16$, $p<0.001$; $F2[1,14]=24.88$, $p<0.0001$; mean % errors, 2% vs 42%; s.e., 1 vs 4.4) whereas no such effect was found for nasal targets (both F's <1; mean % errors, 13% vs 14%; s.e., 2.4 vs 2.5).

3. Combined analyses: Experiments 2a and 2b

We tested if Dutch listeners' phoneme monitoring performance on the stops would be modulated by the language familiarity factor (Dutch versus English). Similar to Experiment 1, this was a between-subject factor but a within-item factor in two-way (Language × Release) ANOVAs. RT analyses showed no main effect of Language ($F1[1,58]<1$; $F2[1,28]=2.09$, $p>01$) and a trend toward a Language × Release interaction which was not significant by subject ($F1[1,58]=3.60$, $p=0.06$) but highly significant by item ($F2[1,28]=20.43$, $p<0.001$). The interaction came from the fact that in processing released (phonological viable) stops, Dutch listeners were faster by 59 ms with native stimuli than with non-native English stimuli ($F1[1,33]=5.75$, $p<0.025$; $F2[1,28]=10.87$, $p<0.003$; Dutch versus English mean RTs, 400 vs 459 ms; s.e., 14.6 vs 20.1), while a nonsignificant opposite pattern was found in processing unreleased (phonological unviable) stops (both F's <1; Dutch versus English mean RTs, 497 vs 476 ms; s.e., 24.3 vs 26.9).

Durational analysis of the released stimuli revealed, however, that the duration of the target consonant (the stop closure and the following release noise) was longer for the English than for the Dutch stimuli (closure, 112 vs 102 ms; release noise, 115 vs 90 ms; closure and release combined, 227 vs 192 ms). We therefore asked whether the fact that the Dutch listeners responded more slowly to the English released stops could be attributable to this durational difference. It is possible that listeners' responses could have been slower when the duration of the target consonant was longer, if their decisions tended to be delayed until they had heard all the available phonetic cues. We tested this possibility by examining, for each subject's data, the correlation between consonant duration and RTs. Variation in RTs was not significantly correlated with consonant duration in most cases. For Experiment 2a, only three out of 18 Dutch listeners (with Dutch stimuli) showed a significant positive correlation (the longer the consonant duration, the slower the RT) at $p<0.05$ (two-tailed), and five listeners showed negative correlation coefficients. For Experiment 2b, none of the Dutch listeners (with English stimuli) showed a significant correlation, and 13 out of 18 listeners showed negative correlation coefficients, which suggests, if anything, that responses were faster when the target consonants were longer. These results indicate that the Dutch listeners' slower responses to the English released stops were not due to the durational difference between the English and Dutch stop releases.

The combined error analysis in Experiment 2 showed a significant main effect of Language ($F1[1,58]=4.11$, $p<0.05$; $F2[1,28]=38.10$, $p<0.001$), such that overall accuracy was significantly higher for Dutch than for English

stimuli (Dutch versus English mean errors, 17% vs 22%; s.e., 1.8 vs 1.8). There was, however, a Language × Release interaction by subject ($F1[1,58]=7.29$, $p<0.01$) but not by item ($F2[1,28]=1.49$, $p>0.2$). Planned pairwise comparisons showed that this trend was due to the fact that when stops were released, there was no accuracy difference between Dutch and English stimuli (both F's <1; Dutch versus English mean errors, 4% vs 2%; s.e., 1.5 vs 1.0); when stops were unreleased, however, accuracy was significantly higher (by 12%) for Dutch stimuli than for English stimuli by subject ($F1[1,25]=5.14$, $p<0.04$; mean errors, 30% vs 42%; s.e., 3.6 vs 3.9), but again not by item ($F2[1,28]=1.09$, $p>0.3$).

4. Combined analyses: Korean and Dutch listeners

Finally, two sets of ANOVAs were run with listener group (Korean versus Dutch) and release condition as independent variables, one with Dutch stimuli (Experiments la and 2a) and one with English stimuli (Experiments 1b and 2b).

In the RT analysis with Dutch stimuli, there was a significant interaction between Listener Group and Release ($F1[1,53]=20.59$, $p<0.001$; $F2[1,28]=98.98$, $p<0.001$). The interaction was due to reverse patterns across the two listener groups. In processing Dutch released stops, Dutch listeners detected the released stops more rapidly than Korean listeners did ($F1[1,29]=19.15$, $p<0.001$; $F2[1,28]=43.92$, $p<0.001$). The reverse was true with unreleased stops: Korean listeners detected the unreleased stops more rapidly than Dutch listeners did ($F1[1,24]=4.78$, $p<0.04$; $F2[1,28]=6.55$, $p<0.02$). In the corresponding error analysis, there was also a significant Listener Group × Release interaction ($F1[1,53]=25.31$, $p<0.001$; $F2[1,28]=7.10$, $p<0.02$). This interaction was again due to reverse patterns of performance: the Dutch were more accurate in detecting released stops ($F1[1,29]=7.66$, $p=0.01$; $F2[1,28]=7.28$, $p<0.02$); the Koreans were more accurate in detecting unreleased stops, significantly so by subject ($F1[1,24]=16.97$, $p<0.001$) and marginally so by item ($F2[1,28]=3.40$, $p<0.08$).

In the analyses with English stimuli, there was a trend towards a Listener Group × Release interaction in the RT analysis by subject ($F1[1,53]=3.10$, $p<0.08$), but the interaction was highly significant by item ($F2[1,28]=22.37$, $p<0.001$). This interaction was again due to opposite patterns in the two listener groups. For the released stops, the difference between listener groups was significant only by item ($F1[1,28]=2.75$, $p>0.1$, $F2[1,28]=5.83$, $p<0.025$); for the unreleased stops this difference was not significant ($F1[1,25]<1$; $F2[1,28]=3.39$, $p<0.08$).

In the corresponding error analysis, however, there was a significant Listener Group × Release interaction ($F1[1,53]=27.23$, $p<0.001$; $F2[1,28]=6.74$, $p<0.02$). This interaction did not reflect opposite patterns in the two listener groups, however: the Koreans were more accurate on the unreleased stops than the Dutch ($F1[1,25]=23.36$, $p<0.001$; $F2[1,28]=4.73$, $p<0.04$), but there was no accuracy difference between the two groups on the released stops ($F1[1,28]=1.88$, $p>0.1$; $F2[1,28]=1.33$, $p>0.2$). This is probably attributable to a floor effect, given that both listener groups were very accurate.

C. Discussion

Perhaps unsurprisingly, Dutch listeners detected released stops in Dutch syllables faster than in English syllables. Similarly, they detected unreleased stops in the Dutch stimuli more accurately than in the English stimuli. Both of these effects reflect global benefits in processing native over non-native speech. The more specific comparison of listening performance on released and unreleased stops, however, provides evidence on the role of phonological knowledge in phoneme monitoring. When presented with native speech materials, Dutch listeners detected released stop targets more rapidly and more accurately than unreleased stop targets. But when they were presented with English spoken stimuli this effect was attenuated: although it was significant in the error analysis, there was no effect in the RT analysis. A violation of the phonological constraints of the listener's native language thus appears to interfere more severely with processing native than non-native speech.

The overall better performance on released stops can be accounted for in terms of the phonological-superiority hypothesis: Speech processing may be better when the sounds are in harmony with the phonological constraints of the listener's native language than when the sounds are phonologically nonviable. It is also possible, however, that the improved performance in detecting released stops is simply due to the richness of cues present in the signal: The more cues to segment identity in the speech signal, the more efficiently the segment is processed (the phonetic-superiority hypothesis). When a stop is released, its identity is cued not only by the formant transition in the vowel but also by the spectral characteristics during the burst, whereas an unreleased stop is perceptually weaker because it is cued only by the formant transition information.

One might argue that the attenuation of the released/unreleased difference in non-native listening (i.e., the Dutch listening to English) offers support for the phonological-superiority hypothesis. If the difference is due to phonological knowledge about the native language, one might expect a weaker effect when the input consists of non-native syllables. But it remains possible that the phonetic cues were stronger in the Dutch than in the American English stimuli. The critical comparisons are therefore the cross-experiment contrasts (i.e., on the Korean versus Dutch listener groups), where phonetic differences, should they exist, are held constant. These comparisons indeed showed that there were significantly different patterns in the two listener groups on both sets of stimuli. This suggests that phonological viability in the native language plays a stronger role in non-native listening than the availability and/or relative richness of acoustic-phonetic cues.

IV. GENERAL DISCUSSION

On the basis of the results of two experiments, we draw three conclusions. First, in line with previous research, per-

ception of non-native and native speech is influenced by the phonological system of the listener's native language. Second, although the richness of acoustic phonetic information also plays a role in consonant identification, this influence in non-native perception can be weaker than that due to native language phonological knowledge. Third, perception of non-native speech is also influenced by the listener's familiarity with the phonetic detail in the non-native language. We discuss each of these points in turn.

In line with the phonological-superiority hypothesis, phoneme recognition is improved in a speech environment which is phonologically viable in the listener's native language: Korean listeners detected unreleased coda stops faster than released coda stops, but Dutch listeners, responding to the same stimuli, detected the released stops more rapidly and/or more accurately. This pattern was confirmed by our cross-experiment comparisons, which showed that, for the unreleased Dutch stops, the Koreans were faster and more accurate than the Dutch, whereas for the released Dutch stops, the Dutch were faster and more accurate than the Koreans. The same pattern, though statistically weaker, was also observed for the English stimuli; we discuss the reasons for the weakening of the effect in the following. Nevertheless, there was still an influence of native phonology in the error rates on the English unreleased stops: Korean listeners missed significantly fewer target phonemes in this condition than the Dutch listeners. Finally, the results indicate that this phonological effect was stronger in native listening (Dutch listeners, Dutch VC's; significant effects in both speed and accuracy) than in non-native listening (Dutch listeners, English VC's; significant effects only in accuracy).

We suggest that listeners' expectations about the acoustic-phonetic form of a stop consonant in coda position, as determined by the phonological sound patterns of the listeners' native language and therefore a lifetime's exposure to those sound patterns, influence ease of phoneme recognition in native and, more strikingly, in non-native listening. Previous research has shown that various aspects of the phonological structure of one's native language influence non-native listening [e.g., phoneme inventory, Costa *et al.* (1998), Flege and Hillenbrand (1986); place assimilation rules, Weber (2001); phonotactic restrictions, Broersma (2005), Weber and Cutler (2006); and rhythmic structure, Cutler *et al.* (1986), Cutler and Otake (1994), Otake *et al.* (1993)]. The present findings add to this body of evidence by showing that native-language experience can determine ease of phoneme identification even in the extreme case where non-native target consonants which are phonologically expected in the listener's native language are in fact phonetically poorer (as when the Korean listeners detected unreleased stops more readily than released stops).

This, then, is our second conclusion: phonological expectations can outweigh phonetic information. It is undeniably true that native and non-native listening depends on the uptake of acoustic-phonetic cues present in the signal. In general, one would therefore assume that speech sounds which are more richly specified (e.g., released coda stops cued by VC formant transition information and by the information in the release burst) would be easier to recognize than sounds which are less well specified (e.g., unreleased coda stops cued only by the VC formant transitions). The present results suggest, however, that at least under some circumstances, poorer acoustic-phonetic information can lead to better phoneme recognition in non-native listening.

The relevant phonological fact that has been the focus of the present study is that Korean stops are obligatorily unreleased in coda position in words spoken in isolation, as compared to Dutch stops, which are generally released in that environment. There is, however, an additional phonological difference concerning coda position in Korean and Dutch which might be relevant. Korean stops are phonologically divided into the categories lenis, fortis and aspirated, and these manners of articulation are cued primarily in the post-release part of the acoustic signal (Cho *et al.*, 2002; Kim *et al.*, 2002). This three-way manner contrast is neutralized completely in coda position (Kim and Jongman, 1996). Furthermore, the three fricatives in Korean (/s,s*,h/) become unreleased alveolar stops in coda position (Kim-Renaud, 1976; Martin, 1992). The situation is very different in Dutch codas. Although there is word-final devoicing in Dutch, this process is incomplete: There are fine-grained phonetic differences between underlyingly voiced and voiceless coda stops (Warner *et al.*, 2004; Ernestus and Baayen, in press). Because of this incomplete neutralization process, five stops can appear in Dutch singeleton codas. Fricatives can also occur in the coda in Dutch. The possible phonetic forms that can occur in coda position are thus more limited in Korean than in Dutch. The functional load in processing consonants in the coda may therefore be lower for Korean than for Dutch listeners. It is possible that this difference may influence perception of coda consonants in the two languages. Our findings do not bear directly on this issue, however, because phonologically viable phonetic forms in the coda position are unreleased in Korean but released in Dutch, and it is this which we manipulated, not the size of the set of coda consonants. A pure test of this set-size hypothesis would require a comparison of two languages with the same type of stops in the coda (either released or unreleased), so that the only relevant factor to consider would be the different number of allowable phonetic forms in the coda stemming from language-specific neutralization processes.

Although poorer acoustic-phonetic information led to faster phoneme recognition in non-native listening by the Koreans, there was some evidence that acoustic-phonetic cues can also be exploited by listeners in non-native speech perception, even if those cues are not the ones used in processing the listener's native language. Koreans were faster on unreleased than on released stops in both Dutch and English. But, for the English stimuli alone, the Koreans were more accurate on the released than on unreleased stops. We suggest that this interaction between the application of phonological constraints and the use of acoustic-phonetic cues in non-native perception depends on language familiarity. Dutch is a truly exotic language to Korean university students, whereas English is, for them, the most familiar non-native language. They are likely to have learned English since they were 12 years old but never to have heard Dutch before. In the course of second-language acquisition, Korean

students might have built up some familiarity with the acoustic-phonetic characteristics of the sounds of English. If so, then even though the violation of the phonological constraints of Korean in English released stops led to slow detection times, familiarity with the form of such stops may have allowed Korean learners of English to exploit the richer set of acoustic-phonetic cues available in the released stops to improve detection accuracy.[1]

On this view, Korean listeners are able to extract efficiently information about stop identity in the formant transitions of the preceding vowel. When there is no release (in both the Dutch and English stimuli), they are therefore able to recognize target phonemes quickly, and quite accurately. When a release follows, however, their phoneme monitoring performance is disrupted, resulting in slower responses to both the Dutch and English released stimuli. Familiarity with English can nevertheless allow Koreans to be very accurate on the English released stops. They have no experience with Dutch and thus the impact of the release-induced disruption is greater, that is, the additional cues in the Dutch released stops are not fully exploited. But the additional information in the English releases, though unable to undo the disruption in processing speed caused by the releases' phonological nonviability, leads to very accurate performance. Thus, if non-native speech contains cues that are not present in the equivalent position in native speech, and if non-native listeners are sufficiently familiar with that language, then those listeners can use those richer cues in phoneme identification.

This use of non-native cues contrasts with the findings of Broersma (2005). She showed that Dutch listeners who were very familiar with English (at least as familiar as the present Koreans were with English) did not process vowel-duration cues to the English coda voicing distinction, unlike a group of native English listeners. The Dutch listeners nevertheless categorized non-native English coda fricatives as voiced or voiceless at least as well as the native English listeners. Broersma suggests that this may have been because the Dutch listeners have learned that vowel duration is not a very informative cue to the voicing distinction in Dutch, and thus do not rely on this cue in non-native listening either. The present results suggest however that it is not necessarily the case that phonetic information that is not valuable in native language perception (or that is even not present in the native language) is ignored when the listener hears a foreign language. One reason for the difference between studies may be due to a difference in cue exposure. The Dutch listeners in the Broersma study have been exposed to differences in vowel duration in their native language, as a cue to vowel quantity (i.e., the phonemic contrast between long and short vowels; cf. Nooteboom, 1972; Nooteboom and Doodeman, 1980) and to other cues to the obstruent voicing contrast. Dutch listeners may thus have learned that vowel duration is a weak cue to obstruent voicing. But the Korean listeners in the present study are never exposed to release bursts in coda position in their native language and therefore cannot learn, during native language exposure, to ignore this information in stop identification or to use it for the recognition of some other sound(s). When Koreans therefore have sufficient exposure to release bursts in non-native listening, they can use the additional information contained in those bursts to improve target recognition accuracy.

The present study has pitted native-language phonological viability against the relative richness of acoustic-phonetic cues in non–native listening. Phonological viability seems to have the upper hand: Phoneme recognition is in general better when the phonetic specification of those phonemes is in keeping with the listener's native phonology, even when that phonetic specification is, in physical terms, poorer. This dominance of phonological knowledge is consistent with theories of non-native speech perception, such as Flege's Speech Learning Model (SLM, e.g., Flege, 1991, 1995) and Best's Perceptual Assimilation Model (PAM, e.g., Best, 1994, 1995, Best *et al.*, 2001). Both models predict that non-native sounds are perceived through some form of phonological filter of the listeners' native language that takes into account the nonnative sounds' phonetic (dis)similarities to native phonetic categories. Previous studies supporting these models, however, have generally been based on cross-linguistic phonological differences concerning the phoneme inventories of the languages in question. The findings of the present study therefore show that the phonological filter created through exposure to a native language is determined not only by the phoneme inventory of that language but also by sound patterns that are driven by phonological (allophonic) rules. As we have just argued, however, the relative richness of phonetic cues can also play a role in non-native listening, at least in a non-native language with which the listeners are familiar. Models of non-native listening must therefore not only take native-language phonological processes into account (both phonemic and rule-driven processes), but also the absolute amount of phonetic information in the nonnative speech stream.

ACKNOWLEDGMENTS

This study was carried out in large part when T. C. was affiliated with the Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands. We thank Kee-Ho Kim at Korea University for helping us with the acquisition of the Korean data. We also thank Mirjam Broersma, Anne Cutler, Elizabeth Johnson, and Roel Smits for their comments at various stages of this project; and Ann Bradlow and three anonymous reviewers for their comments and suggestions. A preliminary report of this research appears as Cho and McQueen (2004).

[1]This language familiarity effect is further supported by an analysis of detection accuracy on the nasals. (We thank an anonymous reviewer for bringing the detection accuracy data on nasals to our attention.) As can be seen in Fig. 1, Korean listeners were more accurate in detecting (for them more familiar) English nasals than (for them unfamiliar) Dutch nasals, especially in the released condition (10% vs 21% errors; $F1(1,24)=7.08$, $p=0.014$; $F2(1,14)=1.93$, $p>0.1$) but also in the unreleased condition (11% vs 20% errors; $F1(1,24)=3.49$, $p=0.174$; $F2(1,14)=1.31$, $p>0.1$). A similar observation can be made from the Dutch listeners' responses to the nasals (Fig. 2). Dutch listeners were more accurate in detecting Dutch nasals than less familiar (non-native) English nasals, but only in the released condition (6% vs 13% errors; $F1(1,29)=6.38$, $p=0.016$; $F2(1,14)=4.45$, $p=0.053$).

(Received 14 June 2005; revised 27 February 2006; accepted 28 February 2006)

Previous investigations have suggested that hearing-impaired (HI) listeners have reduced masking release (MR) compared to normal hearing listeners (NH) when they listen in modulated noise. The current study examined the following questions that have not been clearly answered: First, when HI listeners are amplified so that their performance is equal to that of NH listeners in quiet and in steady noise, do HI listeners still show reduced MR with modulated noise when compared to NH listeners? Second, is the masking release the same for sentences and CV syllables? Third, does forward masking significantly contribute to the variability in performance among HI listeners? To compensate for reduced hearing sensitivity for HI listeners, the spectrum levels of both speech and noise were adjusted based on the individual hearing loss. There was no significant difference between the performance of NH listeners and that of HI listeners in steady noise and in quiet. However, the amount of MR for sentences and for CV syllables was significantly reduced for HI listeners. For sentence recognition, the amount of MR seemed to be more related to hearing sensitivity for low-to-mid frequencies than to forward masking. In contrast, forward masking thresholds appear to be a major contributor to the amount of MR for syllable recognition. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188688]

I. INTRODUCTION

Hearing-impaired (HI) listeners often report difficulty understanding speech in the presence of background noise. Several investigators have suggested that the Articulation Index (AI, French and Steinberg, 1947) can account for the speech recognition performance HI listeners with mild-to-moderate hearing loss (e.g., Dubno and Dirks, 1989; Pavlovic *et al.*, 1986; Zurek and Delhorne, 1987). According to this hypothesis, HI listeners with mild-to-moderate hearing loss should understand speech in quiet as well as normal hearing (NH) listeners if the whole dynamic range of speech were made audible. The effect of steady noise on HI listeners becomes more detrimental than it is to NH listeners because HI listeners already have reduced redundancy of the speech signal in quiet because portions of speech information are below the thresholds (Van Tasell, 1993). Nevertheless, if the AI function for a certain speech material and signal-to-noise ratio (SNR) is known, the speech recognition ability of HI listeners in steady noise can be predicted based on their thresholds.

However, differences in speech recognition performance between NH and HI listeners become more apparent if the noise is fluctuating in level (Bacon *et al.*, 1998). In amplitude modulated noise, NH listeners can benefit from brief moments in which they experience a favorable SNR. This results in a better ability to understand speech in modulated than in steady noise. Depending on the depth and rate of fluctuation the degree of masking release in NH listeners can range from 2 to 30 dB (Gustafson and Arlinger, 1994; Howard-Jones and Rosen, 1993; Miller and Licklider, 1950). Compared to NH, HI listeners show significantly less masking release (Bacon *et al.*, 1998; Eisenberg *et al.*, 1995; Festen and Plomp, 1990; Gustafsson and Arlinger, 1994; Nelson *et al.*, 2003). The amount of masking release remains reduced even when thresholds of HI listeners are close to those of NH listeners except at higher frequencies (Dubno *et al.*, 2002) or when speech signals are presented at above threshold levels (Eisenberg *et al.*, 1995).

In an effort to explain these findings in terms of decreased audibility in HI listeners, Trine (1995) examined the relationship between the amount of masking release and the average pure-tone threshold. He asked listeners to adjust the level of either the noise masker or speech signal to the point where they could understand speech 50% of time. The noise was steady or modulated by an 8 Hz square wave at different modulation depths. Trine found a high negative correlation (correlation coefficient of either −0.81 or −0.88 depending on the overall level of speech and noise) between the degree of hearing loss and the amount of masking release. Therefore, he inferred that if the dips in the modulated noise were above threshold (so that modulation depth was not affected by hearing loss), both NH and HI listeners would show similar amounts of masking release.

However, it has been argued that reduction in masking release in HI listeners could not be accounted for by reduced audibility alone. For example, Eisenberg *et al.*(1995) compared consonant recognition of HI listeners in steady and

[a)]Electronic mail: shjin@uwyo.edu

modulated noise with performance of NH listeners who were tested with and without spectrally shaped background noise that simulated hearing loss. NH listeners performed significantly better in modulated noise than in steady noise, both with and without spectrally shaped noise. In comparison, the investigators examined masking release of HI listeners when the speech and noise were spectrally shaped and amplified to compensate for the loss of hearing sensitivity. Even with speech and modulated noise that were audible, HI listeners still showed less release from masking, relative to NH listeners.

Suprathreshold psychoacoustic abilities other than audibility, such as spectral resolution, temporal resolution, or auditory integration, have been linked to understanding speech in fluctuating noise. For example, Peters *et al.* (1998) suggested that HI listeners have reduced ability to use both spectral and temporal gaps in the background noise because of deficits in frequency selectivity as well as reduced audibility associated with hearing loss. Peters *et al.* measured speech reception thresholds (SRTs) of four different groups of listeners in various noise conditions: young and elderly listeners with normal hearing and young/elderly listeners with moderate to severe hearing loss. The hearing in noise test (HINT) sentences were used to measure SRT of each participant in the presence of six different background noises: a steady noise shaped by the long-term average spectrum of HINT sentences (called HINT noise), a single competing female talker, a HINT noise with temporal fluctuations, a HINT noise with spectral gaps in several frequency regions and a noise with both temporal and spectral gaps. To compensate for reduced audibility for HI listeners, HINT sentences and the background noises were amplified using linear amplification combined with frequency-response shaping (NAL amplification). The results showed that both young and elderly HI listeners had significantly higher SRTs than the normal-hearing groups even when amplified speech and noise were presented to HI listeners. When the background noise was temporally and spectrally modulated, the differences between NH and HI listeners were much greater (7–15 dB) than when the noise was steady (2–3 dB). Reduced audibility as well as suprathreshold deficits were considered as a possible contributor to the poorer SRTs of HI listeners.

It has also been speculated that reduced temporal resolution associated with cochlear hearing loss (Glasberg *et al.*, 1987; Kidd *et al.*, 1983; Nelson and Freyman, 1987) might play a role in speech perception with fluctuating noise (Festen and Plomp, 1990; Dubno *et al.*, 2002). Temporal resolution has been considered as an important characteristic for listeners to understand fast time-varying stimuli like speech. Listeners need to be able to follow acoustic signals in sequence and to put them together into whole meaningful speech. One of the common methods to examine temporal resolution is forward masking which would be a relevant measure in the context of speech recognition in modulated noise (Festen, 1993; Dubno *et al.*, 2002). That is, brief release in dips of fluctuating noise may be affected by recovery from masking from the preceding peaks of noise, which is similar to the forward masking paradigm. A long recovery time may make speech information in dips less audible.

Plack *et al.* (2002) hypothesized that all the major nonlinear processes of forward masking in NH listeners can be accounted for by the nonlinear response characteristics of basilar membrane (BM). One of the nonlinear properties of temporal masking is that increments in masker level do not produce equal increments in masked threshold (Moore and Glasberg, 1983). For example, if the masker level is increased by 10 dB, the amount of forward masking is only increased by 3 dB. This results in nonlinear growth of the forward masking function. Sensorineural hearing loss is presumably related to a loss of nonlinear BM response (Ruggero *et al.*, 1997). If the hypothesis of forward masking is true, HI listeners should show a loss of nonlinear function in forward masking (Plack *et al.*, 2002). In fact, findings from HI listeners in forward masking experiments have supported this assumption. That is, the growth of forward masking increases linearly as masker level increases, which results in linear growth of forward masking in HI listeners (Kidd *et al.*, 1983; Oxenham and Plack, 1997). This means that HI listeners might be more affected by forward masking at a given masker level than would NH listeners.

Bacon *et al.* (1998) speculated that reduced masking release in HI listeners could be partially accounted for by reduced temporal resolution. They measured SRTs in the presence of temporally modulated speech-shaped noises from three groups of listeners: HI listeners, NH listeners, and those with NH who listened to speech in the spectrally shaped noise to simulate hearing loss of HI listeners (NM). The results showed that NM and some HI listeners (5 out of 11 NH listeners) had similar amount of masking release that was less than NH listeners. On the other hand, the rest of the HI group showed significantly less release of masking than the NM group. This suggests that the extra amount of reduced masking release in some HI listeners is not the result of reduced audibility only. Their auditory systems might be more susceptible to forward masking due to cochlear hearing loss so that these listeners may not have as much masking release as other listeners did. Unfortunately, the relationship between masking release and forward masking was not demonstrated because the investigators did not measure forward masking.

Recently, Dubno *et al.* (2002) investigated the effect of aging on masking release and the possible contribution of simultaneous and forward masking thresholds to consonant recognition in modulated noise. Both younger and older listeners in that study had thresholds less than or equal to 20 dB HL at octave frequencies from 0.25 to 4.0 kHz. The average thresholds for older listeners were 10 dB higher than those for younger listeners. To minimize differences in audibility in quiet, Dubno *et al.* presented threshold-matching noise, which resulted in equivalent masked thresholds for all listeners. Results showed reduced masking release and poorer simultaneous and forward masking thresholds in older subjects than those in younger listeners. Older subjects also showed reduced recovery from forward masking compared to younger listeners. Dubno *et al.* concluded that speech rec-

TABLE I. Audiometric hearing thresholds in dB HL as a function of frequency in Hz.

ognition in modulated noise might be associated with age-related increases in thresholds in forward and simultaneous masking.

However, the measurement of consonant recognition in fluctuating noise introduced some variability in the Dubno *et al.* (2002) study. The timing of each syllable presentation was random and independent of the noise. That is, the location of the consonant portion of the syllable was random with respect to the peaks and valleys of the noise. Critical acoustic cues for consonant recognition mostly lie in the brief onsets of consonants. If 50 ms on- and off-periods of modulating noise (the noise was modulated by a 10 Hz square wave) were randomly placed in the CV syllable, the critical information could be completely covered by the "on" period of noise or not covered at all. In that case, it is not clear whether listeners truly had masking release (listening in dips) or that the critical consonant cues were masked by chance. To test masking release for CV syllables, it may be necessary to present modulated noise at a fixed delay with respect to the onset of consonant rather than at a random delay. In addition, Dubno *et al.* tested forward masking at only one masker delay. Additional detail is needed to fully understand the relationship between forward masking and performance in gated noise.

The relationship between suprathreshold abilities and speech preception in modulated noise is not clear from the studies by Bacon *et al.* (1998) and Dubno *et al.* (2002). In the current investigation, differences in performance of NH and HI listeners for speech perception (sentence and consonant recognition) were examined in various types of noise. A primary goal was to investigate how temporal resolution associated with cochlear hearing loss plays a role in the perception of speech in modulated noise. To lessen the effects of reduced hearing sensitivity on performance of HI listeners both speech and noise for individual listeners were processed through linear amplification with frequency-response shaping based on his/her hearing sensitivity. Amplification was applied based on half-gain rule settings, so that HI listeners would obtain maximal signal audibility. Our goal was that HI listeners would be amplified sufficiently to achieve performance in quiet and in steady noise that was equivalent to NH listeners. Both sentences and consonants were selected as stimuli in an attempt to describe the potential effects of temporal resolution on different types of speech stimuli. For consonant stimuli, both fixed and random timing was employed to further describe potential effects of prior stimulation on the onsets of consonants. In addition, differences in the age range between NH and HI group were made to be small in order to minimize any effect of aging.

Three questions are addressed here. First, when HI listeners are amplified so that their performance is equal to that of NH listeners in quiet and in steady noise, do HI listeners still show reduced masking release when compared to NH listeners? Second, is the masking release the same for sentences and CV syllables? And finally, does forward masking explain a significant proportion of the variability in performance among HI listeners?

II. METHODS

A. Participants

Two groups of native speakers of English, NH and HI, participated in the current study. The age range for the NH group was 20–25 years and for the HI group 20–52 years. The NH group consisted of eight listeners with thresholds no more than 15 dB HL across audiometric frequencies (250–8000 Hz). The HI group consisted of nine individuals with sensorineural hearing loss who have thresholds more than 20 dB HL but no more than 70 dB HL across audiometric frequencies. The individual thresholds for the HI group are shown in Table I.

B. Stimulus preparation and procedures

1. Speech recognition

For speech recognition in noise, sentence recognition and consonant recognition in consonant-vowel (CV) syllables were used. For the sentence recognition test, IEEE sentences spoken by five male and five female talkers were used. Blocks of ten sentences were presented with each block containing one sentence spoken by each talker. Sentences were presented in random order. Each sentence consisted of five key words. Noise stimuli were generated by using the Tucker-Davis wave form generator (TDT WG1) and passed through a 30-band equalizer to match the spectrum of noise with the long-term spectrum of the IEEE sentences.

Noise stimuli were steady or gated with 2 ms cosine-squared ramps, implemented with 50% duty cycle and 100%

modulation depth. The modulation rates were 8 and 16 Hz, which results in the duration of the peaks of the modulating noise at 62.5 ms and 31.25 ms, respectively. Modulation rates of 8 and 16 Hz were selected because Nelson *et al.* (2003) found that the most masking release in NH listeners occurred at these rates. SNR was computed based on the long-term rms of the noise and the speech. SNRs of −5 and −10 dB were used for both NH and HI listeners. The noise always started 10–100 ms prior to the onset of sentences and ended briefly after each sentence. Two blocks of sentences were used per condition. A total of 12 blocks (2 SNRs × 3 modulation rates × 2 repetitions) in each noise condition and 2 blocks in the quiet condition were presented to each listeners in a random order.

Speech stimuli for consonant recognition consisted of 69 CV syllables made by combining 23 English consonants with the vowels /a/, /i/, and /u/ that were spoken by a female talker. Each syllable was presented in random order per block. These syllables were presented in steady-state noise, random-phase modulating noise, and controlled-phase modulating noise at −5 and −10 SNR. Random-phase modulating noise was similar to what Dubno *et al.* (2002) employed. That is, a period of peaks and valleys in modulating noise were implemented in speech randomly so that they were independent of the onset of CV syllables. In the controlled-phase noise condition, on the other hand, peaks of the modulating noise were implemented in a way that the onset of the consonant (which contains critical cues for consonant identification) occurred at the midpoint of a dip in the masking noise. Both random and controlled modulated noises had modulation rates of 8 and 16 Hz. Speech stimuli (both IEEE sentences and CV syllables) were presented about 40 dB above the pure tone average in order to minimize differences in audibility between groups. Listeners were asked to repeat back what they heard after the presentation of each sentence of CV syllable. The experimenter circled the responses on an answer sheet.

For NH listeners, the overall level of speech was fixed at 70 dB SPL. For each HI listener, however, the overall level of the speech and noise (for both sentence and syllable conditions) was adjusted based on his/her hearing sensitivity. For example, from Table I, HI1 has a mild-to-moderate hearing loss at mid to high frequencies for the tested ear. To amplify the level of speech and noise at the frequency range where HI1 has the most hearing loss but to maintain the level at other frequencies, speech and noise were passed through a Rane GE 60 graphic equalizer shaped to approximate the half-gain rule for each individual HI listeners. For NH listeners, natural speech and broadband noise shaped by the long-term spectrum of either IEEE sentences or CV syllables were presented without any amplification. Figure 1 shows the levels of IEEE sentence and speech-shaped noise at −10 dB SNR compared to the hearing sensitivity for NH group on average and for HI1.

2. Forward masking thresholds

The temporal resolution of each participant was examined by using a forward masking paradigm. The levels of the probe tone that were required for a listener to detect the probe following the noise masker were measured for 20 ms probes of 2000 and 4000 Hz. These frequencies were selected because the critical information for speech recognition is located primarily in the higher frequency areas in comparison to low frequencies (French and Steinberg, 1947). In support of this, Dubno *et al.* (2002) reported that the correlation between speech recognition scores and forward masking thresholds at 2000 and 4000 Hz was higher than the correlation between speech recognition and forward masking at 500 and 1000 Hz. Participants' absolute thresholds in quiet were measured for the two tones before measuring masked thresholds in the forward masking paradigm.

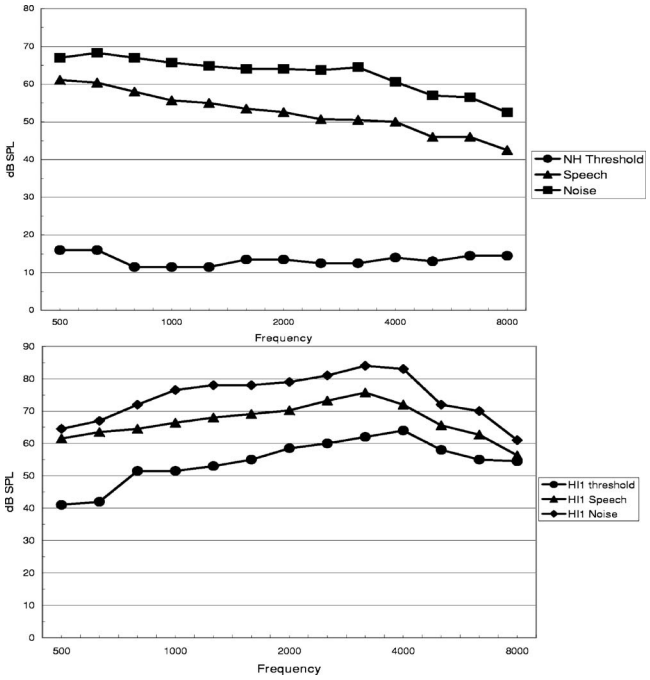

FIG. 1. Long-term spectra for IEEE sentences and speech-shaped noise along with hearing thresholds on average in dB SPL for the NH group in top panel and for hearing-impaired subject 1 (HI1) in the lower panel.

The masking noise was speech-shaped broad band noise that was used in the sentence recognition test. For HI listeners, the 300 ms noise was presented at the two levels that were used to produce −5 and −10 dB SNR in the sentence recognition test. Since the speech signals were presented at 40 dB SL, the absolute level of the noise (in dB SPL) for the HI listeners varied depending on his/her thresholds. Therefore, for HI listeners, the noise levels were 45 or 50 dB SL. The noise levels for all NH listeners were fixed at 70 and 85 dB SPL for two reasons. First, speech-shaped noise at 70 dB SPL represents a typical conversation level. Second, previous investigations (Nelson and Freyman, 1987; Dubno and Dirks, 1989) suggested that some HI listeners show greater amounts of masking only because the higher noise levels in dB SPL (compared to those for NH listeners) were used to compensate for loss of hearing sensitivity. Therefore, in the current investigation, 85 dB SPL was used for the NH group in order to compare temporal resolution at an approximately matched absolute noise level.

The duration between the offset of the masker and the onset of the signal (signal delay) were 8, 16, 32, and 64 ms. There were a total of 18 conditions: 2 frequencies $\times 2$ masker levels $\times 4$ signal delays ($n=16$) plus 2 thresholds in quiet (total $n=18$ conditions). A threshold for each condition was obtained three times. If the variance among the thresholds in a condition were greater than 2 dB, the same condition was repeated until any combination of three thresholds varied within 2 dB. All thresholds were obtained using a three-interval forced-choice adaptive procedure (Levitt, 1971) with a decision rule that estimates the signal intensity required for 79% correct performance. The blocks ended after the 12th reversal. A threshold was calculated from the latter 8 of 12 reversals. The step size was 4 dB for the first two reversals and then decreased to 2 dB for the remainder of the block. A trial consisted of a 200 ms warning interval, three observation intervals separated by 400 ms, and an answer interval terminated by the listener's responses. During each answer interval, the listeners were asked to press either 1, 2, or 3 from a keyboard indicating which observation interval she/he heard the signal. Each interval was marked by a visual cue on the computer monitor. Correct answer feedback was presented on the monitor after each listener's response. Listeners were seated in a sound-treated room and heard a tone and noise through an earphone. The visual cues such as "Ready," "Listen," and "Respond" appeared on the monitor in front of the listeners. Each subject had at least 1 h of practice before data collection began.

C. Analysis

Results of each task were entered into Analysis of Variance (ANOVA) with repeated measures to examine differences between groups (NH versus HI) and main effects within a group (SNR, gate frequencies, signal delay). Thresholds from the temporal masking experiment and hearing sensitivity were correlated with the amount of release from masking in sentence recognition as well as in syllable identification. Those with high correlation coefficients ($r>0.6$) were included in a regression analysis to find which test results best predicted performance in speech recognition in gated noise. For example, if forward masking thresholds and auditory thresholds at 2000 Hz were highly correlated with the masking release in sentence recognition, two regression models were constructed and the fits of the two equations were compared using an F test. Based on these findings, we might be able to further attribute a lack of masking release with deficits in temporal resolution as well as loss of hearing sensitivity.

III. RESULTS

A. IEEE sentence recognition

Figure 2 shows the percent correct key word identification in different noise conditions (no noise, steady, and gated noise) for both NH and HI listeners at the SNR of −5 and −10 dB, respectively. For each noise condition, solid black bars on the far left side represent average percent correct and standard deviation for NH group. Each bar in different patterns shows the performance of each HI listener. The mean key word identification score in quiet was 97.8% (s.d.=3.7) for the HI group and 99.8% (s.d.=0.46) for the NH group. At −5 dB SNR, the range of performance for HI listeners in steady noise was from 34% to 52% ($M=41.5$, s.d.=5.9) and from 37% to 55% ($M=44.4$, s.d.=7.1) for NH listeners. At −10 dB SNR, HI listeners performed from 7% to 19% ($M=10.6$, s.d.=5.8) and for the NH group scores ranged from and 4% to 21% ($M=12.2$, s.d.=4.5). Apparently, the two groups performed very similarly in quiet and steady noise.

To avoid possible ceiling and floor effects, the results were converted using the arcsine transformation [$y=\text{arcsine}(\sqrt{\text{PC}\times 100})$] where PC is the percent correct scores and y is the transformed data. According to Howell (1997), the arcsine transformation is useful to stretch out both ends of data relative to the middle. Transformed data were then analyzed using an ANOVA with a group as between subject factor and the percent correct scores as a within subject factor. Even with transformed data, group differences were not significant in quiet [$F(1,15)=2.007$, $p=0.177$] and in steady noise [$F(1,15)=3.518$, $p=0.08$].

This suggests that the presentation levels of amplified speech for each HI listener yielded equivalent audibility to those for NH group. As a result, both NH and HI listeners showed comparable performance in quiet and in steady noise.

When noise was modulated, however, performance of HI listeners was significantly poorer than that of the NH group as shown in Fig. 2. Whereas NH listeners identified 81%–97% key words at −5 SNR and 64%–96% at −10 SNR for both gate frequencies, HI listeners only scored 36%–74% and 13%–58%, respectively.

Figure 3 shows the amount of improvement (or masking release) as the difference between the percent correct scores for gated noise and in comparison with those for steady noise. The improvement of the NH listeners from gating was about 50% for −5 dB SNR and 70% for −10 dB SNR. This suggests when background noise gets louder, NH listeners benefit more from momentary gaps in the gated noise in terms of absolute change. For the HI group, the amount of masking release (MR) ranged from −8% to 34% at −5 dB SNR and from −3% to 45% at −10 dB SNR. Those who had the most hearing loss (HI2 and HI6) showed the least masking release. Compared to the NH group, HI participants took less advantage of gating and the amount of MR was relatively constant across noise levels.

Since the baseline (percent correct in steady noise) and the best scores (percent correct in quiet) for each listener varied somewhat, it was worthwhile to examine a "normalized masking release" (NMR) relative to each listener's performance difference between baseline and best scores. That is, NMR represents a ratio of the amount of masking release obtained to the amount of possible benefit from gating. For example, HI2 had masking release of 34% at 8 Hz, −5 SNR. His baseline and best scores were 38% (with steady noise) and 99% (in quiet) and the difference between these was 61%. It can be assumed that HI2 could benefit from gating at most by 61%. However, his performance improved by only 34% out of the possible 61%, which results in a ratio of 0.56.

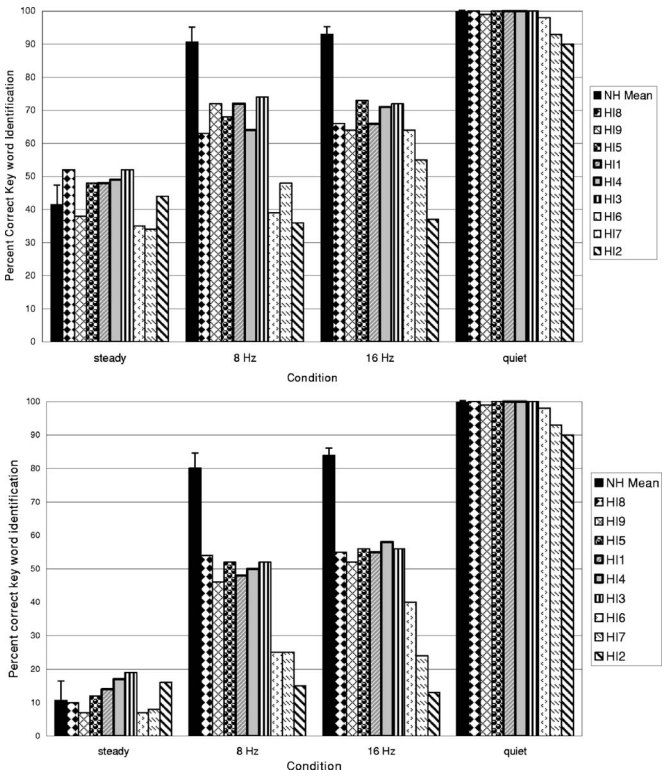

FIG. 2. Percent correct keyword identification of HI listeners and the NH group for sentence recognition at −5 dB SNR (upper panel) and −10 dB SNR (lower panel.) Note: the data for the quiet condition are the same in both upper and lower panels. They are shown for comparison in each panel.

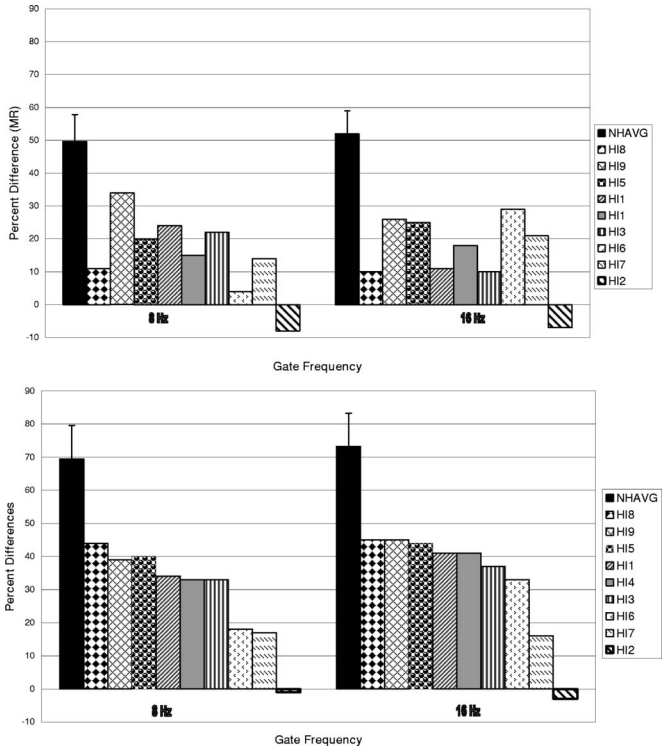

FIG. 3. The amount of masking release (MR) for individual HI listeners and for the NH group for sentence recognition at −5 dB SNR (upper panel) and −10 dB SNR (lower panel).

In the current study, this ratio is called a NMR. The amount of NMR shows that NH listeners could take advantage of gating about 0.8 (80% of the possible gain) whereas HI listeners only could gain 15% to 55%. Even considering those best HI listeners (HI1, HI3, and HI5, for example), their NMR was significantly less than those of NH listeners.

In a two-way ANOVA with repeated measures, group (either NH or HI) was a between-subject factor and the dependent variables were PC, MR, or NMR. ANOVA results indicate significant effects of group on all three dependent variables ($p<0.01$). For example, for NMR, there was significant effect of group [$F(1,15)=60.5$, $p<0.0001$]. In contrast, the level of noise (dB SNR) and gate frequency had no significant effect on NMR ($p>0.05$). There was no significant interaction. Clearly, the HI listeners obtained significantly less masking release than did NH listeners, despite the fact that their performance in quiet and in steady noise were not significantly different from NH listeners.

B. CV syllable recognition

Figure 4 shows the percent correct syllable identification of NH and HI listeners when the onset of the noise burst was either random or fixed relative to the onset of consonants at −5 dB SNR. Similarly, Fig. 5 demonstrates percent correct in fixed and random conditions at −10 dB SNR. In quiet, the mean syllable identification score was 93.25% (s.d.=2.71) for the NH group and 89% (s.d.=4.52) for the HI group. In the presence of steady noise, the means for NH listeners were 43% (s.d.=4.9) at −5 SNR and 12.5% (s.d.=4.5) at −10 SNR whereas those for HI listeners were 43% (s.d.=4.3) and 20.2% (s.d.=2.6), respectively. Consistent with the results from sentence recognition, the ANOVA indicated that the consonant identification scores of the NH and HI groups were similar to each other when syllables were presented in quiet [$F(1,15)=5.530$, $p=0.053$] or with steady noise [$F(1,15)=5.935$, $p=0.058$].

As with sentences, NH listeners performed significantly better than HI listeners did in the presence of gated noise. Figures 6 and 7 show the amount of MR for the different noise conditions. Compared to the random condition, the performance of each listener in both NH and HI groups seems to be better in the fixed condition across gate frequencies. A three-way ANOVA (2 SNR × 2 gate frequencies × 2 conditions) with repeated measures indicates significant effects of condition (random versus controlled phase) on MR [$F(1,15)=34.377, p=0.000$] and on NMR [$F(1,15)=59.87, p=0.000$]. Like the sentence recognition task, NH listeners showed significantly greater MR and NMR than did HI listeners for CV syllable recognition. The controlled-phase scores were significantly better than the random-phase scores. There were no significant differences between gate frequencies.

C. Temporal resolution

As stated previously, for HI listeners, the noise levels were 45 or 50 dB SL except HI2, HI5, and HI7. (HI5 could not finish all sessions because of her limited schedule for the study. HI2 and HI7 could not be tested at higher levels because the equipment was limited to provide 50 dB SL relative to their hearing sensitivity.) A three-way ANOVA with

TABLE II. Slopes of forward masking function.

	Low level		High level	
	2 kHz	4 kHz	2 kHz	4 kHz
Average NH	−3.8	−3.5	−4.69	−4.28
HI1	−1.84	−3.27	−2.8	−3.29
HI2	−2.1	−1.8	CNT	CNT
HI3	−2.98	−0.8	−2.95	−1.6
HI4	−2.68	−2.17	−2.96	−3.07
HI5	DNT	DNT	−1.6	−3.27
HI6	−3.11	−1.8	−4.1	−2.67
HI7	−2.9	−1.2	−2.62	CNT
HI8	−3.38	−2.3	−3.4	−2.4
HI9	−3.1	−2.49	−3.1	−2.25

repeated measures (probe frequency × noise level × time delay) for the NH listeners indicated that there was a significant effect of noise levels on masked thresholds at 2 kHz $[F(1,7)=20.475, p=0.005]$ but not at 4 kHz. The main effects of time delay on masked thresholds are significant for both 2 and 4 kHz tones.

When the forward masked thresholds were plotted as a function of probe delay in ms in log scale, those who had the lower thresholds in quiet showed the better thresholds in the presence of the masker across probe delays. This implies that the masked thresholds were greatly affected by hearing sensitivity for signal tones in quiet. Table II demonstrates the slope of each function of masked thresholds plotted along the time delay in log scale. This slope could be considered as a rate of recovery from nonsimultaneous maskers. NH and HI listeners with better thresholds in quiet at 2 kHz (HI 3, 6, 8, and 9) and at 4 kHz (HI6, 8, and 9) showed relatively faster recovery rate (steeper slope) than other listeners with greater hearing loss. A three-way ANOVA (probe frequency × noise level × time delay) with repeated measures found that both probe frequency $[F(1,15)=4.632, p=0.048]$ and time delay $[F(3,45)=347.464, p=0.000]$ had significant main effects. There was no main effect of the presentation level of the noise $[F(1,15)=0.011, p=0.918]$. Only the two-way interactions between time delay and other factors (group, probe frequency and level) showed significant effects. The differences between groups were also significant $[F(1,15)=106.542, p=0.000]$.

As indicated by Nelson and Freyman (1987), comparing the amount of masking rather than the masked thresholds might provide a way to examine temporal effects independent of hearing sensitivity. In order to examine the temporal resolution of individual participants with minimal effect of reduced hearing sensitivity, thresholds in quiet for each frequency tone were subtracted from the masked thresholds across time delay. Figure 8 demonstrates the amount of masking in dB SPL at 2 and 4 kHz tones for NH and HI listeners. The mean threshold for the NH group at the noise level of 70 dB SPL is plotted along with thresholds of HI listeners obtained at 45 dB SL. Similarly, the mean for the NH group at 85 dB SPL is charted with the results of HI listeners at 50 dB SL. A three-way ANOVA (probe frequency × noise level × time delay) with the amount of forward masking as a dependent variable and with a group as a between-subject factor showed significant group differences $[F(1,15)=16.730, p=0.001]$. The main effects of the level of the noise, and the time delay and only the interaction between group and time delay were significant. In general, NH listeners had greater amount of masking and yet faster recovery (steeper slope) than most of HI listeners with few exceptions.

D. Regression analysis

One of the main purposes of the current investigation was to determine the possible contributions of hearing sensitivity (audiometric pure tone thresholds) and temporal resolution to speech perception in gated noise. Therefore, the results of forward masking and hearing sensitivity were correlated with NMR at −5 SNR for all 17 listeners. When all factors and all listeners were included, the effect of hearing threshold explained a large proportion of the variance. The results showed that the correlation coefficients for the 8 Hz gate frequency were quite similar to those for 16 Hz. The hearing sensitivity of most audiometric frequencies and forward masked thresholds at 2 and 4 kHz were strongly correlated with NMR in sentence recognition ($r>0.8$) but not the amount of forward masking or the slope of forward masking functions. One possible reason for that is because the correlation might be overwhelmingly affected by hearing sensitivity when the results of the NH group were included. Compared to the NH group whose hearing sensitivity and performance in different tasks were very uniform, HI listeners in the current study had various hearing thresholds across the audiometric frequencies and showed different performance levels. Therefore, if only the results of HI listeners were correlated, it might be possible to observe the differential contribution of hearing sensitivity and suprathreshold abilities that affect masking release of HI listeners. Thus, only the results from HI listeners were included in the analysis. Table III shows the relationship between NMR for sentences, hearing sensitivity, and the performance in forward masking (masked thresholds, masking amount, and slope) for HI listeners only. The masking amount was the difference between the threshold of 2 kHz (or 4 kHz) in quiet and the forward masked threshold. Only a few factors (hearing sensitivity at 0.5 and 1 kHz and forward masking threshold at 2 kHz) retained a relatively strong correlation ($r>0.6$) with NMR for sentences. These are highlighted in bold in Table III.

Using these factors, three different regression models were constructed in order to analyze the differential contributions of hearing sensitivity and forward masking threshold to NMR. The NMR for 8 and 16 Hz gate frequencies at −5 dB SNR were analyzed separately because the correlation coefficients were slightly different for the two gate frequencies. The full model containing all significant factors predicted NMR at 8 Hz gating based on performance in forward masking threshold at 2 kHz as well as hearing sensitivity for 0.5 and 1 kHz tones. The fall model for NMR for 16 Hz gating was similar to the one for 8 Hz. Sub-model 1 predicted NMR based on hearing sensitivity only whereas sub-

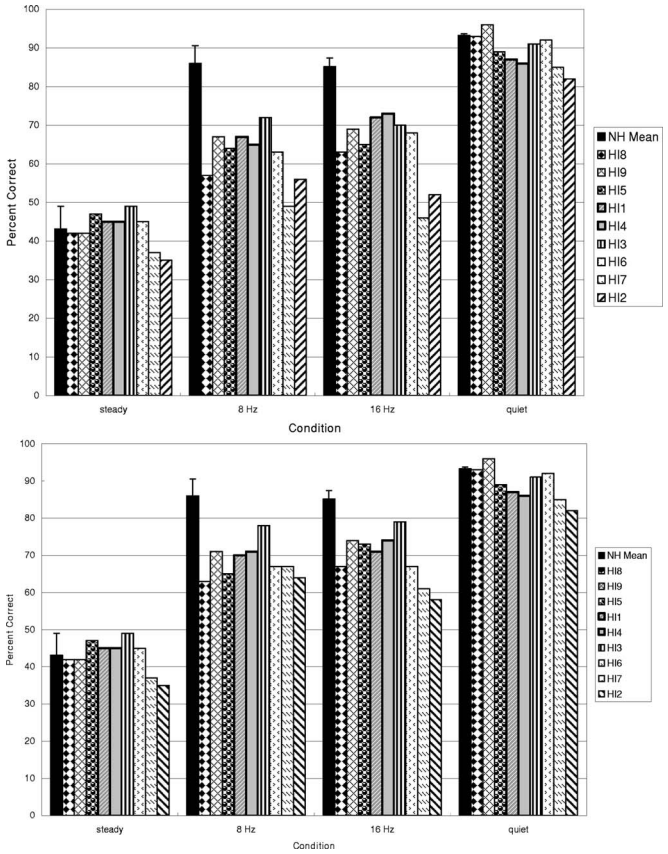

FIG. 4. Percent correct CV syllable identification for individual HI listeners and the NH group for the random phase (upper panel) and the fixed phase (lower panel) conditions at −5 dB SNR. Note: the data for the quiet condition are the same in both upper and lower panels. They are shown for comparison in each panel.

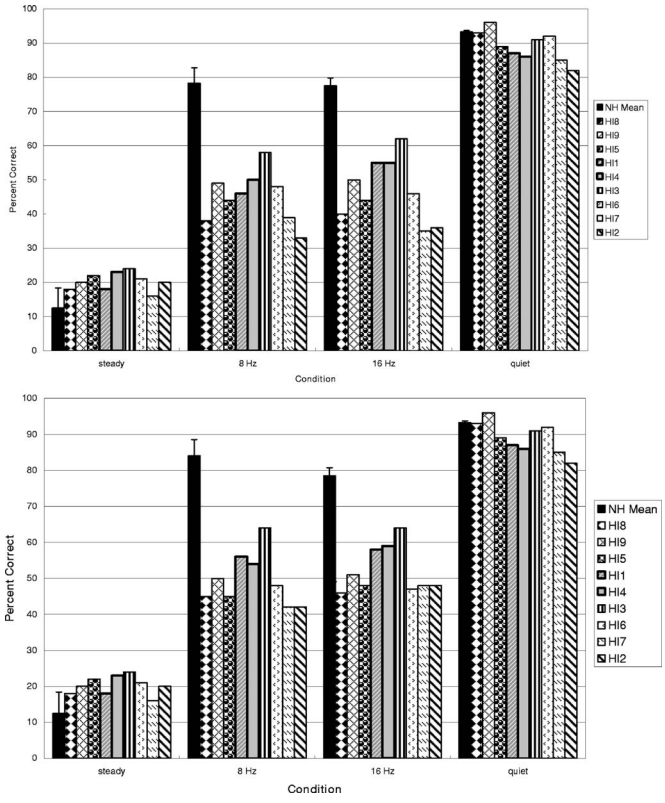

FIG. 5. Percent correct CV syllable identification for individual HI listeners and the NH group for the random phase (upper panel) and the fixed phase (lower panel) conditions at −10 dB SNR. Note: the data for the quiet condition are the same in both upper and lower panels. They are shown for comparison in each panel.

model 2 only included forward masking thresholds (eliminating hearing sensitivity) (see Table IV). Three regression models were constructed to predict the NMR at 16 Hz for −10 SNR. The MI model consisted of forward masking threshold at 2 kHz as well as hearing sensitivity for 0.5 and 1 kHz tones. Sub-model 1 predicted NMR based on hearing sensitivity only whereas sub-model 2 only included forward masking thresholds.

The results show that the dependent variable was well predicted by the factors in the model. The multiple-correlation-squared (R^2) for each model indicates the strength of the relationship between the NMR and the predictors such as hearing sensitivity or forward masking thresholds. For most of the sentence recognition conditions, when the hearing sensitivity at low-to-mid frequencies was taken out of the model (which becomes the sub-model 2), the R^2 decreased considerably. This suggests that hearing sensitivity at low-to-mid frequencies accounts for a substantial amount of the variance in the NMR for sentence recognition. The toward masking threshold did not seem to play a large role in sentence recognition in gated noise because the differences in R^2 between the full model and sub- model 2 (which consists of hearing sensitivity alone with forward masking removed) were relatively small.

Table V shows the correlation between the NMR for syllable identification and the results of other tasks at −5 SNR. Compared to those for sentences, hearing sensitivity across frequencies was not strongly related to the NMR. Only the forward masked thresholds and the masking amount (highlighted in bold in Table V) show moderate correlation ($r > 0.6$). There were no strong correlations between any factors and NMR at −10 SNR. (A full regression analysis for syllable identification is not included here because very few factors showed strong correlation with masking release for CV syllables.)

IV. GENERAL DISCUSSION

Common environmental noises are typically temporally fluctuating. It is important to understand how HI listeners perform when background noise is fluctuating, or gated, rather than steady. In these situations, it may be that performance would not be easily predicted by signal audibility alone. While we cannot completely rule out subtle audibility differences between NH and HI listeners, nevertheless HI listeners in this study were sufficiently amplified so that their performance was comparable to that of normal-hearing listeners in quiet and steady noise. Even under those nearly ideal amplification conditions, the HI listeners showed significant decrements in masking release. This finding was true for both sentences and for CV syllables, suggesting that masking release cannot be accounted for simply on the basis of audibility of speech in noise. When audibility differences between NH and HI listeners were reduced, modest effect of forward masking was seen for CV syllable recognition.

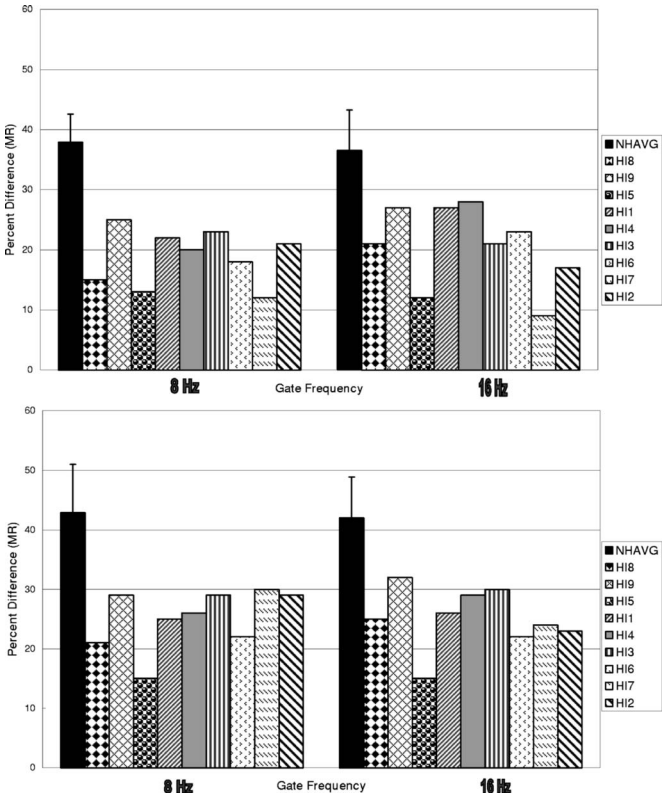

FIG. 6. The amount of MR for individual HI listeners and the NH group for the CV syllables in random phase (upper panel) and fixed phase (lower panel) conditions at −5 dB SNR.

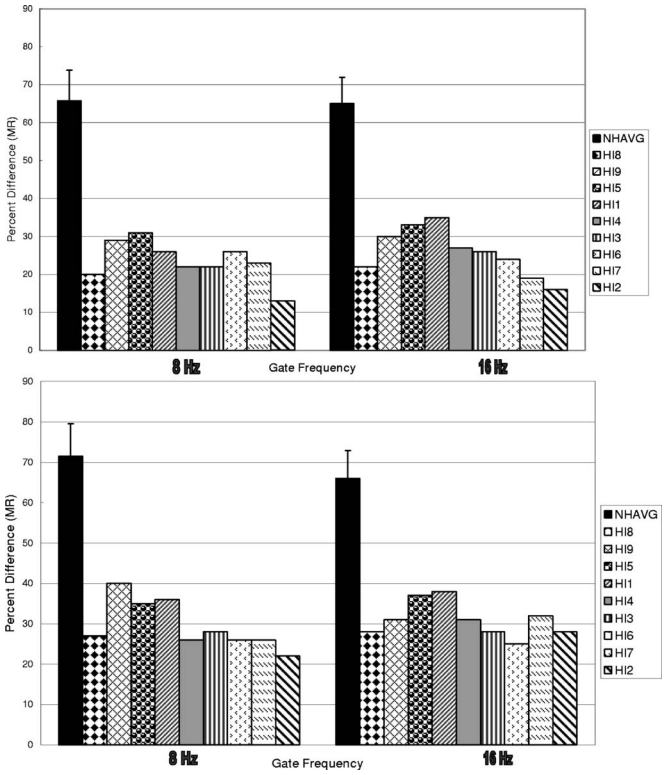

FIG. 7. The amount of MR of individual HI listeners and the NH group for the CV syllables in random phase (upper panel) and fixed phase (lower panel) conditions at −10 dB SNR.

A. Sentence recognition

These findings extend the findings of previous investigations in which amplified speech and noise were used for HI listeners and show that even with appropriate amplification, HI listeners experience significantly reduced MR. For example, Peters *et al.* (1998) employed a linear amplification formula with appropriate frequency response shaping that is commonly used for a hearing aid. The amplification substantially improved. SRTs in quiet and steady noise for the younger and older HI participants. Compared to SRTs for NH listeners, however, the SRTs of the HI listeners were still poorer. Therefore, the amplification used in previous investigations did not seem to provide an adequate amount of speech information to compensate for individual hearing loss. Even when sufficient amplification was used HI listeners were less able to use speech momentary gaps in gated noise. Some investigators (Trine, 1995; Van Tasell, 1993; Peters *et al.*, 1998) have tried to explain deficits of HI participants in gated noise as a result of reduced audibility. That is, even though speech stimuli are audible, those momentary decreases in the intensity of the masker might be below the hearing thresholds so that full "dips" are not available. Therefore, HI listeners would not have as much masking release as NH listeners. In addition, Peters *et al.* (1998) found that even with the amplification, the SRT of HI listeners was worse than the SRT of NH listeners in a background noise with spectral and/or temporal gaps. It was suggested that the linear amplification might not provide sufficient gain to restore audibility of the entire dynamic range of speech.

However, the lack of audibility alone does not seem to explain the reduced masking release of HI listeners in the current investigation because the sentence recognition of HI listeners in quiet (and in steady noise) was very similar to that of NiH listeners. As an alternative explanation, Dubno *et al.* (2002), and Bacon *et al.* (1998), proposed that abnormal forward masking might predict the rack of the masking release in HI listeners. In the current study, however, forward masking does not appear to predict MR for sentence materials. The amount of forward masking varied among the HI listeners, though typically when FM thresholds and quiet thresholds were compared, HI listeners showed less forward masking at short masker durations than did NH listeners. In general, their FM function slopes were shallower than those of NH listeners. This is consistent with previous investigations such as Nelson and Freyman (1987). Correlation coefficients between sentence recognition and amount of FM were low and regression models indicate that the addition of FM to the models adds little to the prediction of performance, apart from the hearing thresholds of the listeners.

To explain the lack of MR in sentence recognition of HI listeners, possible contribution of alternative suprathresholds will be investigated as a follow-up. Peters *et al.* (1998), Mackersie *et al.* (2001) and other investigators speculated that reduced spectral resolution and auditory integration due to the cochlea hearing loss could be responsible for the reduced masking release.

B. CV syllable identification

The results of the current CV syllable identification task were consistent with those of the sentence recognition task.

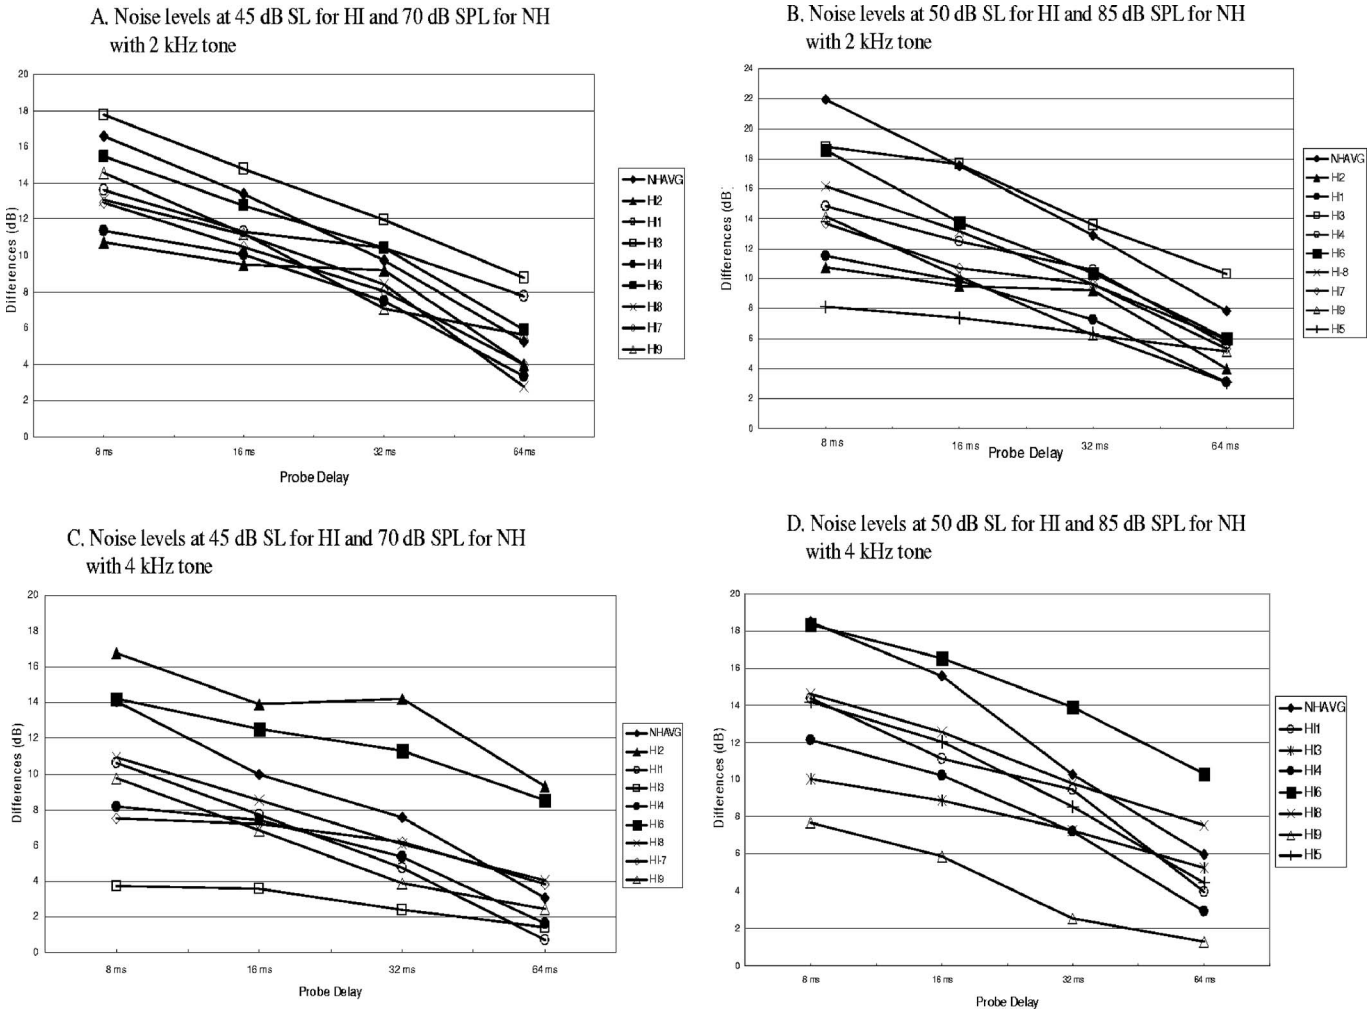

FIG. 8. The amount of forward masking of individual HI listeners at 45 dB SL [(a) and (c)] and 50 dB SL [(b) and (d)] compared to the group average performance of NH listeners at 70 dB SPL [(a) and (c)] and 85 dB SPL [(b) and (d)].

That is, the scores of NH listeners in quiet and in steady noise were not significantly different from those of HI listeners whereas the performance in the gated noise was substantially poorer for HI listeners than NH listeners. The percent correct scores, the amount of masking release, and the normalized masking release were analyzed separately as dependent variables. Consonant recognition of NH and HI listeners was also examined in the presence of no noise, steady noise, and gated noises. Dubno and her colleagues (2002) also investigated benefits of modulated maskers for syllable recog-

nition (either CV or VC syllables) only when the timing of syllable presentation was random and independent of the noise cycle. Two conditions (either random or control phase) were implemented in the current experimental design. The results show that when the periods of gated noise were controlled relative to the onset of consonants, the performance of both NH and HI listeners was significantly better than the random condition regardless of the noise level. In other words, if the peaks of noise were always placed shortly after the onset of consonants as in controlled conditions the listeners were able to hear out more cues for each consonant. Thus randomly phased noise seemed to be more effective maskers for syllable recognition and are more realistic since fluctuating noise would occur rather by chance in a real life. However, when syllables are used in a speech recognition task, interpretation of th results might need to be made more cautiously.

The recent study by Dubno *et al.* (2002) compared syllable identification of young NH listeners to those of older listeners with near normal hearing up to 4 kHz. Although the older listeners have near normal thresholds, the average thresholds of older group were 10 dB higher at mid-to-high frequency than younger group. The investigators found that forward-masked thresholds of the elderly listeners were elevated and the poorer asked thresholds were significantly correlated with the elderly listeners' reduced masking release. In the current study, the amount of forward masking at 2 kHz was positively correlated with CV recognition in gated noise. (Refer to Table 5.) Interestingly, forward masking was more highly correlated with CV recognition in noise gated at 8 Hz than in noise gated at 16 Hz, which is contrary to the assumption that shorter gap durations in the noise would be more negatively affected by abnormal forward masking.

C. Differences between sentence and CV materials

Over the decades, various investigators have demonstrated the differences in the amount of masking release between NH and HI listeners with a range of speech materials. For example, Dubno *et al.* (1989, 2002) used CV or VC syllables, while Eisenberg *et al.* (1995) used nonsense syllables and SPIN sentences. HINT or IEEE sentences were employed in other studies (Bacon *et al.*, 1998; Mackersie *et al.*, 2001; Nelson *et al.*, 2003). The results from the current investigation suggested similar principles underlying speech recognition in fluctuating noise would be demonstrated regardless of the type of speech stimuli. That is, most listeners are able to benefit from momentary dips in noise, and the amount of masking release varies corresponding to hearing sensitivity of listeners. A simple ANOVA with stimulus type (either IEEE sentence or CV syllable) as a dependent variable showed that when the SNR is fixed, the differences in NMR for CV syllables (in either random or control condition) and IEEE sentences were not significant. Speech material types do not seem to play an important role in measuring speech perception in fluctuating noise. However, it does appear that forward masking has significantly stronger relationship to CV identification than to sentence recognition.

V. CONCLUSION

Listeners with sensorineural hearing loss demonstrate significantly reduced masking release from gated noise, even when stimuli are amplified so that their performance matches that of normal-hearing listeners in quiet and in steady noise. This finding was true for both sentence and CV syllable stimuli. This finding has implications for understanding the common complaints of HI listeners in background noise. Amplification may not be expected to fully restore understanding to normal levels in fluctuating noise. Abnormal forward masking seems to be an incomplete explanation of these findings, especially for recognition of sentences. Further studies will be undertaken that will continue to explore additional factors such as spectral resolution and auditory grouping, which may help to explain the findings further.

(Received 28 July 2003; accepted 21 February 2006)

This paper presents a rule-based method to determine emotion-dependent features, which are defined from high-level features derived from the statistical measurements of prosodic parameters of speech. Emotion-dependent features are selected from high-level features using extraction rules. The ratio of emotional expression similarity between two speakers is defined by calculating the number and values of the emotion-dependent features that are present for the two speakers being compared. Emotional speech from Interface databases is used for evaluation of the proposed method, which was used to analyze emotional speech from five male and four female speakers in order to find any similarities and differences among individual speakers. The speakers are actors that have interpreted six emotions in four different languages. The results show that all the speakers share some universal signs regarding certain emotion-dependent features of emotional expression. Further analysis revealed that almost all speakers in the analysis used unique sets of emotion-dependent features and each speaker used unique values for the defined emotion-dependent features. The comparison among speakers shows that the expressed emotions can be analyzed according to two criteria. The first criterion is a defined set of emotion-dependent features and the second is an emotion-dependent feature value. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188647]

I. INTRODUCTION

Over the last few decades human emotions and behavior have been research topics within different scientific areas. Researchers from the fields of acoustics and prosody have also become interested in examining human emotions. Most research activities on emotional speech focus on analyzing the prosody of speech signals. The majority of papers about emotions in speech concerns the English language (Murray and Arnott, 1993; Gobl and Ni Chasaide, 2000; Cornelius, 1996). Very often emotional expression in speech is examined from acted speech (Kwon *et al.*, 2003; Ververidis *et al.*, 2004; Pereira, 2000). Emotions in acted speech are usually called simulated emotions. Over the last few years several analyses of emotional expression in speech have been accomplished, such as using a Wizard of Oz (WOZ) approach, from television talk shows, or data from call centers (Batliner *et al.*, 2003; Amir *et al.*, 2003; Ang *et al.*, 2002). These sources normally provide nonacted emotional expression, so-called authentic emotions. However, actors seem to interpret emotional speech with an artistic goal that is far from producing speech similar to nonacted speech (Auberge *et al.*, 2004). In acted emotional speech it is hard to evaluate whether the production of simulated emotions is identical to authentic emotions (Auberge *et al.*, 2004). Batliner *et al.* (2003) compares results from the automatic emotion recognition of simulated emotions as interpreted by actors, with the authentic emotions produced by the WOZ method. Simulated emotions in this research were recognized significantly better than authentic emotions. Douglas-Cowie *et al.* (2000), Batliner *et al.* (2000), and Murray and Arnott (1993) present and discuss, in detail, the usages of simulated and authentic emotions in the research of emotion expression in speech.

It is well-established that speech prosody also contains information about a speaker's emotions. Prosody is divided into several components: intonation, tempo, and loudness. Intonation is the changing voice pitch pattern over an utterance, used to convey information (Arnfield, 1994). Tempo is the speaking rate and is usually measured in syllables or words per second. Loudness is an auditory impression of the amount of energy in sounds (Roach, 1994). In speech, intonation is represented as pitch, tempo as duration of phonemes, and loudness as the energy of a speech signal.

In speech analysis a dilemma always exists over the usages of short-term or long-term features. Emotional speech prosody has mostly been analyzed using long-term features rather than short term. Long-term features are usually determined over a time window at the sentence or paragraph level. Short-term features are determined over windows with a smaller duration. The window length for short-term features is on the order of the duration of words, syllables, or even smaller units. Researchers for this topic state that long-term features identify emotion better than short-term (Li and Zhao, 1998; Schuller *et al.*, 2003). Most researchers focus on the influence of emotions on fundamental frequency ($F0$) and duration (Banse and Scherer, 1996; Fairbanks and Pronovost, 1939; Williams and Stevens, 1972; Fairbanks and Hoaglin, 1941; Murray and Arnott, 1993; Noad *et al.*, 1997). Research into emotions in speech also includes work on the influence of emotion on speech quality (Gobl and Ni Chasaide, 2000; Kienast *et al.*, 1999). Many researchers have investigated simulated and authentic emotions in emotional

[a)]Electronic mail: kacic@uni-mb.si

speech in regard to basic emotions (anger, joy, fear, and sadness) (Ekman, 1972). They found that joy, anger, and fear have a higher mean $F0$ and amplitude, with greater $F0$ and amplitude variations than neutral speech. Sadness has an opposite influence on $F0$ and amplitude than emotions such as anger, joy, and fear. Sadness has low mean $F0$ and amplitude, and low variations of $F0$ and amplitude (Banse and Scherer, 1996; Fairbanks and Pronovost, 1939; Williams and Stevens, 1972; Noad *et al.*, 1997). Speech rate also varies among emotions. The highest speech rate is for neutral and angry speech, and the slowest for sad speech. Some prosody parameters of emotional speech differ from study to study, while others are consistent (Cowie *et al.*, 2001). Sad speech usually has low values of pitch, but some studies have shown pitch to be high in sad speech (Pereira, 2000). There is also disagreement on the durational aspects of anger, happiness, and fear. Some report longer duration, some report faster speech rate, and some report lower speech rate (Cowie *et al.*, 2001; Davitz, 1964; Williams and Stevens, 1972; Coleman and Williams, 1979; Fonagy, 1978).

In the area of human-machine communication, emotions could be used for emotional speech synthesis and emotion recognition. Emotion recognition usually relies on statistical methods, which require large databases with many speakers. For recognition of emotional speech, a study of authentic emotions would be more appropriate than using simulated emotions. It may well be sufficient, for the purpose of synthesis, to study a single speaker so that his or her manner of emotional expression could be modeled (Douglas-Cowie *et al.*, 2000). The aim there would be to modify the output of speech synthesis systems in order to produce speech that sounds naturally emotional. This is essentially the same goal as that of actors (Johnstone, 1996).

Research into cross-cultural emotional expression shows both universality, and differences, in emotional signs between different cultures. Cross-cultural research of emotional expression in speech has tended to be of less interest than emotions by facial expression. This is due to the methodological problems of data collection, and vocal parameters being more difficult to measure than facial expressions (Frick, 1985). Facial signs of emotional expression have been researched by, among others, Ekman (1972), Izard (1971), and Bruner and Tagiuri (1954). Research into emotional expression in speech between different cultures has been carried out by Wallbott and Scherer (1995), Frijda (1986), Ohala (1984), and Amir and co-workers (2004). Research into emotion recognition for the English and Japanese languages has been done by Tickle (1999, 2000), when it was found that people recognize emotions in other languages, but not as accurately as in their own. Researchers who investigated emotional expressions of the face found that there are some universal signs of emotional expression, but there are also differences in different languages (Ekman, 1994).

Thus, there is an increasing need for emotion modeling. Various software agents need emotion models to communicate with humans in the most natural ways. These software agents need models for emotion recognition using the face, body movements, or speech, and for synthesis of emotions in the animation of a software agent's face and body movements, and in synthesized speech (Camurri and Coglio, 1998). Almost all researchers model emotion for speech synthesis using rules. A review of emotional speech synthesis is presented by Schröder (2001), who gathered and defined rules for specific emotions, which are combined from the works of Burkhardt (2000), Cahn (1990), and Murray (1989). Murray and co-workers (1989), who designed the HAMLET system, and Cahn (1990), who designed the AFFECT EDITOR system, also used rules for emotion modeling. These models are used for emotional speech synthesis using formant synthesizers. The disadvantage of a formant synthesizer is the low naturalness of synthesized speech. Diphone and corpus-based synthesizers reach a higher naturalness of synthesized speech, but have lower control over emotion parameters (Schröder, 2001). Modification of the prosody parameters in synthesized speech from diphone or corpus-based synthesizers can be done, but modification of speech quality parameters is more difficult. Researchers like Heuft and coworkers (1996), Rank and Pirker (1998), Murray (1989), and Montero and co-workers (1998) carried out mainly diphone or corpus-based emotional speech synthesis. All these authors used models with rules.

The aim of this current research is to investigate several questions regarding the modeling of prosody for emotional speech synthesis. The first question is: How many speakers should be used for modeling emotional speech prosody? As already mentioned, Douglas-Cowie and co-workers (2000) proposed the use of a single speaker so that his or her manner of emotional expression can be modeled. If a group of speakers was to have similar emotional speech characteristics, the prosody model could have some universal features. This kind of prosody model, therefore, could possibly be used for an emotional speech synthesizer having different voices with less, or no, adaptation to emotion expression for a particular voice. One of the major tasks facing automatic emotion detection is the automatic recovery of relevant features (Cowie *et al.*, 2001). As speech from several speakers should be used for the recovery of relevant features (Kwon *et al.*, 2003; Ververidis *et al.*, 2004), it might be expected that all speakers may have the same set of features affected by emotions. Therefore, the next question is, which and how many features of emotional speech are common to different speakers? To answer this, relevant features should be extracted from each speaker, separately.

This paper presents a novel rule-based method for defining emotion-dependent speech prosody parameters and their values. As prosody was the main concern of this research, the characteristics of pitch, energy, and duration of speech segments were analyzed. A proposed rule-based method is described in detail and the analyzed results are given for nine speakers. The output of the proposed method is compared to the results of principal component analysis (PCA), which is used as a statistical method for extracting relevant features from emotional speech. Emotion-dependent features are compared between different speakers, and a ratio of emotional expression similarity is calculated for each pair of speakers.

II. RULE-BASED EMOTION-DEPENDENT FEATURE EXTRACTION METHOD

In the proposed rule-based emotion-dependent feature extraction method, the pitch contour ($F0$) of the speech signal, durations of phonemes and pauses, energy of the speech signal, derivative ($\Delta F0$) of speech signal pitch contour, and derivative of speech signal energy contour are defined as low-level features. These features represent intonation in the speech signal.

The high-level features used in the proposed method are composed of statistical measurements of prosody parameters such as pitch, duration, and energy. Different researchers have found many prosody high-level features that were correlated to emotions (Banse and Scherer, 1996; Noad and coworkers, 1997; Murray and Arnott, 1993). Based on reports from the literature, we defined a set of high-level features as an initial set of features. A similar set of high-level features was also used by Banse and Scherer (1996), Noad nad coworkers (1997), Murray and Arnott (1993), Lee and Narayanan (2003), Kwon and co-workers (2003), and Lee and coworkers (2004).

The proposed method selects those features, from a large set of high-level features, that determine specific emotions. At the beginning of the process, all high-level features are normalized. Equation (1) represents normalized high-level features to reduce intraspeaker variability.

$$xn_{i,j} = \frac{x_{i,j}}{\bar{x}_i}, \tag{1}$$

where $xn_{i,j}$ is the normalized value of the ith feature in the jth sentence, $x_{i,j}$ is the ith feature in the jth sentence, $\bar{x}_i$ is the mean value of the ith feature. The xn stands for the normalized value. Each high-level feature is normalized with a speaker's high-level feature mean value, according to Eq. (1).

Pell (2001) found that sentence length has an influence on some prosody measurements. Therefore, test recordings should be separated according to sentence length. In our case, the sentences used for evaluation of the method were divided into five groups. The first group contained isolated words, the second short sentences, the third middle-length sentences, the fourth long sentences, and the fifth group was composed of context-dependent sentences.

Five classes of emotional feature values were used, equivalent to Banse and Scherer's (1996) classification of emotional feature values. The histogram of all the high-level feature values ranges from 0 to 2. As an illustrative example a histogram was determined for the first English male speaker (see Fig. 1), from the database used in the experiments. The mean value of all the normalized features of the first English male speaker was 1, and the standard deviation 0.094. The range of normalized high-level feature values was divided into five classes. Table I shows the output value and corresponding range of each class. Values 1.2 and 0.8 represented a deviation from mean value that was equal to 2 $\times$standard deviation. The values 1.05 and 0.95 were deviations from the mean value for half of the standard deviation. Two classes were above the value 1 and two classes were below the value 1 (see Table I). Class 1 represented values that were well below mean, class 2 values below mean, class 3 values around mean, class 4 values above mean, and class 5 values that were well-above mean.

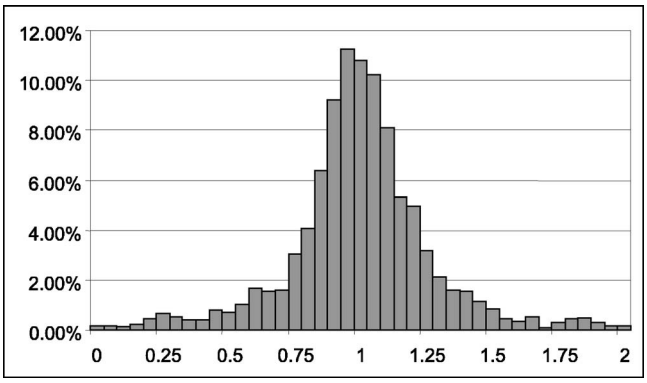

FIG. 1. Histogram of normalized high-level features for English male speaker (M1) for all values of high-level features.

The mean values of each group's normalized high-level features and for each session ($\bar{X}_{i,e,r,s}$) were classified according to Table I, and the result was denoted as $C_{i,e,r,s}$. $C_{i,e,r,s}$ was the value of the ith normalized high-level feature of the eth speaking style, of the rth group, and of the sth session of recordings (more recordings of the same sentences were made for the same emotion over different time instants—e.g., to enable emotion consistency evaluation). For example, $C_{i,e,r,s}$ could be the vowel duration value for anger, for a group of long sentences, session E1, and is denoted by $C_{\text{vowel duration,anger,long sentences,E1}}$.

The following rules were defined for extracting emotion-dependent features:

(1) Rule 1. If $C_{io,eo,ro,E1}$ and $C_{io,eo,ro,E2}$ have different values, then feature xn_{io} is denoted as an emotion-independent feature for emotion e_0. For example, if the vowel duration value for anger, group of long sentences, session E1 is different from the vowel duration value for anger, group of long sentences, session E2, then the vowel duration is denoted as an emotion-independent feature for anger.
(2) Rule 2. If $C_{io,eo}$ for all groups of the same emotion has different values, then the feature xn_{io} is denoted as an emotion-independent feature for emotion e_0. For example, if the vowel duration values for anger, for groups from isolated words to context-dependent sen-

TABLE I. Class number, range of high-level feature values that belong to the class, output value for high-level feature, and a brief description of which high-level feature values belong to which class.

Class num.	Range	Output value	Description
1	$xn_{i,j} < 0.8$	−2	Values are well below mean.
2	$0.8 \leqslant xn_{i,j} < 0.95$	−1	Values are below mean.
3	$0.95 \leqslant xn_{i,j} < 1.05$	0	Values are around mean.
4	$1.05 \leqslant xn_{i,j} < 1.2$	1	Values are above mean.
5	$1.2 \leqslant xn_{i,j}$	2	Values are well above mean.

$xn_{i,j}$-normalized high-level feature of ith feature in the jth sentence

tences, do not have the same values, then the vowel duration is denoted as an emotion-independent feature for anger. These two rules are applied for each feature and for each emotion. Features that are not denoted as emotion-independent features are subject to one additional rule.

(3) Rule 3. If C_{io} has the same values in all speaking styles, then the feature xn_{io} is also denoted as an emotion-independent feature for all emotions. For example, if the vowel duration mean value for all defined emotions is the same, then the vowel duration is defined as an emotion-independent feature for all emotions.

If feature xn_{io} is unclassified as an emotion-independent feature, then feature xn_{io} is denoted as an emotion-dependent feature. Emotion-dependent features should discriminate between speaking style according to emotion and not to sentence type or recording times. The first rule assures that emotion-dependent features are consistent with recording times. The second rule assures that emotion-dependent features are consistent with sentence type, and the last rule assures that emotion-dependent features discriminate between different emotions.

A. Definition of a feature vector

The rule-based method we use relies on high-level input features. In our case, high-level means statistical representations of low-level features. The low-level features were calculated from speech and determined prosody parameters.

1. Calculation of low-level features

Low-level features represent the acoustical characteristics of speech prosody. The pitch contour ($F0$) of the speech signal, duration of phonemes and pauses, energy of speech signal, derivative ($\Delta F0$) of speech signal pitch contour, and derivative of speech signal energy contour were defined as low-level features. These features represent intonation in the speech signal.

Various methods could be used for the calculation of pitch, energy, and duration. Methodology using a normalized cross-correlation function (Qian and Kimaresan, 1996) was used to extract the $F0$ from speech signals. This method calculated one pitch value per 10 ms. The rms (root-mean-square) method calculated energy from speech signals. Rms calculated energy in a square window that was 10 ms long at a frame rate of 5 ms. Phoneme segmentation was carried out using the HTK toolkit (Young *et al.*, 1997). Here, the speech signal was first pre-emphasized with a factor of 0.95. Twelve mel-cepstral coefficients and energy were used as a feature vector, as well as the first and second derivatives of the mel-cepstral coefficients. The cepstral coefficients were calculated using a Hamming window (5 ms long) at a frame rate of 2.5 ms. Normalization of cepstral mean value was used before acoustic modeling, where 3-state left-right hidden Markov models (HMMs) were applied. The emission probabilities were modeled using continuous Gaussian mixture densities. The models for all phonemes, for pauses between words, and the start and end points of sentences were used in the acoustic modeling.

The training database consisted of all the sentences of one speaker (speech recorded in all sessions and for all emotional states). Global mean values and variances were estimated on initialization. HMM parameters were re-estimated with six iterations of the Baum-Welch algorithm. In the next stage, the number of Gaussian mixture densities was increased in the following order: 1, 2, 4, 6, 8. Two iterations of the HMM parameter estimations were performed after each increase in the number of Gaussian mixture densities. Segmentation was done on all the sentences of one speaker, over all the emotional states.

2. Definition of high-level features

All of our high-level features were sorted according to their particular low-level features. The first group of high-level features was derived from $F0$ and $F0$ derivative ($\Delta F0$), and consisted of the mean value, standard deviation, minimal value, maximal value, and range of $F0$. The high-level features derived from $\Delta F0$ were the mean value, standard deviation, minimal value, maximal value, and range of $\Delta F0$. The range represented the difference between minimal and maximal values.

The second group of high-level features encompassed features that were calculated from the energy contour and its derivative: mean value, standard deviation, word and syllable energy, a derivative's mean value, and a derivative's standard deviation. Syllables were defined from phonetic transcriptions.

The third group consisted of features that were extracted from phoneme duration: words, syllables, vowels, fricatives, affricates, sonorants, plosives, and pause duration.

High-level features represent information about the speaker's prosody over an entire sentence.

III. EXPERIMENT

The analysis of emotional speech requires various methods from acoustics, speech science, and statistics. Emotional speech prosody with long-term features was used for the experiments described in this paper. The window used for the long-term features corresponded to the duration of sentence length, which was also the length of the recording. To evaluate the proposed rule-based method, we decided to use emotional speech from the Interface[1] databases (Hozjan *et al.*, 2002) in order to analyze the prosody patterns of emotional speech. The Interface databases contain acted emotional speech from speakers of different nationalities and genders.

All the high-level features, mentioned in Sec. II, represented input data for the emotion-dependent feature extraction method. This method was used on the speech of each speaker independently. It selected 14 emotion-dependent features from the defined 26 high-level features. These 14 features represented a union of these features from all nine speakers. The results for each speaker are presented in detail in Sec. IV.

The complete analysis was done automatically in three stages on an MS Windows-based PC machine. The low-level

and high-level features were calculated in the first and second stages, and the emotion-dependent features were determined in the third. Each stage used different software. The software for the calculation of pitch, energy, and derivatives was developed using the algorithms described in Sec. II A 1. The calculation of high-level and emotion-dependent features was done with Perl scripts and further analysis used MS EXCEL.

A. Principal component analysis (PCA)

Statistical methods, such as principal component analysis (PCA), which analyzes the significance of individual feature vector components, have been used in previous analyses of emotional features (Li and Zhao, 1998). In these analyses the speech of all speakers involved was used for the extraction of emotional features, and no speaker-dependent features were analyzed.

The results of the rule-based method proposed in this paper were compared with the results of statistical methods found in the literature, as well as with the results of PCA analysis.

PCA was used to verify the significance of the defined 26 high-level features, from the standpoint of discriminative significance. PCA examines the variance structure of the data and finds those directions in the feature space that have significant variations (Everitt and Dunn, 1992). PCA was also used in this study to analyze the importance of individual components in the feature vector. Altogether 14 emotion-dependent features were extracted for all speakers in the databases, using the rule-based method described in Sec. II. PCA was used in such a way as to reduce the 26-dimensional feature space to 14.

Linear correlations between individual components of the vector y can be transformed using the following expression:

$$y = A^T \cdot x, \tag{2}$$

where y represents a new feature vector, x an input feature vector, and A the transformation matrix. PCA analysis begins with the following expression:

$$C \cdot A = A \cdot \lambda, \tag{3}$$

where C is the covariance matrix, A the transformation matrix, and λ the diagonal matrix with the diagonal elements being the eigenvalues. If Eq. (3) is solved, then the values for the individual elements of the diagonal matrix λ and all the values of the transformation matrix A become results. The individual values of the diagonal matrix λ correspond to the individual feature variances. In the next step of the PCA analysis, the elements of the diagonal matrix λ and corresponding columns of the transformation matrix A were sorted according to the values of the diagonal matrix λ. The number of rows in the transformation matrix A, introduced in Eq. (3), was reduced to the size of the new vector y. At the end of the PCA analysis, the new vector y was calculated using Eq. (2). The transformation matrix A is often called the eigenvector matrix. A more detailed explanation of the PCA analysis is described in Everitt and Dunn (1992).

TABLE II. Norm of 14 dimensional transformation vectors calculated from the reduced transposed transformation matrix A and corresponding features sorted by significance.

	Features	Norm of transform vectors
1	Mean value of Δenergy	0.999
2	Duration of affricates	0.979
3	Duration of plosives	0.907
4	Duration of sonorants	0.905
5	Duration of fricatives	0.866
6	Standard deviation of energy	0.864
7	Duration of syllables	0.853
8	Mean value of $\Delta F0$	0.816
9	Duration of vowels	0.778
10	Minimal value of $F0$	0.719
11	Mean value of $F0$	0.684
12	Duration of phonemes	0.663
13	Maximal value of $F0$	0.656
14	Syllable energy	0.626
15	Maximal value of $\Delta F0$	0.619
16	Minimal value of $\Delta F0$	0.607
17	Duration of words	0.595
18	$F0$ Range	0.589
19	Standard deviation of $F0$	0.586
20	Duration of pauses	0.579
21	Standard deviation of $\Delta F0$	0.552
22	$\Delta F0$ Range	0.544
23	Word energy	0.513
24	Energy of high frequencies	0.508
25	Standard deviation of Δenergy	0.452
26	Mean value of energy	0.433

Instead of the last step of the PCA analysis, the norm of transformation vectors should be calculated in order to determine the significance of feature variance. The norm of transformation vectors is calculated from the reduced transposed transformation matrix A. In the reduced transformation matrix A, the values in the rows represent the amount of high-level feature contribution to the new feature vector y. The transformation vector z_i from the reduced transposed transformation matrix A is extracted for each high-level feature i. The norm of transformation vector z_i is calculated for each high-level feature i. The norm of transformation vector z_i represents the portion by which the high-level feature i contributes to the new feature vector y. The norm of transformation vector z_i represents the significance of the ith feature variability.

The norms of 14 dimensional transformation vectors z_i for all 26 high-level features are given in Table II. The high-level features were sorted in order of significance. According to PCA, the first feature (Δenergy mean value) is the most important and the 26th feature (energy mean value) is the least important.

Eight of the 14 emotion-dependent features from the rule-based analysis lie in the first half of Table II. Some emotion-independent features, such as the mean value of Δenergy or affricate durations, were placed in higher positions of importance according to PCA. PCA handles features by considering variations in the features' values. In contrast, our rule-based method additionally considers important con-

ditions such as recording times, sentence type, and discrimination between emotions. Recording time is determined by the recording session, and the sentence type ranges from isolated words to context-dependent sentences. Nevertheless, PCA analysis confirms that the majority of emotion-dependent features has significant variations and that these features are suitable for further analysis. Six such features are listed in the second part of Table II and their variances have less discriminative power. The rules defined in Sec. II assure that all emotion-dependent features discriminate between emotions, and therefore all the emotion-dependent features were used in further analysis.

B. Databases

All speakers from the Interface databases are used in our analysis. The Interface databases have nine speakers, who belong to four nationalities: English, Slovenian, French, and Spanish. The recordings are made by actors. Each database contains recordings of actors for one language. The English database uses one female and two male speakers. The Slovenian, French, and Spanish databases contain one male and one female speaker each.

1. Corpus of Interface databases

The corpora for the English, Slovenian, French, and Spanish Interface databases are designed mainly for emotional speech synthesis. Therefore, the corpora of the databases contain all phonemes in each language. The English corpus contains 186, Slovenian 190, French 175, and Spanish 184 sentences, respectively. All corpora are developed within the same specifications. In all languages the number of sentences is higher than that required by the specifications, in order to increase the frequency of rare phonemes in the corpora. The structure of the corpora is the same for the English, Spanish, Slovenian, and French Interface databases. The minimal number of isolated words, short, medium, and long sentences, and sentences that are context-dependent is defined in the specification of the Interface corpora. Short sentences are composed of five to eight words, medium sentences of nine to 13 words, and long sentences of 14 to 18 words.

2. Speech material

The Interface databases were recorded by the various research teams that were partners in the Interface project. The Slovenian and English Interface databases were recorded at the University of Maribor, Slovenia, the Spanish at the Universitat Politecnica de Catalunya, Spain, and the French at Scansoft, France. These corpora were recorded for six emotions and various numbers of neutral speaking styles. The emotions used in the databases are those defined by Cornelius (1996) as the "big six." Different types of neutral styles are recorded, as the Interface databases may also be used for nonemotional speech synthesis. The number of neutral speaking styles was not defined in the specifications, so each partner decided individually the number and types of neutral speaking styles. The English and Slovenian databases include two neutral styles: slow/soft and fast/loud neutral styles. The French database includes basic neutral, slow/soft, and fast/loud speaking styles. The Spanish database includes five different neutral styles: basic, slow, soft, fast, and loud.

This paper tries to find those prosody parameters that are influenced by emotions. Therefore, a minimal number of neutral speaking styles was chosen in the analysis. The basic neutral speaking style was selected from the Spanish and French databases. The English and Slovenian databases do not include the basic neutral speaking style, so both slow/soft and fast/loud neutral styles were used in the analysis described in this paper.

Databases consist of two sessions (E1 and E2). Each session contains recordings of the entire corpus for all six emotions and all defined neutral speaking styles. Session E2 was recorded at least 14 days after session E1, according to specifications. The aim of this was to ensure emotional speech parameter consistency. Each speaker uttered at least 2.000 recorded sentences. In the analysis 23.520 sentences were used altogether.

The Slovenian and Spanish Interface databases were evaluated by a subjective listening test to evaluate emotion expression in speech. In the Spanish Interface database emotions were recognized, on average, with an accuracy of 80% and in the Slovenian Interface database the accuracy of emotion recognition was 58%. In the listening test the intensity of emotions was evaluated and not the naturalness of the emotions. Details of the subjective evaluation test are described in Hozjan *et al.* (2002).

3. Recording conditions

The recordings of the Interface databases were made in studio environments using a high-quality studio microphone. The sampling frequency was 48 kHz with a sample size of 16 bits. Feature calculation used recordings that were downsampled to a sampling rate of 16 kHz.

IV. RESULTS AND DISCUSSION

Table III presents the emotion-dependent features for all speakers involved in the analysis. This table presents the number of these features and their values for each speaker and for each defined emotion. The missing values in Table III are a consequence of the rules described in Sec. II. The emotion-independent features for specific emotions are noted by the missing values. The shaded columns in Table III represent the emotion-independent features for each specific speaker. The differences between the sets of emotion-dependent features are outlined using shaded columns. The values of emotion-dependent features in Table III range from −2 to 2, according to the classes of output values of emotion-dependent features given in Table I. The emotion-dependent features were determined for each speaker individually. Each speaker, except Spanish ones, had a different set of emotion-dependent features. They had, altogether, 14 emotion-dependent features. These features were: mean value of $F0$ (mean $F0$), standard deviation of $F0$ (SD $F0$), minimal value of $F0$ (min $F0$), maximal value of $F0$ (max $F0$), range of $F0$ (range $F0$), standard deviation of $\Delta F0$ (SD $\Delta F0$), minimal value of $\Delta F0$ (min $\Delta F0$), maximal value of $\Delta F0$ (max $\Delta F0$),

TABLE III. Values of emotion-dependent features for all nine speakers in the Interface databases for each emotion. The emotion-dependent features in the table range from −2 to 2, according to the classes of output values described in Table I.

range of $\Delta F0$ (range $\Delta F0$), duration of phonemes (phoneme), duration of vowels (vowel), duration of fricatives (fricative), duration of sonorants (sonorant), and duration of plosives (plosive). The names in the brackets are used in Table III.

The results of the analyses in this study are similar to the results of other authors such as Banse and Scherer (1996), and Noad and co-workers (1997). The difference between our study and others is in the interpretation of results. Other authors compare emotions to a neutral speaking style. Emotion-dependent feature values were extracted in this research according to the mean value defined from all emotions, including neutral speaking styles. This comparison was made to allow emotion-dependent feature comparison between different speakers. When the emotion-dependent feature values in our research are compared to neutral speech, the results are similar to the results of other authors. For emotions with high arousal (anger, joy, and surprise), the high values of $F0$ features and the low duration feature values can be compared favorably with the neutral speaking style. Emotions with low arousal (disgust and sadness) have low values of $F0$ features and low duration feature values compared to neutral speech.

The values for emotion-dependent features for the same emotion differed for all speakers. Common emotion-dependent features were defined to enable a comparison of emotion expression with the extracted emotion-dependent features. They were defined for two speakers, and were those features that were present for both. For example, the set of common emotion-dependent features for the Spanish male and the Spanish female was composed of all emotion-dependent features (see Table III) for both, because these two had the same set of emotion-dependent features. Furthermore, the English female and the French female from the database had the following set of common emotion-dependent features (see Table III): mean value of $F0$, standard deviation of $F0$, maximal value of $F0$, duration of fricatives, sonorants, and plosives. Each pair of speakers may have had different sets of common emotion-dependent features. The ratio of emotional expression similarity was defined using common emotion-dependent features. The number of common emotion-dependent feature values that are equal for the same emotion was estimated, and is defined as the number of features with the same value. The ratio of emotional expression similarity is defined as the ratio between the number of common emotion-dependent features with the same value and the number of all common emotion-dependent features of two speakers being compared. In Fig. 2 the ratio of similarity is expressed as a percentage and is depicted as a bubble for each pair of speakers. The area of the bubble is equal to the ratio of similarity.

Two neutral styles were used for analysis of the Slovenian and English speakers, and one neutral style was used for the French and Spanish speakers. A basic neutral speaking style was used for the French and Spanish speakers. When the ratio of similarity was calculated between the English or Slovenian and French or Spanish speakers, then the fast neutral speaking style was excluded from the comparison. Our method for calculating the ratio of similarity requires an equal number of emotions for both speakers. In our experience from the Interface databases, the slow neutral speaking styles of the English and Slovenian speakers have a greater similarity with the Spanish and French neutral speaking styles than the fast neutral speaking style.

In Fig. 2, two groups of speakers had a high ratio of emotional expression similarity. The first group consisted of the Slovenian male, the Slovenian female, and the second English male (in Fig. 2 the second English male speaker is marked as EngM2). The second group of speakers encompassed the Spanish male, the Spanish female, and the French male. The members of both groups had a high ratio of emotional expression similarity values among each other. The first English male (EngM1), the English female, and the French female speakers were not included in these two groups, but they had a high ratio of similarity values with several speakers of the Interface databases. The first English male and English female had a high ratio of emotional expression similarity with the Spanish male and the Spanish

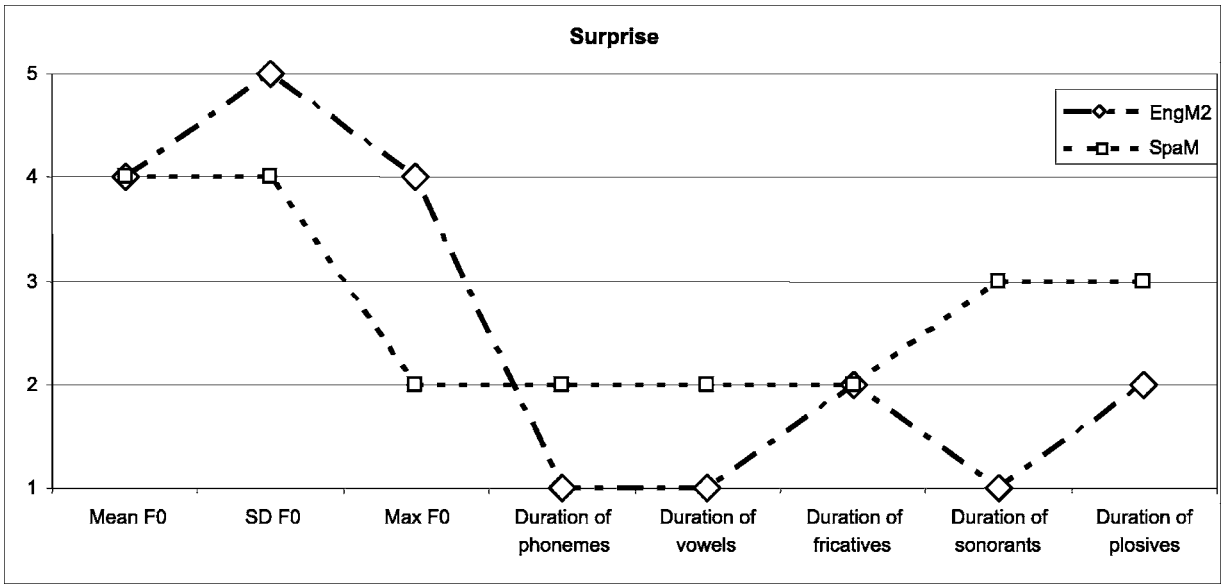

FIG. 3. Common emotion-dependent features for the second English male (EngM2) and Spanish male (SpaF) speakers for surprise.

female. The French female had emotional expression similar to the Slovenian male, Spanish male, Slovenian female, and French male.

Figures 3 and 4 show common emotion-dependent features for speakers with the lowest and the highest ratios of emotional expression similarity, which can be seen from Fig. 3, as most of the common emotion-dependent features have different values. Figure 3 presents the common emotion-dependent features of the second English speaker (EngM2) and the Spanish speakers for emotion surprise. This emotion was selected as it exhibits a similar ratio of common emotion-dependent features and had the same values as the ratio of emotional expression similarity between the two compared speakers for all emotions. These two speakers had the lowest ratio of emotional expression similarity. Figure 4 presents the common emotion-dependent features of the Slovenian male and female speakers for the emotion anger. The Slovenian speakers had the highest ratio of similarity, as most of the common emotion-dependent features had the same values (see Fig. 4).

The experimental results show that our rule-based method defines a set of emotion-dependent features and their values when a speaker expresses emotion. The first two rules of our rule-based method select features for each emotion separately; therefore, the features are specified by emotion alone. Only the last rule considers features among all emotions.

The results of our rule-based method for emotion-dependent feature extraction demonstrate that the described method is capable of extracting such features from speakers of different gender and nationality. The ratio of emotional expression similarity shows that some similarities can be de-

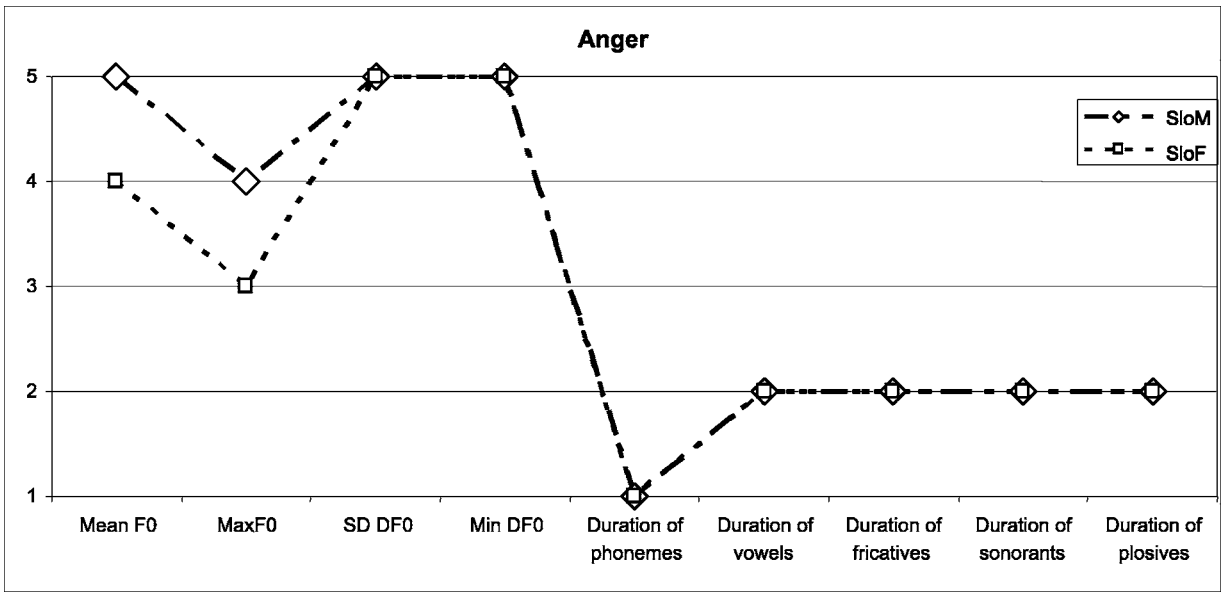

FIG. 4. Common emotion-dependent features for Slovenian male (SloM) and female (SloF) speakers for anger.

tected for all speakers. For example, all speakers had high values for almost all $F0$ features for anger (high values are values of 3 or greater), except for the standard deviation value of $\Delta F0$ for the first English male speaker, the maximal value of $\Delta F0$ for the English female speaker, and the maximal value of F0 for both Spanish speakers.

The results also show that the speakers from the Interface databases use different sets and values of emotion-dependent features to express their emotions in speech. Pereira (2000), and Cowie with co-workers (2001) show in their literature review that some features are remarkably consistent across all studies while others are quite variable. Similarly, it has been found in our analysis that there are some similarities of emotion-dependent feature values among all speakers, and the values of some emotional features are different for the same emotion.

Detailed analyses of the emotion-dependent features indicate that almost all speakers have unique sets of emotion-dependent features, except for the Spanish speakers. Fourteen emotion-dependent features were extracted altogether for all speakers. The significance of the emotion-dependent features was confirmed using PCA analysis. PCA was used as a statistical method for the extraction of features during emotion detection for all speakers involved in the analysis. Eight of the 14 emotion-dependent features were among a significant half of all 26 high-level features. These high-level features placed in the significant half are high-level features with significant variations according to PCA. The difference between PCA and the rule-based method is that PCA, as a statistical method, uses statistical measurement (variance) as a measure of significance. Our rule-based method uses, as a measure of importance, the sentence type, recording time, and emotions. Because both methods use different measures of significance, the PCA and the rule-based methods together confirm that the majority of emotion-dependent features is unaffected by recording times and sentence types, but is affected by emotions and have significant variations. Out of 14 emotion-dependent features, only five were present for all speakers. These five features could represent universal signs of emotional expression in speech for the speech databases used, and could serve as general emotion models for emotional speech synthesis. All speakers also had unique emotion-dependent feature values for all emotions, and each speaker, except for the Spanish speakers, had a unique set of emotion-dependent features. This indicates that each speaker in the databases expresses emotions differently. It can, therefore, be concluded that each speaker can perform each emotion in speech differently from other speakers using different sets of emotion-dependent features and/or values. Therefore, in speech synthesis, emotions should be modeled using the emotion-dependent parameters of only one speaker. If emotional expressions were to be modeled from more than one speaker, then the differences in emotional expression between different speakers should not be modeled, but only those characteristics of emotions that are common to all speakers. The best modeling for emotional speech synthesis, therefore, should be expected if only one speaker is selected for the modeling of emotions, as proposed by Douglas-Cowie and co-workers (2000). The extracted emotion-dependent features could possibly be used in emotional speech synthesis, as a small number of parameters controlling speech prosody are usually used in speech synthesis. The speakers from the Interface databases had from 8 to 11 emotion-dependent features. This number of features represents the amount of prosody parameters that could be controlled, at the same time, in emotional speech synthesizers. From these the $F0$ features and duration features are already used in emotional speech synthesizers, as can be found in the literature. According to the available literature, $\Delta F0$ features have not been used in emotional speech synthesis so far. As $\Delta F0$ features have proved to be emotion dependent, it would be reasonable to use them along with $F0$ and duration features to control prosodic parameters in emotional speech synthesis.

An analysis of authentic emotions should be made in order to verify our rule-based method for emotional speech in general. The results for authentic emotions are not expected to be the same as the results presented in this article, because it was shown in the literature (Batliner, 2003) that authentic emotions are less recognizable than acted emotions. In contrast, the results from our study could suggest that authentic emotion on a speaker level could be as recognizable as acted emotions, but the differences among different speakers who express authentic emotions are higher than the differences among speakers who express acted emotions. Usually this effect decreases the recognition rate.

V. CONCLUSION

This paper presents a rule-based method for the extraction of emotion-dependent features and an analysis of the experimental results. Statistical measurements of prosody parameters were used to define high-level features, from which the emotion-dependent features were selected using the extraction rules. Based on predefined rules, this method selected emotion-dependent features for each speaker individually, and independent of each other. The method thus enables comparison of emotion-dependent feature values between different speakers. Furthermore, the ratio of emotional expression similarity between two speakers was defined by calculating the number and values of the emotion-dependent features that are present for the two speakers being compared.

The proposed rule-based method was used to analyze emotional speech from four different languages, using male and female actors. In the analysis, nine speakers were used in order to find any similarities and differences among individual speakers, and to compare the results with those from other studies. The ratio of emotional expression similarity was calculated in order to compare the expressions of emotion between different speakers.

The results show that all the speakers showed some universal signs regarding certain emotion-dependent features of emotion expression. For example, all speakers had values of emotion-dependent features higher or equal to 0 for the emotions of anger and joy. However, further analysis showed that each emotion was expressed differently, which can be seen through the different sets of emotion-dependent features

and/or with different emotion-dependent features' values, when compared with results from all the speakers.

The comparison among speakers using the proposed emotion-dependent feature extraction method shows that the expressed emotions can be analyzed according to two criteria. The first criterion is a defined set of emotion-dependent features and the second is an emotion-dependent feature value. The results also show that almost all speakers from the Interface databases use a unique set of emotion-dependent features and that all the speakers had unique values of emotion-dependent features for each emotion.

The ratio of emotional expression similarity, however, indicates that speakers could be grouped together according to the values of the emotion-dependent features they used for emotional expression. The ratio of similarity for all cases is higher than 20% for the speakers in the Interface databases.

Our conclusions can be drawn mainly for prosody modeling in emotional speech synthesis, as both the emotional speech synthesizer and the actors have the same goal in the production of emotional speech. The extracted emotion-dependent features could be particularly appropriate for modeling individual speakers' emotions in emotional speech synthesis, as a set of emotion-dependent features for a specific speaker contains a small number of features that could be used for controlling prosody parameters in an emotional speech synthesis system.

(Received 31 August 2005; revised 24 February 2006; accepted 26 February 2006)

Interaction of reed and resonator in reed organ pipes without and with the resonator has been investigated. The wave form of the sound generated without the resonator attached is a periodic train (with the frequency of reed vibration) of decaying high frequency oscillation. The frequency of this oscillation is independent of the frequency of the reed vibration; it corresponds roughly to the fundamental acoustic resonance of the shallot. Another rather surprising phenomenon was also observed: without the pipe resonator, the reed vibration frequency, and correspondingly the sound frequency is a continuous function of the reed vibrating length, but when the resonator is added "forbidden" frequency domains occur in the vicinity of the eigenfrequencies of the resonator, and the sound frequency jumps abruptly from below to above each resonance frequency of the resonator, when the reed is shortened. This effect can be explained by the coupling between two oscillating systems, the reed and the acoustic resonator. The presented investigations result in a better understanding of the acoustical and mechanical aspects of sound generation in reed pipes, which may allow organ builders and voicers to easier pipe design and more accurate voicing to obtain the desired sound. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188372]

I. INTRODUCTION

Although nearly all pipe organs include reed (lingual) pipes as well as flue (labial) pipes, much less research has been reported on reed pipes than on labial pipes.[1–3] In most reed pipes the reed vibrates against a fixed shallot and modulates the flow of air passing through the shallot into the resonator. In reed pipes there is a rather complicated interaction between the vibrating reed and the pipe resonator.[4–6]

A typical reed pipe is shown in Fig. 1. Air under pressure flows from the windchest through the bore into the boot and through the thin opening into the shallot. The wind sets the thin, flexible tongue (reed) into vibration; this in turn modulates the flow of air passing through the shallot into the resonator. The reed is pressed against the open side of the shallot by a tuning wire ("Stimmkrücke") that can be adjusted up and down to tune the vibrating reed. The pipe voicer generally adjusts the reed and the resonator to produce the best sound and then tunes the pipe by adjusting the tuning wire.[7,8]

In an earlier paper we reported on measurements of reed vibration in reed organ pipes without the resonators.[9] We reported three rather surprising phenomena: the frequency of the reed plucked by hand is shifted upwards for large-amplitude plucking; the blown frequency is significantly higher than the plucked one; and peaks halfway between the harmonics of the fundamental frequency appear in the spectrum of the reed velocity.

In this paper, we discuss reed vibrations with resonator and sound generation in the reed pipe with and without the resonator.

II. EXPERIMENTAL METHOD

The experimental apparatus is similar to that described in our earlier paper.[9] The pipes were tested on a slider chest, with the wind supplied by an organ blower and pressure regulator. Wind pressure was measured on a water manometer. Because the response of a reed pipe is very much dependent on the speed of the pressure onset, the pipe was switched on by means of a pallet activated by an electromagnet. We found that a sudden pressure onset was needed in our experiments for stable reed oscillations.

A window was installed on the boot so that the reed could be observed while it vibrated. The velocity was recorded by means of a laser vibrometer (Polytec OFV 3000). A $\frac{1}{4}$-inch microphone (B&K 4135) was inserted into the shallot wall to record the sound pressure inside the shallot, and another microphone (B&K 4165) recorded the sound pressure near the open end of the pipe.

The reed velocity and the sound pressure inside the shallot, as well as the sound pressure near the open end of the pipe were recorded as the vibrating reed length was varied by means of the tuning wire. The wind pressure was set to the optimal value (80 mm water gauge) for sounding the pipe, as recommended by an experienced organ voicer. Sound pressure and reed velocity wave form were recorded both with and without the pipe resonator in place. Sound spectra, velocity spectra, and frequency were obtained with the help of a dual-channel FFT analyzer (HP 35670A).

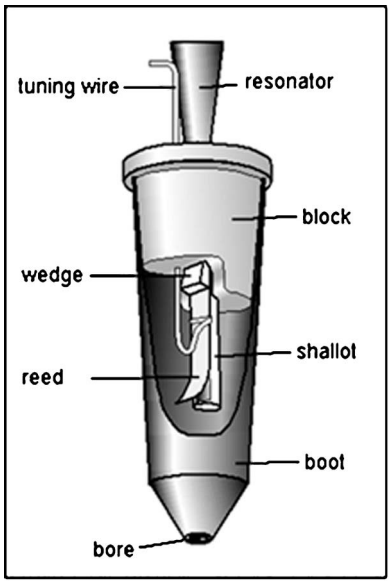

FIG. 1. The foot (boot) of a reed pipe.

The natural resonances (eigenfrequencies) of the pipe resonator were determined by measuring the frequency response of the resonator to an external acoustic excitation. Pink noise was radiated by a small loudspeaker placed close to the larger opening (mouth) of the conical resonator, and the sound pressure at the narrow end (throat) was measured by a small microphone.

A G4 Trompette pipe was used for the study presented in this paper. The conical resonator of the pipe was 687 mm long with diameters 9.2 and 65 mm at the ends (conical angle, 4.7 degree). The shallot was also slightly conical (internal diameters, 6.5 mm at upper end and 8 mm at the lower end), with a length of 56.5 mm and a wall thickness of 1.5 mm. The opening on the side of the shallot has a triangular shape with 4.8 mm maximal width and 40.4 mm height. The reed (tongue) was made from bronze. It has a trapezoidal shape with length of 55.8 mm and widths of 7.2 mm and 5.5 mm at the ends. The thickness of the reed is 0.312 mm. The 5.5 mm width end was clamped by means of a wedge into the block of the pipe. The total length of the reed from the wedge to the free end was 45 mm. The vibrating length could be adjusted from 37.5 mm to 15 mm.

III. RESULTS

A. Sound in the shallot without the resonator

In this case the resonator is not attached to the boot of the pipe. The system, as shown in Fig. 1, consists of the boot, the shallot inserted into the block and the reed, attached to the shallot. This system, when blown, produces quite a strong sound, whose frequency can be tuned continuously by the tuning wire. It has been shown[9] that the oscillation of the reed is generated and maintained by hydrodynamic forces due to the air flow through the gap between the shallot and reed; therefore, no acoustic feedback is necessary for the reed vibration. Sound is produced by the modulated volume flow into the shallot.

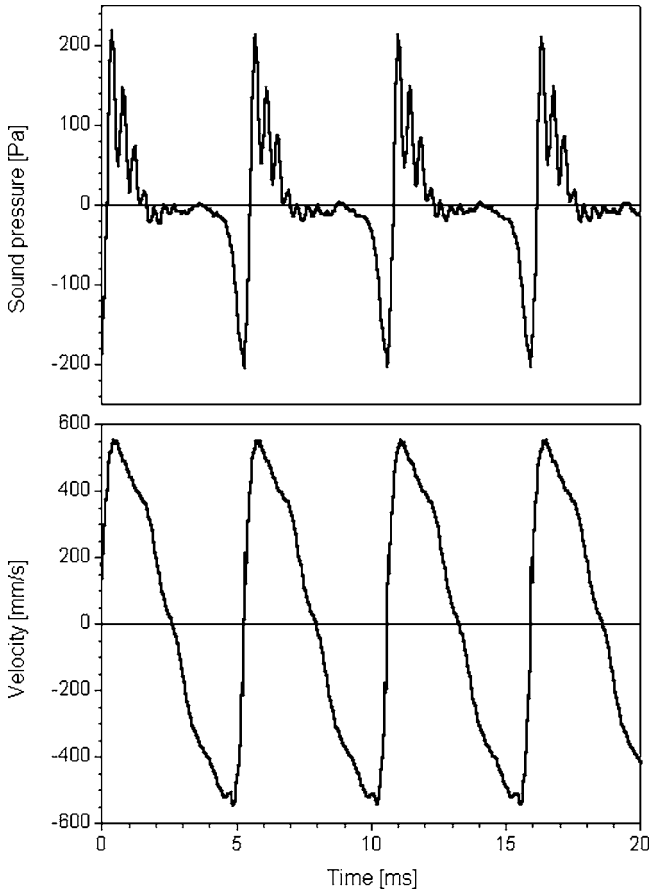

FIG. 2. Sound pressure wave form in the shallot (upper graph) and reed velocity wave form (lower graph) without the resonator attached for a 37.5 mm reed length. The sign of the velocity is negative when the reed moves toward the shallot.

The pressure wave form in the shallot was markedly different from that of the velocity wave form of the reed. Sound pressure and reed velocity are plotted in Fig. 2 for a 37.5-mm reed length. The sign of the velocity is negative when the reed moves towards the shallot. When the reed approaches the shallot, it slows down, turns around, and speeds up very rapidly. As the gap decreases, the pressure in the shallot drops and reaches a minimum value when the velocity is zero, i.e., at the lower turning point of the reed vibration, where the gap is the narrowest.

The sound pressure wave form includes two components: a strong bipolar pressure pulse and a high frequency oscillation. This oscillation begins when the reed moves away from the shallot, and as the gap increases, its frequency shifts upwards, diminishes in amplitude, and dies out. Sound pressure wave forms in the shallot are shown in Fig. 3 for three different reed lengths (31.5, 30.5, and 28.5 mm). The high frequency oscillations show a striking similarity for different reed lengths. Although the period of the sound signal decreases with the reed length, the high frequency oscillations are almost identical.

Spectra of a single period of the bandpass-filtered (1 kHz–8 kHz) sound pressure wave forms in the shallot are shown in Fig. 4 for 31.5, 30.5, and 28.5 mm reed lengths. As expected, broad maxima around 2500 Hz can be observed, corresponding to the ~0.4 ms period of the high frequency

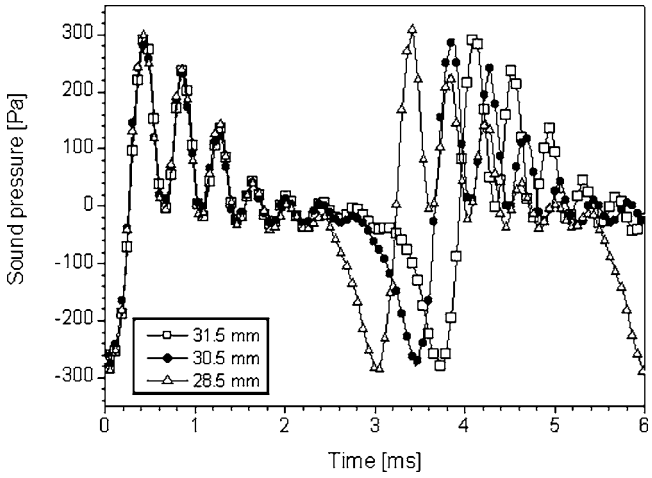

FIG. 3. Sound pressure wave forms in the shallot (without the resonator) for reed lengths of 31.5 mm, 30.5 mm, and 28.5 mm.

oscillations in Fig. 3. The peak amplitude increases with decreasing reed length. This behavior corresponds to the increasing rms vibration amplitude shown in Fig. 9.

The high-frequency oscillation in the shallot will be more and more concealed by the strong bipolar pulse as the vibration frequency increases. The number of the high frequency oscillation periods is gradually reduced as the vibration period decreases. Sound pressure wave forms in the shallot for smaller reed lengths are presented in Fig. 5. Only 2–3 periods of the high frequency oscillation can be recognized, but its frequency is still independent on the vibration frequency of the reed.

B. Reed vibration with resonator

The frequency of the vibrating reed of a blown G4 Trompette pipe with resonator attached was investigated for different reed lengths. The frequencies of the resonator modes were determined by placing a loudspeaker excited with pink noise about 10 cm from the open mouth of the resonator (tilted so as not to cause standing waves) and measuring the sound pressure with a small microphone about

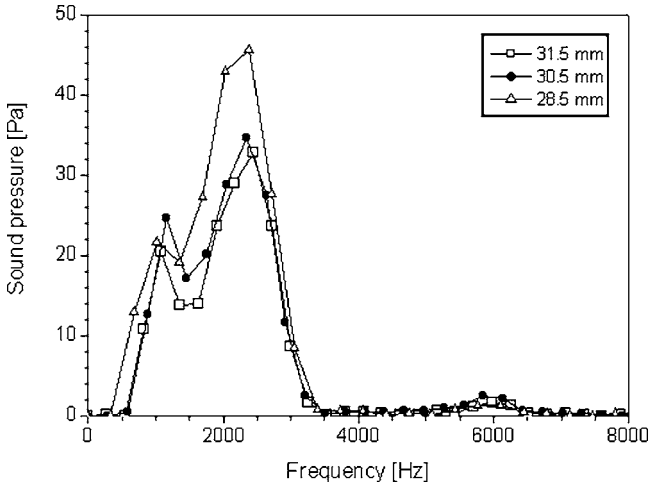

FIG. 4. Spectra of one single period of the sound in the shallot (without the resonator) for reed lengths 31.5 mm, 30.5 mm, and 28.5 mm.

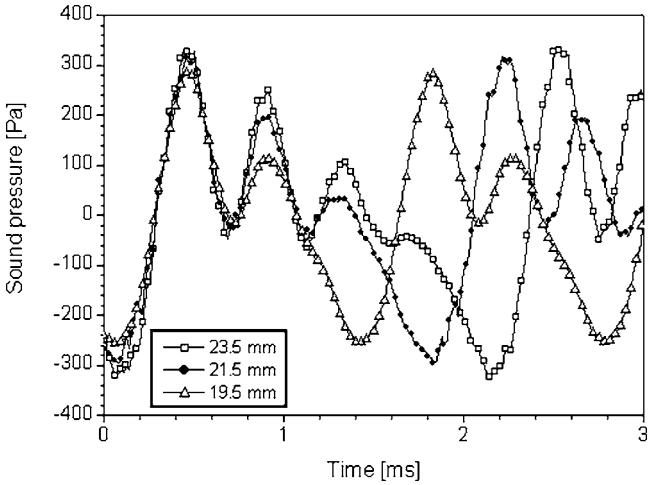

FIG. 5. Sound pressure wave forms in the shallot for reed lengths of 23.5 mm, 21.5 mm, and 19.5 mm. Two or three periods of the higher frequency oscillation in the shallot can still be recognized during each period of the reed vibration.

3 cm from the open throat (the smaller opening of the conical resonator). The eigenfrequencies of the resonator were determined from the frequency response shown in Fig. 6. The first four resonance frequencies are 242.5, 486, 729, and 973 Hz. Note that these frequencies are almost perfectly harmonic.

The effect of the resonator on the reed velocity and pipe sound was investigated for several reed lengths. The measurement was started by the maximum adjustable length (37.5 mm) of the reed with attached resonator. The pallet valve was opened, and was kept open for the entire duration of the measurements. That is, all the measurements were carried out in steady state. Reed velocity, the sound pressure in the shallot and at the open end of the resonator was recorded first, then the resonator was removed and the reed velocity and the sound pressure in the shallot were recorded again. The resonator was attached again, the reed was shortened, and the measurement procedure was repeated. Thus five signals (two reed velocity signals and three sound pressure signals) were recorded at each adjusted reed lengths.

The length to be adjusted was always approached from

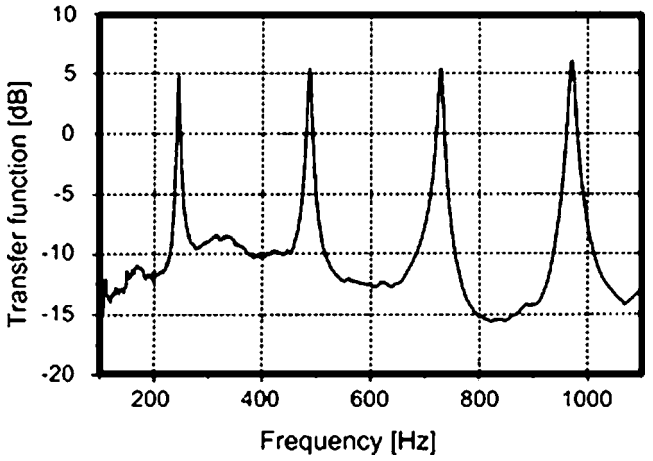

FIG. 6. Resonator transfer function (output spectrum and/or input spectrum) showing the first four acoustic modes of the resonator.

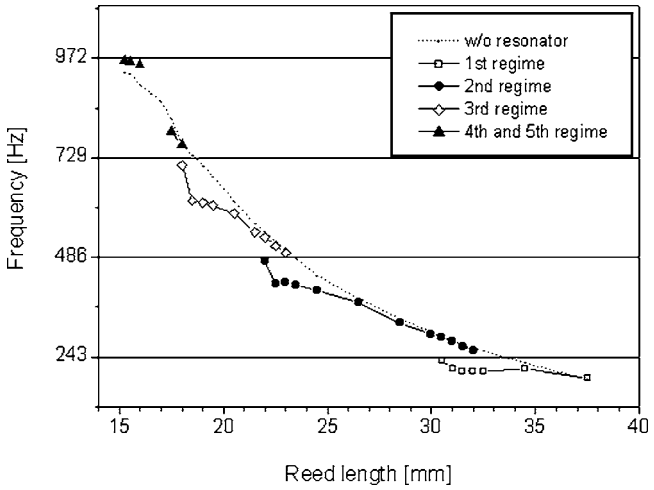

FIG. 7. Reed vibration frequency versus vibrating length with and without the resonator. The first four resonance frequencies (eigenfrequencies) of the resonator are shown as horizontal lines. The nominal frequency of the pipe (207.7 Hz) lies on the almost horizontal part of the first regime of the oscillation. Note the frequency jump and hysteresis near each resonator frequency.

both directions; i.e., by shortening and by lengthening the vibrating part of the reed. If the sound of the pipe was different for the two cases, the five measurements were carried out for both cases.

The frequency of the vibrating reed is shown as a function of reed length in Fig. 7, both with and without the pipe resonator attached. The blowing pressure was 80 mm water in this experiment. The reed frequency varies smoothly with reed length without the resonator, as would be expected,[9] but attaching the resonator lowers the frequency of the reed and also produces five distinct regimes of sounding, separated by four discontinuities, as the system jumps from one regime to the next one. Between the sounding regimes the sound is unstable, and between the second and third regimes there is a small range over which the pipe did not sound.

A hysteresis can also be observed: the reed length of jumping depends on the direction of tuning. This phenomenon occurs when the pipe is kept sounding and the tuning wire is shortened or lengthened in very fine steps. In this way the sound frequency can be brought into the regime of hysteresis, where two stable oscillations are possible at each reed length. In this regime (a domain of about 1.5–2 mm), two sounds with different pitch and timbre occur quite randomly for a given reed length, when the pipe is switched on and off. Certainly, this reed length domain cannot be used for musical purposes.

The first four resonance frequencies of the resonator (marked as dotted horizontal lines in Fig. 7) lie in the frequency domain of the observed discontinuities. Note that the nominal frequency of this pipe (207.7 Hz) is located on the almost horizontal part of the first regime at ~31.5 mm reed length.

Reed velocity wave forms with and without the resonator attached are shown in Fig. 8. The two wave forms are quite similar for 37.5 mm reed length, when the frequencies are close to each other [Fig. 8(a)]. When the frequency with the resonator is smaller than without it, the wave form is also

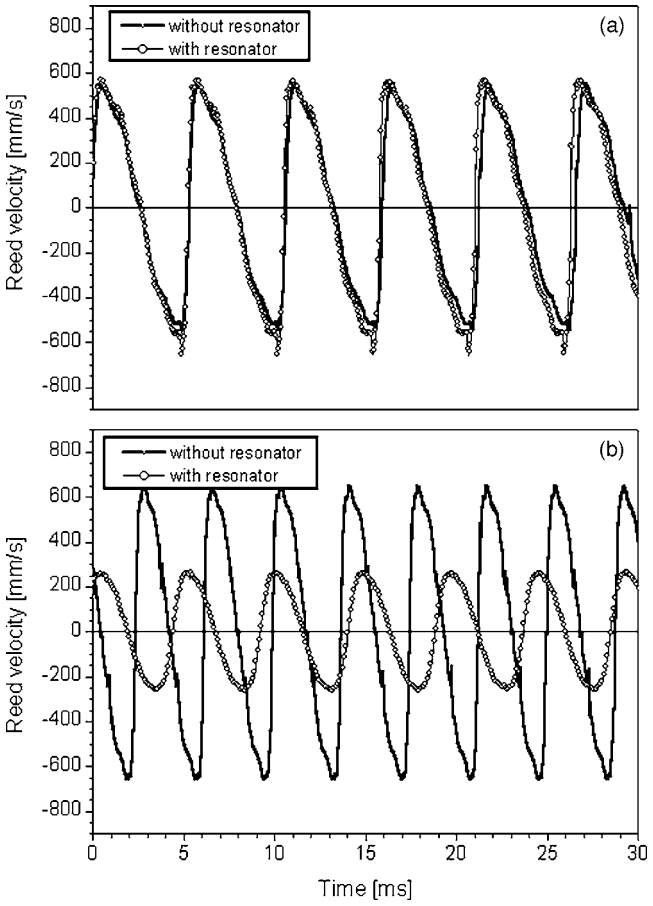

FIG. 8. Reed velocity wave forms for 37.5 mm (upper curve) and 32.0 mm (lower curve) reed lengths with and without the resonator. (a) Wave forms are similar when frequencies with (f=190.1 Hz) and without (f=187.8 Hz) the resonator are close to each other; (b) amplitude is smaller and wave form smoother when the frequency with (f=207.1 Hz) the resonator is smaller than without (f=259.1 Hz) it.

different. The amplitude of the vibration for 32.0 mm reed length [Fig. 8(b)] is much smaller, and the curve is much smoother, i.e., the high frequency content is reduced. At certain reed lengths (for example, at 30 mm and 21.5 mm) the vibration completely dies out.

The reed is unstable in such cases. Although it is possible to adjust the reed length to stop the vibration, the pipe cannot maintain this state indefinitely; it will start to sound after a while. The silent periods can be maintained for up to about 1 minute.

The amplitude of the vibration can be characterized by the rms values calculated from the velocity wave forms. They were plotted against reed frequency in Fig. 9, where the rms amplitudes without the resonator are also shown. Attaching the resonator, the vibration amplitude decreases, and it dies out at certain reed lengths. Around the first three eigenresonance frequencies of the pipe resonator (marked as vertical grid lines) the "forbidden" frequency domains can be clearly seen. The pipe cannot be tuned to a frequency in a "forbidden" domain. The frequency jumps over these domains, when the length of the reed is changed continuously by the tuning wire. The width of the forbidden domains was around 3–4 semitones (minor or major fifths). In order to get a strong, bright sound at a given note, the resonator should

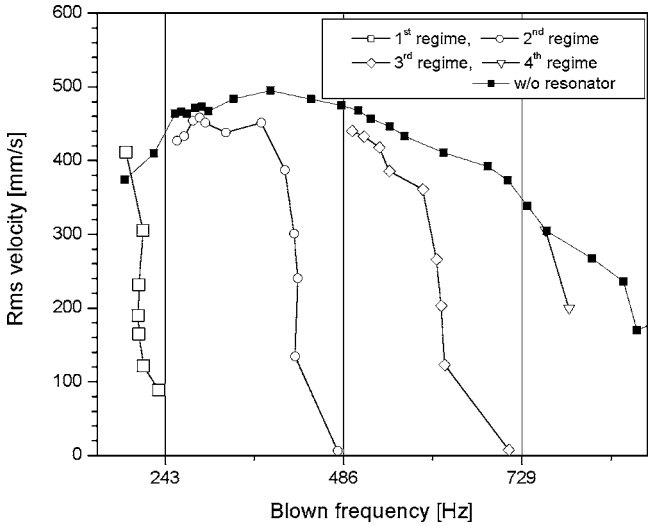

FIG. 9. Rms values of reed velocity without and with the resonator versus frequency. In the first case the rms curve is rather smooth with a maximum around 26.5 mm reed length (387 Hz). With resonator the rms amplitude of the vibration decreases rapidly as the frequency approaches the eigenfrequencies of the resonator from below.

be tuned about 1 semitone below the frequency of that note, so that the required frequency lays over the upper boundary of the "forbidden" domain. On the other hand, the resonator should be tuned about 3 semitones above the required frequency for a soft sound. For example, the resonator of the investigated reed pipe was tuned to 243 Hz, about 3 semitones over the nominal frequency of 207.7 Hz of the pipe. These results contradict the opinions given in Chaps. 13.4 and 17.11 of Ref. 10.

C. Sound in the shallot and at the mouth of the resonator

When the resonator is attached, the sound in the shallot is strongly influenced by the resonator. Sound pressure wave forms are presented in Fig. 10, where wave forms measured in the shallot with and without resonator are shown for the 37.5 mm reed length. The main changes are the significant

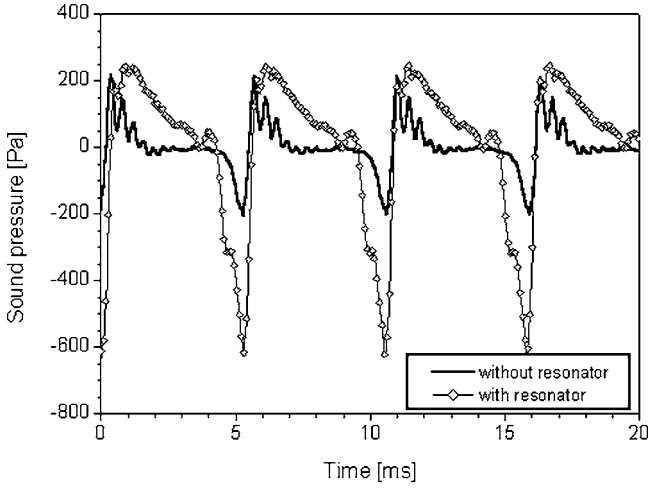

FIG. 10. Sound pressure in the shallot with (dashed curve) and without (solid curve) the resonator for 37.5 mm reed length.

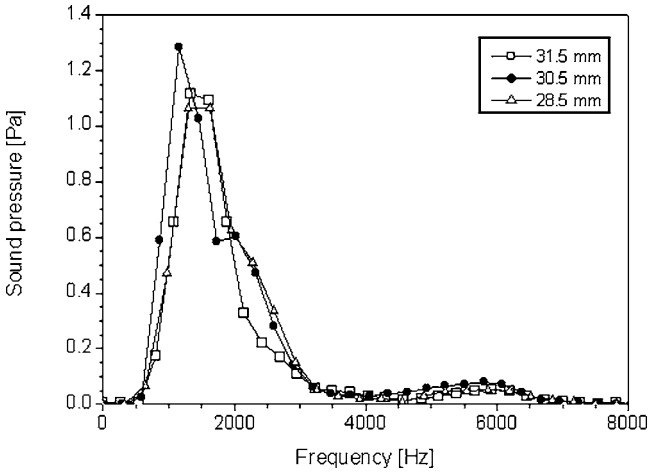

FIG. 11. Sound spectra of a single period at the open end of the resonator for the same three reed lengths (31.5 mm, 30.5 mm, 27.5 mm) as in Fig. 4.

increase of the negative part of the bipolar pressure pulse and the reduction of the amplitude and frequency of the high frequency oscillation.

Spectra of one single period of the bandpass-filtered (1 kHz–8 kHz) sound at the mouth of the resonator are shown in Fig. 11 for three (31.5, 30.5, and 28.5 mm) reed lengths. Broad peaks occur around 1500 Hz; their shape and amplitude is quite similar, in spite of the different sound frequencies (268.9 Hz, 290.0 Hz, and 326.0 Hz). These pipe frequencies can be found in the second regime shown in Figs. 7 and 9. The high frequency oscillation within a single sound period is shifted down to about 1.5 kHz from the 2.5 kHz range observed without the resonator, but it is still quite independent on the reed vibration (and sound) frequency.

Sound pressure wave forms measured in the shallot and close to the open mouth of the resonator are shown in Fig. 12 for 37.5 mm reed length. The wave form at the open mouth (upper curve) shows the characteristic pattern of reed pipe sound: a periodic train of a rapidly developing oscillation followed by a very rapid decay. Note that the sound pressure at the mouth is 20 to 50 times smaller than in the shallot (lower curve). Since the cross sectional area of the open mouth is about 50 times larger than that of the throat inserted into the block, such a reduction of the pressure can be expected.

IV. EVALUATION OF THE RESULTS

A. Sound in the shallot

A possible explanation of the observed sound pressure wave form in the shallot can be given as follows: The strong bipolar pressure pulse (see Fig. 2) is generated by the flow through the gap, which is modulated by the vibration of the reed. This bipolar pressure pulse is produced by aerodynamic forces and it provides the feedback for reed oscillation, as discussed in Ref. 9. Simultaneously, it excites the fundamental acoustic resonance of the shallot. Thus, sound generation in the shallot can be regarded as a by-product of the reed oscillation.

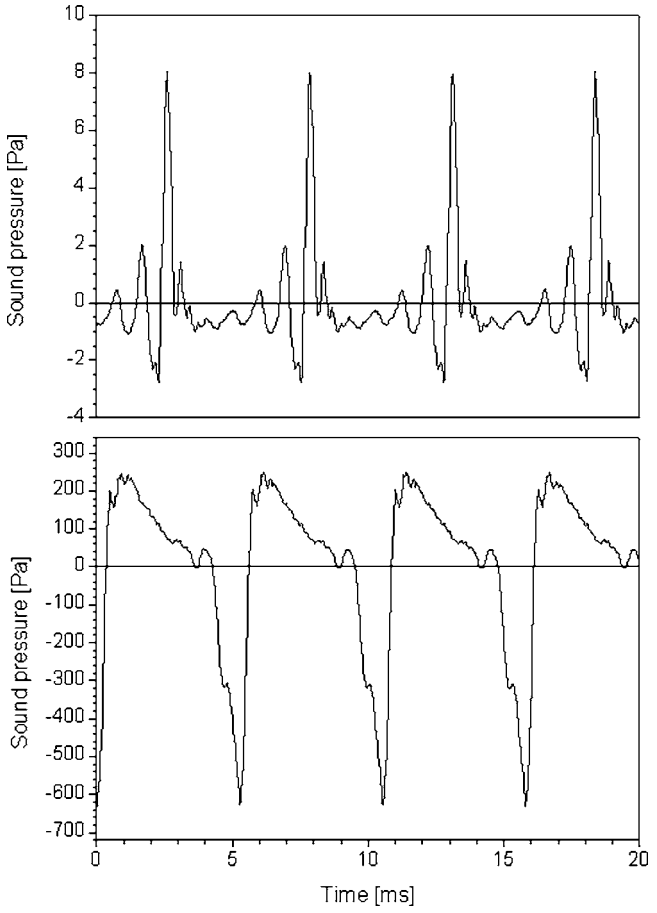

FIG. 12. Sound pressure wave forms in the shallot (lower curve) and close to the pipe mouth (upper curve) for 37.5 mm reed length.

The shallot is essentially a brass tube with open ends (an open end in the block and a side opening covered by the reed with a gap between the shallot and the reed) as shown in Fig. 1. The length of the shallot is 56.5 mm and it is inserted into the bore of the block. The inner diameter of the shallot is 6.5 mm. The length of the bore in the block above the shallot is about 23.5 mm, thus the entire length of the acoustic resonator tube is 80 mm with a jump of the cross sectional area with a factor of about 2 at 56.5 mm. The estimations of the fundamental frequency of such an acoustic system lead to values in the range of 2–3 kHz. The peak frequencies in Fig. 4 lay in this domain around 2500 Hz; thus it is reasonable to assume that the observed high frequency sound in the shallot corresponds to the fundamental acoustic resonance frequency of the shallot tube.

The frequency of the sound generated in the shallot is not constant as shown in Fig. 3 and in our earlier experiments,[4,5] it is shifted slightly upwards as the reed length increases. This effect can be explained by the reduction of the effective length of the shallot. As the reed rolls up from the shallot the length of the closed part of the shallot will be smaller; moreover, the end correction will also be smaller (it is inversely proportional to the square root of the area[10] of the opening). Both effects increase the eigenfrequency of the shallot.

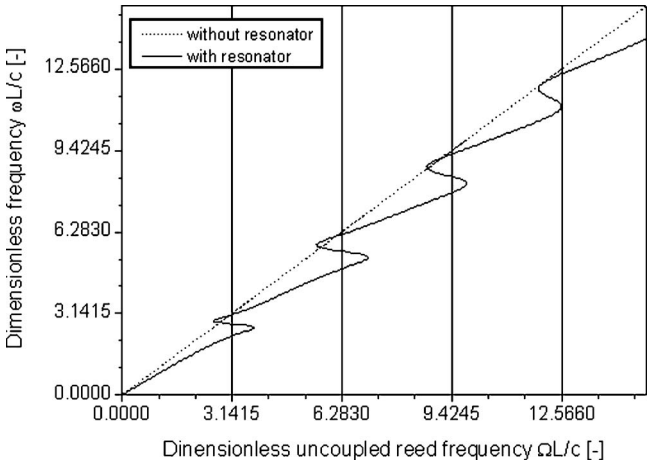

FIG. 13. Calculated dimensionless resonance frequency ($\omega L/c$) of the coupled reed and resonator as a function of the dimensionless reed frequency ($\Omega L/c$) without the resonator. Note the triple-valued function when the reed frequency is close to the eigenfrequencies of the resonator at the multiples of Pi.

B. Reed vibration with the resonator

The effects of reed-resonator coupling were very similar to those observed previously.[4] At the first occasion this behavior came as somewhat of a surprise. Although no experimental data have been published previously, to our knowledge, it has generally been felt that both the reed and the pipe resonator are tuned to the desired sounding frequency, which is mainly determined by the natural frequency of the reed.[10] The results in Figs. 7 and 9 show, however, that the resonator can lower the reed frequency by as much as 20% below its blown frequency without the resonator, when the reed frequency approaches an acoustic resonance from below. The vibration of the reed became more and more damped until the oscillation ceases. By further shortening the length of the reed, it starts to vibrate again with about the same frequency as the blown frequency without resonator. The reed pipe cannot sound in a frequency range of about 3–4 semitones around each acoustic mode frequency of the resonator ("forbidden" frequency domains).

This behavior can be explained by assuming that the reed and the acoustic resonator form a coupled vibrating system. A simple physical model of the coupling is discussed in the Appendix . In this model it is assumed that the particle velocity at the throat of the resonator equals the velocity of the reed, thus the input acoustic flow of the resonator can be given by the product of the area A of the throat and the reed velocity u. On the other hand, the force acting on the reed can be given as the product of the sound pressure p at the throat and the surface S of the reed. These assumptions are formulated in Eq. (A1) of the Appendix. The resonance frequencies of the coupled system and the damping of the reed are calculated from the dispersion equations (A8) as functions of the uncoupled reed frequency. The results of the calculations are shown in Figs. 13 and 14, while the measurement results of Fig. 7 are replotted for comparison in Fig. 15. The calculated (dimensionless) frequencies $\omega L/c$ of the coupled system are plotted versus the (dimensionless) reed frequency $\Omega L/c$ in Fig. 13, where ω, Ω, L, and c are the

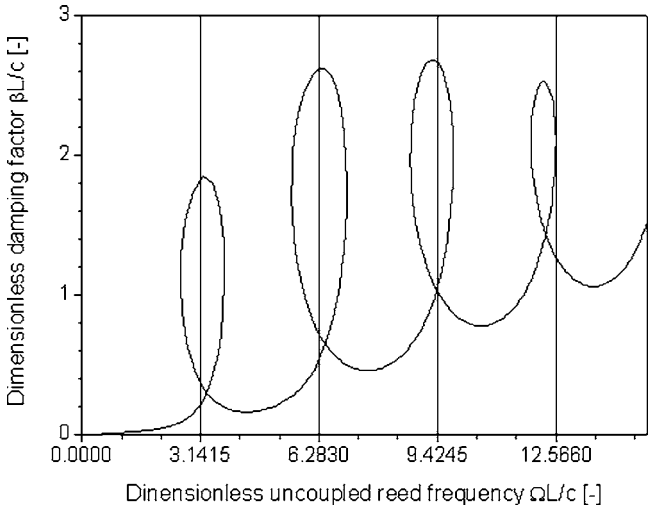

FIG. 14. Dimensionless damping constant of the reed vibration of the coupled reed-resonator system as a function of the dimensionless reed frequency ($\Omega L/c$) without the resonator.

angular frequency of the sounding reed pipe, the angular frequency of the sound and reed vibration without the resonator, the length of the acoustic resonator and the velocity of sound, respectively. The dispersion curve in Fig. 13 contains an instability region around each acoustic eigenfrequency. In these regions the curve is three valued. The lower and upper parts of the dispersion curve have positive slopes; these parts describe stable solutions of the dispersion equations. The middle part has a negative slope; in that domain the solution is unstable.

The (dimensionless) damping coefficient $\beta L/c$ of the reed (where β is the attenuation coefficient of the reed in s^{-1}) is shown as a function of the (dimensionless) uncoupled reed frequency in Fig. 14. The damping of the reed vibration increases significantly as the uncoupled vibration frequency approaches the instability region.

The calculated curve in Fig. 13 helps to understand the measured one in Fig. 15. Physically, the sound pressure at the narrower end of the conical resonator will oppose the vibration of the reed, as its frequency approaches an acoustic resonance. This effect results in a lowering of the reed frequency and an increase of the damping of the reed.

However, the comparison of Figs. 13 and 15 also show that the simple model of coupling can only qualitatively explain the observed phenomena. The calculated and measured frequencies differ quite significantly, but the main features of the dispersion curves are similar.

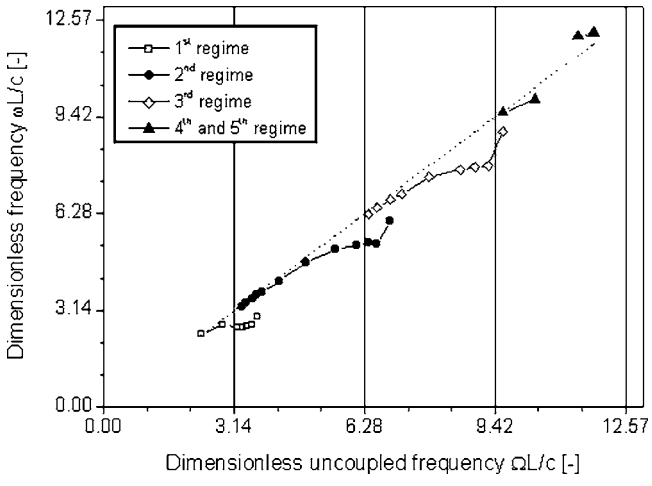

FIG. 15. Measured dimensionless frequency of the coupled reed and resonator as a function of the dimensionless reed frequency ($\Omega L/c$) without the resonator (Fig. 7 replotted). Note the similarity in overall appearance and the differences in details between the calculated curve in Fig. 13 and the measured curve in this figure.

C. Sound in the shallot and at the mouth of the resonator

Without the resonator the sound is dominated by the fundamental acoustic mode of the shallot. After attaching the resonator the acoustic system becomes much more complicated. If there is no change in cross section between the shallot and the resonator tube, the system can be treated as a single acoustic resonator. In practice, however, there is a cross section mismatch between the shallot and the resonator which reflects the acoustic wave. The reflection coefficient, calculated from the diameters of resonator and shallot is about 0.33. In such cases the shallot acts further on as an acoustic resonator, but its resonances will be shifted down because of the acoustic load of the resonator tube. The fundamental shallot mode can couple to those higher eigenmodes of the conical resonator tube whose frequencies are close to the shallot's frequency. However, the eigenfrequencies of the conical tube are more stable than that of the shallot; thus they can stabilize the frequency of the shallot mode. This effect can be observed by comparing the single period spectra in Figs. 4 and 11. The broad peaks are shifted down in frequency, and become narrower, when the resonator is attached.

It is well known, that a periodic signal can be regarded as a convolution of a periodic train of Dirac δ pulses and of the wave form of one single period. Correspondingly, the spectrum of a periodic signal can be regarded as the product of the spectrum of the Dirac δ-pulse train and the spectrum of a single period. The former contains an infinite series of harmonic lines; the latter determines the envelope of the resulting spectrum. Therefore, the broad peaks observed in the single period sound spectra can influence the formant structure of the sound of reed pipes. This may be the physical ground for the empirical experience of organ builders about the significant influence of the size and shape of the shallot on the timbre of the pipe sound.

Since the frequency domain of the formant established by the shallot mode does not change when the pipe is tuned, the formant maximum is shifted continuously over the overtones in the course of tuning. This is one reason why the timbre of reed pipes changes when tuned. The other reason is the change in the damping of the reed vibration. As the reed vibrates more smoothly, the bipolar pressure pulse will be broader, and less high frequency sound can be excited in the shallot and resonator. This effect can be observed in Fig. 8.

V. DISCUSSION OF THE RESULTS

In a clarinet, the reed resonance is much (6 to 10 times) higher than the blown note. The oscillation condition (that the negative of the real part of the reed admittance must be greater than the real part of the pipe admittance; see Eq. 13.12 in Ref. 10) can be satisfied by any of the lower pipe modes. However, the lowest mode has the highest impedance, so that the clarinet prefers to vibrate in this mode, although overblowing can coax it to vibrate in a higher mode (change to a higher register). In the Trompette organ pipe, on the other hand, the frequency appears to be stable to change in the wind pressure, and the jump to a higher frequency regime requires a shortening of the vibrating reed length. The observed frequency jumps, however, cannot be regarded as mode transitions. The reed pipe cannot sound at the mode frequencies of the resonator.

The rather surprising effects of reed-resonator coupling can be qualitatively explained by the simple physical model presented in the appendix . The coupling parameters depend on the density and thickness of the reed and on the length, the average diameter, the conical angle and the attenuation coefficient of the acoustic resonator.

The high-frequency oscillations observed inside the shallot were also somewhat of a surprise. Although they are less prominent with the pipe resonator attached than without it, they could strengthen certain high harmonics in the pipe sound, contributing a formantlike effect. That is, the timbre of a reed pipe may be influenced by the size and shape of the shallot. This statement corresponds to the experience of organ building. Reed pipe makers and voicers use a broad variation of shallot shapes and sizes in their work to produce the desired timbre and speech of the reed pipes.

The data reported in this paper are from a single G4 Trompette pipe, but similar effects are observed in other reed pipes as well.[11] In a rankett pipe, having a closed cylindrical resonator, the frequency jumps are not as well defined, as shown in Fig. 7.

VI. CONCLUSION

Contrary to the opinion often expressed, coupling between the vibrating reed and the pipe resonator appears to be a very important factor in the acoustical behavior of reed organ pipes. In this respect, they resemble the woodwind instruments. Without the pipe resonator, the reed vibration frequency is a continuous function of the reed vibrating length, but when the resonator is added the frequency jumps abruptly from below to above each resonance frequency of the resonator.

Although design of reed organ pipes is a well-developed art, it has developed as an empirical art and is very time consuming. It is believed that a good understanding of the acoustical and mechanical aspects of sound generation in these pipes will allow organ builders and voicers to more easily and more accurately voice them so as to obtain the desired sound.

ACKNOWLEDGMENTS

The research was financially supported by the Förderverein Orgelforschung (FOF). The authors express their thanks to Neville Fletcher for his helpful comments and to the organ builder B. Welde for providing the reed pipes for the measurements. One of the authors (T.D.R.) expresses thanks to the Fraunhofer-Institut Bauphysik, Stuttgart for supporting his research visit.

APPENDIX

It is assumed that the reed and the conical resonator form a coupled system. The acoustic pressure at the smaller opening of the resonator provides a force on the reed, while the velocity of the reed provides the input acoustic flow for the resonator,

$$Z_m u + Sp = 0, \quad Au + Y_a p = 0, \tag{A1}$$

where u, Z_m, S, p, A, and Y_a are reed velocity, the mechanical impedance of the reed, the surface area of the reed, acoustic pressure, area of the resonator opening and acoustic input admittance of the resonator, respectively.

Nontrivial solution of Eq. (A1) exists only if the determinant is zero,

$$Z_m Y_a - AS = 0. \tag{A2}$$

Dividing by the product AS the following dispersion equation can be derived:

$$z_m y_a = 1, \tag{A3}$$

where $z_m = Z_m/S$ and $y_a = Y_a/A$ are the specific impedance of the reed and the specific input admittance of the resonator, respectively.

The specific acoustic input admittance of an open conical resonator is given as[10]

$$y_a = \frac{1}{\rho c}\left(\frac{1}{jKR_1} + \frac{1}{j\tan KL}\right), \tag{A4}$$

where ρ, c, R_1, L, $K = k - j\kappa = (\omega/c)(1 - j\alpha)$, ω and α are the air density, sound velocity, the distance of the input opening from the origin of the cone, the length of the resonator, the complex wave number, the angular frequency and the dimensionless loss factor of the resonator, respectively. The dimensionless loss factor α can be expressed by the quality factor of the resonator as $\alpha = 1/2Q$. The quantity R_1 can be determined from the input radius r_1 and the half-angle of the cone $\varphi/2$ as $R_1 = r_1/\sin(\varphi/2)$.

By separating the real and imaginary parts the specific acoustic input admittance can be written as follows:

$$\begin{aligned} y_a &= \frac{-1}{\rho c}(R_a - jI_a) \\ &= \frac{-1}{\rho c}\left(\frac{\alpha E}{x} + \frac{\sinh(\alpha x)\cosh(\alpha x)}{\sin^2 x + \sinh^2(\alpha x)}\right) \\ &\quad + \frac{j}{\rho c}\left(\frac{E}{x} + \frac{\sin x \cos x}{\sin^2 x + \sinh^2(\alpha x)}\right), \end{aligned} \tag{A5}$$

where $x=\omega L/c$ is the dimensionless frequency variable and $E=L\sin(\varphi/2)/r_1(1+\alpha^2)$.

The reed is regarded as a simple harmonic oscillator with the mechanical impedance,

$$Z_m = -2\beta m - j\frac{m(\Omega^2-\omega^2)}{\omega}, \tag{A6}$$

where m, Ω, and β are the effective mass of the reed, the resonance frequency and the damping constant of the reed, respectively.

In the vicinity of the eigenfrequency of the reed, its specific impedance can be approximated as follows:

$$z_m = \frac{-\rho_r d_r c}{L}\left(2\gamma + j\frac{X^2-x^2}{x}\right), \tag{A7}$$

where ρ_r, d_r, $\gamma=\beta L/c$, and $X=\Omega L/c$ are the density, the thickness, the dimensionless damping constant and resonance frequency of the reed, respectively.

By substituting Eqs. (A5) and (A7) to (A3) and separating the real and imaginary part the following pair of equations can be derived for the unknown quantities γ and X^2:

$$2xR_a\gamma + I_a X^2 = x^2 I_a + Cx, \quad 2xI_a\gamma - R_a X^2 = -x^2 R_a, \tag{A8}$$

where $C=\rho L/\rho_r d_r$.

The solution of (A8) is given by the following expressions:

$$\gamma = \frac{R_a C}{2(R_a^2+I_a^2)}, \quad X^2 = x^2 + \frac{xI_a C}{(R_a^2+I_a^2)}. \tag{A9}$$

The solution of the dispersion equation (A3) for parameter values of $\gamma=0.06$, $E=6.0$, and $C=4$ are presented in Figs. 13 and 14.

(Received 24 August 2005; revised 18 February 2006; accepted 22 February 2006)

Echocardiography requires imaging of the heart with sound propagating at varying angles relative to the predominant direction of the myofibers. The degree of anisotropy of attenuation can significantly influence ultrasonic imaging and tissue characterization measurements *in vivo*. This study quantifies the anisotropy of attenuation of freshly excised myocardium at frequencies typical of echocardiographic imaging. Results show a significantly larger anisotropy than previously reported in specimens of locally unidirectional myofibers. Through-transmission radio frequency-based measurements were performed on specimens from 12 ovine and 12 bovine hearts. Although ovine hearts are closer in size to human, the larger size of bovine hearts offers the potential for specimens in which myofibers are more nearly unidirectionally aligned. The attenuation coefficient increased approximately linearly with frequency. The mean slope of attenuation with frequency was 3–4 times larger for propagation parallel than for perpendicular to the myofibers. At perpendicular insonification, slopes between ovine and bovine myocardium were approximately equal. However, attenuation in bovine specimens was larger for angles approaching parallel. The difference in results for parallel appears consistent with what might be expected from increased myofiber curvature associated with smaller lamb hearts. Quantitative knowledge of anisotropy of attenuation may be useful in understanding mechanisms underlying the interaction of ultrasound with myocardium. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188333]

I. INTRODUCTION

Attenuation plays a significant role in ultrasonic imaging and tissue characterization. Ideally, measurements of the anisotropy of attenuation in myocardium would be representative of results for myofibers oriented along a single direction. However, such measurements are precluded by the regional myofiber architecture of the heart which is complex (Greenbaum *et al.*, 1981; Harrington *et al.*, 2005; LeGrice *et al.*, 1995; Streeter *et al.*, 1969). The purpose of this investigation was to quantify the anisotropy of attenuation in freshly excised myocardial tissue in which the myofibers are locally unidirectional and to compare those results with earlier measurements of attenuation on freshly excised myocardium. Results presented in the current study show a larger anisotropy of attenuation in myocardium than previously reported. A quantitative knowledge of myocardial attenuation and its dependence on angle of insonification with respect to the local predominant direction of myofibers may be important in echocardiographic modeling and the proper interpretation of diagnostic results. For example, by accounting for myocardial attenuation, the well-known phenomenon of drop out in the lateral and septal walls in parasternal short-axis echocardiographic views of the heart can be mitigated in studies of wall motion and estimates of ventricular volume (Aygen and Popp, 1987; Holland *et al.*, 1998; Melton and Skorton, 1983; Perez *et al.*, 1992; Recchia *et al.*, 1993). In addition, quantitative characterization of cardiac tissue through analyses of the apparent backscatter are influenced by attenuation. The cyclic variation of myocardial backscatter has shown promise as a diagnostic tool (Barzilai *et al.*, 1984; Castaldo *et al.*, 2000; Ciliberto *et al.*, 1996; Colonna *et al.*, 1999; D'Hooge *et al.*, 2000; Di Bello *et al.*, 2001; Finch-Johnston *et al.*, 2000; Goens *et al.*, 1996; Hancock *et al.*, 2002; Holland *et al.*, 2004; Kovacs *et al.*, 2004; Mottley *et al.*, 1984; Naito *et al.*, 1994; Ohara *et al.*, 2005; Pasquet *et al.*, 1998; Pislaru *et al.*, 2001; Rijsterborgh *et al.*, 1993; Sagar *et al.*, 1990; van der Steen *et al.*, 1997; Vandenberg *et al.*, 1991; Vered *et al.*, 1989; Wickline *et al.*, 1986; Yuda *et al.*, 2002). However, measurements of the cyclic variation of "apparent" integrated backscatter (uncompensated for the effects of attenuation) are influenced by both the attenuation of overlying tissue as well as that occurring in the region-of-interest. Recent steps have been taken with excised, formalin-fixed tissue toward the goal of measurement of myocardial attenuation *in vivo* using two-dimensional B-mode images (Baldwin *et al.*, 2005; Sosnovik *et al.*, 2001a; Sosnovik *et al.*, 2001b) and M-mode (Baldwin *et al.*, 2005; Baldwin *et al.*, 2004). The ability to separate the contributions of attenuation from the cyclic variation of the "apparent" integrated backscatter may lead to a better understanding of the underlying physiological or pathophysiological mechanisms of observed results. In addition, myocardial attenuation measured over the heart cycle may prove to be a useful marker of disease in its own right (van der Steen *et al.*, 1991; Wear *et al.*, 1989).

Previous studies have reported the attenuation of freshly excised myocardial tissue in the low frequency range (typical

 0001-4966/2006/119(5)/3130/10/$22.50

for adult echocardiographic imaging) at insonification perpendicular and/or parallel to the predominant orientation of the myofibers (Brandenburger *et al.*, 1981; Dwyer *et al.*, 2000; Fei and Shung, 1985; Fei *et al.*, 1987; Klepper *et al.*, 1981; Mimbs *et al.*, 1980). Early studies from this laboratory examined the anisotropy of attenuation for angles of insonification (over a complete rotation) in freshly excised canine heart (Mottley and Miller, 1990). These investigations observed a clear anisotropy of attenuation in myocardium and demonstrated that the net attenuation through a length of myocardial tissue depends upon the angle of the myofibers encountered along the path of the ultrasonic beam. However, measurements from that study were performed on specimens excised in a different orientation which may have included some off-angle components. The purpose of this study is to measure the anisotropy of attenuation of freshly excised myocardium, at frequencies typical of those used in clinical echocardiography, in specimens in which individual myofibers were nearly unidirectionally aligned. This was accomplished by careful excision of specimens in specific anatomical orientations. Broadband measurements of the anisotropy of attenuation were performed on tissues from standardized regions of 12 ovine and 12 bovine freshly excised hearts. These measurements represent a further step towards the eventual goal of measurements of attenuation *in vivo*.

II. METHODS

A. Preparation of specimens and acquisition of ultrasonic data

A total of 36 tissue specimens from 12 freshly excised lamb hearts and 45 tissue specimens from 12 freshly excised cow hearts were investigated in this study. The hearts were obtained within 30 min of slaughter from a local commercial slaughterhouse and immersed in 0.9% saline solution at room temperature prior to specimen coring. From each ovine heart, three cylindrical plugs were cored, two from the left ventricular free wall and one from the septum using a 14.5 mm inner-diameter coring tool. Specimens were cored from endocardium to epicardium such that the axis of rotation of the cylindrical specimens was oriented orthogonal to the epicardial surface of the heart. The two left ventricular free wall specimens were cored in approximately the same plane perpendicular to the apex-to-base axis of the heart and superior to the anterior and posterior papillary muscles. The septal specimens were cored approximately halfway between the plane of the left ventricular specimens and the apex.

The larger size of bovine hearts permitted a total of four cylindrical plugs to be cored. Three were prepared in an identical manner to that for the ovine specimens, and an additional left ventricular specimen was obtained in the same plane as the other left ventricular specimens as described above, but from the region between the anterior and posterior papillary muscles. In addition, specimens were cored from bovine anterior papillary muscles. However, because of the sometimes irregular shapes of the anterior papillary muscles and the resulting difficulty of coring specimens in which myofibers should be approximately unidirectional, specimens oriented at angles near parallel insonification may involve myofibers that were off angle in elevation. This standardized method of coring provided for a regional comparison of the anisotropy of the myocardial specimens.

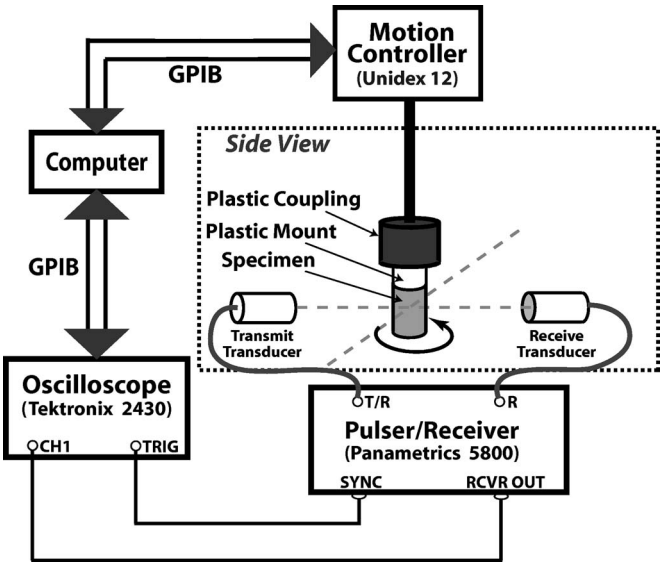

FIG. 1. Experimental setup for performing measurements of the anisotropic properties of myocardial attenuation.

Each myocardial specimen was cored from an intact left ventricle at room temperature that had been stored in the saline solution to reduce the potential for osmotic effects. Immediately after coring, the specimen was mounted and then immersed in a water bath (also at room temperature) approximately 5 to 10 min prior to measurements. The total time from death of the animal to completion of all measurements on that particular heart was approximately three to five hours. Temperature changes during any one data acquisition were no more than 0.1 °C. Figure 1 shows the equipment set up for measurements. The through-transmission radiofrequency data were acquired using a matched pair of 5 MHz focused piezoelectric transducers (Panametrics V309, 1/2 in. diameter; Panametrics, Waltham, MA) separated by twice the nominal focal length of 2 in.. Each tissue specimen was positioned symmetrically at the focus of both transducers and the ultrasonic beam was centered on the midmyocardial region of each specimen. An electric pulse was generated with a Panametrics 5800 Pulser/Receiver operating in pitch/catch mode and sent to the transmit transducer. The through-transmitted signal was received by the second transducer, amplified by the Panametrics 5800, and digitized with a Tektronix 2430A oscilloscope (Tektronix, Beaverton, OR).

For data acquisition, the plastic mount of each myocardial specimen was friction fit into a cylindrical plastic coupling that was, in turn, attached to the metal shaft of the rotational axis. A Unidex 12 motion controller (Aerotech, Pittsburgh, PA) was utilized to permit the measurement assembly to have x, y, and z translational movements as well as rotational freedom. A computer (Apple Computer, Cupertino, CA) served as a data acquisition system controller and off-line storage device for digitized data. Each myocardial specimen was rotated under computer control by a measurement angle, θ (incremented in 5° steps). Substitution through-transmission data were obtained by averaging 32 radio-

frequency traces at each incremented angle over a complete rotation. In addition, immediately after through-transmission data acquisition, pulse-echo data were acquired for specimen thickness measurements at each incremented angle. Corresponding water path reference data were obtained to within ±0.1 °C of the corresponding specimen data.

B. Inherent curvature of myofibers in myocardial specimens

In order to measure the anisotropy of attenuation inherent to the myofibers in myocardial tissue, a specimen would ideally be obtained in which the myofibers are perfectly unidirectional. Visual inspection and histological studies of postmortem human hearts by Greenbaum *et al.* (1981) and studies of canine hearts by Streeter *et al.* (1969) have shown that myofibers are predominantly circumferential in the midwall of the left ventricle, but rotate into and out of the short axis (transverse cross-sectional) plane near the endocardial and epicardial surfaces. Myocardial specimens were cored radially in a plane parallel to the standard short axis echo view of the heart as shown in Fig. 2 (upper panel). The specimen core diameter was chosen in order to be large enough to permit approximately perpendicular incidence of the ultrasonic beam with the surface of the myocardial tissue. (In the focal zone, calculated −6 dB beamwidths were 2.0, 1.2, and 0.9 mm at 3, 5, and 7 MHz, respectively). In addition, in our experience, the core diameter needed to be of sufficient size to yield specimens of uniform shape. As illustrated in Fig. 2 (lower panel), although measurements were performed by rotating a measurement angle θ about the axis of symmetry of the cylindrical specimen, a certain amount of circumferential curvature of the myofibers was unavoidable and remained approximately constant throughout rotation upon data acquisition. This curvature was most pronounced for angles of insonification near parallel to the predominant direction of the myofibers ($\theta \approx 0°$) and, in principle, should have no effect when myofibers are primarily perpendicular to the direction of insonification ($\theta \approx 90°$).

When the tangent to myofibers on the axis of rotation is approximately parallel to the direction of insonification, the tangent to myofibers at the edge of the specimen can be approximated to be at an angle ϕ_{maximum}, where

$$\sin \phi_{\text{maximum}} = \frac{r_{\text{specimen}}}{R_{\text{left ventricle}}} \tag{1}$$

with r_{specimen} the radius of the specimen and $R_{\text{left ventricle}}$ the radius of the left ventricle (see Fig. 2, upper panel). We estimate the angle ϕ_{maximum} for bovine myocardial specimens to be approximately 4° to 7°, and approximately 18° to 28° for ovine myocardial specimens in this study. The larger size of bovine hearts offers the possibility of obtaining myocardial specimens in which the circumferential curvature of the myofibers is less and myofibers are more nearly unidirectionally (uniaxially) aligned than for the case of the smaller ovine hearts.

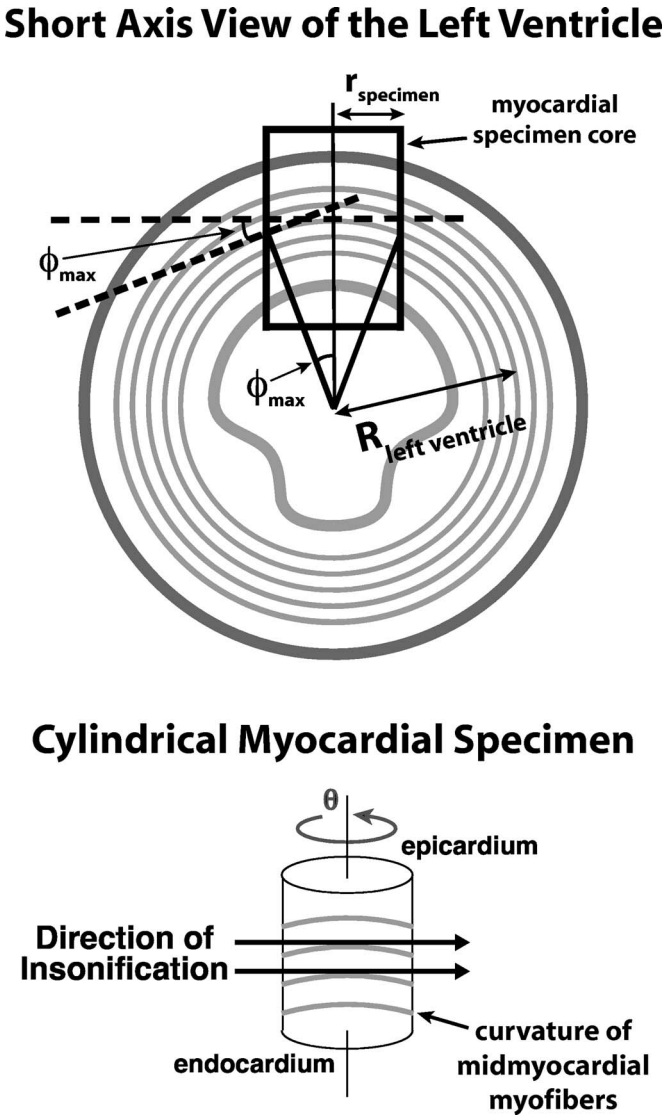

FIG. 2. Approach to coring myocardial specimens used in this study (upper panel). Midmyocardial myofibers are expected to exhibit a circumferential curvature such that myofibers near the edges are at an angle ϕ compared to myofibers in the center that are parallel to the direction of insonification (lower panel).

C. Minimizing potential contributions to phase cancellation at the face of a piezoelectric transducer

Because of the cylindrical shape of the myocardial specimens, the potential exists for a refractive alteration of the beam direction. This could result in a variation in the portion of the through-transmitted beam captured by the receiving transducer as well as phase cancellation at the face of the receiving piezoelectric transducer. Both of these effects could result in potential errors in the measured attenuation coefficient and the frequency dependence of the attenuation (Busse and Miller, 1981a; Busse and Miller, 1981b; Miller *et al.*, 1976; Mimbs *et al.*, 1980; Verdonk *et al.*, 1996). Several steps were taken to minimize the potential for errors associated with phase cancellation. Focused transducers were used for data acquisition because previous measurements in freshly excised, intact myocardium using focused transducers exhibited no significant phase cancellation effects (O'Donnell *et al.*, 1977). Care was taken to align the scan-

ning apparatus and minimize precession of the specimen upon data acquisition (Mimbs *et al.*, 1980; Verdonk *et al.*, 1996). In addition, myocardial specimens were excised with the largest possible diameter for study (14 mm) in order to permit as close as possible to normal insonification at the surface of the myocardial specimens. As a check of the potential extent of phase cancellation artifact, measurements of the anisotropy of attenuation in eight formalin-fixed myocardial specimens were compared with two-dimensional pseudoarray scan measurements of the same specimens using a 0.5 mm needle hydrophone. Mean measurements of the frequency dependence of attenuation as a function of angle of insonification showed no significant differences between the two methods of measurement.

D. Analysis of ultrasonic attenuation data

The experimental procedure involved a through-transmission substitution technique where the specimen to be measured replaces a portion of the water whose attenuation was small enough to be neglected for the frequencies and path lengths used in this study. In this approach, the measured power spectra with and without the specimen inserted are compared in order to determine the attenuation coefficient. Without the specimen, a reference through-transmitted radiofrequency signal is obtained whose power spectrum is given by

$$|V_{\text{reference}}(f)|^2 = \Gamma(f)|P(f)|^2, \tag{2}$$

where f is frequency, $\Gamma(f)$ represents measurement system dependent effects that are the same for both reference and specimen, and $|P(f)|^2$ is the frequency-dependent power spectrum of the transmitted pulse. A myocardial specimen is then inserted into the path of the insonifying beam. The power spectrum of the through-transmitted signal is given by

$$|V_{\text{specimen}}(f,\theta)|^2 = \Gamma(f)|P(f)|^2(T_I^2)e^{-2\alpha(f,\theta)L(\theta)}, \tag{3}$$

where T_I^2 is the combined intensity transmission coefficient associated with the crossing of a single plane wave at a water-to-tissue interface and a tissue-to-water interface, $\alpha(f,\theta)$ is the amplitude attenuation coefficient as a function of frequency and angle of insonification relative to the predominant direction of the myofibers, and $L(\theta)$ is the thickness of the tissue. The factor of 2 in the exponential is present because power, rather than amplitude, is being measured. The signal loss, as a function of f and θ, in units of decibels (dB), is given by

$$\text{signal loss}_{\text{decibels}}(f,\theta) = 10\log_{10}\frac{|V_{\text{reference}}(f)|^2}{|V_{\text{specimen}}(f)|^2} \tag{4}$$

$$= -10\log_{10}(T_I^2) + (20\log_{10}e)\alpha(f,\theta)L(\theta). \tag{5}$$

The first term on the right-hand side of Eq. (5) is an "insertion loss" resulting from nonunity transmission at interfaces.

Previous studies have demonstrated a linear with frequency dependence of the attenuation coefficient over a band-limited frequency range in many soft tissues (Mimbs *et al.*, 1980; Mottley and Miller, 1990; Tu *et al.*, 2003; Verdonk *et al.*, 1996). We consider a Taylor series expansion of the attenuation coefficient about the center frequency of the useful bandwidth: $\alpha(f,\theta) = \alpha_0(\theta) + \beta(\theta)\cdot(f) + \cdots$. The slope of attenuation then becomes

$$\beta_{\text{decibels}}(\theta) = \frac{\frac{\partial}{\partial f}\text{signal loss}_{\text{decibels}}(f,\theta)}{L(\theta)}. \tag{6}$$

Because of the derivative, the slope is not influenced by frequency-independent transmission losses at the boundaries. To calculate the slope of attenuation at any given angle of insonification, the power spectrum (expressed in decibels, dB) of the through-transmitted specimen pulse was subtracted from the power spectrum of the reference pulse. Any differences in equipment gains used to capture the two signals were properly taken into account in the subtraction of the two spectra. A line was fit to the resulting signal loss as a function of frequency using a least-squares fit over the useful bandwidth (3 to 7 MHz). The slope of the best fit line, in units of dB/MHz was divided by the thickness of the specimen $L(\theta)$ to obtain the slope of attenuation in units of dB/(cm MHz) as a function of angle θ. Individual specimen thickness was determined with ultrasonic pulse echo measurements in an approach that has been described previously (Baldwin *et al.*, 2005).

III. RESULTS

The anisotropy of the slope of attenuation in freshly excised ovine and bovine myocardium is shown in the top panels of Figs. 3 and 4, respectively (mean ± one standard deviation). In both cases, peaks near parallel insonification are more narrow than troughs near perpendicular insonification. For ovine myocardium, slopes of attenuation range from 0.52 ± 0.07 dB/(cm MHz) for perpendicular to 1.88 ± 0.17 dB/(cm MHz) for parallel insonification. In the case of bovine myocardium, slopes of attenuation range from 0.55 ± 0.16 dB/(cm MHz) for perpendicular to 2.22 ± 0.23 dB/(cm MHz) for parallel insonification. The bottom panels of Figs. 3 and 4 show corresponding values of the attenuation coefficient at 3 MHz, typical of frequencies employed in echocardiographic imaging, expressed in dB/cm (using $\alpha \cong \beta \cdot f$).

For 27 out of 36 freshly excised ovine specimens measured, the temperature was maintained between 19.1 and 20.1 °C. For the remaining nine ovine specimens, temperature extremes were 17.6 to 19.1 ° C. Mean results excluding these specimens were not significantly different. For 38 out of 45 freshly excised bovine specimens measured, the temperature was maintained between 19.3 and 20.4 °C. For the remaining seven bovine specimens, temperature extremes were 16.2 to 18.8 °C. As with the lamb hearts, mean results excluding these specimens were not significantly different.

As shown in Fig. 5, a comparison of results from different regions of the left ventricle and septum show relatively close agreement for all angles of insonification, both for ovine and bovine myocardium. Left ventricular free wall regional averages include specimens taken from just superior to the anterior papillary muscle (12 for lamb and 11 for cow), from just superior to the posterior papillary muscle (12 for

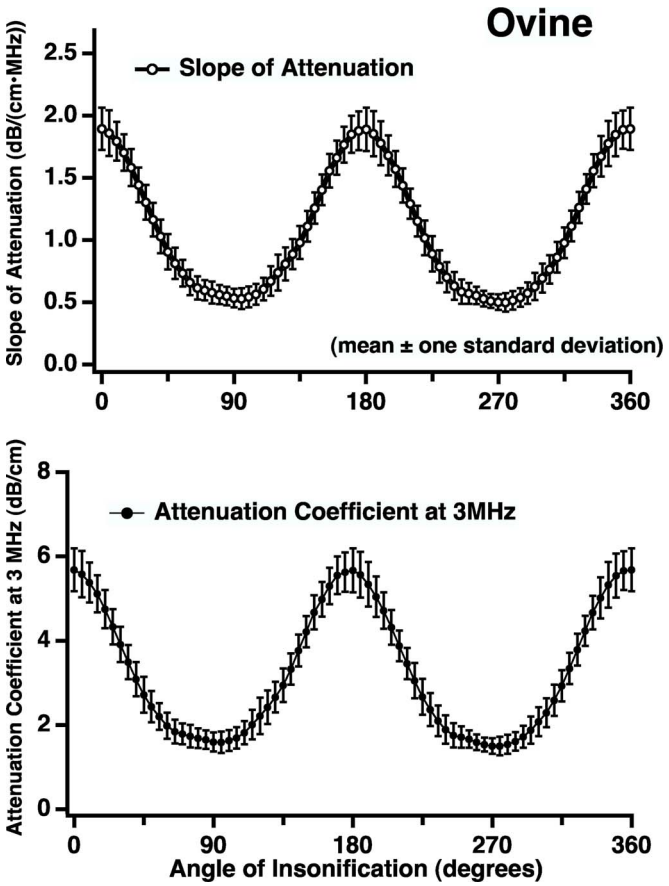

FIG. 3. Slope of attenuation [in dB/(cm MHz)] in freshly excised ovine myocardium (mean±one standard deviation) (upper panel). Corresponding attenuation coefficient at 3 MHz (dB/cm) (lower panel).

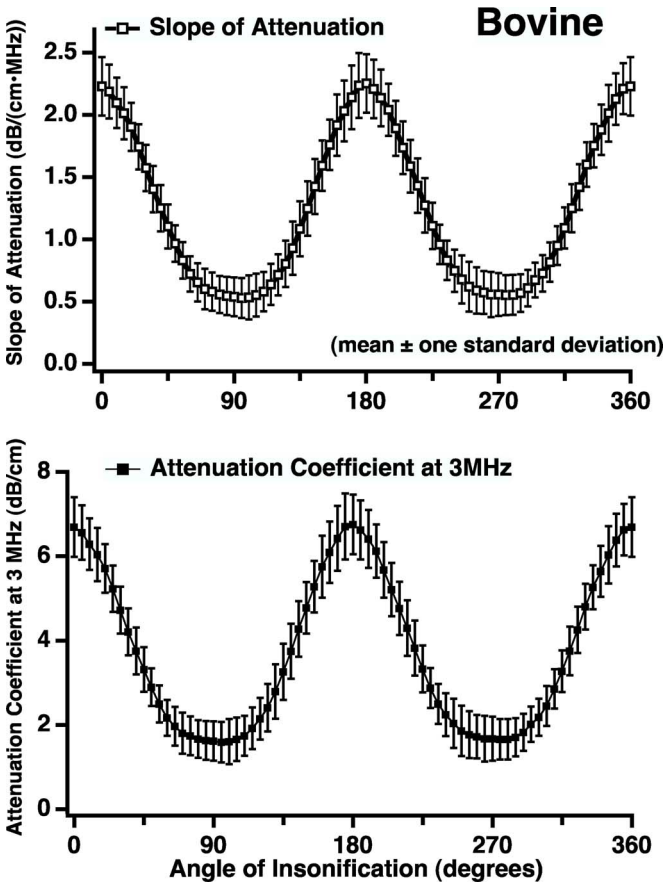

FIG. 4. Slope of attenuation [in dB/(cm MHz)] in freshly excised bovine myocardium (mean±one standard deviation) (upper panel). Corresponding attenuation coefficient at 3 MHz (dB/cm) (lower panel).

lamb and 11 for cow), and from between the two papillary muscles (12 for cow). Septal regional averages include specimens taken approximately halfway between the plane of the left ventricular specimens and the apex (12 for lamb and 11 for cow).

For angles of insonification near perpendicular to the myofiber direction, there is good agreement between ovine and bovine myocardial results, as seen in Fig. 6 (top panel). Values of attenuation are less near parallel insonification for lamb specimens in which the circumferential curvature of the myofibers is expected to be larger than for the more nearly unidirectional myofibers of the cow specimens. Uncertainties (shown in Fig. 6 as ±one standard deviation) are in general larger for angles near parallel insonification than for those near perpendicular insonification, and larger for bovine than for ovine results. The mean slope of attenuation in bovine anterior papillary muscles is shown in Fig. 6 (bottom panel) for comparison. Good agreement between papillary results and those from left ventricular and septal bovine specimens is seen at perpendicular insonification where papillary myofibers are expected to be aligned primarily perpendicular to the direction of insonification. Uncertainties become relatively large for slopes of attenuation in papillary muscles at angles near parallel insonification.

IV. DISCUSSION

Results of this study of freshly excised myocardium indicate a larger anisotropy of attenuation than previously reported. The ratio of the mean slope of attenuation for myocardium with myofibers oriented at parallel insonification to that for perpendicular insonification was measured to be 3.6 in ovine myocardium and 4.0 in bovine myocardium. Maxima appear more sharply peaked compared to minima (as can more clearly be seen by viewing Figs. 3 and 4 upside down). This suggests a greater sensitivity of measured slope of attenuation for slight angular deviations from insonification parallel than from insonification perpendicular to the myofibers. Table I shows that in all cases, for both current measurements and previous ones, uncertainties are larger for parallel insonification than for perpendicular. This behavior might be expected as a consequence of slight deviations in specimen fiber angle and measurement alignment as examined below.

In measurements of anisotropy in a specimen exhibiting uniaxial symmetry (unidirectional fiber alignment), the specimen is ideally prepared such that fibers are aligned relative to a rotational axis that is perpendicular to the fiber direction. In this way, the anisotropy can be measured by rotating the specimen about a measurement angle θ. Hence the direction of insonification ranges from rigorously perpendicular to rigorously parallel to the direction of the fibers. This ideal situation is depicted in the spherical coordinate system of Fig. 7(a) where the polar angle $\phi=90°$ and the angle between the direction of insonification and the direction of the myofibers Γ ranges between 0° and 90° as the

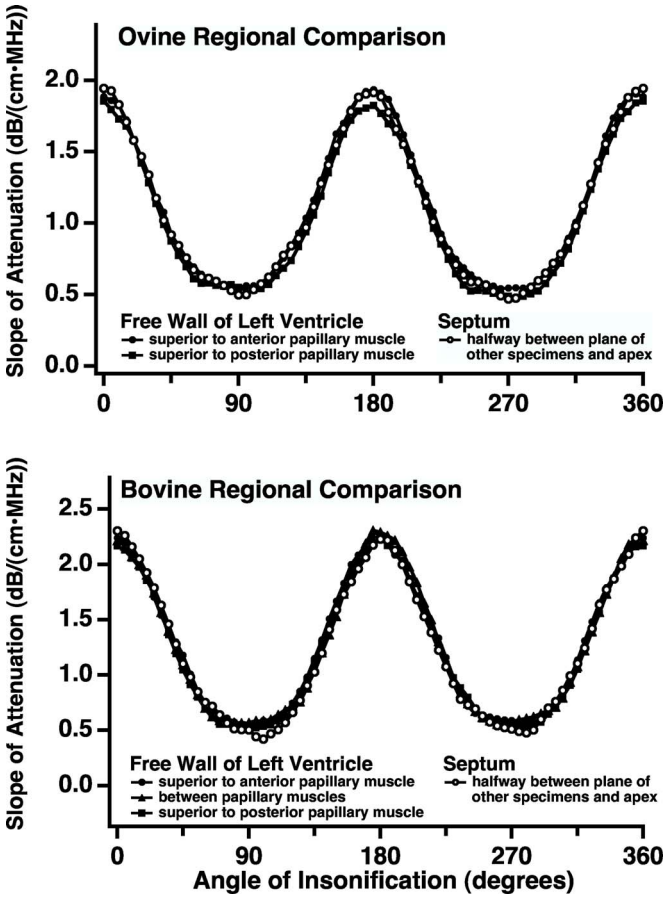

FIG. 5. Comparison of results from different regions of the left ventricle and septum for ovine (upper panel) and bovine (lower panel) myocardial specimens. Left ventricular free wall regional averages include specimens taken from just superior to the anterior papillary muscle and just superior to the posterior papillary muscle (and additionally for bovine myocardium from between the two papillary muscles). Septal regional averages include specimens taken approximately halfway between the plane of the left ventricular specimens and the apex.

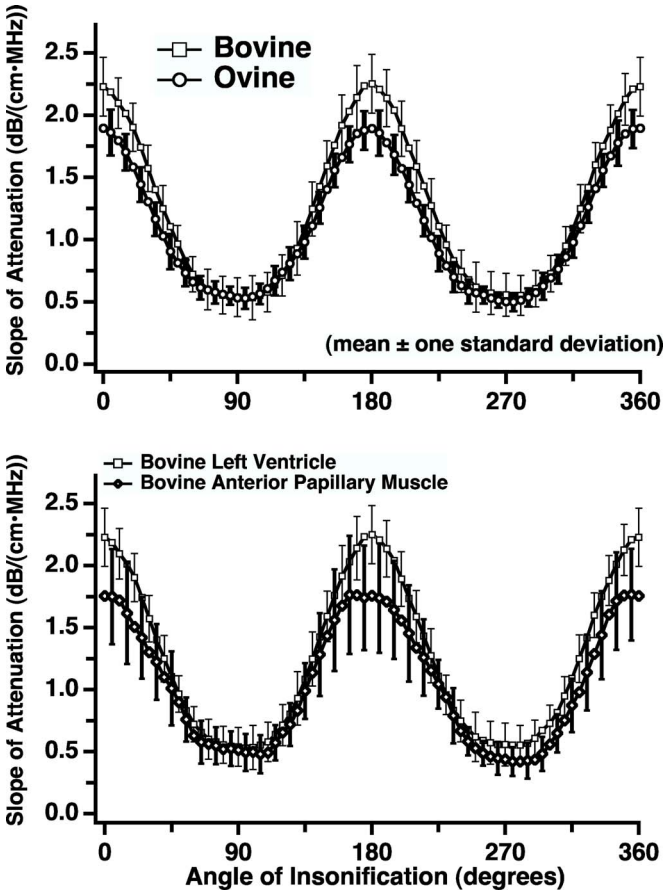

FIG. 6. Comparison of slopes of attenuation for cow and lamb myocardium (mean±one standard deviation) (upper panel). Comparison of average results for bovine anterior papillary muscles with average left ventricular results (lower panel).

measurement angle θ is varied from 0° to 360° during the course of measurement (a result of the symmetry of the uniaxial specimen). The angle Γ is computed according to the equation (Mottley and Miller, 1988)

$$\Gamma = \cos^{-1}[|\cos(\theta)|\sin(\phi)]. \quad (7)$$

In practice, however, because of the complex three-dimensional fiber architecture of the heart and the possibility for slight angular deviations in specimen preparation and measurement, small deviations from the ideal situation are likely. Because acoustic properties are determined by the angle between the direction of insonification and the direction of the myofibers, it is important to examine how this angle Γ differs from the measurement angle θ in the presence of a polar component ϕ as depicted in Fig. 7(b). This makes it possible to know better how to separate the actual angular dependence of ultrasonic properties of the specimen (reflected in changing angle Γ) from the effects of experimental angular deviations in individual fiber orientation or measurement alignment as the specimen is rotated by a measurement angle θ when interpreting measured data.

The upper right-hand panel of Fig. 7(b) shows how deviations of the polar angle ϕ from 90° affects the actual angle Γ between the direction of insonification and the direction of the myofibers. Figure 7(c) shows how the actual angle Γ differs from the measurement angle θ (the ideal case) as the polar angle is progressively altered away from perpendicular. At a measurement angle of θ=90° or 270°, the angle Γ=90° regardless of the value of the polar angle ϕ. However, as the measurement angle θ approaches parallel, larger deviations of the polar angle ϕ from perpendicular result in increasingly higher values of Γ (larger deviations from the ideal value of Γ=0° when ϕ=90°). Attenuation has been observed to vary systematically as a function of the angle between the direction of insonification and the predominant myofiber orientation, with a minimum perpendicular and a maximum parallel to the direction of the myofibers. Thus, because the measured attenuation actually depends on the angle Γ, any polar component (resulting from slight specimen misalignment or deviations of the myofibers from perfectly parallel) as the measurement angle θ is incremented should result in a progressively larger decrease from the actual values (in the ideal measurement case) as the measurement angle θ approaches parallel insonification. Based on these geometric considerations alone, this might be expected to lead to slightly lower and broader peaks in the measured anisotropy of attenuation, and reported results may represent lower limits of the magnitude and angular dependence for angles of insonification near parallel. Furthermore, as a con-

sequence of slight experimental variations that could lead to slightly varying polar components ϕ from specimen to specimen, the behavior of the angle Γ described above would be expected to lead to larger uncertainties in measured attenuation for measurement angles θ near parallel than near perpendicular. This behavior is consistent with current as well as previous measurements of myocardial anisotropy in Table I.

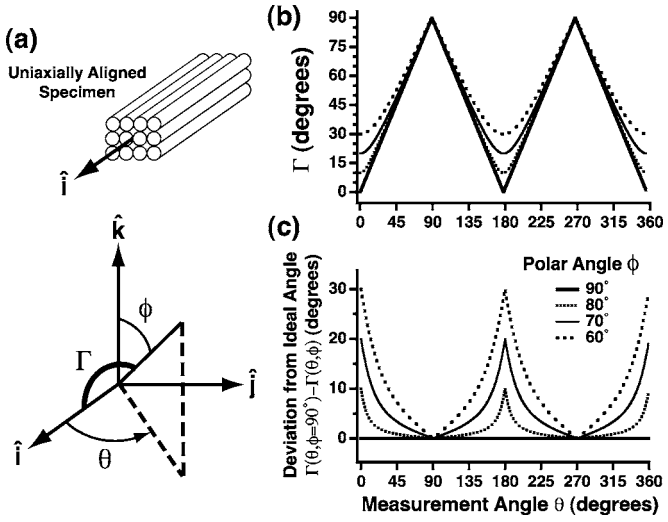

FIG. 7. (a) Spherical coordinate system in which θ is the measurement angle, ϕ is the polar component that may result from slight deviations in specimen fiber angle and measurement alignment, and Γ is the actual angle between the direction of insonification and the direction of the myofibers. (b) Γ as a function of the measurement angle θ for deviations of the polar angle ϕ from 90°. (c) Difference between the actual angle Γ in the ideal case of polar angle ϕ=90° and that in the presence of specific polar components.

A. Comparison of results to previous studies

When comparing results from different sets of specimens or studies, it is of interest to observe from Fig. 7(c) that the difference in $\Gamma(\theta, \phi=90°)$, the ideal measurement of anisotropy and $\Gamma(\theta, \phi)$, the measurement in practice, becomes less sensitive to small deviations of the measurement angle θ from perpendicular as the polar angle ϕ approaches perpendicular. Furthermore, Γ becomes identical to θ for perpendicular insonification regardless of the value of the polar component ϕ. Thus, based on geometric considerations alone, better agreement might be expected among different studies with slightly different measurement configurations and specimen preparations for angles near perpendicular than for angles near parallel. As seen in Table I, values for freshly excised ovine and bovine myocardium reported in this study show very good agreement with previous measurements of freshly excised canine myocardium for perpendicular insonification (Brandenburger *et al.*, 1981; Klepper *et al.*, 1981; Mottley and Miller, 1990; O'Donnell *et al.*, 1977). The measurements by O'Donnell, *et al.* (1977) were performed using phase sensitive piezoelectric transducers like those employed in this study, whereas those of Klepper *et al.* (1981), Brandenburger *et al.* (1981), and Mottley and Miller (1990) were performed using a phase insensitive acoustoelectric receiving transducer.

At parallel insonification, Klepper *et al.* (1981) and Brandenburger *et al.* (1981) reported a slope of attenuation of 1.65±0.17 dB/(cm MHz). This value is slightly smaller, but in agreement with the mean value of 1.88±0.17 dB/(cm MHz) measured in the current study in

similarly sized ovine hearts (within one standard deviation). In the previous study, tomographic methods of data reconstruction were employed that required a set of measurements sampled perpendicular to the beam direction at small intervals in a cross-sectional plane across the entire myocardial specimen for each angle of rotation (Brandenburger *et al.*, 1981; Klepper *et al.*, 1981). It has been shown that in an object such as a section of myocardium that can be modeled as a superposition of anisotropic media whose anisotropy axes are parallel to a plane in space (a superposition of anisotropic media with varying polar components ϕ), then the ensemble will exhibit an anisotropic angular variation whose functional dependence is identical to that of the constituent media, but whose anisotropy magnitude is bounded by (less than or equal to) the anisotropy magnitude exhibited by the individual components of the media (Brandenburger *et al.*, 1981). Thus, in order to measure the magnitude of anisotropy of the individual components, in this case the myofibers, it would need to be possible to obtain specimens in which individual myofibers are aligned uniformly along a single direction and such that they can be measured over a full range of angles from strictly parallel to strictly perpendicular to the direction of insonification. Any deviation from achieving strictly parallel insonification would result in a lower measured maximum value of attenuation. The authors state that "Because the muscle fibers in the heart do not all lie in the plane in which the measurements were made, the 2.6 to 1 anisotropy may reflect a lower bound on the value that would be observed if all fibers were confined to the plane of the measurement" (Brandenburger *et al.*, 1981).

Results for parallel insonification reported by Mottley and Miller (1990) of 1.20 ± 0.20 dB/(cm MHz) are significantly smaller than values reported in the other studies. This behavior may be a consequence of a difference in the way that the canine specimens were cored in that investigation. In the present study, specimens were cored from endocardium to epicardium such that the axis of rotation of the cylindrical specimens was oriented orthogonal to the epicardial surface of the heart (and consequently, orthogonal to the midmyocardial myofibers) as depicted in the upper and lower panels of Fig. 2. This approach permits a straightforward way to minimize the potential for off-angle coring of specimens relative to the direction of the midmyocardial myofibers and allows for insonification at all angles of rotation to be strictly in the midmyocardial region where myofibers are circumferential (Fig. 2, lower panel). Specimens were cored in the earlier study by Mottley and Miller (1990) "such that their axes were parallel to the long axis of the heart" (normal to the short axis plane of the heart shown in Fig. 2 (upper panel)) and "took in all of the heart wall from endo- to epicardium." Any deviation of the myofibers from perfectly parallel to the direction of insonification would cause the actual angle Γ to differ from the measurement angle θ for angles approaching parallel and would be expected to decrease the observed attenuation. Furthermore, based on considerations from previous histologic studies (Greenbaum *et al.*, 1981; Harrington *et al.*, 2005; LeGrice *et al.*, 1995; Streeter *et al.*, 1969), such a coring included some unavoidable transmural portions approaching subendocardium and subepicardium at the edges of the cylindrical specimens where myofibers are oriented progressively into and out of the short axis plane of Fig. 2 (upper panel) (Mottley and Miller, 1990). The Mottley and Miller (1990) study also employed transmission tomographic techniques to eliminate the need for separate specimen thickness measurements by averaging a series of ultrasonic scan lines acquired laterally across the entire myocardial specimen for each angle of insonification (Mottley and Miller, 1990). For angles of insonification near parallel to the circumferential myofibers of the midmyocardium, such measurements would also include in their averages scan lines near the subendocardial and subepicardial lateral edges of the specimen which may lower the average measured attenuation. This effect would not be expected to occur at perpendicular angles of insonification, because when the sound propagates perpendicular to the circumferential direction, it is primarily perpendicular to all of the myofibers (both subendocardial and subepicardial as well as midmyocardial myofibers). These trends in expected differences are consistent with the differences between the measurements of Mottley and Miller and the results of the current study.

B. Potential effects of inherent curvature of myofibers in myocardial specimens

The difference in attenuation between ovine and bovine myocardial specimens is maximum at parallel insonification. As the angle approaches perpendicular insonification, the agreement between lamb and cow results improves, until they are in complete agreement at angles near perpendicular [see Fig. 6 (upper panel)]. These characteristics of the measurements may result, in part, from increased circumferential myofiber curvature over the cylindrical specimens of the lamb hearts. As seen in Fig. 2 (lower panel), such deviation between lamb and cow results might be expected to be largest at angles near parallel insonification and least at angles near perpendicular where insonification is primarily perpendicular to the myofibers. The effect of myofiber curvature may be to introduce a net polar component ϕ as the measurement angle θ is varied. One approach for estimating the expected difference between ovine and bovine results at parallel insonification is as follows. The expected decrease in attenuation at parallel incidence might be inferred from results of this study by examining the measured angular dependence of the attenuation upon rotation of the bovine myocardial specimens about measurement angle θ (assuming the curvature in that case does not have a significant effect), shown in Fig. 4 (upper panel). As the insonifying beam passes through the specimen, the angle between it and the local tangent to the myofibers ϕ encounters a range of values from the maximum at the near edge of the specimen, to zero at the center of the specimen, and again to the maximum at the far edge of the specimen. The expected value of slope of attenuation might be estimated by averaging the measured bovine values in Fig. 4 (upper panel) corresponding to the range of angles ϕ encountered. For ovine specimens, values of ϕ are estimated to range between $\pm(\phi_{\text{maximum}} \approx 23^\circ)$ about parallel insonification. Based on these considerations, the corresponding average would lead to an expected slope of

attenuation of approximately 2.0 dB/(cm MHz). This value is slightly larger than, but within the uncertainties of the average measured value for lamb myocardium at parallel insonification [1.88±0.17 dB/(cm MHz)] as seen in Fig. 6 (upper panel). Although myofibers of bovine specimens are locally more nearly parallel than those of ovine specimens, we note that measurement uncertainties are larger for bovine than for ovine specimens, as can be seen in the upper panel of Fig. 6. Although the same diameter coring tool was used for preparing both the ovine and bovine tissue, the larger epicardial to endocardial thickness of the bovine specimens resulted in a tendency for them to hang in such a way that they were more elliptical in cross section with an average diameter less than that for the more circular ovine specimens. The increased variability of the bovine data may result from the slightly more irregular shape of the bovine specimens that might have led to slightly larger specimen to specimen variation in myofiber angle. These results demonstrate the potential value of taking into account myofiber curvature and angular shifts within a region-of-interest when making attenuation measurements. Factors to consider include heart size as well as region-of-interest size and local fiber orientation within the heart.

C. Considerations regarding papillary muscle results

Good agreement between results of attenuation in papillary muscle specimens compared to those from the left ventricle is seen in Fig. 6 (lower panel) for perpendicular insonification. For reasons indicated in Sec. II, however, specimens oriented at angles near parallel insonification may involve myofibers that are off angle in elevation and have correspondingly larger deviations of the polar angle from 90°. Consequently, measured peaks in attenuation may represent significantly lower limits of expected attenuation in papillary muscles at these angles. The difficulty of coring specimens in which myofibers are approximately unidirectional may be further indicated by the relatively larger standard deviations of papillary muscle results near parallel insonification compared with those near perpendicular insonification and compared with corresponding left ventricle results at parallel insonification.

V. SUMMARY

The degree of anisotropy of attenuation in freshly excised myocardium suggests the potentially significant influence of attenuation on ultrasonic imaging and tissue characterization measurements *in vivo*. The attenuation coefficient was found to increase as a function of frequency in an approximately linear manner and to increase monotonically as a function of angle of insonification from a minimum perpendicular to a maximum parallel relative to the direction of the myofibers. The mean slope of the attenuation coefficient with respect to frequency was three to four times larger for propagation parallel than for propagation perpendicular to the myofibers. Measured attenuation values are less sensitive to slight angular shifts near perpendicular insonification than near parallel. Detailed quantitative knowledge of the anisotropic behavior of attenuation with angle of insonification of the myofibers may be valuable in understanding the mechanisms of observed myocardial attenuation *in vivo*.

(Received 27 September 2005; revised 26 January 2006; accepted 10 February 2006)

Kohonen self-organizing neural networks, also called self-organizing maps (SOMs), have been used successfully to recognize human phonemes and in this way to aid in human speech recognition. This paper describes how SOMS also can be used to associate specific information content with animal vocalizations. A SOM was used to identify acoustic units in Gunnison's prairie dog alarm calls that were vocalized in the presence of three different predator species. Some of these acoustic units and their combinations were found exclusively in the alarm calls associated with a particular predator species and were used to associate predator species information with individual alarm calls. This methodology allowed individual alarm calls to be classified by predator species with an average of 91% accuracy. Furthermore, the topological structure of the SOM used in these experiments provided additional insights about the acoustic units and their combinations that were used to classify the target alarm calls. An important benefit of the methodology developed in this paper is that it could be used to search for groups of sounds associated with information content for any animal whose vocalizations are composed of multiple simultaneous frequency components. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184227]

I. INTRODUCTION

Research on animal vocalizations that contain multiple simultaneous frequency components often focuses on the general, aggregate structure of those vocalizations. Frequency and time parameters are gathered and an entire vocalization is characterized as a collection of frequency-time attributes. In some studies these aggregate properties of sounds have been compared for overlap using spectrogram cross correlation (Clark *et al.*, 1987). Alternatively information has been extracted and analyzed statistically using multivariate methods such as Principal Components Analysis or Discriminant Function Analysis (Eakle *et al.*, 1989; Galeotti and Pavan, 1991; Slobodchikoff *et al.*, 1991; Galeotti *et al.*, 1993; Blackshaw *et al.*, 1996; Hill and Lill, 1998; Slobodchikoff *et al.*, 1991; Ackers and Slobodchikoff, 1999; Lengagne, 2001; Sousa-Lima *et al.*, 2002; Baker and Logue, 2003).

As an example of studies that focus on the general aggregate structure of vocalizations consider Fig. 1, which shows how sound spectrograms can be used to visually distinguish between different types of alarm calls vocalized by Gunnison's prairie dogs. The shape of the spectrogram on the left is typical of dog-elicited alarm calls and the shape of the spectrogram on the right is typical of coyote-elicited alarm calls. In past studies analyses related to the general structure of alarm calls have been performed on data by measuring various macroscopic properties of collections of similar sound spectrograms of alarm calls. Properties such as ascending slope, descending slope, dominant frequency, and subdominant frequency were measured and the data was then subjected to discriminant function analysis (Slobodchikoff *et al.*, 1991). Note that the sound spectrograms in Fig. 1 were created from the same database that provided the data for the experiments discussed in this paper.

In the types of studies referred to above, the macroscopic structure of vocalizations is examined while the detailed internal structure, the acoustic microstructure, of the vocalizations is left unexamined and unappreciated. One striking illustration of this is the case of repetitive vocalizations of animal signals; it is generally assumed that repeated vocalizations from a given animal convey the same information even when the frequency-time parameters of their sound spectrograms vary. However, alarm calls are an example of repetitive vocalizations whose internal variations might be highly significant. Alarm calls are often given as a series or *bout* of repetitive elements, as in the case of alarm calls vocalized by Gunnison's prairie dog (*Cynomys gunnisoni*) in the presence of predators (Slobodchikoff *et al.*, 1991). This paper presents a methodology for investigating the possibility that the variations in the acoustic properties of animal alarm calls are highly significant because these variations indicate the existence of distinct acoustic structures that encode information.

A link between acoustic microstructures and information encoding in alarm calls has been suggested by earlier studies

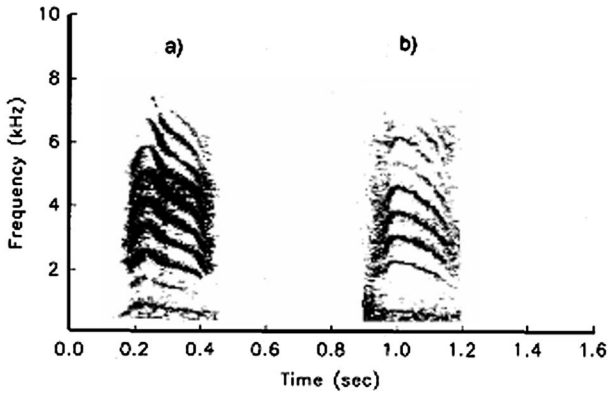

FIG. 1. Sound spectrograms showing a typical dog-elicited alarm call on the left-hand side and a typical coyote-elicited alarm call on the right-hand side.

of Gunnison's prairie dog vocalizations. In two studies (Placer and Slobodchikoff, 2000, 2001), composites of frequency ratio information taken from small partitions of Gunnison's prairie dog alarm calls were used to classify those calls according to the species of predator that was present when the calls were vocalized. These results suggested that information about predator species was encoded in the acoustic microstructure of the alarm calls examined. However, the composite frequency ratio distributions did not themselves reveal the details of the acoustic structure of individual alarm call partitions nor did they provide any clues about how these small-scale acoustics might be organized to encode information in the macroscopic structure of an alarm call.

In a later study (Placer and Slobodchikoff, 2004), Gunnison's prairie dog alarm calls were decomposed into numerous equal-sized partitions and the four most energetic frequency components of each partition were extracted. The two lowest frequencies of the four were then used to identify the acoustic unit associated with any given partition. When the acoustic units created by this process were examined, it was discovered that there were unique acoustic units and combinations of acoustic units that occurred exclusively in vocalizations associated with specific predator species. These exclusive sounds were used to classify alarm calls according to the species of predator that was present when the calls were vocalized. However, the accuracy of the classifications of individual alarm calls were modest and varied significantly according to different criteria that were applied in the study. Nonetheless, the results of this research also suggested a potential link between acoustic microstructure and information encoding and they began to reveal some of the important features of the acoustic microstructure of alarm calls.

In the work described in this paper new, more accurate techniques are developed that are used to recognize small-scale acoustic structures in animal alarm calls that might be used to encode information. These techniques are based on the self-organizing map (SOM) algorithm of Kohonen (1998). A SOM or Kohonen map is an artificial neural network that classifies input data into a number of clusters that are based on the features of the input data itself. In other words, a SOM is not told what the categories of interest are; the SOM uses its input data to discover for itself what the relevant categories are. This is a particularly important attribute for the study discussed in this paper where the relevant categories are acoustic units whose structures or features are not yet well understood.

Self-organizing maps have been shown to be effective in the automatic recognition of human speech. Kohonen used a SOM to create a recognition system for human speech that could detect phonemes from a continuous speech signal (Kohonen, 1988). This "phonetic typewriter," as Kohonen called it, was used to recognize both Finnish and Japanese phonemes. Since then SOMs have been used for the phoneme-based recognition of a number of other languages including Chinese (Wu *et al.*, 1992) and Slovene (Mihelic *et al.*, 1992). SOMs have also been used as more general feature extractors of human speech that can utilize contextual information (Kangas *et al.*, 1992). In sender recognition experiments with six mouse lemur males, Zimmermon and Lerch used a high performance Kohonen map trained for continuous human speech recognition. The success rate in recognizing these six individual males varied from 55.6% to 100% (Zimmerman and Lerch, 1993).

This paper describes how SOMS can be used to characterize and identify classes of acoustic units that are associated with specific information content in animal vocalizations. A SOM was trained to identify clusters of acoustic units in Gunnison's prairie dog alarms where each cluster contained sounds with similar acoustic properties. Individual sounds belonging to specific clusters as well as combinations of these sounds were found to be associated exclusively with alarm calls vocalized in the presence of a specific predator species. These sounds and sound combinations were used with high accuracy to classify the targeted alarm calls according to the species of predator that was present when the alarm calls were vocalized. Furthermore, the topological structure of the output layer of the SOM was shown to reveal interesting characteristics of these sounds and their combinations. The details of these experiments are presented in the following sections of this paper.

II. MATERIALS AND METHODS

This study utilized digitized versions of Gunnison's prairie dog alarm calls that were recorded over a period of 10 years (1988–1997) at two separate prairie dog colonies. Uher Model No. CR160AV and Sony TC-D5PRO II cassette recorders and a Sennheiser ME-88 shotgun microphone were used to record the alarm calls. Additional details about this library of alarm calls can be found in Placer and Slobodchikoff (2004). A total of 300 alarm calls was selected from this database where 100 alarm calls were vocalized in the presence of dogs, 100 in the presence of coyotes, and 100 in the presence of hawks. A system of computer programs was created by one of the authors (J.P.) that performed all the data analysis presented in this paper. Some of these programs were implemented using MATLAB, a high-performance numeric computation software package, and other programs were implemented using the computer language Java.

The experiments discussed in this paper consisted of five distinct steps. First, each of the 300 alarm calls utilized in the

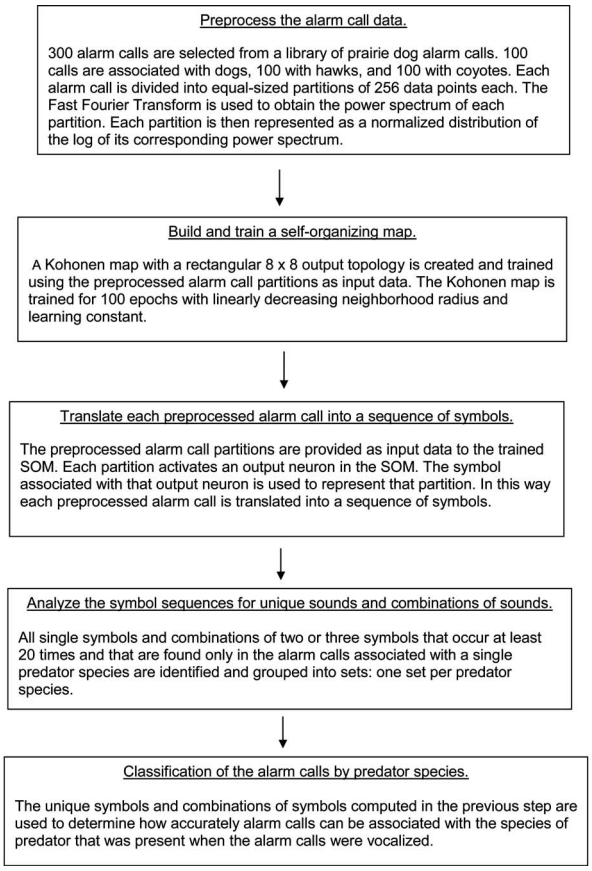

FIG. 2. The experimental protocol used to classify prairie dog alarm calls by the predator species that was present when the calls were vocalized.

experiments was preprocessed using the fast Fourier transform. Second, a self-organizing map was trained using the preprocessed data as input. Third, the trained SOM was used to translate the preprocessed alarm call data into sequences of symbols where each distinct symbol represented a distinct cluster of similar acoustic units. Fourth, the sequences of symbols were examined for single symbols and combinations of two or three symbols that were found exclusively in the alarm calls associated with a specific predator species. Fifth, these unique symbols were then used to classify the alarm calls according to the predator species present when the calls were vocalized. Furthermore, relationships among the unique symbols were examined. A graphical representation of these steps is given in Fig. 2. Each of these steps is described in detail in the sections provided below.

A. Preprocess the alarm call data

Each of the 300 alarm calls utilized in this study was preprocessed. Every alarm call was divided into equal-sized partitions of 256 data points each. The fast Fourier transform (FFT) was then applied to each partition's data points in order to compute a power spectrum of the frequencies contained in that partition. The alarm call data had been recorded at 44 100 samples per second and each partition contained 256 data points so the resolution of the FFT was just over 172 Hertz (44100/256). Since the upper limit of the frequencies that needed to be examined was only 9000 Hertz, each power spectrum contained 52 power values (the floor of 9000/172). A normalized distribution of the log of each power spectrum was then used to represent each partition. When the preprocessing just described was complete, each alarm call had been translated into a sequence of 25 vectors, where each vector contained 52 values.

B. Build and train a self-organizing map

A Kohonen map (SOM) was implemented for this experiment using the language Java. A SOM has two layers: an input layer and an output layer. Each neuron in the input layer is connected to each neuron in the output layer where each connection between an input neuron and an output neuron contains a weight. The input layer simply holds the values of the current input vector. The Kohonen map used in the experiments discussed in this paper had 52 input neurons, one neuron for each value in the normalized distribution of the log of the power spectrum of an alarm call partition. Since each input neuron was connected to each output neuron, every output neuron had 52 weights associated with it.

The output neurons of a SOM can be arranged in a number of different spatial or topological structures. The SOM used in these experiments had an output layer that consisted of a simple 8×8 rectangular grid of neurons. During training, when an input vector is provided to a SOM, the output neuron whose weight vector is closest to the value of the input vector (i.e., the winning neuron) has its weights adjusted so that they more closely resemble the values of the input vector. Furthermore, not only are the weights of the winning output neuron adjusted, but the neurons in a neighborhood surrounding that output neuron also have their weights adjusted to more closely resemble the input vector. The closeness between two vectors was determined by a simple Euclidean distance measure.

The neighborhood radius for the SOM used in this experiment began at 4 neurons and was decreased linearly as training progressed. The degree of adjustment of weights in a SOM is determined by a learning constant. When the weight vector on the winning output neuron is adjusted to align more closely with the current input vector, the learning constant limits the amount of this alignment. With a learning constant of 1.0, the weight vector would be moved so that it is exactly aligned with the input vector. A learning constant of 0.5 would cause the weight vector to be moved half of the distance to complete alignment. In this experiment the learning constant began with the value 0.7 and was decreased linearly to the value 0.05 as training progressed. Both the neighborhood radius and the learning constant reached their final values of 0 and 0.05, respectively, one-half of the way through the SOM training session. In the second half of the session, called the convergence phase, the neighborhood vanishes so that only the winning neuron itself is adjusted with each input. Furthermore, the learning constant is quite small so that the SOM slowly refines and adjusts the weights on its winning output neurons.

A training session of a SOM consists of repeatedly presenting the vectors in the input data set (the preprocessed alarm calls in our case) to the SOM and allowing the SOM to adjust the weights on its connections. The SOM used in this

S57	S58	S59	S60	S61	S62	S63	S64

experiment was trained for 100 epochs. One epoch is completed when all of the vectors in the input data set have been presented to the SOM. One major result of training a SOM is that the weights of its output neurons approach values that represent groups or clusters of similar vectors in the input data set. In effect, each output neuron becomes an exemplar of a class of similar vectors in the input data set. Recall that each vector in the input data set used in this experiment represents the acoustic unit found in a partition of one of the 300 target alarm calls. Therefore, the output nodes of the SOM used in this experiment represented clusters of similar acoustic units found in the partitions of the alarm calls utilized for the experiment.

Another major result of training a SOM is found in the topology or spatial ordering of its output layer. Since neighborhoods of output neurons have their weights adjusted together, similar input patterns will be recognized by output neurons that are spatially close to each other in the output layer of the SOM. In the experiments discussed here, this means that similar acoustic units will be found in neurons that lie close to each other in the 8×8 output grid of the SOM.

C. Translate each preprocessed alarm call into a sequence of symbols

After the SOM was trained in this experiment, it was then used to translate each preprocessed alarm call into a sequence of symbols. To understand how this was done consider that the output layer of the SOM was an 8×8 matrix of neurons. Each neuron had a unique symbol associated with it according to its position in the matrix. The mapping of symbols to output neurons is shown in Table I. Each cell in the matrix in Table I represents an output neuron in the SOM used in these experiments. The text contained in any given cell is the name of the symbol associated with that cell. After training the SOM, the preprocessed partitions composing each alarm call were once again provided as input to the trained SOM. Each input vector (i.e., preprocessed partition) provided to the SOM was replaced by the symbol associated with the winning neuron produced by that input vector; thus, each partition in each alarm call was replaced by a specific symbol. In this way, each preprocessed alarm call was translated into a sequence of symbols. For example, the sequence of symbols

S9S46S40S40S23S35S35S35S42S35S23S35S42S35S35S35S8S40

was produced when the trained SOM was used to translate one of the preprocessed alarm calls that had been vocalized in the presence of a dog.

D. Analyze the symbol sequences for unique sounds and combinations of sounds

After this translation process in which each preprocessed alarm call was expressed as a sequence of symbols, the symbols contained in the translated alarm calls were analyzed in order to identify any single symbols (monograms), neighboring pairs of symbols (digrams) and sequences of three symbols (trigrams) that were found only in the alarm calls associated with a particular species of predator. During this part of the analysis only monograms, digrams, and trigrams that occurred at least 20 times in the target alarm calls were examined. This precaution was meant to guard against the use of acoustic units that rarely occurred and that might be artifacts of the arbitrary way in which alarm calls were partitioned. Three sets of symbols were constructed: one for monograms, digrams, and trigrams that occurred only in alarm calls associated with coyotes, another set for monograms, digrams, and trigrams that occurred only in alarm calls associated with dogs, and a third set for monograms, digrams, and trigrams that occurred only in alarm calls associated with hawks.

E. Classification of the alarm calls by predator species

In principle, any alarm call that could be shown to contain a monogram, digram, or trigram that was uniquely associated with a given predator species could itself be unambiguously associated with that same predator species. Thus, the three sets of unique monograms, digrams, and trigrams described above were used to classify the alarm calls by predator species. The percentage of alarm calls that could be identified unambiguously in this way for a given predator species was considered the percentage of correctly identified alarm calls for that predator species.

III. RESULTS

Kohonen maps are initialized with random connection weights before training. One consequence of this is that the final connection weights that result from any given training session will vary. This, in turn, means that the results of translating alarm calls into symbol sequences and the associated classification accuracies will vary among a number of separately trained SOMs. Therefore, in order to determine average classification accuracies, 10 experimental runs, each performed with a separately trained Kohonen map (SOM), were executed. The data resulting from these 10 experimental runs are given in Table II.

Each row in Table II except the last gives the data associated with a separate experimental run. The last row provides the means of all the data generated in the 10 experiments with standard deviation values given in parentheses. The first value of each row simply gives an identifying num-

TABLE II. Statistics for the alarm calls correctly classified by predator species with the standard deviations for the final averages given as parenthesized values.

Average %Correct	86.1 (6.64)	100 (0)	88.9 (3.70)	91.67 (2.57)

ber for that experimental run. The second, third, and fourth values give the percentage of alarm calls classified correctly for the predator species dog, hawk, and coyote, respectively. The last value provides the average correct classification for that run across all species of predators.

Table I, which maps symbols to output neurons, is expanded in Table III to include information about the monograms, digrams, and trigrams that were found to be unique to a particular predator species. The name in bold at the top center of each cell (output neuron) is the name of the symbol associated with that cell. If that symbol is found at the start of one or more monograms, digrams or trigrams found exclusively in alarm calls associated with only one predator species, then all of those monograms, digrams, and trigrams are listed below the symbol. Cells that contain such lists also specify the relevant predator species in parentheses next to the cell's symbol name at the top of the cell. Symbols associated with cells that contain no lists below their symbol name simply do not occur at the beginning of a monogram, digram or trigram that is unique to a particular predator species.

To better explain Table III some examples are needed. Consider the cell named **S24**. This cell contains a list with only one digram (*S24S21*), which begins with symbol *S24*. This digram is found only in the alarm calls associated with the species coyote; the species name is shown in parentheses next to the cell's symbol name. Now consider cell **S62**. The list in this cell contains two digrams, *S62S62* and *S62S37*, both of which begin with symbol *S62*. The digram *S62S62* indicates that the sound associated with symbol *S62* is held across two partitions of an alarm call. Notice again that the predator species coyote is specified in parentheses next to the cell's symbol name. Finally, consider cell **S4**. The predator species specified in this cell is dog and the list provided in the cell simply contains *S4*. This means that the monogram *S4* occurs only in alarm calls associated with dogs; therefore, no digrams or trigrams associated exclusively with dogs begin with the symbol *S4*.

Other types of information can also be gained from Table III. For example, notice that the cells associated with dogs and coyotes each tend to have short lists of unique monograms, digrams, and trigrams. However, the cells associated with hawks tend to contain long lists. A closer look at these long lists reveals that combinations of a small group of symbols (S35, S51, S53, S58, and S60) are used to create most of the digrams and trigrams in all of the lists associated with hawks. These same symbols are used in differing orders and combinations throughout the lists.

IV. DISCUSSION

Kohonen maps were used to associate individual alarm calls with specific predator species with average accuracies of greater than 91%; these results demonstrate that Kohonen maps are useful tools for exploring and identifying sounds associated with specific information content in animal vocalizations. Furthermore, analysis of the digrams and trigrams specific to a particular predator species revealed certain types of symbol patterns associated with specific predator species. For example, in Table III, digrams and trigrams associated with hawks were regrouped into new lists where the same two symbols were used in each digram or trigram. This regrouping revealed how particular symbols can occur in different orders or be expressed for varying lengths of time or both. As an example, consider the list below that is composed of digrams and trigrams associated only with hawks, where each digram and trigram contains only the symbols S53 and S60:

S53S60, S53S53S60, S60S53, S60S53S53.

The symbol sequences in the list above indicate that the symbol S53 can occur either before or after the symbol S60. In other words, the relative order of the two sounds is not fixed. Furthermore, recall that S53 represents a sound (acoustic unit) expressed in a single partition of an alarm call whereas S53S53 represents the sound S53 expressed across two partitions of an alarm call. Thus, in the list above the sound represented by symbol S53 can be expressed for a single partition of time (S53S60, S60S53) or it can be held across two partitions of time (S53S53S60, S60S53S53). Similar kinds of relationships can be found in digrams and trigrams containing different pairs of symbols. Whether these patterns of symbols represent a first glimpse of lexical structures or a first glimpse of syntactic structures in prairie dog alarm calls is yet to be determined. However, the patterns are clearly evident and they are seen to occur in vocalizations restricted to a specific predator species.

It should also be mentioned that the variety of symbols (sounds) associated with specific predator species in Table III is probably less diverse than it might seem at first. Symbols that lie close to each other in the Kohonen map output layer and that are unique to the same predator species might well represent slight variations of the same basic sound. For example, consider cells **S25** and **S26**, which list digrams unique to alarm calls associated with dogs. These cells are located next to each other and the digram in each cell only contains the symbol named by that cell. Thus, it is likely that symbols *S25* and *S26* refer to the same basic sound expressed in slightly different ways. In human speech, where the pho-

nemes are known, several different output neurons located close together in a given SOM will recognize variations of the same phoneme. It seems reasonable to assume that a particular meaningful sound found in a nonhuman animal vocalization also would be expressed with some variation.

One area for future research would be to combine the recent progress made in using formants to identify acoustic structures in alarm calls (Slobodchikoff and Placer, 2006) with the knowledge gained from the experiments discussed in this paper. Specific formant information could be combined with the general spectral information utilized by the Kohonen maps to see if an improvement in the performance of the SOMs is achieved. Improvement in SOM performance, reflected by improved classification accuracies, would result in more accurate clustering of like sounds and would provide more detailed information about the small-scale acoustic structure of the vocalizations.

Another fruitful area for future research would be to apply the techniques discussed in this paper to recordings of animal vocalizations that allow the exploration of new types of information encoding. For example, we are now preparing to use Kohonen mapping techniques to study a newly recorded set of alarm calls that will allow us to search not only for predator species information but also for descriptive information about predators and for information about the individuals that are vocalizing. In future work, as the Kohonen methodology is applied to recordings of alarm calls vocalized in a wide variety of situations, it might be possible to

develop an acoustic dictionary for prairie dog communications. In such a dictionary each acoustic pattern in a large collection of such patterns would be associated with specific information content. It would then be possible to examine all the patterns found in the dictionary in order to attempt to develop a general theory ofthe lexical structure of prairie dog communications. The development of this type of rudimentary lexicon for prairie dog communications would also make it possible to attempt a higher level examination of the complete structure of alarm calls to see if a syntactic structure could be determined for these calls. Information about a possible syntactic structure of alarm calls might even allow the synthetic creation of alarm calls for playback experiments.

Most of the work done by researchers on animal vocalizations has been focused on the macrostructure and general acoustic characteristics of those vocalizations. Consequently, not many tools have been developed with which to study the acoustic microstructure of animal vocalizations. Yet, the vocalizations of a growing number of animals are being shown to contain referential communication which conveys information about types of predators, degrees of danger, and other details about the world in which these animals live. These discoveries suggest that understanding the small-scale structure of animal vocalizations might be vitally important to determining the level of complexity of those communications and the actual information they contain. New methodologies and software tools for studying the acoustic microstructure of animal vocalizations need to be created so that detailed models and analyses related to these communications can be developed. The experiments described in this paper show how Kohonen maps might well provide one class of these needed tools.

Tissue deformation induced by radiation force from Gaussian transducers

Matthew R. Myers
Center for Devices and Radiological Health, HFZ-170, U. S. Food and Drug Administration, Rockville, Maryland 20852

(Received 29 August 2005; revised 21 February 2006; accepted 21 February 2006)

Imaging techniques based upon the tissue mechanical response to an acoustic radiation force are being actively researched. In this paper a model for predicting steady-state tissue displacement induced by a radiation force arising from the absorption of Gaussian ultrasound beams is presented. A simple analytic expression is derived that agrees closely with the numerical quadrature of the displacement convolution integrals. The analytic result reveals the dependence of the steady-state axial displacement upon the operational parameters, e.g., an inverse proportional relationship to the tissue shear modulus. The derivation requires that the transducer radius be small compared to the focal length, but accurate results were obtained for transducer radii comparable to the focal length. Favorable comparisons with displacement predictions for non-Gaussian transducers indicate that the theory is also useful for a broader range of transducer intensity profiles. I. INTRODUCTION

Imaging applications based upon the mechanical response of tissue to acoustic radiation force show promising clinical potential (Nightingale *et al.*, 2001; Palmeri and Nightingale, 2004; Walker 1999). An important metric used to assess the feasibility of these applications is the tissue deformation field resulting from the absorption of an ultrasound beam of specified characteristics. Mathematical models are valuable for predicting deformation as a function of tissue properties, transducer characteristics, and acoustic power levels.

Sarvazyan *et al.* (1998) derived a solution to the displacement equation in terms of an inverse Hankel transform, to study the strain induced during shear-wave elasticity imaging. Walker (1999) computed the deformation due to a focused ultrasound beam modeled as a series of absorbing disks. The intensity was assumed constant within each disk. The sum over the disk forcing functions was performed numerically. Nightingale *et al.* (2001) estimated the strain and displacement for radiation forces typical of remote palpation. Their model assumed a point load for the localized force. Lizzi *et al.* (2003) performed finite-difference simulations of tissue displacement, and analyzed how the induced motion is affected by the stiffness of the lesion during focused ultrasound surgery. Palmeri *et al.* (2005) utilized the finite-element technique to develop a general model for computing the tissue response to acoustic radiation force.

In this paper, an analytic expression for the steady-state deformation generated by an acoustic radiation force is developed. It is assumed that the amplitude distribution on the transducer face has a Gaussian amplitude shading. The Gaussian stipulation, along with the assumption that the focal length is long compared to the transducer radius, allows the final solution for the steady-state axial displacement to be given in terms of a simple, closed-form expression. This expression is advantageous in elucidating the role of the various operational parameters, and for providing rapid estimates of tissue response. Additionally, the simple functional form is useful for inclusion in standards and guidelines for the safe use of imaging modalities.

In the following section the asymptotic model is developed. In Sec. III, calculations are performed to test the accuracy of the model relative to a full, two-dimensional quadrature over the acoustic intensity distribution. The parameter values provided by Walker (1999) are used in the calculations. In Sec. IV some of the features of the displacement field elucidated by the model are discussed, and the limits of validity of the asymptotic approach are provided.

II. METHOD

We first consider a point force located at the origin in an elastic medium, acting in the axial (z) direction. The axial displacement due to the force of magnitude F is given by Love (1944):

$$w = D\left(\frac{z^2}{R^3} + \frac{\lambda + 3\mu}{\lambda + \mu}\frac{1}{R}\right), \tag{1}$$

where

$$D = \frac{F(\lambda + \mu)}{8\pi\mu(\lambda + 2\mu)}. \tag{2}$$

Here λ and μ are the Lame' constants for the medium, z is the axial coordinate of the observation point, and $R=(x^2+y^2+z^2)^{1/2}$ is the distance from the origin to the observation point. For a volumetric force with density (force/volume) f, the total displacement may be obtained by convolving (1) with f:

$$w(x,y,z)=\int \frac{f(x',y',z')(\lambda+\mu)}{8\pi\mu(\lambda+\mu)} \times\left(\frac{(z-z')^2}{[(x-x')^2+(y-y')^2+(z-z')^2]^{3/2}} +\frac{\lambda+3\mu}{\lambda+\mu}\frac{1}{[(x-x')^2+(y-y')^2+(z-z')^2]^{1/2}}\right)dV'. \tag{3}$$

The quantity multiplying the force density f is the Green's function for an infinite medium, and hence (3) will not, in general, satisfy the exact conditions at the boundary, e.g., at the transducer face. This issue is discussed further in Sec. IV.

We consider next the case where the force density arises due to the absorption of a propagating ultrasound beam. The density f is given by the rate of attenuation of ultrasound intensity divided by the speed of sound. Within the plane-wave approximation for the beam,

$$f=2\alpha I/c \tag{4}$$

(Nightingale *et al.*, 2001), where α is the amplitude absorption coefficient. We suppose that the ultrasound beam is focused and propagating in the $+z$ direction, and that it possesses Gaussian amplitude shading. The intensity profile for the beam is given by (Wu and Du, 1990),

$$I=I_0B^{-1}A_1(z)\exp[-2A_1(r/a)^2]\exp(-2\alpha z), \tag{5}$$

where

$$A_1(z)=\frac{B}{\frac{B^2z^2}{r_0^2}+\left(1-\frac{z}{z_f}\right)^2}. \tag{6}$$

Here B is the Gaussian coefficient at the transducer, z_f is the geometric focal length of the transducer, and $r_0=\frac{1}{2}ka^2$, k being the acoustic wavenumber and a the transducer radius. Upon using (4)–(6) in (3) and switching to cylindrical coordinates, we obtain the following expression for the axial displacement at a point located along the transducer axis:

$$w(x=0,\ y=0,\ z)=w_1+w_2, \tag{7}$$

$$w_1=\frac{\alpha(\lambda+\mu)I_0}{2Bc\mu(\lambda+2\mu)}\int_0^\infty dr'\int_0^\infty dz'\,A_1(z') \times\exp[-2A_1(r'/a)^2] \times\exp(-2\alpha z')\frac{r'(z-z')^2}{[r'^2+(z-z')^2]^{3/2}}, \tag{8}$$

$$w_2=\frac{\alpha(\lambda+3\mu)I_0}{2Bc\mu(\lambda+2\mu)}\int_0^\infty dr'\int_0^\infty dz'\,A_1(z') \times\exp[-2A_1(r'/a)^2] \times\exp(-2\alpha z')r'[r'^2+(z-z')^2]^{-1/2}. \tag{9}$$

Expressions (8) and (9) require the properties of the medium to be uniform. We first consider displacement at the focus $z=z_f$. After making the transformations

$$\rho=\frac{(2A_1)^{1/2}r'}{a},\quad \zeta=\frac{z'-z_f}{z_f}, \tag{10}$$

we obtain for (9),

$$w_2=\frac{\alpha(\lambda+3\mu)I_0a^2}{4Bc\mu(\lambda+2\mu)}e^{-2\bar\alpha}\int_0^\infty d\rho\,\rho e^{-\rho^2} \times\int_{-1}^\infty d\zeta\frac{e^{-2\bar\alpha\zeta}}{\{\delta^2\rho^2[\epsilon^2(\zeta+1)^2+\zeta^2]+\zeta^2\}^{1/2}}, \tag{11}$$

where

$$\delta=\frac{a}{(2B)^{1/2}z_f},\quad \bar\alpha=\alpha z_f,\quad \epsilon=\frac{Bz_f}{r_0}=\frac{2Bz_f}{ka^2}. \tag{12}$$

The parameter ϵ is the reciprocal of the transducer gain. The parameter δ, proportional to the reciprocal of the transducer f number, measures the transducer radius relative to the transducer focal length. When δ is small, asymptotic methods can be employed to perform the integral in (11), in the following way.

We employ the method of matched asymptotic expansions (Van Dyke, 1975) to construct an integrand that approximates that in (11) when $\delta\ll1$. We first consider just the ζ integral, and break it up into the intervals $(-1,0)$ and $(0,\infty)$. The corresponding integrals over these intervals we denote I_- and I_+. When ζ is of magnitude 1 (outer integrand), the integrand of I_+ is approximately equal to

$$\frac{e^{-2\bar\alpha\zeta}}{\zeta}. \tag{13}$$

For the inner integrand where ζ is small (of magnitude $\epsilon\delta$), the integrand of I_+ may be approximated by

$$\frac{1}{(\delta^2\rho^2\epsilon^2+\zeta^2)^{1/2}}. \tag{14}$$

The common representation of the integrand of I_+, obtained by expanding the outer integrand for small ζ or the inner integrand for large ζ, is equal to $1/\zeta$. The composite representation for the integrand of I_+, equal to the inner+outer-common, is given by

$$\frac{e^{-2\bar\alpha\zeta}}{\zeta}+\frac{1}{(\delta^2\rho^2\epsilon^2+\zeta^2)^{1/2}}-\frac{1}{\zeta}. \tag{15}$$

The composite representation is integrable over $(0,\infty)$ and may be integrated to

$$I_+=-\log(\epsilon\,\delta\rho)-C_e-\log(\bar\alpha). \tag{16}$$

Here C_e is Euler's constant (≈0.577). Repeating the same process for the interval $(-1,0)$ yields

$$I_-=\log(2)-\log(\epsilon\,\delta\rho)+\int_0^1\frac{e^{2\bar\alpha t}-1}{t}dt. \tag{17}$$

The integral in (17) may be expressed in terms of an exponential integral $Ei(x)$ (Gradshteyn and Ryzhik, 1980). However, in regions of maximum displacement (see Sec. III), this term is typically less important than the logarithmic term, and a less accurate expression suffices. We ap-

proximate the integrand by a line connecting the integration end points (trapezoidal rule), resulting in an integral equal to $\bar{\alpha}+(\exp 2\bar{\alpha}-1)/2$. The total ζ integral then becomes

$$I_- + I_+ = \log(2) - 2\log(\epsilon\delta\rho) - \log(\bar{\alpha}) - C_e + \bar{\alpha} + (\exp 2\bar{\alpha} - 1)/2. \tag{18}$$

Inserting (18) into (11) and using

$$\int_0^\infty \rho \log(\rho) e^{-\rho^2}\, d\rho = -C_e/4 \tag{19}$$

(Gradshteyn and Ryzhik, 1980) yields the asymptotic approximation for w_2:

$$w_2 = \frac{\alpha(\lambda+3\mu)I_0 a^2}{8Bc\mu(\lambda+2\mu)} e^{-2\bar{\alpha}} \left[\log\left(\frac{2}{\bar{\alpha}}\right) - 2\log(\epsilon\delta) + \bar{\alpha} + \frac{e^{2\bar{\alpha}}-1}{2} \right]. \tag{20}$$

The other contribution to the axial displacement, w_1 [Eq. (7)], may also be estimated using the method of matched asymptotic expansions. The process is similar to that for w_2. When the result is combined with (20), we have the complete approximation to the axial displacement at the focus:

$$w(0,0,z_f) = \frac{\alpha I_0 a^2 e^{-2\bar{\alpha}}}{4Bc\mu} \left\{ -\frac{(\lambda+\mu)}{(\lambda+2\mu)} + \left[\log\left(\frac{2}{\bar{\alpha}}\right) - 2\log(\epsilon\delta) + \bar{\alpha} + \frac{e^{2\bar{\alpha}}-1}{2} \right] \right\}. \tag{21}$$

For tissues it is typically the case that $\lambda \gg \mu$. (See Sec. III.) Using this approximation, along with the definitions of α, δ, and ϵ (12), we obtain

$$w(0,0,z_f) \approx \frac{\alpha I_0 a^2 e^{-2\alpha z_f}}{4Bc\mu} \left[2\log\left(\frac{ka}{\sqrt{B}}\right) - \log(\alpha z_f) + \alpha z_f + \frac{e^{2\alpha z_f}-3}{2} \right]. \tag{22}$$

Equation (22) represents the axial displacement at the focus ($z=z_f$). To determine the axial displacement at points on the z axis different from the focus, we return to Eq. (10). We use the coordinate z in the ζ transformation instead of z_f. Upon making this replacement and continuing the analysis, we find that the denominator in the ζ integral is

$$\{\delta^2\rho^2[\epsilon^2(\zeta+1)^2 + (z_f/z - 1 + \zeta)^2] + \zeta^2\}^{1/2}. \tag{23}$$

For $\delta \ll 1$ and ζ and z_f/z values of order unity, this expression is approximately equal to $|\zeta|$, as is the case for the denominator of the ζ integral in (11). When ζ is small, (23) can be approximated by $[\delta^2\rho^2(\epsilon^2+(z_f/z-1)^2)+\zeta^2]^{1/2}$, compared with $[\delta^2\rho^2\epsilon^2+\zeta^2]^{1/2}$ for the corresponding term of (11), which appears in (14). By comparing these two small-ζ approximations, it can be seen that if we make the assignment

$$\epsilon' = [\epsilon^2 + (z_f/z - 1)^2]^{1/2}, \tag{24}$$

and define the parameters of (12) in terms of z rather than z_f, the analysis beginning with (14) is identical to the case of $z=z_f$. The final result for the displacement in the z direction at location z can be obtained directly from (21):

$$w(0,0,z) = \frac{\alpha I_0 a^2 e^{-2\overline{\alpha'}}}{4Bc\mu} \left\{ -\frac{(\lambda+\mu)}{(\lambda+2\mu)} + \left[\log\left(\frac{2}{\overline{\alpha'}}\right) - 2\log(\epsilon'\delta') + \bar{\alpha}' + \frac{e^{2\overline{\alpha'}}-1}{2} \right] \right\}. \tag{25}$$

Here

$$\delta' = \frac{a}{(2B)^{1/2}z}, \quad \overline{\alpha'} = \alpha z, \quad \epsilon' = \left[\left(\frac{2Bz}{ka^2}\right)^2 + \left(\frac{z_f}{z} - 1\right)^2 \right]^{1/2}. \tag{26}$$

If we insert the expressions of (26) directly into (25), and as in (22) assume $\lambda \gg \mu$, we arrive at the simplified result for the axial displacement at location z:

$$w(0,0,z) \approx \frac{\alpha I_0 a^2 e^{-2\alpha z}}{4Bc\mu} \left[2\log\left(\frac{ka\gamma}{\sqrt{B}}\right) - \log(\alpha z) + \alpha z + \frac{e^{2\alpha z}-3}{2} \right], \tag{27}$$

where

$$\gamma(z) = \left(1 + \frac{k^2a^4(z_f - z)^2}{4B^2z^4}\right)^{-1/2}. \tag{28}$$

Using (12) and remembering that ϵ is the reciprocal of the gain G, (28) can be expressed as

$$\gamma(z) = \left[1 + G^2\left(\frac{z_f}{z}\right)^2\left(1 - \frac{z_f}{z}\right)^2\right]^{-1/2}. \tag{29}$$

III. RESULTS

To test the accuracy of the asymptotic approximation (27), the displacement field was calculated by both (27) and the double integrals in (7)–(9). The tissues considered by Walker (1999)—vitreous, breast, and liver—were used in the calculations. The material properties used in the calculations are shown in Table I. The attenuation and speed of sound are the values quoted by Walker (1999), and the Lame' constants are derived from Walker's values of the Elastic modulus and Poisson's ratio (Love 1944). It can be seen that the approximation $\lambda \gg \mu$ is appropriate for the organs considered.

TABLE I. Mechanical properties of tissues considered in calculations.

	α (dB/cm/MHz)	c (m/s)	λ (N/m^2)	μ (N/m^2)
Breast	0.75	1510	1.67×10^6	3330
Liver	1.17	1540	5.8×10^5	1170
Vitreous	0.1	1513	16.7	0.033

Also following Walker (1999), a focal length of 1.0 cm, a transducer radius of 0.25 cm, and a frequency of 10 MHz were used in the calculations. The peak intensity I_0 for the Gaussian beam was set to 0.0123 W/cm^2, corresponding to an average intensity of 0.0062 W/cm^2 at the transducer. This

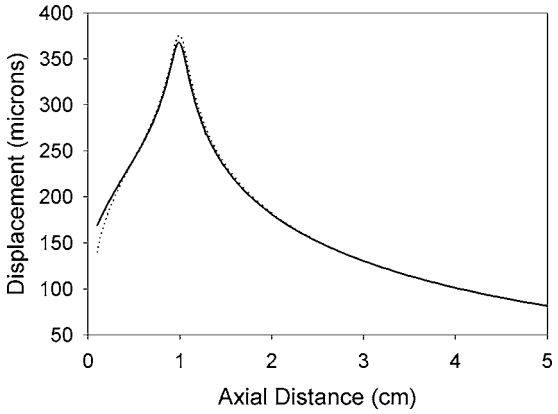

FIG. 1. Axial displacement as a function of axial distance, for vitreous tissue. Intensity=1 W/cm^2 at focus, in water. Transducer diameter =0.5 cm, focal length=1.0 cm, frequency=10 MHz. Solid line—numerical integration of convolution integral. Dotted line—asymptotic model.

value corresponds to an average intensity of 1.0 W/cm^2 at the focus, in water. The Gaussian coefficient B was set to 1.0.

The double integrals in (7)–(9) were performed using a numerical implementation of Simpson's rule on an IBM RS6000/44P workstation. The upper limits of integration on r' and z' [infinite in (8) and (9)] were increased until doubling the values resulted in less than a 0.1% change in the integral. Final upper limits used were $10a$ for the radial integral and $40z_f$ for the axial integral.

Figure 1 depicts the axial displacement as a function of distance for the vitreous tissue. A sharp peak in the displacement occurs at the beam focus ($z=1$ cm). The displacement at the focus is approximately 0.037 cm for the ultrasound intensity considered. The difference between the numerical result and that predicted by (27) is less than a few percent, except at very small axial distances, where the analytical result is lower.

The corresponding curves for breast tissue are shown in Fig. 2. The magnitude of the displacement is seen to be much smaller than for vitreous, at all locations. Two slight peaks, one at the focal length and one at slightly less than half the focal length, can be seen in a broad region of maximum displacement. The analytical prediction is slightly higher in

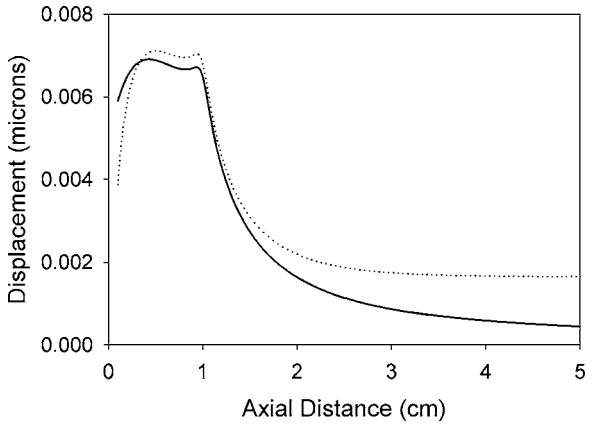

FIG. 2. Axial displacement as a function of axial distance, for breast tissue. Intensity=1 W/cm^2 at focus, in water. Transducer diameter=0.5 cm, focal length=1.0 cm, frequency=10 MHz. Solid line—numerical integration of convolution integral. Dotted line—asymptotic model.

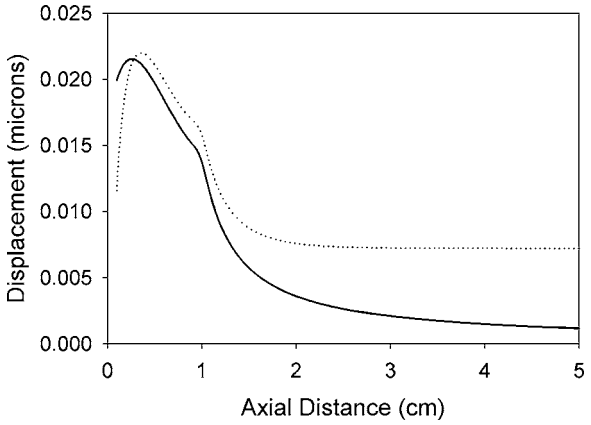

FIG. 3. Axial displacement as a function of axial distance, for liver tissue. Intensity=1 W/cm^2 at focus, in water. Transducer diameter=0.5 cm, focal length=1.0 cm, frequency=10 MHz. Solid line—numerical integration of convolution integral. Dotted line—asymptotic model.

this plateau region. As with the vitreous tissue, the analytical result drops off rapidly for very small axial distances. Beyond about 1.5 focal lengths, the analytical result significantly exceeds the numerical one.

For the liver (Fig. 3), there is a sharp peak in the displacement curve occurring well ahead ($z\approx 0.25$ cm) of the focal zone. Again the analytical result slightly exceeds the numerical computation in the region of maximum displacement, as well as for axial distances up to a focal length. Beyond a focal length, the discrepancy becomes significantly larger. As with the breast and vitreous, the analytical approach considerably underestimates the displacement very close to the transducer. Displacement magnitudes are comparable to those for the breast, and much smaller than those for the vitreous.

A second set of parameters was used in a study to quantify the dependence of axial deformation upon attenuation, for different transducer sizes. Three different transducer radii were considered—0.25, 0.5, and 1.0 cm—with the total radiated power held constant at 0.12 W. The frequency was 5 MHz, the shear modulus μ 1170 N/m^2, and the focal length 2.0 cm. The displacement at the focus was computed using (27) and plotted in Fig. 4. The attenuation of maximum displacement decreases slightly with increasing transducer radius; for $a=1$ cm it is about 2.3 dB/cm. Over the entire range of attenuations, doubling the transducer radius (while decreasing the intensity to hold the power constant) from 0.25 to 0.5 cm provides the same increment in displacement as doubling the radius from 0.5 to 1.0 cm.

IV. DISCUSSION

The requirement that the focal length be long compared with the transducer radius (small δ) allows the displacement at a given axial location to be split into contributions due to ultrasound absorption at that location and absorption over the rest of the beam. In the derivation using matched asymptotic expansions [Eqs. (13)–(20)], the region near $\zeta=0$ represents the volume close to the observation point, while larger values of ζ represent the rest of the beam. Roughly speaking, of the bracketed terms in (27), the single term not containing the

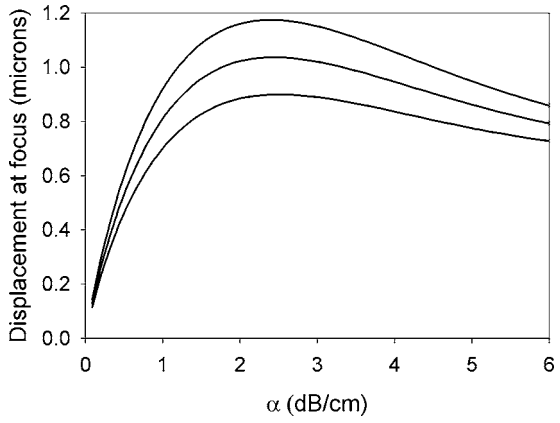

FIG. 4. Axial displacement at the focus as a function of attenuation, for transducer radii of 1.0 cm (top curve), 0.5 cm (middle), and 0.25 cm (bottom). Power is held constant at 0.12 W. Frequency is 5 MHz, the shear modulus 1170 $\mathrm{N/m^2}$, and the focal length 2.0 cm.

attenuation is the local contribution, while the other terms represent the contribution from the remote sections of the beam. For a slightly attenuating medium such as the vitreous, the first term in brackets in (27) dominates the others near $z=z_f$, and displacement in the focal region is essentially a local effect. This is consistent with the peaked profile of Fig. 1. For a highly attenuating medium such as liver, the first bracketed term is smaller than the others, even at the focus, and the displacement at the focus is due mostly to distributed forces throughout the beam. Hence, only a slight deviation is seen in the displacement curve at the focus in Fig. 3.

Near the transducer, local effects cannot be separated from the boundary contribution, and the approximation breaks down. The analytical result is thus seen to deviate from the numerical one for small axial distances in Figs. 1–3. For the calculations performed, accuracy is better than 20% if the observation point z is kept greater than $0.15z_f$.

The deviation between the analytic predictions and numerical results for larger values of αz (larger axial distances in Figs. 2 and 3) is due partly to the limitation of the inner approximation to the exponential term [$\exp(2\alpha\zeta)\approx 1$ for small ζ], leading to (17), and partly to the approximation to the exponential integral in (17). A numerical implementation of $Ei(x)$ would result in closer agreement between the asymptotic theory and numerical integration of (7)–(9), for all values of αz. However, since the affected region is considerably beyond the location where maximum displacement occurs, the added complexity was not deemed worthwhile. The model as presented in this paper is accurate (error $<20\%$) for $\alpha z<1.5$, that is, the focal length cannot significantly exceed the ultrasound attenuation length.

The results of Fig. 4 follow the behavior predicted analytically by (27). For constant power (i.e., constant I_0a^2) and large ka, the increase in displacement with increasing radius is determined by the logarithmic term in (27), and, hence, doubling the radius results in an increase proportional to log 2, independent of radius. Also, (27) predicts a maximum displacement for $\alpha=1/(2z_f)$ when ka is large. For the parameters chosen, this attentuation producing maximum displacement (in the limit of large ka) is 2.2 dB/cm, close to what is observed in Fig. 4.

For a Gaussian beam, the average intensity across the transducer face is $I_0/2B$ (Wu and Du, 1990). The acoustic power as a function of the axial location is given by

$$W(z)=\frac{1}{2}I_0\pi a_{\mathrm{eff}}^2\exp(-2\alpha z), \tag{30}$$

where $a_{\mathrm{eff}}=a/\sqrt{B}$ is the effective transducer radius. The acoustic power (per unit length) dissipated at location z is $-W'(z)=2\alpha W(z)$. Expressing (27) in terms of $W'(z)$, we obtain

$$w(0,0,z)\approx\frac{-W'(z)}{4\pi\mu c}\left(2\log(ka_{\mathrm{eff}}\gamma)-\log(\alpha z)+\alpha z+\frac{e^{2\alpha z}-3}{2}\right). \tag{31}$$

Equation (30) may be interpreted as the displacement for a general focused transducer of radius a_{eff} and power $W(z)$. Since the transducer power level and effective radius considered in this paper match those of Walker (1999), as do the tissue properties, a comparison with the results of Walker (1999) based upon a transducer without Gaussian shading can be meaningfully performed. Indeed, the plots of Walker closely match those in Figs. 1–3 in the locations where the asymptotic theory is valid, roughly $0.15\ \mathrm{cm}<z<1.5$ cm. This region includes the focal zone and region of maximum displacement. The agreement provides evidence that the asymptotic theory can be applied to non-Gaussian transducers via (31).

In the calculations of Sec. III, the bracketed quantity in (31) divided by 4π was a constant of magnitude 1 over a wide range of parameter values. Thus, for very quick estimates, the magnitude of the displacement field may be approximated by

$$w(z_f)\approx -W'(z)/\mu c. \tag{32}$$

This combination approximates the axial displacement at the focus to within 20%, for all three tissues considered in Figs. 1–3.

A useful alternative form of (32) may also be obtained by using (30), and expressing I_0 in terms of the focal intensity I_f via (5):

$$w(z_f)\approx\frac{4\pi\alpha I_f z_f^2}{\mu c(ka)^2}. \tag{33}$$

Here z_f is the focal length and k the acoustic wave number. The value of αz_f considered by Lizzi *et al.* (2003) is too large for the full expression (31) to be valid, however, a comparison of sorts can be made on the basis of (33). After inserting the parameters ($f=4.09$ MHz, $\alpha=0.5$ dB/(cm MHz), $\mu=400\ \mathrm{N/m^2}$, $a=2.1$ cm, $I_f=345\ \mathrm{W/cm^2}$) of Lizzi *et al.* (2003) in (33), we obtain a displacement of approximately 110 microns. Lizzi *et al.* measured and computed a displacement of approximately 50 microns at the end of the 5 ms push exposure. Examining the convergence of the displacement curves (Fig. 9 of Lizzi *et al.*) for times during the exposure, we can extrapolate to a steady-state displacement on the order of

100 microns. The empirical observation of Nightingale *et al.* (2001) that displacements on the order of tens of microns require intensities on the order of 300 W/cm^2 can also be verified using (33). Following Nightingale *et al.* (2001) and setting $\mu=400$ kPa, $f=7.2$ MHz, $\alpha=0.432$ cm^{-1}, $a=2.5$ cm, and $z_f=5$ cm (for $F/1$), we arrive at a displacement of 12 microns when the focal intensity is 300 W/cm^2.

Palmeri *et al.* (2005) employ a rectangular array and highly transient conditions, and hence a direct comparison cannot be made between their results and those of this study. However, the functional dependence of displacement upon $1/\mu$ predicted by the present model [e.g. (27) or (33)] can be investigated using the experimental and finite-element results of Palmeri *et al.* The shear moduli for the 100 bloom, 150 bloom, and 200 bloom phantoms of Palmeri *et al.* are 2.83, 6, and 7.67 kPa, respectively, and the maximum displacements for the three phantoms are 10.1, 4.2, and 3.0 μm. Assuming an inverse proportional dependence upon shear modulus, the maximum displacement for the 200 bloom phantom relative to the maximum displacement for the 150 bloom is 0.78. The experimental value is 0.71 (±0.15), while the finite-element simulations give 0.80. The ratio of the maximum displacement for the 100 bloom phantom relative to the maximum displacement for the 150 bloom is 2.12 based upon a $1/\mu$ dependence, while the experiments and finite-element simulations give 2.40 (±0.35) and 1.85, respectively. These results provide some confirmation of the simple $1/\mu$ dependence, though it must be noted that the maximum displacement may occur at different axial locations for the different phantoms, while the displacement ratios calculated strictly upon a $1/\mu$ dependence assume that z is the same in all cases.

The asymptotic approach formally requires that the transducer radius a be small compared to the focal length z_f. The calculations of Sec. III were extended to larger transducer radii, maintaining the focal length at 1.0 cm. The accuracy of the analytic expression degraded with increasing a/z_f, however, the error in the displacement at the focus was only 8% for $a=z_f/2$ (transducer diameter equal to focal length), and 23% for $a=z_f$. The accuracy of the asymptotic model is likely to suffice for transducer geometries applicable to radiation-force imaging.

As noted in Sec. II, an infinite-medium Green's function was employed to derive the convolution-integral solution (3) for the axial displacement. This approximation, equivalent to assuming that the region $z<0$ is filled with a medium possessing identical elastic properties to the region $z>0$, but with no absorbed energy, precludes the enforcement of a boundary condition on the transducer face. In the important case where $\delta<1$, $\alpha z_f<1$, $\epsilon\ll 1$ (focal length larger than transducer radius, moderate attenuation, high gain), the displacement near the focus is dominated by the local radiation force, and the boundary effects are likely to be ignorable. For the analogous case of temperature rise computed using the infinite-medium Green's function, Wu and Du (1990) found that the temperature rise computed via an expression similar to (3) underestimated the solution imposing a zero-temperature boundary condition on $z=0$. The difference at the focus was less than 10%. The relative error compared to the solution imposing a zero-derivative condition at $z=0$ is about 20%. For high levels of attenuation, where the maximum displacement is achieved close to the transducer, the error associated with ignoring the boundary condition on $z=0$ is likely to be higher. As noted by Walker (1999), a more sophisticated Green's function could be employed in these cases.

V. CONCLUSION

The asymptotic model presented in this paper helps analyze the mechanical response of tissue to acoustic radiation force. The primary result of the model is given by (31). For tissue and transducer properties typical of radiation-force imaging, (31) accurately predicts the axial tissue displacement in critical areas such as the focal zone and region of maximum displacement. For quantitative accuracy, the axial distance of interest must be less than about 1.5 attenuation lengths, i.e., $\alpha z<1.5$. The model formally requires that the transducer radius be small compared to the focal length, but accurate results were obtained for transducer radii comparable to the focal length. Similarly, the model is developed for a transducer with Gaussian amplitude shading, but calculations showed that when expressed in terms of average power dissipation, the model appears to be applicable to more general intensity profiles.

(Received 29 September 2005; revised 27 January 2006; accepted 15 February 2006)

Acoustic structures of sound in Gunnison's prairie dog alarm calls are described, showing how these acoustic structures may encode information about three different predator species (red-tailed hawk—*Buteo jamaicensis*; domestic dog—*Canis familaris*; and coyote—*Canis latrans*). By dividing each alarm call into 25 equal-sized partitions and using resonant frequencies within each partition, commonly occurring acoustic structures were identified as components of alarm calls for the three predators. Although most of the acoustic structures appeared in alarm calls elicited by all three predator species, the frequency of occurrence of these acoustic structures varied among the alarm calls for the different predators, suggesting that these structures encode identifying information for each of the predators. A classification analysis of alarm calls elicited by each of the three predators showed that acoustic structures could correctly classify 67% of the calls elicited by domestic dogs, 73% of the calls elicited by coyotes, and 99% of the calls elicited by red-tailed hawks. The different distributions of acoustic structures associated with alarm calls for the three predator species suggest a duality of function, one of the design elements of language listed by Hockett [in *Animal Sounds and Communication*, edited by W. E. Lanyon and W. N. Tavolga (American Institute of Biological Sciences, Washington, DC, 1960), pp. 392–430]. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2185489]

I. INTRODUCTION

The alarm calls of some animals have been shown to have referential meaning. These calls refer to something in the external environment of the animal, such as a predator, that elicits an alarm response. A number of animals have calls for terrestrial and for aerial predators. These animals include many ground squirrels (*Spermophilus spp*) (Owings and Hennessy, 1984), chickens (*Gallus gallus domesticus*) (Evans and Evans, 1999), tree squirrels (*Tamiasciurus hudsonicus*) (Greene and Meagher, 1998), dwarf mongooses (*Helogale undulata*) (Beynon and Rasa, 1989), and suricates (*Suricata suricatta*) (Manser, 2001; Manser *et al.*, 2001). In each of these species, a terrestrial predator elicits an acoustically different alarm call from that elicited by an aerial predator. A few animal species have been shown to have specific vocalizations for different predator species or categories of predators. Such referential meaning has been documented for vervet monkeys (*Cercopithecus aethiops*), Diana monkeys (*Cercopithecus diana*), Campbell's monkeys (*Cercopithecus campbelli*), and prairie dogs (*Cynomys gunnisoni*). Vervet monkeys have calls for three different types of predators: snake or python, leopard, and eagle (Cheney and Seyfarth, 1990). Diana monkeys and Campbell's monkeys have calls for leopards (*Panthera pardus*) and crowned-hawk eagles (*Stephanoaetus coronatus*) (Zuberbuhler, 2000, 2001).

Gunnison's prairie dogs, which are found in the grasslands of northern Arizona, northern New Mexico, southern Colorado, and eastern Utah, have alarm calls for four different species of predator: hawk (*Buteo jamaicensis*), human (*Homo sapiens*), coyote (*Canis latrans*), and domestic dog (*Canis familiaris*) (Placer and Slobodchikoff, 2000, 2001), as well as vocalizations for objects in their environment that are not known to them but could potentially represent a predator (Ackers and Slobodchikoff, 1999). The escape responses of the prairie dogs differ to the different predators (Kiriazis, 1991; Slobodchikoff, 2002; Kiriazis and Slobodchikoff, 2006). When a human appears at the edge of the colony, all of the prairie dogs run to their burrows and dive inside. When a red-tailed hawk dives toward the colony in an attempt to capture a prairie dog, only the animals in the immediate flight path of the hawk run to their burrows and dive inside. The remaining animals outside the flight path typically stand on their hind legs and watch the progress of the hawk. When a coyote appears, all the animals in the colony run to the lips of their burrows and stand upright in an alert posture, and prairie dogs that are below ground emerge to stand at their burrows so that most of the colony is above ground, watching the coyote. When a domestic dog appears, the prairie dogs stand in an alert posture, and only run to their burrows if the dog comes near. In playback experiments, Kiriazis and Slobodchikoff (2006) showed that the escape responses of the prairie dogs to playbacks of the calls for the different predators when no predator is present are the same as when a predator appears and elicits alarm calls and escape responses from the animals in the colony. Of these four predators, humans represent perhaps the greatest threat,

[a)]Electronic mail: con.slobodchikoff@nau.edu

shooting large numbers of prairie dogs (Vosburgh and Irby, 1998). Coyotes and hawks are responsible for the majority of nonhuman predation, while domestic dogs seem to represent relatively little threat as predators (Verdolin and Slobodchikoff, 2002).

In addition to containing information about the species of predator, Gunnison's prairie dog alarm vocalizations also provide information about specific details of an individual predator. Slobodchikoff *et al.* (1991) found that Gunnison's prairie dogs incorporated information into their calls about specific colors of shirts, such as blue, green, yellow, and grey, worn by different humans, and also found that the calls incorporated details of the size and shape of the individual humans. When Slobodchikoff *et al.* (1991) had humans of different sizes and shapes walking through prairie dog colonies wearing the same white laboratory coat that obscured physical features, the prairie dogs incorporated less information into their alarm calls about the individual humans than when the humans were not wearing the laboratory coat. A recent study has shown that the other four species of prairie dogs in North America (the black-tailed, *Cynomys ludovicianus*, found in the western part of the Midwest; the Mexican, *C. mexicanus*, found in central Mexico; the white-tailed, *C. leucurus*, found in western Colorado and northeastern Utah; and the Utah, *C. parvidens*, found in southwestern Utah) can also incorporate information into their alarm calls about different shirt colors worn by humans (Frederiksen, 2005). The calling patterns of the Gunnison's prairie dogs differ depending on whether a predator is approaching slowly or rapidly, providing the prairie dogs with a wide range of information about the species of predator, the individual characteristics or description, and the rate of approach (Kiriazis, 1991; Slobodchikoff, 2002). This represents a complex communication system that appears to exceed the amount of information encoded in the calls of many other species with referential labeling.

In earlier studies (Placer and Slobodchikoff, 2000, 2001) an artificial neural network was used to classify Gunnison's prairie dog alarm calls by species of predator. Each alarm call was decomposed into several equal-sized time periods and the ratios of the frequencies present in each period were computed. The frequency ratios in all time periods for a given alarm call were then combined to represent that alarm call. This measure of frequency ratios was used as input to a neural network. The classification results clearly showed that frequency ratios could be used to classify predator-specific prairie dog alarm calls. However, although high classification accuracy was achieved in that study, the frequency ratios did not retain time-dependent information nor did they provide information about the underlying acoustic structure of the calls.

Analysis of the acoustic structure of such alarm calls in mammals has most often focused on a description of the sound frequencies and time-dependent parameters of those frequencies. For example, the alarm calls of vervet monkeys (*Cercopithecus aethiops*) and rhesus macaques (*Macaca mulatta*) have been analyzed in terms of the fundamental frequencies (*F*0) (Hauser and Fowler, 1992), and vervet monkeys (Seyfarth and Cheney, 1984; Owren and Bernacki, 1988), Barbary macaques (Macaca *sylvanus*) (Fischer *et al.*, 1995), baboons (*Papio cynocephalus*) (Owren *et al.*, 1997; Fischer *et al.*, 2002), and Diana monkeys (*Cercopithecus diana*) (Riede and Zuberbuhler, 2003) have been analyzed in terms of frequency, time, and amplitude parameters. These analyses have not searched for deeper acoustic structures within the alarm calls.

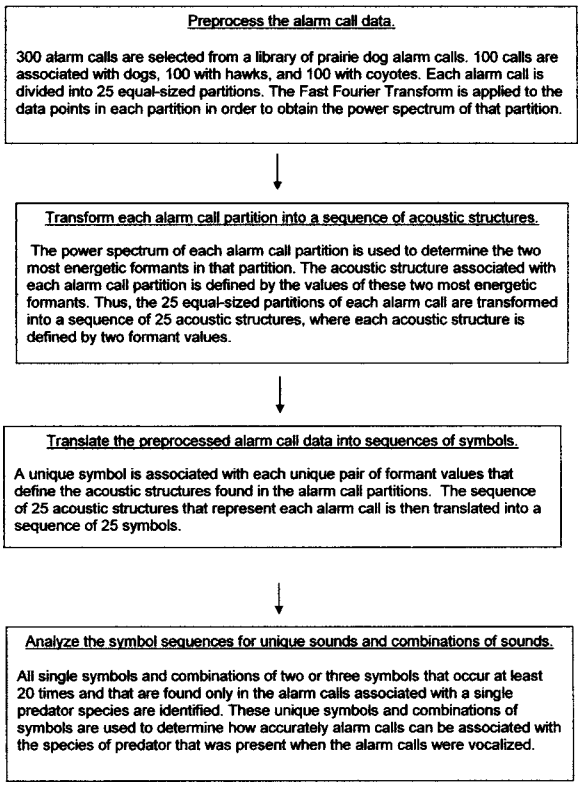

FIG. 1. Summary of the methods used in the analysis.

II. METHODS

The methods that produced the research discussed in this paper are described in detail in Placer and Slobodchikoff (2004) and are summarized in Fig. 1. Three hundred (300) Gunnison's prairie dog alarm calls were selected from a large collection of tape recordings obtained over a 10-year period (1988–1997) at two separate prairie dog colonies described in Slobodchikoff *et al.* (1991). Details about this database can be found in Placer and Slobodchikoff (2004). One hundred (100) calls were vocalized in the presence of dogs, 100 in the presence of hawks, and 100 in the presence of coyotes. The alarm calls were converted into simple digitized time-domain recordings and processed to reduce background noise using the software package Cool Edit 2000. One of the authors (JP) created a system of computer programs to analyze these alarm calls using the high-performance numeric computation software called MATLAB and the computer language Java.

Each of the digitized alarm calls was divided into 25 equal-sized partitions. Figure 2 shows a digitized alarm call that has been divided into 25 partitions. The mean total times of the calls for the different predators were as follows: coyote: 0.193 ± 0.014 s (mean$\pm$SD), $N=100$ calls; dog:

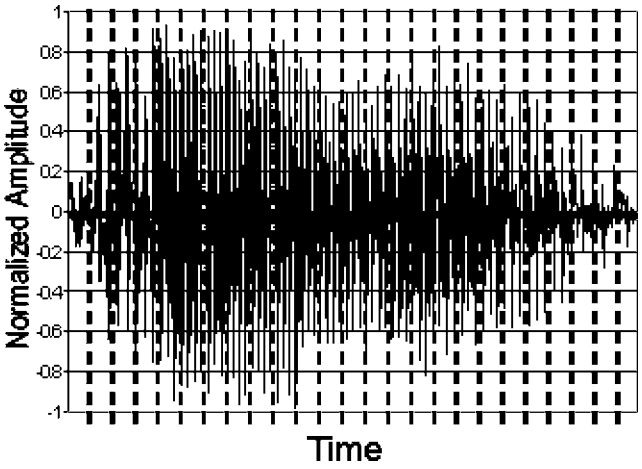

FIG. 2. A prairie dog call divided into 25 partitions.

0.134±0.020 s, N=100 calls; hawk: 0.084±0.007 s, N=100. The mean times of the individual partitions were the following. Coyote: 0.0148±0.003 s (mean±SD), N=2500 partitions; dog: 0.0103±0.0015 s, N=2500 partitions; hawk: 0.0065±0.0005 s, N=2500 partitions.

The fast fourier transform was then applied to the data points in each alarm call partition in order to produce a normalized power spectrum of the sound frequencies contained in that partition. The computer analysis software then used the eight most energetic frequencies of each power spectrum to determine the two most prominent formants (designated $F1$ and $F2$) contained in that alarm call partition, where formant values were rounded to the nearest multiple of 300 Hz. Figure 3 shows a typical power spectrum taken from one partition of a divided alarm call. The eight data points that lie above the horizontal line in the figure are the largest power values that are used to compute the two most energetic formants in this partition. The power values that are clustered together as contiguous data points are treated as part of a single formant. The lowest frequency in such a cluster is used to represent that formant. Formants are vocal tract resonances that appear as hills or raised sections in a power spectrum. A number of techniques for identifying the highest or most prominent formants were experimented with and the simple technique of using only the eight most energetic frequencies in each power spectrum produced the best results (Placer and Slobodchikoff, 2004).

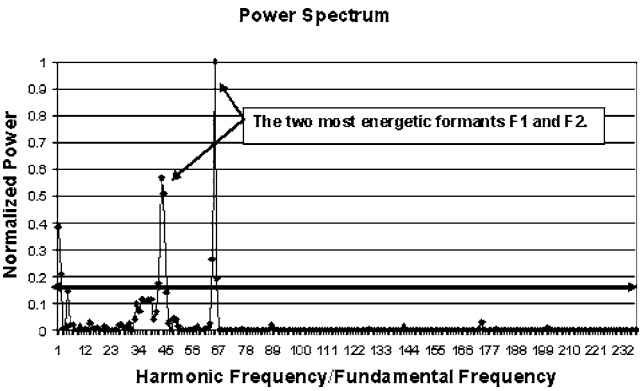

FIG. 3. The power spectrum of a partition of a prairie dog alarm call vocalized in the presence of a hawk. The two most energetic formants were used to identify distinct acoustic units. The values on the vertical axis are normalized because the absolute values of the power are not relevant. The values on the horizontal axis represent an index expressed in simple integers, derived by dividing the harmonic frequencies in the power spectrum of the partition by the fundamental frequency in that partition.

Each of the two formants computed for each alarm call partition was represented by a single sound frequency. Thus, the acoustic structure associated with each partition was defined by two frequencies that represented that partition's two most energetic formants. Using this procedure, each alarm call would be divided into 25 equal-sized partitions and each partition in turn would be represented by two formant frequencies. In this way, each of the 300 alarm calls used in this study was translated into a sequence of 25 acoustic structures where each acoustic structure was represented by two simple frequencies (see Tables I–III).

Working with these translated alarm calls, the analysis software examined each acoustic structure in each alarm call. Each unique pair of frequencies that defined an acoustic unit

was assigned a unique symbol and that symbol was used to replace the acoustic unit. For example, assume the acoustic unit (300 Hz, 600 Hz) was encountered during this phase of the processing. If that exact pair of frequencies had been encountered previously, then a symbol would already have been used to represent them and that symbol would be used to replace the pair of frequencies. However, if this was the first time that particular pair of frequencies was encountered, a new symbol would be generated and the new symbol would be used to replace the pair. The names of the symbols always began with an "S" that was followed by a simple integer. Thus, if a new symbol was to be created and 25 symbols had already been generated, then the new symbol's name would be "S26." Using these techniques the alarm calls that had been translated into sequences of acoustic units were now translated into sequences of symbols. Shown below is an example of an alarm call vocalized in the presence of a coyote that has been translated into a sequence of 25 symbols:

S14S7S6S17S5S4S9S13S18S9S8S19S4S7S8S4S7

S6S6S4S19S4S19S8S13

Once the alarm calls were translated into sequences of symbols, the sequences were then searched for single symbols (monograms), pairs of contiguous symbols (digrams), and triplets of contiguous symbols (trigrams) that were found exclusively in the alarm calls associated with a particular predator species. Alarm calls found to contain a monogram, digram, or trigram that was uniquely associated with a given predator species could be unambiguously associated with that same predator species. Thus, monograms, digrams, and trigrams unique to a given predator species were used to classify the alarm calls by predator species. Only symbols that occurred at least 20 times in the target alarm calls were used in the classification process in order to guard against using infrequently occurring acoustic units that might simply be artifacts of the sound processing techniques utilized. Only symbols that occurred at least 50 times were considered to be common symbols that are used in the descriptions of the results below.

A similarity index was calculated based on counts of occurrence of the different acoustic symbols within the three types of calls. The index was calculated as

$$\text{similarity index} = \sum \frac{A \text{ or } B \text{ (whichever has the smaller number of occurrences)}}{A + B}$$

where A is the frequency of occurrence of a symbol in the calls elicited by one predator, B is the frequency of occurrence of the same symbol in the calls elicited by the other predator, and the index is summed over all of the symbols that are common to the calls of both predators.

III. RESULTS

Most of the common acoustic structures (>50 occurrences) were found in calls associated with all three predators, but the proportions of acoustic structures varied. In alarm calls elicited by coyotes, there was only a single acoustic structure (S15) that was unique to coyote calls (Fig. 4). In alarm calls elicited by domestic dogs, there was also only one acoustic structure (S120) that was unique (Fig. 5). In alarm calls elicited by red-tailed hawks, there were six acoustic structures (S153, S154, S155, S157, S161, and S162) that were unique to red-tailed hawk calls (Fig. 6). The proportion of occurrence of the symbols in the three types of calls was significantly different (coyote-hawk, $\chi^2 = 1770/2$ (Bonferroni correction) $= 885$, df $= 23$, $p < 0.001$; hawk-dog, $\chi^2 = 1374/2$ (Bonferroni correction) $= 687$, df $= 22$, $p < 0.001$; coyote-dog, $\chi^2 = 679/2$ (Bonferroni correction) $= 340$, df $= 19$, $p < 0.001$; χ^2 values were calculated on the basis of counts of occurrences). Based on the occurrence of acoustic structures in the calls, hawk calls and coyote calls had a similarity of 0.159, hawk calls and dog calls had a similarity of 0.134, and coyote calls and dog calls had a similarity of 0.218.

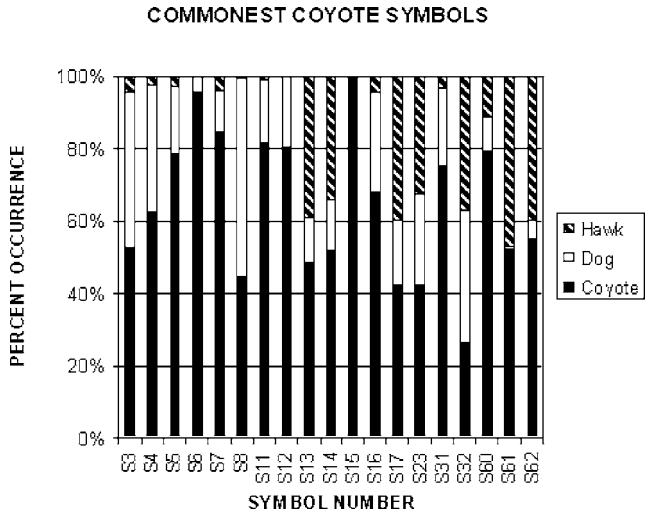

FIG. 4. The most common acoustic structures found within calls elicited by coyotes. Only one acoustic structure (S15) is unique to coyote calls.

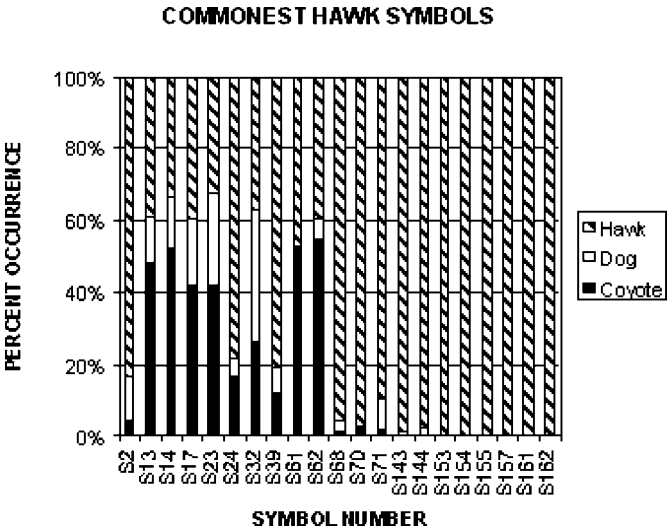

FIG. 6. The most common acoustic structures found within calls elicited by red-tailed hawks. Six acoustic structures (S153, S154, S155, S157, S161, S162) are unique to red-tailed hawk calls.

When digrams and trigrams were considered, there were more unique combinations. A number of these consisted of repetition of the same acoustic structure in contiguous partitions. Dog elicited calls had a unique trigram consisting of the same acoustic structure (S120) repeated in three adjacent partitions (S120S120S120), and another unique trigram consisting of an acoustic structure (S47) also repeated in three adjacent partitions (S47S47S47). Coyote elicited calls had three unique digrams and two unique trigrams. Of the digrams, one consisted of repetition of the same acoustic structure in two adjacent partitions (S6S6), and two consisted of two different acoustic structures in adjacent partitions (S16S60; S7S6). The two unique trigrams in coyote elicited calls were repetitions of the same acoustic structures in three adjacent partitions (S5S5S5; S7S7S7). Hawk elicited calls had eight unique digrams and one unique trigram. Of these, three consisted of repetitions of the same acoustic structures in adjacent partitions (S68S68; S70S70; S154S154), and five consisted of associations of different acoustic structures in adjacent partitions (S2S154; S68S70; S70S68; S154S157; S154S143). The unique trigram in hawk elicited calls consisted of a repetition of the same acoustic structure (S68) in three adjacent partitions (S68S68S68).

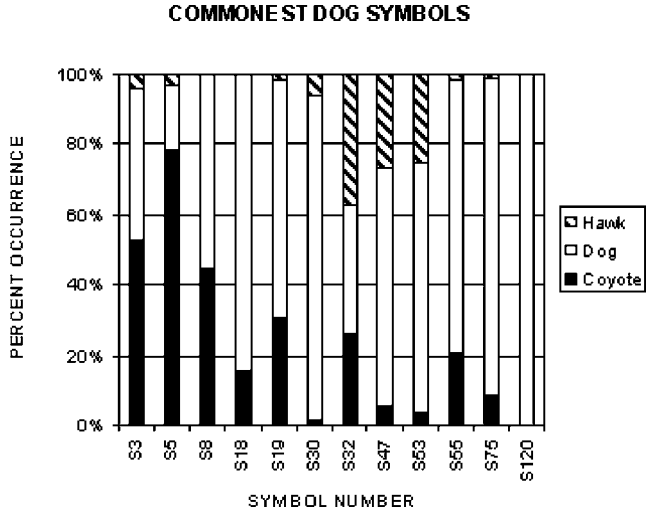

FIG. 5. The most common acoustic structures found within calls elicited by domestic dogs. Only one acoustic structure (S120) is unique to domestic dog calls.

Using the unique monograms, digrams, and trigrams, we subjected the original data to a classification analysis to determine how well these unique acoustic structures can identify the calls to the correct predator species. We found that 67% of the dog elicited calls were correctly classified as dog, 73% of the coyote elicited calls were correctly classified as coyote, and 99% of red-tailed hawk elicited calls were correctly classified as hawk, giving an overall classification average of 80% correct classification. When we plotted all of the acoustic structures that made up the unique monograms, digrams, and trigrams, we found that the acoustic structures associated with these unique grams for each predator species seemed to cluster in different regions (Fig. 7). Hawk-associated acoustic structures generally had higher formant frequencies for both $F1$ and $F2$ than the coyote- or domestic dog-associated frequencies, which had lower formant frequencies.

When we ranked the acoustic structures by ascending $F1$ frequency (Figs. 8–10), the acoustic structures produced a pattern in which the higher formant frequency increased in one symbol and then decreased in the following symbol for many of the symbols. This is a pattern similar to that seen in the structure of English vowels when the two lowest formants associated with each vowel are plotted (Fig. 11) [source of frequencies for English vowels (Kim, 1991)].

IV. DISCUSSION AND CONCLUSIONS

The same acoustic structures were found in calls associated with all three species of predator. However, the distribution of these acoustic structures was different for each of the three predators. This suggests two points. One is that the acoustic structures could be used as building blocks for larger units that might have meaning, in a way analogous to how phonemes are used in human languages to build words

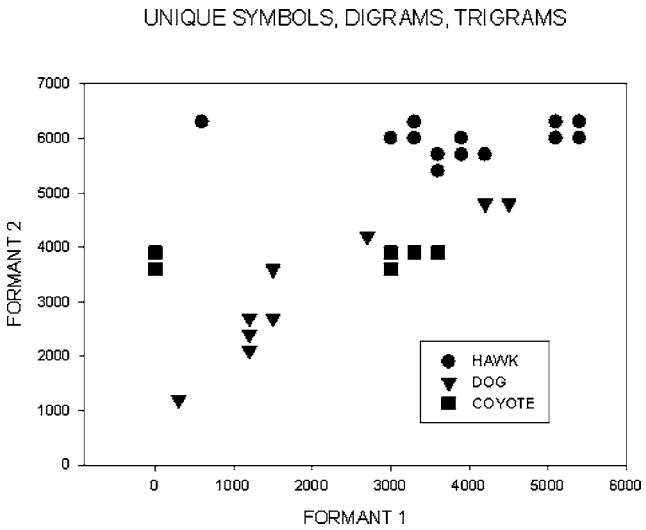

FIG. 7. Formant frequencies found in unique monograms, digrams, and trigrams associated with red-tailed hawk, coyote, and domestic dog alarm calls. The F1 and F2 frequency (Hz) values for each symbol that is part of a unique combination have been plotted, even though that symbol may be part of a unique digram or a unique trigram.

and sentences. This suggests that prairie dog alarm vocalizations might contain duality, i.e., that larger units of semantic significance are made up of smaller units that can be combined in different ways to produce many different larger units. This is one of the design features of language listed by Hockett (1960) for human and animal languages and has not been shown previously in animal vocalizations. The other point is that perhaps some or many acoustic structures might be used to express additional information beyond the species of predator present when an alarm call is vocalized. This hypothesis is consistent with the work of Slobodchikoff *et al.* (1991), who demonstrated that prairie dog calls contain information associated with size, shape, and color of different individuals within a predator species, and it is consistent with the work of Kiriazis (1991), who showed that prairie dog calls contain information related to direction and speed of approach of predators.

The vowellike acoustic structures in prairie dog alarm calls are perhaps not surprising, given that at least one non-

human primate, the baboon (*Papio cyncephalus*), is known to produce grunts that have acoustic properties similar to those of human vowels (Zhinkin, 1963; Andrew, 1976; Owren *et al.*, 1997). Also, other animals have been found to be able to discriminate among some human vowels. For example, cats (Dewson, 1964), chinchillas (Miller, 1977), baboons (Hienz and Brady, 1988), and pigeons (Hienz *et al.*, 1981) have been shown to be able to discriminate between some of the human vowels. Among the nonhuman primates, vervet monkeys (*Cercopithecus aethiops*) and Japanese macaques (*Macaca fuscata*) were able to discriminate between some of the common English vowels (Sinnott, 1989). Perhaps there is a limited number of ways in which information might be encoded in vocalizations that have multiple formants. However, we should point out that the duration of English vowels varies between 0.180 and 0.330 s (Lieberman and Blumstein, 1988), while the acoustic structures that we have identified vary between 0.0065 and 0.0148 s in du-

ration. Since the entire alarm calls of the prairie dogs vary between 0.084 and 0.193 s in duration and there is a considerable amount of information encoded within that total time interval, it is possible that prairie dogs might process acoustic information more rapidly than humans.

Somewhat more surprising is the acoustic structure of these vowellike sounds. In humans and other primates, vowellike sounds are produced through a combination of the first two formants, that is, the two formants with the lowest frequencies (Owren *et al.*, 1997). In prairie dog alarm vocalizations, the most accurate associations of alarm calls with predator species occurred when the two most dominant formants, the ones carrying the most acoustic energy, were used, rather than the first two. Perhaps this is an adaptation to the long-distance propagation of sound in the alarm call, since prairie dog calls travel over long distances, often through vegetation that can potentially filter out some frequencies (e.g., see Perla and Slobodchikoff, 2002).

Using an artificial neural network to classify black-capped chickadee (*Poecile atricapillus*) call note types

Michael R. W. Dawson, Isabelle Charrier, and Christopher B. Sturdy[a)]
Department of Psychology, Centre for Neuroscience, University of Alberta, Edmonton, Alberta T6G 2E9, Canada

(Received 9 May 2005; revised 17 October 2005; accepted 2 March 2006)

The "chick-a-dee" call of the black-capped chickadee (*Poecile atricapillus*) contains four note types, A, B, C, and D that have important functional roles. This provides strong motivation for studying the classification of acoustic components of the call into different note types. In this paper, the spectrograms from a sample of A, B, and C notes (370 in total) were each described as a set of 9 summary features. An artificial neural network was trained to identify note type on the basis of these features, and was able to obtain better than 98% accuracy. An internal analysis of this network revealed a distributed code in which different hidden units generated high activities to different subsets of notes. By combining these different sensitivities, the network could discriminate all three types of notes. The performance of this network was compared to a discriminant analysis of the same data. This analysis also achieved a high level of performance (95%). A comparison between the two approaches revealed some striking similarities, but also some intriguing differences. These results are discussed in terms of two related issues: developing a research tool for note classification, and developing a theory of how birds themselves might classify notes. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2189028]

I. INTRODUCTION

Songbirds are a popular model for the study of vertebrate acoustic communication (e.g., Slater, 2003). One reason for this is that the circumstances under which songbirds learn song from a model can be viewed as being analogous to human language learning (Doupe and Kuhl, 1999; Goldstein *et al.*, 2003). That said, song is not the only class of vocalizations that songbirds learn from a model. For example, songbirds also learn *calls* that are used in the context of specific behavioral interactions. As a result, more general studies of acoustic signaling and communication in songbirds are broadening their scope to include examinations of learned calls and other vocalizations in addition to learned songs (e.g., Hailman and Ficken, 1996; Hughes *et al.*, 1998; Vicario *et al.*, 2002). The purpose of this paper is to report the results of one such examination of the notes of a learned call of a small songbird native to North America, the black-capped chickadee (*Poecile atricapillus*). We show that when the notes of this call are represented as small sets of acoustic features, a nonlinear statistical method (artificial neural network) and a linear statistical method (linear discriminant analysis) are both capable of using these features to correctly classify notes into different note types.

The black-capped chickadee is one songbird that has provided a great deal of information about learned calls. One of the learned calls for this species is the "chick-a-dee" call, for which the species was named (Ficken *et al.*, 1978). Chick-a-dee calls contain four note types, labeled A, B, C, and D. Chick-a-dee calls are interesting because while their component notes are generated in a fixed order (A→B→C→D), in a particular call note types can be either repeated or omitted. As a result, a seemingly infinite variety of different chick-a-dee calls can be produced (e.g., ACCCCD, ABDDD; see Figs. 1 and 2 for examples of calls and the constituent note types, respectively). Indeed, the combinatorial nature of the chick-a-dee call has been used to draw interesting analogies between it and human speech (Hailman, 1985).

The different note types from which the chick-a-dee call is composed are important for a number of reasons. First, chickadees appear to vary the note-type composition of their chick-a-dee calls depending on the particular context (e.g., Ficken *et al.*, 1994; Gaddis, 1985; Smith, 1972), suggesting that different distributions of note types within calls convey different information. Second, chickadees fail to respond in a species-typical fashion to the playback of chick-a-dee calls that have an atypical syntax. Reduced responsiveness can be caused by gross syntactical violations, such as complete reversal of call syntax (DCBA rather than ABCD); (Charrier and Sturdy, 2005), or from more subtle syntactical violations (CACACA instead of AAACCC; Clucas *et al.*, 2004). Third, even more subtle alterations of notes within chickadee calls can cause birds to treat calls as atypical. Charrier and Sturdy (2005) found that chickadee calls with the correct syntax (ABCD) but in which each individual note was time-reversed, thus altering both amplitude and frequency modulation patterns of the notes within the calls, led to significantly reduced responding compared to normal calls. Fourth, black-capped chickadees are themselves able to discriminate and categorize the different note types of the chick-a-dee call, although they sometimes confuse adjacent note types (Sturdy *et al.*, 2000). Finally, different chick-a-dee call note

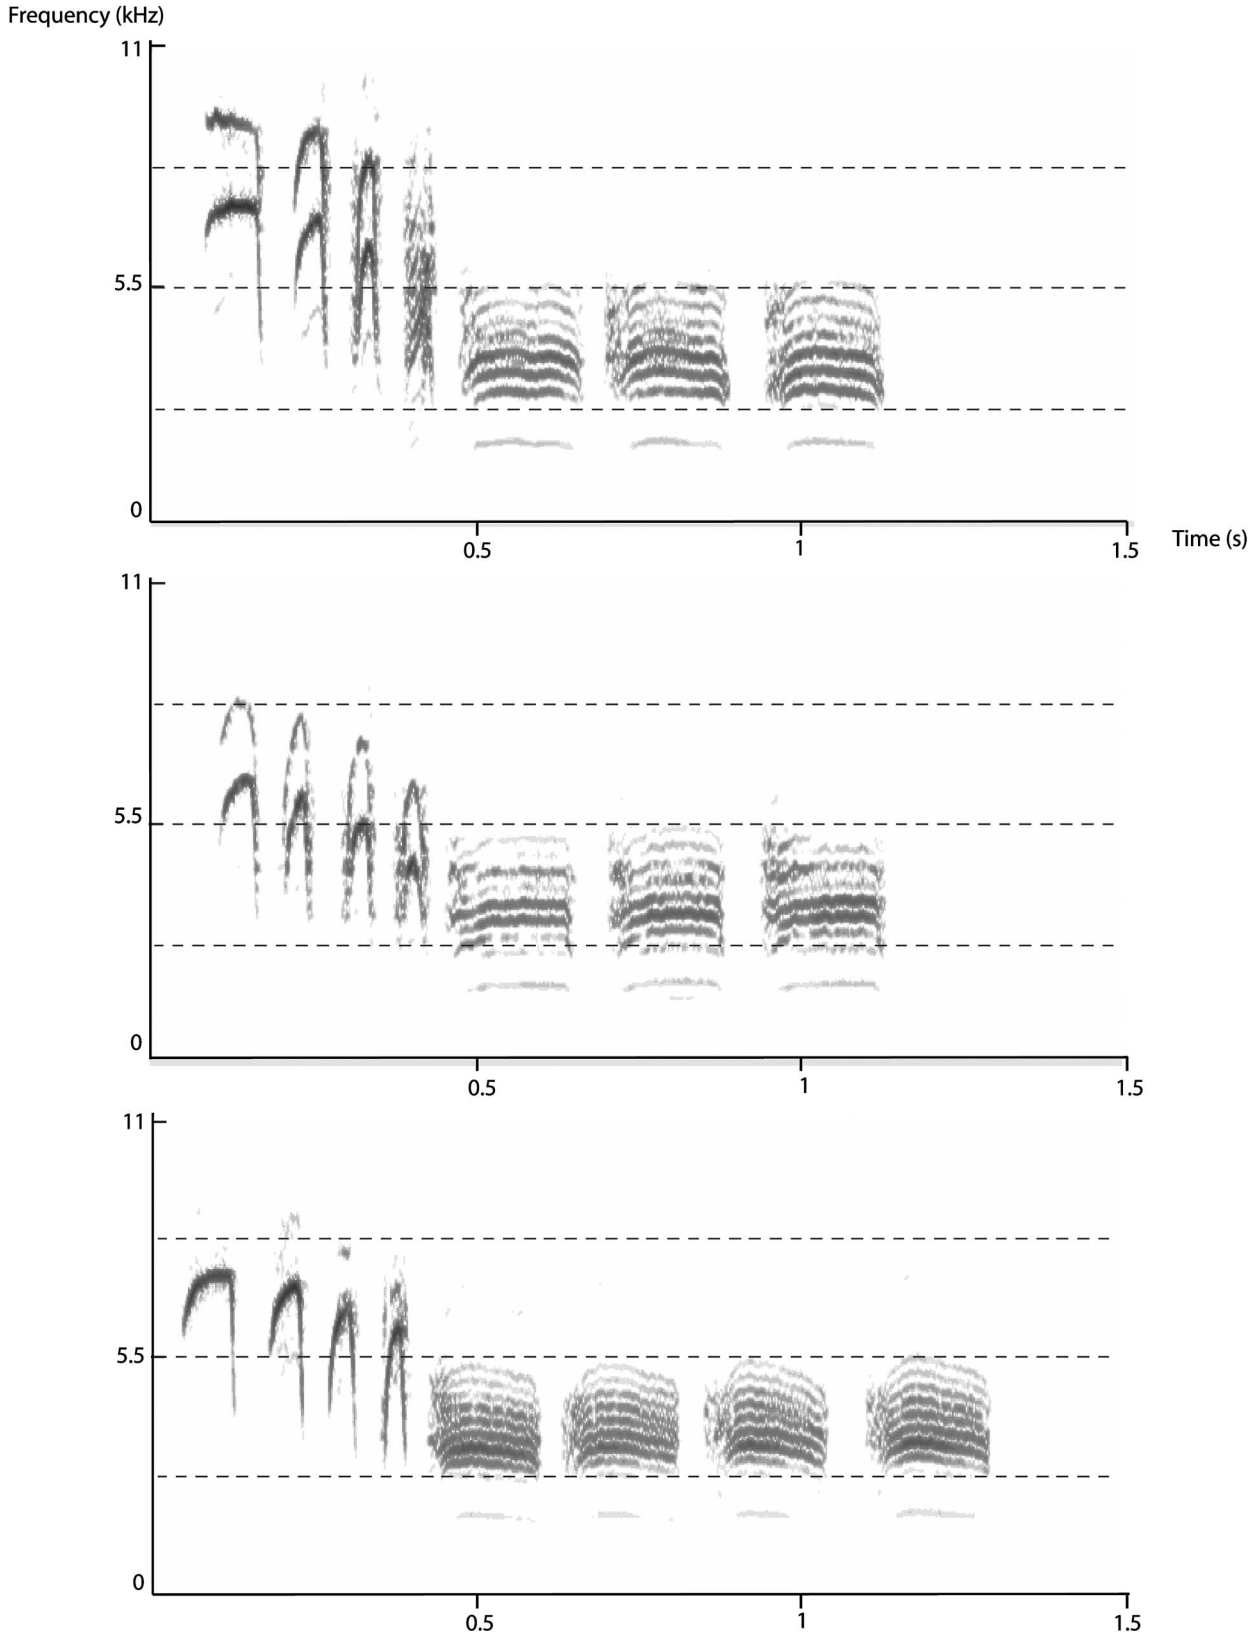

FIG. 1. Sound spectrograms of black-capped chickadee chick-a-dee calls from 3 different birds. The note composition of these calls is AABCDDD (top) AABBDDD (middle), and AAABDDDD (bottom), respectively. (Hamming window size=1024 points, frequency precision=21 Hz).

types have been associated with conveying specific information. For instance, the D note appears to be critical for birds being able to distinguish between chick-a-dee calls from members of their flock from the same kind of calls produced by members of a foreign flock (Mammen and Nowicki, 1981; Nowicki, 1983). The C note appears to be used to indicate the location or availability of food sources (Freeberg and Lucas, 2002). Taken together, it seems clear that the

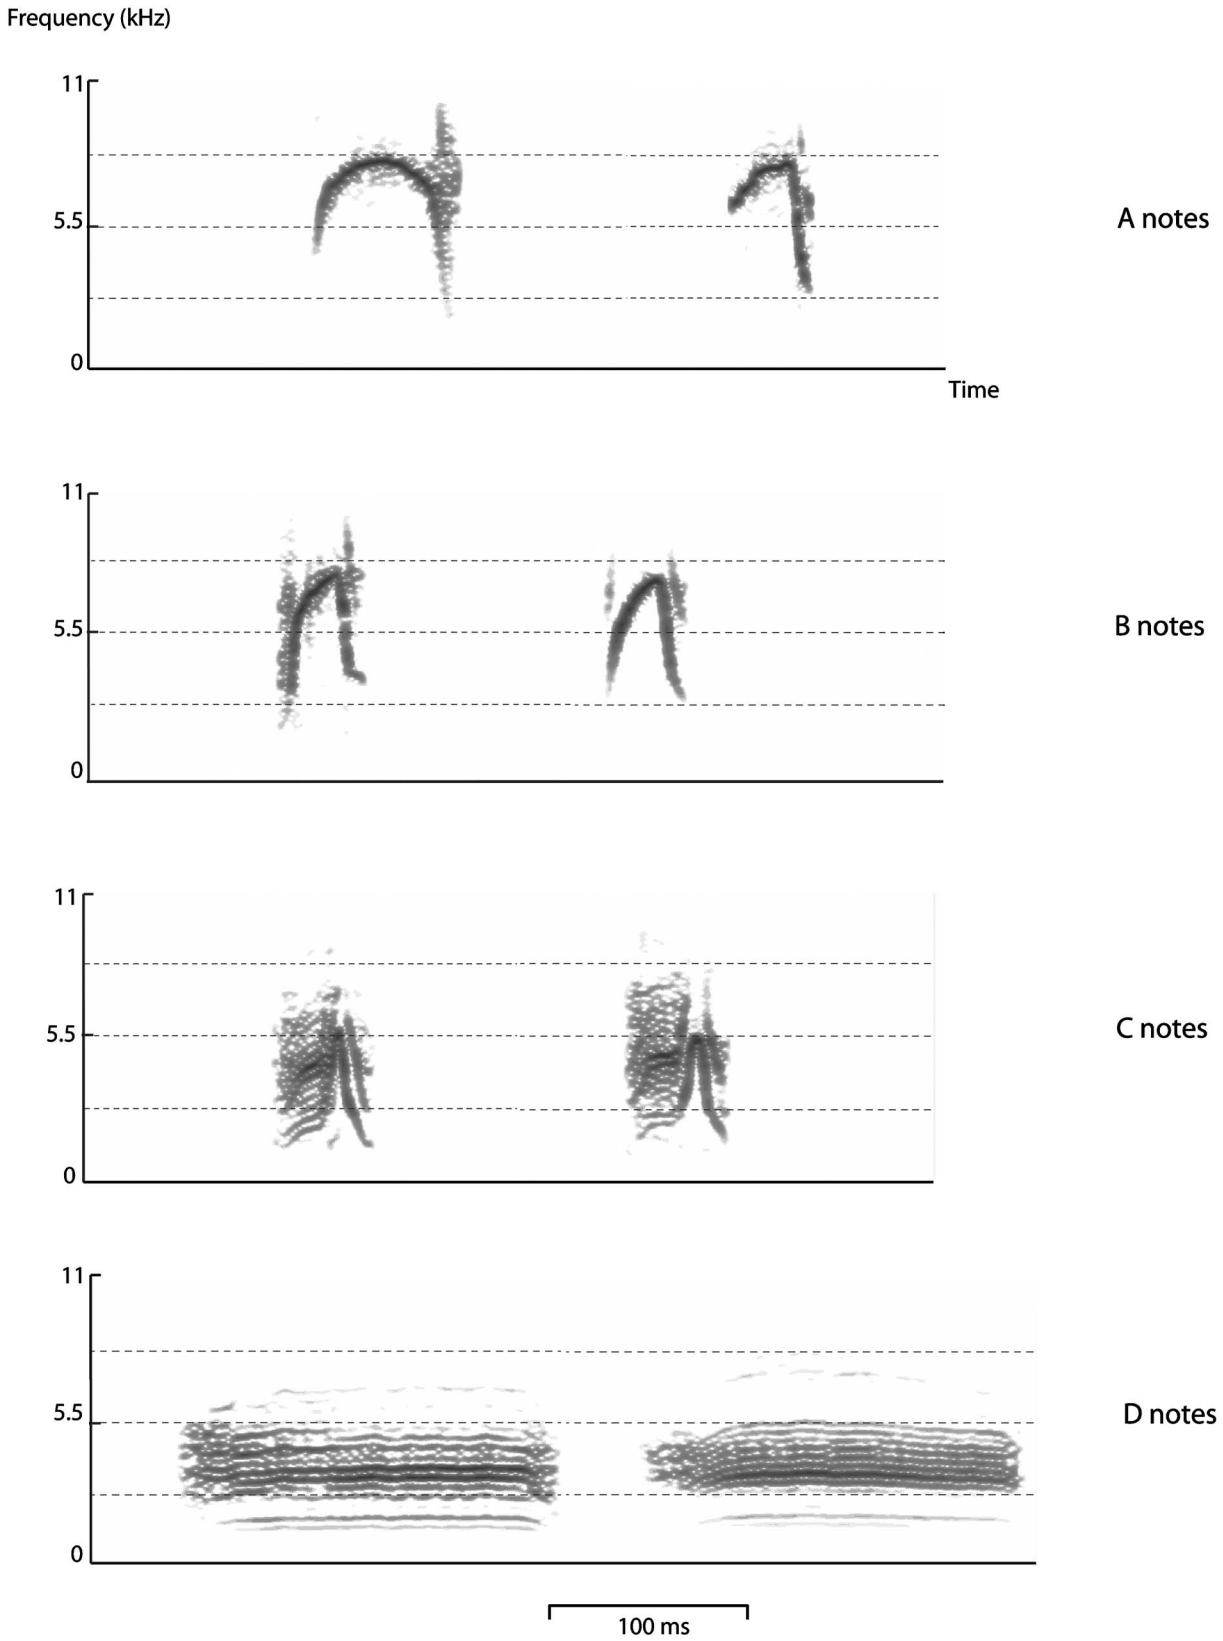

FIG. 2. Sound spectrograms of the four different note types found in black-capped chickadee chick-a-dee calls: A, B, C, and D notes. Exemplars for each note type from 2 different birds. (Hamming window size=1024 points, frequency precision=21 Hz).

accurate perception of individual note types in the chick-a-dee call is a crucial and fundamental building block of chickadee's acoustic communication system.

The fact that the constituent notes of the chick-a-dee call have important functional roles provides strong motivation for studying the classification of acoustic components of the call into one of the four different note types. Nowicki and Nelson (1990) describe such note classification as identifying natural categories in the acoustic signal. They point out that one critical research question is to determine how black-

capped chickadees themselves identify such natural categories. A related and equally crucial question, studied in detail by Nowicki and Nelson, is how researchers themselves can identify these natural categories to aid in studying the properties of the call.

The traditional approach to this classification problem is exemplified by bioacousticians, who examine the visual representation of a vocalization (e.g., a chick-a-dee call) in the form of a sound spectrogram, and use visual features of the call to identify and classify its component note types. This technique has been used by several researchers to classify the notes of vocalizations from several songbird species [e.g., mountain chickadee, *Poecile gambeli*, chick-a-dee call notes, Bloomfield *et al.* (2004); Carolina chickadee, *P. carolinensis*, chick-a-dee call notes, Bloomfield *et al.* (2005); Black-capped chickadee chick-a-dee call notes, Charrier *et al.* (2005); Ficken *et al.* (1978); and Nowicki and Nelson (1990); zebra finch, *Taeniopygia guttata*, song notes, Sturdy *et al.* (1999b)]. Some of these visual classifications have been verified with the species that produces them via operant conditioning discrimination tasks (e.g., Sturdy *et al.*, 1999a, 2000), providing a necessary validation to the visual classification. That said, not all visually-guided classifications of animal vocalizations have been verified empirically, and depending on the species under study, many laboratory-based verifications may be impractical or impossible to conduct.

A less subjective approach to identifying natural categories of notes is to take spectrograms as raw data for traditional statistical analyses. Nowicki and Nelson (1990) provided one example of this approach. They took spectrograms representing 240 different notes (60 notes from each of 4 different birds), and cross-correlated all possible pairs of notes from this dataset. They then took the resulting correlation matrix and analyzed it with multidimensional scaling (MDS). MDS is a technique that provides a graphical representation of data, where data instances are represented as points in a multidimensional space (Kruskal and Wish, 1978). The more similar two instances of data are to one another, the nearer are their corresponding points in the space. Nowicki and Nelson found that a two-dimensional space provided an excellent account of their data. The MDS plot revealed a good segregation of each note type into different clusters with little overlap. This result was particularly encouraging because Nowicki and Nelson included D notes in addition to A, B, and C notes in their analysis. Because D notes are dramatically different than the other three in terms of acoustic properties, their inclusion possibly made differences between A, B, and C notes less apparent.

Another approach, also explored by Nowicki and Nelson (1990), is to take raw spectrograms and summarize them into a more tractable set of summary features. These summary features can then be used as input to a variety of statistical methods as an aid to note classification.

For example, Nowicki and Nelson (1990) described each of their non-D notes, that is A, B, and C notes (a sample of 185 stimuli), as a small set of different acoustic features that were derived from the spectrogram of the note. These features included such measurements as the total note duration, the starting, peak, and ending frequencies of the note, and so on. They created a matrix of correlations between every pair of notes on the basis of these features, and then performed principal components analysis on this matrix. They were able to account for over 68% of the variance in the correlation matrix with three principal components. They then described each of the 185 notes in terms of their loadings on these three factors, and processed this stimulus representation with *k*-means cluster analysis. They found that three clusters provided the most parsimonious account of the data.

A classification matrix based on the *k*-means solution indicated that this statistical approach generated a 77.3% agreement with visual classification of notes. That is, 143 of the notes were given the same classification that was assigned after a visual inspection of the spectrogram. With respect to misclassifications, 8 of the 71 A notes were classified as B notes, and 6 were classified as C notes. Similarly, 1 of the 65 B notes was classified as an A note, and 22 were classified as C notes. Finally, 5 of the 49 C notes were classified as B notes.

On the one hand, Nowicki and Nelson (1990) demonstrated that it is possible to use a variety of statistical analyses to classify notes in such a way that there is a high amount of agreement between statistical classifications and visual classifications. On the other hand, their research raises two questions that deserve additional study. First, is it possible to improve the already good fit between statistical and visual classifications by exploring alternative statistical methods? Second, is it possible to explore some form of statistical classification that might provide additional insight into how the birds themselves might perform note classification?

The purpose of this paper is to explore both of these questions by examining the ability of an artificial neural network to classify notes when these notes are described as a small set of features that have been derived from a spectrogram. The artificial neural network that we investigated is called a multilayer perceptron. In comparison to traditional statistics, this kind of network can provide classification power because it determines an optimal nonlinear combination of features. This kind of technique is also of interest because many researchers have argued that it is more biologically plausible than other techniques (Clark, 1989; McClelland *et al.*, 1986; Schneider, 1987; Smolensky, 1988). As a result, if one can produce an artificial neural network that is capable of classifying note types, this network might suggest general ways in which note classification is performed by the birds themselves.

This paper proceeds as follows. First we describe the methods used to obtain and summarize a set of A, B, and C notes from the chick-a-dee call. Second, we provide a brief overview of the multilayer perceptron, and examine its ability to classify this new set of notes. Third, to compare this approach to more traditional statistical approaches, we explore the ability of discriminant analysis to classify this same set of stimuli. Finally, we use the results of these two sets of analyses to discuss some issues related to the statistical and to the biological classification of chick-a-dee call notes.

II. METHODS

The animals, recording procedure, acoustic measurements, and analyses have been published previously (Charrier *et al.*, 2004) and will be outlined only briefly here.

A. Animals

Six male and four female adult black-capped chickadees were captured during the winters of 2002 and 2003 from two locations in Alberta. Birds were housed in individual cages, had *ad libitum* access to food and were maintained on natural day–night cycle typical for the season in Edmonton and at approximately 20 °C.

B. Recording procedure, signal acquisition, and analysis

Each bird was recorded until we had a sample of at least 20 calls for each bird. Recordings (effective frequency range: 90–12 000 Hz) were digitized at 44 100 Hz, 16 bit samples/s using a 16 bit DartDisk Direct-to-Disk recorder (Engineering Design, Belmont, Massachusetts, USA). Calls were analyzed using SIGNAL version 4.0 (Engineering Design 2003).

From a sample of 100 calls, 370 non-D (i.e., A, B, and C) notes were visually classified and measured (205 A notes, 134 B notes, and 31 C notes) as was described in a previous paper (Charrier *et al.*, 2004). Nine acoustic features, partially based on the methods described in Nowicki and Nelson (1990), were measured including: start frequency (SF in hertz), peak frequency (PF in hertz), end frequency (EF in hertz) all of which were measured on a digital spectrogram [window size=1024 points, frequency precision=43 Hz; Fig. 2(a)] using a cutoff amplitude of −35 dB relative to the peak amplitude in the note. We also measured the loudest frequency (F_{max} in hertz) using a power spectrum [average window size=4096 points, frequency precision=11 Hz; Fig. 2(c)]. The duration measurements included were ascending duration (AD in milliseconds), descending duration (DD in milliseconds), and total duration (TD in milliseconds), and were measured on a digital spectrogram [window size =256 points, temporal precision=5.8 ms; Fig. 2(b)].

Two other measurements of frequency modulation were also made: the slope of the ascending frequency modulation [FM_{asc} in hertz per milliseconds following the formula (PF–SF)/AD] and the slope of the descending frequency modulation [FM_{desc} in hertz per milliseconds following the formula (EF–PF)/ DD].

C. Data preprocessing

There is a tremendous range in the values of the different input features that were described earlier. This raised a concern about how the artificial neural networks would perform on these raw data, because the processing units of the networks must "squash" input values into a narrow range of from zero to one. We decided to preprocess the data in such a way that the range of the input features would be reduced, but the essential characteristics of the raw data would be unchanged. This was accomplished by normalizing the value of each feature. That is, for each feature we took the 370 features values and converted them into z-scores. This preprocessed data served as the input to both of the different classification tools that are described in the following.

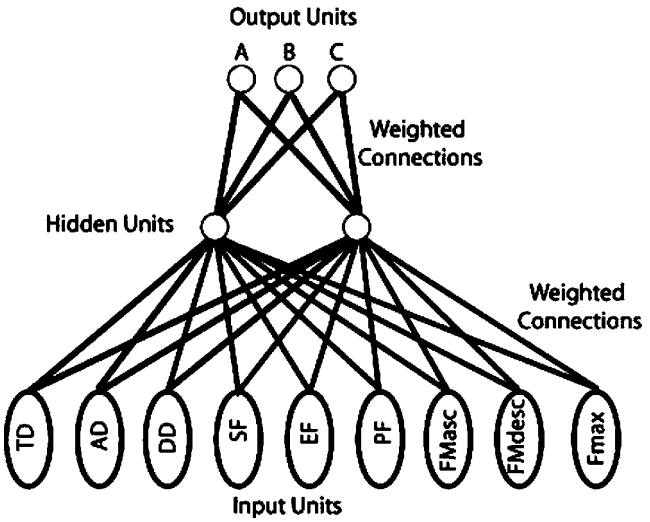

FIG. 3. An example multilayer perceptron. The network trained in the current manuscript is illustrated in which two hidden units processed the values of nine input features in order to assign a note to one of three different output categories.

D. Note classification by artificial neural networks: A brief introduction to artificial neural networks

An artificial neural network is a computer simulation of a "brain-like" system of interconnected processing units (see Fig. 3). In general, such a network can be viewed as a multiple-layer system that generates a desired response to an input stimulus. The stimulus is provided by the environment, and is encoded as a pattern of activity in a set of input units. The response of the system is represented as a pattern of activity in the network's output units. Intervening layers of processors in the system, called hidden units, detect features in the input stimulus that allow the network to make a correct or appropriate response.

The behavior of a single processing unit in this system can be characterized as follows: First, the unit computes the total signal being sent to it by other processors in the network. Second, the unit adopts a particular level of internal activation on the basis of this computed signal. Third, the unit generates its own signal, which is based on its level of internal activity, and sends this signal on to other processors.

The signal sent by one processor to another is transmitted through a weighted connection, which amplifies or attenuates a numerical signal being sent through it. This is accomplished by multiplying the signal's value by the weight associated with the connection. The weight defines the nature and strength of the connection. For example, inhibitory connections are defined with negative weights, and excitatory connections are defined with positive weights. Strong connections have strong weights (i.e., the absolute value of the weight is large), while weak connections have near-zero weights.

The pattern of connectivity in an artificial neural network (i.e., the network's entire set of connection weights)

defines how signals flow between the processors. As a result, a network's connection weights are analogous to a program in a conventional computer (Smolensky, 1988). However, in contrast to a conventional computer, an artificial neural network is not given an explicit program to perform some desired task. Instead, the network is taught to do the task.

Multiple layer networks (i.e., networks that contain one or more layers of hidden units), are frequently trained with a learning procedure called the generalized delta rule (Rumelhart *et al.*, 1986). One starts with a network that has small, randomly assigned connection weights. The network is then taught by presenting it a set of training patterns, each of which is associated with a known correct response. Each pattern is presented to the network's input units, and (on the basis of its existing connection weights) the network generates a response to it. An error term for each output unit is calculated by measuring the difference between the desired response of the unit and its actual response.

Error is used to modify connection weights by sending it backwards through the network. Once the error term for each output unit has been calculated, the weights of the connections directly attached to each output unit are modified. Then the output units send their error as a signal through the modified connections to the next layer of hidden units. Each hidden unit computes its overall error by treating the incoming error signals as net input (i.e., a hidden unit's total error is the sum of the weighted error signals that it is receiving from each output unit). Once a hidden unit has computed its overall error, then the weights of the connections that are directly attached to it can be modified. This process can be repeated, if necessary, to send error signals to the next layer of hidden units, and stops once all of the connections in the network have been modified. By repeating this procedure a large number of times for each pattern in the training set, the network's response errors for each pattern can be reduced to near zero. At the end of this training, the network will have a very specific pattern of connectivity (in comparison to its random start), and will have learned to perform a particular stimulus/response pairing.

E. Network architecture

The network trained in this study was a multilayer perceptron with 9 input units, 2 hidden units, and 3 output units (see Fig. 3). Each input unit was used to represent one of the 9 spectrogram features; the input data for network training is identical to that used as predictors in the discriminant analysis reported later. Each input unit was connected to each hidden unit, and each hidden unit was connected to each output unit. There were no direct connections between input units and output units. The hidden units and the output units used the sigmoid-shaped logistic function to convert their incoming signals into internal activity that ranged between 0 and 1.

The network was trained to activate an appropriate output unit to classify a 9-feature input pattern. If the input pattern was an "A" note, then the network was trained to turn the first output unit on (and to turn the other two output units off). If the input pattern was a "B" note, then the network was trained to turn the second output unit on. If the input pattern was a "C" note, then the network was trained to turn the third output unit on.

TABLE I. Classification of three types of input notes (first column) into three note classes by an artificial neural network.

	Note type according to artificial neural network			
Note type from visual examination	A	B	C	% correct
A	203	3	0	98.5
B	1	132	1	98.5
C	0	0	30	100
Total	195	144	31	98.6

F. Training

The ANN was trained using generalized delta rule. Initially, all connection weights were randomly assigned values between 0.1 and −0.1. The biases of the output unit and the two hidden units (which are analogous to neuronal thresholds) were initialized to a value of 0. The network was trained with a learning rate of 0.1 and zero momentum. Weights and biases were updated after the presentation of each training pattern. Each input pattern was presented once during a training epoch. Prior to each epoch, the order of presentation of the individual patterns was randomized. Pilot studies had indicated that the ANN never converged to a perfect solution to this problem—that is, it never learned to classify all of the notes with 100% accuracy. As a result, the achievement of perfect performance could not be used as a criterion to terminate training. Instead, the network was trained to the point that total network error (i.e., the sum of squared errors, with the sum taken over all of the output units and all of the training patterns) reached an acceptably low level. For the network reported in this paper, this was accomplished after training it for 2000 epochs. At the end of this amount of training, network SSE was 6.02. As is shown in the following, this level of SSE is associated with a very satisfactory degree of classification performance.

III. RESULTS

A. Network performance

The first question of interest at the end of network training concerns the amount of agreement between the visual classification of note types and the classifications performed by the network. In order to make this comparison, we first converted the activation patterns in the network's three output units into a specific note classification (A, B, or C). This was easily accomplished, because for each of the input notes, one of the output units generated activity of 0.9 or higher, while the other output units generated activity of 0.1 or lower. We classified the network's response by assigning it the note name associated with the output unit that was producing high activity. Table I provides the relationship between the visual classifications and the network classifica-

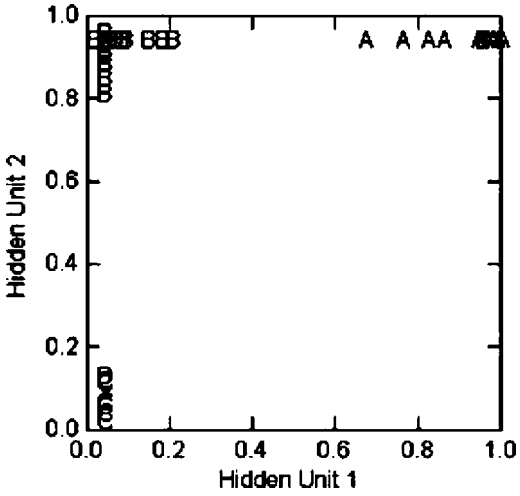

FIG. 4. The distribution of note types as a function of the activity produced in each hidden unit. See the text for details.

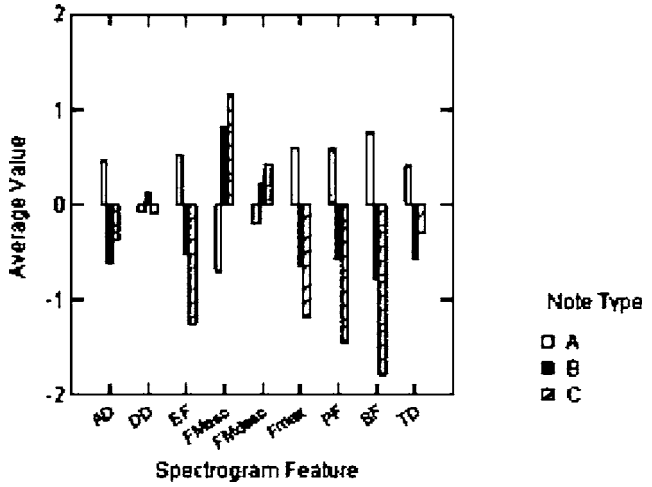

FIG. 5. Average values of the normalized features for each of the three note types. See the text for details.

tions. As can be seen from that table, the network was extremely accurate, misclassifying only 5 of the 370 stimuli for an accuracy level of 98.6%.

How is the network capable of performing at this high level? Some information relevant to answering this question can be obtained by examining the responses of the hidden units to all of the input patterns. In this network, the role of the hidden units is to map each pattern from a nine-dimensional space defined by the input features into a two-dimensional space defined by hidden unit activity. That is, each pattern can be described as a point in a two-dimensional space in which the coordinates of the point are provided by the activities produced by the pattern in the two hidden units.

A graph of this space is provided in Fig. 4. In this graph, each input pattern is represented as a letter that provides the note's type according to visual classification. By examining this graph, it appears that the two hidden units have very well defined functional roles. Hidden unit 1 is an "A-note detector," producing high activity to notes that belong to the A category, and producing little activity to other notes. In contrast, hidden unit 2 is a "not-C note detector," producing high activities to notes that do not belong to the C class, and producing near zero activities to notes that do belong to this class. These two hidden units classify notes as follow, then: if hidden units 1 and 2 are both on, the note is assigned to class A. If hidden units 1 and 2 are both off, then the note is assigned to class C. If hidden unit 1 is off, and hidden unit 2 is on, then the note is assigned to class B. This classification scheme works for 365 of the 370 notes in the training set.

How do these two hidden units respond in this fashion to discriminate between the different note types? One approach to answering this question requires an examination of the average feature profile of each note type in relation to the size of the connection weights that feed into each hidden unit.

Figure 5 provides the first type of information that is required for this interpretation. It is a graph of the average feature values for each of the three different note types in the training set. Two important observations follow from this graph. First, the feature profile for the average A note is markedly opposite to the feature profiles for the other two note types—the bars for each of its features point in an opposite direction than do the corresponding bars for the other two note types. Indeed, when the profile of the A note in Fig. 5 is correlated with the B note profile, the result is −0.99. When the A note profile is correlated with the C note profile, the result is −0.94.

The second important observation from this graph is the similarity of the profiles for B and C notes. For almost all of the features, the bars for these two notes presented in Fig. 5 point in the same direction. The correlation between these two profiles is 0.89. The difference between the two notes, as indicated in Fig. 5, would appear to be the fact that for many of the features the average C note has a more extreme value than does the average B note.

In order for a hidden unit to differentially respond to the various note types, the connection weights that feed into the hidden unit must transform the input features in such a way that the total signal is high for some notes (causing the hidden unit to activate) and is low for other notes (preventing the hidden unit from activating). Consider hidden unit 1, which generates high activity to A notes, and which generates little activity to B or C notes. The connection weights for this unit are presented in Table II. The bias for this unit, which is analogous to the unit's threshold, is also presented in Table II. The total signal coming into this unit from a pattern is equal to the sum of the input values of the features, after these input values have been multiplied by the weights. This signal is then combined with the bias, and passed as an input into the logistic equation $[f(net_i)=1/(1+\exp(-net_i+\theta_j))$, where net_i is the total signal and θ_j is the bias] to convert net input into an activation value that falls in the range from 0 to 1.

The connection weights for hidden unit 1 are arranged in such a way that A note features tend to generate high positive net inputs, while features from the other two note types generate strong negative net inputs. For example, if the average feature values of an A note from Fig. 5 are converted into a net input using the weights in Table II, the result is 31.36. In contrast, the average feature values of a B note produce a net

TABLE II. Connection weights from the 9 input units (features) to the two hidden units of the network. The bias of each hidden unit—analogous to a threshold—is also provided.

Input unit	Hidden unit	
	1	2
Unit bias	6.55	28.33
TD	−2.20	−4.08
AD	−0.05	−0.57
DD	−4.24	10.82
SF	33.88	29.80
PF	8.73	−9.36
EF	−16.20	1.94
FM_{asc}	−7.11	4.41
FM_{desc}	1.96	−6.06
F_{max}	−2.80	0.04

input of −19.08, and the average feature values of a C note produce a net input of −49.18. Clearly, if one views the weights feeding into this hidden unit as a vector, then the orientation of this vector is far more similar to the orientation of the vector an average set of A note features than to the orientation of the vectors representing B and C notes.

This is not to say that all of the input features have equal importance in determining the response of hidden unit 1. The following regression equation includes only those input features that were found to be significant predictors of hidden unit 1's activity, and accounted for 80.1% of the variance in this activity ($F_{5364}=293.83, p<0.0001$):

$$\mathrm{H1}_{\mathrm{activity}} = 0.375\ \mathrm{SF} - 0.114\ \mathrm{EF} - 0.114\ \mathrm{FM}_{\mathrm{asc}} + 0.059\ F_{\max} - 0.039\ \mathrm{TD} + 0.550.$$

From Fig. 5, it can be seen that all of these features correspond to average feature values that demonstrate the largest differences between A notes and the other two note types. The one exception is peak frequency (PF). However, this feature has a very large correlation with F_{max} ($r=0.964$), and because of this redundancy the inclusion of PF in the regression equation would not provide a significant increase in predictive power.

A similar analysis can be provided for hidden unit 2, whose connection weights and bias are also presented in Table II. This hidden unit has a different function than hidden unit 1: it generates low responses to C notes, and high responses to the other two note types. Again, this is because the orientation of its weight vector is more similar to the orientation of the average feature vectors for A and B notes, and much less similar to the orientation of the average feature vector for a C note. When average features for A and B notes are combined with the Table II weights to produce hidden unit 2 net input, the results are 42.19 and 15.84, respectively. In contrast, when the average features of a C note are used to determine net input, the result is −10.54.

Again, not all nine input features are equally important for determining the activity of this hidden unit. The following regression equation includes only those input features that were found to be significant predictors of hidden unit 1's activity, and accounted for 47.0% of the variance in this activity ($F_{6363}=53.60, p<0.0001$):

$$\mathrm{H2}_{\mathrm{activity}} = 0.332\ \mathrm{SF} - 0.214\ F_{\max} + 0.152\ \mathrm{PF} - 0.098\ \mathrm{TD} + 0.087\ \mathrm{FM}_{\mathrm{asc}} + 0.042\ \mathrm{DD} + 0.916.$$

From Fig. 5, it can be seen that many of these features correspond to average feature values that demonstrate the largest differences between A notes and the other two note types. Indeed, there are numerous features shared in both regression equations. Interestingly, this equation includes PF and not EF, these two features have a high correlation with each other ($r=0.672$), and EF also has a high correlation with F_{max} ($r=0.68$). This equation also includes an additional variable not found in the first regression equation, DD.

B. Note classification using discriminant analysis

The previous section demonstrated that a neural network is able to classify chick-a-dee call notes, described in terms of a small set of spectrogram features, with a very high degree of accuracy. This was accomplished by having two different hidden units separate one note type from the other two (in one case, A from B and C; in the other, A and B from C), and by then combining the activities of these hidden units to segregate all three note types. The hidden units operated by weighting input features in such a way to maximize the distinction between note types, and appeared to favor features that seem to distinguish note types (Fig. 5). Therefore it may not be surprising, though it is interesting, to find that both hidden units are sensitive to an overlapping set of note features, though they weight these features differently, and that one hidden unit is also sensitive to a handful of features that the other unit is not sensitive to.

While these results are encouraging, it is important to compare them to those produced by alternative classification methods. For instance, can traditional statistical methods perform this classification task as well as the neural network did? If so, do these methods use the same sets of features, or do they use an alternative method to classify notes? In this section, we investigate these questions by using discriminant analysis to categorize notes using the identical data that were presented to the neural network that was described previously.

C. Discriminant analysis

When researchers are faced with data cases that can be assigned to a set of predefined classes, they often classify the data using discriminant analysis (e.g., Klecka, 1980), although Nowicki and Nelson (1990) did not study this method. Discriminant analysis is similar in many ways to multiple regression. Discriminant analysis determines a set of discriminant functions that can be used to categorize each instance. Each discriminant function has the form of a regression equation, $L=b_1x_1+b_2x_2+\cdots+b_nx_n+c$, where L is the value of the function, each b_i is a discriminant coeffi-

TABLE III. Classification of three types of input notes (first column) into three note classes by discriminant analysis.

Note type from visual examination	Note type according to discriminant analysis A	B	C	% correct
A	193	13	0	94
B	2	129	3	96
C	0	2	28	93
Total	195	144	31	95

cient, each x_i is a predictor variable, and c is a constant. If there are k different classes that cases can be assigned to, then discriminant analysis will compute a set of k different discriminant functions. The coefficients of these functions are selected in such a way that classification errors are minimized. A case is classified by providing its input features as the predictors for each of the discriminant functions. The case is assigned to the class whose discriminant function generates the maximum value.

We used discriminant analysis to classify the 370 notes into the three predefined classes of A, B, and C on the basis of the 9 input features that were described earlier. Table III provides the classification matrix that was produced from this analysis. In general, while discriminant analysis was slightly poorer at classifying the note types than was the artificial neural network, its performance was still excellent: it correctly classified 95% of the 370 notes.

As noted earlier, in order to make the classifications that are summarized in Table III, three different discriminant functions—one for each note type—had to be computed. Each of these functions is similar to the connection weights that were presented in Table II, insofar as each discriminant function is a set of coefficients that are used to weight an input pattern's features to make a classification decision. The constants and discriminant coefficients for the three discriminant functions are provided in Table IV.

As was the case for the two hidden units of the neural network, not all of the input features are equally important contributors to the discriminant functions. Table V provides the F-test of the contribution of each predictor variable to the set of discriminant functions. As can be seen from Table V, six of the nine note features were statistically significant predictors. Table V reveals a striking similarity between the discriminant analysis of the notes and the classifications made by the artificial neural network. All six of the statistically significant contributors in Table V also appear in at least one of the regression equations that were reported earlier; four of the six appear in both of the regression equations. This suggests that the classification power of both techniques may be rooted in processing similar sets of features. Only one feature (DD) was not a significant contributor in the table below, but was a significant contributor in the regression equation that predicted the activity of hidden unit 2.

The similarities between the discriminant analysis and the artificial neural network, in terms of their sensitivity to input features, suggest that a more detailed comparison of the two is in order. Table VI provides such a comparison. It presents the correlations between the two sets of connection weights in Table II (excluding the biases) and the three sets of coefficients in Table IV (excluding the constants).

These correlations are very informative. First, consider the correlations among the three sets of coefficients. The discriminant function for A notes has a strong negative correlation with the other two discriminant functions; however, the discriminant functions for B and C notes have a strong

TABLE IV. Discriminant coefficients for the three discriminant functions used to classify the 370 notes into classes A, B, and C on the basis of the 9 predictors listed in the leftmost column.

Predictor	Discriminant Function A	B	C
Constant	−3.027	−3.033	−14.696

TABLE VI. Pearson product moment correlations between the two vectors of connection weights that feed into the neural network's hidden units and the three vectors of coefficients for the discriminant functions.

	H1 weights	H2 weights	A function	B function	C function
Weights for hidden unit 1	1.000				
Weights for hidden unit 2	0.600	1.000			
Discriminant function for A	0.958	0.649	1.000		
Discriminant function for B notes	−0.979	−0.663	−0.966	1.000	
Discriminant function for C notes	−0.860	−0.583	−0.958	0.851	1.000

positive correlation. This suggests that the discriminant functions are taking advantage of the same regularities in note properties that the artificial neural network also exploited. Recall from Fig. 5 that, on average, A notes have an opposite feature profile to both B and C notes, while B and C notes have similar profiles, but that C notes tend to have more extreme feature values. The relationships between notes in Fig. 5 are consistent with the correlations between discriminant function coefficients in Table VI.

Now consider the correlation between the connection weights and the discriminant function coefficients. Recall that in order to be classified as an A note, a note's features must produce higher activity in the A function than in the other two discriminant equations. In this sense, the discriminant function for A notes has exactly the same function as hidden unit 1 in the network, which only generates high activity to A notes. One can see in Table VI that this similarity in function is reflected in the strikingly high correlation between the weights for hidden unit 1 and the discriminant function for A notes. Convergent evidence for this is reflected in the extreme negative correlations between these weights and the other two sets of coefficients; this mirrors the relationship between the A function coefficients and the other two sets of coefficients. In short, the mechanisms feeding into hidden unit 1 are functionally equivalent to the discriminant function for classifying A notes.

In contrast, the relationship between the connection weights for hidden unit 2 and the discriminant functions is less clear. On the one hand, the correlations are all quite strong, and show the same general pattern as the weights for hidden unit 1: a positive relationship with the A function's coefficients, and a negative relationship with the other two sets of coefficients. This is to be expected, perhaps, because of the relationships between average note profiles in Fig. 5, which showed an opposite trend of features between A notes and the other two note types. This is also to be expected because there is a strong positive correlation between the two sets of connection weights, indicating that they should have similar relationships to the three discriminant functions.

On the other hand, because none of the correlations involving the weights of hidden unit 2 are as high as those for hidden unit 1, we are not in a position to declare any functional equivalence. However, this is completely consistent with our previous analysis of that unit (e.g., Fig. 4). Hidden unit 2 generates high activity to A notes or B notes, and does not respond to C notes. Therefore its behavior, unlike that of hidden unit 1, is much less likely to be directly related to any one of the discriminant functions.

IV. DISCUSSION

It was noted earlier that there are two important and related issues concerning note identification in the chick-a-dee call. The first is the development of an objective research tool for identifying note types in the lab. The second is the development of a theory about how the birds themselves process the acoustic signal to identify the different note types.

With respect to the first issue, the above-reported results are significant in several respects. They show that two very different techniques—artificial neural networks and linear discriminant analysis—are capable of classifying notes with a very high degree of accuracy. This is the case even when the large amount of information contained in a spectrogram is reduced to a small, manageable set of descriptive features. For our stimuli, the artificial neural network achieved an accuracy level of over 98%, and discriminant analysis achieved an accuracy level of 95%, for a relatively large set of stimuli (370 notes). The fact that both techniques performed so well would indicate that there is little reason to prefer one technique over another. Either method would perform extremely well as a note classification tool in a research lab.

With respect to the second issue, our analysis of the methods by which both techniques classified notes provides some important information to be considered in the development of a theory of how the birds themselves process acoustic signals to classify notes.

First, both the neural network and the discriminant analysis were able to classify notes by focusing on a particular subset of acoustic features. From a statistical perspective, it would appear that these features are particularly useful for note classification. The empirical issue that this observation raises is whether black-capped chickadees also focus on these features when they process this call.

Recent research from our laboratory suggests that in fact, black-capped chickadees do in fact attend to at least a subset of the acoustic features described here. Charrier *et al.* (2005) trained black-capped chickadees on four different note type discrimination tasks, A+B−, A−B+, B+C− and B−C+, and then conducted transfer tests with two sets of probe stimuli to determine to which features birds were attending in order to solve the task. Test notes were either pitch shifted, with the overall pitch of the note shifted up or down in frequency, or truncated notes, with either the ascending portion or descending portion presented. The results of these tests were quite clear. When notes were shifted in pitch toward the pitch space of another note type (e.g., when A notes had their overall note pitch lowered closer to that typical for B notes) the perception of that note also shifted from one type to the next. Further, birds could discriminate among note types using only the ascending portion of the note, and could generally do so better than using the descending portion of the note. This suggests that pitch cues contained in the notes such as SF, PF, EF and F_{max}, as well as particular "dynamic" temporal/spectral cues such as FM_{asc}, are salient to the birds and control the perception of note types in the chick-a-dee call. Interestingly, these same features also appear to contribute to the functioning of the ANN reported here, based on the interpretation of the activity of hidden units 1 and 2, and, suggesting that perhaps the ANN is tapping into similar features when it sorts notes as when the birds themselves do an analogous task.

A second important piece of information, related to the first, is the fact that both statistical techniques took advantage of the fact that when notes are described as normalized sets of summary features, B and C notes are more related to one another (and therefore harder to discriminate from one

another), while A notes seem quite different (Fig. 5). This was reflected in the patterns of correlations among the three sets of discriminant function coefficients, and in the fact that one of the functional components of the neural network was an A note detector. Again, this raises empirical questions about how birds process this call. Which note types do they appear to have more trouble discriminating? If they behave as if A notes are easier to differentiate than the other two note types, then this would suggest that the birds are processing a similar set of features as those represented in Fig. 5. However, if a different pattern of difficulties is in evidence, then this would suggest that the birds are processing different feature profiles.

Initial research on note type perception (Sturdy *et al.*, 2000) did in fact suggest that birds confused A, B, and C note types. When the pattern of errors was more closely examined, some interesting patterns emerged. Rewarded A note were confused with unrewarded B notes, rewarded B notes were confused with unrewarded A *and* unrewarded C notes, and rewarded C notes were confused with unrewarded B notes. These results, of an apparent perceptual continuum from A to B to C notes, mirrored the observation made earlier by Hailman *et al.* (1985) of a production continuum in these same notes types when the call is produced. Said another way, A notes, although sometimes confused, are only confused with one note type, B notes, whereas B notes are confused with both A and C note types. C notes are confused with B notes more than A notes, but Sturdy *et al.* also found that there was a trend for C notes to be confused with the next note type in the call sequence, D notes, not analyzed in the current paper. These findings provides some support, albeit indirectly, for the notion that both the birds and the ANN have difficulty in similar note type assignments, with A notes being misclassified less often than either B or C notes. This notion would have to be tested directly, perhaps by determining the number of notes of each type that a bird could discriminate, and to what level of accuracy, possibly in a choice task that required the discrimination and classification of all three note-types simultaneously, in a fashion similar to that of the ANN.

A third important point of information is that while the two techniques that we studied demonstrated similarities in features being processed, and also demonstrated some functional similarities, there were important differences between them too. The key similarity between the two techniques was that both included a distinct detector for A notes. By definition, the discriminant analysis produced distinct detectors for B and for C notes as well. Importantly, the artificial neural network did not develop these latter two types of detectors. Instead, its second hidden unit was an A or B note detector, which only turned off to C notes.

This difference between the two techniques demonstrates two different representational formats. In a local representation, each functional component of a system has a particular localized role, and can perform a meaningful task independently of the other functional components. The three discriminant functions created by the discriminant analysis are example of such local functional components. In contrast, artificial neural networks often develop distributed codes (Dawson, 2004; Dawson *et al.*, 2000a; Dawson *et al.*, 2000b; Dawson and Piercey, 2001; Hinton *et al.*, 1986; Leighton and Dawson, 2001). In a distributed code, different functional components of a system may not individually function in a fashion that can be directly related to the system's output. Instead, the meaningfulness of the functional components requires that their separate functions be considered simultaneously. The artificial neural network demonstrated this kind of representation. While the one hidden unit can be considered as being a local component (an A note detector), the behavior of the second hidden unit only makes sense when considered in the context of the behavior of hidden unit 1. That is, the representation is distributed because whether a note is an A, B, or C requires considering the activities of both hidden units at the same time (see the previous discussion of Fig. 4).

This is an important point for developing a theory of how birds process acoustic signals because it demonstrates that even when one focuses on the same set of features, there are different ways in which these features can be combined or processed to mediate note classification. The two techniques that we have described in this paper demonstrate two different approaches to using similar sets of features to make the same kind of classification. As theories of how chickadees process acoustic signals become related to the brain, one issue to address is whether acoustic features are represented in a local or distributed fashion. One advantage of artificial neural networks is that they provide examples of possible neural representations that can be used to guide this aspect of theory development (Dawson, 2004).

(Received 10 October 2005; revised 24 January 2006; accepted 14 February 2006)

Simultaneous tone-tone masking in conjunction with the envelope-following response (EFR) recording was used to obtain tuning curves in porpoises *Phocoena phocoena* and *Neophocaena phocaenoides asiaeorientalis*. The EFR was evoked by amplitude-modulated probes with a modulation rate of 1000 Hz and carrier frequencies from 22.5 to 140 kHz. Equivalent rectangular quality Q_{ERB} of the obtained tuning curves varied from 8.3–8.6 at lower (22.5–32 kHz) probe frequencies to 44.8–47.4 at high (128–140 kHz) frequencies. The Q_{ERB} dependence on probe frequency could be approximated by regression lines with a slope of 0.83 to 0.86 in log-log scale, which corresponded to almost frequency-proportional quality and almost constant bandwidth of 3–4 kHz. Thus, the frequency representation in the porpoise auditory system is much closer to a constant-bandwidth rather that to a constant-quality manner. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184290]

I. INTRODUCTION

The auditory system of mammals functions as a bank of frequency-tuned bandbass filters which performs frequency analysis of sound signals. In the majority of mammals, passbands of these filters are roughly frequency proportional (except lowest frequencies); in other words, filter quality (the ratio of center frequency to the passband width) is almost constant throughout a major part of the frequency range of hearing. This feature is known as a constant-Q (quality) representation of frequencies in the auditory system. In humans, this regularity is known from the very first measurements of critical ratios (Fletcher, 1940) and critical bands, which are psychophysical equivalents of auditory filters (Zwicker, 1961). Later this regularity was confirmed in a variety of psychophysical investigations in humans with the use of various paradigms of frequency-tuning measurements: frequency-tuning curves [see Zwicker (1974) for a review], narrow-band noise masking [critical bands, see Zwicker (1982) for a review], notch-noise masking (Patterson, 1976; Patterson *et al.*, 1982), not to mention numerous other studies. To summarize the great number of psychophysical investigations, several analytical expressions have been proposed to describe filter bandwidth variation with central frequency (Greenwood, 1961; Zwicker and Terhardt, 1980; Moore and Glasberg, 1983; Glasberg and Moore, 1990). All of them are rather close to one another. For example, a simple equation given by Glasberg and Moore (1990) may be considered. Its original form suggested by the authors is

$$\mathrm{ERB} = 24.7(4.37F + 1), \tag{1}$$

where ERB is the filter equivalent rectangular bandwidth in Hz and F is the central frequency in kHz. With expression of both ERB and frequency in equal units, this equation may be presented as

$$\mathrm{ERB} = 0.108F + 24.7\ \mathrm{Hz}, \tag{2}$$

where F is frequency expressed in the same units as ERB. That is, at all frequencies above a few hundred Hz, where the constant of 24.7 Hz can be neglected, the filter bandwidth is of an almost constant proportion (10.8%) of frequency; respectively, the filter quality Q_{ERB} is constant and equal to $1/0.108 = 9.26$.

The very same regularity has been demonstrated by tuning curves obtained in humans and some mammals using evoked potentials such as cochlear action potentials (AP) (Dallos and Cheatham, 1976; Eggermont, 1977; Harris, 1978; Abbas and Gorga, 1981; Gorga and Abbas, 1981; Harrison *et al.*, 1981) and auditory brain-stem responses (ABRs) (Mitchell and Fowler, 1980; Salvi *et al.*, 1982; Gorga *et al.*, 1983; Brown and Abbas, 1987). The majority of these studies presented the quality of the obtained tuning curves as Q_{10} (the center frequency divided by the bandwidth at a level 10 dB above the tip of the curve) which is about twice lower than Q_{ERB}, but the principal result was the same: the quality was almost constant throughout a wide frequency range.

[a]Electronic mail: popov_vl@sevin.ru
[b]Electronic mail: alex_supin@sevin.ru
[c]Electronic mail: wangd@ihb.ac.cn
[d]Electronic mail: wangk@ihb.ac.cn

These and many other data led to a generally adopted idea that each relative frequency unit (e.g., octave) occupies a constant space on the basilar membrane (about 4 mm per octave in humans), as well as each critical band occuping a constant space (Greenwood, 1961). The result is a frequency-proportional filter (or critical band) width, which is the same as a constant filter quality.

The only well-known significant deviation from this rule is the auditory system of mustache bats. It has expanded representation of a narrow (a few kHz) frequency band around 60 kHz with much higher filter quality than at frequencies both above and below this "acoustic fovea" (e.g., Suga, 1978; Pollak and Casseday, 1989; Pollak, 1992). This exception of a common rule is obviously associated with properties of the biosonar of mustache bats, which employs narrow-band acoustic pulses of around 60-kHz frequency and requires very fine frequency analysis in just this frequency range to detect Doppler shift arising due to movement of the prey.

In the study described herein, we encountered another intriguing deviation from the rule of constant-Q frequency representation in the auditory system. We investigated hearing abilities of porpoises (Phocoenidae, Cetacea). The investigations of hearing of these small cetaceans were motivated both by concern for their protection and conservation and for their unique bioacoustics. Similar to many other odontocetes (toothed whales, dolphins, and porpoises), phocoenids have extremely wide frequency range (more than 150 kHz) and high sensitivity of hearing, obviously associated with their ability to echolocate (rev. Au, 1993; Supin *et al.*, 2001). However, contrary to many other odontocetes, phocoenids use for echolocation narrow-band pips instead of wide-band clicks (Dubrovskii *et al.*, 1971; Møhl and Andersen, 1973; Kamminga *et al.*, 1986, 1996; Kamminga, 1988; Li *et al.*, 2005). Therefore, some specific features of frequency tuning of hearing might be expected. Bearing this in mind, measurements of frequency tuning of porpoise's hearing were carried out. The measurements were done with use of the evoked-potential method in conjunction with the simultaneous tone-tone masking paradigm. The tone-tone masking (both the probe and masker are tones) provides tuning curves (masked thresholds as a function of frequency difference between the probe and masker) which reflects the auditory frequency-tuned filter form. The use of tuning-curve paradigm in conjunction with evoked-potential recording has already demonstrated its effectiveness for measurements of frequency tuning of hearing in a few species of cetaceans (Supin *et al.*, 1993; Popov *et al.*, 1995; Supin *et al.*, 2001). Therefore, the same method was used to investigate hearing of porpoises. These measurements provided unexpected results indicative of frequency representation more close to *constant-B* (bandwidth) rather than to *constant-Q* (quality). These results are presented herein.

II. METHODS

A. Subjects, facilities, and experimental design

Experimental animals were one harbor porpoise *Phocoena phocoena* (an adult female) and two Yangtze finless porpoises *Neophocaena phocaenoides asiaeorientialis*, a male and female.

Investigation of the harbor porpoise was carried out in facilities of the Utrish Marine Station of the Russian Academy of Sciences, Black Sea coast, Russia. The animal was kept in a pool ($9\times4\times1.2$ m^3) filled with sea water. During the experiment, the animal was taken from the home pool and placed on a stretcher in a plastic bath $4\times0.6\times0.6$ m^3 filled with sea water in such a manner that the dorsal surface of the head with the blowhole remained above the water surface. The walls and bottom of the bath and the water surface in front of the animal's head were covered by sound-absorbing material (rubber with cone-shaped closed air cavities) to reduce sound reflections and make the stimulus sound field more uniform.

Investigation of the finless porpoises was carried out in facilities of the Institute of Hydrobiology of the Chinese Academy of Sciences, Wuhan, P. R. China. The animals were kept in a pool ($20\times7\times3.0$ m^3) filled with fresh water. During the experiment, the animal was taken out of the home pool, placed on a stretcher in a wooden bath $2.25\times0.85\times0.6$ m^3 filled with water, and positioned in the same manner as the harbor porpoise. The walls and bottom of the bath were covered by open-cell neoprene to reduce sound reflection.

The care and use of all the animals were performed under the Guidelines of the Russian Ministry of Higher Education on the use of animals in biomedical research adhering to the Ethical Principles of the Acoustical Society of America.

B. Evoked-potential recording

The evoked-potential recording technique was similar for both the harbor porpoise and finless porpoises. For non-invasive evoked-potential recording, suction-cup electrodes were used consisting of a 15-mm stainless steel disk mounted within a 60-mm silicon suction cup. The active electrode was fixed at the vertex head surface, 5 cm behind the blowhole, above the water surface. The reference electrode was fixed at the dorsal or pectoral fin. The electrodes were connected by shielded cables to the input of a custom-made EEG amplifier that provided 88-dB gain within a frequency range of 200 to 5000 Hz, as defined at −3-dB points of 6-dB/oct slopes. The amplified signal was digitized and collected using an E-6040 data acquisition board (National Instruments) and stored in computer memory. To extract signal from noise, the digitized signal was coherently averaged (1000 original records per one averaged record) using triggering from the stimulus onset.

C. Sound signals

Sound signals were digitally synthesized at an update rate of 500 kHz and digital-to-analog converted by the same E-6040 board, amplified, attenuated, and played through a B&K 8104 transducer. The transducer was positioned at a distance of 60 cm in front of the animal's head, near the front wall of the bath. The playback channel was calibrated both before and after the experiments by positioning a calibrated

receiving hydrophone (B&K 8103) at the same location as the animal's head. Both probe and masker levels are specified below as their rms values.

Two kinds of sound signals were used to obtain frequency-tuning curves: probes and maskers. Probes were 20-ms-long sinusoidally amplitude-modulated tone bursts, modulation rate was 1000 Hz, and modulation depth was 100%. These parameters of modulation were chosen since they are optimal to produce in odontocetes (dolphins and porpoises) a robust rhythmic evoked-potential response (Supin *et al.*, 2001). Carrier frequencies of probes varied from 22.5 to 140 kHz, separated by $\frac{1}{4}$- or $\frac{1}{8}$-oct steps. Modulation always started from a zero phase in coherence with evoked-response collection. The probe bursts were presented at a rate of 10 s^{-1}.

Maskers were continuous nonmodulated tones. Their frequencies varied around the probe-carrier frequency with steps of 0.5 to 1.5 kHz. Intensities of probes and maskers were varied by independent attenuators with 5-dB steps; after attenuation, the probe and masker were mixed and emitted through the common transducer.

Even though the walls of the baths were covered with sound-attenuating material, some sound reflections from the bath walls and water surface were inevitable, thus resulting in interference patterns in the small enclosed space. To assess the influence of these interference patterns on the stimulus parameters, sounds were monitored by a B&K 8103 hydrophone near the animal's head. The monitoring showed that despite the sound reflections within the bath, the real modulation depth of the stimuli remained not less than 70%–80%, and local sound levels varied by not more than 5 dB.

D. Masked threshold evaluation and tuning-curve derivation

For tuning-curve derivation, probe levels 40 dB above absolute ABR thresholds were used. Thus, at thresholds from 50 to 80 dB *re*:1 μPa depending on frequency (Popov *et al.*, 1995, 2005), probe levels varied from 90 to 120 dB *re*:1 μPa. For masked threshold evaluation, masker level was varied while keeping the probe level constant. A 16-ms-long part of the rhythmic evoked-potential response to the sinusoidally modulated probe stimulus, from 6 to 22 ms, was Fourier transformed to obtain its frequency spectrum. The magnitude of 1-kHz peak was plotted as a function of masker intensity and an oblique near-threshold part of the plot not longer than 20 dB was approximated by a straight regression line [the criteria for selection of a range for straight-line approximation are motivated in more detail by Supin *et al.* (2001)]. The intersection of this line with the zero-amplitude level was adopted as a masked threshold estimate. This threshold-determination procedure was repeated at 6 to 12 masker frequencies around the probe frequency. The resulting function of masked threshold versus masker frequency was taken as the tuning curve.

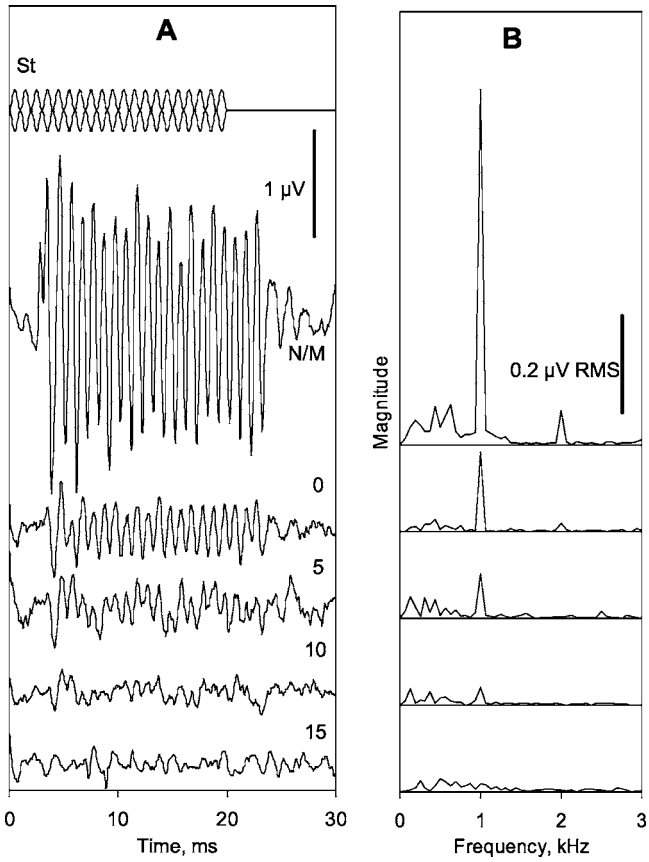

FIG. 1. Examples of EFR records (A) and their frequency spectra (B) at different masker-to-probe ratios. The finless porpoise, male. Probe 128 kHz, 90 dB *re*:1 μPa; masker 128 kHz, level (dB *re* probe) indicated near the records, N/M —no masker (control).

III. RESULTS

A. Evoked response waveform and manifestation of masking

Amplitude-modulated probe sounds evoked robust rhythmic responses, which followed the modulation rate, i.e., the envelope-following response (EFR). As Fig. 1(A) exemplifies, a probe of a moderate intensity (40 dB above the response threshold) without a masker evoked a response of more than 1 μV peak-to-peak amplitude (no-masker control). The burst onset evoked a small transient on-response, which after a few milliseconds transformed to EFR. Both the start and the end of the response appeared with a few ms lag relative to the stimulus. This lag provided a good opportunity to check artifact contamination of records. The response-free initial part of the records showed clearly that the records were not contaminated with electromagnetic artifacts; as well, the response persistence until about 4.5 ms after the stimulus end showed the physiological nature of the response.

The same probe in masker background evoked smaller responses. As the masker level increased (from 0 to 15 dB above the probe level in Fig. 1), EFR diminished until it disappeared in the noise.

Frequency spectra of the records are shown in Fig. 1(B). These spectra were obtained by Fourier transform of a part of the record, from 6 to 22 ms. This 16-ms window contained a

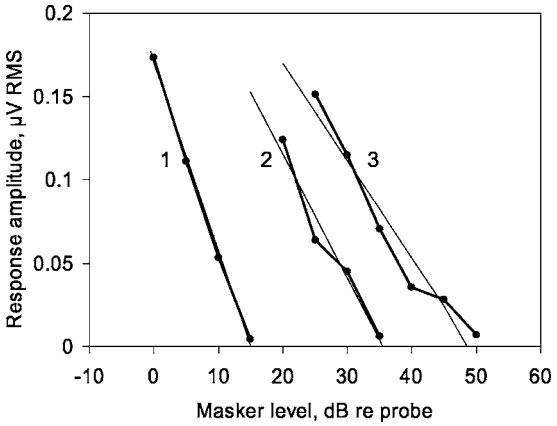

FIG. 2. EFR magnitude dependence on masker-to-probe ratio at different masker-to-probe frequency spacings. The finless porpoise, male. Probe 128 kHz, 90 dB *re*:1 μPa. Masker frequencies: 128 kHz (1), 131.5 kHz (2), and 135 kHz (3). Masker level (abscissa) in dB *re* probe level.

major part of the EFR record but did not contain the latency and the initial transient part of the response. At masker levels below 15 dB, all the spectra featured a peak at the probe envelope frequency of 1 kHz. At the masker level of 10 dB, this peak was comparable with the spectrum noise level but still definite, and at the masker level of 15 dB it completely disappeared.

Figure 2 demonstrates the masked threshold determination procedure. The magnitude of the 1-kHz peak of the response spectrum was taken as an estimate of the response magnitude and plotted against masker level. The near-threshold part of the plot could be satisfactorily approximated by a straight regression line crossing the zero-amplitude level in a point accepted as the threshold estimate.

As it usually is in the tuning-curve paradigm, masked thresholds depended on frequency difference between the probe and masker. The lowest masked threshold (i.e., the most effective masking) appeared at a coincidence of the probe and masker frequencies. With the difference increase, the masked threshold increased. Figure 2 exemplifies response amplitude versus masker intensity functions at three probe-to-masker frequency differences: (1) zero, (2) 3.5 kHz, and (3) 7 kHz. The example demonstrates increasing the masked threshold from 15.0 dB (relative to the probe level) at the zero difference to 35.5 dB at a 3.5-kHz difference and further to 48.6 dB at a 7-kHz difference.

Using the same procedure, masked thresholds were determined at a variety of masker frequencies around the probe frequency to obtain a tuning curve as a masked threshold versus masker frequency function (at a certain probe frequency). The same measurements were repeated at probe frequencies from 22.5 kHz (in the harbor porpoise) or 32 kHz (in the finless porpoises) to 140 kHz, thus obtaining a family of tuning curves. Lower probe frequencies were not tested since evoked-response amplitude was too low at lower frequencies [as described by Popov and Supin (2001)] and did not provide satisfactory precision of measurements. Higher probe frequencies were not tested because of proximity to the upper limit of the frequency range of hearing.

The family of tuning curves obtained from the harbor

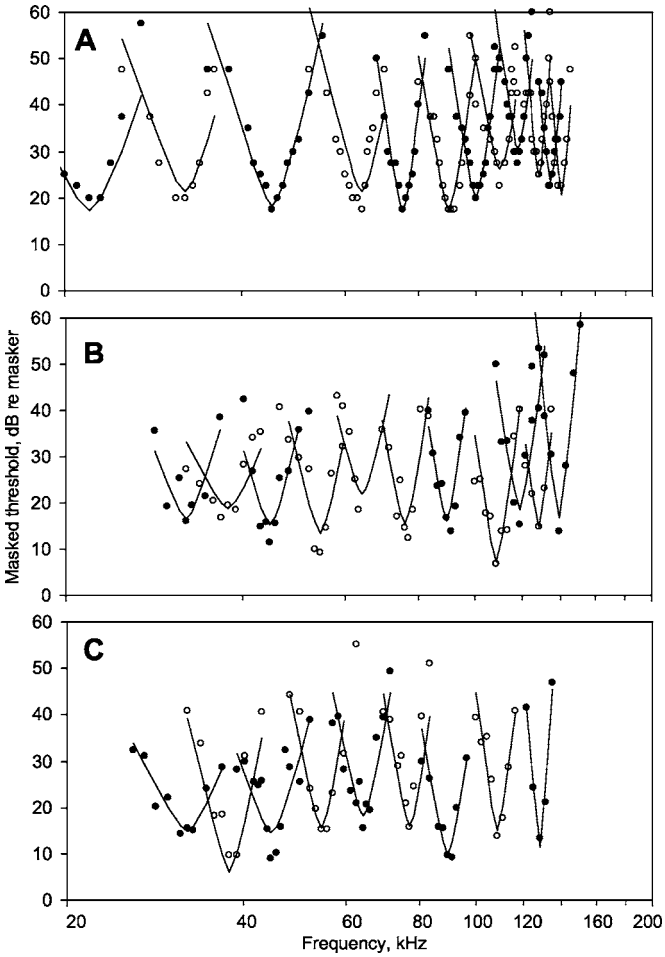

FIG. 3. Tuning curve families obtained in three subjects: the harbor porpoise (A), finless porpoise female (B), and finless porpoise male (C). The curves are masked thresholds as functions of masker frequency. Dots represent experimental data, curves—roex approximations.

porpoise is presented in Fig. 3(A), and similar families obtained in the finless porpoises are presented in Figs. 3(B) and 3(C). All the families looked rather similar. In particular, a noticeable feature of all the tuning curves was that they are not of a constant width when plotted on a log frequency scale, thus indicating nonconstant Q across the frequency scale: high-frequency tuning curves were much more acute than low-frequency ones.

In order to characterize the curves quantitatively, the experimental points were approximated by the rounded-exponential (*roex*) function, which is widely used to approximate auditory filters. Its original form suggested by Patterson *et al.* (1982) is

$$W(g) = (1 + pg)e^{-pg}, \tag{3}$$

where $W(g)$ is the filter form in terms of transferred power, g is the normalized frequency deviation from the center, and the term p determines the filter tuning. ERB of the *roex* function is

$$B = F\int_{-\infty}^{\infty}(1+pg)e^{-pg}\,dg = 4F/p, \tag{4}$$

where B is ERB and F is the center frequency. Respectively, the quality Q is

$$Q = F/B = p/4. \tag{5}$$

Curves like those presented in Fig. 3 may be approximated by an inverted *roex* function with $W(g)$ presented on a dB scale:

$$T(g) = T_{\min} - 10\log[W(g)], \tag{6}$$

where $T(g)$ is the masked threshold and $T_{\min}$ is the minimal masked threshold at the curve tip. To approximate experimental data by *roex* functions, the parameters $T_{\min}$ and p were adjusted to reach the best fit to experimental data according to the least-mean-square criterion. These approximating functions are presented in Fig. 3 along with the experimental points. The obtained value of p was used to calculate ERB and Q of the curves according to the equations presented above. The result was obvious dependence of Q on the probe frequency: from 8.3–8.6 at rather low frequencies (22.5–32 kHz) to 44.8–47.4 at high frequencies (128–140 kHz).

All the obtained values of Q are presented in Fig. 4 as functions of probe frequency. All the functions look rather similar: neglecting some data scatter, there was an almost proportional increase of Q with frequency. Being presented on log-log scales, these functions were satisfactorily approximated by straight lines (r^2 from 0.85 to 0.91, Table I).The slope of these regression lines in the three subjects varied from 0.83 to 0.86, as presented in Table I. In other words, the dependence of Q on frequency might be approximated by a function

$$Q = q_0 F^k, \tag{7}$$

where F is frequency, q_0 is a quality at $F=1$, and k determines the degree of Q dependence on F. Constant (frequency-independent) Q corresponds to $k=0$; frequency-proportional Q corresponds to $k=1$. The found values of k from 0.83 to 0.86 indicated not exact but almost frequency-proportional Q. With such degree of dependence, approximated Q increased from around 10 to around 40 within a frequency range from 30 to 150 kHz.

According to Eqs. (5) and (7), ERB dependence on frequency was approximated as

$$B = F/Q = F^{1-k}/q_0. \tag{8}$$

ERB approximations computed in such a way were little dependent on frequency, e.g., from around 3 kHz at 30-kHz frequency to around 4 kHz at 150-kHz frequency.

IV. DISCUSSION

The tuning curves presented above were obtained in conditions of nonideal acoustic field. Even though the walls of the experimental baths were covered with sound-attenuating material, sound interference resulted in some spatial variation of both the sound level and modulation depth. Nevertheless, we suppose that the obtained tuning curves are credible because of the reasons as follows.

(i) As shown (Supin and Popov, 1995), variation of modulation depth influences the envelope following response amplitude rather than threshold. So, it could not influence the form of tuning curves based on masked thresholds.

(ii) Variation of sound (both the probe and masker) levels by ±5 dB does directly influence the masked threshold estimates. However, this variation should increase the data scatter, but could hardly systematically influence the width of tuning curves.

At least two features of the porpoise's tuning curves described above deserve attention: (*i*) very high quality (up to 40) in the upper part of the hearing frequency range and

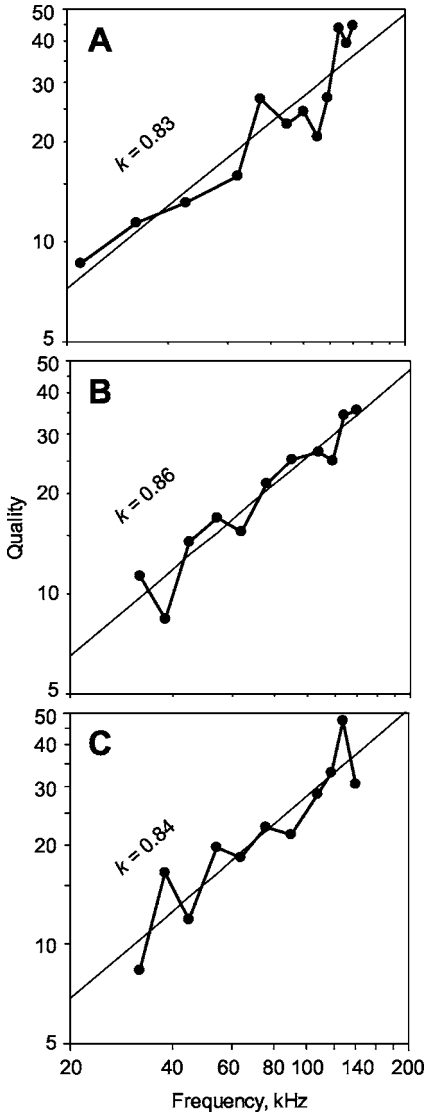

FIG. 4. Frequency-tuning quality (Q) dependence on frequency in three subjects: the harbor porpoise (A), finless porpoise female (B), and finless porpoise male (C). Solid lines—experimental data, thin straight lines—approximating regression lines. k is indicated for each regression line.

(*ii*) tuning dependence on frequency which is much closer to a constant-bandwidth rather than to a constant-quality manner.

The frequency tuning of $Q_{\mathrm{ERB}} \approx 40$ is several times more acute than that in many mammals and humans ($Q_{\mathrm{ERB}} \approx 10$, see Sec. I). However, this feature of the porpoise's tuning curves is not very surprising, since auditory filters with quality higher than 30 were already described in a few dolphin species (Supin *et al.*, 1993; Popov *et al.*, 1995, 1997; Klishin *et al.*, 2000).

The cause of very acute frequency tuning in dolphins and porpoises is not known yet, but we may hypothesize that it is associated with the wide frequency range of their hearing. Indeed, both frequency tuning and temporal resolution in the auditory system are limited by passbands of peripheral filters. Acute frequency tuning requires narrow passbands whereas high temporal resolution requires wide passbands. Thus, increasing frequency-tuning acuity above a certain limit is only possible at the cost of decreased temporal resolution and vice versa. However, this contradiction becomes less limiting at high frequencies, because at high frequency F, auditory filters can combine high quality with wide passband. Thus, at high frequencies, acute frequency tuning does not prevent high temporal resolution. Odontocetes (toothed whales, dolphins, and porpoises) have frequency ranges of hearing of more than 100 kHz, in particular, up to 150 kHz in porpoises, which is several times wider than in the majority of terrestrial mammals (except bats). This frequency range allows combining acute frequency tuning with high temporal resolution.

The dependence of tuning on frequency found in porpoises was unexpected. Contrary to the majority of terrestrial mammals and humans, this dependence is much closer to constant-B rather than to constant-Q representation.

In principle, the constant-B frequency representation is not prohibited by any auditory mechanisms. In particular, it is typical of the lowest part of the frequency range of the human's hearing: as follows from Eqs. (1) and (2), at low frequencies, ERB cannot be infinitely narrow and therefore approximates a constant value of around 25 Hz. But it is only typical of the lowest part of the frequency range. Within the upper part, a constant-Q (or approaching constant-Q) representation is more typical of both humans and a variety of mammals. We analyzed, retrospectively, data obtained in a few mammal species which are commonly used in hearing investigations, in order to calculate Q dependence on frequency within an upper part of the frequency range. For critical-band data (Gourevitch, 1970; Pickles, 1975; Seaton and Trahiotis, 1975; Ehret, 1976; Nienhuys and Clark, 1979), Q was calculated as the frequency-to-band ratio; for tuning-curve data (McGee *et al.*, 1976; Mitchell and Fowler, 1980; Serafin *et al.*, 1982; Popov *et al.*, 1995; Klishin *et al.*, 2000), $Q_{10\ \mathrm{dB}}$ estimates were directly taken. The Q dependence on frequency was approximated by a log-log regression line, exactly in the same manner as we did for the experimental data presented above. The values obtained for the factor k [see Eq. (5)] are presented in Table I along with our experimental data. Many of them were not far different from zero, thus indicating the constant-Q representation; in some cases, k reached values as high as 0.4–0.5, thus indicating a representation type intermediate between constant-Q and constant-B. But only in porpoises did values as high as 0.85 indicate a representation type much closer to constant-B rather than to constant-Q.

It is remarkable that frequency-tuning measurements in a few dolphin species carried out with the use of the very same technique (tuning curves obtained with sinusoidally amplitude-modulated tones as a probe, continuous tones for simultaneous masking, and EFR as an indicative response) resulted in a representation type much closer to constant-Q (Popov *et al.*, 1995; Klishin *et al.*, 2000). So, the unusual manner of frequency-tuning dependence on frequency in porpoises cannot be explained by some peculiarities of the methods used for hearing investigation in cetaceans. It may be considered as a real feature of the porpoise's auditory system.

It should be noted that the results presented above do not cover the entire frequency range of hearing but only the upper part of this region. We failed to perform measurements precise enough at lower frequencies, so the type of frequency representation in the low-frequency range in porpoises remains uncertain. But the investigated high-frequency region is just one where constant-Q representation appears normally in other mammals. So the representation manner in porpoises really differs from that in other mammals and humans.

Again, we know nothing about the cause of such type of frequency representation. One of the advantages of such an organization is that a constant bandwidth of peripheral auditory filters provides a constant limit for temporal resolution throughout all the frequency range. A filter of a bandwidth B is capable of transferring modulation rates up to $B/2$; thus, the porpoise's auditory filters of a bandwidth of 3–4 kHz are capable of transferring amplitude modulations of a signal as fast as 1.5–2 kHz. This value is very close to estimates of temporal resolution of the dolphin's and porpoise's hearing obtained by both psychophysical and evoked-potential methods [see reviews Au (1993) and Supin *et al.* (2001)].

Comparison of in-air evoked potential and underwater behavioral hearing thresholds in four bottlenose dolphins (*Tursiops truncatus*)

James J. Finneran
U.S. Navy Marine Mammal Program, Space and Naval Warfare Systems Center, San Diego, Code 2351, 53560 Hull Street, San Diego, California 92152

Dorian S. Houser
Biomimetica, 7951 Shantung Drive, Santee, California 92071

(Received 14 September 2005; revised 23 January 2006; accepted 3 February 2006)

Traditional behavioral techniques for hearing assessment in marine mammals are limited by the time and access required to train subjects. Electrophysiological methods, where passive electrodes are used to measure auditory evoked potentials (AEPs), are attractive alternatives to behavioral techniques; however, there have been few attempts to compare AEP and behavioral results for the same subject. In this study, behavioral and AEP hearing thresholds were compared in four bottlenose dolphins. AEP thresholds were measured in-air using a piezoelectric sound projector embedded in a suction cup to deliver amplitude modulated tones to the dolphin through the lower jaw. Evoked potentials were recorded noninvasively using surface electrodes. Adaptive procedures allowed AEP hearing thresholds to be estimated from 10 to 150 kHz in a single ear in about 45 min. Behavioral thresholds were measured in a quiet pool and in San Diego Bay. AEP and behavioral threshold estimates agreed closely as to the upper cutoff frequency beyond which thresholds increased sharply. AEP thresholds were strongly correlated with pool behavioral thresholds across the range of hearing; differences between AEP and pool behavioral thresholds increased with threshold magnitude and ranged from 0 to +18 dB.

I. INTRODUCTION

Marine mammal hearing capabilities have traditionally been assessed using behavioral response paradigms (e.g., Johnson, 1967; Schusterman and Moore, 1978; Moore and Schusterman, 1987; Awbrey *et al.*, 1988; Kastak and Schusterman, 1998; Finneran *et al.*, 2002; Kastelein *et al.*, 2002). In these methods, operant conditioning techniques are used to train animals to perform specific actions when they hear sounds. Features of the sound (e.g., amplitude, frequency) are varied and the subject's responses recorded and used to estimate thresholds or other desired features of the auditory system. These techniques provide the most direct assessment of the performance of the auditory system. For some smaller cetaceans, behavioral techniques have been used to define auditory system features such as temporal integration (Johnson, 1968), auditory filter widths (Au and Moore, 1990; Finneran *et al.*, 2002), auditory fatigue (Schlundt *et al.*, 2000; Nachtigall *et al.*, 2004), and receiving directivity (Au and Moore, 1984; Kastelein *et al.*, 2005).

Behavioral techniques require considerable access to subjects for training before reliable data can be obtained, thus preventing these methods from being used on larger marine mammals not routinely kept under human care. Behavioral approaches are also time consuming, both for initial training and data collection. The limited availability of subjects and the required time and costs have limited the number of individuals and species of marine mammals tested with behavioral techniques. At present, behavioral hearing thresholds have been obtained in only about 21 of the more than 100 extant marine mammal species. The National Research Council (National Research Council (NRC), 2000) stated that "population-level audiograms of many individuals are necessary for establishing baseline hearing capabilities and normal hearing loss in marine mammals" and has repeatedly recommended that studies be conducted to obtain such data (NRC, 1994; 2000). The NRC Ocean Studies Board further singled out the need to individually train behavioral hearing test subjects as the "major barrier to large-scale testing of the hearing of many individuals of the same species" (NRC, 2000). The need to specifically train individuals for hearing tests has prevented widespread testing, even at facilities with large numbers of trained marine mammals.

Electrophysiological hearing tests use passive electrodes to detect small voltages generated by the brain in response to acoustic stimuli. The voltages, called auditory evoked potentials (AEPs), are routinely measured in infants, children, and patients who are unwilling or unable to respond behaviorally. AEP methods are attractive alternatives to behavioral methods because they are fast and require minimal cooperation from the subject. AEPs have been measured in several marine mammal species, including bottlenose dolphins (Ridgway *et al.*, 1981; Popov and Supin, 1990b), harbor porpoises (*Phocoena phocoena*; Popov *et al.*, 1986), belugas (*Delphinapterus leucas*; Popov and Supin, 1987), killer whales (*Orca orcinus*; Szymanski *et al.*, 1999), tucuxi dolphins (*So-*

talia fluviatilis; Popov and Supin, 1990a), Amazon river dolphins (*Inia geoffrensis*; Popov and Supin, 1990c), the false killer whale (*Pseudorca crassidens*; Supin *et al.*, 2003; Yuen *et al.*, 2005), a striped dolphin (*Stenella coeruleoalba*; Andre *et al.*, 2003), Risso's dolphin (Grampus griseus; Dolphin, 1997) the finless porpoise (*Neophocaena phocaenoides asiaeorientalis*; Popov *et al.*, 2005), sea lions (*Zalophus californianus*; Bullock *et al.*, 1971) and harbor seals (*Phoca vitulina*; Wolski *et al.*, 2003).

The broader application of AEPs to the study of marine mammal hearing would permit more rapid collection of information on marine mammal auditory systems and address issues acknowledged by the NRC as limiting our understanding of marine mammal hearing at the population level. Unfortunately, most AEP measurements have occurred in laboratory settings using a single individual and there are few direct comparisons between AEP and behavioral hearing thresholds in the same individual.

This paper describes an AEP system developed to address a need for periodic hearing assessment of dolphins at the U.S. Navy Marine Mammal Program at the Space and Naval Warfare Systems Center, San Diego (SSC San Diego). Navy dolphins are trained to find and mark the location of underwater objects and waterborne intruders. To accomplish these tasks, they rely upon their biological sonar (echolocation) system. Since echolocation requires both generation of outgoing pulses and reception (hearing) of returning echoes, loss of hearing sensitivity would eventually decrease a dolphin's ability to detect and identify targets. Periodic hearing assessments of Navy dolphins are therefore needed to identify those animals with degraded hearing. This paper presents the operating principles and performance characteristics of the AEP system. AEP hearing thresholds obtained in air are compared to underwater behavioral thresholds in the same subjects to determine their suitability as proxies for underwater behavioral data. System effectiveness and the time required for hearing estimates in delphinids are discussed relative to the goals of routine screening of Navy dolphins and expanding our knowledge of population level audiometry within marine mammal species.

II. METHODS

A. Subjects

The subjects were four bottlenose dolphins: BLU (female, 39-y, 200 kg), BUG (male, 23-y, 190 kg), BUS (male, 24-y, 180 kg), and WEN (male, 21-y, 210 kg). All subjects had previously participated in cooperative psychophysical tasks, including auditory detection tasks. Subjects were housed in floating netted enclosures, 9×9 to 12×24 m, located in San Diego Bay (SD Bay), California. The study followed a protocol approved by the Institutional Animal Care and Use Committee of the Biosciences Division, SSC San Diego, and followed all applicable U.S. Department of Defense guidelines for the care of laboratory animals.

B. AEP measurements

AEP measurements were conducted in air. In-air measurements were preferable to underwater measurements because AEP amplitudes are generally larger in air compared to those collected underwater (seawater provides an alternative low resistance path for the electrical potentials), and the AEP measurements could be coupled to clinical examinations of dolphins, which are performed with the dolphin removed from water.

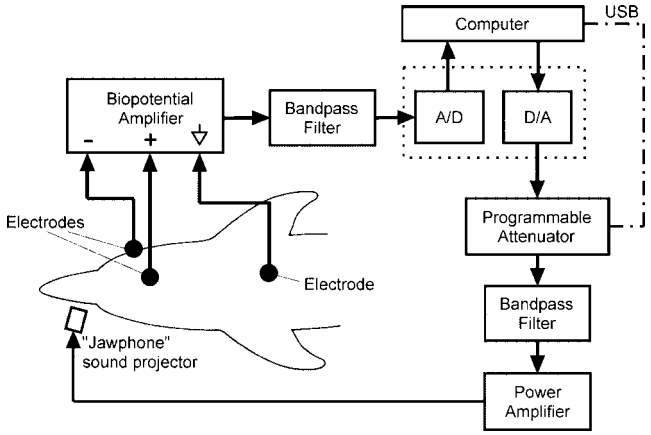

FIG. 1. AEP measurement system configuration.

1. Hardware

Figure 1 is a block diagram of the AEP measurement system. A personal computer (PC) with a multifunction data acquisition card (National Instruments PCI-MIO-16E-1) was used to generate sound stimuli and digitize the evoked responses. Sound stimuli were attenuated (Tucker-Davis Technologies PA-5), bandpass filtered (Krohn-Hite 3C module, 1–150 kHz), and amplified (Hafler P1000) before being presented to the subject. The attenuator featured a USB interface that allowed the PC to programmatically change the attenuation.

Sounds were presented to the subjects using piezoelectric sound projectors embedded in silicon rubber (Rhodia V-1065) suction cups. The suction cup-embedded projectors have been labeled "jawphones" in prior literature (Moore *et al.*, 1995; Brill *et al.*, 2001). The jawphone was placed on the subject's lower jaw, in the pan region, a site which has been previously demonstrated to be an important pathway for high frequency sound reception in dolphins (Brill *et al.*, 1988; Møhl *et al.*, 1999a). Jawphones were calibrated by measuring underwater rms sound pressure levels (SPLs) at a distance of 15 cm from the jawphone [Fig. 2(a)]. The 15-cm distance between jawphone and calibration hydrophone was based on the estimated distance between the jawphone attachment point and the auditory bullae. This distance was measured from a computed tomography (CT) scan of WEN (Houser *et al.*, 2004). SPLs were measured using a calibrated hydrophone (B&K 8105) and charge amplifier (B&K 2692 or 2635). Three individual jawphones, designated JP1, JP2, and JP4, were used. Table I details the size and operating range of the various jawphones. JP1 was used above 100 kHz; JP2 and JP4 were used at and below 100 kHz. Figure 2(b) compares the transmitting voltage response (the SPL at 15 cm in response to a 1-V jawphone input) mea-

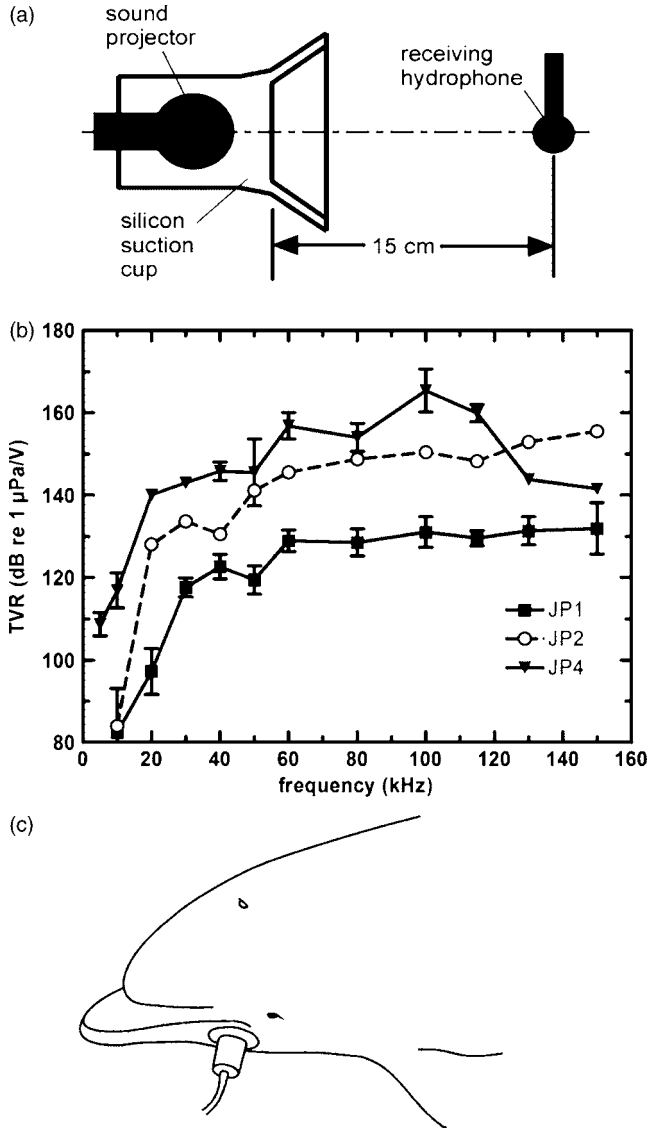

FIG. 2. (a) Jawphone construction and calibration arrangement. (b) Transmitting voltage response (TVR) from jawphones measured at 15 cm. (c) Example of jawphone position on subject.

sured from the various jawphones. Figure 2(c) shows the attachment site of the jawphone for testing the left ear.

Two types of surface electrodes were used to detect evoked potentials: disposable electrodes consisting of a flexible, conductive, self-adhesive Ag/Ag–Cl pad (Ambu Neuroline 710 series) and reusable 6 and 10 mm diameter gold cup electrodes (e.g., Grass FH-E6G series) embedded in 25 mm diameter silicon suction cups. Electrode placement sites were dried using gauze pads and/or alcohol swabs prior to placement. Disposable electrodes were subsequently covered with waterproof bandages (Nexcare Absolute Waterproof) to prevent contact with water periodically sprayed over the dolphin. Reusable electrodes were protected from contact with water by the suction cup itself. A three-electrode configuration was used: the active (+) electrode was placed near the vertex, approximately 10 cm posterior of the blowhole and offset approximately 2 cm contralateral of the ear being tested; the reference (−) electrode was placed contralateral of the ear being tested, just posterior to the external auditory meatus; and the ground (common) electrode was placed on the subject's back near the dorsal fin. When using reusable suction cup electrodes, the exact position of the active electrode varied depending on the shape of the subject's head, i.e., in some cases, curvature of the head prevented attachment of the suction cup electrodes at the desired site behind the blowhole. The electrode signals were amplified and filtered using a biopotential amplifier (Grass IP-511). The biopotential amplifier output was proportional to the voltage difference between the active and reference electrodes. The biopotential amplifier gain was fixed at 100 000. High and low-pass filters varied from 100 to 300 Hz and 3 to 10 kHz, respectively, depending on the stimulus modulation frequency and measurement sampling rate. Additional filtering (Krohn-Hite 3C, bandpass from 0.1 to 5 kHz) was sometimes used, depending on signal quality. The resulting signal was digitized by the PCI-MIO-16E-1 at either 15 or 20 kHz.

TABLE I. Jawphone properties.

Jawphone	Projector	Suction cup base diameter (cm)	Suction cup length (cm)	Frequency range (kHz)
JP1	EDO 1066	2.5	4.0	115–150
JP2	EDO 1066	4.0	6.0	10–100
JP4	ITC 1042	4.0	6.0	10–100

2. Stimuli

Sound stimuli consisted of sinusoidal amplitude modulated (SAM) tones, resulting in steady-state, periodic AEPs with a fundamental at the modulation frequency. An evoked response such as this that is phase-locked to the amplitude modulation rate is sometimes called the envelope following response (EFR) or auditory steady-state response (ASSR) (Dolphin and Mountain, 1993; Rance *et al.*, 1993; Dolphin *et al.*, 1995). Eleven carrier frequencies, from 10 to 150 kHz were tested. These frequencies were chosen to cover the effective range of bottlenose dolphin echolocation (Au, 1993). The modulation rate was 1 kHz. Modulation rate transfer function (MRTF) measurements have shown this rate to produce a strong evoked response in *T. truncatus* (Dolphin *et al.*, 1995; Supin and Popov, 2000; Finneran and Houser, 2004). This was verified by measuring MRTFs on BLU and WEN prior to threshold measurements. The amplitude modulation function was chosen to produce a stimulus with a three-component frequency spectrum (carrier plus sidebands).

BLU and WEN were tested using both intermittent and continuous SAM tones while BUG and BUS were tested only with continuous SAM tones. For intermittent presentations, tone durations varied from 12 to 15 ms (the majority were 13 ms), with a 1 ms cosine envelope rise and fall. Intermittent stimuli were presented at a rate of approximately 50/s. Continuous stimuli were presented for approximately 10 s.

Stimulus generation and evoked response recording were controlled using custom software. Artifact rejection was implemented in software; signals greater than 20 μV

were normally rejected. Frequency analysis was performed on 19 ms epochs for continuous stimuli and 10–13 ms epochs for intermittent stimuli. For continuous stimuli, the first epoch containing the response latency and initial transients was not included in the frequency analysis; for intermittent stimuli, the portions of the evoked response corresponding to the rise/fall of the stimulus were not included. Time durations for frequency analysis were constrained to integral multiples of 1 ms (the harmonic period of the modulation) to avoid spectral leakage in the frequency domain. Coherent averaging (typically 500–1000 averages) was performed in the frequency domain; this allowed the mean amplitude and phase at the modulation frequency, as well as confidence intervals, to be obtained.

Figure 3(a) shows examples of ASSR waveforms measured from BLU in response to an intermittent 30 kHz SAM tone. At high SPLs, responses are easily detectable from the waveforms; however, at lower SPLs the responses become indistinguishable from noise in the time domain. Figure 3(b) shows the frequency spectra of the waveforms from Fig. 3(a). The primary feature of interest for detection of the evoked response is the spectral peak at the 1 kHz modulation frequency.

3. Response detection

The magnitude-squared coherence (MSC) was calculated during each AEP measurement and used to objectively determine if the measured AEP component at the modulation frequency was statistically different from noise (Dobie and Wilson, 1989; Dobie, 1993; Dobie and Wilson, 1996). MSC is a ratio of the power (at a single frequency) contained in the "grand" coherent average to the average of the powers within individual "segments" or "subaverages" of the total data stream. The MSC provides a ratio of the signal power to signal-plus-noise power and varies from zero (all noise) to one (all signal). The MSC calculation used 20 subaverages. Critical values for MSC, using $\alpha=0.01$, were obtained from Amos and Koopmans (1963) and Brillinger (1978). If the calculated MSC was greater than the critical value, the AEP at the modulation frequency was considered to be detected. This process of objective response detection provided a yes/no result for each AEP measurement and permitted adaptive procedures for adjusting stimulus levels (e.g., modified staircase technique). MSC calculations were done on-line during test procedures to permit the use of adaptive search techniques during data collection.

4. Data collection

Data collection began with a stimulus SPL of 80 dB re 1 μPa. An automated staircase technique was used to adjust stimulus levels to quickly reach threshold. Stimulus levels were decreased after each detected response (a "hit") and increased after each measurement without a detected response (a "miss"). The amount the stimulus was raised or lowered (the step size) started at 30 dB and was reduced after each "reversal"—a transition from a hit to a miss or a miss to a hit. The step size was multiplied by 0.4 after each miss-hit reversal and 0.6 after a hit-miss reversal. Unequal multipliers were used to avoid repeated testing at the same levels, provide a more continuous distribution of stimulus

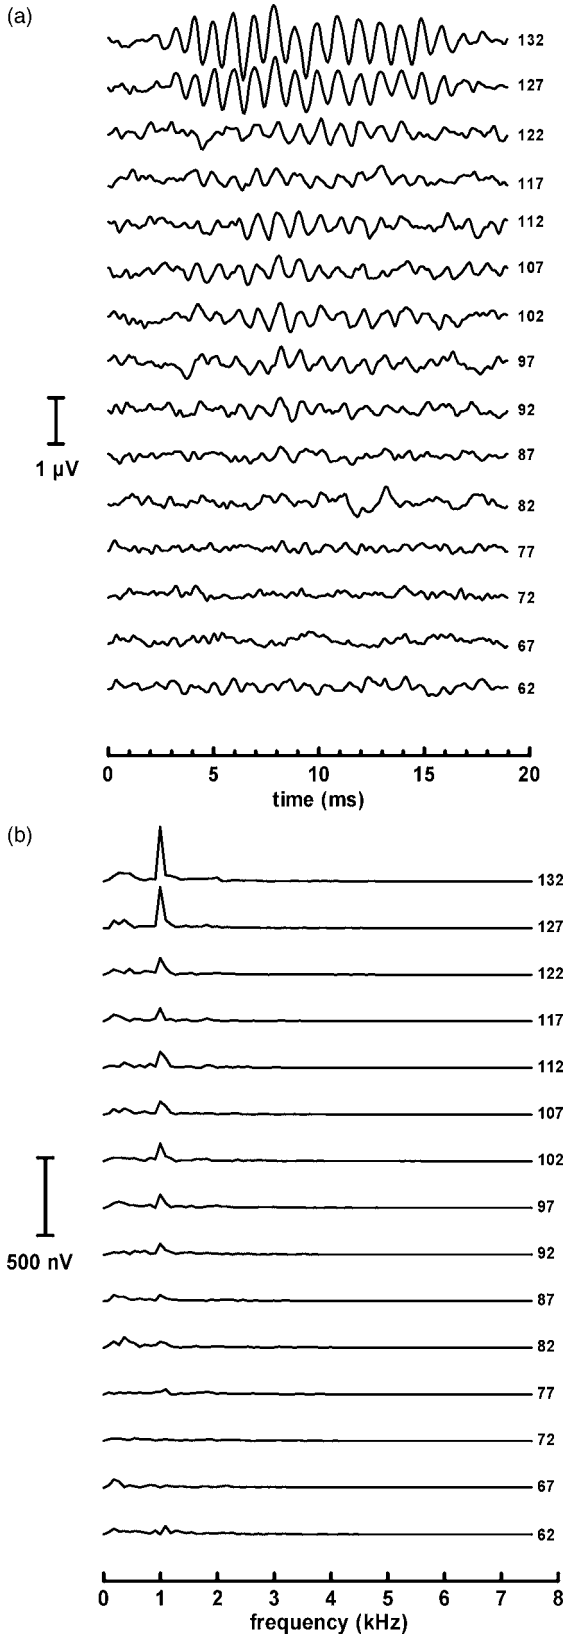

FIG. 3. (a) Steady-state AEP (a) waveforms and (b) frequency spectra measured at different stimulus SPLs for subject BLU, 30 kHz carrier frequency, 1 kHz modulation frequency. The frequency spectra were calculated from a 10 ms analysis window. The numbers next to each series indicate the stimulus SPL (dB re 1 μPa).

levels tested, and to increase the chance of obtaining a hit on the next trial. Multiple samples were not taken at the individual stimulus levels to avoid an uneven sampling of stimuli and ensure that time was available for sampling at all of the frequencies of interest. The staircase was terminated when the step size was reduced below 4 dB.

Considering only responses that were detected, a linear regression was then performed on the AEP amplitude versus stimulus SPL data. Detected responses with amplitudes greater than 400 nV were excluded from the regression analysis. Testing was concluded if the regression r^2 value from a minimum of four detected responses reached 0.9. If the minimum r^2 value was not obtained, additional measurements were conducted at SPLs selected to fill the gaps within the AEP amplitude versus stimulus SPL data. With each additional detected response, another regression was performed on the data series. This process was repeated until the criterion r^2 was met or until a maximum of eight detections at different SPLs was made. When necessary, additional stimulus levels were tested to ensure sufficient data for post-hoc threshold estimates. (This was most often required when a plateau in the AEP amplitude versus SPL data confounded the automated logic.) Using these techniques, a single ear could be tested (at eleven frequencies) in approximately 45 min.

5. Threshold estimation

A post-hoc linear regression technique was used to estimate hearing thresholds for each of the frequencies tested. Linear regression was first performed on the four detected responses with the lowest amplitudes. If the regression r^2 was less than 0.9, additional points obtained at consecutively higher stimulus levels were added to the regression analysis until the r^2 criterion of 0.9 was met or an obvious plateau was reached in the AEP amplitude data. The AEP threshold was defined as the stimulus SPL at which the extrapolated regression line reached 0 V. Almost all regressions were based on more than four points; however, in a few cases, only three points could be included in the regression. If a three point regression could not be performed using detected responses, the data at that frequency were excluded.

Figure 4 shows the amplitude (upper panel) and phase angle (lower panel) at the modulation frequency for the data shown in Fig. 3 and illustrates the threshold estimation procedure. The filled symbols represent detected responses according to the MSC calculation; open symbols indicate measurements that were not statistically different than noise. The solid line shows the linear regression applied according to rules outlined above. In this case, the four lowest amplitude responses resulted in an $r^2=0.92$, so no additional points were included. The dashed line shows the extrapolation of the regression to estimate the threshold (72 dB re 1 μPa).

Each ear of WEN and BLU was tested at least three times and the mean of the threshold estimates are reported here. BUG and BUS were only tested once (except BUG's right ear which was tested twice on the same day at 40 kHz).

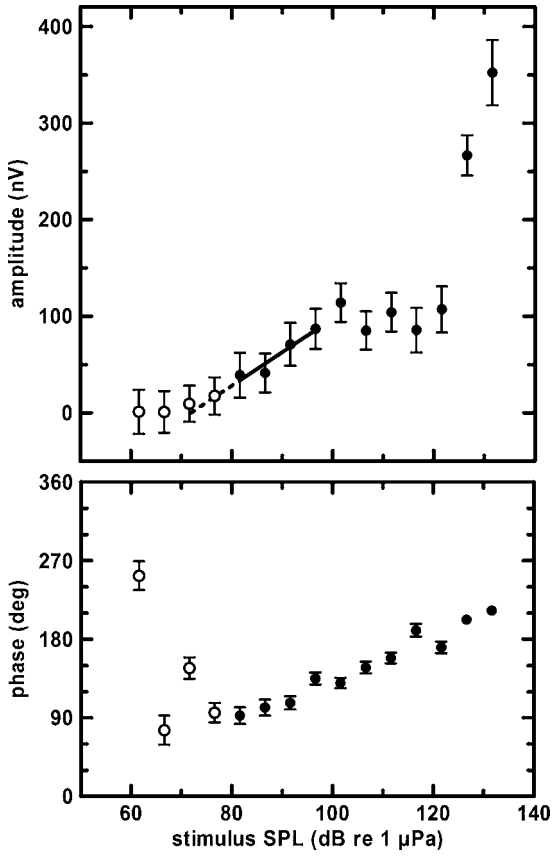

FIG. 4. Steady-state AEP (rms) amplitude and phase as functions of stimulus SPL for the data shown in Fig. 3. Symbols represent mean values; error bars show the 95% confidence intervals. The filled symbols represent detected responses (MSC values were greater than the critical value, MSC_{crit}); the open symbols represent measurements without statistically detected responses ($MSC < MSC_{crit}$). The solid line shows the linear regression performed on the lowest four detected responses ($r^2=0.92$). The dashed line is an extrapolation of the regression line to 0 V. The stimulus SPL at which the dashed line intersects the x-axis is the estimated threshold (72 dB re 1 μPa).

C. Behavioral measurements

Behavioral thresholds were measured underwater in SD Bay (all subjects) and an above-ground pool (BLU only). Ambient noise spectral density levels in the pool ranged from approximately 50 dB re 1 $\mu Pa^2/Hz$ (at 10 kHz) to 40 dB re 1 $\mu Pa^2/Hz$ (50 kHz); noise levels in San Diego Bay were approximately 20 dB higher (Finneran *et al.*, 2005).

Behavioral thresholds for BLU and WEN were obtained before or concurrently with AEP measurements (data were collected over a period of several months). BUG and BUS were tested under "blind" conditions; AEP measurements were conducted first, then behavioral measurements were performed by independent investigators. AEP thresholds were not disclosed until the behavioral testing was complete.

Table II compares test parameters for each subject. All subjects were behaviorally tested using 500 ms duration test tones with linear rise/fall times of 20 ms or larger. BLU, BUS, and WEN were trained to whistle in response to hearing test tones and to remain quiet otherwise. BUG was trained to press a response paddle in the presence of a tone. Fifty-percent of the trials were no-tone ("catch") trials, except for a few sessions with BUS where the tone/no-tone

TABLE II. Behavioral hearing test parameters.

	Subject			
	BLU	BUG	BUS	WEN
Location	Pool, SD Bay	SD Bay	SD Bay	SD Bay
Method	(Descending) Staircase	(Descending) Staircase	(Descending) Staircase	(Descending) Staircase
Trial presentation	MFR	Single interval	Single interval	Single interval
Response	Whistle	Paddle press	Whistle	Whistle
Tone duration	500 ms	500 ms	500 ms	500 ms
Step size	2 dB	2 dB	2 dB	2 dB
Threshold estimate	10 rev. (Pool) 6 rev. (SD Bay)	10 rev.	10 rev.	6 rev.
Reinforcement	Variable	Fixed	Fixed	Fixed

ratio was adjusted to 65/35 to maintain a false alarm rate of around 10%–15%. Stimulus SPLs were adjusted using a staircase procedure (Cornsweet, 1962) with a 2-dB step size for threshold estimates. Threshold estimates were based on 6 (WEN and BLU in SD Bay) or 10 (BUG, BUS, and BLU in the pool) consecutive hit-miss or miss-hit reversals. BUG, BUS, and WEN were tested in the context of a single interval experiment where the subject was rewarded (correct response) or recalled (incorrect response) after each trial. The behavioral threshold procedure for BLU was based on the Method of Free Response (MFR) (Egan *et al.*, 1961) and described in detail by (Finneran *et al.*, 2005). For all subjects, thresholds from independent sessions were averaged to yield a mean threshold estimate based on minimum of two (BUG, BUS) or three (BLU, WEN) independent measurements. At most frequencies, WEN and BLU were tested 4–6 times.

D. Statistical analysis

Left and right ear AEP thresholds for BLU obtained with intermittent and continuous stimuli were compared using a one-way ANOVA (GraphPad Software, 2003). A Tukey-Kramer post-test was used to compare all four data sets: Left ear, continuous; left ear, intermittent; right ear, continuous; right ear, intermittent.

III. RESULTS

Figure 5 presents the behavioral thresholds measured for BLU, BUG, BUS, and WEN. Three of the four subjects showed varying degrees of high-frequency hearing loss, with upper cutoff frequencies ranging from approximately 80 kHz (BUG) to 30 kHz (BUS). WEN possessed full range hearing with an upper frequency cutoff of approximately 140 kHz. Low-frequency thresholds in SD Bay were elevated, presumably from masking caused by the relatively high ambient noise levels.

Figure 6 compares AEP thresholds for BLU measured using both continuous and intermittent stimuli. For this subject, responses could not be detected above 100 kHz at the highest SPLs the jawphones could generate. No significant differences between threshold estimates using intermittent or continuous tones were observed for BLU ($p > 0.05$); for the remaining analyses, intermittent and continuous data were pooled to produce a single mean threshold at each frequency for each ear.

Figure 7 compares the left and right ear AEP thresholds estimates for BLU to behavioral thresholds measured in SD Bay and the pool. All threshold estimates reveal poor high frequency hearing, with AEP and pool behavioral threshold estimates rising at about 47 dB/octave above 30 kHz. Below 40 kHz, a clear separation exists between the behavioral thresholds measured in the pool and SD Bay, most likely from the ambient noise differences between the two environments.

Figure 8 compares BLU's AEP thresholds (ordinate) to the behavioral thresholds measured in the pool (abscissa). The dashed line represents the ideal case in which behavioral and AEP thresholds are identical. AEP threshold estimates tended to be higher than the behavioral estimates. Differences between thresholds (AEP minus behavioral) increased with threshold magnitude and ranged from 0 to +18 dB, with a mean of 8 dB. AEP thresholds were strongly corre-

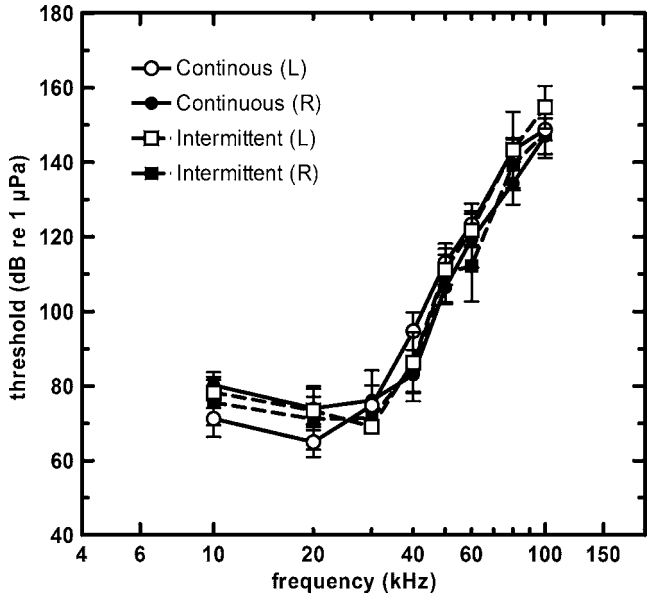

FIG. 6. Comparison of in-air steady-state AEP hearing thresholds for subject BLU obtained from left (L) and right (R) ears using continuous and intermittent stimuli. Symbols represent mean values; error bars show the mean ± one standard deviation. There were no statistically significant differences between the thresholds at a particular frequency.

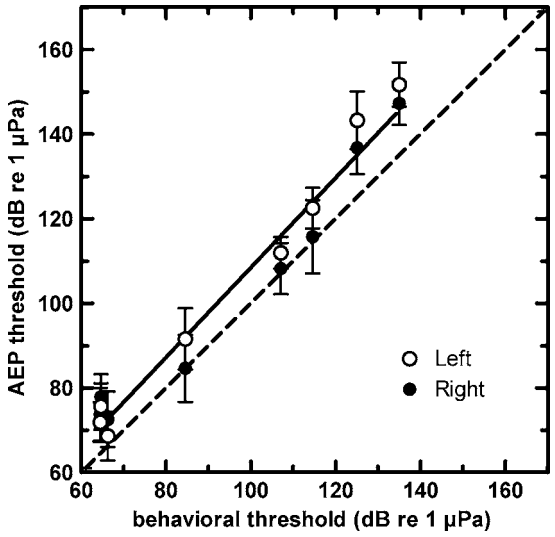

FIG. 8. In-air AEP threshold estimates vs behavioral thresholds measured in the pool for subject BLU. Symbols are mean values. Error bars represent ± one standard deviation. The solid line is a linear regression performed on the experimental data.

lated with behavioral thresholds across the range of hearing (r=0.98) with a regression equation slope of 1.1. The mean AEP thresholds from both ears ranged from 3 to 15 dB above the pool behavioral thresholds.

Figures 9–11 compare AEP and behavioral thresholds for WEN, BUG, and BUS, respectively. Both BUG and BUS exhibited poor high-frequency hearing, with thresholds increasing above 60 and 20 kHz, respectively. In contrast, WEN's thresholds remained relatively low across the expected functional range for dolphins and did not increase until the frequency exceeded 130 kHz. For all three subjects, AEP threshold estimates and behavioral estimates agreed closely as to the upper cutoff frequency beyond which thresholds increased sharply.

Figure 12 compares the AEP thresholds to the SD Bay behavioral thresholds for all four subjects. AEP threshold estimates below 40 kHz were generally lower than behavioral estimates, probably because the behavioral thresholds were masked by ambient noise at these frequencies. At high frequencies, AEP estimates tended to be higher than behavioral estimates, especially in WEN, the only subject with relatively low thresholds at high frequencies. Mean AEP thresholds (average of both ears) were within −26 to +20 dB of the SD Bay behavioral thresholds for all four subjects. AEP threshold estimates for individual ears ranged

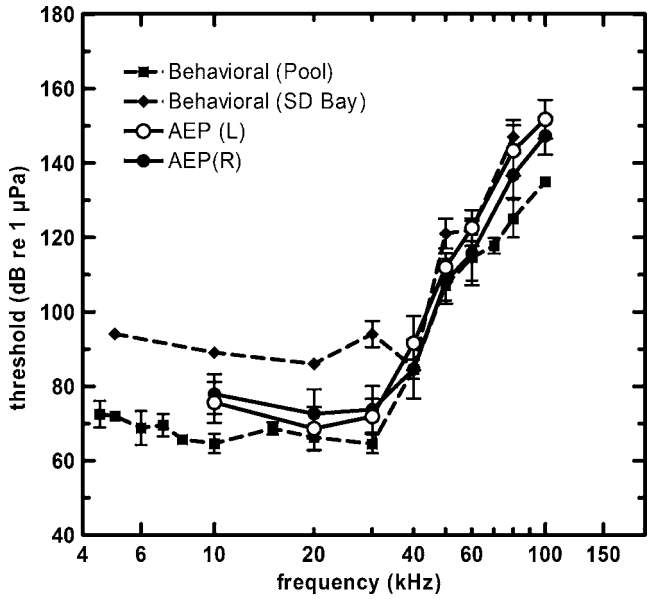

FIG. 7. In-air AEP and underwater behavioral hearing thresholds measured for BLU. Symbols are mean values. Error bars represent ± one standard deviation.

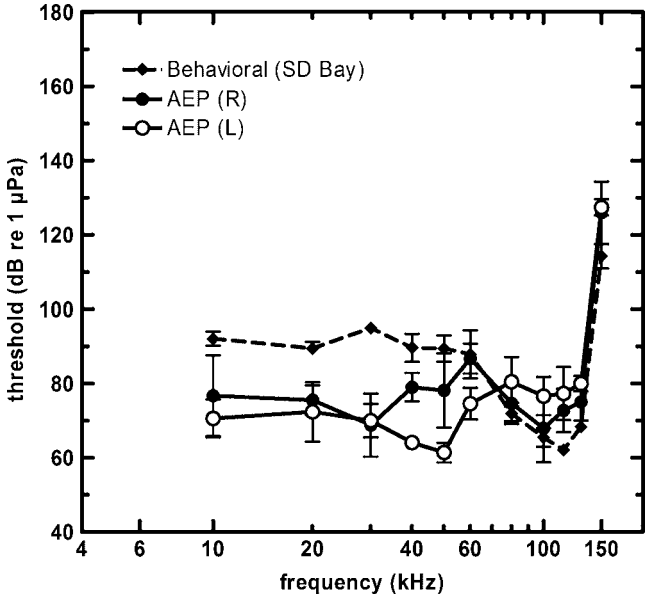

FIG. 9. In-air AEP and underwater behavioral hearing thresholds measured for WEN. Symbols are mean values. Error bars represent ± one standard deviation.

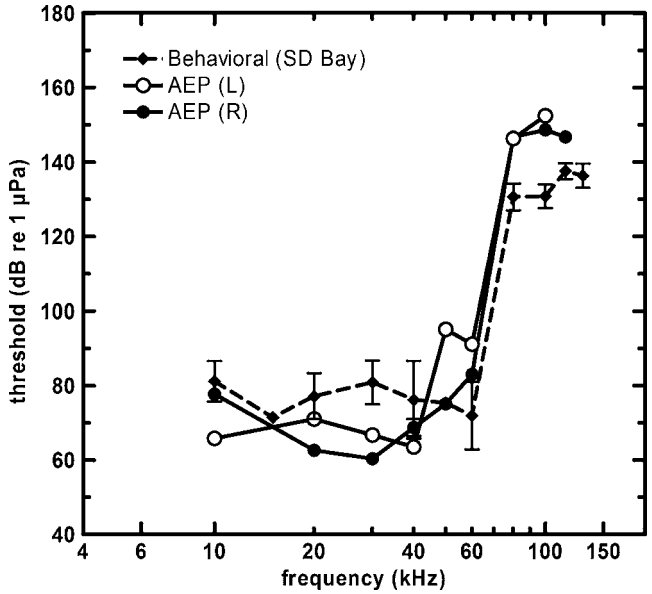

FIG. 10. In-air AEP and underwater behavioral hearing thresholds measured for BUG. Symbols are mean values. Error bars represent ± one standard deviation.

from −28 to +22 dB. Excluding comparisons at 40 kHz and below, where masking likely affected threshold measurements, mean AEP thresholds (average of both ears) were within −20 to +20 dB of the SD Bay behavioral thresholds for all four subjects, with a mean difference of +6 dB.

IV. DISCUSSION

A. Behavioral thresholds

Comparisons of behavioral thresholds between the BLU and WEN for SD Bay and the pool suggest that thresholds measured in SD Bay were masked by ambient noise at frequencies up to at least 40 kHz, and possibly higher. BUS and

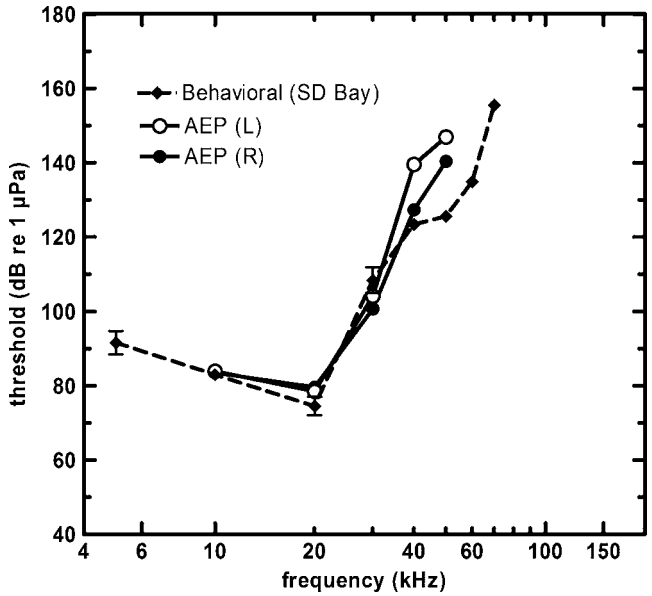

FIG. 11. In-air AEP and underwater behavioral hearing thresholds measured for BUS. Symbols are mean values. Error bars represent ± one standard deviation.

BUG had similar thresholds at low frequencies; however, their thresholds were consistently lower than thresholds for BLU and WEN. The similar shapes, but roughly 10 dB shift in amplitude, of the threshold curves for thresholds for WEN and BUG suggest that motivational, methodological, or calibration differences may have affected threshold estimates. An implicit assumption is often made that behavioral thresholds are correct and that any differences between AEP and behavior threshold estimates are attributed to errors in the AEP estimate. It must be remembered that the classical behavioral threshold is a statistical concept depending on experimental and motivational factors as well as the subject's sensitivity. Changes in a subject's response bias or differences in threshold estimation methods will affect the numeric thresholds obtained. Until standard methods for marine mammal behavioral threshold estimates are developed, comparisons between AEP and behaviorally measured data should consider the details of how the data were collected.

B. AEP thresholds

1. AEP methodology

The relationship between the AEP amplitude and the stimulus SPL, called the input/output function or AEP growth curve, is nonlinear (Fig. 4). The plateau and subsequent increase in the input/output function have been proposed to result from auditory adaptation during stimulation, followed by increased activation from spectral spreading at higher SPLs (Supin *et al.*, 2001). The shape may also reflect basilar membrane displacement, which exhibits a similar nonlinear response believed to arise from a combination of active and passive processes (Pickles, 1988). Identification of the linear regions and plateaus within the nonlinear input/output function requires sufficient measurements and under sampling the curve can result in unsatisfactory threshold estimates (Lins *et al.*, 1995; Vander Werff and Brown, 2005). The existence of a plateau can confound automatic threshold testing logic and, if occurring sufficiently close to the noise floor, prevent the application of regression techniques.

As the stimulus SPL is lowered, the AEP amplitude will, at some point, become indistinguishable from noise. Discriminating AEP responses from noise based only on visual observation cannot avoid some degree of subjectivity and a dependence on observer skill. Furthermore, AEP threshold estimates based on a regression technique can be markedly skewed by inclusion/rejection of individual points within the regression (Vander Werff and Brown, 2005).

This study employed an objective technique (the MSC) to distinguish responses from noise and avoid problems associated with observer subjectivity. This allowed objective decisions to be made regarding the presence or absence of a response. Data collection and stimulus adjustment could thus be automated to a great extent, since the presence or absence of a response could be used as a basis for adjusting the stimulus SPL for the next trial. Figure 4 illustrates the utility of statistical approaches; without objective response detection, one may be tempted to include the three highest amplitude undetected responses in the regression, producing a potentially erroneous threshold estimate.

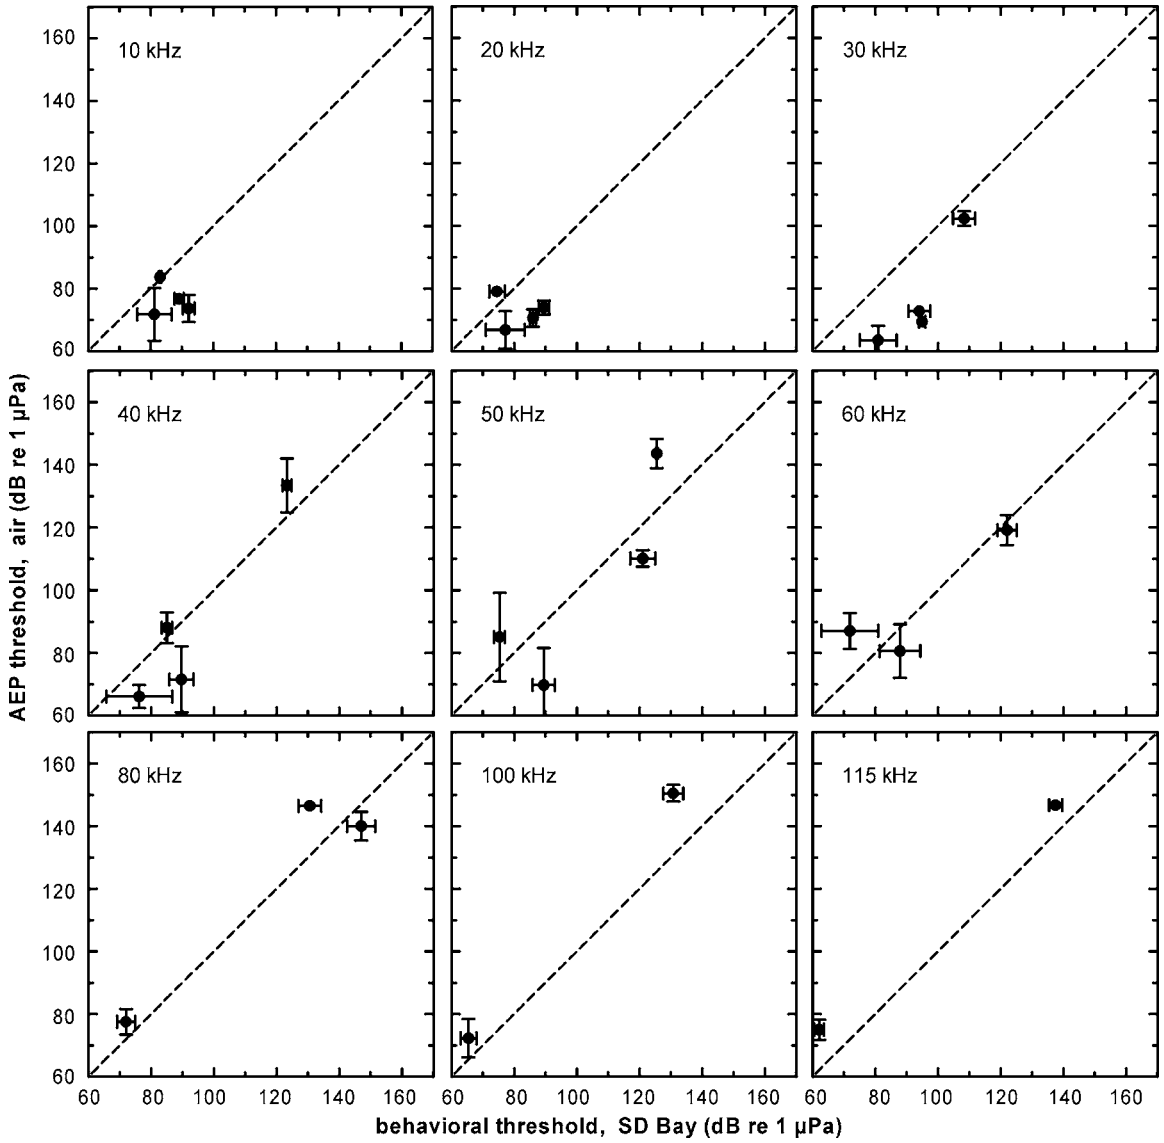

FIG. 12. In-air AEP thresholds plotted versus the San Diego Bay behavioral thresholds. Each panel shows data from all four subjects (if possible) for a single frequency. Error bars represent ± one standard deviation. The dotted line indicates where perfect agreement (equivalence) between the threshold predictions would occur. Note that frequencies below 40 kHz are likely to be masked, augmenting differences between behavioral and AEP estimates of hearing sensitivity at these frequencies.

2. Relationships between AEP and behavioral data

Because they were not affected by masking noise in SD Bay, behavioral thresholds in the pool provide more appropriate comparisons to the AEP thresholds than behavioral data obtained in SD Bay. The largest differences between the two threshold estimates occurred at the lowest (10 kHz) and highest frequencies (80 and 100 kHz). The magnitude and direction of the differences between AEP and behavioral thresholds agree with previous comparisons in humans with normal hearing and sensorineural hearing loss (Lins *et al.*, 1995; Rance *et al.*, 1995; Aoyagi *et al.*, 1999; Dimitrijevic *et al.*, 2002; Vander Werff and Brown, 2005) and show similarly strong correlations in predicted thresholds (Rance *et al.*, 1995; Vander Werff and Brown, 2005). The results reveal that in-air AEP thresholds measured using the techniques described here are useful proxies for underwater behavioral data, especially with respect to the audiogram shape and upper cutoff frequencies.

3. Left/right ear differences

Differences between BLU's left and right thresholds were small (relative to the standard deviation), ranging from 2 to 7 dB, whereas WEN's left ear had 12–17 dB lower thresholds between 40 and 60 kHz, but 6–10 dB higher thresholds between 80 and 130 kHz. BUG and BUS had similar thresholds for their left and right ears at most frequencies (most frequencies were only tested once, so there are no variance measures for these data). The ability to differentiate the relative hearing sensitivity between two ears would be beneficial in clinical diagnoses of auditory system dysfunction as well as the characterization of auditory system health in animals that might be used in psychoacoustic research. At present it is not clear how best to compare behavioral thresholds obtained binaurally with monaural AEP data. The mean of the left and right ear thresholds seems a reasonable approach, especially when the thresholds are

similar; however, one could imagine an animal with large sensitivity differences between ears relying on the more sensitive ear during binaural tests.

4. Continuous and intermittent stimuli

No difference between threshold estimates for BLU was found when using either continuous or intermittent stimuli. Continuous stimuli allow data to be acquired more rapidly because the same amount of time domain response data will take less time to acquire using continuous stimuli than with intermittent stimuli. The duration of the time segment available for spectral analysis dictates the resulting frequency resolution (frequency "bin" width). Assuming that the noise spectral density is relatively flat, smaller frequency bins will result in lower noise levels, making detection of responses near threshold easier. So, for identical data collection time periods, continuous stimuli would allow longer time segments for analysis and lower noise levels. The primary advantage of intermittent stimuli is that the response latency may be observed. This allows one to clearly separate physiological response from stimulus artifacts, which may have zero latency. In many cases, this advantage can offset the additional time that is required for data collection.

5. Approach limitations

The AEP threshold estimation in delphinids using the combined techniques described here is promising given that estimates demonstrate a similar degree of variation between behavioral and physiological estimates that are observed with other species. However, electrophysiological techniques have limitations when applied as surrogates for behavioral tests. Some limitations may be controlled from a methodological standpoint (e.g., the two methods typically do not use equivalent stimuli), while others are inherent to physiological measures (e.g., animals are "noisy" because of spontaneous brain activity and myogenic potentials). Differences between AEP and behavioral thresholds quantified for the methods used in this study should not be broadly applied because they are likely to vary as a function of methodology. For example, underwater, direct field stimulation of a subject may result in sound transmission to the ear via acoustic pathways that are not used when the sound projector is coupled to a point on the lower jaw of an animal that is out of the water.

The delivery of acoustic stimuli through a jawphone has been previously applied in studies of dolphin audition (Moore *et al.*, 1995; Mohl *et al.*, 1999; Brill *et al.*, 2001), but no standard approach exists for jawphone calibration. In this study, the jawphone was calibrated underwater as would be a free transducer with the receiving hydrophone 15 cm away. This approach does not account for potential distortion of the stimulus signal resulting from coupling the jawphone to the animal. The impact of the coupling is unknown. Nor can it presently be verified whether the direct path distance from the coupling point to the auditory bulla is representative of the true acoustic path to the ear, thus validating that distance for use in future calibrations. However, jawphones constructed for this project have effectively been calibrated against the animals on which they were used, i.e., by comparison of AEP and behavioral threshold estimates. The agreement between threshold estimates, within the variation expected between AEP and behavioral methods, suggests that the calibration used for this project is suitable for the types of animals and circumstances under which the jawphone is used.

6. Approach benefits

The AEP approach used here to estimate hearing thresholds in dolphins has characteristics that make it attractive for use on captive, stranded or wild caught marine mammals. The statistical approach to signal detection and defined rules for inclusion of data points used in the regression analysis diminish the potential bias introduced by the subjective selection of data for threshold estimation. Increasing the application of such objective approaches to AEP threshold estimates can help reduce interstudy variability and facilitate comparisons of results from different studies. Because it employs an automated search algorithm, automated statistical detection of signals and threshold estimation, and automatic transition between test frequencies, the approach permits rapid testing across a broad range of frequencies. The testing of 11 frequencies from 10 to 150 kHz was achieved in approximately 45 min, and the sensitivity of both ears was obtained in 1.5 h. It is important to note that the total of 1.5 h is a single test session in which the full range of hearing of both ears was tested. This relatively short testing time substantially exceeds the rate at which behavioral hearing tests can be performed (e.g., weeks to months) and permits multiple animals to be rapidly tested in sequence. Due to the potential impact of handling stress, the ability to rapidly test animals is a major consideration when dealing with stranded and rehabilitated animals and efforts to collect AEP threshold estimates from these animals will benefit from the implementation of rapid data acquisition systems.

V. CONCLUSIONS

The automated methodology described here offers advantages to assessing hearing sensitivity in delphinids by increasing the rapidity of data collection and the objectivity of the data analysis. Threshold estimates derived from this approach in four bottlenose dolphins demonstrated agreement with behavioral thresholds: (1) differences were consistent with the magnitude and variation of those observed in similar clinical studies; (2) the upper cutoff frequency of hearing sensitivity determined by both methods were close. AEP thresholds measured using the techniques described here are useful proxies for underwater behavioral data.

ACKNOWLEDGMENTS

We thank R. Dear and C. Schlundt for invaluable help in data collection and analysis and L. Green, C. Quintos, L. Lewis, E. Linberg for animal training. Behavioral audiograms for BUS and BUG were provided by D. Katsak and L. Dankiewicz. S. Ridgway, D. Carder, and P. Moore provided much helpful advice and technical assistance. Financial support was provided by the U.S. Office of Naval Research,

Marine Mammal S&T Program and the SSC San Diego In-House Laboratory, Independent Research (ILIR) program.

PROGRAM OF

The 151st Meeting of the Acoustical Society of America • Providence, Rhode Island • 5–9 June 2006
Rhode Island Convention Center

NOTE: All Journal articles and Letters to the Editor are peer reviewed before publication. Program abstracts, however, are not reviewed before publication, since we are prohibited by time and schedule.

MONDAY MORNING, 5 JUNE 2006 ROOM 555AB, 8:30 TO 11:30 A.M.

Session 1aAA

Architectural Acoustics: Current Topics in Architectural Acoustics

Lily M. Wang Chair
Univ. of Nebraska—Lincoln, Architectural Engineering, Omaha, NE 68182

Contributed Papers

8:30

1aAA1. An online ear training program designed for students, acousticians, and architects. Nozomi Kamiya, Ning Xiang (Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, nkamiya@eilarassociates.com), and Mendel Kleiner (Chalmers Univ. of Technol., SE-41296 Gothenburg, Sweden)

As part of a continuing research initiative at the Program in Architectural Acoustics at Rensselaer Polytechnic Institute, an online ear training program has been designed and implemented for scholars active in architectural acoustics, as well as professional acousticians and architects. The project aims to provide users the opportunity to learn to evaluate selected acoustical parameters without the employment of measurement equipment. The author believes that this training program will be indispensable for those who seek careers in fields related to acoustics for such skills are currently considered to be obtainable through professional experience in the field alone. The program was created using Macromedia Flash animations to develop an interactive training environment. Features such as user identification and an animated user interface create a personalized and entertaining experience while a score tracking system and high score table encourage friendly competition amongst users. As a result, users are compelled to return for successive training sessions which promote long-term growth and learning. Basic requirements for participation include an installed version of the Flash plug-in, an internet-enabled computer, and a pair of headphones.

8:45

1aAA2. Speech intelligibility of lecture halls. Lauren Ronsse (Univ. of Kansas, 1312 Louisiana St., Lawrence, KS 66044, lronsse@ku.edu)

For this project, different large lecture halls were analyzed using various speech intelligibility measurement techniques. The goal was to determine how well these measurements correlate with each other and convey speech intelligibility. Objective speech intelligibility and other related acoustical measurements were made throughout each hall at varying distances from the speaker. These measurements were repeated in each hall in a standardized manner, allowing the results from the different halls to be compared effectively. These objective measurements were related to the subjective analysis of the hall to determine which measurements indicate an appropriate speech intelligibility level for that space. Background mechanical system noise was introduced into some of the halls to determine the effect on speech intelligibility. Some of the halls tested were modeled in an architectural acoustics computer program to determine how well the actual measurements correlate with the predicted measurements. Measurement techniques and results of the study will be presented.

9:00

1aAA3. A shape variable acoustic panel system for multipurpose rooms. Ken Andria (Acoust. Dimensions, 145 Hugenot St., Ste. 406, New Rochelle, NY 10801, andriak@gmail.com) and Mendel Kleiner (Chalmers Univ. of Technol., SE-41296 Gothenburg, Sweden)

This work proposes an acoustically effective alternative to current passive acoustic solutions. Typical systems involve moving panels to one of either reflective, absorptive, or diffusive surface states. By varying the

shape of an array of ceiling reflectors, acousticians can achieve more precise control of the room response to better serve a wider range of acoustic scenarios. The results of scale model testing show how a single system can direct, absorb, or diffuse sound energy so that the room will be appropriate to four distinct programmatic events: lectures, gathering, simultaneous sources, and flat effect. By including microphones and a digital signal processing system the panel system may be designed to adaptively change its behavior to suit that of the current room use.

9:15

1aAA4. Acoustical design of St. Margaret's Chapel. Akira Ono and Minoru Nagata (Nagata Acoust. Inc., Hongo-Segawa Bldg.3F, 2-35-Hongo Bunko-Ku Tokyo113-0033)

St. Margaret's School is an all-girls high school located in the quiet, upscale Suginami Ward of Tokyo. The school's St. Margaret's Chapel was built some 70 years ago and included a pipe organ. The school decided to replace it with a new pipe organ and commissioned Taylor & Boodie, a U.S. organ builder. They requested adjustments to the chapel's room acoustics so that the new organ would sound its best. Before the project began, the chapel's reverberation time measured 1.4 s at 63 Hz and 1.8 s at 500 Hz and 1 kHz. That is, the reverberation time was shorter for low register sounds. The immediate challenge we faced on this project was the school's requirement that the chapel not be altered at all visually. St. Margaret's Chapel has historical value that the school wished to preserve. The framework of the chapel building and its floor are entirely made of wood. Moreover, the area around the altar is wood paneling. Upon investigation, we confirmed that the vibrations of these wood elements were absorbing the low register sounds. We determined that strengthening the walls and floor of the altar area would be an effective strategy to improve the chapel's acoustics.

9:30

1aAA5. Sound absorption in concert halls: Rectangular versus other shapes; Sabine versus Eyring equations. Leo L. Beranek (975 Memorial Dr., Ste. 804, Cambridge, MA 02138, beranekleo@ieee.org)

The accurate calculation of reverberation time in a concert hall in advance of construction is vital because it relates directly to the volume of the hall, a critical architectural parameter. The calculation can be by either the Sabine or Eyring equations which, broadly speaking, requires two quantities, the absorption coefficients of the seated audience plus orchestra and those of the nonaudience areas, i.e., side walls, ceiling, and the like. The two formulas require different sizes of absorption coefficients. The Sabine and Eyring equations are analyzed here, including their relative accuracies. A means for deriving the Eyring absorption coefficients when the Sabine coefficients are known is presented. Based on published acoustical and architectural data for 20 selected concert halls, which are of two shapes, the audience and chair absorption coefficients are calculated. It is concluded that for the same audience area and a given midfrequency reverberation time the volume of a hall is directly proportional to the midfrequency audience absorption coefficient, which, in turn depends on the type of chair and the shape of the hall. New audience absorption coefficients for medium and heavily upholstered chairs and for the two types of hall are presented.

9:45

1aAA6. An efficient algorithm for Bayesian energy-decay analysis in architectural acoustics. Ning Xiang and Paul Calamia (Grad. Prog. in Architectural Acoust., Rensselaer Polytechnic Inst., Troy, NY 12180)

Sound energy-decay analysis, including experimental determination of reverberation times in single-space enclosures and decay-time estimation in acoustically coupled spaces, has relied primarily on Schroeder backward integration of room impulse responses. Recent work has demonstrated that model-based Bayesian approaches [Xiang *et al.*, J. Acoust. Soc. Am. **110**, 1415–1424 (2001); **113**, 2685–2697 (2003); **117**, 3705–3715 (2005)] can be very useful for such analysis in architectural acoustics. In order to remove any concern of a high computational load within the Bayesian framework, this paper describes a search algorithm for the model-based Bayesian approaches which leads to an efficient analysis method, not only for multiple decay rates in acoustically coupled spaces but also for classical reverberation time estimation. Implementation of the algorithm within the Bayesian framework is discussed, and its performance with respect to other existing algorithms is analyzed using experimentally measured room impulse responses.

10:00–10:15 Break

10:15

1aAA7. Experimental investigations of acoustically coupled spaces. Zuhre Su, Ning Xiang (Grad. Prog. in Architectural Acoust., Rensselaer Polytechnic Inst., Troy, New York 12180), and Jason E. Summers (Acoust. Div. Naval Res. Lab., Washington, DC 20024)

Recently, architectural acousticians have been increasingly interested in halls that incorporate coupled-volume systems because of their potential for creating desirable effects in meeting conflicting requirements between clarity and reverberance. Previous works on coupled spaces include studies on theoretical formulation of energy exchange between coupled volumes and applications of Bayesian inference for estimating decay parameters in such spaces. Frequency dependence of sound-energy decay is one of the essential aspects of acoustically coupled spaces that has not yet been extensively investigated. In order to understand the behavior of sound-energy decay over different frequency ranges, experimental studies are carried out. Room impulse responses are collected through real-size and scale-model measurements. Schroeder integrations followed by Bayesian decay analysis reveal location sensitivities over different frequency bands in coupled spaces. This paper discusses extensive analysis results from Bayesian analysis of experimentally measured room impulse responses.

10:30

1aAA8. Subjective response to absorption and aperture size variations in complex computer-modeled coupled volume systems. David T. Bradley and Lily M. Wang (Architectural Eng., Univ. of Nebraska-Lincoln, 1110 S. 67th St., Omaha, NE 68182-0681, dbradley@mail.unomaha.edu)

Computer models of an imagined but realistic coupled volume concert hall have been made to obtain room impulse responses for several different configurations of the space. A coupled volume concert hall is typified by a large, absorbent main volume linked to a smaller, reverberant auxiliary space through a series of sonically transparent openings. Absorption and aperture size have been modified in this study to create each configuration of the virtual hall. Auralizations of the configurations have been used in paired-comparison tests to determine listener preference for the various sound fields, including some that exponentially decay and others that show a double-sloped decay. The results from this subjective testing were statistically analyzed using Thurstone Case V and multidimensional scaling methods. These results will be presented and contrasted with objective parameters extracted from the impulse responses generated by the computer modeled-configurations of the hall.

10:45

1aAA9. Measurements and verification of two mosques in Saudi Arabia. Wasim A. Orfali and Wolfgang Ahnert (Inst. of Techn. Acoust., Tech. Univ. Berlin, Einsteinufer 25, 10587 Berlin, Germany, orfaliwasim@hotmail.com)

Two prestigious mosques, Holy Haram in Makkah and Prophets Mosque in Medinah, have been selected to investigate their acoustical properties. With portable measurement setup basic parameters like reverberation time, intelligibility numbers, sound level distribution, and others have been measured. This was done with and without a sound system installed at the site. In postprocessing the results have been compared with recommendations developed by us for different mosque sizes. Also, proposals are given for further improvements in the existing sound quality. Finally, suggestions for future newly constructed mosques are derived.

11:00

1aAA10. A sound encounter or deaf ignorance: Coherence of new buildings to old mosques. Quinsan Ciao (Dept. of Architecture, Kuwait Univ., P.O. Box 5969, Safat 13060, Kuwait)

This is to raise the issue of a common phenomenon occuring within the booming development of many Islamic cities where a building site is nested within the common cluster of old mosques. The location and exisitance of mosques are fixed as God-given constraints and so is the voice of calling for prayers. The sound of worshiping infiltrated in all urban interior/exterior spaces. A brief study shows the split views in an Arab city where freedom of expression is progressing. Should the new buildings embrace the spiritual deeds and be the powerful bearer of the Holy Tune? Should we try to prevent the noise from interfering with the modern day function? Are there any design guidelines? A quick overview shows that the majority of new buildings recently built in Kuwait City neglected the subject, particularly the large projects commissioned to western design firms whose consultants may have less awareness of the issues related to the small-scale religious entities. This creates not only challenges to their proposal of an ideal form, but also the need for a unique answer to the acoustics regarding the sound of worship. A project involving students' works was carried out to explore the possibilities of tackling the problem.

11:15

1aAA11. Perceptual acoustics in the Mapparium. William M. Hartmann (Dept. of Phys. and Astron., Michigan State Univ., 4230 BPS Bldg., E. Lansing, MI, 48824, and Dept. of Biomed. Engr., Boston Univ. Boston, MA 02215), H. Steven Colburn, and Gerald Kidd, Jr. (Boston Univ., Boston, MA, 02215)

The Mapparium is a hollow, stained-glass globe, 30 ft. in diameter, at the Mary Baker Eddy Library in Boston. It allows visitors to see the continents of the world from the perspective of an observer inside the Earth. The ears of a visitor walking across the glass bridge traverse a diameter in the equatorial plane. The acoustical properties of this space are of secondary importance, but they are so remarkable that they amaze everyone who experiences them. Extensive listening and recording experiments within the Mapparium (prior to the renovations of 2002) revealed some of the acoustical effects in detail, with source and receiver points near the bridge diameter. Among the effects are the following: anomalous broadband point-to-point amplitude transfer functions with maxima (whispering gallery) and spatially compact minima; localization illusions wherein a source on the listener's left is heard on the right, or high- and low-frequency parts of a sound are localized differently, or sound images change in elevation as the listener walks; spatially compact regions of flutter echo; and spatially unstable reflections of one's own voice. [Work facilitated by the Mary Baker Eddy Library for the Betterment of Humanity.]

MONDAY MORNING, 5 JUNE 2006 ROOM 550AB, 8:55 TO 11:35 A.M.

Session 1aAB

Animal Bioacoustics: Acoustic Interactions in Animal Groups I

Andrea M. Simmons, Chair
Brown Univ., Dept. of Psychology and Neuroscience, Providence, RI 02912

Chair's Introduction—8:55

Invited Papers

9:00

1aAB1. Interference risk and dynamic shifts in calling in the gray treefrog. Joshua Schwartz (Dept. of Biological and Health Sci., Pace Univ., 861 Bedford Rd., Pleasantville, NY 10570, jschwartz2@pace.edu)

Male gray treefrogs call to attract females under challenging acoustic conditions. With increases in chorus density, background noise levels and the chance that male calls will be overlapped increase. Call overlap may jeopardize the probability of mating because females prefer advertisement calls in which the internal pulse structure of calls is not obscured to those that are overlapped by other calls. With increases in the level of acoustic stimulation, males lengthen the duration of their calls but simultaneously reduce call rate such that pulse effort changes little. The interference risk hypothesis was tested, which proposes that males change their calling in a fashion that insures that, on average, there will be a sufficient number of pulses and interpulse intervals clear of acoustic interference per call to attract a female. However, a series of female choice experiments employing call alternatives of different durations, rates, intensity levels and degrees of call overlap refuted this hypothesis. Results leave open the possibilities that the dynamic shift in the two components of pulse effort are related to the problem of call detection in a noisy environment or are responses by males to the perceived threat of competition for females. [Work supported by NSF.]

9:20

1aAB2. Signal timing by the gray treefrog, *Hyla chrysoscelis*: Responses to conspecific and heterospecific advertisement calls. Vincent Marshall (Beckman Inst., Univ. of Illinois, 405 North Mathews Ave., Urbana, IL 61801)

Breeding choruses often consist of multiple species sharing the same communication channel. Whether and how a signaler adjusts the timing of its signals, an often important predictor of receiver response, may therefore depend on the species identity of its neighbor. How males of the gray treefrog, *Hyla chrysoscelis*, adjusted advertisement call timing towards the calls of conspecifics and those of the closely related, syntopic species, *H. versicolor*, was examined. During interactions between calling males, calls were timed such that there was little signal overlap regardless of whether the neighbor was conspecific or heterospecific. In response to playbacks of conspecific and heterospecific advertisement calls, males generally avoided producing calls during either stimulus type,

and instead produced them during the silent gaps between stimuli. There were, however, significant differences in the latencies of response to conspecific and heterospecific signals. Males produced calls with shorter latencies after the heterospecific calls, which resulted in their often rapid placement within the silent intervals between stimuli. In contrast, calls produced after conspecific stimuli almost always had a distinct gap after the stimulus ended. These results are discussed in light of hypotheses for the function of adjustments in the timing of acoustic sexual signals.

9:40

1aAB3. Temporal organization of bullfrog choruses. Andrea M. Simmons, James A. Simmons (Dept. Psych. & Dept. Neurosci., Brown Univ., Providence, RI 02912, Andrea_Simmons@brown.edu), and S. D. Deligeorges (Boston Univ., Boston, MA 02215)

Choruses of advertisement calls of male bullfrogs (*Rana catesbeiana*) were recorded at two different ponds with an array consisting of two 4-microphone sensors to locate and identify calling individuals. The array determined the bearing of frogs from two positions located 10 m apart along the edge of the pond. Frogs were segregated and classified as individuals from the cluster of bearing intersections provided by the two sensor units for each note making up the advertisement calls. At one pond, 6 frogs were identified by bearing intersections, and 2 additional frogs, picked up by only one sensor unit, were separately identified from the pitch of their calls. At the other pond, 9 frogs were localized and 3 additional frogs were identified. Some frogs called independently, with coincident calling between pairs occurring at or near chance levels. These frogs usually were located remote from one another in the pond. At both ponds, a group of 2–3 frogs located in relative proximity called in partially overlapping temporal sequences that recurred throughout recording sessions. Members of the group may have to recognize each other acoustically in order to maintain the integrity of the timing sequence across multiple repetitions. [Work supported by NIH and DARPA.]

10:00–10:20 Break

10:20

1aAB4. Cues used by female barking treefrogs (*Hyla gratiosa*) to assess distances to potential mates. Christopher G. Murphy (Dept. of Biol., James Madison Univ., MSC 7801, Harrisonburg, VA 22807)

In chorusing insects and amphibians, females have the potential to choose from among a number of males located at various distances from the choosing female. In barking treefrogs, the distance to potential mates influences female choice, with females choosing a more attractive call over an unattractive call until the distance to the source of the more attractive call, relative to the source of the unattractive call, becomes too great. Two- and eight-speaker playback experiments were used to determine which cues females use to assess the distances to potential mates. These playback experiments ruled out three possible cues: degradation of signal quality, amplitude at the location of the female, and the sound gradient (how rapidly call amplitude increases as a sound source is approached). Additional playbacks showed that females consistently preferred signals with the highest source amplitude, even when the amplitude of that signal at the location of the female was lower than that of another signal during a substantial proportion of the approach by the female. These results indicate the source amplitude is an important cue in mate choice and suggest that females use a complex mechanism (e.g., triangulation) to judge distance to potential mates.

10:40

1aAB5. The causes and evolutionary consequences of a conflict between species and mate-quality recognition. Karin S. Pfennig (Dept. of Biol., CB#3280, Univ. of North Carolina, Chapel Hill, NC 27599-3280, kpfennig@email.unc.edu)

Mate choice typically involves the identification of conspecifics (species recognition) and the identification of mates that provide females with enhanced fitness (mate-quality recognition). When high-quality conspecifics possess advertisement signals that resemble those of heterospecifics, however, females may be unable to engage in both species and mate-quality recognition simultaneously. This conflict between species and mate-quality recognition may require that females trade off the benefits of mating with high-quality males with the risk of heterospecific matings. In spadefoot toads, females face a conflict between species and mate-quality recognition because the advertisement calls of high-quality conspecifics resemble those of heterospecifics. Because of this conflict, females compromise on male quality to ensure conspecific matings. Moreover, this trade-off has seemingly caused spadefoot toads to evolve smaller body size, reduced fecundity, and different patterns of sexual dimorphism in populations where heterospecifics are present (sympatry) versus populations where heterospecifics are absent (allopatry). Thus, a conflict between species and mate-quality recognition can have profound impacts on how females use male advertisement signals to choose mates, sexual selection, and morphological evolution in different populations, and even the fitness of individuals in sympatry relative to those in allopatry.

1aAB6. The *cocktail party problem*: What is it? How can it be solved? And why should students of bioacoustics study it? Mark A. Bee (Dept. of Ecology, Evolution, and Behavior, Univ. of Minnesota, 1987 Upper Buford Circle, Rm. 100, St. Paul, MN 55108)

Auditory scene analysis refers to mechanisms that parse a composite acoustic waveform into perceptually distinct auditory *objects* or *streams* that correspond to distinct sound sources in the environment. A familiar and well-studied example of a difficult auditory scene analysis task is the *cocktail party problem*, which refers to the difficulty we have perceiving speech in noisy social environments comprised of multiple people talking simultaneously. Students of human hearing and computer engineering study auditory scene analysis, in part, because people with hearing impairments and computer algorithms for speech recognition do a poor job of solving the cocktail party problem compared to people with normal hearing. Of course, the cocktail party problem is not unique to humans. The animal behavior literature provides numerous examples of cocktail-party-like social environments for animal acoustic commu-

nication (e.g., choruses, roosts, colonies, creches). Compared to previous work on humans, however, students of animal bioacoustics have devoted little attention to how animals that signal in groups or networks solve their own cocktail party problems. This talk will briefly review some issues in auditory scene analysis relevant to the study of animal acoustic communication and present the case for why these issues deserve further study by students of bioacoustics.

1aAB7. Observation and modeling of a spatiotemporal pattern in fish chorusing. Gerald L. D'Spain, Heidi H. Batchelor, and Catherine L. Berchok (Marine Physical Lab., Scripps Inst. of Oceanogr., 291 Rosecrans St., San Diego, CA 92106)

A numerical model was developed to predict the unusual spatiotemporal characteristics of sciaenid chorusing recorded offshore of the Southern California coast. The model, based on the physics of excitable media, is composed of a random distribution of units (fish) on a 2D grid that inhabits one of three states: resting, excitable, and active. Temporal evolution of a unit's state is determined by transition laws. The temporal character of chorusing (increases in ocean sound levels by factors of 2 to 5 for 10–20 s followed by 15–20 s periods of lower levels) can be predicted using a Poisson waiting time distribution, once the proper parameters are selected. For some parameters, the predicted chorusing levels evolve into a continuous din rather than displaying a cycling nature. In one experiment, the spatial evolution of chorusing also has a periodic nature; each chorus begins off the Mexican coast and the chorusing region propagates 25 km upcoast until the fish just south of San Diego harbor reach a chorus peak 16–20 s later. Predicting this observation for arbitrary initial conditions requires coupling between units, achieved by incorporating the received sound level into the probability of transitioning from excitable to active states. [Work supported by ONR.]

Session 1aBB

Biomedical Ultrasound/Bioresponse to Vibration: Brown Tadpoles and Red Herrings I: Boiling Inertial Cavitation and Nonlinearity in High Intensity Focused Ultrasound Lesion Formation

R. Glynn Holt, Chair

Boston Univ., Dept. of Aerospace and Mechanical Engineering, 110 Cummington St., Boston, MA 02215

Invited Papers

8:00

1aBB1. A chair's introduction to brown tadpoles: What's all the fuss about? R. Glynn Holt (Dept of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, rgholt@bu.edu)

A brief background of the work in understanding irregular HIFU thermal lesion formation will be presented to motivate the current session. Several basic arguments for asymmetric lesion formation will be framed, highlighted by examples of *in vivo* occurrence. Several fundamental questions will be posed, with the hope that such questions will be addressed, clarified, and answered by the speakers and panel members (as well as the audience) by the end of the session. Along with conceptual discussions of relevant mechanisms, recommendations for usage of terms to describe and distinguish these mechanisms will be encouraged.

8:15

1aBB2. Microbubble cavitation, boiling, and nonlinear acoustic propagation in high-intensity focused ultrasound thermal therapy. P. J. Kaczkowski, M. R. Bailey, L. A. Crum (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, peter@apl.washington.edu), V. A. Khokhlova (Moscow State Univ., Moscow 119992, Russia), and A. Anand (Philips Research USA, Briarcliff Manor, NY 10510)

The investigation of high-intensity focused ultrasound (HIFU) as a tool for noninvasive thermally ablative therapy has required deeper understanding of the relative roles of nonlinear mechanisms involved in heat deposition. Attempts at quantifying the dose response to particular exposure conditions *in vitro* are complicated by the interplay of several mechanisms. These include microbubble cavitation, nonlinear acoustic propagation and attenuation, dependence of tissue parameters on temperature and temperature history, and formation and evolution of vapor bubbles due to boiling. One immediately evident consequence of such effects is distortion of coagulative lesion shape and size, colloquially evolving from cigars to tadpoles. Developing a quantitative understanding of the relative roles of relevant nonlinear mechanisms is not straightforward, yet is desirable for design of algorithms for therapy planning and real-time monitoring using ultrasound. A historical perspective of research toward this end will be presented along with a recommendation for suitable terminology for the various physical acoustic regimes encountered in HIFU therapy. [Work supported by Army MRMC, NIH DK43881, NSBRI SMS00402, and RFBR.]

8:45

1aBB3. The relevance of bubbles in clinical high-intensity focused ultrasound treatments. Gail ter Haar (Phys. Dept., Inst. of Cancer Res., Royal Marsden Hospital, Sutton, Surrey, SM2 5PT, UK)

Until recently there has been a dichotomy of opinion as to the utility of bubbles in clinical HIFU treatments. On the one hand uncontrolled acoustic cavitation can lead to lesions of unpredictable shape, size, and position, while on the other, lesions containing bubbles are visible on conventional B-mode ultrasound images, and clinically are generally regarded as being indicative of tissue destruction. In some HIFU treatments of cancer, therefore, the ultrasound exposure levels are increased until bright ups are seen on the real time ultrasound scan of the target volume. It is now known that, in the presence of acoustic cavitation, the rate of heating is considerably enhanced, and investigations are under way to establish whether controlled cavitation induction can be used to speed up clinical HIFU treatments. When temperatures in excess of 100 °C are achieved in tissue, tissue water boiling will occur. This too will result in enhanced scatter in the ultrasound image. Boiling will also result in tissue destruction. The clinical implications of bubble activity will be reviewed in this paper.

9:15

1aBB4. Bubble nucleation, growth and dissolution in soft tissue. Charles C. Church (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

Vapor bubbles of sufficient size to serve as cavitation nuclei may form spontaneously in tissue in regions of very low interfacial tension. In the absence of an acoustic wave or other mechanical stress, such nuclei will quickly dissolve and disappear from the medium. Under the influence of an acoustic wave, however, these microbubbles may grow to many times their initial size and then collapse violently, a process known as inertial cavitation. The *in vivo* energetics of the nucleation process are treated by assuming tissue to be a homogeneous fluid, while the initial dynamics of nucleated bubbles are modeled by treating tissue as an isotropic, viscoelastic solid. It is shown that the rate of nucleation-cavitation events is highly sensitive to the instantaneous tissue temperature and moderately sensitive to the rarefactional pressure. The effect of tissue elasticity is to increase the threshold pressure for inertial cavitation and decrease the rate of rectified diffusion relative to bubbles in water. Finally, the increased rigidity of denatured soft tissue enhances the persistence of gas/vapor bubbles following the acoustic pulse.

1aBB5. A model for irregular lesion formation including cavitation bubbles and boiling. Tianming Wu, Caleb H. Farny, Ronald A. Roy, and R Glynn Holt (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Nonlinear propagation and scattering of incident sound due to the presence of gas/vapor bodies and temperature-dependent sound speed and acoustic absorption have been found to contribute to irregular lesion formation during high-intensity focused ultrasound therapy. The appearance and importance of these mechanisms are dependent on the intensity of insonating sound and the medium properties. In the regime where the focal pressure is slightly above the cavitation threshold and the medium possesses sufficient nuclei, photographic observations and model simulations for tissue phantoms reveal that tadpole lesions start to develop prior to large-scale boiling; however, enhanced heating from inertial cavitation greatly accelerates the progression to boiling. The relative time scales for cavitation-triggered boiling and bubble dissolution are studied in order to yield insight on how to control pulse-mode HIFU insonation in order to either avoid bubble behavior outright or utilize cavitation and boiling to promote therapy. [Work supported by the Dept. of the Army (Award No. DAMD17-02-2-0014) and the Center for Subsurface Sensing and Imaging Systems (NSF ERC Award No. EEC-9986821).]

10:15

1aBB6. The dependence of temperature rise and cavitation dose on acoustic pressure during high-intensity focused ultrasound (HIFU) application. Caleb H. Farny, Tianming Wu, R. Glynn Holt, and Ronald A. Roy (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, cfarny@bu.edu)

Given sufficient nuclei, inertial cavitation can greatly enhance heating rates during HIFU application. In the absence of bubble shielding effects, one might assume that increasing the driving pressure amplitude will serve to enhance both the temperature elevation and the amount of cavitation activity. Here we report on measurements in agar-graphite phantoms that show that during HIFU application, cavitation dose and temperature rise do increase with increasing pressure but only to a point where there is a measurable decrease in the 2.5–3-MPa range followed by further increase with higher pressures. This behavior can be predicted using single-bubble dynamics with allowed equilibrium bubble sizes that are consistent with waterlike viscosity values for an effective Newtonian fluid host [see Yang *et al.*, J. Acoust. Soc. Am. **116**, 3423–3431 (2004) for details]. These results can serve to help guide an optimal pressure as well as develop a further understanding of the bubble parameters and energy dissipation mechanisms involved in HIFU. [Work supported by the Dept. of the Army (Award No. DAMD17-02-2-0014) and the Center for Subsurface Sensing and Imaging Systems (NSF ERC Award No. EEC-9986821).]

10:30

1aBB7. Interpreting passive cavitation detection signals during high-intensity focused ultrasound (HIFU). Jamie R. T. Collin and Constantin C. Coussios (Dept. of Eng. Sci., Univ. of Oxford, 17 Parks Rd., Oxford OX1 3PJ, UK)

Inertial cavitation is known to be associated with significantly enhanced rates of heating during cancer treatment by high-intensity focused ultrasound (HIFU). However, during prolonged exposure, the cavitation region gradually shifts towards the HIFU transducer, causing shielding of the original focus. It is hoped that controlling the HIFU field to constrain cavitation to the focal region will lead to sustained enhanced focal heating, thus reducing treatment times and improving treatment resolution. Monitoring of cavitation can be achieved during insonation by using a focussed passive cavitation detector (PCD) to listen for broadband noise emissions resulting from microbubble collapse. The ability to effectively control the cavitation field relies on accurate interpretation of the PCD data. During HIFU exposure of a tissue-mimicking material, it was noted that the frequency content of the PCD signal shifted downwards with increasing phantom propagation path length to the PCD, as a result of depth-dependent attenuation. This has significant implications for the effective sensing volume of the PCD. In addition, it was noted that separate analysis of the peak and rms time-domain PCD values provides an incomplete description of inertial cavitation activity, but that combining these two parameters enables a better understanding of bubble cloud dynamics.

10:45

1aBB8. An amplitude-modulated harmonic motion imaging method for mapping tissue ablation. Caroline Maleke, Mathieu Pernot, and Elisa Konofagou (Dept. of Biomed. Eng., Columbia Univ., 1210 Amsterdam Ave., New York, NY 10027)

Previously, a single-element focused transducer method inducing amplitude-modulated (AM) radiation force deep within the tissue was introduced. This technique offers real-time capability for monitoring the change in the tissue mechanical properties during focused ultrasound (FUS) therapy. In this paper, we extend the application of this technique for 2D mapping of the FUS lesion. The harmonic radiation force was generated by a 4.68-MHz focused transducer modulated at 50–100 Hz. Radio frequency (rf) data were acquired at 7.5 MHz with a PRF of 6.5 kHz, and displacements were estimated using a 1D cross-correlation algorithm on successive rf signals. A bandpass analog filter with $fc1 = 5$ MHz and $fc2 = 8$ MHz was employed to remove the spectrum of the focused beam. The real-time monitoring method was adjusted to induce 2-s sonication time using a continuous wave, followed by 100-ms AM signal to image tissue displacements. The experiments were performed on *ex vivo* porcine liver. The tissue was raster-scanned before and after lesion formation. Results indicated that displacement amplitudes decreased after lesion formation due to the associated elasticity change, and thus 1-cm-diameter lesions were accurately mapped. Future investigations of this technique will include temperature and coagulation mapping *in vivo*.

11:00

1aBB9. Development of a cell-embedded tissue-mimicking ultrasound phantom. Yunbo Liu and Pei Zhong (Dept. of Mech. Eng., Duke Univ., Durham, NC, 27708, pzhong@duke.edu)

An optically transparent cell-embedded tissue-mimicking phantom was developed to study high-intensity focused ultrasound (HIUF)-induced gene activation *in vitro*. The phantom was constructed by using agarose hydrogel embedded with dispersed rat mammary carcinoma (Mac) cells that were stably transfected with GFP plasmid under the control of hsp70B promoter. Thermally sensitive bovine serum albumin (BSA) proteins were also incorporated in the phantom so that both lesion formation and gene activation could be quantified simultaneously following HIFU exposure. Both acoustic (sound speed, attenuation, acoustic impedance, B/A ratio) and thermal properties (thermal conductivity and thermal diffusivity) of the phantom were characterized in a temperature-dependent manner. At a peak temperature between 70 °C and 90 °C and a 10-s exposure using a 3.3-MHz HIFU transducer, the inducible GFP gene expression patterns in the phantom were analyzed and compared with the corresponding 3-D temperature distribution quantified by thermocouple measurements. Overall, the cell-embedded tissue-mimicking phantom was found to be a versatile tool for investigating HIFU-induced gene activation and it may also be used for general ultrasound bio-effect studies. [Work supported by NIH.]

11:15

1aBB10. Effects of short-pulsed focused ultrasound: Histological study on the rabbit brain *in vivo*. Natalia Vykhodtseva, Nathan McDannold, and Kullervo Hynynen (Dept. of Radiol., Brigham and Women's Hospital, and Harvard Med. School, 75 Francis St., Boston, MA 02115)

Histological effects of short-pulsed focused ultrasound at pressure amplitudes beyond the cavitation threshold were studied. One hundred thirty-one locations in the brains of 27 rabbits were sonicated using a 16-sector focused transducer (1.63 MHz; $D/F = 10/8$ cm; burst lengths $= 1–100$ ms; PRF $= 1–100$ Hz, total exposure $= 10$ s). A range of effects was observed: (1) Affected blood vessels without any damage to the brain parenchyma. (2) Local lesions with homogenized core, which consisted of a pudding-like mass arranged in a helically coiled, layered fashion in some lesions. In the large lesions, core was completely liquefied. (3) Hemorrhagic and torn regions with fragmented and liquefied tissues, characteristic of inertial cavitation effects. (4) Circular-shaped lesions with a concentric annular pattern: a small central core was surrounded by three or more morphologically different circular layers. (5) Thermal lesions, which had the features of thermal lesions produced by lower-power sonications. These findings appeared to be associated with the nonlinear ultrasound absorption and cavitation-related effects, which could be exploited for new therapies. [Work sponsored by: NIH Grant Nos. R01CA076550 and R25CA089017.]

11:30

1aBB11. Focused ultrasound-induced opening of the blood-brain barrier in mice. James J. Choi, Mathieu Pernot, Scott A. Small, and Elisa E. Konofagou (Columbia Univ., 351 Eng. Terrace, Mail Code 8904, 1210 Amsterdam Ave., New York, NY 10027, ek2191@columbia.edu)

The feasibility of blood-brain barrier (BBB) opening in the hippocampus of mice using transcranial focused ultrasound (FUS) was investigated on simulations and *in vivo* experiments. A micro-CT scan of an excised mouse skull was performed (resolution: 0.01 mm) and mappings of porosity, speed of sound, density, and attenuation were calculated. A 1.5-MHz wave propagating through the skull mappings was simulated, revealing a well-formed beam, minimal attenuation, and minute focus displacement. These results were verified with needle hydrophone measurements through five excised mouse skulls. In experiments *in vivo*, three mice were intravenously injected with a bolus of 0.01-mL ultrasound contrast agents (Optison) and the brains were sonicated transcranially. Ultrasound sonications (frequency: 1.5 MHz; burst length: 20 ms; duty cycle: 20%; acoustic pressure range: 2.0 to 2.7 MPa) were applied five times for 30 s per shot with a 30-s delay between shots. High-resolution (9.4 tesla), contrast-enhanced MR imaging revealed BBB opening and slow permeation of gadolinium from the posterior cerebral artery (10-min postinjection) through the surrounding tissue (35-min postinjection) and to the entire left hippocampus (95-min postinjection). These results demonstrate the feasibility of localized, noninvasive BBB opening in mice using transcranial FUS for potential precise drug delivery.

11:45

1aBB12. Focused ultrasound-induced transgene activation in skeletal muscles. Xiaochun Lu, Georgii Sankin (Dept. of Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708), John Madden, and Pei Zhong (Duke Univ., Durham, NC 27708)

Focused ultrasound (FUS)-induced gene activation in the skeletal muscles of a rat model was investigated. Plasmids that encode the luciferase gene under the control of hsp70B promoter were transfected into the skeletal muscles of the hind limbs of a rat model by electroporation. One day following the gene transfection, the left hind limb was treated with 3.3-MHz FUS by raster scan of a 9×9-mm^3 area while the right hind limb was used as control. The output of the FUS transducer was adjusted to produce a rapid *in vivo* temperature rise (< 4 s) to three different temperature plateaus in the range of 40–50 °C, 50–60 °C, and 60–70 °C for a treatment duration up to 30 s. One day following FUS treatment, gene expression *in vivo* was analyzed and tissue injury assessed by H&E staining. It was found that *in vivo* gene activation and tissue damage were highly correlated with thermal dosage. The highest gene activation was produced by the FUS at 50–60 °C with an exposure time of 20 s, which was found to be statistically equivalent to the gene activation produced by water-bath hyperthermia (42 °C for 35 min). At this thermal dose, FUS-induced tissue injury was sublethal and could recover in a week.

1aSPa1. Introduction to deconvolution. Peter A. Jansson (Jansson Associates, 19 Arthur Dr., Hockessin, DE 19707)

Deconvolution tasks will always lie at the frontier of knowledge in many fields, almost by definition, because measurement resolution often defines the state of our knowledge. Rising in the latter 20th century from near-disreputability, first to usefulness, then necessity in some disciplines, the varied techniques of deconvolution have assumed an increasingly important role in the scientist's tool kit. This talk will trace deconvolution's development with examples, including many firsts, drawn from spectroscopy, radio astronomy, cell biology, color science, and diverse other fields. Following a tutorial introduction, detail will be provided on modern super-resolving methods, and lesser-known topics such as selected-ordinate image (SORI) processing.

8:10

1aSPa2. Room-acoustic energy decay analysis and acoustic landmine detection within Bayesian framework. Ning Xiang and Tomislav Jasa (Grad. Program in Architectural Acoust., Rensselaer Polytechnic Inst., Troy, NY 12180)

Model-based signal processing has been applied in sound energy decay analysis in enclosures for estimation of reverberation times [N. Xiang, J. Acoust. Soc. Am. **98**, 2112–2121 (1995)] and estimation of diverse decay times to quantify sound energy decay in coupled spaces. Recent works using Bayesian approaches have demonstrated success in this application [Xiang *et al.*, J. Acoust. Soc. Am. **110**, 1415–1424 (2001); **113**, 2685–2697 (2003); **117**, 3705–3715 (2005)]. Similar approaches have also been applied in acoustic landmine detection [Xiang & Sabatier, J. Acoust. Soc. Am. **113**, 1333–1341 (2003)] for target detection and target localization. Respective models have been developed for each application in order to apply model-based Bayesian approaches in two different acoustical regimes. Using experimentally measured field data, this paper demonstrates an example of data analysis solutions developed for the room-acoustics application which can also be applied to another physical regime: acoustic landmine detection.

8:30

1aSPa3. Geometric methods for real-world imaging problems. Eric Miller, Gregory Boverman, Emre Guven, Mohamed Khamed ben hadj Miled (Dept. ECE, Northeastern Univ., Boston, MA 02115, elmiller@ece.neu.edu), Robin Cleveland (Boston Univ., Boston, MA 02215), and Basak Ulker Karbeyaz (Analogic Corp., Peabody, MA 19610)

The extraction of information concerning the internal structure of a medium given sparsely sampled, externally collected data is a ubiquitous problem arising in application areas ranging from the large-scale (geophysical prospecting and environmental remediation) to the small (biomedical imaging and nondestructive evaluation). The sensors used to collect data are equally diverse, encompassing the full spectrum of electromagnetic and mechanical modalities. In spite of the broad variety seen in this class of problems, many share underlying common challenges making the application of core processing methods of potential utility across a range of specific problems. In this talk, we discuss the application of geometric parametrizations to problems we have encountered in geophysical and biomedical imaging problems using optical, ultrasonic, and electromagnetic sensors. Estimating the geometry of a tumor, plume of toxic waste, or lesion created in the process of hyperthermia cancer treatment often reduces the ill-posed nature of the imaging problem and allows for the extraction of parameters directly linked to the application-specific information we seek to recover from the data. We shall discuss three approaches we have used to parametrize shape as well as our experience in applying these methods to real-world data.

8:50

1aSPa4. Applications of acoustic-wave-field downward continuation to geophysical and medical imaging. Lian-jie Huang, Michael Fehler (Los Alamos Natl. Lab., MS D443, Los Alamos, NM 87545, ljh@lanl.gov), Nebojsa Duric, and Peter Littrup (Karmanos Cancer Inst., Detroit, MI 48201)

We introduce acoustic imaging methods using wave-field downward continuation and describe their application to geophysical imaging and ultrasonic breast imaging. We have developed a number of novel migration imaging methods based on the acoustic-wave equation in heterogeneous media. They have been successfully applied for imaging complex structures beneath buried salt bodies in which the velocity is often more than twice that of the surrounding sediment within the Earth. The length scale in seismic imaging problems is on the order of 100 times of the seismic wavelength. Even though the frequency used in ultrasonic breast imaging is at a few megahertz, which is a million times higher than seismic frequency, its length scale is also on the order of 100 times of the ultrasonic wavelength in the breast. On the other hand, there are many differences between seismic imaging and ultrasonic breast

imaging. For example, the sizes of imaging objects are 10–100 wavelengths for seismic imaging but on the order of the wavelength or less for ultrasonic breast imaging. We have successfully applied the wave-equation-based migration methods to ultrasonic breast imaging. We will present imaging examples both in seismic imaging and ultrasonic breast imaging.

9:10

1aSPa5. High-resolution acoustic and optical imaging underwater. Hanumant Singh (Deep Submergence Lab., Appl. Ocean Phys. and Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, hsingh@whoi.edu)

High-resolution sensing from underwater platforms continues to be limited by the mismatch between sensor resolution and available navigation information. In this talk we explore a similar set of solutions that works across the diverse applications and sensing modalities associated with multibeam sonar and optical camera systems. By utilizing results from the simultaneous localization and mapping (SLAM), computer vision and photogrammetric communities we examine the role of sensor consistency for overlapping sensor swaths to yield a far more accurate representation of the environment. We present our work in the context of real data acquired from a variety of autonomous underwater vehicles (AUVs) and remotely operated vehicles (ROVs) in a variety of locations including shallow-water coral reef surveys with the Seabed AUV, mapping the RMS TITANIC at 4100 m from the Hercules ROV and multibeam mapping of the TAG hydrothermal mound on the Mid-Atlantic Ridge at 2800 m.

9:30

1aSPa6. Development of equivalent circuit analogies that can predict the loading effects of a multilayered structure on an electro-acoustic transducer. Karl Fisher (Lawrence Livermore Natl. Lab., 7000 E Ave., Livermore, CA 94551)

A technique is being developed based on a direct correlation between the electrical impedance of a standard electro-acoustic transducer and the mechanical loading it experiences when placed in contact with a layered elastic structure. Quantitative structural information can be determined empirically provided that there is an accurate calibration standard to compare the measured electrical impedance to. Normally this would be accomplished using a mechanical structure with known dimensions and construction. However, in some instances this may not be practical. The goal is to investigate simple and accurate calibration standards based on electrical circuit analogies to quantify resonant measurements on multilayered elastic structures. [This work was performed under the auspices of the U.S. Department of Energy by University of California, Lawrence Livermore National Laboratory under Contract W-7405-Eng-48.]

1aSPa7. Applying geophysical imaging algorithms to nondestructive evaluation problems. Sean K. Lehman, Karl A. Fisher (L-154, Lawrence Livermore Natl. Lab., 7000 East Ave., Livermore, CA 94550), Robert A. Clapp, and Brad Artman (Stanford Univ., Palo Alto, CA)

The Center for Subsurface Sensing & Imaging Systems (CenSSIS, www.censsis.neu.edu) has been advancing the concept of "Diverse Problems-Similar Solutions," whereby imaging, inversion, and tomography (IIT) algorithms developed for one field or physical regime are applied to another. Following this philosophy, algorithms developed for geophysical imaging have been successfully applied to a nondestructive evaluation (NDE) problem in a planar multilayer. The depths and acoustic frequencies of geophysical problems are on the orders of kilometers and sub-hertz, while those of NDE are millimeters and megahertz. Just the same, the propagation phenomenon is entirely wave-based in both cases and thus, algorithms developed for one can be applied to the other. [This work was performed under the auspices of the U.S. Department of Energy by University of California Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48. UCRL-ABS-216281.]

10:15

1aSPb1. The method of adjoint field in inverse scattering of plane waves. D. N. Ghosh Roy (Ctr. For Adv. Imaging Res. (UCAIR), Univ. of Utah, 729 Arapeen Dr., Salt Lake City, UT 84108), S. J. Norton (Geophex, Ltd., Raleigh, NC 27603), and M. Schable (Univ. of Utah, Salt Lake City, UT 84108)

The notion of the adjoint operator/field is introduced, and its general importance in physical sciences briefly discussed. The applications of the adjoint in the solutions of inverse scattering problems for plane-wave excitation are overviewed for both obstacles and inhomogeneities. The method is then illustrated by applying it to a specific problem, namely the volume reconstruction of an

acoustic object by inverse scattering. Calculations of noise propagation from the data to the reconstructed image in inverse scattering using the adjoint field algorithm are presented. These calculations are then specialized to the case of Born approximation. Finally, the similarities and differences between inverse scattering and X-ray tomographic covariance are pointed out.

10:35

1aSPb2. Gradient-based shape optimization of an acoustic horn. Daniel Noreland (Laboratoire de Mecanique et d'Acoustique, 31 chemin Joseph Aiguier, 13402 Marseille Cedex 20, France, Erik Bangtsson, and Martin Berggren (Uppsala Univ., 751 05 Uppsala, Sweden)

Numerical shape optimization is employed in order to improve the transmission properties of an acoustic horn. Wave propagation in the horn is modeled by the Helmholtz equation, which is solved using a finite element method. The shape is modified by changing the position of the mesh points along the contour of the horn. The optimization uses a quasi-Newton algorithm, with the gradient of the cost function computed by solving the adjoint equation for the discretized forward problem. Key points are the mesh movement scheme and different procedures in order to enforce smooth design updates for a large number of degrees of freedom. Convergence is fast, and the resulting horns have good transmission properties over a wide frequency band.

10:55

1aSPb3. Adjoint-based sensitivity analysis of fluid-structure interaction vibrations. Haw-Ling Liew and Peter M. Pinsky (Dept. of Mech. Eng., Stanford Univ., Stanford, CA 94305-4040, pinsky@stanford.edu)

Adjoint-based sensitivity analysis for the cavity fluid-structure interaction vibrations problem, with the inclusion of prestress and internal pressurization, is considered. The formulation employs a continuum approach in which the adjoint model is defined by employing a new duality relation between the sensitivities and the adjoint variables. For complex problems, such as fluid-structure interaction, the new duality relation provides an unambiguous approach for the construction of the adjoint variational problem in contrast to the standard approach. It also provides useful insight into the interpretation of the adjoint method. The resulting adjoint formulation for sensitivities is based on evaluation of inner products of the adjoint and state variables and is efficient because it requires the calculation of the adjoint field only once, regardless of the number of decision variables. In order to assess the accuracy of the adjoint approach for sensitivities in fluid-structure interaction problems, a model problem is considered and exact and analytical adjoint sensitivities are compared. The method is then applied to a finite element human eye model to compute the sensitivities with respect to elasticity constants and intraocular pressure for application to inverse estimation of those properties. The results are presented using a particularly effective multidimensional visualization technique.

1aSPb4. An efficient reconstruction algorithm for inverse scattering based on sensitivity analysis and adjoint equations. Gonzalo R. Feijoo (Woods Hole Oceanograph. Inst., MS 11, Woods Hole, MA 02543)

A common approach when developing imaging algorithms is to construct a linear model that relates the measured data to the properties of interest in the medium. But often a linear model cannot be constructed due to the relevant physics of the problem under study. In these cases, approaches based on optimal control theory offer several advantages: (1) a unified theory can be constructed to deal with different underlying physics and (2) a generic set of algorithms can be developed to solve the resulting system of nonlinear equations. Nonetheless, these methods tend to be too costly for solving problems but those involving few parameters. In this talk a new efficient algorithm for the inverse obstacle problem is presented without making the usual assumptions of a weak scatterer. The algorithm is based on optimal control theory but, different from other methods, it does not rely on iterative techniques to obtain a solution. Rather, it computes a scalar field which is a first approximation to the location and shape of the objects. This scalar field is easily computed in terms of the incident radiation used to probe the medium and an adjoint field constructed from the measured scattering pattern.

1aSPb5. Analytic derivation of adjoint nonlocal boundary conditions for a stratified ocean bottom in parabolic approximation. John S. Papadakis, Evangelia T. Flouri (Inst. of Appl. & Computational Math., F.O.R.T.H., P.O. Box 1527, 71110 Heraklion, Greece), Matthias Meyer (Royal Netherlands Naval College, The Netherlands), and Jean-Pierre Hermand (Univ. libre de Bruxelles, B-1050 Bruxelles, Belgium)

In underwater acoustics various types of nonlocal boundary conditions have been developed to handle the semi-infinite bottom in parabolic approximations and to efficiently reduce the computational domain. This paper proposes new exact nonlocal boundary conditions suitable for a layered ocean bottom and presents an analytic derivation of the corresponding adjoint equations. The new boundary condition has the form of a Neumann-to-Dirichlet map (NtD) that explicitly contains the geoacoustic parameters of the stratified bottom, i.e., thickness, density, sound speed, and attenuation of each layer. By means of the analytic adjoint, exact gradient information can be obtained which in turn allows a direct inversion of these parameters using a gradient-based optimization scheme. 1aSPb6. Inferring marine animal characteristics using multi-angle scatter. Jules S. Jaffe and Paul L. D. Roberts (Marine Physical Lab, Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238)

An important goal in using active sonar systems to assess underwater animals *in situ* is the inference of animal dimension. Although 180-deg backscatter provides an estimate of target reflectivity, in many situations the reflected energy is not easily related to animal size. An additional degree of freedom, rarely exploited, is to measure animal scatter at a multiplicity of angles. Although this is more challenging from a technical point of view, the benefit of this additional information can make it worthwhile. The interpretation of multi-angle scatter from marine organisms can

be most easily understood in the context of diffraction tomography. Depending upon the details of the scattering process, in fortuitous circumstances a complete set of angular data can be inverted to compute the three-dimensional scattering potential which can ultimately lead to a complete inversion for animal morphology. In cases where it is impractical to collect a complete set of angular data it is often possible to infer characteristic dimensions of the animal from an analysis of the obtainable multi-angle data. The interpretation of multi-angle scatter data in the context of diffraction tomgraphy therefore presents opportunities to infer ecologically significant information about animal populations.

Underwater Acoustics and Acoustical Oceanography: High-Frequency Ambient Noise

Juan I. Arvelo, Chair
Johns Hopkins Univ., Applied Physics Lab., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099

Chair's Introduction—9:30

Invited Papers

9:35

1aUW1. Recent developments in ambient noise processing. Martin Siderius, Michael B. Porter (HLS Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130), and Chris H. Harrison (NATO UnderSea Res. Ctr., La Spezia, Italy)

For many sonar applications noise is an annoyance and great effort is expended to minimize its impact. It may be surprising that ocean acoustic noise can itself be used in ways that rival or surpass complex sonar systems with controlled sound sources. Although ocean noise has been studied for many years, recent developments have led to exciting new ways to exploit the noise field for practical applications. In particular, by cross correlating the noise measured on two sensors one can recover a reasonable estimate of the impulse response between the sensors. This coherent processing was first demonstrated for sensors horizontally separated, however, it was also recently applied to vertically separated sensors. The vertical configuration leads to a type of passive fathometer that not only determines water depth but also reveals the seabed layering. A second development uses beamforming on the incoherent noise field to estimate bottom reflection loss. Combining these coherent and incoherent techniques leads to powerful ways to determine the properties of the seabed. This presentation will provide a summary of these recent developments and will show how these are combined for profiling the geoacoustics of the seabed using noise. Examples will be shown using both measured and simulated data.

9:55

1aUW2. High frequency noise modeling: Dependence on application. Chris H. Harrison (NATO Undersea Res. Ctr., Viale S. Bartolomeo 400, 19138 La Spezia, Italy, harrison@nurc.nato.int)

It is tempting to think that one could build a practical, general purpose noise model suitable for high or low frequencies and any application. For many signal processing and system applications this may be true, and one could incorporate directionality and spatial coherence. Recent developments in the use of wind-and sea-surface noise to determine geoacoustic properties by cross correlating hydrophone signals or beams demonstrate the need for more detail. The correlation peaks that correspond to absolute distances or ranges clearly require (frequency domain) coherence in any simulation. In contrast, layer information derived from angular reflection loss measurements by spectral factorization does not require coherence since it originates from an angular power spectrum. In both these cases the assumption of a uniform sheet of incoherent sources is adequate. However, to investigate the temporal statistics in either case, for instance to estimate averaging times, requires a fairly detailed model of the surface wave spatial field. Thus, the noise model is very much application dependent. These mechanisms and effects will be discussed in the context of experimental data.

10:15

1aUW3. Air-deployable sonobuoy array concepts and their performance against high-frequency noise anisotropy. Juan I. Arvelo, Jr., Patrick Ferat, and Ronald Mitnick (Appl. Phys. Lab., Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099)

High-frequency sonobuoy arrays with vertical aperture were developed and tested to exploit the noise anisotropy for enhanced array gain [Ferat and Arvelo, J. Acoust. Soc. Am. **114**, 2462–2463 (2003)]. Afterwards, an inexpensive and conformal piezoelectric wire material was employed in the design and construction of a volumetric array [Arvelo *et al.*, J. Acoust. Soc. Am. **116**, 2650 (2004)]. However, detection performance of air-deployed sonobuoys is severely affected by noise interference through the beamformers sidelobes. An improved sonobuoy system design with in-buoy processing for sidelobe suppression is introduced and its detection performance in anisotropic wind noise with nearby shipping interference is evaluated and compared against previous designs in selected environmental conditions. The high-frequency array gain for increased vertical aperture will be compared against the gain for increased horizontal aperture to explore coherence limitations. The effects of array tilt, as well as interelement amplitude, phase, and topology errors, on the performance deterioration of the new design will also be addressed. [This effort is supported by the Maritime Sensing (MS) Program of the Office of Naval Research (ONR Code 321).]

1aUW4. Ambient noise directivity in the East China Sea: Model/data comparison. Daniel Rouseff and Dajun Tang (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105)

In general, the vertical directivity pattern of high-frequency ambient noise is anisotropic. For measurements made beneath a shallow-water mixed layer, the observed noise directivity often displays a trough in the horizontal called the ambient noise notch. This notch develops because noise sources near the sea surface generate sound that propagates at relatively steep grazing angles. The directivity pattern is also generally asymmetric about the horizontal notch. This asymmetry develops because the seabed is an imperfect reflector of sound relative to the sea surface. In the present work, ambient noise data taken in the 1- to 5-kHz band during the 2001 East China Sea Experiment are analyzed and compared to models. The noise notch model integrates three components: an internal wave model, a noise model, and an acoustic propagation model that uses transport theory. It is shown how the depth and width of the observed noise notch are consistent with model predictions when internal waves of moderate strength are included in the calculation. The observed asymmetry in the directivity pattern is consistent with predictions when the correct bottom reflectivity is used. Future ambient noise measurements and tests for the models are described. [Work supported by ONR.]

11:10

1aUW5. Low-frequency noise from a bubble plume formed by a plunging water jet. Michael J. Buckingham (MPL, SIO, UCSD, 9500 Gilman Dr., La Jolla, CA 92093-0238)

Wind-driven, low-frequency ambient noise in the ocean may be due to bubble clouds created by wave breaking. To investigate this idea, a laboratory experiment was performed in which a vertical jet of fresh water plunged into a fresh water pool, to form a conical plume of bubbles beneath the surface. Both the jet speed, uj, and the air entrainment ratio, q, were carefully controlled and monitored. The power spectra of the sound from the plume, measured with an adjacent hydrophone, exhibit a sequence of nonuniformly spaced peaks below 1 kHz, which are associated with the resonances of the bubble-plume cavity. Each eigenfrequency scales accurately as $(1/uj)^{1/2}$ and approximately as $(1/q)^{1/4}$. A theoretical analysis of these scalings, based on a momentum-flux argument, shows that the sound speed profile within the plume varies as the square-root of depth down the axis. Using this square-root profile in the wave equation, an analytical solution for the pressure field within the plume is obtained, from which an explicit expression for the eigenfrequencies is derived. These theoretical eigenfrequencies, predicted from the conical geometry and square-root sound speed profile, exhibit the same nonuniform spacing and inverse-fractional power-law scalings as seen in the data. [Research supported by ONR.]

11:30

1aUW6. Robustness and constraints of high-frequency ambient noise inversion for sonar performance estimation. Juan I. Arvelo, Jr. (Appl. Phys. Lab., Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099) and Andrea Prosperetti (John Hopkins Univ., Baltimore, MD 21218)

Perhaps the most dominant source of error in sonar performance estimation in shallow waters is the geoacoustic description of the seafloor. Various investigators have studied the possible use of ambient noise to infer some key parameters such as the critical angle, geoacoustic properties, or bottom loss. Most operational sonar performance models and tactical decision aids require the bottom loss as a function of grazing angles and frequency to describe the reflected acoustic energy off the ocean floor. Harrison and Simons [Harrison & Simons, ''Geoacoustics inversion of ambient noise: A simple method,'' J. Acoust. Soc. Am. **112**, 1377 (2002)] described a simple measurement approach to infer the bottom loss from ambient noise measurement on a vertical line array. This approach is well suited as an environmental measurement approach during naval operations. The robustness and operational constraints of this measurement approach are quantified using a high-frequency ambient noise model that accounts for wind, shipping, and thermal noise [Ferat & Arvelo, ''Mid-Frequency Ambient Noise Directivity And Array Response in Range-Dependent Environments,'' High-frequency Ocean Acoustics Conference Proceedings, 2004)]. The effects of array tilt, nearby shipping noise, water absorption, thermal noise, surface-noise dipole pattern, and array beam response on sonar performance estimation are demonstrated. Mitigating factors to maximize estimated bottom loss accuracy will also be outlined.

11:45

1aUW7. Emergence of the Green's function from ambient noise in moving media. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Earth System Res. Lab., 325 Broadway, Boulder, CO 80305, oleg.godin@noaa.gov)

A rather general proof of a connection between two-point correlation function of ambient noise and the elastodynamic Green's function relies on the reciprocity principle [K. Wapenaar, Phys. Rev. Lett. **93**, 254301 (2004)]. In this paper, the flow reversal theorem [O. A. Godin, Wave Motion **25**, 143–167 (1997)] is applied to extend this result to moving, inhomogeneous fluids and problems involving flow-structure interactions. In the motionless case, the time derivative of the cross-correlation function of ambient noise gives an estimate of the sum of the causal and acausal time-dependent Green's functions between the two receivers. In the moving medium, the result is shown to be similar, but the acausal Green's function corresponds to sound propagation in a medium with reversed flow. Therefore, instead of redundant information, combination of the causal and acausal Green's functions contains additional useful data on flow velocity field in the medium. The data contained in the two-point cross-correlation function of ambient noise are analogous to the data that would be obtained in a reciprocal transmission experiment employing acoustic transceivers located at the two points. Possible applications of the theoretical results obtained to passive remote sensing of ocean and atmosphere are discussed. [Work supported in part by ONR.]

Session 1pAA

Architectural Acoustics and Noise: Acoustics of Multi-Family Housing

Gary W. Siebein, Chair
Univ. of Florida, Dept. of Architecture, P.O. Box 115702, Gainesville, FL 32611-5702

Chair's Introduction—1:00

Invited Papers

1:05

1pAA1. Comparison of measurement indices of noise intrusions in multi-family housing. Gary Siebein, Hyun Paek, and Chris Jones (Siebein Associates, Inc., 625 NW 60th St., Ste. C, Gainesville, FL 32607)

Methods for measuring sound levels associated with transportation, impact, and airborne sound intrusions in multi-family housing are well established in the field. This paper compares field testing of assemblies where complaints and retrofits have been involved where traditional assessments of intruding noises showed compliance with design criteria, but where residents and/or building owners perceived problems. Case study 1 involves noise from airplanes approaching a runway at a large international airport as heard in an all-glass high-rise condominium evaluated by LDNs and SELs of actual flyovers in computer models and in a full size mock-up of a typical unit built on site. Case study 2 involves noise from outdoor amplified entertainment propagating into neighborhoods as evaluated by various noise ordinance criteria. Case study 3 involves footstep noise through flooring systems comparing IIC ratings with actual sound pressure levels of people walking on floors above. Case study 4 compares noise and vibration levels for various pieces of mechanical equipment before and after retrofit with NC, RC, and other room criteria. Auralizations of the case studies will be shown along with measurement data to illustrate the diagnostics made in each case.

1:30

1pAA2. Legal and acoustical issues in multifamily housing. Jeff Lapin (Lapin and Leichtling, LLP, 200 South Biscayne Blvd., Ste. 3150, Miami, FL 33131)

There are a plethora of legal issues that arise with respect to the suitability of design criteria and acoustical performance of multifamily housing properties. When complaints arise from residents, field testing can be done to determine if the units as constructed meet the design criteria or condominium documents. Questions can arise about the reasonableness of the criteria, the scientific validity of the testing process, the evidentiary value of test results, the type and extent of reasonable remedies, and allocation of responsibility among interested parties in resolving the dispute. This paper will identify the legal issues involved in disputes between private parties regarding acoustical issues such as soundproofing, as well as the use of acoustical criteria and testing as forming the legal basis for complaints and as a vehicle for resolving disputes involving the acoustical performance of buildings once they are occupied. The rights and duties existing under the common law of nuisance which allows people to enjoy their property free from unresonable interference will be examined along with the impact prescriptive requirements in building codes or condominium documents has on disputes involving acoustical performance in multifamily housing. The specific laws of one state will be used in the case studies as examples of situations that can arise where acoustical consultants deal with legal issues in multifamily housing.

1:55

1pAA3. Field airborne sound isolation in multifamily construction evaluation of metrics within ASTM E336. John J. LoVerde and David W. Dong (Veneklasen Associates, 1711 Sixteenth St., Santa Monica, CA 90404, jloverde@veneklasen.com)

ASTM E336 defines several metrics describing airborne sound isolation for wall and floor/ceiling assemblies within multifamily dwellings. The standard mirrors the procedures for laboratory testing of sound transmission class (STC) in defining field STC (FSTC), which does not include flanking paths and is therefore virtually impossible to measure in the field. The current standard includes provisions for the measurements of apparent STC (ASTC) which include flanking paths, and field measurements within multifamily dwellings typically report ASTC even though applicable building codes require the reporting of FSTC. The standard also provides two noise reduction metrics, noise isolation class (NIC) and normalized NIC (NNIC). Analysis of the relationships of ASTC, NNIC, and NIC will be presented along with a survey of field test results and correlation with subjective reactions of occupants within multi-family dwellings. The analysis shows that the additional work required to determine the ASTC or NNIC is not warranted because it provides no additional useful data, and that the proper metric for evaluation of acoustical performance in the field for multifamily dwellings is NIC.

2:20

1pAA4. Design parameters for impact sound insulation in lightweight wood and steel structures. John J. LoVerde and David W. Dong (Veneklasen Assoc., 1711 Sixteenth St., Santa Monica, CA 90404, jloverde@veneklasen.com)

One of the challenges in the acoustical design of multifamily wood and steel joist buildings is reducing low-frequency sounds from footfalls on both carpeted and isolated hard-surfaced floors. Theoretical calculations and field-testing experience indicate that low-frequency impact noise in lightweight structures is clearly audible, and that traditional isolation methods do not reduce low-frequency impact noise to inaudibility [Blazier and DuPree, J. Acoust. Soc. Am. **96**, 1521–1532 (1994)]. We report numerous measurements performed on wood-frame assemblies in the United States using the tapping machine method as defined in ASTM E1007. The impact sound-pressure level was measured down to the 20-Hz third-octave band, instead of 100 Hz as described in the standards. Representative case studies will be presented showing the effect of changes in construction on occupant complaints. The results indicate that the unweighted level in the 50–80 Hz third-octave bands correlates much better with occupant reaction than any of the other metrics [LoVerde and Dong, J. Acoust. Soc. Am. **112**, 2201 (2002); LoVerde and Dong, INCE Inter-Noise 2004 Proceedings, 167 (2004)]. Factors in the design of successful lightweight floor/ceiling assemblies, including structural design parameters, shall be presented along with corresponding acoustical performance and subjective reactions.

2:45

1pAA5. Old mills, new condos; sound isolation in mill building conversion projects. Benjamin Markham, Jonah Sacks, and Rose Mary Su (Acentech Inc., 33 Moulton St., Cambridge, MA 02138)

Up and down the New England Coast, century-old mill buildings are being converted into condominium and apartment buildings amidst one of the biggest housing booms in recent memory. While the inherent acoustical conflicts in multi-family dwelling are not new (oft-cited HUD guidelines are approaching their 40th birthday), the flood of mill conversions is bringing to light a number of new constructions that architects use to chop former factories into discrete living spaces. This paper will present field-collected data and case studies that illustrate some of the problems and common pitfalls associated with mill building conversion projects. Among the construction details discussed include exposed timber ceilings that run continuously across gypsum board partitions, the creative reuse of existing brick walls, and some acoustical properties of wood deck construction common to many mill buildings.

3:10–3:25 Break

3:25

1pAA6. Comparison of acoustical measurements of demising walls in luxury condominiums and townhomes to illustrate the importance of decoupling the mass layers. Robert M. Lilkendey and Gary W. Siebein (Siebein Associates, Inc., 625 NW 60th St., Ste. C, Gainesville, FL 32607)

Field Sound Transmission Class (FSTC) tests and acoustical measurements of impact noise from cabinet door and drawer impacts were made of demising walls in a number of multifamily luxury townhomes and luxury condominium tower units due to complaints from residents about noise intrusion from adjacent living units. The demising wall constructions included concrete or cmu with gypsum board attached, gypsum board on wood studs, and gypsum board on metal studs. The results of these measurements will be presented to illustrate the need to decouple the mass layers to maximize the acoustical performance. A case study of one project will be presented showing the effects of incremental changes made to a base wood stud wall with gypsum board on each side (STC 36) in which added mass (STC 44), added mass plus decoupling (STC 62), and decoupling with reduced additional mass (STC 58) were tested in an effort by the developer to strike a balance between acoustic performance and cost.

3:50

1pAA7. Condominium noise issues: Problem solving with flooring systems and solving flooring system problems. Jospeh Still (Proflex Products, Inc., 3406 Dean St., Naples, FL 34104, proflex@verizon.net)

With increasing frequency, condominiums are being designed without suspended ceilings. At the same time, the popularity of hard floor coverings such as tile continues to grow. These factors combine to create significant problems with impact noise in these buildings. Architects and acoustical engineers have looked to the flooring industry for noise-reduction solutions, and the response has been the production of a wide variety of sound-reducing systems. However, not all of these impact insulation sound reduction systems are acceptable for hard-surface flooring. The total performance of the floor/ceiling system including acoustical as well as durability tests should always be carefully scrutinized, evaluated, and verified by acoustical consultants. Furthermore, strict adherence to proper installation techniques by contractors is essential to achieving the sound reduction performance that should be expected of a given product. Among the major topic areas addressed in this paper are the current flooring industry standards for underlayment systems; realistic expectations for sound reduction and durability from various types of flooring and underlayment systems; and recommended changes in architectural specifications for flooring. This paper also includes practical guidelines for evaluating and verifying the claims made for flooring systems regarding impact sound reduction and several problem-solving examples from real-world applications.

4:15

1pAA8. Noise in a multifamily housing area in Mexico City. Sergio Beristain (P.O. Box 12-1022, Narvarte, 03001, Mexico, City, Mexico, sberista@hotmail.com)

Noise in a multifamily housing site is complex and hard to handle due to economic, cultural, educational, income, and many other reasons. The site studied here is surrounded by commercial and services areas, which increases the noise problem. Most of the complaints do not go too far due to lack of specific regulation and lack of knowledge of which existing one might be applicable, but even when legal action is taken, noise is hard to evaluate mainly because noise sources are off when authority shows up.

4:30

1pAA9. A jury study of noise isolation between condo units incorporating QuietZone® acoustic wall framing in the common wall. Dick Godfrey, Harry Alter, and Clarke Berdan, II (Sci. & Technol., Owens Corning, 2790 Columbus Rd., Granville, OH 43023)

Two identical side-by-side two-story condo units with basements were built in the newly built Owens Corning Building Science and Innovation Center. These units incorporated modern features such as multistory great rooms with adjoining kitchens. Home offices, bedrooms, and basements were located on opposite sides of the common wall. It is common practice to use double-stud walls between adjacent units in multifamily construction. It is also good practice to have a noncontiguous floor plate between units. Instead of a double-stud wall, these units incorporated QuietZone® acoustic wall framing (resilient stud), and other Owens Corning recommended noise control measures. The wall transmission loss characteristics were measured in the field and in the laboratory. A laboratory jury study was conducted to investigate the adequacy of perceived noise isolation between the units for various source and background noise types and levels.

Session 1pAB

Animal Bioacoustics: Acoustic Interactions in Animal Groups II

Joshua Schwartz, Chair
Pace Univ., Dept. of Biology, Pleasantville, NY 10570

Invited Papers

1:00

1pAB1. Signal detection theory and noisy communication. Lori Wollerman (Dept. of Biol., Hood College, 401 Rosemont Ave., Frederick, MD 21701, lwollerman@hood.edu)

Signal detection theory (SDT) has had little influence on thinking about the evolution of animal communication, despite its wide application in psychology. SDT is a model that describes the detection of signals in the presence of noise, a situation that clearly applies to animals that communicate in aggregations, such as many frogs and singing insects. Through SDT we can better understand fundamental issues about the evolution of communication. In many realistic signaling conditions receivers are unable to avoid making an error of one sort or another regardless of the criterion they use for responding to signals. Signals that are more exaggerated would be more detectable and receivers would be more likely to respond to these signals than to those that are less exaggerated and less detectable. Signal detection theory therefore provides a sufficient explanation for the exaggeration and elaboration of male displays used to attract females for mating. Moreover, principles of SDT apply to any communicatory interaction. Thus, SDT establishes universal conditions that any hypothesis regarding the evolution of signals must satisfy.

1:20

1pAB2. Discrimination of noise-contaminated communication signals by grasshoppers. Bernhard Ronacher (Biol.. Dept., Humboldt Univ., Berlin, Germany)

When using acoustic signals in order to find—and possibly select between—mates, grasshoppers face two major problems: the arriving signals are usually degraded by various kinds of noise, while as much information as possible should be extracted quickly. Major cues for signal recognition are the temporal patterns of amplitude modulations of grasshopper songs. Within the nervous system, signal classification is rooted in the spike trains provided by the sensory neurons and will be constrained by the variability of spiking responses. Several intrinsic sources further contribute to spike-train variability, which can be considerable even in the case where undistorted acoustic signals arrive at the receiver. Using van Rossum's [Van Rossum, M. Neural. Comp. **13**, 751–763 (2001)] method to compute spike-train distances, we quantified the variability of neural responses and showed that the temporal information

necessary to discriminate between songs of different conspecifics is preserved surprisingly well, even in the responses of single neurons. By comparing behavioral and neurophysiological data, we now aim at determining how well this information can be used by the animals, and how closely or remotely their nervous systems approach the performance of an ideal observer.

1:40

1pAB3. Mechanisms and evolution of chorusing interactions in acoustic insects and anurans. Michael Greenfield (Dept. of Ecol. & Evolutionary Biol., Univ. of Kansas, Lawrence, KS 66045)

Chorusing displays of acoustically signaling insects, and their counterparts among bioluminescent species, are acknowledged to include some of the great spectacles of the living world [Wilson, *Sociobiology*, Harvard University Press (1975)]. These communal displays are noteworthy for the sheer numbers of participating individuals, the volume of sound or brilliance of light produced, and a precise choreography in space and time, which often gives rise to striking alternation or synchrony between neighbors. Here, potential mechanisms that may generate such temporally structured choruses are reviewed and then the evolution of these communal displays is discussed. Under certain conditions alternation or synchrony may be adaptive *per se*, and the mechanisms that generate chorusing interactions are directly favored by selection. But, in other cases alternation and synchrony are merely epiphenomena, group effects that emerge as by-products of simple interactions between signaling neighbors; these interactions are, in effect, responses to psychoacoustic effects in perception. Simulation models inspired by various acoustic insects demonstrate how complex choruses may represent emergent properties of these simple responses. The models also show how feedback loops may arise by which these emergent properties can yet influence the simple interaction responses from which they originated.

2:00

1pAB4. Call synchronization in *Neoconocephalus nebrascensis* (Orthoptera, Tettigoniidae): Cooperation rather than competition? Johannes Schul, Katy E. Klymus, and Joshua A. Deily (Biological Sci., Univ. of Missouri, 207 Tucker Hall, Columbia, MO, 65211, schulj@missouri.edu)

Male calls of the katydid *Neoconocephalus nebrascensis* consist of 1000-ms-long verses separated by silent pauses of 800 ms. Verses of neighboring males exhibit remarkable synchrony during which leader-follower relationships often remain unchanged over extended periods of time. Such call synchrony is often the consequence of female preference for leading calls. We tested female phonotaxis on a walking compensator in response to male calls presented alone or as pairs. Females did not respond to continuous calls, but required a distinct verse structure for positive phonotaxis. Surprisingly, more than 18-dB modulation depth between verses and silent pauses was required to elicit female responses. When the delay between two simultaneously presented calls was between 0 and 600 ms, females did not exhibit any biologically relevant leader preference. Females did not show significant phonotaxis to alternating calls. Given that females require a modulation depth of 18 dB, call alternation even between distant males would effectively mask the attractive temporal pattern of both males' calls. Only through call synchronization do males achieve an attractive pattern. This, together with the absence of a biologically relevant female preference for leading calls, indicates that males do not compete but rather cooperate during call synchronization to preserve an attractive temporal call pattern.

2:20

1pAB5. Chorusing in fishes. David Mann and James Locascio (Univ. of South Florida, College of Marine Sci., 140 7th Ave. S., St. Petersburg, FL 33701, dmann@marine.usf.edu)

Many fishes in the family Sciaenidae engage in nightly chorusing events where sound production starts near dusk and lasts for several hours. This paper examines the periodicity and dynamics of chorusing in the Sciaenidae. Underwater acoustic recorders have been deployed in southwest Florida to record sound production with a high temporal resolution (10 s of recording every 10 min) over a large spatial area. Sound production was dominated by three sciaenid species: silver perch (*Bairdiella chyrsoura*), sand seatrout (*Cynoscion arenarius*), and spotted seatrout (*Cynoscion nebulosus*). Sounds produced by black drum (*Pogonias cromis*), gafftopsail catfish (*Bagre marinus*), and gulf toadfish (*Opsanus beta*) were also recorded. Sound levels in sciaenid choruses typically reach levels of approximately 110–120 dB *re* 1 μPa spectrum level, and are among the loudest sources of sustained ambient noise in temperate and subtropical coastal waters. Little is known about the behavior accompanying sound production, because it occurs in turbid water at night. The use of hydrophone arrays to document fine-scale spatial patterns of sound production will be discussed.

2:40–3:00 Break

3:00

1pAB6. Social complexity can drive vocal complexity: Group size and information in chickadee calls in Carolina chickadees. Todd Freeberg (Dept. of Psych., Univ. of Tennessee, Knoxville, TN 37996, tfreeber@utk.edu)

There is considerable variation in systems of vocal communication in animals. One hypothesis to explain this variation is that the complexity of the social group influences the groups vocal complexity. This social complexity hypothesis for communication is also central to recent arguments for human language origins, but experimental tests of the hypothesis are lacking. This study investigated whether group size, a fundamental component of social complexity, influenced the complexity of the chickadee call, a call system functioning in social organization of Carolina chickadees, *Poecile carolinensis*. This call system has been studied in chickadees and related species, and is structurally and functionally rich in its note composition. Complexity of calls was measured using uncertainty (diversity) related to note composition, based on Shannon's mathematical theory of communication. In unmanipulated field settings, calls of individuals in larger groups had greater complexity (more information) than calls of individuals in smaller groups. In aviary settings manipulating group size, individuals in larger groups used calls with greater complexity than individuals in smaller groups. These results indicate that social complexity can influence communicative complexity in this species.

3:20

1pAB7. Acoustic interactions in broods of begging nestling birds. Andrew G. Horn and Marty L. Leonard (Dept. of Biol., Dalhousie Univ., Halifax, NS B3H 4J1 Canada)

Begging by nestling birds has become a model system in the study of the evolution of reliable signaling. The transmission and reception of begging signals, however, remain largely unexplored. Especially puzzling is how, or indeed whether, the calls that accompany most begging displays can convey information to parents, given that several nestlings may be calling at once within the cramped confines of the nest. Most previous work on groups of acoustic signalers has involved signalers that are much more widely spaced, such as chorusing insects and frogs. Here, we review our research on how the begging calls of tree swallows, *Tachycineta bicolor*, convey information to parents. Various call features correlate with nestling need, and playing back calls to parents affects both how often they deliver food to the nest and which nestling they feed once they arrive. Nestlings adjust their calls in response to signal interference, albeit crudely, by adjusting call rate and amplitude. Begging calls and the contexts in which they occur vary enormously across species, so that other species likely use different strategies to overcome acoustic interference. Indeed, begging displays offer promising and barely tapped opportunities for developmental and comparative studies of acoustic signaling in groups.

3:40

1pAB8. Vocal exchanges in wild bottlenose dolphins. Nicola J. Quick and Vincent M. Janik (Sea Mammal Res. Unit, Univ. of St Andrews, Fife, Scotland, KY16 8LB, UK, njq@st-andrews.ac.uk)

This study investigated the behavioral context of stereotypic whistle exchanges in wild bottlenose dolphins off north-east Scotland to infer function from whistle usage. Concurrent acoustic and nonacoustic behavioral data sampling was conducted during focal follows. Passive acoustic localization using a four-element distributed array was used to identify vocal exchanges (i.e., whistles from different individuals within 3 s of each other). Vocal exchanges of stereotypic (two whistle types produced repeatedly by at least two animals) nature occurred during 12 focal follows from 10 separate days containing 108 whistles that could be localized. Exact randomization tests (10 000 iterations), using whistles from exchange and nonexchange periods within each follow, showed that the observed number of exchanges (i.e., whistles produced by different individuals within 5 s of each other) was significantly different than the value that resulted from randomization. Vocal exchanges occurred prior to dolphin subgroups joining in 9 out of 10 observed joins. Only 2 of 11 vocal exchanges were not followed by a join. Vocal exchanges of stereotyped whistles between individuals appear to be important in coordinating joins in wild dolphin groups. Further analysis of exchange whistles showed that their degree of stereotypy equalled that found in signature whistles.

1pAB9. Convergence of calls as animals form social bonds. Peter L. Tyack (Biol. Dept., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, ptyack@whoi.edu)

In many species capable of vocal production learning, the acoustic properties of calls from different individuals can converge when they are housed together in captivity or form social bonds in the wild. This has been demonstrated for animals as diverse as songbirds, parakeets, bats, cetaceans, and primates. In many species of songbirds, territorial neighbors have repertoires with several shared songs. Males can use the shared songs during territorial disputes, and birds escalate or de-escalate a countersigning interaction by choosing to reply with a song match, a repertoire match, or an unshared song. For most other species, call convergence is thought to reflect a group-distinctive identifier, with shared calls reflecting and strengthening social bonds. I will discuss examples of call convergence in primates, birds, elephants, and cetaceans. The breadth of the use of production learning for call convergence suggests that this may have been an important selective pressure for the evolution of production learning. Some species have well-developed capabilities of imitating distinctive calls of other individuals or groups. This capability of learning to imitate an arbitrary signal for an arbitrary referent may have evolved out of simpler forms of vocal convergence.

4:20

1pAB10. Bad vibrations: Mechanosensory risk assessment by red-eyed treefrog embryos. Karen M. Warkentin, Michael S. Caldwell (Dept. of Biol., Boston Univ., 5 Cummington St., Boston, MA 02215), and J. Gregory McDaniel (Boston Univ., Boston, MA 02215)

Red-eyed treefrogs, *Agalychnis callidryas*, lay gelatinous egg masses on vegetation overhanging ponds; tadpoles fall into the water upon hatching. Embryos hatch up to 30% prematurely in attacks by egg-eating snakes, but not in other intense but benign disturbances, such as storms. We used modal analysis and vibration recordings from clutches in natural disturbances to characterize the vibrational environment of embryos, and playbacks to assess if vibrations cue hatching, and how vibration characteristics affect hatching behavior. Escape hatching can be induced by snake vibrations, without actual snakes, and embryos distinguish between the vibrational patterns of snake attacks and rainstorms. Benign and dangerous disturbances overlap in individual temporal and frequency characteristics, but can be distinguished using combinations of features. Both frequency and temporal characteristics of vibrations affect the hatching response. Embryos use at least two temporal pattern elements—disturbance duration and interdisturbance interval—and respond to a limited range of low frequencies. These are all necessary elements of a composite cue. Moreover, higher frequencies, found in rainstorms but not attacks, reduce hatching. This is the most detailed examination of mechanisms underlying embryo decision making to date, and a demonstration of the importance of vibrational information in predator-prey interactions. 1pAB11. Attracting insects with an acoustic laser. Kent Lau and Steven Garrett (Schreyer Honors College and the Grad. Program in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804-0030)

It has been demonstrated that female Mediterranean fruit flies (*Ceratitis capitata*) are attracted to a trap by a pure tone at approximately the spectral peak (330 Hz) of the males mating call [Mankin *et al.*, J. Econ. Entomol. **97**, 1299–1309 (2004)]. Recent research [Sueur *et al.*, "Sound radiation around a flying fly," J. Acoust. Soc. Am. **118**, 530–538 (2005)] suggests that a more complex tone that combines an amplitude-modulated fundamental and a second-harmonic component could produce more effective acoustic bait. We will describe a thermoacoustic sound source [S. L. Garrett and R-L. Chen, Echoes **10**, 4–5 (2000)] that combines two closely tuned quarter-wavelength resonators designed to produce a beating fundamental of adjustable modulation depth. A third source produces the second harmonic. The trio of sources generates the desired signal at levels of 90 to 100 dB 1 meter from the array. Since the sound is produced from electrically heated filaments, no oscillators, amplifiers, or electro-acoustic transducers are required. When the pair of fundamental resonators are placed side-by-side, the beating occurs uniformly in space. When placed back-to-back, the dipolar radiation pattern rotates to produce the beating in time at any fixed location. We hope to have results with insect subjects by the time of the meeting. [Work supported by an endowment from United Technologies Corporation.]

1pAO1. Localization and geoacoustic inversion by using 20-Hz signals of finback whales on the New Jersey Shelf. Altan Turgut and Bruce Pasewark (Naval Res. Lab., Acoust. Div., Washington, DC 20375)

One-second duration 20-Hz signals of finback whales were recorded on three vertical line arrays (VLAs) and a bottomed horizontal line array (HLA) during the RAGS03 experiment conducted on the New Jersey Shelf. Modal analysis indicated that most signals, recorded over a 3-week period in December of 2003, contained a weak, early-arriving mode-2 and strong, late-arriving mode-1 component. These modal characteristics are exploited in a broadband matched-field algorithm to localize individual finback whales and to perform geoacoustic inversions. Bearing estimation of individual whales is obtained by performing horizontal beamforming on the HLA data. Range estimation results are verified by time-of-flight triangulation using single hydrophone data from each VLA location. Geoacoustic inversion results were comparable to those previously obtained from chirp sonar data. Localization results indicated that most finback whales traveled near the shelfbreak front where food might be abundant. [This work was supported by the ONR.]

1pAO2. A method to reduce geoacoustic inversion uncertainties caused by water column fluctuations. Ying-Tsong Lin and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

A linear method is developed to reduce the effects of small sound-speed fluctuations in the water column on geoacoustic inversions. Sound-speed fluctuations are considered as a source of physical model error, and their influence on the acoustic data used for determining geoacoustic parameters is estimated by linear perturbation theory. The idea of this method is to project acoustic data onto a space that is insensitive to water sound-speed fluctuations. To determine this space, the singular value decomposition is applied to the kernel of the linear perturbation equation, which links the fluctuations to the acoustic data. This approach will reduce the number of data points available for inversion. Because of this, empirical orthonormal function analysis is employed to represent the sound-speed fluctuations by a small number of modes, which effectively increases the number of projected data points. This method is demonstrated by a numerical test case, using linear internal waves with the Garrett-Munk spectrum to vary the water column in time and space. The influence of the higher-order terms neglected in the linear perturbation equation on the performance of this method is also discussed.

1pAO3. Tabu inversion in the East China Sea. Zoi-Heleni Michalopoulou (Dept. of Mathematical Sci., New Jersey Inst. of Technol., Newark, NJ 07102, michalop@njit.edu), James H. Miller, and Gopu R. Potty (Univ. of Rhode Island, Narragansett, RI 02882)

Tabu, a global optimization method that exploits search history to explore the parameter space in a structured manner, has been shown to perform well in geoacoustic inversion with both real and synthetic data. To investigate the efficacy and adaptability of Tabu search to various ocean environments, we conducted Tabu inversion for broadband data (at frequencies between 20 and 600 Hz) collected in the East China Sea during the ASIAEX experiment. A simple incoherent Bartlett objective function was considered. Localization results and geoacoustic estimates obtained via Tabu closely match ground truth information and parameter estimates obtained with other inversion methods. Appropriate hierarchical ordering of the unknown parameters ensured identification of the global maximum of the objective function within only a few forward model calculations. [Work supported by ONR.]

1pAO4. Validation of statistical estimation of transmission loss in the presence of geoacoustic inversion uncertainty. Chen-Fen Huang, Peter Gerstoft, and William S. Hodgkiss (Marine Physical Lab., Scripps Inst. of Oceanogr., La Jolla, California 92093-0238)

Often the ocean acoustic environment is not well known and sonar performance prediction will be affected by this uncertainty. Here, a method for characterizing transmission loss (TL) is proposed which incorporates these environmental uncertainties. The statistical estimation of TL based on the posterior probability density of environmental parameters obtained from the geoacoustic inversion process is the main theme of this

study. First, a Markov chain Monte Carlo procedure is employed to sample the posterior probability density of the geoacoustic parameters. Then, these parameter uncertainties are mapped to the transmission loss domain, where a full multidimensional probability distribution of TL as a function of range and depth is obtained. In addition, TL is also characterized by its summary statistics including the median, percentiles, and correlation coefficients. The approach is illustrated using a data set obtained from the ASIAEX 2001 East China Sea experiment. Based on the geoacoustic inversion results, the predicted TL and its variability are estimated and then compared with the measured TL. In general, the results show that approximately 80% of the observed TL data fall within 90% of the TL probability distribution.

1pAO5. Passive matched-field inversion for thick-sediment characterization. Donald R. DelBalzo, Robert S. Linzell, and Lisa A. Pflug (Planning Systems, Inc., 40201 Hwy. 190 E., Slidell, LA 70461, ddelbalzo@plansys.com)

Acoustic field estimation in shallow-water, littoral areas is severely limited by environmental uncertainty, especially regarding sediment property characteristics. Direct methods of obtaining geophysical data are expensive, so inverse methods have recently become popular. Most techniques rely on inverting signals from controlled active sources. This work is focused on inverting signals with unknown source levels from surface ships of opportunity at unknown ranges. A range-staggered technique is employed to create a range-dependent sediment description, with ever-increasing confidence as additional surface ships are analyzed. Matched-phase techniques are applied in a simulated shallow-water environment with a single vertical array and high signal-to-noise ratios. The inversion process is evaluated as a function of frequency bandwidth, number of hydrophones, and array length. The simulations indicate significant potential for passive, range-dependent, thick-sediment characterizations out to ranges of tens of water depths in shallow water. [Work sponsored by SPAWAR.]

1pAO6. Bayesian layer-stripping inversion of seabed reflection data. Jan Dettmer, Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC, Canada), and Charles W. Holland (Appl. Res. Lab., The Penn State Univ., State College, PA)

This paper develops a Bayesian inversion technique for recovering multilayer geoacoustic profiles using seabed reflection data. The measured data originate from acoustic time series windowed for a single bottom interaction, which are processed to yield spherical reflection coefficients (i.e., a response function of frequency and angle analogous to plane-wave reflection coefficients). Replica data are computed using a wave number-integration model (OASES) to calculate the full complex acoustic pressure field, which is processed to produce a similar seabed response function. The inversion results are compared to those obtained using plane-wave reflection coefficients. To address the high computational modeling costs, the Bayesian algorithm is implemented for a massively parallel computer. Further, the data are time windowed and divided into several layer packets, wherein each packet contains the seabed response to a certain depth. This layer-stripping approach uses the results of the previous layer packet as prior information for subsequent packets. The resulting posterior probability density for the final packet is considered the full solution to the inverse problem, and is interpreted in terms of optimal parameter estimates, marginal distributions, credibility intervals, and parameter correlations.

2:30

1pAO7. Estimation of poroelastic parameters from measured reflectivity. Tracianne Neilsen (Brigham Young Univ., N283 ESC, Provo, UT 84602) and Marcia Isakson (Appl. Res. Labs., Univ. of Texas at Austin)

The reflectivity of sound at a water-sediment interface contains information about the properties of the sediment. Estimates of these properties can be obtained by optimizing the match between the magnitude of the measured reflectivity, as a function of grazing angle and frequency, and values computed using a poroelastic sediment model. A traditional simulated annealing approach yields such parameter estimates but little information about the uncertainty associated with those estimates. An alternate approach computes the posterior probability distributions (PPDs) for the parameters using a fast Gibbs' sampler approach. The PPDs not only indicate the most probable values for each parameter, but the widths of the distributions also provide an understanding of the uncertainty and the dependence of the data-model mismatch on each parameter. Both of these methods are applied to reflectivity measured in a laboratory tank over a frequency band of 77–147 kHz and grazing angles of 7–49 deg. [Work suppported by ONR, Ocean Acoustics.]

1pAO8. Time-reversal operator target focusing using optimal beam sets. G. F. Edelmann, J. F. Lingevitch, D. M. Fromm, C. F. Gaumond, and R. Menis (U.S. Naval Res. Lab., 4555 Overlook Ave., SW, Code 7145, Washington, DC 20375, edelmann@nrl.navy.mil)

Time-reversal operator (TRO) methods can be used to focus sound on an ocean target using a time-reversal mirror. In order to increase the signal-to-noise ratio, the TRO can be measured by transmitting simultaneously the entire array instead of transmitting source by source. The so-called beam-space. TRO is measured by transmitting a set of orthogonal beams. Acoustic propagation will be simulated in a realistic range and time-dependent ocean environment measured during the TREX04 experiment [Gaumond, J. Acoust. Soc. Am. (in press)]. This paper will compare four different sets of beams: Hadamard, phased planar, spatially phased, and modal. The first two methods require no *a priori* environmental knowledge, the third requires only waveguide depth, and the final requires a sound-speed profile and geoacoustics measured at the TRM. Results will be discussed in terms of signal gain, complexity to implement, and coherence in an inhomogeneous ocean environment varying in both time and space. [Work supported by the Office of Naval Research.]

1pAO9. Perturbation of arrival times in sound pulses propagating in shallow water through moving internal solitons. Mohsen Badiey (Ocean Acoust. Lab., Univ. of Delaware, Newark, DE 19716), Valery Grigorev, Boris Katsnelson (Voronezh State Univ., Voronezh 394006, Russia), and James Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Sound pulse propagation in shallow water is studied. We assume a geometry where an acoustic track crosses the wave-front of a moving internal soliton (IS) or train of solitons. During propagation, sound pulses undergo perturbation due to mode coupling. For each individual mode selected at the receiver, we observe a set of incoming pulses, each having different arrival times. Time-frequency analysis is carried out for the modal arrival times for different frequencies, emphasizing the dependence on position of the moving solitons. It is shown that the maximum amplitude of the incoming pulses created at the ISs due to mode coupling has approximately the same arrival time, independent of frequency. This invariant arrival time is determined by waveguide parameters and corresponds to maximal coupling of different pairs of modes. Analysis is carried out both for a model shallow water channel and for real experiment

data (SWARM95, NRL acoustic track). Satisfactory agreement is demonstrated, and physical interpretation of observed effect is discussed. [Work is supported by ONR and RFBR.]

3:30

1pAO10. Sediment models for the East Coast based on *a priori* information, geological data, and sediment inversions. Gopu R. Potty, James H. Miller (Dept. of Ocean Eng., Narragansett, RI 02882), and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

A preliminary sediment model for the U.S. East Coast with particular emphasis on the Shallow Water-2006 experimental site is presented. This sediment model will describe the bottom as layers of sediments with different properties. The layering information will be based on geological, geophysical, stratigraphy models and inversion results. The surface sediment description will be based on the Effect of Sound on Marine Environment (ESME) sediment models for the U.S. East Coast. This sediment model, developed as part of the ESME initiative, draws from a variety of data sources including the sediment texture database maintained by the United States Geological Survey. This database coupled with Hamilton, Biot-Stoll (with reduced number of parameters), or Buckingham models (to define the sediment geoacoustic properties) has the potential for providing an efficient surface sediment representation with large spatial coverage. Other sources of data, which will be used to develop the preliminary sediment model, include published sediment core data from the region and inversions results. The use of empirical orthogonal function-based sediment parametrization for inversions will be explored. This study will provide sediment data for the preliminary experimental design efforts prior to the experiment in 2006. [Work supported by Office of Naval Research.]

3:45

1pAO11. Estimating geoacoustic parameters from broadband data from the New Jersey shelf. Yong-min Jiang, N. Ross Chapman (School of Earth and Ocean Sci., Univ. of Victoria, P.O. Box 3055, Victoria, BC V8W 3P6, Canada, chapman@uvic.ca), and Mohsen Badiey (Univ. of Delaware, Newark, DE 19716)

This paper presents the geoacoustic inversion of broadband data to estimate the sea bed parameters of SWARM95 site. The data set used in this study contains air gun signals that were transmitted at the depths of 25 and 45 m, respectively, below the sea surface, while the source ship was maneuvering at small speed (towing); the signals then were collected at the ranges around 5 km by a vertical line array. A canonical geoacoustic model was generated first according to previous experimental research results, for the purpose of a parameter sensitivity study; then both hybrid optimization and Bayesian inversion techniques were applied to the real data. The data error covariance matrix is estimated to resolve the spatial correlated data error in Bayesian inversion approach. Since the ratio of range and water depth is rather large in this study, only the geoacoustic parameters at the top of the sediment are sensitive in the inversion. The optimization results show the consistency of sensitive geoacoustic/geometric parameter estimations over the ranges and different source depths. Bayesian inversion gives the estimation uncertainties of the geoacoustic properties by marginal probability distributions. [Work supported by ONR.]

4:00

1pAO12. Comparison of transmission loss data with predictions based on inverted seabed parameters from the Yellow Sea '96 experiment. Lin Wan, Ji-Xun Zhou, and Peter H. Rogers (School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405, gtg446p@mail.gatech.edu)

Transmission loss is useful in sonar performance prediction. In this paper, the transmission loss data as a function of range, frequency, and propagation direction are obtained from the Yellow Sea '96 experiment. The experiment was conducted along two radial directions up to 55 km and a quarter of a circle with a radius of 37 km. About 300 broadband explosive sources were detonated above and below the thermocline in the experiment. The seabed acoustic parameters are inverted from the broadband explosive source data. Based on the inverted seabed parameters, the transmission loss is predicted and compared with the experimental data. [Work supported by ONR.]

4:15

1pAO13. The Ionian Sea rainfall experiment. Jeffrey Nystuen (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), Eyal Amitai (George Mason Univ., Fairfax, VA), Emmanouil Anagnostou, and Marios Anagnostou (Univ of Connecticut, Storrs, CT 06269)

Rainfall on the sea surface generates a loud and distinctive sound underwater. This sound propagates downward and is attenuated, producing an effective listening area, or an equivalent "catchment basin" for a listening device that is a function of depth and frequency. Acoustical measurements of rainfall are reported from 60, 200, 1000, and 2000-m depths from a mooring in the Ionian Sea off the southwestern coast of Greece (37N, 21.5E) from January to April 2004. These measurements are compared to colocated high-resolution coastal X-band radar (XPOL) rainfall reflectivity measurements. The XPOL reports the spatial distribution of the rain over the listening areas of the acoustic rain gauges (ARGs). Roughly ten rainfall events, including drizzle, squall line, and heavy rainfall were recorded. The results demonstrate the inherent spatial averaging of the rainfall signal with depth. This spatial averaging is desirable when comparisons are made to satellite measurements of oceanic rainfall as such measurements also have inherent spatial averaging. The data also verify that a viable signal for acoustical rainfall measurement is present at 2000 m, allowing this technology to be transferred to deep-ocean instrumentation platforms such as ARGO floats and bottom-mounted cabled systems. [Work supported by NSF Oceanography.]

4:30

1pAO14. Haro Strait geometry from time-domain data. A. Tolstoy (A. Tolstoy Sci., 1538 Hampton Hill Circle, McLean, VA 22101)

This paper presents results which relate to the geometry of various Haro Strait scenarios. In particular, from the time-domain data we can estimate the source range, source depth, individual phone ranges, individual phone depths, and water depths at the source and at the array. These parameters are optimally estimated based on the time-domain signals alone. We assume that the bottom is sloping, consider up to four reflections (surface, bottom, surface-bottom, and bottom-surface), and allow for up to 16 phones of data. We see that nonuniqueness can still be an issue even using a great deal of time-domain data. However, these parameters are nearly uniquely estimated if additional constraints are considered, particularly on the arrays. Some of the optimal parameters are "confirmed" by simulating the signals for the predicted geometries by means of a pulse PE (RAMGEO) propagation code (courtesy of M. Collins) and then comparing those simulated signals with the observed data.

1pAO15. Modeling sound progation in shallow water including dynamic internal wave fields. Kyle M. Becker (Appl. Res. Lab., Penn. State Univ., P.O. Box 30, State College, PA 16804-0030)

Shallow-water acoustic fields are dominated by effects due to multiple interactions with the bottom. Particularly at low frequencies, the acoustic field can be modeled as a sum of normal modes that satisfy local waveguide properties. For a point source in the water column, the acoustic field is characterized in depth and range by constructive and destructive interference of the propagating modes in range. When including a range-dependent sound-speed field in the water column, such as that caused by internal waves, mode coupling occurs which can impact the observed interference pattern. In previous work, these effects have been considered by modeling acoustic propagation through a moving solibore, or by con-

sidering fixed 2D realizations of the sound-speed field. In this work, acoustic fields are generated for the case of a propagating internal wave field. In this case, the modal source function and local normal modes are constantly changing. The impact of these changes on the resulting modal interference pattern is examined for frequencies between 50 and 1000 Hz. In addition, fields are compared as would be measured on fixed versus synthetic aperture horizontal arrays. [Work supported by an ONR Ocean Acoustics Entry-Level Faculty Award.]

1pBB1. Vapor bubbles and sound. Andrea Prosperetti (Dept. of Mech. Eng., Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218, prosperetti@jhu.edu)

The paper focuses on the differences between the behavior of gas and vapor bubbles in a sound field. The stiffness of a gas bubble derives from the compression of the gas, while that of a vapor bubble is due to the release of latent heat and the consequent heating of the bubble contents. As a consequence, while the resonance frequency of a gas bubble is approximately inversely proportional to its radius, that of a vapor bubble varies like the inverse radius to the power 2/3. At sufficiently low frequencies, vapor bubbles have no stiffness at all. An oscillating vapor bubble may pick up by diffusion some gas dissolved in the liquid, which has a strong effect on the dynamics. These and other effects will be illustrated in the presentation. [Work supported by NASA Grant NNC05GA47G.]

1:30

1pBB2. Cavitation-enhanced ultrasound heating *in vivo*: Therapy protocols, mechanisms, and acoustic and MRI monitoring. S. D. Sokka (Philips Research North America, 345 Scarbarough Rd., Briarcliff Manor, NY 10510, sham.sokka@philips.com), N. Vykhodtseva, and K. Hynynen (Brigham and Women's Hospital, Harvard Med. School, Boston, MA 02115)

Focused ultrasound is currently being developed as a noninvasive thermal ablation technique for benign and cancerous tumors in several organ systems. Although these therapies are designed to ablate tissue purely by thermal means, cavitation can occur. These bubbles can be unpredictable in their timing and location and often interfere with thermal therapies. However, gas bubbles *in vivo* have some potential useful features for therapy. In this research, we design and test *in vivo* ultrasound exposures that induce cavitation at appropriate times and take advantage of their absorption enhancing properties while yielding reliable lesion sizes and shapes. In addition, MRI and acoustic methods to monitor and potentially control cavitation induction and the associated therapy are investigated. Finally, histology of the resulting cavitation-enhanced heating lesions is performed to assess the type of tissue damage. We demonstrate that cavitation-enhanced heating can be reliable and useful with the appropriate therapy protocol. Properly timed cavitation during thermal therapy yields larger lesions at lower powers taking advantage of bubbles' higher absorption. In addition, we show that bubble clouds that result from cavitation can block ultrasound wave propagation, providing a means to protect vital tissues during ablation of nearby pathology.

1pBB3. Nonlinear mechanisms of heating by high-intensity focused ultrasound. Vera A. Khokhlova (Dept. of Acoust., Faculty of Phys., Moscow State Univ., Moscow 119992, Russia, vera@acs366.phys.msu.ru), Michael R. Bailey, Michael S. Canney, Peter J. Kaczkowski, and Lawrence A. Crum (Univ. of Washington, Seattle, WA)

Two major nonlinear mechanisms are known to influence HIFU heating: acoustic nonlinearity and cavitation. Heating may also result in formation of boiling vapor bubbles that grow much larger than the cavitation bubbles. The relevant role of these phenomena was investigated experimentally and numerically in a gel phantom. HIFU pressure thresholds for shock formation, cavitation, and boiling were measured using a fiber-optic probe hydrophone, passive cavitation detection, ultrasound and optical imaging, and thermocouples. The KZK and Bio-heat equations were employed to simulate experimental conditions. Elevated static pressure was applied to suppress bubbles and increase the boiling temperature, thus isolating the pure effect of acoustic nonlinearity in comparison of heating between short, high-amplitude and long, low-amplitude pulses of equal average intensity. The experimental results indicated that both nonlinear mechanisms accelerated lesion production with acoustic nonlinearity responsible for the greater effect. It was observed that lesion distortion and migration was due to boiling detected in as little as 40 ms within the center of the lesion, in agreement with nonlinear acoustic simulations. These data indicate that acoustic nonlinearity and the boiling play a significant role earlier in HIFU treatments than previously anticipated. [Work supported by the NSBRI-SMS00402, RFBR, NIH FIRCA and DK43881.]

2:30

1pBB4. The multiple facets of bubble-enhanced high-intensity focused ultrasound (HIFU) lesion formation. Ronald A. Roy, Caleb H. Farny, Tianming Wu, and R. Glynn Holt (Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Exposure to high-intensity focused ultrasound can in some cases result in bubble formation. These bubbles can accelerate heating and contribute to the formation of irregularly shaped lesions. The relevant mechanical and thermal effects depend critically on several factors, such as temporal peak and temporal average acoustic intensity, pulse duration and duty cycle, bubble equilibrium sizes, tissue temperature, and tissue acoustic, rheological, and thermal properties. We will present a summary description of what physical effects matter, when, and why. Implications for HIFU treatment monitoring through the active and passive bubble detection are discussed. [Work supported by the Dept. of the Army (award No. DAMD17-02-2-0014) and the Center for Subsurface Sensing and Imaging Systems (NSF ERC Award No. EEC-9986821).]

1pBB5. Measurement and modeling of nonlinear waveforms in high-intensity focused ultrasound fields. Michael S. Canney, Michael R. Bailey (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), Vera A. Khokhlova, Misha A. Smagin, Oleg A. Sapozhnikov (Moscow State Univ., Moscow 119992, Russia), and Lawrence A. Crum (Univ. of Washington, Seattle, WA)

Direct measurement of HIFU fields *in situ* is important for the accurate prediction of thermal and mechanical bioeffects, as well as for the development of standards for medical systems. An experimentally validated numerical model can be an effective tool in both laboratory and clinical settings when direct measurements are not possible. Calculations with a KZK-type model and measurements with a fiberoptic probe hydrophone were employed together to characterize HIFU fields in water and in a tissue-mimicking gel. To determine the boundary conditions for simulations, the normal velocity distribution on the transducer surface was reconstructed using acoustic holography and combined with acoustic power measurements. At the focus, highly nonlinear waveforms ($+700$ and -150 bars peak pressures) were obtained both experimentally and numerically, which differed significantly from waveforms linearly extrapolated from low-amplitude results. Strongly distorted shock waveforms were localized in an axial region much smaller than the half-maximum beamwidth of the transducer excited at low level. At the highest excitation levels, the simulations predicted frequency content higher than was measurable in our configuration. Simulations also show that if these frequencies are not included, predicted heating rates are significantly lower. [Work is supported by NIH DK43881, NSBRI SMS00402, and RFBR.]

3:30

1pBB6. What is boiling during high-intensity focused ultrasound. Wayne Kreider, Michael R. Bailey, and Lawrence A. Crum (Ctr. for Industrial & Med. Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, wkreider@u.washington.edu)

For treatments that use high-intensity focused ultrasound (HIFU), it is important to understand the behavior of bubbles in the context of both large acoustic pressures and elevated temperatures in the surrounding medium. Based upon clinical and experimental observations, any preexisting cavitation nuclei in tissue or blood are likely to be less than 1 micron. For HIFU conditions characterized by megahertz frequencies and pressures on the order of megaPascals, gas bubbles less than a micron in radius can grow explosively. Calculations for a single, spherical bubble imply that the resulting bubble motions are significantly influenced by evaporation and condensation processes. Consequently, at both high and low ambient temperatures, HIFU-driven bubbles may best be described as gas-vapor bubbles that can exhibit rectified transfer of both heat and noncondensable gases. Moreover, increased vapor pressures associated with ambient temperatures at or above ''boiling'' may not lead to unbounded bubble growth as expected for a quasistatic bubble in a superheated medium. Instead, calculations suggest that growth of boiling bubbles can be confined. [Work supported by NIH T32 EB001650, NIH DK43881, and NSBRI SMS00402.]

3:45

1pBB7. Modeling the inertial cavitation threshold for tissue-mimicking gels seeded with laser-irradiated gold nanoparticle nuclei. Tianming Wu, Ronald A. Roy, and R. Glynn Holt (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Previous experiments demonstrated the acoustic cavitation threshold in a tissue-mimicking phantom was lowered from 4.5 to 1 MPa by seeding the optically transparent phantom with light-absorptive gold nanoparticles and irradiating these absorbers with ns-pulsed laser light with radiant exposure less than 10 mJ/cm^2. The absorption of laser energy deposits a remarkable amount of heat into the particle and surrounding liquid. Under appropriate acoustic conditions, explosive vaporization occurs and the resultant vapor cavity expands many times its initial size and collapses inertially. A three-stage model is developed to account for prenucleation heating, nucleation and formation of the vapor cavity, and follow-up vapor bubble dynamics. The acoustic pressure and laser-radiant exposure thresholds are determined by examining the radius-time evolution of the cavity. The acoustic threshold decreases when laser exposure increases but the efficiency of light depends on its pulse length and the particle size. A strategy for choosing optimal particles to generate inertial cavitation with acoustic and optic energy inputs is suggested. [Work supported by the Dept. of the Army (Award No. DAMD17-02-2-0014) and the Center for Subsurface Sensing and Imaging Systems (NSF ERC Award No. EEC-9986821).]

Session 1pNS

Noise and Underwater Acoustics: Marine Noise Topics

Michael Bahtiarian, Chair
Noise Control Engineering, 799 Middlesex Turnpike, Billerica, MA 01821

Contributed Papers

2:00

1pNS1. The acoustic design of the research vessel SHARP. Michael Bahtiarian (Noise Control Eng., 799 Middlesex Turnpike, Billerica, MA 01821)

The R/V HUGH R. SHARP is a general purpose research vessel that is owned and operated by the University of Delaware. It has been designed to achieve the International Council for the Exploration of the Seas (ICES) underwater noise limit for Fisheries Research Vessels. This paper describes the design process, construction details, and final results with regard to the acoustic design of this ship. Both compartment airborne noise and underwater radiated noise predictions were carried using a proprietary shipboard noise prediction program. Noise control treatments that were used include: vibration isolated machinery, double-stage isolated diesel generators, damping tiles, special acoustic insulation, and floating floors. After the vessel was completed a series of at-sea tests was performed to check compliance to vibration, compartment noise, and underwater noise. Two problems were discovered with underwater noise levels. One was related to a gearbox and the other was related to the propellers. A discussion of both issues and the final results are given in the paper. [Support provided by the University of Delaware, College of Marine Studies, in particular Mr. Matthew Hawkins, Director of Marine Operations.]

2:15

1pNS2. Results of flow-field quantities from computational fluid dynamics (CFD) analysis of a flow-excited Helmholtz resonator. Paul Zoccola, Joseph Slomski, and Theodore Farabee (Carderock Div. Naval Surface Warfare Ctr., 9500 MacArthur Blvd., West Bethesda, MD 20817)

A flow-excited Helmholtz resonator was modeled using a hybrid RANS/LES CFD solver. Solutions were obtained for a speed where the excitation was fully coupled to the response of the cavity, and for a lower speed, where it was not. The cavity and speeds modeled were chosen to replicate a prior experiment by one of the authors. Flow-field quantities analyzed include the energy production term and the energy flow vector field. These were compared to experimental data where available. Results at resonant and nonresonant conditions were also compared.

2:30

1pNS3. Performance of unstructured hybrid Reynolds averaged Navier-Stokes/large-eddy simulation methods in simulating shear-driven cavity flows. Joseph Slomski, Paul Zoccola, Michael Ebert (Carderock Div., Naval Surface Warfare Ctr., 9500 MacArthur Blvd., West Bethesda, MD 20817), and Srinivasan Arunajatesan (Combustion Res. and Flow Technol., Inc., Pipersville, PA 18947)

Two separate, unstructured hybrid RANS/LES methods are used to simulate both resonant and nonresonant shear-driven cavity flows. The first method uses an upwind-biased discretization for the inviscid flux calculations in the governing equations, along with a nonlinear $k-e$ turbulence closure for RANS regions, and the Smagorinsky subgrid-scale closure for LES regions. The second method uses an upwind-biased discretization for the inviscid flux terms which is modified to reduce the inherently high dissipation in the associated Riemann solver when applied to cell faces not orthogonal to the flow direction. The second method uses a $k-e$ closure for RANS regions. In LES regions, the second method solves a transport equation for subgrid turbulent kinetic energy, relating this energy to a spectrum for the energy-inertial-dissipation range, which allows calculation of a less dissipative eddy viscosity. Both methods are applied to a three-dimensional, deep cavity problem, at resonant and nonresonant flow conditions. Resulting pressure-time series are compared to experimental measurements.

2:45

1pNS4. Radiated noise signature of a ship in maneuvers. Boris Vasiliev (DRDC-Atlantic, 9 Grove St., P.O. Box 1012, Dartmouth, NS B2Y 3Z7, Canada, boris.vasiliev@drdc-rddc.gc.ca)

Underwater acoustic radiated noise of ships is usually measured for constant course and speed. The measurements are often averaged over the ship's aspect to yield the radiated noise signature. Consequently, dependence of the radiated noise on the ship's aspect or maneuvers is generally unknown. This talk will present measurements of the broadband and demodulated noise signatures of two research vessels. Variation of the signatures with ship aspect, acceleration, and turn rate will be discussed.

3:00

1pNS5. Reducing underwater radiated noise from gravel islands. Jesse Spence (Noise Control Engineering, 799 Middlesex Tpke., Billerica, MA 01821, jesse@noise-control.com)

Methods for reducing underwater noise radiated from gravel islands used for oil and natural gas production have been investigated. This study focused on operations for one gravel island, the Northstar, located in Prudhoe Bay, Alaska, during standard oil production activities in open water conditions. Various transmission paths have been examined, including direct airborne transmission, vibratory paths, and other secondary paths. Direct measurements of airborne noise, vibration, and underwater noise were used to determine the prominence of each noise path. General treatment options and details are given for those noise paths deemed to be significant. [The author would like to thank the U.S. Minerals Management Service for their funding and support, and BP Exploration (Alaska) Inc. and Greeneridge Sciences Inc. for their support and assistance.]

3:15

1pNS6. Vertical directionality of noise at two shallow water sites. Timothy F. Duda, James F. Lynch, Arthur E. Newhall (Woods Hole Oceanograph. Inst., AOPE Dept., MS 11, Woods Hole, MA 02543), and Philip A. Abbot (Ocean Acoust. Services and Instumentation Systems, Inc., Lexington, MA 02421)

Noise recorded with 16-element vertical line arrays moored at two sites near 80-m water depth has been analyzed. One site is south of New England (Shelfbreak PRIMER, June 1996), the other south of China in the South China Sea (ASIAEX, May 2001). Both sites exhibited downward

refracting conditions, so that a noise notch is realizable, and both exhibit internal gravity waves. The waves were more plentiful and of larger amplitude at the South China Sea site. Sound in a 40-Hz band centered at 135 Hz was extracted and separated into vertical beams using delay and sum beamforming. At each location, noise lower than the median level exhibited a peak near zero degrees for each data set (near-horizontal arrival). Noise higher than the median level in the New England data set exhibited a 5-dB noise notch, with peak levels at about ± 15 deg. Noise higher than the median level in the South China Sea data set did not show the notch and was essentially flat between 10 and -10 deg. The results are consistent with observed fluctuating propagation between fixed sources and receivers at the sites, and with differences in coupled-mode propagation through the two internal-wave fields.

3:30

1pNS7. Vertical directionality of midfrequency surface noise in downward-refracting environments. Cathy Ann Clark (NUWC, Bldg. 1320, Rm. 457, 1176 Howell St., Newport, RI 02841)

The vertical directionality of ambient noise due to surface agitation in the midfrequency range (0.5 to 10 kHz) for a subsurface receiver has a characteristic shape, knowledge of which may enhance shallow-water operations. In general, the noise level is highest at upward-looking angles and attenuated at downward-looking angles depending on the nature of the bottom. In environments with a negative profile gradient, the noise level is also greatly reduced in a low-angle shadow zone or ''notch'' at angles around 0 deg. This paper reviews the character of vertical noise directionality by examining a small number of measured data sets and considering the underlying physical mechanisms that drive the form of the distribution. A discussion of the implications for receiving sonar systems is followed by model reproduction of the measured data sets.

MONDAY AFTERNOON, 5 JUNE 2006 ROOM 551AB, 1:00 TO 4:35 P.M.

Session 1pPA

Physical Acoustics: Celebration of the Work of Brown University

Murray S. Korman, Cochair
U.S. Naval Academy, Physics Dept., Annapolis, MD 21492

Humphrey J. Maris, Cochair
Brown Univ., Dept. of Physics, Providence, RI 02912

Stephen V. Letcher, Cochair
Univ. of Rhode Island, Dept. of Physics, Kingston, RI 02881-0817

Chair's Introduction—1:00

Invited Papers

1:05

1pPA1. A short history of physical acoustics at Brown. Robert T. Beyer (Dept. of Phys., Brown Univ., Providence, RI 02912)

Modern acoustics at Brown began with Bruce Lindsay. Lindsay had been a student of atomic theory, but switched to acoustics during and after WWII. He found strong support from the Office of Naval Research (ONR), and brought to the department Arthur Williams, Peter Westervelt, Jordan Markham, Bob Morse, Rohn Truell, Wes Nyborg, and many others. Honors in the Society among this group included three presidencies, two gold medals, and several silver awards, as well as Lindsay's role of 20 years as Editor-in-Chief. The author of this paper recently found himself described in a German publication as ''Schatzmeister'' (look it up) of the Acoustical Society of America. Rohn Truell moved to Applied Mathematics at Brown and developed a second acoustics group there, which included Charles Elbaum and Humphrey Maris. From acoustic filters to nanosecond technology, the subject moved forward. But, we were all following Bruce Lindsay.

1:35

1pPA2. Reminiscences of Brown University during the 1950s. Wesley L. Nyborg (Phys. Dept., Univ. of Vermont, Burlington, VT 05405)

After World War II, Brown University was known internationally as one of several major centers for fundamental research in physical acoustics, with faculty and students engaged in studying properties of sound fields in gases, liquids, and solids, under linear and nonlinear conditions. Students came to Brown to benefit from this atmosphere and went on to establish their own programs at

other institutions. In the Physics Department the emphasis among areas of acoustics changed with time, following nationwide trends. For a few faculty and students, there was increased activity in areas of physical acoustics which were proving to be important to the emerging fields of biophysics and biomedical engineering. These areas included ultrasound field description, ultrasound propagation, radiation pressure, and acoustic streaming, to which major contributions had been made by R. B. Lindsay, A. O. Williams, Jr., R. T. Beyer, and P. J. Westervelt, among others. In this talk, specific examples will be discussed.

1:50

1pPA3. Acoustic methods used in condensed matter physics from the mid-1950s and beyond. Charles Elbaum (Dept. of Phys., Brown Univ., Providence, RI 02912)

A brief overview will be presented of various acoustic methods that were used at Brown University to study some aspects of condensed matter physics, in the period from the mid-1950s and beyond. The main emphasis will be directed to studies of dislocation dynamics in the context of mechanical properties (elastic and plastic) of solids, to phase transitions in solids, to metallic glasses, and to properties of liquid and solid helium.

2:05

1pPA4. The Metals Research Laboratory and the development of instrumentation for acoustics research at Brown University. Bruce Chick (RITEC Inc., 60 Alhambra Rd., Ste. 5, Warwick, RI 02886)

People I worked with and instrumentation that was developed during 30+ years at the Metals Research Laboratory at Brown University, and what that original instrumentation has led to.

2:20

1pPA5. The development of picosecond ultrasonics. Humphrey J. Maris (Dept. of Phys., Brown Univ., Providence, RI 02912, humphrey_maris@brown.edu)

Brown University has been a center for acoustics research for a very long time. Over the past 20 years, efforts have been directed towards the development of a new measurement technique that makes possible experiments on very thin films and other small structures of current interest in the computer industry. This method has also made it possible to make sound attenuation measurements over the frequency range from 10 GHz up to approximately 1000 GHz. The method will be described and some examples of its application will be presented.

2:35–2:50 Break

2:50

1pPA6. Professor Peter Westervelt and the parametric array. Thomas G. Muir (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, One Coliseum Dr., University, MS 38677) and Murray S. Korman (U. S. Naval Acad., Annapolis, MD 21402)

Work on the interaction of large-amplitude waves in fluids, leading up to the discovery of the parametric array, is mentioned, starting with Thuras, Jenkins, and O'Neil ["Extraneous frequencies generated in air carrying intense sound waves," J. Acoust. Soc. Am. **6**, 173–180 (1935)]. Westervelt's theory for the scattering of sound by sound ["Scattering of sound by sound," J. Acoust. Soc. Am. **29**, 934–935 (1957)], is reviewed. The discovery of arraylike and directivity properties of colinear waves interacting nonlinearly, as remembered by Peter Westervelt (private communication to Muir, 2005), is discussed. The formulation of the parametric array, illustrated from the original manuscript [Westervelt, P. J., "Parametric acoustic array," J. Acoust. Soc. Am. **35**, 535–537 (1963)], is discussed, expounding on its elegance and utility in opening new avenues for research and development, as well exploring its assumptions and limits of applicability. Subsequent benchmark experiments and theoretical mode relaxing the assumptions and extending the range of applicability, are mentioned. The First and Second International Symposia on Nonlinear Acoustics (1968 and 1969) are remembered, photographically, with mention of several discoveries made by the luminaries at that time. Numerous practical applications, developed over the past 45 years, are then briefly illustrated. Westervelt's mentorship with graduate students at Brown is discussed. [Work in large part, supported by the U.S. Navy.]

3:05

1pPA7. Graduate level acoustics at Brown University 1950–1955. Samuel A. Elder (U. S. Naval Acad. (Ret.), 308 Halsey Rd., Annapolis, MD 21401)

When Sam Elder considered graduate school he had in mind going into some exotic field like low-temperature physics, but when Dr. Lindsay offered him a good deal on a teaching assistantship, he could not turn it down. Then, when he started there in 1950, he began to realize that Brown was becoming known as a powerhouse of research in acoustics, so he happily changed his direction in order to study under that great man. As editor of JASA, Lindsay and the other acoustics experts he had gathered around him were at the very heart of the Society and it was an exciting time to be there.

3:20

1pPA8. Acoustics at Brown during the late 1950s and early 1960s and its impact on two of its students. John L. Butler (Image Acoust., Inc., 97 Elm St., Cohasset, MA 02025) and Stephen V. Letcher (Univ. of Rhode Island, Kingston, RI 02881)

The Brown University Physics Department researched a wide range of acoustics covering the frequency band from infrasonic to ultrasonic and linear to nonlinear compression in gases and liquids. Although JLB's research at Brown focused on the attenuation of sound in various liquids, he was mostly fascinated by the means for generating and receiving sound and still is today. SVL's research also involved measuring sound absorption in various liquids. Except for one experiment we were two nonlinear holdouts in the heyday of the field. As a means for appreciating and understanding the activities in the acoustics lab at Wilson Hall, the paths of these two students will be traced. We start from their desire to go to Brown, through their experiences and research there, as well as their interaction with the other students and professors and on to their present positions and more recent research. Some of the research will be illustrated with photos, results, and FEA animation.

3:35

1pPA9. Ah well!—The unflappable A.O. Williams, Jr.. Peter H. Rogers (Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332)

A student of Art Williams in the late sixties reflects on his experiences at Brown and on the career of his mentor.

3:50

1pPA10. Parametric acoustic array and P. J. Westervelt: A tribute. Kenneth G. Foote (Woods Hole Oceanogr. Inst., 98 Water St., Woods Hole, MA 02543)

Discovery of the parametric acoustic array, that is, its principle, by P. J. Westervelt [J. Acoust. Soc. Am. **35**, 535–537 (1963)] is justly famous. Reasons are given for this claim, including its unprecedented character and its usefulness, which is witnessed by a number of operational acoustical devices whose applications span subbottom profiling, marine archaeology, mine detection, and fish swimbladder resonance absorption spectroscopy, among others. New applications continue to be found, as to backscattering by swimbladder-bearing fish for sizing and quantification. These applications may be supported and extended by current efforts to develop a standard-target calibration protocol. While the larger community has pursued such applications, while also defining limits to the performance of the parametric acoustic array, the achievement represented by the essential discovery remains undiminished. In this tribute, some comments are also made of a personal sort on Westervelt's approach to science and teaching.

4:05

1pPA11. Nonlinear interactions in the 1970s: Tribute to the work of Robert T. Beyer. Murray S. Korman (Phys. Dept., U. S. Naval Acad., Annapolis, MD 21402) and Timothy K. Stanton (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Professor Beyer was our thesis advisor and supported, motivated, and directed both T.K.S's and M.S.K's Ph.D. research in the area of nonlinear underwater acoustics at Brown University. T.K.S performed experiments in an effort to measure the nonlinear interaction of sound with noise, while M.K.S did experiments involving the scattering of sound by sound in the presence of turbulence. Along the way T.K.S designed and built a complex intensity meter and measured the growth of the nonlinearly generated sidebands with propagation distance, while M.S.K designed and built a hot-film anemometer and measured the angular dependence of the spectral broadened sum frequency versus angle. We also learned ultrasonics and nonlinear acoustics from our mentor, who wove in the works of Rayleigh, Lighthill, and Westervelt along the way. Beyer also gave us a passion for the history that goes beyond the science. In the spirit of ''once a graduate student, always a graduate student,'' and ''don't just stand there go write a thesis,'' in our tribute to Beyer we will try to tell the ''vintage story'' that is spun around Professor Beyer the scientist, author, and teacher who established B/A, and made the earliest measurements on the parametric array.

4:20

1pPA12. Study of parametric excitation of nonlinear vibrations in strings. David A. Brown and Xiang Yan (Acoust. Res. Lab. and Dept. of Phys., Adv. Technol. & Manufacturing Cntr., Univ. of Massachusetts Dartmouth, 151 Martine St., Fall River, MA 02723)

The vibration of a string apparatus can easily be modified to demonstrate and study the parametric excitation of nonlinear acoustic vibrations. As faculty at Brown University were pioneers in both the study of nonlinear acoustic phenomena and introducing clever teaching apparatus to illustrate the principles of this science, it seems fitting to present the results of our study in this special session. The direct drive inductive transducer generates an alternating force, which drives a fixed-free aluminum thin beam that is tuned at resonance with the addition of mass. The string is attached to the free end of the beam and a dual pulley system and micro-positioning rail allows for the continuous adjustment of tension. The orientation of longitudinal vibrations in the string modulates the tension and excites transverse resonance modes that match the condition of half the drive frequency. The classic results of highly bent tuning curves are illustrated in this system by adjusting the tension (sound speed) in the string such that the resonance versus wave number spectra can be observed. Thus such a system may be useful in introducing the student to the study of parametric excitation of nonlinear vibrations in simple systems.

Session 1pPP

Psychological and Physiological Acoustics: Amplitude Modulation, Binaural Hearing, Decisions, and Speech (Poster Session)

Emily Buus, Chair
Univ. of North Carolina, 1115 Bioinformatics Bldg., Chapel Hill, NC 27599

Contributed Papers

All posters will be on display from 1:00 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 5:00 p.m.

1pPP1. Frequency discrimination in amplitude-modulated maskers. Emily Buss, Joseph W. Hall, III, and John H. Grose (Univ. of North Carolina at Chapel Hill, 130 Mason Farm Rd., CB 7070, 1115 Bioinformatics Bldg., Chapel Hill, NC 27599, ebuss@med.unc.edu)

Under some conditions, the detection threshold for a pure tone signal masked by a bandpass Gaussian noise can be reduced by the introduction of amplitude modulation (AM) to the masker. Previous data suggest that this advantage may be reduced for discrimination tasks, such as frequency discrimination of a masked tone [Hall *et al.*, J. Acoust. Soc. Am. **102**, 1746–1754]. In the present study, frequency discrimination thresholds were estimated for a 500-Hz pure tone presented at a range of levels (3, 6, and 12 dB *re*: masked detection threshold). The masker was either a Gaussian noise or an AM noise (bandpass filtered 50–4000 Hz), with a range of square wave AM rates (10–40 Hz). Masking release was greater for 10-Hz AM than 40-Hz AM, but frequency discrimination was better for the 10 than the 40-Hz rate when measured at equal sensation levels. This result suggests that temporal resolution and integration may have important contributions to frequency discrimination measured for tones presented in modulated maskers. [Work supported by NIH NIDCD Grant R01 DC000418.]

1pPP2. Sensitivity to across-frequency detection cues in binaural hearing. Joseph W. Hall, III, Emily Buss, and John H. Grose (Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27599-7070)

The detectability of an $S\pi$ signal in a narrow-band No masking noise can be improved by the addition of comodulated No flanking noise bands [Hall and Cokely, J. Acoust. Soc. Am. **83**, 1839–1845(1988)]. This effect is relatively unreliable, however, occurring in only about 50% of listeners. The present study examined whether the effect can be made more reliable by slightly reducing the interaural correlation of the masking noise. For such a masker, interaural correlation fluctuates as a function of time. For the stimuli used here, the on-signal and the comodulated flanking bands shared the same pattern of interaural correlation as a function of time. The rationale was that the flanking bands could potentially be used as templates to help the auditory system distinguish the ongoing interaural differences of the slightly decorrelated on-signal noise band from the interaural differences introduced by the $S\pi$ signal. Results from all six of the listeners tested showed improved $S\pi$ detection in conditions where the on-signal and flanking bands had the same pattern of interaural correlation. This effect can be considered a form of binaural profile analysis wherein signal detection is aided by an across-frequency analysis of binaural cues. [Work supported by NIH NIDCD R01 DC00397.]

1pPP3. The contribution of envelope and carrier to cues for tone-in-noise detection in narrow-band reproducible noises. Sean A. Davidson (Dept. of Biomed. and Chemical Eng., Inst. for Sensory Res., Syracuse Univ., 621 Skytop Rd., Syracuse, NY, 13244), Robert H. Gilkey (Wright State Univ., Dayton, OH 45435), H. Steven Colburn (Boston Univ., Boston, MA 02215), and Laurel H. Carney (Syracuse Univ., Syracuse, NY 13244)

To elucidate the roles of envelope and carrier cues in detection of a 500-Hz tone in 50-Hz bandwidth noise under N_0S_π conditions, hit- and false-alarm rates were collected for 4 sets of reproducible stimuli. The envelopes and carriers from two sets of stimuli (each with 25 signal-plus-noise and 25 noise-alone waveforms) were extracted and recombined to form 2 new sets (each having the carriers from one of the original sets and the envelopes from the other). Noises were preselected to produce minimal spectral splatter in the recombination processes. Preliminary results for signal-plus-noise trials suggest that carrier cues (e.g., temporal fine structure) are dominant over envelope cues (i.e., response patterns were more similar between sets with the same carriers but different envelopes, than between sets with the same envelopes but different carriers); however, carrier cues cannot completely explain the data. Results for noise-alone trials suggest that both envelope cues and carrier cues contribute to listener responses. Further analyses will explore potential interactions between monaural and binaural stimulus properties, as well as interactions between interaural envelope cues and carrier cues. [Supported by NIH DC007798(SAD), DC001641(LHC), and DC00100(HSC).]

1pPP4. Responses of cochlear nucleus units recorded from chinchillas trained to discriminate iterated rippled noise from flat-spectrum noise. William P. Shofner (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405)

Behavioral responses obtained from chinchillas using a stimulus generalization paradigm show that the perception of pitch strength is dependent on the stimuli used for training. When animals are trained to discriminate a cosine-phase harmonic tone complex (COS) from a flat-spectrum, wideband noise (WBN), generalization gradients indicate that animals rely primarily on temporal information in the envelope. Gradients from animals retrained to discriminate infinitely iterated rippled noise (IIRN) from WBN indicate animals rely more on information in the fine structure. Thus, chinchillas learn to use the information in the fine structure when trained with an appropriate stimulus. In order to begin to examine whether there exists a neural correlate of this learning at the level of the cochlear nucleus, single-unit responses to IIRNs and WBN were recorded from three anesthetized chinchillas that had received considerable behavioral training in discriminating IIRNs from WBN. Preliminary data were ob-

tained for 19 single units consisting of primarylike, chopper, and onset response types. All-order interspike-interval histograms obtained for IIRNs and WBN were qualitatively similar to those obtained from naive, untrained animals for each unit type. Quantitative comparisons among units recorded from trained and untrained animals will be presented. [Work supported by NIDCD R01 DC005596.]

1pPP5. On the rate of decay of forward masking and its relation to cochlear compression. Enrique A. Lopez-Poveda and Ana Alves-Pinto (Instituto de Neurociencias de Castilla y Leon, Universidad de Salamanca, Avda. Alfonso X El Sabio s/n, 37007 Salmanca, Spain)

Recent psychoacoustic studies [e.g., Lopez-Poveda *et al.*, J. Acoust. Soc. Am. **113**, 951 (2003)] have suggested that cochlear compression extends to a wider range of frequencies in the apex than in the base of the cochlea. This conclusion was drawn from the analysis of the slopes of temporal masking curves (TMCs) on the assumption that forward masking decays at the same rate for all probe and masker frequencies. This study aims to verify the conclusion stated above using a different assumption. TMCs for normal hearing listeners were measured for probe frequencies (Fp) of 500 and 4000 Hz and for masker frequencies of 0.4, 0.55, and 1.0 times the probe frequency. Measurements were made for probes of 9- and 15-dB sensation level. The assumption was that given a 6-dB increase in probe level, linear cochlear responses to the maskers should lead to a 6-dB vertical shift of the corresponding TMCs, while compressive responses should lead to bigger shifts. Results are consistent with compressive cochlear responses to the 0.4Fp and 0.55Fp maskers at 500 Hz but linear responses at 4000 Hz, in line with the conclusions from earlier studies. [Work supported by the Spanish FIS (PI020343, G03/203), MEC (CIT-390000-2005-4), and FEDER.]

1pPP6. Amplitude modulation detection by infants and adults. Lynne Werner (Dept. Speech & Hearing Sci., Univ. of Washington, 1417 N.E. 42nd St., Seattle, WA 98105-6246)

Infants' and adults' intensity processing was examined by estimating the modulation depth required to detect amplitude modulation in a broadband noise. The infants were either 3 or 6 months old. An observer-based response method was used. Modulation depth was varied adaptively to estimate thresholds. The noise was presented continuously at 70 dB SPL. Listeners detected 4-Hz modulation presented for 4 s. Adults thresholds were similar to those reported in the literature for trained listeners. Infants' thresholds were substantially worse than those of adults, but 3- and 6-month-olds did not differ. This result is consistent with previous reports that 6–9-month-olds are immature in intensity discrimination. However, it is surprising that little change in performance occurs between 3 and 6 months, because infants of these ages differ in other measures of intensity processing. [Work supported by NIDCD.]

1pPP7. Across-channel gap detection in cochlear implant listeners. John H. Grose, Emily Buss, and Joseph W. Hall, III (Dept. Otolaryngol.-HNS, Univ. N. Carolina at Chapel Hill, 1115 Bioinformatics CB# 7070, Chapel Hill, NC 27599-7070)

In normal hearing, gap detection thresholds are elevated when the leading and trailing markers of a gap differ widely in frequency or are presented to different ears; thresholds are also elevated by the introduction of amplitude modulation (AM) to the markers. This study assessed whether similar effects can be observed in a group of high-performing, MED-EL COMBI 40+ cochlear implant users, a subset of whom are bilaterally implanted. In experiment 1, markers were equal-amplitude 3-kHz pulse trains of random duration (40–80 ms) delivered through a research interface. Thresholds were low (<1 to 6 ms) when the two markers were presented on a single electrode channel and increased when the markers were on different channels within an ear or across ears. In experiment 2, markers were AM pulse trains of random duration (100–150 ms). These were generated by multiplying a 3-kHz, equal-amplitude pulse train with the envelope of a 50- or a 300-Hz bandpass filtered Gaussian noise; the envelope was either uncompressed or compressed with an exponent of 0.2. Thresholds were elevated by AM at both rates, with larger effects for the uncompressed envelope. These patterns of results are similar to those observed in normal hearing. [Work supported by NIDCD 5R01DC1507.]

1pPP8. Effects of aging and masker-level variability on backward-masked frequency discrimination. Blas Espinoza-Varas (Commun. Sci. & Disord., OU Health Sci. Ctr., Oklahoma City, OK 73190), Hyun-sook Jang (Hallym Univ., Chuncheon, South Korea), and Praveen Jajoria (OU Health Sci. Ctr., Oklahoma City, OK 73190)

Backward-masked frequency discrimination thresholds (FDTs) were measured to probe the ability to ignore irrelevant auditory information in young and older adults. For 1500-Hz, 40- or 60-ms, 75-dB-SPL target tones, FDTs were measured unmasked and in three backward-masked conditions in which a 1500-Hz, 80-ms, 75-dB-SPL masking tone followed the target with 20–240-ms ISI. In two masked conditions, there was within-trial irrelevant variability in masker level, with negative or positive polarity (i.e., 75 ± 5 or 10 dB SPL) but not in the third. The no-variability condition yielded more backward masking in older than in young adults. Irrespective of polarity, masker-level variability elevated the FDTs of both age groups, but relative to those of the young, the elders' elevations were larger and did not decrease with training; elders had difficulty learning to ignore irrelevant variability. In young adults, the decrease in FDTs with training tended to be steeper with negative than with positive level variability. Memory capacity and long-term memory constraints seem to limit the elders' ability to ignore irrelevant information.

1pPP9. Detection thresholds for amplitude modulation of noise with simultaneous modulating tone. Jonathan Pincas and Philip J. B. Jackson (CVSSP, Dept. Electron. and Elec. Eng., Univ. of Surrey, Guildford, GU2 7XH, UK, jon@pincas.co.uk)

In speech, the combination of amplitude-modulated (AM) noise and a low-frequency periodic source characterizes voiced fricative sounds. To investigate the modulation's contribution to fricative auditory quality, AM white noise, with simultaneous sinusoidal component at the modulating frequency, provided stimuli for perceptual tests. Two AM detection-threshold experiments were conducted to establish the effect of varying the relative amplitude and phase of the tone. In the first experiment, tone and noise stimuli were separated within each trial by short pauses; in the second, the tone played continuously throughout the trial. AM detection thresholds when the tone was absent were similar to previously published thresholds for AM noise with no tone (averaging approximately -22 dB). The effect of the quieter tones (10–30 dB tone-to-noise ratio, TNR) was dependent on test condition. In the broken-tone experiment, a slight increment in threshold occurred for all relative phases. The constant-tone experiment revealed impaired detection when tone and noise modulation were in phase, and the converse when in antiphase (5-dB difference in threshold at 30-dB TNR). As TNR increased further (40–50-dB TNR), thresholds rose in all cases. Future work is needed to evaluate how this detectable AM percept influences quality and categorization of fricatives.

1pPP10. Static and dynamic spectro-temporal gap detection. David A. Eddins (Dept. of Otolaryngol., Univ. of Rochester, 2365 S. Clinton Ave., Ste. 200, Rochester, NY 14618) and Christine E. Carlson (Univ. at Buffalo, Buffalo, NY 14514)

Frequency-dependent measures of temporal processing are often based on temporal gap detection measured using sinusoids or bandpass noise. Some natural sounds, such as speech, are better characterized as relatively broadband sounds with low-amplitude portions restricted to narrow frequency regions. The present study reports the perception of analogous

stimuli: static and dynamic spectro-temporal gaps embedded in broadband noise. In the first experiment, the temporal gap created a static spectral notch, the duration of which was the independent variable (gap duration in ms) and the width of which was fixed, in separate conditions being either 800 Hz or equal to one or three ERBs (equivalent rectangular bandwidth). The spectral notch was centered at either 800, 1600, 3200, or 6400 Hz. Gap onset relative to stimulus onset varied from 10 to 320 ms. In the second experiment, the temporal gap created a dynamic spectral notch, the lower and upper cutoff frequencies of which varied over the duration of the temporal gap much like a frequency sweep. Experimental parameters included the bandwidth of the notch in octaves and notch center frequency at gap onset and gap offset. The data will be considered in terms of temporal resolution, frequency resolution, and across-channel processing.

1pPP11. Psychophysical and physiological assessment of the representation of high-frequency spectral notches in the auditory nerve. Ana Alves-Pinto (Instituto de Neurociencias de Castilla y Len, Universidad de Salamanca, Avda. Alfonso X El Sabio, 37007 Salamanca, Spain), Alan R. Palmer (MRC Inst. of Hearing Res., Nottingham NG7 2RD, UK), and Enrique A. Lopez-Poveda (Universidad de Salamanca, 37007 Salamanca, Spain)

High-frequency spectral notches such as those generated by the pinna are useful for sound localization. Because their center frequency (6–8 kHz) is beyond the cutoff of phase locking, the common view is that the internal representation of such notches does not involve the timing of action potentials and that, instead, they must be exclusively represented in terms of auditory nerve rate profiles. Recently, we [A. Alves-Pinto and E. A. Lopez-Poveda, J. Acoust. Soc. Am. **118**, 2548 (2005)] have shown that the threshold notch depth for discriminating between a flat-spectrum noise and a noise with a square spectral notch centered at 8 kHz varies nonmonotonically with increasing sound level, and that discrimination is worst for levels around 80 dB SPL. Here, we show that the information in the auditory nerve rate profiles is insufficient to account for this psychophysical result, and that temporal information is almost certainly used for discriminating between noise bursts with and without high-frequency spectral notches.

1pPP12. Spatiotemporal coding based on the responses of individual auditory-nerve fibers. Michael G. Heinz (Dept. of Speech, Lang., Hearing Sci. and Biomed. Eng., Purdue Univ., 500 Oval Dr., West Lafayette, IN 47907, mheinz@purdue.edu)

Spatiotemporal coding has been suggested to provide a robust representation of vowel spectra, pitch, and tones in noise. However, much of the quantitative support has come from modeling studies because of the inherent variability in physiological population studies. A spectro-temporal manipulation procedure (STMP) was developed to simulate spatiotemporal patterns from the responses of individual auditory-nerve (AN) fibers to frequency-shifted stimuli with features placed around the fibers' best frequency. Individual AN fiber responses from anesthetized cats were measured for vowellike stimuli as a function of vowel and background-noise level. Similar to previous population studies, the STMP results show that spatiotemporal coding of vowel spectra (quantified using ALSR) is more robust than average-rate coding as vowel or background-noise level increases. The STMP results also suggest that the response phase transition near low-frequency formants may not be sharp enough to provide as robust encoding as previously suggested. This method of simulating spatiotemporal patterns from individual AN fiber responses may be particularly useful for studying the effects of sensorineural hearing loss because it is particularly difficult to obtain large populations of responses from animals with hearing loss. Preliminary data have been collected from cats with noise-induced hearing loss. [Work supported by NIH/NIDCD R03DC007348.]

1pPP13. Individual differences in dynamic binaural-masking-level differences at 500 Hz in listeners older than 50 years. Michael A. Akeroyd (MRC Inst. of Hearing Res., Scottish Section, Glasgow Royal Infirmary, 16 Alexandra Parade, Glasgow G31 2ER, UK)

One demonstration of binaural sluggishness is that the binaural masking level difference (BMLD) for a tone burst is strongly dependent upon the rate of modulation of the interaural correlation of a masking noise [D. W. Grantham and F. L. Wightman, "Detectibility of a pulsed tone in the presence of a masker with time-varying interaural correlation;" J. Acoust. Soc. Am. /bf 65, 1509–1517 (1979)]. This paradigm was used to measure such dynamic BMLDs for a group of 18 listeners, aged 50–78 and with low-frequency hearing losses of 7–43 dB. The signal was a 20-ms, 500-Hz tone placed in the temporal center of a 500-ms, 100–2000-Hz, 63-dB overall-level noise. The interaural correlation of the noise was either fixed at 1.0 (static conditions) or 100% modulated (dynamic conditions). As expected, the dynamic BMLD reduced as the modulation rate increased; the across-listener means were 11, 8, 6, 2, 0, and 0 dB at rates of 0.5, 1, 2, 4, 8, and 16 Hz. But the individual differences were substantial: e.g., for the 11 listeners who showed a static BMLD of 15 dB or more, their 2-Hz dynamic BMLDs varied between 2 and 10 dB. Those listeners with poor dynamic thresholds (and so more sluggish than the others) may have increased difficulties in detecting sounds in changing spatial environments.

1pPP14. The role of monaural spectral cues in modeling the precedence effect. Pavel Zahorik (Dept. of Psychol. and Brain Sci., Univ. of Louisville, Louisville, KY 40292, pavel.zahorik@louisville.edu)

Various evidence suggests that the precedence effect may generalize to spatial locations of sound source and echo that minimize binaural information available to the listener. In these situations, it is likely that monaural spectral cues to the direction of the source+echo composite. Here a model of directional sound localization that incorporates both binaural temporal cues and monaural spectral cues is described and evaluated. The binaural portion of the model relies on interaural cross-correlation to extract binaural cues to lateral direction. The monaural spectral portion uses a spectral correlation metric to evaluate the similarity of the incoming sound spectrum with a catalog of spectral shapes resulting from a listener's own head-related transfer functions (HRTFs) to known source directions. The model was used to predict sound localization performance of seven human listeners in 16 spatial configurations of source and echo (presented using virtual auditory space techniques with individualized HRTFs), including six configurations where binaural information was minimized (four on the median plane). In general, precedence effects that relied primarily on spectral cue information were considerably less predictable than those that relied on binaural information. [Work supported by NIDCD.]

1pPP15. Interaural correlation and loudness. Barrie A. Edmonds and John F. Culling (School of Psych., Tower Bldg., Park Pl. Cardiff Univ., Cardiff, CF10 3AT, UK)

When the same sound is presented to both ears rather than to just one, a phenomenon called binaural summation occurs, in which the overall loudness is greater than when either ear is individually stimulated. The present investigation focused on the effect of interaural correlation on this phenomenon. An adaptive matching paradigm was used to measure the difference in intensity between monotic, diotic, uncorrelated, and anticorrelated bands of noise needed to equate them in loudness. The results for 460–540-Hz bands showed (1) consistent with binaural summation, diotic noise was matched to monotic noise that was 4.6 dB more intense and (2) uncorrelated noise was matched to diotic noise that was 2.0 dB more intense. Anticorrelated and diotic noises did not differ significantly in intensity when matched in loudness. Similar results were observed for 100–900-Hz bands: (1) was extended to 6.5 dB and (2) remained at 2.0 dB, but

anticorrelated noise was now matched to diotic noise that was 1.0 dB more intense. For 100–5000-Hz bands results showed (1) was extended to 5.5 dB, (2) was reduced to 1.0 dB, and anticorrelated noise was now matched to diotic noise that was 0.5 dB more intense.

1pPP16. The inclusion of time-varyng jitter in the equalization-cancellation model of binaural processing. Rui Wan, N. I. Durlach, and H. Steven Colburn (Hearing Res. Ctr. and Dept. of Biomed. Eng., Boston Univ., 44 Cummington St., Boston, MA 02215)

A more realistic version of the analytically defined equalization-cancellation(EC) model of binaural processing can be simulated in the time domain by introducing time-varying jitters, both in time and amplitude. Although the classic EC model can predict a wide range of binaural-masking-level-difference (BMLD) data in binaural detection, it is more reasonable physiologically to assume that internal noise is time varying, as opposed to the original assumption that the internal time and amplitude errors are different from waveform to waveform but stay constant within a waveform. In the current study, the BMLD predictions for both the analytical model and the simulation are compared for the representative conditions(N_oS_π, $N_\pi S_o$, N_oS_m). It is also proved theoretically that the simulation results converge to the analytical prediction in the $N_{\tau_n}S_{\tau_s}$ case. Differences between the EC model and the simulation are discussed. Applying this simulation to speech perception based on the speech intelligibility index(SII) in anechoic environments predicts binaural advantages consistent with results described in the literature (Zurek,1993). The simulation is also being applied to the speech-transmission-index (STI) prediction in complex environments. [Work supported by NIDCD R01 DC00100.]

1pPP17. Effects of correlated and uncorrelated interfering noise on interaural time delay (ITD) detection. Andrew J. Kolarik and John F. Culling (School of Psych., Cardiff Univ., Tower Bldg., Park Pl., Cardiff, CF10 3AT, UK, kolarika@cf.ac.uk)

Results are reported from two binaural discrimination experiments. The first measured ITD discrimination threshold for broadband noise in the presence of interaurally correlated interfering noise. Six listeners performed an adaptive 2I-2AFC discrimination task with 100-ms stimuli composed of delayed and diotic noises (0–3 kHz) mixed in various proportions (1, 0.75, 0.563, 0.422, 0.316, 0.237, and 0.178). A regression analysis showed that thresholds doubled for every halving of the proportion of delayed noise power in the stimulus. The second experiment measured ITD discrimination thresholds for a range of interaural correlations obtained by mixing correlated and uncorrelated noise before applying the delay. Three listeners performed 2I-2AFC discrimination tasks at correlations of 1, 0.75, 0.5, 0.25, 0.2, 0.15, 0.1, and 0.05, and durations of 100, 500, and 1000 ms. Seventy-one percent of the threshold were obtained using psychometric functions. Thresholds more than doubled for each halving of the correlation at all three stimuli durations tested.

1pPP18. Monaural and binaural cues to signal detection. John F. Culling (School of Psych., Cardiff Univ., Tower Bldg., Park Pl., Cardiff, CF10 3AT, UK)

When a signal is added to random noise in the NoSπ configuration it has two effects on the stimulus at the signal frequency: the correlation is reduced and the energy is increased. Both changes may contribute to the detection and discrimination of signals. A signal-level discrimination task (2I-FC) was used to measure the strength of each cue and their combination across a wide range of signal-to-noise ratios (-20–0 dB). The signal was a band of noise (462–539 Hz). The masker was a broadband noise (10–3000 Hz) of fixed sound level. Conditions were NoSπ, NoSo, and correlation manipulation within the target band equivalent to NoSπ. At low signal-to-noise ratios, performance was determined by the correlation change, but at higher signal levels both cues became ustable and discrimination was better in NoSπ than in the correlation-manipulation condition. Analysis using signal-detection theory indicated that these data could not be explained by assuming the two cues were independent.

1pPP19. Informational masking: Effects of similarity and uncertainty for detection of a high-frequency amplitude-modulated tone. Frederick J. Gallun, Christine R. Mason, and Gerald Kidd, Jr. (Dept. of Speech, Lang. and Hearing Sci. and Hearing Res. Ctr., Boston Univ., 635 Commonwealth Ave., Boston, MA 02215)

Detection of a 3-kHz target tone with 125-Hz amplitude modulation (AM) was measured in the presence of maskers that varied in their similarity to the target. Spectro-temporal similarity was varied in that maskers were tones, narrow-band noises, or AM tones. Similarity in terms of interaural configuration was varied by presenting maskers diotically while target was presented (1) diotically, (2) monotically, or (3) with its envelope delayed at one ear. All maskers had four narrow-band components with center frequencies (CFs) between 1 and 5 kHz. Masker CFs were varied on every block, trial, or interval of a 2IFC procedure, resulting in three levels of masker-frequency uncertainty. As expected, the spectro-temporally similar AM maskers caused greater masking than pure-tone or noise maskers. Surprisingly (and at variance with previous results), varying similarity by interaural configuration had no effect. Increasing masker uncertainty resulted in more masking only for the AM masker. These results suggest that (1) the effects of uncertainty are most pronounced in conditions where maskers and targets are similar and (2) more study is needed of the factors responsible for binaural release from informational masking. [Work supported by NIH/NIDCD and AFOSR.]

1pPP20. Improving listener decision strategy in the perception of complex auditory events. Jesse Flint (Psych. Dept., Binghamton Univ., PO Box 6000, Binghamton, NY 13902), Richard Pastore, and Jeremy Gaston (Binghamton Univ., Binghamton, NY 13902)

Natural auditory events are complex. In perceiving these events, listeners tend to use various, and not necessarily optimal, samplings of information. Prior research examined static and dynamic source and sound characteristics for a posture contrast (upright versus stooped) in human gait, identifying several acoustic cues that sometimes differentiate the posture contrast (e.g., pace, spectral slope and amplitude), but with no one acoustic cue always doing so. Successful listener decision strategy thus needs to be a complex process of attending to and evaluating several cues in a flexible manner. With a long-term goal of determining how to improve listening skills, the current research examines ways to enhance attention to and decisions about specific acoustic cues to the posture distinction. For the stimulus property of pace, both information (or knowledge) of cue relevance and experience making relative decisions about the cue, as opposed to experience with sample stimuli, significantly improve listener decision strategy in making the posture judgment. The current study provides a similar evaluation for the acoustic cue of spectral slope. [Research supported by grant from NSF.]

1pPP21. Effect of decision weights and internal noise on the growth of d' with N. Erica Lenhart and Robert A. Lutfi (Dept. of Communicative Disord., Univ. of Wisconsin, Madison, WI 53706)

A general finding of psychoacoustic studies is that detectability d' of a noisy signal grows less than optimally with the number N of independent observations of the signal. Traditional accounts attribute the nonoptimal growth to a form of central internal noise that accumulates with each observation. A more recent interpretation, however, implicates an upper limit on the number of observations that listeners can process at any one time in a given stimulus. The latter account was clearly favored in the present study by the results of a COSS analysis [Berg "Observer efficiency and weights in a multiple observation task," J. Acoust. Soc. Am. **88**, 149–158 (1990)] applied to the detectability of level increments added

to simultaneous and sequential N-tone patterns. Estimates of decision weights showed a predominant reliance of listeners on no more than 2–3 tones in each pattern independent of N. Measures of weighting efficiency systematically decreased with N while noise efficiency remained constant across N. The results are discussed in terms of their implications for the interpretation of early experiments on the effects of the bandwidth-duration product on signal detection. [Research supported by NIDCD Grant 5R01DC1262-14.]

1pPP22. Individual differences in source identification for synthesized impact sounds. Robert A. Lutfi (Dept. of Communicative Disord., Univ. of Wisconsin, Madison, WI, 53706) and Raman Arora (Univ. of Wisconsin, Madison, WI, 53706)

Impact sounds were synthesized according to standard textbook equations given for the motion of freely vibrating bars, membranes, and plates. In the two-interval, forced-choice procedure highly practiced listeners identified from these sounds various physical attributes of these sources and the manner in which they were driven to vibrate. A COSS analysis of the trial-by-trial data [Berg, "Observer efficiency and weights in a multiple observation task," J. Acoust. Soc. Am. **88**, 149–158 (1990)] revealed large differences across listeners in the acoustic cues used within each identification task, but similarity in the cues used within listeners across tasks. Only in conditions in which the acoustic information for identification was highly constrained did listeners use identical cues. Despite the large individual differences in listening strategy, identification accuracy was similar across listeners. Where there were differences in identification accuracy the differences appeared large, related to differences in internal noise and not listening strategy. [Research supported by NIDCD Grant 5R01DC006875-01.]

1pPP23. Using multidimensional scaling to determine distances in the perceptual space of rolling sounds. Christophe Stoelinga, Dik Hermes (Technische Universiteit Eindhoven, Den Dolech 2, P.O. Box 513, 5600MB Eindhoven, The Netherlands), and Armin Kohlrausch (Philips Res. Labs. Eindhoven, 5656AA Eindhoven, The Netherlands)

We recorded sounds generated by a ball rolling over a wooden plate. Ball diameter, rolling speed, and plate thickness were varied. In a difference-scaling experiment, the important dimensions of the space spanned by these sounds were determined. All sounds were combined in pairs and subjects were asked to quantify the difference they heard in each pair. In this way all possible perceptual differences could play a role in the difference scalings without a need to interpret these differences in terms of underlying object properties such as size or speed. Using multidimensional scaling, a good fit for the scaled differences was obtained with a minimum of three dimensions. None of the dimensions corresponded directly with one of the three mechanical parameters varied in the rolling sounds. Differences in speed lead to a smaller distance in the thus-obtained perceptual space than differences in size, for the ranges we used. This corresponds to results from experiments where the subjects were directly asked to judge size and speed differences using the same sounds. Remarkably, the plate thickness resulted in large distances in perceptual space, while this mechanical property is poorly recognized when participants are directly asked for it.

1pPP24. Optimizing information-transfer rates for human communication. Charlotte M. Reed, Nathaniel I. Durlach (Res. Lab. of Electron., MIT, Cambridge, MA 02139, cmreed@mit.edu), and Hong Z. Tan (Purdue Univ., West Lafayette, IN 47907)

This research is concerned with investigating the factors that contribute to optimizing information-transfer (IT) rate in humans. This issue has important ramifications for the design of human-machine interfaces in a wide variety of applications, including virtual environment and teleoperator systems as well as sensory aids for persons with impaired vision and/or hearing. Based on the results of several early studies from the 1950s, a general rule of thumb has arisen in the literature which suggests that IT rate is dependent primarily on the stimulus delivery rate and is optimized for presentation rates of 2–3 items/second. Thus, the key to maximizing IT rate is to maximize the information in the stimulus set. Recent data obtained with multidimensional tactual signals, however, appear to be at odds with these conclusions. In particular, these current results suggest that optimal delivery rate varies with stimulus information to yield a constant peak IT rate that depends on the degree of familiarity and training with a particular stimulus set. We discuss factors that may be responsible for the discrepancies in results across studies including procedural differences, training issues, and stimulus-response compatibility. [Research supported by Grant No. R01-DC00126 from NIDCD, NIH.]

1pPP25. A miniature, low-cost, user-friendly personal sound-level dosimeter. Harold A. Cheyne, II and Thomas E. von Wiegand (Sensimetrics Corp., 48 Grove St., Ste. 305, Somerville, MA 02144-2500, harold@sens.com)

The objective of this research is to develop a miniature, low-cost, user-friendly personal sound-level dosimeter that can meet the ANSI S1.25-1991 standard. This dosimeter is intended for people whose work-related or recreation-related activities expose them to noises that cause hearing loss. In contrast to typical dosimeters that are controlled by a manager or clinician, the wearer of the miniature dosimeter will also control it and receive its data output to better appreciate his or her sound exposure dose. To significantly miniaturize the dosimeter and lower its cost as compared to typical dosimeters, it will have a reduced feature set, simplified signal processing, an inexpensive microphone capsule, and a microcontroller rather than a digital signal processor. Preliminary tests, using a Texas Instruments embedded controller and an LCD display, suggest that approximations to the standard dosimeter function blocks can be made while maintaining the ANSI tolerances. Tests with inexpensive microphone capsules show acceptable drift due to temperature and humidity for a dosimeter. Following further testing for compliance with the ANSI standard, a limited set of field tests is planned, with wearers using both the miniature dosimeter and a commercial dosimeter, to compare their dosimetry performance.

1pPP26. Intimacy in performance venues: Towards a socioecological methodology. Bobby Gibbs, II (Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180), Jonas Braasch, and T. Krueger (McGill Univ., Montreal, QC, Canada)

Intimacy can be subjectively defined as the feeling of closeness to performance. Intimacy has been widely correlated with the initial time delay gap, the delay between the direct sound and early reflections in a venue [Beranek, *Concert and Opera Halls: How They Sound* (Acoustical Society of America, New York, 1996)]. Contemporary research suggests that visual stimuli have considerable bearing upon intimacy perception [e.g., Cabrera and Nguyen, J. Acoust. Soc. Am. **116**, 2475 (2004)]. Building upon paradigms of ecological psychology, the author hypothesizes that social affordances, perceived offerings of social propinquity in a venue, will significantly enhance the auditory impression of intimacy. A socioecological approach to weigh the hypothesis is proposed wherein auditory perception is evaluated in the context of both the physical and the social environment. The methodology will employ interviews, ethnographic analyses, field studies, and laboratory tests. The research results will likely have immediate ramifications for the tools of visualization and auralization, its acoustical analogue. The study has broader ramifications for the design process, engendering the possibility of more humane design of artistic listening spaces through understanding reciprocal relationships between physical, acoustical, and social domains. [Work supported by ASA Minority Fellowship and RPI Humanities, Arts, Architecture, and Social Sciences Fellowship.]

1pPP27. How do task instructions influence speech-on-speech masking? Karen S. Helfer and Richard L. Freyman (Dept. of Commun. Disord., Univ. of Massachusetts, 7 Arnold House, Amherst, MA 01003-0410)

This study examined how the nature of instructions to the listener affects masking in speech perception. A new set of stimuli (the TVM sentences) was recorded from three male talkers. These sentences, which are similar to the widely used CRM sentences but are open-set and therefore more difficult, have the format *NAME discussed the *** and the *** today*, where *NAME* is Theo, Victor, or Michael and *** is a one- or two-syllable noun used for scoring (e.g., *Theo discussed the airplane and the textbook today*). On a given trial, three sentences were presented simultaneously (one beginning with each of the three names), each spoken by a different talker. Subjects participated in 6 Name conditions (where they were told to repeat the sentence beginning with a certain name) and in 12 voice conditions (where they were told to listen for a certain voice with which they had been familiarized). Stimuli were presented in both spatially coincident and spatially separated conditions at 3 S/N ratios. Analyses of differences in percent-correct performance among the listening conditions and of error patterns (e.g., errors related to confusion between target voice and masking voices versus errors related to energetic masking) will be shown. [Work supported by NIH DC01625.]

1pPP28. Segregation of vowel sequences having spectral cues reduced using a noise-band vocoder. Etienne Gaudrain, Nicolas Grimault (UMR CNRS, 5020 50 av. T. Garnier 69366 Lyon Cedex 07, France), Eric W. Healy (Univ. of South Carolina, Columbia, SC 29208), and Jean-Christophe Bera (Inserm UMR 556, Lyon, France)

Previous studies have shown that a reduction in spectral cues can be associated with a deficit in pitch-based sequential segregation. The difficulties experienced by hearing-impaired listeners in cocktail party situations may then be explained in part by a segregation deficit due to the broadening of auditory filters. The reduced speech-recognition abilities of cochlear implant users in noisy environments could also potentially be related to a loss of spectral cues leading to a segregation deficit. The current study was designed to test the ability of listener's hearing cochlear implant simulations to segregate sequences of vowels having alternating $F0$ values simulating concurrent voices. The vowels were either unprocessed or processed using noise vocoders having limited numbers of channels. Performance on the segregation task was evaluated using a paradigm in which listeners judged the temporal order of items within the sequence. By relating systematic reductions in the number of channels to performance on the segregations task, the current results have the potential to clarify potential limitations placed upon auditory scene analysis by cochlear implant processing.

1pPP29. Acoustic cues for improved speech recognition in combined acoustic and electric hearing. Ying-Yee Kong and Robert P. Carlyon (MRC—Cognition & Brain Sci. Unit, 15 Chaucer Rd., Cambridge, CB2 2EF, England)

Speech recognition in noise improves with combined acoustic and electric hearing compared to electric hearing alone. Here, we investigate the contribution of four low-frequency hearing cues (fundamental frequency ($F0$), first formant ($F1$), voicing, and glimpsing) to speech recognition in combined hearing. Normal-hearing listeners heard vocoded speech in one ear and low-pass (LP) filtered speech in the other. Three conditions (vocode alone, LP alone, and combined) were tested. Target speech with an average $F0$ of 120 Hz was mixed with a time-reversed masker sentence (average $F0 = 172$ Hz) at three SNRs (5,10,15 dB). The LP speech aided performance at all three SNRs. $F1$ cues were then removed by replacing the LP speech with an LP equal-amplitude harmonic complex with the same $F0$ contour as the target speech, and an amplitude that was modulated by that of the target's voiced portions. The benefits of combined hearing disappeared at 10- and 15-dB SNR, but persisted at SNR = 5 dB. The same happened when, additionally, $F0$ cues were removed by fixing the $F0$ of the harmonic complex at 150 Hz. The results are consistent with a role for the $F1$ cue and of voicing and/or glimpsing cues, but not with a combination of $F0$ information between the two ears.

1pPP30. Listening in the valleys with cochlear implants: Speech perception versus psychophysics. Monita Chatterjee and Shu-Chen Peng (Hearing and Speech Sci., 0100 LeFrak Hall, Univ. of Maryland, College Park, MD 20742)

Unlike listeners with normal hearing who can benefit from masking release with modulated noise, cochlear implant users show little release from masking when identifying words in sentences. Little is known about basic mechanisms underlying masking release in speech perception. In the present study, phoneme recognition was evaluated in implant users with tense vowels (/a, i, u, e, o/) and plosives (/p, t, k, b, d, g/) in quiet, steady-state noise and modulated noise at different signal-to-noise ratios (SNRs). In parallel psychophysical experiments, both modulation sensitivity and electrode discrimination were measured in the presence of on- and off-channel maskers, with different fluctuating envelopes. Results from three implant users indicated that unlike the previous findings with sentence materials, these individuals showed some masking release in phoneme recognition. All three participants exhibited masking release with the tense vowels at some SNRs, but only one showed release with the plosives. Modulation detection interference (MDI) was observed in these participants to varying degrees. Whereas MDI was observed in the two participants exhibiting little release with the plosives, no MDI was observed in the participant exhibiting release with the plosives. The relationship between implant users' phoneme recognition and psychophysical performance will be discussed. [Work supported by NIDCD-R01DC04786.]

1pPP31. A theoretical model of cochlear processing improves spectrally degraded speech perception. Evan C. Smith and Lori L. Holt (Dept. Psych. & The Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA 15213, evan@cnbc.cmu.edu)

Smith and Lewicki, Neural Comp. **17**, 19–45, 2005a; Adv. Neural. Inf. Process. Syst. **17**, 1289–1296, 2005b; Nature, **439**, 7079, 2006, demonstrated that mammalian hearing follows an efficient coding principle (Barlow, Sensory Communications, 217–234, 1961; Atick, Network, **3**(2), 213–251, 1992; Simoncelli and Olshausen, Ann. Rev. Neurosci., **24**, 1193–1216, 2001; Laughlin and Sejnowski, "Communications in Neuronal Networks," Science, **301**, 1870–1874 2003). Auditory neurons efficiently code for natural sounds in the environment, maximizing information rate while minimizing coding cost (Shannon, Science, **270**, 303–304, 1948). Applying the same analysis to speech coding suggests that speech acoustics are optimally adapted to the mammalian auditory code (Smith and Lewicki, Neural Comp. **17**, 19–45, 2005a; Adv. Neural. Inf. Process. Syst. **17**, 1289–1296, 2005b; Nature, **439**, 7079, 2006). The present work applies this efficient coding theory to the problem of speech perception in individuals using cochlear implants (CI), for which there exist vast individual differences in speech perception and spectral resolution (Zeng *et al.*, Auditory Prostheses and Electric Hearing, **20**, 1–14, 2004). A machine-learning method for CI filterbank design based on the efficient-coding hypothesis is presented. Further, a pair of experiments to evaluate this approach using noise-excited vocoder speech (Shannon *et al.*, Bell Systems Technical Journal **27**, 379–423, 623–656, 1995) is described. Participants' recognition of continuous speech and isolated syllables is significantly more accurate for speech filtered through the theoretically-motivated efficient-coding filterbank relative to the standard cochleotopic filterbank, particularly for speech transients. These findings offer insight in CI design and provide behavioral evidence for efficient coding in human perception.

1pPP32. Processing of speech in complex listening environments by individuals with obscure auditory dysfunction. Kim Block, Sandra Gordon-Salant (Dept. of Speech and Hearing Sci., Univ. of Maryland College Park, 0100 Lefrak Hall, College Park, MD 20742), Monica Hawley, and Craig Formby (Univ. of Maryland School of Medicine, Baltimore, MD 21201)

Obscure auditory dysfunction (OAD) is a disorder for which patients report excessive amounts of difficulty understanding speech in the presence of background noise, despite no obvious evidence of hearing loss. It has been hypothesized that OAD may be the result of mild cochlear dysfunction, central auditory processing deficits, and/or psychological disorders. We evaluated 10 persons with self-reported problems understanding speech in noisy environments and 10 controls. Both groups had normal-hearing sensitivity and excellent word recognition in quiet. The following tests were administered to each participant: DPOAE and ABR assessment, central auditory processing screening, personality inventory, and tests involving speech recognition in complex environments. The speech recognition measures were a subset of tests reported in Hawley *et al.* [J. Acoust. Soc. Am. **115**, 833–843 (2004)] and were designed to probe binaural processing ability, as well as spectral and temporal processing of speech in complex environments. The OAD participants had poorer overall speech recognition ability than did the controls in both single- (1.5 dB, $p=0.017$) and two-competitor environments (0.9 dB, $p>0.05$). However, the reported problems in these OAD participants are not attributable to poor binaural processing. [Funding provided by NIDCD.]

1pPP33. Predictions of speech quality under conditions of noise and distortion. James Kates (GN ReSound and Univ. of Colorado, Dept. Speech Lang. and Hearing Sci., 409 UCB, Boulder, CO 80309, jkates@gnresound.dk), Kathryn Arehart, Lewis Harvey, Jr., and Melinda Anderson (Univ. of Colorado, Boulder, CO 80309)

Noise and distortion reduce speech intelligibility and quality in audio devices such as hearing aids. The purpose of this study is to quantify and model the effects of signal degradation on the perception of speech quality in normal-hearing and hearing-impaired listeners. The stimuli were sentences subjected to eight different levels of additive noise, peak clipping, and center clipping distortion. The subjects listened to all possible comparisons of pairs of the 24 degraded sentences, and for each comparison indicated their preference. Multi-dimensional analysis is used to model the subject decision spaces, and the data are also modeled using a one-dimensional metric to predict the subject quality judgments. The one-dimensional metric is an extension of the procedure developed by Kates and Arehart [J. Acoust. Soc. Am. **117**, 2224–2237 (2005)] to model speech intelligibility. That approach is based on dividing the speech signal into three amplitude regions, computing the coherence for each region, and then combining the three coherence values across frequency in a calculation based on the speech intelligibility index (SII). The one-dimensional and multi-dimensional analyses are able to accurately model the quality perception of both normal-hearing and hearing-impaired listeners. [Work supported by GN ReSound and Centers for Disease Control.]

1pPP34. Cognitive effects of noise reduction strategies. Anastasios Sarampalis (Dept. of Psych., Univ. of California at Berkeley, 3210 Tolman Hall, Berkeley, CA 94720, asaram@berkeley.edu), Sridhar Kalluri, Brent W. Edwards (Starkey Hearing Res. Ctr., Berkeley, CA 94704), and Ervin R. Hafter (Univ. of California at Berkeley, CA 94720)

Noise reduction algorithms that attempt to improve speech intelligibility in noise have been used in hearing aids for decades. Yet, the surprising result has been that they are not effective in improving the speech reception threshold (SRT). One explanation is that the artificial processing is redundant, providing the same information as that extracted by the listener's own auditory system. Our working hypothesis is that natural processing is effective only if there are sufficient cognitive resources to support it and that a reduction in those resources may increase the functional value of the computational algorithm. In the present experiments, subjects performed in a dual-task paradigm in which they listened to and repeated sentences presented in a noisy background while doing a competing visual task, such as a simple driving game. Using driving performance as an indicator of mental effort, we evaluate the effects of different noise reduction algorithms on speech reception. The logic is that, while there will be a loss in performance due to doing two difficult tasks at once, this loss will be smaller when auditory sentences are processed by noise reduction.

1pPP35. Strategies for phonological learning. McNeel G. Jantzen and Betty Tuller (Ctr. for Complex Systems and Brain Sci., Florida Atlantic Univ., 777 Glades Rd., Boca Raton, FL 33431)

An adult's ability to perceive speech sounds that do not occur in their native language is influenced by the relationship between the new and native language phonology and by the individual's capacity to perceive acoustic differences. The study investigated how learning a non-native speech sound occurs over time. First, a perceptual mapping procedure was performed using a synthetic continuum that ranged from the Malayalam voiced, unaspirated, dental stop consonant to the American English alveolar [d]. Subjects identified the stimuli (2AFC) and judged the goodness of stimuli as exemplars of each of the two categories. Next, subjects received 15 sessions (one/day) of 2AFC training with feedback, using natural stimuli produced by native speakers of Malayalam and performed the difference ratings on selected pairs of synthetic stimuli. The perceptual mapping procedure was repeated immediately following training and at two weeks post. Results are consistent with previous work [Case, *et al.*, "The dynamics of learning to hear new speech sounds," Speech Pathol., Nov. 17 (2003)]. Moreover, comparison of results from the different tasks suggests that some subjects learn the acoustic differences among stimuli, while others treat the stimuli as belonging to two phonological categories. [Work supported by NSF and ONR.]

1pPP36. Perception of roughness by people with normal hearing and sensorineural hearing loss. Jennifer B. Tufts (Univ. of Connecticut, 850 Bolton Rd., Unit 1085, Storrs, CT 06269, jennifer.tufts@uconn.edu) and Michelle R. Molis (Portland VA Medical Ctr., Portland, OR 97207)

Anecdotal and laboratory evidence indicates that many people with sensorineural hearing loss have difficulty perceiving music clearly, even when the musical sounds are loud enough to be audible, or are amplified through hearing aids. A better understanding of the music perception difficulties faced by hearing-impaired people is required in order to improve assistive listening technology for music listening, performance, and appreciation. One important aspect of music appreciation is the perception of dissonance between combinations of tones (e.g., the tritone). A recent study [J. B. Tufts, M. R. Molis, and M. R. Leek, J. Acoust. Soc. Am. **118**, 955–967 (2005)] showed that people with sensorineural hearing loss perceive differences in musical dissonance to be less salient than do normal-hearing people. Various acoustic and perceptual factors contribute to musical dissonance, but one of the most important is auditory roughness. In the present study, roughness regions for amplitude-modulated tones at several carrier frequencies, two different modulation depths, and several presentation levels were established using magnitude estimation techniques in normal-hearing and hearing-impaired listeners. Differences in the perception of roughness between the listener groups will be discussed with regard to implications for music perception in people with sensorineural hearing loss.

1pPP37. Automatic perceptual tuning of hearing aids for multidimensional perceptual preferences. Shih-Hao Lin, Pei-Chun Li, and Shuenn-Tsong Young (Inst. of Biomed. Eng., Natl. Yang-Ming Univ. No. 155, Sec. 2, Linong St., Taipei City 112, Taiwan, young@bme.ym.edu.tw)

The numerous parameters of modern digital hearing aids and the multi-dimensional perceptual preferences of a subject present the audiologist with a difficult fitting task. A system was designed for integrating various real-world stimuli selected from the questionnaire of the most important hearing aid benefits for people in Taiwan and common fitting guidelines, and an automatic modified simplex procedure to perform efficient search for the optimal preference structure in a subject's perceptual space. Three experiments were conducted using six normal and six hearing-impaired subjects. Four parameters, the low-frequency gain, high-frequency gain, compression threshold, and compression ratio, were varied to find the desired tonality in the first experiment, the desired Mandarin speech intelligibility in the second, and the overall satisfaction in the third. The results showed that the modified simplex procedure worked efficiently for all cases, however, the test-retest reliabilities of the last two were lower than that of the first experiment. Besides, the preferred parameters were different by comparing the intersubject judgments for the same objective and the within-subject judgments for different objectives. The results indicated that there are multiple peaks in one's response surface and further studies are required to improve reliability and satisfaction when fitting more complicated parameter sets.

Session 1pSC

Speech Communication: Speech Perception (Poster Session)

Michael J. Kiefte, Chair
Dalhousie Univ., Human Communication Disorders, 5599 Fenwick St., Halifax, NS, B3H 1R2, Canada

Contributed Papers

All posters will be on display from 1:30 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 4:30 p.m.

1pSC1. The role of vowel-to-consonant transitions in the perception of phonological consonant length. Benjamin B. Hansen (Dept. of Linguist., Univ. of Texas, CAL 501, Austin, TX 78712)

It has been noted [S. Kawahara, Univ. of Mass. Occasional Papers in Linguistics 32: Papers in Optimality Theory (2005)] that more sonorous consonants are less likely to occur as geminates in the world's languages. Two experiments were performed to test whether a phonetic parameter, the vowel-to-consonant formant transition duration, relates to the possible neutralization of the length distinction for more vowel-like consonants. In a production experiment the consonant constriction and onset transition durations are measured for Persian geminate and singleton consonants spoken at three speaking rates. Stops, fricatives, nasals, liquids, glides, and glottal consonants are studied. Segments that are predicted to be less likely to occur as geminates have longer transitions at all speaking rates. A perception experiment based on manipulated palatal glide stimuli demonstrates that listeners have more difficulty categorizing a consonant as long or short if the transition is longer. Difficulty of categorization is measured both by reaction times and the slope of the curve-fitted cumulative identification model, where a flatter slope indicates a less distinct perceptual boundary.

1pSC2. Auditory distinctiveness and the perception of voiceless stop consonants in continuous speech. Jason Bishop (Eastern Michigan Univ., 612 Pray-Harrold Hall, Ypsilanti, MI 48197, jbishop@emich.edu)

Explaining the way in which listeners cope with the apparent lack of acoustic invariance as well as the phonetic ambiguity frequently encountered in continuous speech has remained problematic for models of speech perception. The voiceless stop consonants /p t k/, for example, are frequently unreleased word-finally. Despite the reduction in articulation and presumably in the distinctiveness of the acoustics signal, listeners appear quite accurate in identifying the correct stop consonant during conversation. Sets of words such as {shop, shot, shock} and {cheap, cheat, cheek} should, given the absence of release of the final stops, be difficult (if not impossible) to distinguish in isolation. In this study, listeners were presented with such lexical stimuli (in isolation as well as in semantically priming sentences) and tested for their perception of the word-final [p t k]. It was found that the amount of distinctive information carried in the acoustic signal for this class of sounds in the environment of interest was insufficient to consistently disambiguate listener impressions; further evidence for lack of perceptual salience is provided by an extremely weak resistance to semantic context effects. The results of this study highlight the value of an auditory dimension to perceptual studies in linguistic phonetics.

1pSC3. Perception of pitch and prominence in a speech context. Alejandro C. Renato (Inst. Genius of Technol., Av. Aa 875, Distrito Industrial, Manaus, Brazil)

Different researchers have proposed a dominance region that refers to the band of harmonics whose frequencies determine the perceived pitch. This work examined the different cues appearing in the dominance region in order to discriminate the pitch and the prominence in a speech context. It has been done as a reiterant speech task. Native Spanish speakers were instructed to imitate the intonation and prominence perceived in the stimuli presented. The stimuli were composed by trisyllabic words of the form CV1CV2CV2, where C was the voiced lateral /l/, V1 = /a/, and V2 the five vowels of Spanish /a/, /e/, /i/, /o/, and /u/. The degree of prominence was varied from the first to the last syllable, and the final tone. The stimuli were passband filtered between 250 and 900 Hz, their harmonics extracted and synthesized in three ways: (a) The unresolved harmonic more close to 600 Hz; (b) The three resolved harmonics around 600 Hz; and (c) The two resolved harmonics with larger amplitud by phonetic

segment, next to the vowel formant. Results indicate that the stimuli (c) described above presents a better relationship between pitch and prominence discrimination.

1pSC4. Effects of reliable spectral-temporal characteristics of listening context on perception of monophthongs and diphthongs. Keith R. Kluender (Dept. of Psychol., Univ. of Wisconsin, Madison, WI 53706-1696) and Michael Kiefte (Dalhousie Univ., Halifax, NS B3H 1R2 Canada)

Brief experience with reliable characteristics of listening context, such as a precursor sentence, alters perception of subsequent vowel sounds [M. Kiefte and K. Kluender, J. Acoust. Soc. Am. **112**, 2248 (2002)]. For example, an appropriately filtered precursor sentence serves to perceptually cancel effects of second formants (F_2) of vowel sounds, forcing listeners to rely solely on spectral tilt for identification. Auditory systems effectively absorb spectral characteristics, including formant peaks, if those characteristics are reliable (redundant) properties of the listening context. Present studies investigate whether this perceptual calibration extends to reliable spectral-temporal properties. Listeners identified a series of stimuli with incremental increases in slope of F_2 that varied perceptually from /u/ to /ui/. When repeated formant transitions, exactly matching those of the target vowels, were added to precursor sentences, /i/ percepts predominated despite no stimuli being appropriate for /i/ in isolation. When repeated formant transitions were reversed in precursors (high to low frequency), the same results were obtained. Because perceptual absorption of reliable acoustic characteristics was indifferent to F_2 trajectory, it appears that processes that calibrate to reliable properties of a listening context are sensitive only to spectral, not temporal, composition of listening context. [Work supported by SSHRC and NIDCD.]

1pSC5. Perceptual absorption of listening context when perceiving musical instruments. Christian E. Stilp and Keith R. Kluender (Dept. of Psych., Univ. of Wisconsin—Madison, 1202 W. Johnson St., Madison, WI 53706)

Brief experience with reliable characteristics of listening context, such as a precursor sentence, alters perception of subsequent vowel sounds. In experiments focused on perception of vowels, effects of preceding context do not depend on sentences being intelligible speech [K.R. Kluender and M. Kiefte, J. Acoust. Soc. Am. **114**, 2335 (2003)]. In the present studies, listeners identified musical instruments (tenor saxophone versus French horn) following a context of speech sentences that are modified by spectral envelope difference filters created to capture differences between saxophone and horn spectra. Precursor sentences were resynthesized renditions of a female talker saying "Please identify this instrument." For a morphed series of sounds with 196 Hz fundamental frequency (G3) varying perceptually from saxophone to horn, listeners are more likely to report hearing a saxophone following a sentence filtered to emphasize spectral characteristics of the horn and vice versa. Consistent with previous studies, these effects are contrastive and indicative of the auditory system absorbing reliable (redundant) properties in the service of emphasizing change and maximizing transmitted information. Perceptual calibration to reliable spectral characteristics does not depend upon sounds being perceived as arising from the same source. [Work supported by NIDCD.]

1pSC6. Compensation for coarticulation: Three theories compared. Navin Viswanathan and James S. Magnuson (Univ. of Connecticut, Storrs, CT 06269)

Classification of a /da/-/ga/ continuum shifts towards more /ga/ responses following /al/ and more /da/ responses following /ar/. Theories explain this as compensation for coarticulation: in natural speech, if speakers must transition from relatively front (/l/) to back (/g/) places of articulation, they will be unlikely to reach the optimal place of articulation. Thus, after /l/, /g/ is likely to be produced further forward than usual and, following /l/, ambiguous tokens in a /d/-/g/ continuum will often be perceived as /g/ with place of articulation shifted by coarticulation. The current study compares the perceptual effects of American English /r/ and /l/ with those of Tamil /R/ (trilled) and /L/ (retroflex). /R/ shares its place of articulation with /l/ but is categorized as an allophone of /r/ by American English speakers. Similarly, /L/ shares its place of articulation with /r/ but is classified as an instance of /l/. However, the acoustic relationships between the Tamil and American English phones are complex, potentially leading to conflicting predictions from auditory contrast and other theoretical explanations of compensation. Our acoustic analyses and experiments examine whether compensation depends upon place of articulation, acoustic cues that might produce contrast effects, or perceptual classification of a phoneme.

1pSC7. Audiovisual asymmetries in speech and nonspeech. Julie M. Brown (Haskins Labs., 300 George St., New Haven, CT 06511, julie.brown@uconn.edu)

The individual contribution of the various perceptual systems to multimodal perception is typically examined by placing information from the various perceptual systems in conflict and measuring how much each contributes to the resulting perception. When one perceptual system dominates perception more than another, it is called intersensory bias. The present research examines intersensory bias using a tapping task in which participants were asked to tap to the frequency of either an auditory or visual stimulus. The stimuli that were used were either nonspeech stimuli, such as a tone and a flashing ellipse, or speech, such as a visual or auditory syllable. In past experiments that have used nonspeech stimuli, audition has been shown to dominate visual temporal perception. Based on the influence of visible speech on auditory speech perception found in the McGurk effect, it was thought that vision might influence temporal perception more when using speech stimuli than nonspeech stimuli. It was found that the speech and nonspeech distinction did not affect intersensory bias. Rather, the amount of information provided by the auditory and visual stimuli predicted the occurrence of intersensory bias. [This research was supported by a NIH grant through Haskins Laboratories, New Haven, CT.

1pSC8. Parsing time and rate normalization versus durational contrast. Eve Brenner-Alsop (Ling. Dept., Univ. of Massachusetts, Amherst, MA 01003-9274)

An acoustic interval is perceived as shorter next to a long neighboring interval than next to a short one. This finding has been attributed to rate normalization (Miller and Liberman, Percept. Psychophys. **25**, 457–465, 1979) and to durational contrast (Diehl and Walsh, J. Acous. Soc. Am. **85**, 2154–2164, 1989). In the first experiment, we present listeners with a vowel varying in duration from short to long in a context where it could be interpreted as one vowel or two in sentences manipulated to sound as though they were spoken at fast, moderate, and slow rates. We predict that the vowel is more often perceived as two vowels in the fast than the slow sentence. The second experiment tests the effect of parsing the vowel into one versus two vowels on judgments of a [b-w] transition duration continuum and a [b-p] voice onset time continuum. If the vowel is parsed into two vowels, a given transition duration or VOT will sound longer and thus more [w] or [p]-like than if it is parsed into just one. Such a result would reflect durational contrast between the transition duration or VOT and the vowel's perceived duration. It would not reflect rate normalization directly but only indirectly via its effect on parsing. [Work supported by NIH.]

1pSC9. Sequential contrast or compensation for coarticulation? Della Chambless and John Kingston (Ling. Dept., Univ. of Massachusetts, Amherst, MA 01003-9274)

English listeners identify a stop ambiguous between /t/ and /k/ more often as "k" after [s] than [sh] (Mann and Repp, J. Acous. Soc. Am. **69**, 548–558, 1981). Judgments shift similarly after a fricative ambiguous between [s] and [sh] when its identity is predictable from a transitional probability bias but perhaps not from a lexical bias (Pitt and McQueen, J. Mem. Lang. **39**, 347–370, 1998, cf. Samuel and Pitt, J. Mem. Lang. **48**, 416–434, 2003). In replicating these experiments, we add a discrimination task to distinguish between the predictions of competing explanations for these findings: listeners respond "k" more often after [s] because they compensate for the fronting of the stop expected from coarticulation with [s] or because a stop with an F3 onset frequency midway between [t]'s high value and [k]'s low value sounds lower after the [s]'s high-frequency energy concentration. The second explanation predicts listeners will discriminate [s-k] and [sh-t] sequences better than [s-t] and [sh-k] sequences because sequential contrast exaggerates the spectral differences between [s-k]'s high-low intervals and [sh-t]'s low-high intervals and distinguishes them more perceptually than [s-t]'s high-high intervals and [sh-k]'s low-low intervals. Compensation for coarticulation predicts no difference in discriminability between the two pairs because it does not exaggerate differences between the two intervals. [Work supported by NIH.]

1pSC10. Sequential contrast and assimilation in the perception of neighboring vowels and consonants. John Kingston, Della Chambless, Daniel Mash, and Jonah Katz (Ling. Dept., Univ. of Massachusetts, Amherst, MA 01003-9274)

Sequential contrast exaggerates perceptual differences between neighboring segments. Our experiments measure this effect in consonant-vowel-stop and stop-vowel-consonant strings. Listeners identify and discriminate vowels from a front-to-back continuum in next-to-coronal versus labial stops, or stops from a coronal-to-labial continuum in next-to-front versus back vowels. If these intervals contrast sequentially, a vowel midway between front and back should sound backer next to a coronal than a labial stop because a coronal concentrates energy high in the spectrum. Similarly, a stop midway between coronal and labial should sound more labial next to a front vowel, because it too concentrates energy high in the spectrum. Exaggeration of spectral differences would also make a front vowel + labial stop versus a back vowel + coronal stop more discriminable than a front vowel + coronal stop versus a back vowel + labial stop. The strings' lexical status is manipulated orthogonally via the other consonant to test whether sequential contrast effects are independent of lexical biases. Both identification and discrimination results show independent sequential contrast effects in stop judgments after front versus back vowels, but assimilation in vowel judgments before labial versus coronal stops. The stop-vowel-consonant strings test whether this difference reflects segment order or a consonants-vowel difference. [Work supported by NIH.]

1pSC11. Perceptual salience and acoustic distance: Evidence from Tagalog nasal-place contrasts. Chandan Narayan (Dept. of Linguist., Univ. of Michigan, 1190 USB, 204 Washtenaw Ave., Ann Arbor, MI 48109-2215)

The acoustics and perception of three Tagalog (Austronesian) nasal-onset places of articulation ([ma], [na], and [nga]) are investigated. In experiment 1, native speakers of Tagalog ($n=13$) were presented with the [ma]-[nga] and [na]-[nga] contrasts (as recorded by a native speaker of Tagalog) in an AX task. As expected, listeners performed according to Tagalog phonology, with successful discrimination of both contrasts ($>90\%$ correct). Listener performance on the [na]-[nga] contrast, however, was significantly lower than performance on [ma]-[na]. In a second experiment, designed to assess the perceptual salience of the [na]-[nga] contrast relative to the [ma]-[na] contrast, native-Tagalog listeners were tested (in an AX task) with the contrasts in signal-dependent (though uncorrelated) noise. Findings are discussed in light of acoustic measurements of multiple repetitions of [ma], [na] and [nga] as produced by three speakers of Tagalog. These acoustic results show that, in F2×F3 space (measured at the NV juncture), [na] is more similar to [nga] than it is to [ma]. In addition, the acoustic and perceptual findings will be interpreted relative to recent findings in the development of nasal-place perception in infancy. [ng=velar nasal.]

1pSC12. Experience-driven effects of visual cues in speech perception. Joseph D. W. Stephens and Lori L. Holt (Dept. Psych. & Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., 5000 Forbes Ave., Pittsburgh, PA 15213, jds2@andrew.cmu.edu)

The integration of information across modalities is a key component of behavior in everyday settings. The current study examined the extent to which experience drives multimodal speech integration. Two groups of participants were trained on combinations of speech sounds with corresponding videos of an animated robot, whose movements and features bore no resemblance to speech articulators. Participants' identification of acoustically presented consonants was influenced by simultaneous presentation of learned visual stimuli in a manner that reflected the correlation structure of auditory and visual cues in training. The influence of novel non face visual cues on speech perception developed over the course of training, suggesting that experience altered the perceptual mechanisms used in combining this cross-modal information. Pairings of auditory and visual cues given to two groups of participants resulted in patterns of bimodal perception that differed in systematic ways. Perceptual integration of the newly learned visual cues with auditory speech was not optimal, reflecting a bias toward the sound cue. The findings are discussed in reference to current models of speech perception and multimodal integration.

1pSC13. Parsing voicing cues: A context effect predicted by feature cue parsing theory. Donna Van Worthe, Jillian Celi, and David Gow (Salem State College, Salem, MA 01970)

Factors including lawful assimilation conspire to produce overlapping temporal distributions of phonetic feature cues for neighboring segments. Gow's feature cue parsing model [Gow, Perception and Physics, **65**, 575–590 (2003)] suggests that listeners rely on perceptual grouping mechanisms to integrate multiple cues and align them with correct segmental positions. While this account was developed to address progressive and regressive context effects found in the perception of lawfully assimilated speech, its strong form predicts that similar context effects may be found in the perception of speech where there is similar overlap in feature cue distribution, even if such overlap is not the result of a lawful phonological process. This hypothesis was examined in a series of speeded 2AFC experiments in which voicing cues were manipulated in adjacent fricatives and stops. A regressive context effect was found in the perception of the fricative in a peace-peas voicing continuum, which was strongly affected by the voicing of a following stop (e.g., pay versus bay). Similarly, listeners showed a progressive context effect in the perception of stops in a pay-bay VOT continuum when these items were preceded by voiced versus voiceless fricatives. These results are discussed in terms of competing interpretations of assimilation context effects. [Work supported by NIH R01DC3108.]

1pSC14. The time course of cross-voice speaking rate normalization. James R. Sawusch (Dept. of Psych., Univ. at Buffalo, Park Hall, Buffalo, NY 14260, jsawusch@buffalo.edu) and Rochelle S. Newman (Univ. of Maryland, College Park, MD 20742)

Individuals vary their speaking rate, and listeners use the speaking rate of precursor sentences to adjust for these changes [Kidd, G. R., "Articulatory-rate context effects in phenone identification," J. Exp. Biol.: Human Percep. Perfor. **15**, 736–748 (1989)]. This speaking rate adjustment is not limited to speech from a single talker [Sawusch & Newman,

''Perceptual normalization for speaking rate II: Effects of signal-discontinuities,'' Percep. Psychophys. **62**, 285–300 (2002)]; if one speaker stops talking and another begins, listeners will use rate information from the first talker to interpret speech in the second. We examined how long this cross-talker effect lasts. A male talker produced a carrier sentence at fast and slow speaking rates. A female talker then produced one or more subsequent words at a constant speaking rate. The final word in the female voice contained a duration-based contrast. We examined how much intervening speech in the female voice was necessary before the male voice's speaking rate no longer influenced perception of the final target word. Results suggest that listeners require approximately 1 s of intervening speech or of silence before they stop using rate information from the male talker. This suggests that rate normalization may be based on a 1-s temporal window, with any speech information that occurs within 1 s in advance of a target phoneme influencing perception of that phoneme.

1pSC15. Contextual effects on the perception of duration. Shigeto Kawahara (Dept. of Linguist., Univ. of Massachusetts, Amherst, 226 South College, Amherst, MA 01003, kawahara@linguist.umass.edu)

English speakers perceive silent intervals with the same duration as longer when preceded by shorter vocalic intervals [Kluender *et al.* ''Vowel length differences before voiced and voiceless consonants: An auditory explanation,'' J. of Phonetics, **16**, 153–169 (1988)]. This may be due to sequential contrast effects which exaggerate perceptual differences between neighboring segments. In Japanese, vowels are longer before geminates than before singletons [Han ''Acoustic manifestations of more timing in Japanese,'' J. Acoust. Soc. Am. **96**, 73–82 (1994)]. Reflecting this correlation, Japanese speakers perceive silent intervals with the same duration as longer (as more ''geminatelike'') when preceded by longer vowels. The same pattern holds when non-speech analogs are used in place of speech stimuli: silent intervals are judged as longer when preceded by longer anharmonic buzzes. These results suggest that the perception of silent duration by Japanese speakers follows the pattern predicted from the acoustic properties of Japanese, but goes in the opposite direction from that predicted if durational contrast determines judgments, as it did for Kluender *et al.*'s (1988) listeners. This suggests that the segmental properties of the listener's native language may influence nonspeech temporal judgments [cf. Moreton and Kusumoto ''Native language determines parsing of nonlinguistic rythmic stimuli,'' J. Acoust. Soc. Am. **102**, 3204 (1997)]. English speakers will be tested on the same tasks to determine whether the perception of the temporal properties of nonspeech signals are generally determined by those of the listeners' native language. [Work supported by NIH.]

1pSC16. Spectral auditory integration and virtual cues to place-of-articulation in stops. Robert Allen Fox, Marc Smith, and Ewa Jacewicz (Speech Percept. and Acoust. Labs., Dept. of Speech and Hearing Sci., The Ohio State Univ., 1070 Carmack Rd., Columbus, OH 43210)

The spectral ''center-of-gravity'' (COG) hypothesis proposed by Chistovich and colleagues for static vowels suggested spectral auditory integration of two or more formant peaks within 3.5 barks. More recently, studies have examined dynamic COG effects by modifying the amplitude of steady-state formants over time in order to create ''virtual'' diphthongs. The present study looks at ''virtual frequency change'' cues to the alveolar-velar place distinction in stops [an extension of Fox and Smith, J. Acoust. Soc. Am. **117**, 2423 (2005)]. First, [d≥-g≥] and [t≥-k≥] series were synthesized with a 50-ms *F*3 transition (with a voiced or voiceless source). Next, matched stimulus series were created with virtual *F*3 transitions by changing the amplitudes of either a pair of sine waves (in [d≥]-[g≥]) or a pair of narrow band noise signals (in [t≥]-[k≥]) whose frequencies did not change. Another matched [t≥]-[k≥] series was produced with both actual and virtual stops bursts (with no *F*3 transitions). Identification of these stimulus series by listeners with normal hearing show that a dynamically changing COG in the initial 50 ms of the token can effectively cue place distinctions in stops as do formant transitions and bursts; however, virtual spectral cues are less salient than formant or burst cues. [Work supported by NIDCD R01DC00679-01A1.]

1pSC17. Listener sensitivity to intensity variation in vowels in coarticulatory context. Ewa Jacewicz and Robert Allen Fox (Speech Percept. and Acoust. Labs., Dept. of Speech and Hearing Sci., The Ohio State Univ., 1070 Carmack Rd., Columbus, OH 43210)

There are two sources of acoustic variation in the relative formant amplitude of a vowel which are unrelated to emphasis-oriented changes in articulatory effort: (1) vowel-specific intrinsic formant frequency pattern, which differs across vowel categories, and (2) the vowel's immediate phonetic (coarticulatory) context. Listener sensitivity to the latter source of variation is examined here to establish the extent to which distortion in the distribution of acoustic energy across the vowel spectrum affects the perception of vowel quality. Synthetic versions of CVC syllables in symmetrical consonant environments were created (using stops or fricatives differing in place-of-articulation and voicing). Formant frequencies and amplitude values were modeled after those found in a large corpus of CVC acoustic data [E. Jacewicz and R. A. Fox, J. Acoust. Soc. Am. **117**, 2623 (2005)]. Initial amplitude values for the first four formants in synthetic CVCs reflected the intensity distribution (and spectral tilt) typical of a vowel coarticulated with these consonants. Subsequent stepwise adjustments to selected formant levels were made to create a range of permissible and not permissible formant amplitude variations in coarticulatory context. Preliminary results indicate that listeners are sensitive to amplitude variation across vowel spectrum as a function of a specific consonant environment. [Work supported by NIDCD R03 DC005560-01.]

1pSC18. The feature [sonorant] in auditory word identification. Danny R. Moates, Russell Fox (Dept. of Psychol., Ohio Univ., Athens OH 45701) Chao-Yang Lee and Sara Kellgreen (Ohio Univ., Athens, OH 45701)

The distinctive feature [sonorant] separates resonants and obstruents. Does this feature mark a difference in the perceptual processing of these consonants? Marks *et al.* [Marks *et al.*, ''Word reconstruction and consonant features in English and Spanish,'' Linguistics, **40**, 421–438 (2002)] showed such an influence in a word reconstruction task. Target words containing an obstruent segment were harder to reconstruct when the obstruent was replaced by a resonant (mismatch condition) than when it was replaced by another obstruent (match condition). Resonant target words showed no such effect. The present study extended Marks *et al.* (2002) using an auditory priming lexical decision task. Participants heard a nonword prime 50 msec prior to another word or nonword target. The prime differed from the target item in just one consonant which either matched the target segment on the feature [sonorant] or mismatched it. Listeners judged whether the target item was a real word or nonword. The obstruents were divided into fricatives and stops, which were compared with resonants in both cases. Latencies for the fricative target words were significantly slower in the mismatch condition than in the match condition but not for stops. The present study validates the effect found by Marks *et al.* (2002) with an online task but shows that it is limited to fricatives.

1pSC19. Perception of acoustically modified Mandarin tones. Chao-Yang Lee (School of Hearing, Speech and Lang. Sci., Ohio Univ., Athens, OH 45701), Liang Tao, and Zinny S. Bond (Ohio Univ., Athens, OH 45701)

How well do listeners recognize tones when only partial acoustic information is available to them? Twelve minimal tone pairs including all six Mandarin tonal contrasts were digitally processed to generate four syllable modifications: silent-center, center-only, onset-only, and intact syllables. The syllables were recorded in two carrier phrases such that the offset of the carrier and the onset of the target were either a match or

mismatch in fundamental frequency. The stimuli were presented in the original carrier phrase, excised from the carrier phrase, or excised and cross spliced with another carrier phrase. Forty native speakers of Mandarin Chinese were asked to identify the tone associated with each syllable. Response time and accuracy were measured. Listeners identified the tones at better than 90% correct with and without context except when they heard the syllable onset only; then, their identification accuracy fell to approximately 80%. A match or mismatch in fundamental frequency between the carrier and target tones made no difference in either reaction time or accuracy. Cross-spliced carrier phrases also did not compromise accuracy or reaction time. Tone 2 was identified least accurately. Listeners also took more time to identify tone 1 and tone 2 than the other two tones.

1pSC20. An acoustic and perceptual investigation of the geminate and singleton stop contrast in Japanese. Kaori Idemaru (Dept. of East Asian Lang. and Lit., Univ. of Oregon, Eugene, OR 97403-1248) and Susan Guion (Univ. of Oregon, Eugene, OR 97403-1290)

Segmental durations are known to be heavily influenced by changes in speech rate such that the durations of members of two contrasting length categories may overlap [Pickett *et al.* "Effects of speaking rate on singleton/geminate contrast in Italian," Phonetica **56**, 135–157 (1999); Hirata & Whiton, "Relational acoustic invariance in the single/geminate stop distinction in Japanese," J. Acoust. Soc. Am. **117**, 2569 (2005)]. Given this, questions arise as to how category distinction is achieved for contrasts signaled by differences in segmental duration. This study investigates the question by examining the production and perception of the Japanese singleton versus geminate stop contrast by adult native speakers. Six native Japanese speakers produced disyllabic words with medial singleton and geminate stops at three speaking rates. Duration of stop closure and a number of relational timings between the closure duration and other segments were examined as potential rate-independent measures distinguishing the two categories. The ratios of stop closure to the preceding mora as well as stop closure to the following vowel remained stable across speaking rate and accurately classified naturally produced tokens. Ten native Japanese listeners participated in an identification task to examine the perceptual relevance of these relational timings. The results indicated an influential role of preceding mora duration and a small role of following vowel duration. The results also suggested that nondurational factor(s) influence perception of the stop length contrast.

1pSC21. Could backward recognition masking play an important role in speech contrasts? Jeremy R. Gaston and Richard E. Pastore (Dept. of Psych., Bingahmton Univ. SUNY, Binghamton, NY 13901)

Auditory backward recognition masking (BRM) is the interference in recognition by a following stimulus for some aspect of a clearly detectable target. BRM has been studied for stationary targets, with its conjectured relevance largely limited to the sensory storage and encoding of simple (nonspeech) auditory properties. Could BRM play an important role for more complex stimuli—specifically speech contrasts? The current study systematically investigates BRM interference for speechlike analogs of $F2$ transitions in varying spectral context that mimic the properties of speech contrasted by place of articulation. Initial and final transitions in isolation show equivalent recognition. Adding a vowel $F2$ equivalent significantly increases thresholds for initial, but not final, transitions. The further addition of a vowel $F1$ equivalent results in an additional significant increase in threshold for initial position transitions, and a significant decrease for final position transitions. The possible importance of BRM in defining speech contrasts is discussed. [Work supported by NSF.]

1pSC22. Acoustic and phonetic discrimination in speech using event-related potentials: A mismatch negativity paradigm. Erin K. Robertson, Randy Lynn Newman, and Marc F. Joanisse (Dept. of Psych., Univ. of Western Ontario, 1151 Richmond St., London, ON, N6A 5C2 Canada)

The interaction of acoustic and phonetic discrimination in speech was studied using event-related potentials (ERPs). Participants consisted of 14 neurologically normal right-handed adults. Data were recorded in response to strong and weak acoustic changes signaling consonant distinctions, using a 64-channel encephalogram and a mismatch negativity (MMN) paradigm. The MMN is an automatic response evoked by stimulus change and is elicited when a train of repeated stimuli (standard) is interrupted by an oddball (deviant) stimulus. Stimuli consisted of one standard and two deviants that differed in their acoustic difference from the standard. All three stimuli were synthetic speech syllables in which $F2$ was manipulated to create a continuum between the syllables "ba" and "da." The standard was the endpoint item "da." The "strong deviant" was the "ba" endpoint item; the "weak deviant" was a more intermediate "ba" item, and therefore acoustically closer to the standard. MMNs were identified for both deviants, but the amplitude was smaller for the weak deviant condition. The data suggest that MMNs are sensitive to both phonetic change and also the magnitude of the acoustic difference within this change. The results are discussed with respect to theories of phonetic and acoustic discrimination in speech perception.

1pSC23. Formant deflection directions of the voiced alveolar stop consonant in different vowel contexts. Kang Li and Brad Story (Speech and Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721, lik@u.arizona.edu)

A parametric model of the vocal-tract area function was used to synthesize a series of alveolar stop consonant constrictions imposed on 9 $/V_1V_2/$ transitions (e.g., /idae/). The constrictions differed in configurations, places of occurrence along the vocal-tract length, and the onset and release times to create different on-glide and off-glide formant deflection patterns. It was hypothesized that the formant deflection directions caused by the onset and release of the consonant constriction relative to the underlying vowel-to-vowel formant transitions (i.e., without consonant perturbations) provide information about the identity of the alveolar stop. Perceptual tests were conducted to assess the phonemic identities of the formant patterns produced by the model. The model parameter settings used to create the consonant constrictions that were perceived as /d/'s were analyzed to study the coarticulation effect between /d/ and different vowel contexts.

1pSC24. Is nonmodal phonation at the end of utterances a cue for speaker recognition by humans? Tamás Böhm (MIT-RLE, Cambridge, MA and BME-TMIT, Magyar Tudósok krt. 2., H-1117 Budapest, Hungary, bohm@tmit.bme.hu)

Many studies of nonmodal phonation report a high rate of interspeaker variation. These experiments also showed that the rate and type of glottalization are characteristic to the speaker. Still, it remains an open question whether human listeners use this information as a cue for recognizing familiar voices. A listening experiment was conducted to investigate this issue, concentrating on utterance-final irregularities. Short utterances produced by four speakers were copy synthesized with the Klatt synthesizer in two conditions: with modal and with nonmodal voice quality in their final regions. Because two of the speakers were reliable "glottalizers" and two seldom "glottalized," one of the two synthesis conditions reflected the speaker's usual utterance-final voice quality and the other did not. These pairs of stimuli were used to test the effect of the presence or absence of utterance-final nonmodal phonation on the identification of voices familiar to the subjects. When asked to choose which one of the two variants is the speaker's voice, listeners preferred the stimuli with the speaker's typical

voice quality at the end. Results will be discussed in comparison with a well-known perceptual cue on speaker identity, the F0 contour. [Work supported by a Fulbright Fellowship.]

1pSC25. Recognition of Mandarin words heard through single and multiple spectral bands. Tien Ho, Pei-Chun Li, and Shuenn-Tsong Young (Inst. of Biomed. Eng., Natl. Yang-Ming Univ., No. 155, Sec. 2, Linong St., Taipei City 112, Taiwan, whosweet@gmail.com)

Two listening experiments were designed to evaluate the applicability of two macroscopic models—the articulation index and the speech recognition sensitivity (SRS) model—towards Mandarin speech recognition. The experiments aimed to identify if there is any synergetic and redundant effect of spectral frequency bands in monosyllabic Mandarin words. In experiment 1, 20 normal-hearing subjects listened to monosyllables through 20 bandpass filters, which have center frequency ranging from 125 to 8000 Hz, 1/3-octave bandwidth, and filter slope of 100 dB/octave. The purpose of experiment 1 was to identify the intelligibility of spectral frequency bands in Mandarin speech. In experiment 2, 10 subjects listened to monosyllables with the combination of 2 or 3 individual bands for investigating the synergetic or redundant interactions. The perceptual outcomes of the second experiment were fitted to both models by statistical regressions, and the results indicated that the contribution of each band to recognition of Mandarin monosyllables was not independent, and the recognition of Mandarin tones, consonants, and vowels showed different redundant and synergetic effects. The SRS model appears to be able to predict the differential effect of linguistic entropy on filter condition.

1pSC26. jTRACE: A user-friendly reimplementation and extension of the TRACE model of speech perception and spoken word recognition. Ted J. Strauss, James S. Magnuson (Dept. of Psych., Univ. of Connecticut, 406 Babbidge Rd., Unit 1020, Storrs CT, 06269), and Harlan D. Harris (New York Univ., New York, NY 10003)

jTRACE is a cross-platform Java reimplementation and extension of the TRACE model of spoken word recognition. TRACE (McClelland and Elman, 1986) is a three-layer interactive-activation model of speech perception that takes a pseudoacoustic input representation and accurately simulates many phenomena of human speech processing. The goals of the reimplementation are to provide a user-friendly version of the model that can run on any current computer platform, extend the model with graphing and scripting tools, and thus provide a tool that is powerful enough for intensive research while easy enough to use in a classroom setting. New features in jTRACE include simulation visualization, results graphing, powerful scripting, internal and external noise parameters, adjustable lexical and phonological characteristics, word recognition metrics, data exporting, and saving/archiving tools. A set of historically relevant simulations is bundled with the program. This feature is ideal for educational applications. Any simulation can be saved in a similar format, promoting sharing and replication. jTRACE was validated quantitatively against the original implementation by replicating key simulations reported in the literature. jTRACE can be downloaded freely from <http://maglab.psy.uconn.edu/jtrace.html> [Work supported by National Institute on Deafness and Other Communication Disorders.]

1pSC27. Nonspeech sounds prime acoustically similar words. Andrew B. Wallace and Sheila E. Blumstein (Dept. of Cognit. and Linguist. Sci., Box 1978, Brown Univ., Providence, RI)

Recent experiments show that nonspeech sounds can shift the perceptual boundaries between the phonetic categories of speech [e.g., Holt, Psych. Sci. **16**, 305–312 (2005)]. The current experiment investigates whether nonspeech sounds will also affect the speed of access to words. Subjects received prime-target pairs in which the target was one of the three words deed, dad, and dude, preceded either by tone complexes which matched the frequencies of the first two formants of each target or by a neutral tone midway between the ranges of F1 and F2. Every prime was paired with every target in a word-identification task. Results demonstrated a priming effect of the nonspeech sounds on acoustically similar speech. Significant differences were found in reaction time, with subjects responding faster when targets were preceded by matched primes than when they were preceded by mismatched or neutral primes. These results support a role for general auditory processes in speech perception and lexical access. [Work supported by NIDCD.]

1pSC28. Acquisition of phonological variants in an artificial lexicon: The role of variant frequency. Eleni Pinnow and Cynthia Connine (Psych. Dept., Binghamton Univ., P.O. Box 6000, Binghamton, NY 13902)

A series of experiments examined the role of exposure frequency in the acquisition of phonological variants (schwa deletion) using an artificial lexicon. During training participants heard either two- (experiment 1) or three- (experiment 2) syllable stimuli produced in both schwa-present and schwa-deleted forms. Frequency of the schwa-present or deleted form was manipulated with high-frequency forms presented eight times and low-frequency forms presented one time. An orthographic version of the stimuli was presented during training as feedback. A lexical decision task performed after training showed a reaction time advantage for the high-frequency variant form for two syllable stimuli. No frequency effect was found for three-syllable stimuli. Experiment 3 presented the three-syllable stimuli across 2 days of training. On each day of training, high-frequency variants were heard 15 times and low-frequency variants were heard once. A reaction time advantage for high-frequency forms was found on day 1 that was reduced on day 2; both days revealed more accurate identification for high-frequency forms. Results will be discussed in terms of previous findings for recognition of schwa deletion variants and possible mechanisms for the lexicalization of phonological variants.

1pSC29. A lexical locus for the integration of asynchronous cues to voicing: An investigation with natural stimuli. Joseph Toscano and Bob McMurray (Dept. of Psych., Univ. of Iowa, E11 SSH, Iowa City, IA 52242)

Speech perception requires integrating multiple asynchronous acoustic cues. Two questions pertinent to the integration of VOT and vowel length in word recognition were examined. First, this study asked whether lexical activation is sufficient to integrate these cues or if a sublexical buffer is required. Second, the role of stimulus type was examined since studies have found different results for synthetic and natural stimuli (Shinn *et al.*, 1985; Miller and Wayland, 1993; Utman, 1998). An eye tracking methodology that is sensitive to timing and small differences in activation was used (McMurray *et al.*, 2002). Stimuli were recordings of words (e.g., ''beach'' and ''peach'') whose initial VOT was manipulated along a nine-step continuum using splicing. The length of the following vowel was modified to create long and short vowels. Participants selected the correct object from screens containing the target, competitor, and two filler objects while eye movements were monitored. A small vowel length effect was found on voicing perception. This effect occurred substantially later in the fixation record than the effect of VOT. Thus, effects of vowel length can be seen in natural speech. Further, these cues each affect lexical activation as soon as they are available; no sublexical integration is required.

1pSC30. Gradient effects of continuous acoustic detail revealed by event-related potentials. Joel Dennhardt, Bob McMurray, Steven Luck, and Joseph Toscano (Dept. of Psych., E11 SSH, Univ. of Iowa, Iowa City, IA 52242, bob-mcmurray@uiowa.edu)

A growing body of research has demonstrated that lexical activation during online word recognition is systematically sensitive to continuous detail in the speech signal (Andruski *et al.*, ''The effect of subphonetic differences on lexical access,'' Cognition **52**, 163–187 1994; McMurray *et al.*, ''Gradient effects of within-catagory phonetic variation on lexical

access,'' Cognition **26**, B33–B42 2002). However, investigations of within-category sensitivity to continuous phonetic cues using electrophysiological measures have typically been consistent with categorical perception (Sharma *et al.*, ''Acoustic versus phonetic representation of speech as reflected by the mismatch negatively event-related potential,'' Electroencephalography & Clinical Neurophys.: Evoked Potentials, **88**, 67–71 1993; Phillips *et al.*, ''Auditory cortex accesses: Phonological categories: An MEG mismatch study,'' J. Cogn. Neurosci. **12**, 1038–1055 2000). This raises the possibility that these findings of gradiency are artifacts of the small number of comparisons made in priming experiments or the eye-movement tasks themselves. This issue was addressed with event-related potentials in a P3 categorization paradigm. Subjects heard tokens from beach/peach or dart/tart continua (9 steps, 0–40 ms of VOT). In each block of trials, one of the four words was the target; one button was pressed for the target word and a different button for any of the nontarget words. The amplitudes of the P2 and P3 components decreased continuously as VOT departed from the target. This was the case even when trials in which subjects identified the token as nontarget were excluded. These results favor a gradient view of lexical activation: lexical processing is gradiently sensitive to continuous speech cues and such cues may facilitate word recognition.

1pSP1. Time reversal and the adjoint imaging method with an application in underwater communication. Oliver Dorn (Universidad Carlos III de Madrid, Avda de la Universidad, 30, 28911 Leganes, Madrid, Spain)

A direct link is established between the time-reversal technique and the so-called adjoint method for imaging. The latter one has been used successfully in medical imaging applications, for example for the early detection of breast cancer in ultrasound tomography. In this application, ultrasound waves are sent through the unknown medium of investigation, and the differences between detected and predicted measurements are computationally back-propagated into the estimated medium in order to determine the correct acoustical parameters. In the application of underwater acoustic communication, the goal is to optimize a given signal, emitted by a base station, such that it focuses on the target user in the desired fashion without interfering with other users who might share the same environment. It turns out that efficient optimization schemes can be derived for achieving this goal, which are very similar to those applied in the above-mentioned medical imaging application, but which can be realized physically in the true (unknown) ocean by iterated physical time-reversal experiments. The close relationship, as well as some differences, between these two applications will be highlighted in this talk. [Financial support for this work from the U.S. Office of Naval Research under Grant N00014-02-1-0090 is gratefully acknowledged.]

1:25

1pSP2. Estimating sound-speed perturbations with full-wave environmental sensitivity kernels. Jit Sarkar, Bruce Cornuelle, W. A. Kuperman (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., Mail Code 0238, La Jolla, CA 92093-0238, bsarkar@ucsd.edu), and Philippe Roux (LGIT-Maison des Geosciences, Grenoble Cedex 9—France)

The acoustic field at a receiving array due to an individual source is affected by changes in the intervening sound-speed profile. This sensitivity has been calculated for broadband signals centered at 3500 Hz and 4-km range using a Born approximation to perturbations in the wave equation. These sensitivity kernels have been verified against range-dependent propagation model results. The range of validity for the linear approximation has been explored as part of these tests. Least-squares methods can be used to estimate the environmental changes from the measured differences in the received signal(s) and prior knowledge of the statistics of the variability. Sample estimates and error statistics, including resolution, will be presented.

1:45

1pSP3. Applications of adjoint models in underwater acoustics. Paul Hursky, Michael B. Porter (Heat, Light, and Sound Research, Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130), Bruce D. Cornuelle, W. S. Hodgkiss, and W. A. Kuperman (Scripps Inst. of Oceanogr., La Jolla, CA 92093)

Complementing a forward model with its adjoint has some nice features that can be helpful in inverse problems. We will review our previous work on constructing an adjoint for forward propagaton using an implicit finite-differences parabolic equation model and some simulated results in inverting for the sound speed in the water column. We will also review how an adjoint can aid in model identification, or the question of how the inverse problem should be modeled (e.g., in inverting for the properties of the bottom, how

many layers should be used to parametrize the bottom). We will demonstrate this for a range-dependent inversion, in which in one case there is a bottom inclusion (bottom properties are abruptly different over some range interval between the source and receiver), and another case where there is an internal wave. After reviewing these examples, we will discuss some practical issues in applying adjoint models to real data.

2:05

1pSP4. Adjoint approach to the physical characterization of a shallow-water environment. Matthias Meyer, Jean-Pierre Hermand (Dept. of Optics and Acoust., Université libre de Bruxelles, av. F. D. Roosevelt 50, CP194/05, B-1050 Bruxelles, Belgium), Mohamed Berrada (Université de Pierre et Marie Curie, 75252 Paris Cedex 05, France), and Mark Asch (Université de Picardie Jules Verne, 80039 Amiens Cedex 1, France)

In underwater acoustics a variety of different applications of adjoint models has been proposed in recent years. Adjoints have been derived for normal modes and for both the standard parabolic equation and Claerbout's wide-angle approximation. This paper reviews the analytic nonlocal boundary control approach proposed in an earlier paper by the authors [Meyer & Hermand, "Optimal nonlocal boundary control of the wide-angle parabolic equation for inversion of a waveguide acoustic field," J. Acoust. Soc. Am. **117**, 2937–2948 (2005)] and presents a numerical extension that allows direct inversion of the geoacoustic parameters that are embedded in a discrete representation of the nonlocal boundary condition at the water-sediment interface. The effectiveness of this numerical adjoint approach for the physical characterization of a shallow-water environment is illustrated with applications for geoacoustic inversion and ocean acoustic tomography. In particular, it is shown how a joint inversion across multiple frequencies can enhance the performance of the optimization process, especially for the case of a sparse receiver array spanning part of the water column. In an additional example we combine the two applications and discuss the feasibility of geoacoustic inversion in the presence of an uncertain sound-speed profile.

2:25

1pSP5. Bathymetry inversion in shallow water using an adjoint method. Isabelle Charpentier (Project Idopt (CNRS, INRIA, UJF, INPG), BP 53, F-38041, Grenoble Cedex 9, France) and Philippe Roux (Universite Joseph Fourier, Grenoble, France)

Bathymetry inversion is performed at low frequency on a kilometer-scale shallow water waveguide between two vertical arrays of sources and receivers. The inversion is based on the use of the adjoint of a wide-angle Pade PE code. The adjoint is obtained using automatic differentiation software. The bathymetry is decomposed under a limited number of spline functions. Inversion results improve with the number of source/receiver pairs and when a multiple-frequency approach is used. Application to experimental at-sea data is discussed.

1pSP6. Time-reversal-based noniterative exact inverse scattering of multiply scattering point targets. Edwin A. Marengo and Fred K. Gruber (Dept. of Elec. and Comput. Eng., Northeastern Univ., Boston, MA 02115)

This research investigates within exact scattering theory time-reversal-based approaches for the inverse scattering in a known but rather arbitrary embedding background medium of an unknown total scatterer composed of a number of dominant subwavelength (pointlike) scattering centers (targets) that are located at unknown positions and have unknown scattering strengths or reflectivities (characterizing a scattering potential). Of particular interest is the formulation of a new inverse scattering method (comprising both inverse support and inverse medium aspects) based on a two-step procedure. The first step (support inversion) consists of the localization of the targets via signal subspace approaches such as time-reversal MUSIC and a new, high-dimensional signal subspace method that is shown to be linked to maximum likelihood estimation. The second step (nonlinear medium inversion) is a new, noniterative scattering strength inversion formula for the reconstruction of the target scattering strengths or reflectivities. Importantly, the derived method is valid even in the presence of multiple scattering between the targets, which is remarkable since the mapping from the reflectivities to the field data is then nonlinear. The theory is illustrated with several computer examples. [Work supported by AFOSR under Grant FA9550-06-01-0013.]

1pSP7. Application of the acoustic adjoint equation to normal mode propagation in a waveguide. Aaron Thode (Marine Physical Lab., Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238)

This presentation reviews work that applied the acoustic adjoint equation to situations where the propagating acoustic field in an oceanic waveguide can be expressed as a sum of normal modes. The acoustic adjoint equation [Norton, "Inertive inverse scattering algorithms: Methods of Computing Fréchet derivatives," J. Acoust. Soc. Am. **106**, 2653–2660 (1999)], Hurksy *et al.*, "Adjoint modeling for acoustic inversion, J. Acoust. Soc. Am. **115**, 607–619 (2004)] which has a form very similar to the Born approximation, provides an expression for multiple-order derivatives of the received acoustic field with respect to an infinitesimal change in an environmental parameter, which in turn can be used to derive the gradient of an error or ambiguity function without resorting to numerical derivatives. For the situation of a range-independent environment, closed-form analytical expressions can be obtained for pressure derivatives with respect to range-independent perturbations in refractive index and density in the water column and sediment, as well as derivatives with respect to frequency. Expressions have also been derived for derivatives with respect to three-dimensional refractive index perturbations, which permits the evaluation of certain horizontal refraction effects of environmental perturbations without resorting to three-dimensional propagation codes. Current work on obtaining derivatives with respect to perturbations in waveguide boundary conditions (bottom bathymetry or sea surface shape) will also be discussed. [Work supported by the ONR Uncertainty Program.]

3:40

1pSP8. Wave-theoretic kernels for long-range ocean travel-time measurements. Bruce Cornuelle, Matthew Dzieciuch (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., Mail Code 0213, La Jolla, CA 92093-0213, bdc@ucsd.edu), and Emmanuel Skarsoulis (Inst. of Appl. and Computational Mathematics, GR-71110 Heraklion, Greece)

Travel-time measurements have been a mainstay of long-range acoustic measurements, but the high sensitivity of ray paths to sound-speed perturbations makes the ray theory questionable. In the ray approximation travel times are sensitive to medium changes only along the corresponding eigenrays. Wave-theoretic modeling can be applied to obtain travel-time sensitivity kernels representing the amount by which ray travel times are affected by localized sound-speed variations anywhere in the medium. Propagation codes using the parabolic equation (PE) approximation allow the efficient calculation of these travel-time sensitivity kernels (TSK) in range-dependent environments that obey reciprocity. At high frequencies, the TSK becomes similar to the ray path. This work will explore the spatial frequency content of the TSK in comparison to expected ocean variability. It will also examine the stability of the TSK for range-dependent environments which produce strong sensitivity of ray paths to initial conditions. [Work supported by ONR.]

4:00

1pSP9. Tangent linear and second-order models from the Born and Rytov approximations. Emmanuel Skarsoulis, George Piperakis (Inst. of Appl. & Comput. Math., FORTH, P.O. Box, 1385, 711 10 Heraklion, Greece, eskars@iacm.forth.gr), and George Makrakis (Univ. of Crete, Crete, Greece)

Adjoint and higher-order methods for the solution of inverse problems in underwater acoustics rely on tangent linear and higher-order models of the forward propagation problem, with respect to the underlying parameters of interest. The use of Born and Rytov approximations is examined for the representation of perturbations of the Green's function and perturbations of the phase, respectively, caused by range-dependent variations of the sound-speed distribution about a range-independent background environment. Using the normal-mode representation for the background Green's function and applying the stationary-phase approach in combination with analytic evaluation at singular points, closed-form expressions are derived for the first- and second-order perturbations of the Green's function, generalizing previous perturbation results derived under the assumption of range independence. The resulting expressions for the phase show the second-order character of the phase (and the associated travel times) in the case of range-dependent, zero-mean sound-speed perturbations.

1eID1. The 2004 Sumatra earthquake and tsunami: Multidisciplinary lessons from an oceanic monster. Emile Okal (Dept. of Geological Sci., Northwestern Univ., 1850 Campus Dr., Evanston IL 60208-2150)

The 2004 Sumatra earthquake was the largest seismic event recorded in 40, perhaps 44, years. The death toll from its tsunami was unprecedented in documented history. Remarkably, the earthquake and tsunami were recorded by many technologies designed for strikingly different purposes, including hydroacoustic sensors of the International Monitoring System of the CTBT, which captured standard (Rayleigh) waves, acoustic (*T*) phases, as well as the pressure component of the tsunami wave itself. I will discuss the contributions of such records, and other systems, to the investigation of the earthquake's source and to the nature of the "high"-frequency (10–20 MHz) components of the tsunami wave in the far field.

2aAAa1. The perforated panel resonator with flexible tube bundle. Yadong Lu (Inst. of Acoust., Chinese Acad. of Sci., 17 Zhongguancun St., P.O. Box 2712, Beijing 100080, PROC, yadong@mail.ioa.ac.cn), Huide Tang (Tianjin Hearing-aid Factory, Tianjin 300161, PROC), Jing Tian (Chinese Acad. of Sci., Beijing 100080, PROC), and Hongqi Li (Beijing Univ. of Technol., Beijing 100022, PROC)

This paper deals with a new type of resonant absorber, i.e., the perforated panel resonator with flexible tube bundle. The acoustical properties of the new sound-absorbing structure are measured and analyzed. From the measurement results and theoretical analysis, the following conclusions can be made. (1) The incorporation of the tube bundle into the resonator absorber is helpful to improve its low-frequency sound absorption. Because the artificial prolongation of air column length inside a hole neck will increase acoustic mass, resonance frequency can be shifted to a lower frequency correspondingly. (2) Compared with traditional perforated panel absorber, the acoustic resistance of the sound-absorbing structure can be increased considerably due to the incorporation of the flexible tube bundle into the resonator absorber, so that higher sound absorption coefficients can be expected. (3) By reasonably utilizing the tube and cavity coupling resonances, the frequency bandwidth of sound absorption of the perforated panel resonator with flexible tube bundle can be expected to broaden. The perforated panel resonator with flexible tube bundle may be used in some cases with strict space limitations and with expectations of increasing the sound absorption at lower frequencies.

8:30

2aAAa2. Measurements and calculations on microperforated sound absorbers. Christian Nocke and Catja Hilge (Akustikbuero Oldenburg, Katharinenstrasse 10, 26121 Oldenburg, Germany)

The sound absorption of microperforated absorbers can be predicted with a high degree of precision. Microperforated absorbers have been made of various materials in many applications. In recent years different manufacturers have offered a variety of microperforated materials. This paper reviews the first microperforated sound absorbers made of foils introduced some 10 years ago. This paper compares measured sound absorption coefficients of the microperforated foil absorber with the theoretical simulations. Theoretical approaches towards layered sound absorbers with microperforated components will be suggested. Finally, future developments in the field of microperforation in room acoustics will be discussed.

8:55

2aAAa3. Practical applications of transparent microperforated and microslit absorbers. Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774)

It has been over 100 years since absorption was introduced as a quantifiable tool in architectural acoustics. Currently, the architectural acoustic community faces ever-changing challenges that require innovative approaches to absorb sound. Due to the importance of day lighting in sustainable design certification, such as LEED, and the concern about particulate material from fiberglass and mineral wool, there has developed a need for transparent and translucent absorptive materials that do not require the use of fibrous porous absorption. One approach has been the development of microperforated and microslit foils, sheets, and panels with submillimeter openings that provide significant viscous losses when spaced from a boundary. This presentation will review the design theory and absorption mechanisms, describe the various commercial materials now available, and illustrate current projects and potential applications.

9:20

2aAAa4. Effect of honeycomb structure in the back cavity on the absorption characteristics of microperforated panel absorbers. Motoki Yairi, Atsuo Minemura (Kajima Tech. Res. Inst., 2-19-1 Tobitakyu Chofu, Tokyo 182-0036 Japan), Kimihiro Sakagami, and Masayuki Morimoto (Kobe Univ., 657-8501 Kobe, Japan)

Since the principle of microperforated panel absorbers (MPPs) was established, many studies have been made on their practical applications. MPPs are typically made of very thin metal or plastic panels to obtain high absorption. However, such a thin, limp panel is in many cases not suitable for an interior finish of room walls because of its insufficient strength. The authors have proposed to use a honeycomb structure attached behind an MPP to stiffen it without deteriorating its acoustical performance. The honeycomb behind an MPP can also be expected to enhance its absorption performance, considering previous studies on porous sound-absorbing layers with the back cavity completely partitioned by a honeycomb structure. In this paper, the effect of honeycomb structure in the back cavity on the absorption coefficient of MPP was experimentally studied. The results suggest that the reverberation sound absorption characteristics become close to those of an MPP without a honeycomb structure for normal incidence. This means that the characteristics are improved with the honeycomb structure to show a higher and broader absorption peak. MPPs can be used more efficiently in more various situations with applying elaborated configurations of backing structures. [Work supported by the Kajima Foundationfs Research Grant.]

9:45

2aAAa5. An ideal absorbing materials in architectural acoustics: Micro-perforated panel absorbers. Ke Liu, Jing Tian, Fenglei Jiao, and Xiaodong Li (Inst. of Acoust., Chinese Acad. of Sci., P.O. Box 2712, Beijing 100080, P.R. China)

Micro-perforated panel absorbers (MPA) can be used to reduce or better the noise in architecture. This absorber was developed in the 1960s, when a robust sound absorber was needed for severe environments, without porous materials. It has a simple structure and the absorption properties can be exactly calculated. The panel can be made of any materials from cardboard to plastic to plywood to sheet metal, for different purposes. Theoretical and experimental investigations on MPA are reviewed in this paper. By reviewing recent research work, this paper reveals a relationship between the maximum absorption coefficient and the limit of the absorption frequency bandwidth. It has been demonstrated that the absorption frequency bandwidth can be extended up to 3 or 4 octaves as the diameters of the micro-holes decrease. This has become possible with the development of the technologies for manufacturing MPA, such as laser drilling, powder metallurgy, welded meshing, and electro-etching to form micrometer-order holes. In this paper, absorption characteristics of such absorbers in random fields are presented and discussed both theoretically and experimentally. This review shows that the MPA has potentials to be an ideal absorbing materials in architectural acoustics in the 21st century.

2aAAb1. Loudspeakers and listening rooms, Part I: The physical sound field. Floyd E. Toole (Harman International Industries, Inc., 8500 Balboa Blvd., Northridge, CA 91329, ftoole@harman.com)

In contrast to the considerable effort invested in concert halls and auditoria for live performances, the design of domestic listening spaces and recording control rooms has evolved with little guidance from science. In this presentation, an examination of the physical aspects of sound in small rooms reveals that traditional acoustical measures, such as reverberation time, are of little value. The reasons have to do with the differentiating facts that loudspeakers are relatively directional, and the rooms are relatively small, relatively absorptive, and furnished with large sound-scattering objects. As a result, at frequencies above about 300 Hz, listeners are in a transitional sound field consisting of direct and early reflected sounds, and a much-diminished late-reflected sound field. Loudspeaker directional properties and the acoustical behavior of the surfaces involved with early reflections are the factors relevant to perceptions. At low frequencies, room modes dominate. Notions of optimum room-dimensional ratios are of value only when loudspeaker and listener locations are known. New solutions, employing multiple subwoofers in configurations that result in selective modal excitation, can yield excellent low-frequency sound for several listeners in both rectangular and nonrectangular rooms.

10:50

2aAAb2. Loudspeakers and listening rooms, Part II: The perception of reflections. Floyd E. Toole (Harman International Industries, Inc., 8500 Balboa Blvd., Northridge, CA 91329, ftoole@harman.com)

A review of the effects of reflections on perceptions of sound quality, direction, image size, spaciousness, speech intelligibility, etc., lending perspective to the matter of which elements might be perceptually important in multichannel sound reproduction systems. In general they appear to be less problematic than is commonly believed. This, combined with the considerable ability of listeners to adapt to certain auditory influences of small rooms, brings into question several popular practices in the design of loudspeakers and listening rooms. Anechoic measurements on loudspeakers that have been done in a manner that anticipates sound reproduction in rooms can be used to calculate a figure of merit. The correlation between the calculated ratings, and those resulting from double-blind listening tests, is high: 0.86. This has implications for the acoustical treatment of rooms, and to the necessity for controlling the sound field at low frequencies. Only then can there be any assurance that the art in recordings will be heard by consumers as it was created in control rooms.

11:10

2aAAb3. Surround monitoring challenges in acoustically small spaces. Russ Berger (Russ Berger Design Group, 4006 Belt Line Rd., Ste. 160, Addison, TX 75001)

Critical listening spaces used to monitor and produce surround sound product are usually required to provide an accurate listening environment for more than one listener. Decisions are made not only about source material content and veracity, but also about how best to process and present the multichannel surround event in a manner that translates the aural experience to a wider audience. Oftentimes this audience is listening in other, less-than-ideal acoustical environments. Practical criteria and solutions are presented here to help overcome the limitations of monitoring surround sound in acoustically small spaces, as well as a discussion regarding first reflection control through the application of space coupling diffusors.

11:30

2aAAb4. Design considerations for an idealized domestic surround-sound listening space. David Moulton (Moulton Labs., 39 Ames Rd., Groton, MA 01450, dmoulton@moultonlabs.com)

I have been actively involved in the production of music for surround-sound systems since the late 1960s, including composition, production, recording (classical, multichannel pop, and experimental), loudspeaker design, and acoustical design. Based on my experiences, I am going to present some design principles (and constraints) for domestic (and public) surround-sound playback spaces, possible loudspeaker configurations, and topologies. I will also suggest a possible ideal domestic music playback space.

Chair's Introduction—8:25

8:30

2aAO1. Hydroacoustic observations of the 2004 megathrust earthquake and other events. Catherine de Groot-Hedlin (Scripps Inst. of Oceanogr., 9500 Gilman Dr., La Jolla, CA 92093-0225)

Hydroacoustic signals (T-waves) generated by the 2004 Great Sumatra earthquake were recorded by a network of 5 small hydroacoustic arrays located in the Indian Ocean at distances of 2800 to 7000 km from the epicenter. The array configurations allow for accurate determination of the receiver-to-source azimuth given coherent arrivals. Analysis of a series of 10-s windows within the T-wave coda shows that the receiver-to-source azimuth varies smoothly as a function of time, suggesting a nonstationary T-wave source. Apparent motion in the T-wave source has also been observed for many small-scale earthquakes and, for those events, reflects T-wave excitation over a broad expanse of the seafloor. For small-scale earthquakes, it is shown that the variations in the source

azimuth are predictable using a seafloor scattering model. The azimuthal variations for the great Sumatra event are shown to be inconsistent with a small-scale source and are thus indicative of the rupture velocity. The data indicate that the rupture proceeded in two distinct phases; initially it progressed northwest at approximately 2.4 km/s along the Sunda trench. At 600 km from the epicenter, the rupture slowed to approximately 1.5 km/s.

8:50

2aAO2. Use of low-frequency marine seismo-acoustics in understanding earthquake processes: Applications to the Great Sumatra-Andaman earthquake. Maya Tolstoy and DelWayne R. Bohnenstiehl (Lamont-Doherty Earth Observatory of Columbia Univ., 61 Rte. 9W, Palisades, NY 10964-8000, tolstoy@ldeo.columbia.edu)

Low-frequency (1–100 Hz) hydroacoustic recordings can provide a wealth of information on earthquake characteristics in the shallow marine environment. This frequency band, considered low frequency for acousticians, is actually high frequency for regional or global seismologists who commonly work with frequencies of a few Hz and below. In some cases this higher frequency data may provide higher resolution of some earthquake characteristics than traditional seismic methods. The 2004 Great Sumatra-Andaman earthquake provides an example where detailed analysis of the T-wave arrival has allowed detailed characterization of changes in rupture velocity that have not proven easy to resolve in traditional seismic data. Our single-station interpretation of the T-wave data shows that the fault ruptured northward from the epicenter in at least two phases with lower rupture velocity in the north. The methods behind this single station approach will be discussed along with possible future uses of this type of data for improving our understanding of earthquake rupture processes, as well as providing a rapid assessment of the size, location, and geographic extent of large submarine earthquakes, and hence their tsunamigenic potential.

9:10

2aAO3. Fault dynamics of Indian Ocean earthquakes derived from the array analysis of T-waves. Jay Pulli and Zachary Upton (BBN Technologies, 1300 North 17th St., Ste. 400, Arlington, VA 22209)

The Great Sumatran earthquake of 26 December 2004 generated some of the largest and longest T-waves ever recorded, and certainly the largest T-waves recorded on modern high-dynamic range hydrophones. For example, the recordings at the Diego Garcia hydroacoustic array indicate a T-wave duration of approximately 15 min. Array processing of these signals by many investigators indicates that the T-wave generation started near the earthquake epicenter and propagated northwest along the trench for nearly 600 km. This corresponds to the faulting zone defined by the aftershock distribution. A dataset of T-wave recordings of Indian Ocean earthquakes has been examined, covering the period 2001 to the present, including events on the oceans ridges and trenches, as well as some interplate events. The recordings were made at Diego Garcia, Cape Leeuwin, and Crozet Island. Event sizes range from magnitude 4 to 8. Bearing versus time is derived via intersensor cross correlations with a time resolution of 0.010 s, corresponding to a bearing resolution of 0.4 deg. Examples of events along the Sumatran Trench are shown with extended T-wave source areas, from which estimates of fault length and rupture velocity are made. These studies further demonstrate the utility of T-phases for understanding seismic source dynamics.

9:30

2aAO4. Using T-phase spectra to estimate rupture depth and static offset of the seafloor. David Salzberg (SAIC/OSD, 1710 SAIC Dr, M/S 1-11-15, McLean, VA 22102, david.h.salzberg@saic.com)

Analysis of *T*-phases recorded from recent tsunamogenic earthquakes indicates that they contain significantly more high-frequency ($>$50 Hz) relative to low-frequency ($>$10 Hz) *T*-phase energy with longer durations ($>$30 s) than nontsunamogenic events. Modeling *T*-phase spectrum explains this observation, where the spectrum of the recorded *T*-phase is the product of the source spectrum, propagation loss in the solid earth, conversion from seismic to acoustic *T*-phase energy, propagation loss in the ocean, and the instrument response. The propagation loss in the ocean can be accurately modeled. Assuming the seismic-to-acoustic conversion is constant over frequency, the remaining unknown term is loss in the solid earth which is primarily due to anelastic attenuation. A refined depth estimate can be obtained by modeling the solid-earth attenuation. That, coupled with the earthquake source mechanism, allows for estimation of the static ocean floor deformation and thus tsunami height. This approach has been applied to two tsunamogenic earthquakes (26, Dec. 2004, 28, Mar. 2005), and one other event. Both tsunamogenic events had significant ($>$1 m) seafloor uplift. In addition, the peak static offset estimated for the 26 Dec. event is consistent with estimates both from other studies, and from observations of the seafloor deformation.

9:50

2aAO5. Sumatra tsunamis recorded on hydophones and seismic stations in the Indian Ocean. Jeffrey A. Hanson and J. Roger Bowman (Science Applications International Corp., 10260 Campus Point Dr., San Diego, CA 92121)

Tsunamis generated by the great Indonesian earthquakes of 26 December 2004 (Mw 9.3) and 28 March 2005 (Mw 8.6) produced high-frequency dispersed signals (5 to 60 MHz) recorded by hydrophone and seismic stations in and around the Indian Ocean. For the first and greater earthquake, the dispersed energy is frequently observed to 30 MHz and in one case to 60 MHz. The high-frequency signals are consistent with pointlike sources. The earliest-arriving tsunami signal is located to a source at 4.3N, 93.8E using event-to-station distances estimated by measuring dispersion and azimuth estimates using an array of hydrophones. Fine structure in the tsunami signal indicates a second high-frequency source just south of Great Nicobar Island. The dispersion of later-arriving energy matches predictions for reflections of the tsunami from bathymetric features in the Indian Ocean basin. For the 28 March 2005 tsunami, the high-frequency dispersion is observed at the Diego Garcia hydrophone station and the AIS seismic station, and tsunami signals without apparent dispersion are seen at four other seismic stations. Phase velocities are estimated at hydroacoustic arrays and agree with linear dispersion theory at frequencies above 12 MHz.

10:10–10:20 Break

10:20

2aAO6. Surface and body waves from hurricane Katrina observed in California. Peter Gerstoft (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman, 92093 La Jolla, CA), Michael C Fehler (Los Alamos Natl. Labs., Los Alamos, NM), and Karim Sabra (Scripps Inst. of Oceanogr., La Jolla, CA)

Hurricane Katrina struck land on 29 August 2005 as one of the strongest storms in the United States. The recent availability of continuous seismic data from a large number of stations enables us to characterize features of hurricane-generated noise in detail. By beamforming noise recorded on a distributed seismic array in southern California, we observe and track both the surface and body *P*-waves generated by Katrina in the 4–20-s period (0.05–0.25 Hz) microseism band. As the hurricane made landfall, the longer-period surface waves weakened, indicating that air/ocean/land coupling was a major factor in their generation. We observed *P*-waves that have propagated deep (1100 km) inside the Earth. These *P*-waves can be back-propagated to the hurricane. These findings demonstrate that ocean microseisms can propagate quite far and open the possibility of further use of seismic noise, even at very low signal level.

10:40

2aAO7. Source areas of midocean microseismic noise. Peter D. Bromirski (Integrative Oceanogr. Div., Scripps Inst. of Oceanogr., 9500 Gillman Dr., La Jolla, CA 92093-0209, pbromirski@ucsd.edu)

Comparison of microseismic noise data collected at the ocean-bottom Hawaii-2 Observatory (H2O), located midway between Hawaii and California, with wind and wave data shows three frequency bands having different source locations. At frequencies from about 0.3 to 0.5 Hz, the noise spectrum shows a strong correlation with overhead wind speed and direction, implying that this energy is generated locally. Correlation of swell height above H2O with microseism energy at frequencies below 0.3 Hz is generally poor, implying that these signals originate at distant locations. The highest noise levels observed occur in the 0.2- to 0.3-Hz band, apparently resulting from the interaction of waves forced by pre- and postfrontal winds from relatively large coincident storms in the same vicinity. Correlation of the H2O microseism levels with NOAA buoy data, with hindcast wave height data over the North Pacific, and with seismic data from mainland and island stations, defines likely source areas of the 0.1- to 0.2-Hz signals. Most of the microseism energy at H2O between 0.08 and 0.2 Hz appears to be generated by high-amplitude storm waves impacting long stretches of coastline nearly simultaneously. [Work supported by the California Department of Boating and Waterways.]

11:00

2aAO8. Sound of hurricane. Konstantin Naugolnykh (ESRL/Zeltech, 325 Broadway, Boulder, CO)

The strong perturbation of atmosphere such as hurricane is accompanied by infrasound radiation. This radiation can be observed at a distance of thousands of miles from the hurricane. The effect of sound radiation is connected apparently to the interaction of the counterpropagating sea-surface waves that produces a sound radiation of the doubled frequency of the surface wave oscillation. [M. S. Longuet-Higgins, A theory of the origin of microseisms]. Theoretical model of the sound generation by the sea-surface waves is developed on the basis of the advanced theoretical approach [Wright *et al.*, ''Hurricane directional spectrum spatial variation in the open ocean,'' J. Phys. Ocean. **31**, 2472–2488 (2000)]. The spectrum of sound radiation is presented as a function of the sea-surface wave features. Some estimation of the parameters of infrasound produced by hurricane is made using the data of Wright *et al.* on the hurricane-produced sea-surface waves spectrum. The diffraction effects are taken into account to evaluate the trapping of the radiation by a horizontal atmospheric waveguide, important for the long-range propagation of the noise. [K. A. Naugolnykh, and S. A. Rybak, ''Sound generation due to the interaction of surface waves,'' Acoustical Physics **49**, 88–90 (2003)].

11:15

2aAO9. Anomalous transparency of the water/air interface for low-frequency sound. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Earth System Res. Lab., 325 Broadway, Boulder, CO 80305, oleg.godin@noaa.gov)

Sound transmission through water/air interface is normally weak because of a stark density contrast between the two media. For a monopole sound source, at depth larger than a wavelength, the ratio R of the acoustic power transmitted into the air to the total emitted acoustic power is a small quantity of the order of the ratio of impedances of air and water. Acoustic transparency of the interface is shown to rise dramatically at low frequencies, where depth of the monopole source is small compared to the wavelength, with R increasing by up to 36 dB. Under certain conditions, almost all of the acoustic energy emitted by a low-frequency monopole source underwater is predicted to be radiated into the air rather than into the water. Physically, higher transparency at lower frequencies is due to increasing role of inhomogeneous waves emitted by the source and a destructive interference of fields in water due to the actual and image sources. The anomalous transparency of the water/air interface may have significant implications for generation of low-frequency acoustic noise in the air by bubbles collapsing underwater and for acoustic monitoring and detection of powerful underwater explosions for the purposes of the Comprehensive Nuclear Test Ban Treaty.

11:30

2aAO10. Low-frequency sound reflection and conversion to Darcy-type type diffusion waves at bottom interfaces with marine sediments. Jason D. Holmes, Allan D. Pierce, William M. Carey (Boston Univ., Boston, MA 02215), and James F. Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

The upper medium is sea water, and the bottom medium is a marine sediment whose physical description is consistent with the theory advanced by Frenkel in 1944 and with the model proposed by Biot in 1961 for a porous medium at low frequencies. Within the sediment, three generic types (modes) of wavelike disturbances are possible. These three modes are here termed the acoustic, shear, and Darcy modes. The first two are governed by propagating wave equations and the third by a diffusion equation. The first and third are dilatational. All three are nominally uncoupled, although coupling occurs at interfaces. When an obliquely incident acoustic wave impinges from the water on the interface, all three types of disturbances are in principle excited in the sediment, and the details of the excitation are governed by interface conditions, whose derivation is reported in the present paper. Each mode has its own characteristic parameters, and the sediment reflection coefficient, considered as a function of angle of incidence and of frequency, implicitly depends on all of these parameters. The question is addressed as to how, given such reflection coefficient data, one might extract the parameters for the Darcy mode for representative realistic experimental circumstances.

11:45

2aAO11. The relation between received microbarom signals and the sea state under a hurricane. Roger Waxler, Kenneth E. Gilbert, and Carrick L. Talmadge (NCPA, University, MS 38677)

It is known that the peak at about 0.2 Hz observed in both seismic (the microseism peak) and infrasound (the microbarom peak) spectra have their origin in the standing wave component of the ocean surface wave spectrum. The largest source of microseism and microbarom radiation is known to be from the sea states built up under hurricanes. In 1963 Hasselmann published a relation between the ocean wave spectrum and the microseism signal produced by the ocean waves. We have recently derived an analogous expression for the microbarom signal. This expression is presented and possible implications for remote monitoring of hurricane intensity are discussed.

2aBB1. Spectral parameter imaging of the corneal stroma. Ronald H. Silverman, Omer Gal, Monica Patel, and D. Jackson Coleman (Weill Medical College of Cornell Univ., 1300 York Ave., Rm. K808, New York, NY 10021)

Frederic L. Lizzi was a pioneer in the fields of high-frequency ultrasound and tissue characterization. This report details use of spectral parameter imaging of very-high-frequency radio frequency data for characterization of the cornea. The corneal stroma consists of broad 1–2-micron-thick belts (lamellae) embedded in a proteoglycan matrix. The lamellae consist of collagen fibrils 30 nm in diameter with center-to-center spacing of about 60 nm. Any disturbance to this orderly arrangement will result in loss of optical transparency. Parameter images representing the slope, intercept, and midband fit to the calibrated power spectrum were generated by post-processing of radio frequency data of 35- and 70-MHz scans of the cornea. Stromal backscatter was significantly higher at 70 MHz than at 35 MHz. In an uncomplicated LASIK-treated cornea examined 6 years postsurgery, significant differences in backscatter between the stroma anterior versus posterior to the LASIK interface were observed. This may relate to alteration in lamellar organization, even in the absence of loss of optical transparency. Frequencies beyond 50 MHz offer a probe of tissue microstructure that could be employed in evaluation of stromal organization. [Work supported by NIH Grant EB000238 and Research to Prevent Blindness.]

2aBB2. Inverse scattering bioacoustics: Under the influence of Fred Lizzi. Michael Insana (Univ. of Illinois, MC 278, 1304 Springfield Ave., Urbana, IL 61801)

A long-standing problem in bioacoustics is the assessment of soft tissue health from an analysis of backscattered echo signals—an inverse problem known as tissue characterization. Pathologists view magnified images of tissue morphology to assess tissue function and grade disease states. Ultrasonic tissue characterization methods are attempts to accomplish the same assessment noninvasively. The goal is not to image the microstructure directly, but rather to diagnose tissues from measurements of statistical moments of the echo spectrum properly normalized to isolate tissue features. Fred Lizzi pioneered this approach and provided an analytical framework used widely. It will be shown how his analysis evolved from classic studies in atmospheric physics to give a clear picture of what is becoming a material science approach to diagnosis using ultrasonics. Dr. Lizzi's methods have been used by many to diagnosis and monitor treatment of cancer from a very small feature space. Others have expanded these methods to discover the sources of ultrasonic scattering in tissue systems and observe dynamic features of physiology. Coupled with elasticity imaging, inverse scattering approaches provide *in vivo* tools for studying the influence of molecular signaling on tissue structure during the progression of cancer and atherosclerotic diseases.

8:30

2aBB3. Stimulation of collagen production with low-intensity acoustics. James Greenleaf, Heather Argedine, and Mark Bolander (Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55901)

Low-intensity pulsed ultrasound is a commonly prescribed therapy for delayed unions and nonunions after fractures. Several prospective double-blind clinical trials have shown that a 1.5-MHz ultrasound signal at a 200-s tone burst repeating at 1 kHz shortens the time to clinically evaluated healing by 30%. We have shown *in vitro* that pulsed ultrasound increases aggrecan gene expression and aggrecan production in chondrocytes, a key cell in the fracture healing process. Because the square wave pulsed 1.5-MHz signal produces radiation force vibration at 1 kHz, we tested the hypothesis that dynamic radiation force, not ultrasound, is responsible for the biological effect of the signal. Experiments showed that a 1-kHz acoustic square wave, simulating the radiation force caused by the clinically used signal, induced chondrogenesis similarly to pulsed ultrasound treatment in ATDC5 cells. These results may have implications for remote ultrasound or acoustic stimulation of different types of strain-sensitive cells in addition to those responsible for fracture healing.

8:50

2aBB4. Noninvasive prostate surgery using high-intensity focused ultrasound. Narendra T. Sanghvi (Focus Surgery, Inc., 3940 Pendleton Way, Indianapolis, IN 46226)

The salient features of ultrasound are to provide both medical diagnostic and therapeutic applications due to its short wavelength in soft tissue. These combinations have motivated us to apply ultrasound for the noninvasive surgery of the prostate diseases for both benign and malignant tumors. Over a decade of engineering and clinical research a successful transrectal ultrasound device, the Sonablate, has been developed and clinically practiced for the treatment of localized prostate cancer as well as benign prostatic hyperplasia. The main advantages of using the Sonablate device are on-line imaging of the prostate in 2D and 3D, accurate therapy planning, and real-time monitoring of treatment. The long-term, over 6 years follow-up clinical results from two multicenter clinical studies indicate no severe long-lasting side effects and acceptable efficacy of the treatment. The primary benefits of this treatment are fewer complications, outpatient procedure, and very quick recovery. The presentation will include design of the device, characterization of therapy and imaging transducer, and treatment parameters for the effective clinical results.

9:10

2aBB5. Quantitative ultrasound techniques. Timothy Hall, James Zagzebski, and Ernest Madsen (Univ. of Wisconsin, 1530 MSC, 1300 University Ave., Madison, WI 53706)

The ultrasound research group at UW-Madison has been pursuing quantitative measurement of the acoustic properties of tissues for more than three decades. Much of that effort parallels the efforts pioneered by Fred Lizzi and colleagues at Riverside Research Institute (RRI). While the RRI group was blazing trails in data acquisition, analysis, and interpretation techniques, the UW group was investigating the limits of measurement accuracy using similar approaches. Wise selection of the tissues to investigate, great intuition regarding fruitful paths, and good hard work resulted in substantial progress and success in the RRI quantitative ultrasound efforts. Careful measurements with high-quality phantoms, in parallel with tissue measurements, resulted in substantial progress in determining limits on quantitative ultrasound measurement accuracy under various experimental conditions. This presentation will highlight some of the differences and similarities in the approaches to quantitative ultrasound by these two groups and how we can use that information in future investigation.

9:30

2aBB6. Therapeutic applications of ultrasound in intracellular drug delivery and tissue ablation. Cheri X. Deng (Dept. of Biomed. Eng., Case Western Reserve Univ., 10900 Euclid Ave., Cleveland, OH 44106-7207)

Biomedical application of ultrasound has been advancing beyond diagnostic imaging. Innovative strategies of therapeutic applications of ultrasound have been exploited that utilize both thermal and mechanical effects generated by ultrasound. For ultrasound mediated intracellular drug and gene delivery, ultrasound has been used to increase cell permeability transiently. We have developed novel techniques to investigate the mechanisms of ultrasound-induced cell porosity or sonoporation in real time at the single cell level. We studied the dynamics of sonoporation and correlation with delivery outcome in mammalian cells, bacteria, and tissues. Applications of high-intensity focused ultrasound (HIFU) include tissue thermal ablation and other applications. We have developed interdisciplinary techniques using real-time fluorescent imaging, acoustic radiation elastography, and optical coherent tomography (OCT) techniques to study the changes of electrophysiology, mechanical, and optical properties of cardiac tissues during focal HIFU cardiac ablation. [Work supported by NIH, ACS, and NSF.]

9:50

2aBB7. Enhanced drug delivery with ultrasound and engineered delivery vehicles. Katherine W. Ferrara, Mark A. Borden, Paul A. Dayton, Azi Kheirolomoom, Dustin E. Kruse, Michaelann Tartis, and Aaron F. Lum (Dept. of Biomed. Eng., UC Davis 451 East Health Sci. Dr., Davis, CA 95616)

We demonstrate that local drug delivery can be achieved by ultrasound, combined with engineered delivery vehicles, where the vehicles have a diameter on the order of nanometers to microns. Delivery vehicles can be created from microbubbles with a thickened shell or a lipid shell decorated with drugs, genes, or nanoparticles. Alternatively, liquid-filled nanoparticles can be employed to carry the desired compound. Ultrasound can deflect these vehicles from the center of the flowstream, can fragment the vehicle releasing its

contents, and may enhance the uptake of the particle or its contents by cells in the desired region. The ultrasonic mechanisms behind these changes are summarized. The addition of targeting ligands to the shell to improve target specificity is also explored. Methods to measure the effectiveness of local drug delivery, including correlative imaging modalities, binding assays, and cytotoxicity assays, will be described. [The support of NIH CA 103828 is gratefully acknowledged.]

2aBB8. Tissue characterization using novel high-frequency models. Michael Oelze (Dept. of Elec. & Comput. Eng., Univ. of Illinois at Urbana-Champaign, 405 N. Mathews, Urbana, IL 61801, oelze@uiuc.edu)

Conventional models for ultrasound tissue scattering at conventional ultrasound frequencies (less than 15 MHz) were insufficient for differentiating between two kinds of solid tumors in mice that had clear morphological differences. F-tests on backscattered power spectra from the two kinds of tumors revealed significant differences between the two curves for frequencies above 16 MHz. New models were constructed to better reflect the ultrasonic interaction with underlying tissue structure. One model considered only the cell nucleus as a dominant source of scattering. A second model, the whole cell model, considered the nucleus and cytoskeletal structure. These models were used at high ultrasonic frequencies (16 to 70 MHz) to characterize the two kinds of tumors and compared with scatterer estimates using a conventional model, the spherical Gaussian model. The nucleus model revealed significant differences between the two kinds of tumors but scatterer estimates did not match the underlying structure as observed from optical photomicrographs. The whole cell model did not reveal significant differences but scatterer estimates matched underlying structure. [Work supported by NIH Grant F32 CA96419 and start-up funds from the Department of Electrical and Computer Engineering at the University of Illinois at Urbana-Champaign.]

10:45

2aBB9. Scattering of high-frequency ultrasound by cells and cell ensembles: In search of the dominant scattering source. Michael Kolios (Dept. of Phys., Ryerson Univ., Toronto, Canada)

High-frequency ultrasound (HFU) imaging (in the range of 20–60 MHz) has been recently enabled by advances in transducer technology and electronics. These high frequencies afford greater image resolution, on the order of 40 microns, at the expense of penetration depth, limited to a few centimeters. The associated ultrasound wavelengths of HFU are 25–75 microns, on the order of the size of cells. Therefore, it is hypothesized that at these frequencies ultrasound tissue characterization will provide more meaningful information about the physical characteristics of cells and any changes that occur in their structure during cancer treatment. The late Dr. Frederic Lizzi pioneered ultrasound tissue characterization and the seminal papers he published provided the impetus for this work. Here, backscatter from individual cells and tightly packed cell aggregates of the same cells (emulating tumors) are examined and compared to theoretical models of ultrasound backscatter. Recent work with a series of cells lines with different sizes and physical characteristics will be presented. It will be shown that for *in vitro* and *in vivo* experiments, the backscatter signal characteristics best correlate with nuclear size.

11:05

2aBB10. Automated coronary plaque characterization with intravascular ultrasound backscatter: *In vivo* and *ex vivo* validation. D. Geoffrey Vince, Anuja Nair, M. Pauliina Margolis, Stacy L. Kirby, Jennifer J. E. Kuznicki (Volcano Corp., Advanced Technology Lab., 9500 Euclid Ave., Cleveland, OH 44195 gvince@volcanocorp.com), Xiaofeng Wang, Barry D. Kuban (The Cleveland Clinic Foundation, Cleveland, OH 44195), and James R. Margolis (Miami International Cardiology Consultants, Miami, FL 33137)

Atherosclerosis is considered both a systemic and local disease. Current diagnostic tools do not allow adequate *in vivo* characterization of lesions. Intravascular ultrasound (IVUS) backscatter analysis has displayed the potential for real-time plaque characterization by advanced spectral analysis. One hundred-fifteen plaques from 51 coronary arteries were imaged *ex vivo* at physiologic pressure, using 20-MHz IVUS transducers. After imaging, the arteries were pressure fixed and matching histology was collected. Regions were selected from histology and corresponding IVUS data were used to build the ''VH'' plaque classification system using spectral analysis and classification trees. VH images were validated *ex vivo* by comparison with histology via 407 selected regions that comprised 162 fibrous, 84 fibro-fatty, 69 necrotic-core, and 92 dense-calcium regions. The overall predictive accuracies were 92.9%, 93.4%, 94.3%, and 99.3% respectively, with sensitivities and specificities ranging from 84% to 99%. Reproducibility was assessed *ex-vivo* and *in vivo* with two pullbacks of IVUS catheters in each. A semiparametric regression model and the *t*-test were used to quantify reproducibility, which was high in each case. VH is a robust technique that provides accurate and reproducible information on plaque composition, with considerable potential for assessment of plaque vulnerability in real time.

2aBB11. Discovery of the ring resonant frequency for noninvasively estimating local elastic modulus of arterial wall. Xiaoming Zhang and James F. Greenleaf (Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905, Zhang.xiaoming@mayo.edu)

Increased stiffness of arteries has recently gained acceptance as an independent risk factor for cardiovascular and many other diseases. Pulse wave velocity (PWV) is widely used for estimating the stiffness of an artery. However, PWV is an average indicator of artery stiffness between the two measuring points, and therefore does not identify local stiffness. In addition, the thickness of the artery is needed to calculate artery elastic modulus. We have discovered that there is a series of ring resonant frequency in arteries that can be used for estimating local arterial elastic modulus. These resonances can be excited by remote palpation with selectively placed ultrasonic radiation force. Experiments on ring resonance were carried out on an excised artery as well as a rubber tube. This family of resonances occurs at relatively low frequency, around 356 Hz for the artery. Estimation of the Young's modulus is 135 kPa by the ring frequency 356 Hz without the requirement of the arterial thickness. The

estimated modulus is very consistent with the other ring resonant frequency measurements. The theory of ring resonance is developed and verified with the rubber tube experiments.

11:40

2aBB12. Imaging with high-frequency annular arrays. Jeffrey A. Ketterling, Sarayu Ramachandran, Ronald H. Silverman (Frederic L. Lizzi Ctr. for Biomed. Eng., Riverside Res. Inst., 156 William St., New York, NY 10038), Orlando Aristizábal, and Daniel H. Turnbull (New York Univ. School of Medicine, New York, NY 10016)

Frederic Lizzi helped pioneer the use of high-frequency ultrasound (HFU) for ophthalmic imaging and disease diagnosis. A limitation of HFU single-element transducers is their limited depth-of-field ($\approx$1 mm). One approach to improve the DOF for HFU applications is to use annular arrays. A five-element, 40-MHz annular array was developed for ophthalmic and small-animal imaging. The array consisted of a 9-μm PVDF film bonded to a patterned, copper-clad polyimide film. An experimental system was assembled to permit the digitization of radio-frequency (rf) data from the array. The rf data were collected from all transmit/receive ring pairs and the data were later postprocessed. The performance of the array was first validated with a wire phantom and then *in vitro* data were acquired from excised bovine eyes and a cadaver eye. *In vivo* data were acquired from an anesthetized rabbit and from mouse embryos. Image comparisons were made between rf data that had been summed with no delay corrections and rf data that had been processed with a synthetic-focusing algorithm. Synthetic-focus images showed a clear improvement in DOF in terms of image brightness and enhanced membrane and cavity-boundary definition. [This research was supported in part by grants from the NIH (EY014371 and NS038461).]

11:55

2aBB13. Ultrasonic and magnetic-resonance spectra in tissue-type imaging for planning and monitoring prostate cancer treatment. Shreedevi Dasgupta, Ernest Feleppa, Jeffrey Ketterling, Sarayu Ramachandran (Riverside Res. Inst., 156 William St., New York, NY 10038), Christopher Porter (Virginia Mason Medical Ctr., Seattle, WA), and Fernando Arias-Mendoza (Columbia Univ., New York, NY)

No reliable method of imaging prostate cancer currently exists. These prostate tissue-typing studies aim to improve the effectiveness of biopsy guidance and treatment monitoring by developing better imaging methods for identifying cancerous prostate tissue. Success will reduce the false-negative rate of biopsies and treatment side-effects. Ultrasonic (US) radio-frequency (rf) echo-signal data acquired during biopsy examinations were used to compute spectral parameters. These spectral parameters along with clinical parameters, e.g., PSA, were used to train a neural network classifier using biopsy results as the gold standard. Cancer-likelihood scores from a look-up table were used to generate tissue-type images (TTIs). The ROC-curve area for US neural-network-based classification was 0.844 $\pm$0.018 vs 0.638$\pm$0.031 for B-mode-based classification, and the sensitivity of neural-network based classification was superior to that of B-mode-guided biopsies. These classification methods are being extended to include magnetic-resonance spectral (MRS) techniques that use the choline to citrate ratio-to-distinguish cancerous from noncancerous prostate tissue. 3D renderings of prostatectomy histology, US, and MR images show encouraging correlations, and combining MRS parameters with US spectral parameters appears to have potential to further improve prostate-cancer imaging. [Work supported in part by NIH Grant CA053561.]

Session 2aED

Education in Acoustics: Hands-On Experiments for High School Students

Uwe J. Hansen, Chair
Indiana State Univ., Dept. of Physics, Terre Haute, IN 47809

Students and senior scientists will staff experiment stations for local high school students who will perform the experiments. These students will thus be exposed to a variety of acoustics principles and get some practical hands-on experience with a number of research tools. Regular ASA meeting participants are welcome to the session as long as their participation does not interfere with student hands-on activities.

Musical Acoustics: Scaling of Musical Intstrument Families

George A. Bissinger, Chair
East Carolina Univ., Dept. of Physics, Greenville, NC 27858

Chair's Introduction—8:25

Invited Papers

8:30

2aMU1. Violin octet scaling revisited. George Bissinger (Phys. Dept., East Carolina Univ., Greenville, NC 27858, bissingerg@mail.ecu.edu)

Schelleng employed only two major resonances to scale the violin to other pitch regions, creating the violin octet: the main air (now labeled A0) to be placed at $1.5x$ and the main wood (B1, actually two modes) to be placed at $2.25x$, the lowest string frequency. B1 employed flat-plate scaling and an empirical relationship between plate mode frequencies and B1. Experimental modal analysis of a complete octet showed flat-plate scaling for the corpus generally worked well, but A0 scaling was unreliable, even with postassembly modifications. Failure of the rigid-cavity Rayleigh relationship for A0 originated from an obvious major omission, cavity wall compliance, and one unobvious source, A0 coupling with the next higher cavity mode A1, which emerged much later via Shaw's network model. Incorporating wall compliance into Shaw's model greatly improved A0 and A1 predictions to within 10% over the octet. Acoustical analysis combined with patch near-field acoustical holography showed that A1, via induced corpus motion, was the most important radiator for the largest instrument in the main wood region and that the B1 modes, via net volume changes, can radiate significantly through the f-holes, two radiation mechanisms never considered in Schelleng's original scaling.

9:00

2aMU2. Violin octet scaling: The practical side. Robert J. Spear (The New Violin Family Assoc., 42 Taylor Dr., Wolfeboro, NH 03894)

Schelleng' scaling procedure attempts to place A0 at $\sim 1.5x$ and the first corpus bending modes at $\sim 2.25x$, the lowest string pitch. An experiment to move A0 into this position (also influencing A1), using the Stradivari model G as reference, helps produce the characteristic sound of the violin in cases where B1 placement was not optimum. The experiments suggest that the model G worked well for the signature modes of a classic violin, successfully scaling at least four instruments (mezzo, alto, tenor, and a small baritone), but that instruments at the extremes—treble and soprano at one end of the scale and both basses at the other—will likely require a refinement of the model G and placement of modes different from those of the reference violin and from each other. Scaling for acoustics and scaling for size are not the entire answer since ergonomic demands are often at odds with both. Geometrical scaling is essential for aesthetics and the uniform shape of the instruments, but it does not hold up well for rib heights, rib thicknesses, and cavity air volumes. This experiment suggests that significant latitude of air and wood mode placement exists within which good results can occur.

9:30

2aMU3. Practical issues in designing strings for different-sized bowed instruments. Fan-Chia Tao (J. D'Addario & Co., P.O. Box 290, Farmingdale, NY 11735, fan.tao@daddario.com)

The playing length and frequency of musical strings are fixed by the design of the instrument. The playing tensions of commercially available strings for standard bowed instruments follow an approximately linear scaling law in relation to string length. However, the string designer can adjust the playing tension to yield different results, and playing tensions have changed throughout history as string technology and playing techniques have evolved. Another string property that can be varied by the string designer is damping. Empirical data suggest that over a wide variety of bowed instruments and frequency ranges, strings with similar damping give similar playing characteristics.

10:00–10:15 Break

10:15

2aMU4. Scaling of reed instruments: The case of the saxophone family. Jean-Pierre Dalmont, Bruno Gazengel (Laboratoire d'Acoustique de l'Universit'e du Maine, 72085, Le Mans cedex 9, France, jean-pierre.dalmont@univlemans.fr), and Jean Kergomard (CNRS, Marseille Cedex 20, France)

The saxophone family is one of the most extended musical instruments family from the contrabass to the sopranino. The timbre of these instruments is unmistakable: there is a small probability to mix up a saxophone with an oboe or a bassoon. Now a question is: What is so specific in the timbre of the saxophones? Notes of various saxophones are recorded, analyzed, and compared with those of other instruments such as the oboe. More specifically, the transient duration and the formant frequency are determined. Then, the question which physical parameters influence the transient duration and the formants is studied. The influence of geometrical parameters such as the cone angle and the length of the cone truncation will be discussed.

10:45

2aMU5. Scaling of flutelike instruments : An analysis from the point of view of the hydrodynamic instability of the jet. Benoit Fabre, Nicolas Montgermont, and Johan Gabriels (Lab. for Musical Acoust., LAM, Paris 6 Univ., Paris, France)

The sound produced by musical instruments of the flute family is the result of the efforts of the instrument maker as well as those of the player. For instance, different instruments of a recorder consort show, on one hand, dimensions optimized by the maker for their individual compass as well as for a global identity and coherence of the whole consort. On the other hand, the players have to adapt their blowing to each instrument of the consort. Therefore, the study of the different instruments has to include the geometry given by the maker as well as the required blowing conditions. The study reported here presents data gathered on different flute families: the geometries and the instrument passive resonances are studied together with the behavior of the instruments under artificial blowing and, finally, under the control of a musician. The analysis of the data in terms of the jet hydrodynamic instability offers an efficient framework to describe the choices of the maker and the adaptation of the player.

Contributed Papers

11:15

2aMU6. A new family of stringed musical instruments. Sophie Léger and Samuel Gaudet (Dept. of Mathematics, Univ. de Moncton, Moncton, NB, E1A 3E9 Canada)

A new family of stringed musical instruments will be introduced. The Tritare™ is the first member of this new family and has evolved from the mathematical analysis of the vibrations of networks of strings [Gaudet *et al.*, J. Sound & Vib. **281**, 219–234 (2005)]. It is a guitarlike instrument that uses six networks of three string sections (Y-shaped networks) instead of the classical single strings. The sounds that it produces can be more or less harmonic depending on the string attack conditions and the physical configurations of the string networks. A method of customizing the frequency spectrum to contain desired harmonic components will be demonstrated. A numerical model, which uses finite differences, used to simulate the 3D nonlinear vibrations of more complex string networks involving several string sections and junction points will also be described. The harmonic analysis of the frequency spectra resulting from the numerical simulations and experimental measurements will be presented, as well as network configurations which produce very unique and interesting tone colors. Some of these configurations form the basis for a new family of stringed musical instruments. The presentation will include a demonstration of the Tritare™.

11:30

2aMU7. Scaling of brasswind instruments. Robert W. Pyle, Jr. (11 Holworthy Pl., Cambridge, MA 02138, rpyle@post.harvard.edu) and Arnold Myers (Univ. of Edinburgh, Edinburgh EH8 9AG, UK)

Consider two musically similar brasswind instruments pitched an octave apart, like trumpet and trombone. The steady-state tones of the trumpet, shifted downwards in pitch an octave by playing a recording at half speed, sound very similar to those of the trombone. The bore shape of the trumpet, however, is not a half-size dimensional replica of that of the trombone. The trumpet bell is about half the size of the trombone bell, but the narrower parts of the trumpet are considerably more than half the diameter of the corresponding parts of the trombone. Acoustic impedance measurements show the Q of air-column resonances to be similar in both trumpet and trombone. This is consistent with the dimensions of the instruments, combined with the dependence of viscous and thermal damping on tubing diameter and frequency. (Viscous and thermal damping dominate radiation damping throughout the normal playing range.) These observations suggest that a plausible scaling law for a family of brasswinds would preserve the pitch-shifted spectrum and the Q of the resonances across members of the family. How well (or poorly) brass makers follow this in practice will be shown from measurements of dimensions and acoustic input impedance on a variety of instruments.

Noise and Architectural Acoustics: Audio-Visual Design in Soundscapes I

Brigitte Schulte-Fortkamp, Cochair
Technical Univ. Berlin, Inst. of Technical Acoustics, Einsteinufer 25, 10587 Berlin, Germany

Bennett M. Brooks, Cochair
Brooks Acoustics Corporation, 27 Hartford Turnpike, Vernon, CT 06066

Chair's Introduction—9:30

Invited Papers

9:35

2aNSa1. Soundscape measurement and analysis. Klaus Genuit (HEAD Acoustics GmbH, Herzogenrath, Germany) and Wade Bray (HEAD Acoustics, Inc., Brighton, MI 48116)

Soundscapes typically include a variety of sources, with individual and collective attributes (level, spectral structure, time structure, and perceived characteristics such as loudness, sharpness, fluctuation, and roughness). Relevant sound sources impinge on listeners from multiple directions and distances. Examples will be given of large differences between conventional and psychoacoustic values as a function of distance, and of multi-source summations. As an example, the subjective loudness difference for sound incidence over a small versus large solid angle for a constant sound pressure level and spectrum is known. Individual-source-relevant information, important in context, may be unrecognized unless spatial hearing is included in soundscape assessment. A demonstration of binaural versus monaural soundscape data acquisition, and subsequent analysis by both conventional and psychoacoustic measures considering human perception including time dependency, will be given. Evidence will be presented for considering human hearing not only in the analysis, but also in the acquisition.

9:55

2aNSa2. Soundscape measurement in an urban area. Brigitte Schulte-Fortkamp (TU-Berlin, Einsteinufer 25, 10587 Berlin, Germany)

This presentation is about a demonstration of soundscape evaluation of an urban area with respect to measurements and interviews. In a recent field study in Berlin, indoor and outdoor measurements were carried out in a residential area in which inhabitants were complaining about noise and vibration due to heavy traffic over day and until late at night. In this context, the question of the appropriate positioning and calibration of the measuring devices in indoor and outdoor measurements was very important. The measurement procedure as well as procedures which determine how to conduct interviews will be described and discussed by taking into account how to make progress in measuring soundscapes. Moreover, the focus will be on necessary contributions to a measurement which usually deals with dB(A) and lacks psychoacoustical measuring factors.

10:15

2aNSa3. Traditional measurement methods for characterizing soundscapes. Bennett M. Brooks (Brooks Acoustics Corp., 27 Hartford Turnpike, Vernon, CT 06066, bbrooks@brooksacoustics.com)

A soundscape may be defined as the acoustical environment at an outdoor location. The physical sound occurring at the location may be from natural or man-made sources, or both. Perception of the soundscape can provide comfort and needed information to the listener, or may be annoying. The existing soundscape may be subject to design modifications for a variety of purposes. The goal could be to protect or enhance some sounds, such as the laughter of children and chirps of wildlife in a park, or the speech in an amphitheater. Conversely, the goal may be to reduce or eliminate unwanted sounds, such as transportation or industrial noise. Engineering and aesthetic soundscape design may proceed based on the characterization of the acoustical environment. The soundscape can be characterized by a number of measured acoustical parameters. Traditionally, these parameters have included A-weighted sound level, spectral content, sound-level statistics and averages, alone or in combination, and sound-level time history. Listener perceptions and nonacoustical parameters, such as time of day or year, community relevance, and listener attitudes may also be applied to soundscape characterization and design. Examples of several different soundscapes, their characterizations, and proposed design modifications will be discussed.

10:35

2aNSa4. Documenting visual context for soundscapes. Tim Lavallee (LPES, Inc., 14053 Lawnes Creek Rd., Smithfield, VA 23430), Vincent Catania (38 Temple St., Boston, MA 02114), and Robert Kull (Parsons, Norfolk, VA 23502)

There are several considerations to make when documenting a given soundscape. Not only is the technical sound information important, but the space, receptor, and visual context are important as well. This is primarily important in furthering the ability of sound and soundscape professionals to communicate with architects, planners, and other engineers—and vice versa. A portable digital

recording system was assembled and used along a high-end digital camera to document a range of soundscapes. These tests were preformed in urban, suburban, and rural areas at different times and in different contextual settings. Both visual and audio information of a locale were documented. Although this method can be simple or complex, the combination of these two components highlights the human factors that are present for a given soundscape. This will be a discussion of the portable equipment and a presentation of sound recordings, spectra, and photographs of a range of soundscapes. The variety and complexity of soundscapes and the benefits of visual clues to add depth to a given documentation effort will be highlighted.

10:55

2aNSa5. Soundscape analysis and acoustical design strategies for an urban village development. Youngmin Kwon, Pattra Smitthakorn, and Gary W. Siebein (Architecture Technol. Res. Ctr., School of Architecture, Univ. of Florida, 134 ARCH, P.O. Box 115702, Gainesville, FL 32611, ymkwon@ufl.edu)

Overall establishment of an acoustical landscape (soundscape) would be the fundamental source of sonic information that is useful in initiating urban design and planning strategies. A soundscape analysis was conducted in conjunction with an urban transportation and community design project targeting the western section of Gainesville, FL. The community was acoustically characterized and analyzed by means of quantitative measurements and qualitative assessments by observation. The measurements included instantaneous, 1-min short-term and 24-h long-term measurements. The parameters involved in these measurements are A-weighted average Lp, Leq, Lmax, Lmin, and LDN. The overall sonic environment of the community as well as the types of sounds that are desirable and noises that are not desireble in the existing and future contexts were identified. The results showed that the community was dominated mostly by traffic noise from several major thoroughfares and by occasional fire alarm noise. Finally, methods or strategies to reduce, buffer, and mitigate the undesirable sounds and to preserve the desirable sounds were suggested. The addition of new characteristics to the soundscape, such as people activity sounds and ''natural'' sounds, were also proposed. The application of acoustical urban design strategies to the specifically proposed urban transportation design plans was further analyzed.

11:10

2aNSa6. Territoriality and sound delimitation of urban space. Cobis Rabah Derbal and Hamza Zeghlache (BP 12 SMK, Constantine 25003, Algeria, cobis.derbal@free.fr)

Whether the urban space is physically materialized or abstracted it is often delimited by perceptive and sociocultural relations. In the present methodological approach, urban space is supposed to be modulated in its delimitation by qualitative and quantitative criteria of its noise environments. This introduces clearly the concept of sound delimitation and of noise environment territoriality. One can notice that sound phenomena are very present and are marking the social practice and behavior in urban spaces and give them a very specific sonority. Just like the visual or sociocultural aspects, the sonority of the public place or the urban noise environment marks their territoriality and spatiality by creating a whole sound environment characteristic of dimensions and forms of the space. The urban noise can thus be an element of marking, connecting, breaking, or structuring spaces which are morphologically and visually irreconcilable. One can speak about sound delimitation of urban space beyond its morphological limits. That delimitation can well articulate the social practice of urban space to its dimensional aspect. The study put out the concept of acoustic space in opposition to morphological space which it is inevitably necessary to reconcile in order to better practice the urban space.

11:25

2aNSa7. Recomposition of the urban sonic environment. Cobis Rabah Derbal and Hamza Zeghlache (BP 12 SMK, Constantine 25003, Algeria, cobis.derbal@free.fr)

Acoustics-related considerations are taken to be secondary in most of the design processes of public places. This fact always leads to an unpredictable noise and urban sonic environment around such spaces. Studies have shown the importance of the noise and the quality of the urban sonic environment in the social practice and in the daily use of public places. These places strongly mark the degree of dynamism of the urban structure of our cities and are often subjected to a very complex situation of noise nuisance. The main aim of the study is to introduce a source of noise that might have an effect of recomposing positively a deficient sonic environment of such places. This approach is also to try to restore the sound in its utilitarian and practical function and to articulate the perception of the spatial and temporal aspects of the public place. It could be an element of transforming urban noise into a peaceful soundscape. A fountain turned out to be that sonic source and it can be easily introduced in the urban environment around the public places. It is a sort of urban instrumentation used in order to recompose or requalify an urban noise environment.

11:40–12:00
Panel Discussion

12:30
Session participants meet in room 554AB for experimental field measurements

1:00–3:00
Experimental field measurements conducted

Note: Panel discussion will be held in Session 2pNSb at 3:00 p.m.

Noise, Education in Acoustics, Engineering Acoustics, and Architectural Acoustics: Essential Acoustical Curriculum for Noise Control Techniques for Engineers, Industrial Hygienists, and Architects

William J. Murphy, Cochair
NIOSH, 4676 Columbia Pkwy., Cincinnati, OH 45226-1998

Ralph T. Muehleisen, Cochair
Illinois Inst. of Technology, Civil and Architectural Engineering, 3201 S. Dearborn, Chicago, IL 60616

Chair's Introduction—8:50

Invited Papers

8:55

2aNSb1. Essential elements of acoustical curricula for noise control engineers. Robert J. Bernhard (Ray W. Herrick Labs., Purdue Univ., 140 S. Intramural Dr., West Lafayette, IN 47907, bernhard@purdue.edu)

Because the supply of noise control and acoustical engineers is small, many of the noise control practitioners practicing in general mechanical engineering fields are retrained on the job. These practitioners are often capable in the area in which they are mentored but lack sufficient background to move to new areas. In order to address a broad range of noise control issues, an engineer must be comfortable to work in waves, or modes, or dBese (engineering controls). The essential curriculum for engineering practitioners would include a foundation in each of these approaches as well as the analytical, computational, and experimental background upon which to build engineering solutions. This presentation will include discussion of how these objectives can be met at the undergraduate level, at the graduate level, and through continuing education.

9:25

2aNSb2. The need for an essential acoustics curriculum and its delivery via distance education. Victor W. Sparrow, Anthony A. Atchley, Karen P. Brooks, and Gerald C. Lauchle (Grad. Program in Acoust., Penn State, 214 Appl. Sci. Bldg., University Park, PA 16802, vws1@psu.edu)

Many individuals have identified a need to better educate engineers, industrial hygienists, and architects with an essential acoustical curriculum including noise control techniques. There are less than a dozen major programs training these individuals, and demand far exceeds the supply of education suppliers. One effective method of providing education to busy professionals who otherwise would not be exposed to an essential curriculum is distance education. Approximately 10 years ago Penn State developed a series of noise control engineering courses delivered through CD-ROM. Now with DSL and cable modems more common, full motion video streaming is a preferred delivery method. Students currently take graduate level courses in acoustics at Penn State via resident education, continuing education, and distance education. There is no reason why an essential acoustical curriculum could not be delivered similarly. One benefit of video streaming is an opportunity for both live and archived lecture material. Students can attend live recitation sections while retaining the ability to see archived material on demand. Technology such as high-bandwidth connections, inexpensive webcams, and microphones also allows two-way audio and video for direct student-instructor interaction.

9:55

2aNSb3. The acoustical education of an architect. Gary Siebein (School of Architecture, Univ. of Florida, 625 NW 60th St., Ste. C, Gainesville, FL 32607)

Sound can provide valuable contributions to the education and practice of architecture. First, architecture students should develop a theory of how sound and other environmental systems can become part of a larger theory of the making of architecture. Second, architects are trained to have highly developed sensibilities in the aesthetic design of space. Expanding the aesthetic component of buildings and environments to include the aural environment has the potential to enrich the fabric of communities and buildings. Third, architecture students must become acquainted with the materials, analytic techniques, and design approaches that acoustical consultants use. Furthermore, for acoustical information to become an integral part of architectural design and education, it must be organized in a way that allows expression or poesis to occur because these aesthetic principles are the building blocks of architectural design. Therefore, the science and engineering principles of noise control and architectural acoustics must be transformed into material that can become spatial, visual, and manipulable in creative ways by a design team. This requires that the basics of acoustics be reformulated in an architectural manner. This paper will address several of the transformations that have been attempted in the architectural curriculum at the University of Florida.

10:25–10:40 Break

10:40

2aNSb4. Acoustics curriculum for architectural engineers. Ralph T. Muehleisen (Civil and Architectural Eng., Illinois Inst. of Technol., 3201 S. Dearborn, Chicago, IL, 60616, muehleisen@iit.edu)

As building design and technology increase in complexity, the need to consider acoustics in the design also increases. For decades, architects have relied on engineers for the design of structural, mechanical, electrical, and lighting systems of buildings, and are increasingly relying on engineers for the design of high-efficiency building enclosures and natural lighting systems. At the same time, building systems have become increasingly integrated, and good design of the building systems requires a very interdisciplinary education. These needs have given rise to the formal discipline known as architectural engineering (AE). With education in architecture, structures, building systems, and construction management, the architectural engineer is uniquely qualified to begin a career as an acoustical consultant. There are now over a dozen ABET-accredited AE programs throughout the country and most offer at least some education in architectural acoustics and noise control. In this talk, the requirements of an acoustics education for architectural engineers are outlined and the curriculum of several AE programs is presented.

11:10

2aNSb5. Industrial noise control engineering principles and standard practices applicable to engineers and industrial hygienists. Robert R. Anderson (James, Anderson & Associates, Inc., 2123 University Park Dr., Ste. #130, Okemos, MI 48864)

Industrial organizations have accepted the notion that noise control is no longer 100% of one person's responsibility, but a collaborative effort among engineers and industrial hygiene professionals. Proven noise control measures exist and are commercially available for many industrial noise sources. There are also noise control concepts and techniques that can be adopted by maintenance and other personnel as standard practices. Awareness of the elements of noise control engineering can offer benefit in areas such as equipment procurement, workplace risk assessment, and manufacturing program planning. The focus of this presentation is to discuss the elements of noise control engineering that manufacturing engineers and industrial hygiene professionals would need to apply out of their university education into practice, and the benefits that would be derived from this information.

Physical Acoustics: Outdoor Sound Propagation

Richard Raspet, Cochair
Univ. of Mississippi, National Ctr. for Physical Acoustics, Coliseum Dr., University, MS 38677

James P. Chambers, Cochair
Univ. of Mississippi, National Ctr. for Physical Acoustics, Coliseum Dr., University, MS 38677

Contributed Papers

9:00

2aPA1. Ground-to-ground sound propagation in cloud-topped boundary layers over land. Roger Waxler, Carrick L. Talmadge, and Kenneth E. Gilbert (NCPA, University, MS 38677)

Sound propagation under cloud-covered skies is discussed. Observations are presented which suggest that under dense cloud cover ground-to-ground sound propagation is dominated by a single mode similar to the classic surface mode for outdoor sound propagation. A theory of sound propagation under cloud covered skies has been developed. It is shown that there is a sound duct centered in the cloud layer. Of the modes in this duct a small number (typically one or two for frequencies up to a few hundred Hz) of ground interacting modes, modes whose amplitudes on the ground are significant, are identified. Over land, one of the ground-interacting modes can be identified with the surface mode.

9:15

2aPA2. A continuously cascaded conformal mapping for sound propagation over irregular terrain. Santosh Parakkal, Kenneth E. Gilbert, and Di Xiao (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, Coliseum Dr., Universtiy, MS 38677)

The so-called earth flattening conformal mapping is a common approach for radio wave propagation over a spherical earth. Applied sequentially (cascaded), it can be used to represent a series of hills, each of which has a constant radius of curvature. We show that the mapping can also be applied to general terrain that has a continuously varying radius of curvature. In the mapped coordinates, the terrain is flat, but the mapped sound speed is $c/\sqrt{J}$, where c is the actual sound speed and J is the Jacobian of the transformation. The continuously cascaded mapping method is outlined, and numerical comparisons are made with a well-tested nonconformal mapping method.

9:30

2aPA3. The absorption of sound on Mars using the direct simulation Monte Carlo. Amanda D. Hanford and Lyle N. Long (Grad. Program in Acoust., The Penn State Univ., University Park, PA 16802, ald227@psu.edu)

The physical properties that govern the absorption of sound on Mars are very similar to those on Earth: classical losses associated with the transfer of acoustic energy into heat, and relaxation losses associated with the redistribution of internal energy of molecules. The difference in molecular composition between Earth and Mars as well as the lower atmospheric pressure on Mars results in larger values for the absorption coefficient on Mars. The direct simulation Monte Carlo (DSMC) method is the simulation tool used for modeling sound propagation in the Martian atmosphere. DSMC describes gas dynamics through direct physical modeling of particle motions and collisions. DSMC is based on the kinetic theory of gas dynamics, where representative particles are followed as they move and collide with other particles. The validity of DSMC for the entire range of Knudsen numbers (Kn), where Kn is defined as the mean free path divided by the wavelength, allows for the exploration of sound propagation in the Martian atmosphere for all values of Kn. Successful application of the DSMC method to acoustic waves in the Martian atmosphere, including the details of molecular relaxation in gas mixtures, will be shown. [Work supported by NASA.]

9:45

2aPA4. Correlation functions of temperature and velocity fluctuations in a turbulent atmosphere. Vladimir E. Ostashev (NOAA/Earth System Res. Lab., Boulder, CO 80305 and Dept. of Phys., New Mexico State Univ., Las Cruces, NM 88003), Sergey N. Vecherin (New Mexico State Univ., Las Cruces, NM 88003), D. Keith Wilson (U.S. Army Engineer. Res. and Development Ctr., Hanover, NH 03755), and Sandra L. Collier (U.S. Army Res. Lab., Adelphi, MD 20783-1197)

von Kármán spectra of temperature and velocity fluctuations are widely used in theories of turbulence and wave propagation in random media, including sound propagation through a turbulent atmosphere. They are probably the simplest generalization of the Kolmogorov spectrum of homogeneous and isotropic turbulence which accounts for the outer scale of turbulence. However, the correlation functions of temperature and velocity fluctuations corresponding to the von Kármán spectra are proportional to the modified Bessel functions and are rather involved. In this paper, we propose to use much simpler correlation functions of temperature and longitudinal velocity fluctuations whose dependence on the distance R between observation points is given by $\exp(-R^{2/3}/L^{2/3})$, where L is the outer length scale. It is shown that the spectra of the proposed correlation functions coincide with the Kolmogorov spectrum in the inertial subrange and are bounded in the energy subrange. For some problems, the proposed correlation functions can simplify analysis of sound propagation through a turbulent atmosphere. Examples of the use of these correlation functions in acoustic tomography of the atmosphere and calculations of the coherence function of a sound field are presented. [Work supported by ARO, Grant DAAD19-03-1-0104.]

10:00

2aPA5. Upward propagation of nonlinear sound and magnetic sound in the atmosphere. Lev Ostrovsky (Zel Tech/NOAA ESRL, R/PSD4, 325 Broadway, Boulder, CO 80305)

As is known, even relatively weak ground-level perturbations (earthquakes, tsunami, explosions) may cause very significant displacements in upper atmospheric layers where the gas density is small. It results in shock formation and subsequent rapid dissipation of wave energy. This presentation deals with the upward propagation of a short, finite-amplitude wave in atmosphere with exponentially decreasing density, including areas where the magnetic pressure prevails, and the acoustic energy is transformed to that of fast and/or slow magnetic sound. The height of shock formation is determined, and the wave attenuation due to shocks is described. Propagation from a localized source is also discussed. Some estimates are given.

10:15–10:30 Break

10:30

2aPA6. Effect of longitudinal coherence on angle-of-arrival estimation in atmospheric turbulence. Sandra Collier (U.S. Army Res. Lab., AMSRD-ARL-CI-ES, 2800 Powder Mill Rd., Adelphi, MD 20783-1197, scollier@arl.army.mil), Vladimir Ostashev (NOAA/Earth System Res. Labs., Boulder, CO 80305), and Keith Wilson (U.S. Army Engineer Res. and Development Ctr., Hanover, NH 03755)

A statistical model that accounts for the effects of atmospheric turbulence on a received acoustic signal has been previously developed [Collier and Wilson, J. Acoust. Soc. Am. **113**, 2704–2718 (2003)]. It was used in calculations of the performance bounds, and of a maximum likelihood estimator (MLE), for the angle of arrival (AOA) of an acoustic signal received at an array operating in atmospheric turbulence with fluctuations described by a von Karman spectrum. This statistical model is based on the moments of a sound field as derived in the theory of wave propagation in a random medium (WPRM) [Ostashev, *Acoustics in Moving Inhomogeneous Media* (E&FN Spon 1997)]. In this model, an approximation to the second moment was used based on the transverse coherence from WPRM. Recently, the longitudinal coherence has been derived for WPRM [Ostashev *et. al*, 151st, Meeting of the Acoustical Society of America (2006)]. We examine limiting cases to determine the effects of the longitudinal coherence on the MLE and Cramer-Rao lower bound of the AOA.

10:45

2aPA7. The coherence function of a sound field propagating in a turbulent atmosphere. Vladimir E. Ostashev (NOAA/Earth System Res. Lab., Boulder, CO 80305 and Dept. of Phys., New Mexico State Univ., Las Cruces, NM 88003), Sandra L. Collier (U.S. Army Res. Lab., Adelphi, MD 20783), and D. Keith Wilson (U.S. Army Engineer. Res. and Development Ctr., Hanover, NH 03755)

The coherence function of a sound field propagating through an atmosphere with temperature and wind velocity fluctuations is important for many practical applications involving microphone arrays. In the literature, the transverse coherence function has been studied in detail, when acoustic sensors are located in a plane perpendicular to the sound propagation path. In this paper, for the case of line-of-sight sound propagation, a closed-form expression for the coherence function of a plane wave is derived for arbitrary location of acoustic sensors. Using this expression, for some limiting cases simple formulas for the coherence function are obtained which are valid for arbitrary spectra of turbulence. Furthermore, the coherence function is calculated and analyzed in detail for the Gaussian and von Kármán spectra of temperature and wind velocity fluctuations. In particular, the longitudinal coherence radius, when acoustic sensors are located along the sound propagation path, is calculated. It is also shown that contours of the coherence radius are elongated perpendicular to this path for relatively small propagation distances, and along it for large distances.

11:00

2aPA8. Measurements of acoustic and seismic pulses from outdoor explosions. Donald G. Albert (ERDC-CRREL, 72 Lyme Rd., Hanover, NH 03755), Keith Attenborough, and Patrice Boulanger (The Univ. of Hull, Hull HU6 7RX, UK)

Measurements of the ground vibrations produced by airborne detonations of C4 were conducted at locations with a variety of ground types, including concrete, soil, forest, tropical vegetation, and snow cover. The measurements show that, although two separate seismic (ground vibrational) arrivals can be detected in all cases, the early seismic arrival from an underground path is always much smaller than the vibration induced by the air blast arrival. The acoustic-to-seismic coupling ratio for the atmospheric wave is a constant with respect to distance and peak pressure at a given location, but varies from site to site, usually between 1 and 14 μm/s/Pa. A conservative empirical equation to predict ground vibration from explosions is derived. This equation predicts that the commonly used

vibrational damage criteria of 12 and 25 mm/s will be exceeded when the peak positive pressure exceeds 480 Pa (147.6 dB) or 1 kPa (154.0 dB), respectively. Either of these levels is much higher than the Army overpressure damage criterion of 159 Pa (138 dB). Thus in most situations damage from blast overpressure will occur long before damaging levels of ground vibration are reached. [This research supported by the U.S. Army Corps of Engineers and SERDP Seed Project SI-1410.]

11:15

2aPA9. Comparison of high-frequency measurements of blast wave propagation to computational model predictions. Alexandra Loubeau and Victor W. Sparrow (Grad. Prog. Acoust., Penn State, 202 Appl. Sci. Bldg., University Park, PA 16802, aloubeau@psu.edu)

In November 2005, the latest in a series of blast wave propagation experiments was conducted with the U.S. Army. Blast waveforms measured with a wideband microphone [W. M. Wright, ONR Report NR-384-321 (1971)] had shorter rise times than those captured with conventional $\frac{1}{8}$ -in. microphones. This indicates that the $\frac{1}{8}$-in. microphone setup did not have the high-frequency bandwidth needed to capture such short rise times. The trend observed is that nonlinear effects steepen the waveform, thereby decreasing the shock rise time, up to a range of 50 m. At 100 m, the rise times had increased slightly, but they were still shorter than they were at 25 m. The experimental results are compared to predictions from a computational model. The model, based on the Pestorius/Anderson hybrid time-frequency domain algorithm, accounts for nonlinearity, geometrical spreading, thermoviscous absorption, and absorption and dispersion due to molecular relaxation. It is found that the model predicts shorter rise times than what was measured with the wideband microphone, but the rise-time variation with range is similar. Atmospheric turbulence present in the experiments, but not accounted for in the model, is a likely cause for the difference in rise times. [Work supported by U.S. Army ERDC CERL.]

11:30

2aPA10. The use of Lorentz transformations for simplifying aeroacoustic boundary value problems. M. H. Dunn (Natl. Inst. of Aerosp., 100 Exploration Way, Hampton, VA 23666, mhd314@aol.com)

The prediction of community noise from aircraft flyovers is computationally complex when arbitrary aircraft configurations are subjected to realistic flows. Mathematically, the problem is described by a set of scattering surfaces (wings, nacelles, and fuselage) moving uniformly with known noise sources in the presence of an inviscid, irrotational, background flow. A four-dimensional (space-time) boundary value problem (BVP) for noise propagation and scattering is defined by the mass and momentum conservation equations along with appropriate hard- or soft-wall boundary conditions on the scattering surfaces and the Sommerfeld radiation condition. This system is augmented by the appropriate Kutta conditions for geometry with edges to produce a uniquely solvable BVP. The governing differential equations are complicated by factors strongly dependent upon the flow field. However, Lorentz transformations can be used to define new independent and dependent variables such that the differential equations depend on the local sound speed plus terms that involve flow gradients. Neglecting flow gradient terms produces the classical wave equation BVP, which can be solved using contemporary numerical methods. The original acoustic variables are easily recovered via the inverse Lorentz transformation. In addition, the formulation can be used to analyze physical conditions under which the uniform flow approximation is valid.

Session 2aPPa

Psychological and Physiological Acoustics: Loudness, Outer Hair Cells, and Otoacoustic Emissions

Walt Jesteadt, Chair
Boys Town National Research Hospital, 555 N. 30th St., Omaha, NE 68131

Contributed Papers

8:15

2aPPa1. A comparison of intensity discrimination and increment detection as measures of intensity resolution. Walt Jesteadt, Jessica Messersmith, Lori Leibold, Samar Khaddam, and Hongyang Tan (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

Intensity resolution can be measured by determining the threshold for discrimination of two stimuli differing only in intensity or by determining the threshold for detection of an increment in a longer duration stimulus. Better resolution has been reported for the latter task, but the results are inconsistent across conditions and subjects. In the present study, data were obtained for the two tasks in a range of conditions for 12 adult subjects with normal hearing. Thresholds for intensity discrimination and increment detection were measured for a 4000-Hz tone presented at 20, 40, 60, or 80 dB SPL, using a two-track adaptive procedure that estimated levels required for 71% and 89% correct. The increment was 20, 40, 80, or 160 ms in duration. The pedestal was either the same duration as the increment or was 200 ms longer, centered on the increment. Thresholds expressed in units of delta L were more uniform across subjects and conditions for increment detection than for intensity discrimination. Thresholds were lower on average for increment detection than for intensity discrimination at pedestal levels above 20 dB, but only at the shorter increment durations, and thresholds were not consistently lower for all subjects. [Work supported by R01 DC006648.]

8:30

2aPPa2. Primary speech frequencies: Adaptation inside versus outside—Inhibition or excitation? Ernest M. Weiler, David E. Sandman (Dept. Of Commun. Sci., Univ. Cincinnati, Cincinnati OH 45267), and Joel S. Warm (Univ. Cincinnati, Cincinnati, OH 45267)

Previously, loudness adaptation from the ipsilateral comparison paradigm (ICP) and the simple adaptation (SA) procedure were compared at primary speech- related frequencies (250 to 4000 Hz), with only the ICP showing significant loudness decline/adaptation [Tannen *et al.*, J. Gen Psychol. **128**, 385–399 (2001)]. Eighty naive undergraduates participated in any one of three subsequent studies of ICP versus SA adaptation. In agreement with Tannen *et al.*, only the ICP showed significant loudness decline/adaptation from 250 to 6000 Hz. However, at 8000 Hz both the ICP and SA show significant adaptation, and correlate significantly. However, despite the lack of correlation between individual scores under 8000 Hz, a further analysis of *group mean* values from 250 to 8000 Hz showed a significant correlation ($r=0.97$, $p<0.001$). Perhaps the SA procedure shows a lack of adaptation at speech frequencies because the method is insensitive. Alternatively, it may be considered that a ''stable platform'' [i.e., no adaptation for *constant* stimuli] favors the perception of the constantly varying speech signals. Support for the ''stable platform'' versus the ''insensitivity'' hypothesis will be discussed.

8:45

2aPPa3. Induced loudness reduction as a function of frequency separation. Jeremy P. Marozeau, Michael Epstein, and Mary Florentine (Commun. Res. Lab., Dept. of Speech-Lang. Pathol. and Audiol., Northeastern Univ., Boston, MA 02155, marozeau@neu.edu)

When a loud tone (inducer tone) precedes a softer tone (test tone), the loud tone can reduce the loudness of the softer tone. This phenomenon is called induced loudness reduction (ILR). The amount of ILR is greatest when the inducer tone and the test tone are presented at the same frequency. As the difference in frequency between the two increases, the amount of ILR decreases [Marks L. E., J. Exp. Psychol. Hum. Percept. Perform. **20**, 382–396 (1994)]. However, the exact course of this decrease with increasing frequency separation has not been thoroughly tested. In this experiment, the amount of ILR produced by a 2.5-kHz 80-dB-SPL inducer was measured from 800 Hz to 6 kHz using a frequency-sweeping test tone. Nine normal-hearing listeners matched the loudness of the test tone to a 70-dB-SPL 500-Hz tone using a tracking procedure. Average results show a maximum amount of ILR between 2.5 and 3 kHz, with a loudness reduction equivalent to 12 dB. This amount decreases with frequency separation, but is still significant when the frequency of the test tone is between 1.5 and 4.5 kHz, corresponding to more than nine critical bands. [Work supported by NIH/NIDCD Grant R01DC02241.]

9:00

2aPPa4. A multicompartmental cochlear model with piezoelectric outer hair cells. Shan Lu, David C. Mountain, and Allyn E. Hubbard (College of Eng., Boston Univ., 8 Saint Mary's St., Boston, MA 01720, slu@bu.edu)

A hydromechanical, multicompartment model of the cochlea, which employed a phenomenological outer hair cell (OHC) cell-body electromotility, was able to mimic the physiologically measured response of the basilar membrane (BM) [A. E. Hubbard *et al.*, "Time-domain responses from a nonlinear sandwich model of the cochlea," in *Biophysics of the Cochlea: From Molecule to Model*, edited by A. W. Gummer (World Scientific, Singapore)]. An improved model that included OHC electroanatomic parameters and scalar electrical parameters was able to mimic cochlear microphonic (CM) data at low frequencies, but not BM responses at high-frequencies, because the OHC membrane capacitance severely reduces OHC transmembrane potential. To improve the high-frequency performance, we used a piezoelectrical model of the OHC. Consequently, the mechanical loading of the OHC translates bidirectionally with the electrical impedance of the OHC. The new model compares well with physiological data from Gerbil at 40 dB SPL [T. Ren and A. Nuttall, "Basilar membrane vibration in the basal turn of the sensitive gerbil cochlea," Hearing Res. **151**, 48–60 (2001)]. [This work was supported by NIH.]

9:15

2aPPa5. Application of force to the cochlear wall: Effect on auditory thresholds, outer hair cell transduction, and distortion-product otoacoustic emissions. Greg A. O'Beirne[a] and Robert B. Patuzzi (The Auditory Lab., Physiol., School of Biomed. and Chemical Sci., Univ. of Western Australia, Crawley WA 6009, Australia)

Described are the changes in cochlear sensitivity and mechanoelectrical transduction during a novel cochlear perturbation: the application of force to the cochlear wall. While numerous methods exist to create *transient* shifts in the operating point of the outer hair cell (OHC) transducer, including low-frequency acoustic bias [G. Frank and M. Kössl, Hear. Res. **113**, 57–68 (1997)] and hydrostatic bias [A. N. Salt and J. E. DeMott, Hear. Res. **123**, 137–147 (1998)], attempts to create *prolonged* operating point shifts are largely thwarted by the numerous sources of ac coupling in the auditory system which prevent transmission of dc stimuli to the hair cells. The application of force sufficient to deform the otic capsule produced a consistent drop in neural thresholds and a sustained bias of the OHC operating point that did not rapidly adapt back to normal. Near-simultaneous measurements of compound action potential thresholds, distortion-product otoacoustic emissions, the OHC transfer curves derived from low-frequency cochlear microphonic waveforms, and the endocochlear potential were performed. The data provide ample evidence of the resistance of the cochlea to dc mechanical stimuli, particularly those which do not cause a large pressure differential across the basilar membrane. [The authors gratefully acknowledge the surgical assistance of Dr. Peter Sellick.] [a]Currently at Department of Communication Disorders, University of Canterbury, Christchurch, New Zealand.

9:30

2aPPa6. Influence of the sweeping direction of the primaries f_1 and f_2 in the assessment of distortion product otoacoustic emissions (DPOAEs) fine structure. Miguel Angel Aranda de Toro, Rodrigo Ordoñez, and Dorte Hammershøi (Dept. of Acoust., Aalborg Univ., Fredrik Bajers Vej 7 B5, DK-9220, Aalborg, Denmark, maat@acoustics.aau.dk)

It was studied if the sweeping direction of the primaries f_1 and f_2 influences fine structure measurements of the $2f_1-f_2$ distortion product otoacoustic emission (DPOAE). Two different methodologies named DPOAE5$_{ASC}$ (ascending sweep) and DPOAE5$_{DES}$ (descending sweep) were implemented with the commercial system ILO96. Both methods perform fine structure measurements in the same frequency range (1.4–6 kHz) with $L1/L2=65/45$ dB, $f_2/f_1=1.22$ and 0.7 s averaging time per primary presented. DPOAE fine structures were measured in the right ear of 14 normal-hearing subjects with both methods in a balanced experiment and without refitting the sound probe. Results showed that the two methods are highly repeatable and able to detect fine structures even in subjects with low S/N. However, when DPOAE5$_{ASC}$ measurements are compared with DPOAE5$_{DES}$, fine structures appear shifted and the level contour is altered. A minor level difference was inadvertently induced due to differences in the level calibration procedure of the two methods employed. The significance of this is currently being studied. [Work supported by the Danish Research Council for Technology and Production.]

Invited Papers

10:15

2aPPb1. Individual susceptibility to noise-induced hearing loss: A review. Donald Henderson (Ctr. for Hearing and Deafness, State Univ. of New York at Buffalo, 137 Cary Hall, Buffalo, NY 14214)

After 40+ years of study, we can conclude that there is a great range of individual differences in susceptibility to noise-induced hearing loss (NIHL). The presentation will review and evaluate the major sources of variances: *acoustic*, where all exposures are evaluated with dBA and some energy-related metric; *exogenous*, where the effects of noise can be mitigated by external factors such as temperature, coexposure to chemicals, smoking, etc.; *endogenous*, where the effects of noise are partially related to an individual's sex, skin color, acoustic reflex, distortion product suppression, degree of fatigue, and genetic factors.

10:45

2aPPb2. Searching the whole genome to identify genes contributing to noise resistance in inbred mouse strains. Bruce L. Tempel, Valerie A. Street (Dept. of Otolaryngol.-HNS and the V.M. Bloedel Hearing Res. Ctr., Univ. of Washington, Seattle, WA 98195-7923, bltempel@u.washington.edu), and Sharon G. Kujawa (Harvard Med. School, Boston MA)

Toward understanding the biological basis of noise resistance and eventual formulation of therapies to prevent noise-induced hearing loss (NIHL), the identification of genes contributing to noise resistance is a critic step. To simplify our whole genome search, we chose to study isogenic, inbred strains of mice. When exposed to noise (octave band 8–16 kHz, 103 dB SPL, 2 h) the good-hearing CBA/CaJ strain showed ~50-dB thresho shift measured 2 weeks postexposure; in contrast 129S6 mice showed ~10-dB shift. Through directed breeding schemes we showed that the noise resistance trait in 129S6 is recessive to CBA. Screening N2 backcross animal for noise resistance suggested a multigenic pattern of inheritance with 4 to 6 genes contributing. Quantitative trait locus (QTL) mapping of 234 N2 animals reveals 4 different chromosomal regions that contribute significantly to the resistance. Congenic strains carrying only one or two of these QTL regions are currently being bred, with the expectation that these strains will show partial noise resistance. Further studies including ancestral haplotype analysis and differential gene expression array analysis will allow us to narrow the contributing genomic regions and identify specific genes contributing to noise resistance. [Work supported by NIH.]

11:05

2aPPb3. Can otoacoustic emissions indicate susceptibility to noise-induced hearing loss in individual ears? Lynne Marshall, Judi A. Lapsley Miller (Naval Submarine Medical Res. Lab., Groton, CT 06349-5900, marshall@nsmrl.navy.mil), and Laurie M. Heller (Brown Univ., RI 02912)

Otoacoustic emissions (OAEs) can potentially be used to identify normal-hearing individuals who are susceptible to imminent noise-induced hearing loss. Until now, there has been no way to monitor an individual's susceptibility dynamically as it varies due to physiological and environmental factors. Although it is known that groups of normal-hearing noise-exposed people have lower than average levels of OAEs, such data have never been used to predict future hearing loss in the same individuals. Here, we discuss two studies where the OAEs and hearing thresholds of individuals were measured before and after hazardous noise exposure. Individuals with normal hearing and low-level or absent OAEs at baseline were at increased risk for acquiring noise-induced hearing loss after the noise exposure. This supports the theory that OAEs can reflect incipient inner-ear damage undetected by standard behavioral hearing tests. Furthermore, OAE efferent strength measures may be predictors of NIHL in humans. The animal data are promising, but developing an efficient OAE test that reliably distinguishes a strong efferent reflex from a weaker one in humans is challenging. [Work supported by ONR & USAMRMC].

11:25

2aPPb4. Noise-induced and age-related hearing loss interactions. Sharon G. Kujawa (Dept. of Otology and Laryngology, Harvard Med. School, and Dept. of Audiol., Massachusetts Eye and Ear Infirmary, 243 Charles St., Boston, MA 02114) and M. Charles Liberman (Massachusetts Eye and Ear Infirmary, Boston, MA 02114)

Noise-induced hearing loss (NIHL) and age-related hearing loss (AHL, or presbycusis) are widespread health problems that will continue to increase as our society ages. NIHL and AHL often coexist in the same ear; however, the conditions under which they interact and the mechanisms by which they do so remain poorly understood. Inspired by epidemiological studies suggesting that noise-exposed ears age *differently* from nonexposed ears [Gates *et al.*, ''Logitudinal threshhold changes in people with audiometric notches,'' Hear. Res. **141**, 220–228 (2000)], we studied interactions between NIHL and AHL in mouse; an animal with a short life span, with intrastrain genetic homogeneity to minimize variability and with interstrain differences in vulnerability which can be exploited to probe mechanisms. Using such models, we have uncovered evidence that early noise exposure can have an ongoing influence on the nature and progression of an age-related hearing loss. The nature of this age-related hearing loss exacerbation is special; it can occur even in ears without permanent threshold shifts from the noise and leads to massive loss of spiral ganglion neurons despite intact hair cell populations. Findings have practical importance for investigations of NIHL in animal models, and may have implications for clinical practices allocating noise-induced and age-related components of hearing loss as strictly additive. [Work supported by NIH.]

2aPPb5. Hearing levels in US adults aged 20–69 Years—National Health and Nutrition Examination Survey (NHANES) 1999–2004. William J. Murphy, Christa L. Themann, and Mark R. Stephenson (Hearing Loss Prevention Team, Natl. Inst. for Occupational Safety and Health, 4676 Columbia Pkwy., MS C-27, Cincinnati, OH 45226-1998)

The National Health and Nutrition Examination Survey (NHANES) is a nationally representative, population-based survey designed to assess the health and nutritional status of the civilian, noninstitutionalized U.S. population. Data were collected through a personal interview regarding health history and through physical examination. Earlier NHANES surveys were conducted on a periodic basis; however, in 1999, NHANES began collecting data on a continuing, annual basis. During NHANES I, which ran from 1971 to 1975, audiometric testing was conducted on adults aged 25–74 years. No subsequent testing of adults was conducted in the NHANES program until 1999, when NHANES began audiometric testing of adults aged 20–69 years. In 2004, the sampling from this age group was completed. This report examines the hearing levels for adults in the United States and compares them with the hearing data from NHANES I. Hearing levels are grouped by age and by ethnicity and gender.

8:20

2aSC1. Defining and enhancing attributes for features. Kenneth N. Stevens (Res. Lab of Elec., Dept. EECS, & Div. Health Sci. & Tech, MIT, Cambridge, MA 02139, stevens@speech.mit.edu)

We take the view that words are represented in memory as sequences of bundles of binary distinctive features. It is further assumed that each feature is defined by a quantal relation between an articulatory attribute and a corresponding acoustic property that provides acoustic cues to the feature. In the speaking process, other acoustic properties are introduced in addition to the defining acoustic attributes, and these contribute additional cues that enhance the perceptual saliency of the feature. For example, the defining attributes for the voicing feature is the presence or absence of glottal vibration during an obstruent consonant, but there are several possible enhancing properties, such as the presence of aspiration noise and a modified fundamental frequency in the following vowel. In running speech, the saliency of a feature may be in jeopardy, especially when there is interfering noise or when gestural overlap weakens some of the cues, particularly those derived from the defining gesture for the feature. An example is the casual production of batman where the closure for /t/ may be eliminated by gestural overlap, but two enhancing gestures ($F2$ transition for the alveolar and the glottalization for /t/) are preserved. [Work supported in part by NIH Grant DC00075.]

8:40

2aSC2. Is some information perceptually primary? John Kingston (Ling. Dept., Univ. of Massachusetts, Amherst, MA 01003-9274, jkingston@linguist.umass.edu) and Randy Diehl (Univ. of Texas, Austin, TX 78712)

The existence of multiple correlates for phonological contrasts invites the hypothesis that one is perceptually primary and that the others enhance the primary correlate. (Stevens Acoustics Phonetics, MIT Press, 1998) particularly emphasizes the perceptual primacy of acoustic landmarks. Our experiments manipulate the quality or variability of the acoustic information in a landmark versus a neighboring nonlandmark to determine whether listeners rely on the landmark or the most reliable information source. Stimuli are synthetic stop-vowel sequences where the stop's place of articulation is conveyed by its burst spectrum—landmark—and the formant transitions to the following vowel—nonlandmark. Parameter values in the two intervals fall on opposite sides of, but close to, a category boundary and convey competing place information. Information is degraded in one interval by broadening the bandwidths of the spectral peaks or formants, or it is made more variable by varying the peaks frequencies or the following vowel quality. If landmark information is perceptually primary, then degrading or varying that information should shift place judgments more toward the category conveyed by the nonlandmark interval than vice versa. However, if the quality or consistency of the information matters, then manipulating either interval should produce comparable shifts in place judgments. [Work supported by NIH.]

9:00

2aSC3. Weighted multiple cues and phonological features. Patrice S. Beddor (Dept. of Linguist., Univ. of Michigan, 1190 Undergraduate Sci. Bldg., Ann Arbor, MI 48109, beddor@umich.edu)

Do speaker-listeners determine a primary phonological feature from among multiple cues for a phonological contrast? Linguistic analyses traditionally postulate a primary feature, yet experimental evidence indicates that speaker-listeners assign relative weights to multiple cues, in context-dependent ways, and that these weighted cues are part of the phonological grammar. In this paper, evidence for a noncategorical, cue-weighted perspective is drawn in part from perception of nasal consonants (Ns). English Ns are shorter before voiceless than before voiced obstruents (in VNC contexts), and anticipatory vowel nasalization is temporally more extensive before the shorter, prevoiceless Ns. Unsurprisingly, listeners' judgments of stimuli in which N duration and temporal extent of vowel nasalization were independently manipulated in CV(N)C sequences (coda C = [t] or [d]) broadly parallel the production data. But individual listeners differed in their cue weightings. Some listeners heard vowel nasalization and the nasal murmur as perceptually equivalent information about the presence of N, other listeners were highly sensitive to vowel nasalization, and still others' cue sensitivity depended on coda voicing. The patterns of responses are difficult to interpret in terms of a primary feature, and the phonological implications of these patterns will be discussed. [Work supported by NSF.]

9:20

2aSC4. Enhancing the durational enhancement of a tone contrast. Carlos Gussenhoven (Radboud Univ. Nijmegen, Letteren, Taalwetenschap, Postbus 9103, 6500 HT Nijmegen, The Netherlands and Queen Mary, Univ. of London, Mile End Rd., London E14NS)

In central and low Franconian dialects of German and Dutch, a lexical tone contrast (accent 1 versus accent 2) exists that is enhanced by a durational difference. While pitch differences vary according to intonation and sentence context, syllables are generally shorter when they have accent 1. In addition, vowels in those syllables are more open, in comparison with vowels in syllables with accent 2. Perception experiments with natural vowels whose acoustic durations had been manipulated revealed that high vowels are perceived as longer by Dutch listeners than midvowels when acoustic durations are equal. It is argued that vowel raising of longer vowels, or vowel lowering of shorter vowels, serves as an enhancement of duration differences. The tendency is widely attested to in the vowel systems of Germanic languages, where short (''lax'') vowels are opener than long (''tense'') vowels, and vowel height is used to enhance a *phonological* duration contrast. In the dialects investigated, vowel height is manipulated to enhance a durational difference, which in turn enhances a tonal contrast. The explanation of the durational illusion of vowel height is the listener's compensation of the universally shorter duration of higher vowels.

9:40

2aSC5. Enhancement between voice onset time (VOT) and *F*0: Evidence from Kera voicing perception. Mary D. Pearce (Univ. College London & SIL. Phonet. and Linguist., UCL, Gower St., London, WC1E 6BT, UK, mary_pearce@sil.org)

Previous research on production data from Kera (a Chadic tone language) has shown that tone plays a major contrastive role, whereas VOT has a lesser role which could indicate an ''enhancing'' relationship. This paper investigates the roles of VOT and *F*0 in Kera voicing perception, and compares this to the nontonal language English. Fifteen Kera and 15 English subjects were given voicing judgment tasks over 200 tokens that had been manipulated in PRAAT to cover a range of VOT and *F*0 values. The results show a marked difference in English and Kera perception reflecting the phonological differences between the two languages. For Kera, *F*0 is of major importance, while the VOT plays a lesser role in the judgment. The present findings are consistent with a view that whereas in English, the VOT is contrastive and *F*0 arguably acts as an enhancing cue, in Kera, the tone is the main contrastive cue to voicing perception while the VOT values enhance the tone cues. A bonus finding from the perception tests is that the relationship between VOT and *F*0 in Kera voicing perception tasks depends on their exposure to French during childhood.

10:15

2aSC6. Commentary on invited papers for "Enhancement and multiplicity of cues in speech." D. H. Whalen (Haskins Labs., 300 George St., New Haven, CT 06511)

Enhancement has been shown to occur in a variety of contexts in the papers presented here. This commentary will examine the similarities of these phenomena and look for their proper level of description within linguistic theory.

10:35

2aSC7. Possible mechanisms of enhancement and multiplicity of cues. Yi Xu (Dept. of Phonet. and Linguist., Univ. College London, Wolfson House, 4 Stephenson Way, London NW1 2HE, UK, yi@phon.ucl.ac.uk)

It has been proposed that phonological contrasts are phonetically realized not only by their primary articulations, but often also by enhancing gestures [Kingston & Diehl "Phonetic knowledge," Language, **70**, 419–454 (1994); Stevens & Keyser, "Primary features and their enhancement in consonants," Language, **65**, 81–106 (1989)]. Meanwhile, enhancement appears to parallel the well-known phenomenon of multiplicity of cues in speech perception [Lisker "Voicing in English: Acatologue of acoustic features signaling /b/ versus /p/ in trochees." Lang. Speech, **29**, 3–11 (1986)]. An interesting question is therefore whether the two are one and the same. By a narrow definition, only articulatory maneuvers not obligated by the articulatory gestures of the phonetic units in question play an enhancing role. Thus not all cues that benefit perception are generated for the sake of enhancement. On the other hand, there may indeed be cases where genuine enhancement occurs, for which a further question is why is it needed in the first place? One possibility is that enhancement is not only for resisting noise in the speech environment, but also for handling the competition among communicative functions that are transmitted in parallel. That is, multiple communicative functions often share the same acoustic/articulatory dimension and such functional crowding may create the need to exploit additional means of encoding. If so, both enhancement and multiplicity of cues could be part of a live process that maintains the effectiveness of speech communication.

All posters will be on display and all contributors will be at their posters from 11:00 a.m. to 12:00 noon.

2aSC8. Enhancement of the vowel quantity contrast in Japanese and German by F0 and vowel quality. Heike Lehnert-LeHouillier (Dept. of Linguist., Univ. at Buffalo, 602 Baldy Hall, Buffalo, NY 14260, hlehnert@buffalo.edu) and D.H. Whalen (Haskins Labs., New Haven, CT 06511)

Previous studies on the perception of vowel quantity in Japanese and German have shown an influence of F0 for Japanese and of vowel quality for German. The current study investigates F0 and vowel quality enhancement of vowel length perception in both languages. Native speakers of Japanese and German were presented with three series of stimuli: (*i*) vowel continua for the vowels /a/, /e/, and /i/ which differed in duration only; (*ii*) vowel continua for the same vowels which differed in duration and the steepness of the F0 fall over the vowel; and (*iii*) vowel continua for the same vowels containing both durational and quality cues. While vowel quantity in the first two series was perceived categorically by Japanese listeners, vowel quantity in the stimuli testing the influence of vowel quality was perceived as gradual rather than categorical by the same listeners. German listeners perceived all series as categorical. Thus F0 cues generally enhance the distinction of the vowel length contrast whereas the presence of quality cues facilitates the distinction in German but impedes the perception of the same distinction in Japanese. This suggests that enhancement of vowel quantity is governed by perceptual cues that are in part language specific.

2aSC9. The role of acoustic familiarity in the perception of L2 contrasts. Gautam K. Vallabha (Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., 4400 Fifth Ave., Mellon Inst. 110, Pittsburgh, PA 15213)

Difficulties in L2 perception are often attributed to assimilation of the L2 contrast by an L1 category or to interference by L1-relevant acoustic cues [Iverson *et al.* "Phonetic training with acoustic cue manipulations: A comparison of methods for teaching English /r/-/p/ to Japanese adults," J. Acoust. Soc. Am. **118**, 3267–3278 (2005)]. These approaches assume that cue weights change slowly over developmental time and are relatively constant for short time scales. An alternative view is that cue extraction and weighting are dependent on the overall familiarity of the current sound, with more familiar sounds facilitating more robust cue extraction and better discrimination [e.g., McFadden and Callaway, JEP:HPP, **25**, 543 (1999)]. This hypothesis was tested with the perception of English sounds by Japanese adults. The Japanese listeners are insensitive to a cue (F3 onset) when it is part of (putatively unfamiliar) English /ra/ and /la/ sounds. The effect of familiarity was evaluated by fixing the range of F3 onsets and manipulating the rest of each sound in two ways: (1) by changing the transition durations to be more suitable for a moraic rhythm and (2) by changing the F1, F2, and amplitude trajectory to be more like the Japanese /r/. Discrimination improved markedly with the latter manipulation, suggesting that cue sensitivity is conditioned upon overall acoustic familiarity. [Work supported by NIH MH64445.]

2aSC10. Learning to ignore a perceptual cue: Nonnative listeners outperform native listeners. Mirjam Broersma (Max Planck Inst. for Psycholinguisti., P.O. Box 310, 6500 AH Nijmegen, The Netherlands, mirjam.broersma@mpi.nl)

Native and nonnative listeners categorized /v/ and /f/ at the end of English nonwords. For each participant, the duration of the previous vowel was kept constant, so that it was not informative and sometimes mismatched other information in the signal. Vowel duration was varied between participants. Previously presented results [M. Broersma, J. Acoust. Soc. Am. **117**, 3809–3901 (2005)] showed that native English listeners relied strongly on the misleading vowel duration cue. For Dutch listeners, no effect of vowel duration was found. Due to the redundancy of information in the signal, Dutch listeners categorized the contrast more categorically than English listeners. New analyses investigated whether Dutch listeners did not attempt to use vowel duration at all, or whether they learned to ignore the misleading cue more easily than the English listeners did. The results showed that Dutch listeners did use vowel duration initially, but stopped using this cue after very few trials. By the end of the practice part (33 trials) the effect of vowel duration had fully disap-

peared. The English listeners used vowel duration as a voicing cue throughout the experiment. This suggests that it may be easier to learn to ignore uninformative perceptual cues in a nonnative language than in one's native language.

2aSC11. Effects of task complexity on perceptual organization of speech cues by older listeners. Jessica A. Rossi-Katz and Kathryn H. Arehart (Dept. Speech Lang. and Hearing Sci., Univ. of Colorado, 409 UCB, Boulder, CO 80309)

Older adults with and without clinically significant hearing loss often report difficulty communicating in multitalker environments. Past work in our laboratory has shown that older listeners with hearing loss benefit less from differences in talkers' vocal characteristics (e.g., fundamental-frequency differences) relative to younger listeners with comparable hearing losses. The present study examined the extent to which age-related changes in the perceptual organization of speech cues are due to task demand. Two experiments used the Coordinate Response Measure to examine how the benefit listeners derive from talker characteristics interacts with the complexity of the response task as a function of both age and hearing status. Stimuli were amplified to assure audibility for listeners with hearing loss. Task complexity depended on whether the distracting signal was linguistically meaningful as well as the level of auditory processing required (discrimination versus identification). Older listeners generally benefited more from talker characteristics when task complexity was reduced (e.g., nonmeaningful distracter). The results are interpreted in the context of an information-processing model in which the increased difficulty of older listeners in multitalker environments is a consequence of reallocating limited resources towards the initial stages of processing at the expense of higher-level stages. [Work supported by Centers for Disease Control.]

8:00

2aSP1. A biomimetic robotic system for localizing gunfire. Socrates Deligeorges, Aleksandrs Zosuls, David Mountain, and Allyn Hubbard (Dept. Biomed. Eng, Boston Univ., 44 Cummington St., Boston, MA 02215, sgd@bu.edu)

Using a biomimetic approach, a new method of acoustic signal processing was created which has tremendous advantages in complex acoustic environments. The biomimetic approach was used as the basis for a system to localize and identify sound sources in noisy and reverberant conditions. The algorithms are based on mammalian hearing and mimic the acoustic processing of the auditory periphery and midbrain. The system uses spectro-temporal cues exploited by the auditory system including such features as interaural time difference (ITD), interaural level difference (ILD), spectral profile, and periodicity content. The initial system of algorithms were designed and tested using the EARLAB [earlab.bu.edu] software modeling environment. The system of algorithms was then adapted to a mixed-signal real-time hardware solution and mounted on an iRobot PackBot robotic platform to perform simple behavioral tasks. The integrated system can detect and localize gunfire in a complex, reverberant acoustic environment and orient a camera towards the shooter. Accuracy in field tests with live fire was 1.5 deg in azimuth. The performance of the prototype platform demonstrates the potential of the biomimetic approach and its applications to practical problems for commercial, civilian, and military acoustic processing. [Work funded by ARL:DAAD19-00-2-0004.]

8:15

2aSP2. The multiple coherence function for sound field prediction. Torsten Leth Elmkjær (Terma AS, Hovmarken 4, DK-8520 Lystrup, Denmark, tln@terma.com)

From the *uniqueness theorem* it is well known that the sound field in a region exterior to the source region can be determined from knowledge of the pressure or the normal fluid velocity *everywhere* on the enclosing surface. In practice the acoustical field quantities are obtained from space-time discretization. The space-time samples on the enclosing surface and arbitrary field points in the interior to the volume will be considered as input and output processes to a multiple-input–multiple-output (MIMO) system, respectively. The *multiple coherence function* $\gamma^2_{y:x}$ provides a measure of linearity between a set of inputs and an output *independent* of the correlation among the inputs. Various system imperfections, however, will lead to a nonunity $\gamma^2_{y:x}$ In particular, spatial sampling, similar to time-domain sampling, requires limited bandwidth to avoid aliasing. Therefore, a sufficient number of sensors must be allocated to ensure $\gamma^2_{y:x} \approx 1$. In this paper a spherical enclosure is investigated. The objective is to express $\gamma^2_{y:x}$ as a function of internal field point position for different space-time sampling strategies. Simulation results for single plane wave, diffuse fields, and multiple-source fields is presented. Measurement results obtained in a reverberant room are discussed. The work is also useful in active control system design.

8:30

2aSP3. Adaptive filtering algoritm for time-variant symmetric α-stable signals. Torsten Leth Elmkjær (Terma AS, Hovmarken 4, DK-8520 Lystrup, Denmark, tln@terma.com)

The existence of non-Gaussian distributed impulsive signals has roots in the *generalized central theorem*. In particular, the symmetric α-stable ($S\alpha S$) distribution has been used to model heavy-tailed phenomena encountered in communication, underwater acoustics, and radar. Most previous work in the field of active control uses some of the numerous variants of LMS algorithm extended with the *filtered-x* scheme. The stable processes, however, do not possess finite second-order moments. Hence, the filter should be based on l_p-norm optimization. The p-norm enters the expression for the tap-weight update $[p(t) < \hat{\alpha}(t)]$. In this work a new adaptive algorithm referred to as regularized normalized least−mean p−norm algorithm [ϵNLM$p(t)$] is presented. A running estimate $\hat{\alpha}(t)$ of the time−variant characteristic exponent of the stable signal is obtained. Hence, by adaptively tuning the filter p−norm a more optimal filter performance results in time−variant situations. Simulation analysis provides insight into the adaptive filter performance for various time−invariant and time−variant noisy signals for $1 < \alpha(t) \leqslant 2$. Moreover, it is demonstrated

that the filter performance is only marginally degraded compared with LMS algorithm for ordinary time−invariant Gaussian noise signals. Performance of an active control system exposed to time−varying heavy−tailed noise signals is presented.

8:45

2aSP4. Loudspeaker defect analysis using ultrasonic harmonic characterization. W. Scott Galway, Matthew A. LaBruzzo, Robert D. Celmer (Acoust. Program & Lab., Univ. of Hartford, 200 Bloomfield Ave., W. Hartford, CT 06117), and Daniel Foley (Independent Consultant, Marlborough, MA 01752)

This study presents the results of an ongoing investigation of defect detection in transducers. Loudspeaker assembly faults, such as a rubbing voice coil, bent frame, loose spider, etc., have traditionally been detected using experienced human listeners at the end of a production line, or through the use of low-order harmonics for total harmonic distortion measurement. The findings of Thompson *et al.* ["Higher-order harmonic signature analysis for loudspeaker defect detection," J. Acoust. Soc. Am. **114**, 2400 (2003)] described a new method wherein the total energy of high-order harmonics groups (10th through the 20th, or 31st through the 40th), were measured and analyzed. This approach demonstrated the ability to delineate distinct signatures that correlated to the root cause of audible rub and buzz distortions. This paper presents the results of a follow-up study using equipment that collected harmonic data up to 100 kHz. Results are presented for ten 5-in. midrange loudspeakers, in which trends for specific acoustic signatures were correlated to known defects. The use of a computer-based electroacoustic measurement and analysis system using frequencies that are inaudible but beneficial for analysis of defects are discussed. [Work supported by Listen Inc., Boston, MA.]

9:00

2aSP5. Adaptive collaborative array trajectories for optimum passive detection. Granger W. Hickman and Jeffrey L. Krolik (Dept. of Elec. and Comput. Eng., Duke Univ., Hudson Hall, Durham, NC 27708)

Two major challenges faced by sensor arrays used for passive sonar detection in littoral ocean channels are the suppression of highly dynamic interferers and signal wave-front mismatch resulting from complex multipath propagation. Large static arrays require accurate signal wave-front modeling and a highly stationary noise field to achieve their maximum potential array gain. In this paper, the detection performance of collaborative unmanned underwater vehicles (UUVs) towing short-line arrays is evaluated. In particular, vehicle trajectories which maximize overall probability of detection are computed as a function of the noise-field directionality and target location probability distribution. The UUV trajectories are constrained to share common endpoints connected by a series of line segments for each vehicle. The probability of at least one far-field detection by at least one UUV over the course of their transit is then maximized with respect to the sequence of the vehicles' headings. The results for a 2D horizontally isotropic noise field indicate that trajectories with a diversity of endfire (or equivalently broadside) bearings maximize detection performance. Scenarios with multiple interferers lead to solutions which minimize backlobe masking of the target. [Work supported by ONR.]

9:15

2aSP6. Data error covariance matrix for vertical array data in an ocean waveguide. Chen-Fen Huang, Peter Gerstoft, and William S. Hodgkiss (Marine Physical Lab., Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238)

Information about the data errors is essential for solving any inverse problem. The likelihood function plays a critical role in describing the data uncertainties in geoacoustic inversion. The choice of likelihood function depends on the statistics of the errors (the difference between observed and estimated fields). In all work to date, the likelihood function has been derived based on an assumption of Gaussian errors. Typically, the errors are assumed to be independent, identically distributed with equal variance (referred to as the error variance), and the error variance is estimated as part of the optimization. Recently, there has been interest in estimating a more full data error covariance matrix. To estimate a truly full data error covariance matrix, we adopt a maximum-likelihood approach based on ensemble averages using the observed errors over many inversions. The approach is illustrated using data obtained during the ASIAEX 2001 East China Sea experiment. The parameter uncertainties resulting from incorporating the full data error covariance matrix are compared with those obtained from the simplified data error covariance matrix characterized by the error variance alone.

9:30

2aSP7. Increasing cross-talk immunity in simultaneous multiple acoustic sources measurements using coded signals. Shu Li and Ning Xiang (Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY, 12180)

Maximal-length sequences (MLS) and related signals demonstrate excellent correlation properties including a pulselike autocorrelation function and a relatively smaller-valued cross-correlation function. They have been increasingly applied in acoustical measurements [Xiang *et al.*, J. Acoust. Soc. Am. **117**, 1889–1894 (2005)]. Recent work employs specialized FFT-based algorithm [Daigle and Xiang, J. Acoust. Soc. Am. **119**, 330–335 (2006)] using MLS-related signals into simultaneous multiple acoustic sources measurements (SMASM). The resulting impulse responses of acoustic channels, however, suffer from cross-talk noise. To enhance cross-talk immunity, this paper proposes an algorithm using pseudoinverse algorithm to improve signal-to-noise ratio in the SMASM. This proposed algorithm applies specialized correlation method and pseudoinverse processing to implement acoustic measurements for the SMASM technique. This paper discusses both simulation and experimental results of the SMASM with the pseudoinverse algorithm to demonstrate considerable improvements in signal-to-noise ratio. This paper also evaluates the efficiency of pseudoinverse algorithm for the increased cross-talk immunity.

9:45

2aSP8. Multi-static target tracking using a bistatic invariance constraint. Jorge Quijano, Manish Velankar, and Lisa Zurk (Portland State Univ., 1900 SW Fourth Ave., Ste. 160-17, Portland OR 97207, zurkl@cecs.pdx.edu)

The ability to track moving targets in shallow water channels is critically effected by bottom reverberation which can generate false alarms and substantially increase the domain of possible tracks. Even with application of advanced tracking algorithms, false alarms degrade performance and increase computational burden. The invariance principle, which predicts structure in the frequency-time domain, has been applied to passive sonar systems but has not been considered for active systems. In this work, a mathematical expression (called the bistatic invariance principle, see companion paper) is proposed as a constraint to discriminate target detections from false alarms and thus reduce the search domain for multi-static tracking algorithms. The constraint does not require knowledge of the underwater environment and is thus robust to environmental uncertainty. The bistatic invariance principle provides a relationship between changes in the bistatic range of a moving target to changes in the source frequency, and this relationship can be used to track the target position over time in broadband active sonar systems. Simulations of the bistatic invariance principle for multi-static active systems are presented and discussed and multi-static tracking performance is characterized for several choices of target scattering matrices and different environmental conditions.

2aSP9. A time-frequency approximation with applications in target recognition. Patrick Loughlin (Univ. of Pittsburgh, 348 Benedum Hall, Pittsburgh, PA 15261)

In active sonar, the received signal can often be modeled as a convolution of the transmitted signal with the channel impulse response and the target impulse response. Because the received signal may have a time-varying spectrum, due, for example, to target motion or to changes in the

channel impulse response, time-frequency methods have been used to characterize propagation effects and target effects, and to extract features for classification. In this presentation, we consider the Wigner time-frequency representation of a received signal modeled as the convolution of the transmitted signal with the channel and target responses. We derive a simple but very insightful approximation that shows the effects of the magnitude and phase of the frequency response of the target and of the channel on the Wigner representation of the transmitted signal. The results suggest possible features for classification, which we discuss. We also consider time-varying effects on the Wigner representation, such as changes in reflected energy due to changes in aspect angle, which we model by amplitude modulation. [Research supported by ONR Grant No. N000140610009.]

10:30

2aSP10. Model-based blind deconvolution for noisy dynamic channels. Michael Roan (Virginia Polytechnic Inst. and State Univ., Blacksburg, VA 24060) and Mark Gramann (Aerosp. Corp., Chantilly, VA)

It is common in acoustics to measure a signal that has been degraded by propagation through an unknown, noisy channel prior to measurement. While only the degraded measured signal is available, the data of interest are the original signal and the channel parameters. Often, it is desirable to reverse the filtering process by application of an inverse filter to recover the original signal. When neither the input signal properties nor the channel properties are known, this process is known as blind deconvolution (BDC). Typically, BDC algorithms assume noiseless, stationary propagation channels and input sources. These assumptions are usually violated in practical applications (e.g., noisy multipath propagation environments with moving source and receiver). To model these effects, predictive techniques are applied to incorporate *a priori* information about the system into the existing blind processing framework. The original contributions of this work follow. First, a novel formulation of the extended Kalman filter (EKF) is proposed. This allows incorporation of *a priori* information into gradient-based blind processing algorithms. This formulation is then applied to the natural gradient (NG) BDC algorithm. Finally, results are presented that suggest significant improvement in signal recovery performance over the NG BDC algorithm for dynamic noisy channels.

2aSP11. Detection of phase-coupled noises in the ocean. M. H. Supriya and P. R. Saseendran Pillai (Dept. of Electron., Cochin Univ. of Sci. and Technol., Kochi—682022, India)

Estimates of power spectral density are being used in a variety of signal processing applications. For the precise characterization of certain noise sources in the ocean, the phase blind power spectral estimation does not yield the required result. Estimates of the bispectrum and bicoherence have been found useful in detecting non-Gaussianity and nonlinearity, in system identification, as well as transient signals. The power spectrum, in general, fails to quantify any nonlinear interactions between the component frequencies. Such interactions induced by second-order nonlinearities give rise to certain phase relations called quadratic phase coupling (QPC). Bispectral analysis, which is based on the third-order cumulant sequence of the signal, can reveal the presence of as well as provide a measure to quantify such phase couplings. Bispectral analyses of various noise data records collected from different ocean noise sources have been carried out and it is seen that the bispectrum is not identically zero, implying the non Gaussian nature of the noise data. This paper presents the bispectral estimation approach for identifying the nonlinearities in the underwater noise-generating mechanisms as well as detecting the presence of quadratic phase couplings, thus leading to the identification of the noise sources.

11:00

2aSP12. Exploiting temporal coherence models to extend detection range. Ronald A. Wagstaff (Natl. Ctr. for Physical Acoust., University, MS 38677)

Turbulent flow over acoustic sensors and other sources of noise can severely corrupt signals and reduce detection range. The ranges can be much greater when based on the temporal coherences of signals and noise instead of their magnitudes. The signals need not be perfectly coherent to be detected at longer ranges, just more coherent than noise. This is illustrated using a fluctuation-based temporal coherence signal-processing model. This model uses measured data to produce temporal coherence patterns that are random for noise, deterministic for signal, and a blend of the two for small, e.g., negative, signal-to-noise ratio (SNR). Fluctuation-based processing techniques are presented for temporal coherence pattern generation, recognition, and automatic identification of signal presence or only noise in a frequency bin. It is shown for both underwater and atmosphere acoustic data that a signal's influence in a frequency bin alters the usual random ''noiselike'' temporal coherence patterns by causing them to cluster. Hence, signal-altered patterns can be recognized and the signals preserved. Corresponding ''noise-only'' patterns, being random, can also be recognized and attenuated, or eliminated. Using these models results in increased SNR and automatic signal detection at longer ranges with greater confidence. [Work supported by ARDEC and SMDC.]

11:15

2aSP13. Generating simulated reverberation using noiselets. Edmund J. Sullivan, Robert P. Goddard (Prometheus Inc., 103 Mansfield St., Sharon, MA 02067), Hyman A. Greenbaum (Anteon Corp., Middletown, RI 02842), and Kevin P. Bongiovanni (Naval Undersea Warfare Ctr., Newport, RI 02841)

Of the approaches to generating stochastic realizations of reverberation time series, the simple point scatterer model (PSM) is appealing because the statistics evolve naturally as the number of scatterers increases. Unfortunately, the number of eigenrays required is often overwhelming, especially for broadband signals. The more common ''variance factorization model'' (VFM) uses far fewer eigenrays to compute a time-dependent estimate of the variance of the reverberation, and applies the spectral factorization theorem to generate a sequence of short-time spectra, which is inverse transformed and concatenated to form the desired time series. However, the variance and factorization steps scale with the square and the cube, respectively, of the number of receiver channels, so the advantage is lost for element-level simulations of complex receivers. The ''noiselet model'' is conceptually similar to the PSM, but the transmit pulse is replaced by an ensemble of precomputed ''noiselets,'' which are sums of randomly weighted and delayed copies of the original transmit pulse. The number of eigenrays is thus comparable to the VFM, but scaling is linear in the number of channels, rendering this method tractable for real-time broadband element-level simulation. Examples are shown for a linear FM pulse at 10 kHz and 400-Hz bandwidth.

11:30

2aSP14. A phenomenological model for sonic crystals based on artificial neural networks. Elies Fuster-Garcia, Vicent Romero-Garcia, Juan V. Sanchez-Perez (ACARMA and Dep. de Fisica Aplicada, ETSICCP, UPV, Cno. de Vera s/n, 46022 Valencia, Spain, jusanc@fis.upv.es), Luis M. Garcia-Raffi, and Enrique A. Sanchez-Perez (ETSICCP, UPV, 46020 Valencia, Spain)

In this paper we develop a phenomenological model that simulates the acoustic attenuation behavior of sonic crystals. The input of the model is a

set of parameters that characterizes each experimental setup and the output is the associated simulated attenuation spectrum. The model consists of a combination of multiresolution analysis based on wavelet functions and a set of artificial neural networks. An optimized coupling of this tool allows us to reduce drastically the experimental data needed and also to have a fast computational model that can be used for technological purposes. [This research has been partially supported by the Generalitat Valenciana (Spain), under Grant GV04B-371, by Comision Interministerial de Ciencia y Tecnologia of Spain, under Grant BFM2003-02302, and by Comision Interministerial de Ciencia y Tecnologia of Spain, Contract Ns. MAT 2003-04993-03.]

11:45

2aSP15. Nonlinear behavior of interacting harmonics in audio spectra. V. Vijayakumar and C. Eswaran (Multimedia Univ., FOSEE, Jalan AIr Keroh Lama, 75450, Melaka, Malaysia)

In this paper we will show how individual harmonics of a frequency-modulated dynamic audio spectrum undergo interactions. This results in nonlinear behavior of the spectrum. We have illustrated the nonlinear behavior with respect to the number of harmonics and the modulation parameter. It is shown that an audio spectrum containing higher-order harmonics is more susceptible to interation among itself. Musical instrument spectra are used to illustrate this effect and audio samples are provided.

2aUW1. The direct path impulse response in bubbly shallow water. Ralph Goodman, Jerald Caruthers, and Timothy Ruppel (Stennis Space Ctr., Univ. of Southern Mississippi, Bay St. Louis, MS 39529)

It is well known that bubbles, even in small numbers, cause significant changes in the acoustic properties of seawater. In shallow water bubbles enter the sea, either by wind-driven breaking waves or by surf-induced rip currents. Both have been observed in acoustic transmission experiments [IEEE, JOE **25**, 507–515 (2000); J. Acoust. Soc. Am. **106**, 617–625 (1999)]. Wind-driven bubbles were observed, during a period of high winds, to reduce sound speed from the undisturbed sea condition of 1520 m/s to about 1494 m/s. From bubble theory, it is estimated that the average bubble void fraction was approximately 2.6×10^{-6}. For a distribution of bubble radius size, $n(a)$, there will be a frequency-dependent sound speed and absorption related by the Kramers-Kronig relation, from which the change in a pulsed signal can be determined. By using a bubble size distribution of $n(a)=Na\times10^{-4}$, for radii between values of 200 and 10 microns and the void fraction estimated above, the dispersion and absorption are calculated. The impulse response can be calculated as a function of range. [Work supported by the Office of Naval Research.]

2aUW2. Modeling nonlinear acoustics in shallow water. B. Edward McDonald (Naval Res. Lab, Washington, DC 20375, mcdonald@sonar.nrl.navy.mil) and William A. Kuperman (Scripps Inst. of Oceanogr., La Jolla, CA 92093)

Lessons learned in modeling nonlinear acoustics and weak shock propagation in deep water are helpful in application to shallow water (mine countermeasures in particular), but the medium is much more complicated. Numerous improvements are needed; Joe Blue's work touched on several of them. First is the need to treat higher propagation angles. Second is the presence of bubbles near the surface and possibly in the bottom. Finally, there are problems introduced by nonlinear propagation in granular sediments. These include greatly increased nonlinearity parameter and time-domain formulation of frequency—linear attenuation. Recent progress in the application of the NPE model [McDonald and Kuperman, "Time domain formulation for pulse propagation including nonlinear behavior at acoustic," J. Acoust. Soc. Am. **81**, 1406–1417 (1987)] to mine countermeasures will be outlined. [Work supported by the Office of Naval Research.]

8:45

2aUW3. Sound waves and shear waves in sediments. Michael J. Buckingham (MPL, SIO, UCSD, 9500 Gilman Dr., La Jolla, CA 92093-0238, mjb@mpl.ucsd.edu)

In a long and illustrious career, Joe Blue made many significant contributions to the discipline of underwater acoustics, although he is probably best known for his work on the design and calibration of hydrophones and hydrophone arrays. Such instrumentation has many applications, including measurements of the geoacoustic properties of marine sediments. In this paper, recent developments on the properties of sound waves and shear waves in sediments will be summarized and certain difficulties that are encountered when attempts are made to match theory to data will be highlighted. Central to the discussion are the compressional-wave and shear-wave dispersion relations, that is, phase speed and attenuation as functions of frequency. In a saturated sediment, the phase speeds and attenuations also depend on various physical properties, for example, the porosity, density, grain size, and overburden pressure (depth). These dependencies will be illustrated using extensive data sets taken from the literature. Any satisfactory theory of waves in sediments must yield correctly not only the dispersion relations but also all the dependencies on the physical properties. A recently developed theory that satisfies these criteria will be discussed in the context of the available data. [Research supported by ONR.]

9:05

2aUW4. Joe Blue's influence on low-frequency, shallow-water acoustics. George V. Frisk (Florida Atlantic Univ., 101 N. Beach Rd., Dania Beach, FL 33004)

As Superintendent of the Naval Research Laboratory's Underwater Sound Reference Division, Joe Blue played a key role in the advancement of low-frequency, shallow-water acoustics. Specifically, his leadership and oversight of this unique facility provided an engineering science environment in which low-frequency transducers were developed, calibrated, and maintained. These assets were made available to the research community in ocean acoustics at reasonable cost and have offered dependable, reliable service for more than 25 years. This talk focuses on advances made using the J15-3 transducer, which emerged as a workhorse in numerous experiments in low-frequency (50–500 Hz), shallow-water acoustics. A series of experiments is described in which this transducer was used as the principal source of sound. These measurements led to an increased understanding of acoustic propagation, geoacoustic inversion, and physical oceanography in shallow water. [Work supported by ONR.]

9:25

2aUW5. A long-range, high-resolution Doppler sonar for fishery stock assessment. Harry A. DeFerrari (RSMAS—Univ. of Miami, 4900 Rickenbacker Cswy., Miami, FL 33149)

A new approach is developed for horizontal-looking active sonar that uses continuous bi-/multistatic transmission of very long period m-sequences. Compared to conventional monostatic ping rather than listen sonar, this approach improves the Doppler resolution by a factor of 20 and increases FOM by perhaps 13 dB by increasing the temporal coherent processing gain. The improved time/Doppler resolution helps to discriminate fish school from bottom reverberation, and improves the resolution of taxonomic parameters of fish assemblages. The improved FOM allows coverage of large areas of shallow oceans with source levels low enough to avoid environmental concerns for marine mammals. The principal obstacle to continuous transmission sonar operation is the masking of the target return by the time and frequency leakage of the direct path arrivals. Unique time-correlation property of m-sequences elimination time leakage and a process calls coordinate zeroing (CZ) eliminates all the Doppler leakage. A linear temporal Doppler search (LTDS) algorithm is used to shift the detection problem to a high-resolution pulse arrival-time/Doppler plane with a noise-limited background. Ultrafast Hadamard transforms lighten the computational burden. The combination of these ideas is presented including the theory, numerical experiments that demonstrate the concept, and verification with real ocean signals.

9:45

2aUW6. Development and application of high-frequency sonars for imaging naturally occurring plumes in the ocean. David R. Palmer (NOAA/Atlantic Oceanogr. and Meteorological Lab., 4301 Rickenbacker Cswy., Miami, FL 33149)

Hydrothermal plumes are formed when hydrothermal solutions are discharged from chimneylike vents on the ocean floor where adjacent tectonic platesare separating. Their study provides information on the transfer of heatand chemicals from the solid earth to the ocean. When high-frequency acousticswas proposed for imaging and studying hydrothermal plumes, Joe Blue contributedin a general way to the development of the effort. In this presentation the history of this effort is reviewed. After an introduction to hydrothermal venting, some of the problems addressed in the development and application of the sonar are discussed. These include sonar calibration, identification of the dominant scattering mechanism, estimating cross sections, and the intrinsic statistical variability associated with incoherent scattering. The results obtained from four sea trials are recalled. These trials involved either three-person, deep-diving submersibles or the JASON/MEDEA ROV system. The opportunities provided by the somewhat surprising progress that has occurredare discussed. Finally, an application of the developed technology is mentioned, acoustical imaging of the bubble plume emitted from the underwater volcano Kick em Jenny.

10:05–10:25 Break

10:25

2aUW7. The art of merging physics and math with biology and psychology to study marine animal acoustics. Mardi C. Hastings (Office of Naval Res., Life Sci. Res. Div., 875 N. Randolph St., Arlington, VA 22203-1995, mardi_hastings@onr.navy.mil)

Joe Blue's most recent contributions to marine animal acoustics resulted from successful collaborations with biologists and psychologists, each bringing their individual expertise to the table and working together to understand how the characteristics of the acoustic field generated by a moving vessel could provide critical insight into the observed behavior of right whales and manatees.

Joe's hands-on approach of going out and actually recording and measuring the sound fields provided data that not only verified his analyses, but also enhanced practical understanding of acoustics in the animal bioacoustics community. His work demonstrated the importance of physics and math in studying complex multidisciplinary acoustic problems and resolving perplexing dichotomies. Examples will be presented showing that Joe's collaborative style is a model for everyone to follow.

10:45

2aUW8. Simulation models of click production in dolphins. Nikolay A. Dubrovskiy and Igor A. Urusovskiy (Andreyev Acoust. Inst., Shvernika Ul, #4, Moscow 117036, Russia)

The simulation model (SM) of dolphin click source originally presented by [Dubrovskiy and Giro, ''Echolocation in Bats & Dolphins,'' Chap. 10, 59–63 (2003)] was further developed by Gladilin, Dubrovskiy, Mohl, and Walberg, Acoust. Phys. **50**, 463-468 (2004). The SM describes movements of a solid sphere frozen in a compliant ring. A jet of air in a duct connecting air cavities brings the sphere into self-oscillations. The SM allows calculating the waveform and sound pressure of the generated clicks. Here the mathematical and simulation model (MSM) of click production in dolphins is further developed. The MSM describes radiation of clicks by bodies comprising of waterlike tissue with different shapes (a ring, a blunted cone) pulsating and (or) oscillating under action of muscles tension. Calculations are made for the energy efficient case when acting force is consecutively applied not to the entire body but to its thin layer, which resulted in action of the progressing wave array. Directivity patterns of such a waterlike compliant body in main directions are similar to that of a rigid body with the same shape and dimensions. Comparisons are made of MSM predictions with properties of an actual radiation field of dolphins (in clicks wave forms, sound pressure levels, and directivity patterns) and dimensions of biological structures supposedly responsible for click production in dolphins.

11:05

2aUW9. A dolphin acoustic tapetum? Sam Ridgway, Brad Blankenship, Dorian Houser, Don Carder (SPAWAR Systems Ctr. San Diego, Div. D235, 53560 Hull St., San Diego, CA 92152-5001), and Carl Hoh (Univ. of California, San Diego, CA 92093)

Many mammals including dogs, cats, deer, and dolphins, but not humans, have a reflective membrane at the back of the eye. This tapetum lucidum affords the light-sensitive retinal cells a second chance for photon-photoreceptor stimulation, enhancing low light visual sensitivity. Dissection of preserved specimens and computed tomography (CT) scans of live dolphins have shown prominent air cavities around the ear, especially medial and posterior. Histologic evaluation of peri-otic tissue revealed epithelial lined air sinuses and erectile tissue containing nerves, ganglia, smooth muscle bands, vascular spaces, and periarterial venous networks. Two dolphins were trained to periodically recognize and respond to a 1.5-s, 70-kHz target tone. In three experiments, 20 target tones were presented through a jaw phone after injection of 18 Fluro-deoxy-d-glucose (FDG). Subsequent positron emission tomography (PET) scans revealed that the tone, to which the dolphin had responded and been rewarded numerous times in the past, elicited a marked increase in metabolism in the erectile tissue medial to the stimulated ear but not the contralateral ear. Tissue around reflective air sinuses medial to the ear become active with acoustic stimulation, suggesting that sinus air may be shaped so as to provide an ''acoustic tapetum'' for dolphins.

11:25

2aUW10. Of manatees and men: A future: Thanks to you, Joe. Edmund Gerstein, Laura Gerstein, Joseph Blue (Leviathan Legacy Inc., 1318 SW 14th St., Boca Raton, FL 33486), and Steve Forsythe (Naval Undersea Warfare Ctr., Newport, RI 02841)

A comprehensive series of underwater psychoacoustic tests was conducted to measure the hearing abilities of the West Indian manatee under varying acoustic conditions. Pure tones, complex noise and real sounds, boat noise and species-specific calls, were presented to captive manatees under various acoustical conditions. The results from more than 30 000 threshold trials define the first behavioral audiograms, directional hearing, and critical masking ratios for any sirenian species. Psychoacoustic tests demonstrate the noise produced by slow-moving boats is more difficult for manatees to hear and locate than the high-energy cavitation noise from faster moving vessels. The dominant frequency spectra of slow-moving boats fall near the fringe of their low-frequency hearing limits and below critical masking ratios. Complementing underwater ambient noise and vessel noise measurements revealed physical propagation factors that further render manatees vulnerable to watercraft collisions in their shallow-water habitats. Ironically, slow speed zones implemented to protect manatees may exacerbate the problem, making vessels difficult to hear, while increasing transect times and opportunities for collisions. By exploiting the manatee's best hearing capabilities, it may be possible to mitigate collision risks with a low-intensity, environmentally friendly acoustic warning device that alerts manatees of approaching vessels. [Research supported by DOD Navy Legacy Program, Inland Navigation District, FFWCC]

11:45

2aUW11. Listening to fish: Applications of passive acoustics to fisheries. Rodney Rountree, Francis Juanes (Dept. of Natural Resources Conservation, UMass Amherst, Holdsworth Hall, Amherst, MA 01003, rrountree@fishecology.org), and Cliff Goudey (MIT Sea Grant College Program, Cambridge, MA 02139)

Passive acoustics is a rapidly emerging field of marine science that until recently has received little attention from fishery scientists and managers. In its simplest form, it is the act of listening to the sounds made by fish and using that information as an aid in locating fish so that their habitat requirements and behaviors can be studied. We believe that, with the advent of new acoustic technologies, passive acoustics will become one of the most important and exciting areas of fisheries research in the next decade. However, widespread unfamiliarity with the technology, methodologies, and potential of passive acoustics has hampered the growth of the field and has limited funding opportunities. Herein, we provide an overview of important new developments in passive acoustics together with a summary of research, hardware, and software needs to advance the field.

Meeting of the Standards Committee Plenary Group

to be held jointly with the meetings of the

ANSI-Accredited U.S. Technical Advisory Groups (TAGs) for:

2pAAa1. Mastering music in a 5.1 world. Adam Ayan (Gateway Mastering Studios, 428 Cumberland Ave., Portland, ME 04101, adam@adamayan.com)

The evolution of 5.1 surround sound in the world of popular music has changed the way artists, producers, and engineers conceptualize their recordings. Along with the artistic benefits of 5.1 surround production come the challenges of working in this relatively new format. Mastering engineers are responsible for making the final sonic enhancements to a recording, musically maximizing the recording, and making it compatible and competitive in the marketplace. 5.1 surround mastering shares many of the same techniques and philosophies as stereo mastering, but also presents a new set of concerns for the mastering engineer. This talk focuses on the specific production and engineering concerns that are unique to the world of 5.1 surround production, specifically as they relate to mixing and mastering techniques.

1:20

2pAAa2. The real reasons you should invest in a surround-sound system. Barbara G. Shinn-Cunningham (Boston Univ. Hearing Res. Ctr., 677 Beacon St., Boston, MA 02215)

Most consumers of surround-sound systems understand that increasing the number and locations of speakers provides better control of perceived source location. The first goal of this talk is to explore why surround-sound systems generally work well in a variety of common settings, even though the acoustic effects of the rooms in which they are used can differ dramatically. What acoustic and psychoacoustic principles come into play? A second goal is to discuss the different perceptual benefits provided by a typical surround-sound system. Specifically, a good system not only allows listeners to hear sources at different directions, but also improves a listener's ability to understand simultaneous sources and monitor a complex auditory scene. Finally, we will discuss why it is important to realize that surround-sound systems are entertainment systems, not simulators. If asked, most consumers would probably argue that surround sound is good because it makes it possible to recreate a realistic auditory experience. In fact, the aim of many recordings and games that use surround-sound technology is not realism, but vicarious thrill and vivid experience. In entertainment, bigger (and louder and more extreme) is better than everyday, ordinary sensations. [Work supported by NIDCD.]

1:40

2pAAa3. The influence of changes in diffusive acoustical treatment on spatial imagery associated with multichannel sound reproduction. William L. Martens (Schulich School of Music, McGill Univ., Montreal, QC, Canada)

Listening experience in the newly constructed, largely diffuse small room at Blackbird Studios has led to the design of a new research space for the Sound Recording program in McGill University's Schulich School of Music. The space was created to allow for experimental investigation of the influence of changes in diffusive acoustical treatment on variation in auditory imagery associated with multichannel sound selections while holding listener location and orientation constant relative to a fixed five-channel loudspeaker array. Preliminary tests suggest that a number of benefits result when low-amplitude indirect sound is provided by diffusive room acoustic treatment within the first 30 ms of the arrival of the loudspeaker signals. Both for conventional multitrack mixes, and for recordings made using multichannel microphone arrays, these benefits include greater Listener EnVelopment (LEV), improved segregation of simultaneously sounding musical sources, and more solid phantom images of virtual sources, especially those located to the listener's extreme sides between front and rear loudspeakers (between 30 and 110 deg of azimuth to the left and right). This paper will summarize those results, and describe the specially designed system of variable acoustic treatment that enables such direct experimental investigation. [Work supported by Canada Foundation for Innovation.]

2:00

2pAAa4. Low-frequency control options in surround-sound critical listening rooms. Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774)

Acoustically small rooms, which are typically used for critical listening, be it mono or surround, can potentially overwhelm the spatial and spectral textures that contribute to an enjoyable listening experience. The options to control potential modal and speaker boundary interference in rooms include optimal dimensional room ratios, optimal speaker/listener placement, optimal multiple subplacement and dedicated low-frequency absorbers, including quarter-wave traps, anechoic wedges, Helmholtz and membrane resonators, and a relatively new and potentially significant addition, the metal plate resonator, which absorbs efficiently down to 50 Hz with a thickness of only 4 in. The design theory, proof-of-performance evaluation testing methods, and optimal placement guidelines for all of these tools will be reviewed.

2:20

2pAAa5. From mono to surround: A review of critical listening room design and a new immersive surround design proposal. Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774)

As our critical listening rooms have evolved from mono to stereo to an ill-fated attempt at quad to full surround, many approaches have been taken in the design of these spaces. This presentation will review significant milestones in this evolution including the early compression ceilings, reflective front-absorptive rear, absorptive front-absorptive rear nonenvironment, absorptive front-diffusive rear, spatio-temporal reflection-free zone front-diffusive rear, and reflection-rich zone in front-diffusive rear. Recently there has been a renaissance in the evaluation of the importance of specular and diffuse reflections in auditory perception. The presentation will conclude with a proposal for a new immersive surround environment, which can be described as an ambient anechoic or ambechoic environment. Fully enveloping diffuse room reflections are 30 dB below the direct sound, as in an anechoic environment, yet the room feels ambient, provides precise localization, and offers a creative work environment for recording and monitoring. An example of a proof-of-concept room will be illustrated and described.

2:40–3:00 Break

3:00

2pAAa6. An innovative professional music recording/monitoring space. George Massenburg (2805 Bransford Ave., Nashville, TN 37204-3101)

A new kind of professional recording/monitoring space has been designed and constructed as part of the Blackbird Studio complex in Nashville, Tennessee. The room will be introduced and the early subjective impressions will be discussed. The objective of this new room was threefold: first, to provide a surround mixing space with much-improved virtual source localization over a broader footprint in the space, second, to provide a highly diffuse space for the recording of live music performances by one or more vocalists and/or

musicians, and third, to investigate a largely diffuse monitoring environment as it might benefit the quality and/or efficiency of professional music mixing in different formats. This presentation will discuss some of the results and some of the surprise outcomes, including practitioner-reported improvements in quickly attaining comprehensive, surgical equalization of sources, possibly attributable to an environment with somewhat more equal reverb times across the frequency spectrum.

3:20

2pAAa7. Surround-sound wish list. Bob Ludwig (Gateway Mastering Studios, Inc., 428 Cumberland Ave., Portland, ME 04101, staff@gatewaymastering.com)

This presentation describes this engineer's involvement with surround sound since the days of vinyl LP, 8-track, and four-channel Quadrophonic sound. It includes my experiences as one of the few mastering engineers hired by Digital Theater Systems in 1997 to master and help establish their new 5.1 surround compact disc. In 2005, the author mastered 2 of the 5 Grammy-nominated ''Best Surround Sound discs''—the SA-CD Dire Straits 20th Anniversary edition of ''Brothers in Arms'' and the Foo Fighters ''In Your Honor'' DualDisc. This presentation also includes a short wish list of issues with popular music surround-sound mixes with some suggestions for improvement.

2pAAa8. Simultaneous equalization of a loudspeaker and a room: Insights from a one-dimensional model. Xi Chen and Timothy Leishman (Acoust. Res. Group, Dept. of Phys. and Astron., Brigham Young Univ., Provo, UT 84602)

In recent years, many audio practitioners have concluded that a room excited by a loudspeaker cannot be effectively equalized. They argue that the free-field response of the loudspeaker may be equalized, but that the room response itself must be ignored. This paper presents a one-dimensional model to illustrate many of the difficulties encountered in past equalization methods that have led to this way of thinking. It explores the spatial-spectral variations of the reproduced sound field that make the methods problematic. It then uses the model to explain the benefits of using total energy density as a basis for equalization instead of acoustic pressure. Both the loudspeaker and the enclosed field can then be simultaneously equalized for nearly optimal results. The method is also implemented effectively using adaptive filtering techniques.

3:55

2pAAa9. A hybrid approach to rendering multichannel audio, using wave-field synthesis and stereophonic techniques, with virtual microphone control. Daniel Valente and Jonas Braasch (Rensselaer Polytechnic Inst., Troy NY 12188)

In the evolution of multichannel audio presentation, a number of formats have emerged including 5.1 surround and wave-field synthesis (WFS). Due to the complexity and number of components required to realize an immersive WFS system, the use in a home theater environment is currently impractical. This study aims to investigate the perceptual advantages of integrating both systems into a hybrid array capable of providing immersive sound for a number of listeners, at a scale that is attainable for the consumer in terms of budget and complexity. In this approach the three front speakers (left, center, and right) are replaced with a linear line array allowing for a better lateral and depth imaging, while increasing the sweet spot. The rendering will be created using Virtual Microphone Control (ViMiC) for both WFS, simulating a line of omnidirectional microphones with ViMiC, and surround sound, which will allows dynamic source movement, speaker positioning, and scalability. The advantage of using this hybrid approach is the application of WFS to home theater systems without facing the complexity of a complete two-dimensional WFS array, while still allowing for an immersive sound presentation. A psychoacoustic evaluation will be presented, as well as measurements of the composed sound field.

Architectural Acoustics and National Council of Acoustical Consultants: Student Design Competition

Robert C. Coffeen, Cochair
Univ. of Kansas, School of Architecture and Urban Design, Lawrence, KS 66045

Norman H. Philipp, Cochair
Yantis Acoustical Design, 720 Olive Way, Ste. 1400, Seattle, WA 98191-1878

Byron W. Harrison, Cochair
The Talaske Group, Inc., 105 N. Oak Park Dr., Oak Park, IL 60301

The Technical Committee on Architectural Acoustics of the Acoustical Society of America and the National Council of Acoustical Consultants are sponsoring this Student Design Competition that will be professionally judged at this meeting. The purpose of this design competition is to encourage students enrolled in architecture, architectural engineering, and other university curriculums that involve building design and/or acoustics to express their knowledge of architectural acoustics in the design of a facility in which acoustical considerations are of significant importance. Submissions will be poster presentations. This competition is open to undergraduate and graduate students from all nations.

The submitted designs will be displayed in this session and they will be judged by a panel of professional architects and acoustical consultants. An award of $1,250 will be made to the submitters of the entry judged "First Honors." Up to four awards of $700 each will be made to submitters of entries judged "Commendation."

Animal Bioacoustics, Acoustical Oceanography, and Underwater Acoustics: Effects of Anthropogenic Sounds on Fishes

Arthur N. Popper, Cochair
Univ. of Maryland, Dept. of Biology, College Park, MD 20742

Richard R. Fay, Cochair
Loyola Univ., Parmly Hearing Inst., 6430 N. Kenmore, Chicago, IL 60626

Chair's Introduction—1:00

Invited Papers

1:10

2pAB1. Anthropogenic sound—Introduction and overview of the ambient and anthropogenic environment. Arthur N. Popper (Dept. of Biol., Univ. of Maryland, College Park, MD 20742) and Richard R. Fay (Loyola Univ., Chicago, IL 60626)

Interest in anthropogenic sound in the marine environment has been directed at concerns about the effects of sound on marine mammals. However, fish make up a far larger and more diverse portion of the oceans than do marine mammals, and they hold considerable economic importance internationally. This has led to a growing interest in the effect of anthropogenic sounds on fish in environments ranging from shallow waters near in-shore shipping lanes to the deep sea. Concerns for effects on fish are parallel to those for marine mammals, and include issues ranging from the death of individual animals to the potential for behavioral changes that could lead to impacts on the survival of populations or species. While the body of data on the effects of anthropogenic sounds on fish is still small, and much of the work is not in the peer-reviewed literature, the number of peer-reviewed studies is growing. The purpose of this special session is to provide an overview of what we currently know about the effects of anthropogenic sound on fish, help define the major outstanding questions on these effects, and to provide the basis for discussion of current and future research in order to help resolve these questions.

1:35

2pAB2. Attempting to define sound exposure metrics for fish. Mardi C. Hastings (Office of Naval Res., Life Sci. Res. Div., 875 N. Randolph St., Arlington, VA 22203-1995, mardi_hastings@onr.navy.mil)

One of the big issues in addressing the biological effects of sound on humans and animals is metrics. For fishes the issue is further complicated because their inner ear responds directly to acoustic particle motion and in some species, indirectly to pressure through multiple pathways. So, metrics based only on pressure can be misleading in developing sound exposure criteria. The decibel scale also confounds the problem because it is used to express not only levels of sound pressure, but also levels of sound power, intensity, and energy. Even for just sound pressure, decibels are used to express peak, peak-to-peak, and time-averaged values, which can hamper extrapolation of laboratory data to anthropogenic sources in the field. Add to that the changes in decibel reference values when going from air to water, more than 25 000 different fish species, and the fact that a significant amount of sound exposure research on fish has been done in small enclosures at low frequencies, and one quickly realizes the difficulties in developing meaningful relationships between sound exposure and observed effects. This presentation will focus on relevant sound exposure metrics, their practical definitions, and their application to quantifying the biological effects of sound on fish.

2:10

2pAB3. Effects of high-intensity sonar on fish. Michele B. Halvorsen, Lidia Eva Wysocki, and Arthur N. Popper (Dept. of Biol., Univ. of Maryland, College Park, MD 20742, apopper@umd.edu)

Studies investigated the effects of exposure to low-frequency active (LFA) sonar on rainbow trout, channel catfish, and pumpkinseed sunfish using an element of the SURTASS LFA. Animals were exposed to sounds that had a received peak level of 193 dB *re*: 1 uPa (rms) (188.5 dB *re*: 1 uPa^2 s SEL). Measurements were made of hearing sensitivity using auditory brainstem response and of behavioral responses. Additional studies were done on pathology of the ear and other organ systems. Trout and catfish both showed temporary threshold shifts immediately after sound exposure, while sunfish showed no threshold shift. However, the amount of threshold shift and frequencies concerned varied. In addition, trout and catfish showed immediate behavioral responses to the sound onsets and in relative distribution during sound presentation. Details of the responses differed between species. There was no mortality in any species attributable to sound exposure during or after experiments. SEM examination of hair cell ciliary bundles of the inner ears did not show any damage. Similarly, there were no effects on the swim bladder or nonauditory tissues. Overall, the effects of LFA on fish depend upon species and appear to be temporary and relatively modest. [Work supported by Chief of Naval Operations.]

2:35

2pAB4. Effects of riverine seismic air-gun exposure on fish hearing. David A. Mann (Univ. of South Florida, College of Marine Sci., 140 7th Ave. S., St. Petersburg, FL 33701, dmann@marine.usf.edu), Peter Cott, Bruce Hanna (Dept. of Fisheries and Oceans, Yellowknife, NT, Canada X1A 1E2), Alex MacGillivray, Melanie Austin (JASCO Res. Ltd., Victoria BC, Canada V8Z 7X8), Michael Smith, and Arthur N. Popper (Univ. of Maryland, College Park, MD 20742)

Seismic airguns produce considerable amounts of acoustic energy that have the potential to affect marine life. This study investigated the effects of exposure to an airgun array in the Mackenzie River Delta on the hearing of three fish species: northern pike (*Esox lucius*), broad whitefish (*Coregonus nasus*), and lake chub (*Couesius plumbeus*). Fish were placed in cages in 1.9 m of water and exposed to 5 or 20 airgun shots, while controls were placed in the same cage but without airgun exposure. Hearing in both exposed and control fish were then tested using auditory evoked potentials (AEPs). Threshold shifts were found for exposed fish as compared to controls in the northern pike and lake chub, with recovery within 24 h of exposure, while there was no threshold shift in the broad whitefish. It is concluded that these three species are not likely to be substantially impacted by exposure to a 2D airgun array used in a river seismic survey. Care must be taken in extrapolation to other species in other environments and to fishes exposed to airguns in 3D tests or where the animals are exposed to a larger number of airgun shots over a longer period of time.

3:00–3:15 Break

3:15

2pAB5. Effects on fish of pile driving, wind turbines, and other sources. Anthony Hawkins (Loughine Ltd., Kincraig, Blairs, Aberdeen AB12 5YT, UK)

The sounds associated with construction work in the sea are reviewed. The installation of offshore oil and gas platforms, the mounting of offshore wind turbines on the seabed, the construction and renovation of harbors and piers, and the laying and trenching of pipelines and cables can be exceptionally noisy activities. The sounds associated with pile driving, in particular, have the potential to injure fish, induce hearing loss, and evoke avoidance reactions. The sound-pressure levels generated in water by these activities are generally measured, but many fish respond to particle motion rather than sound pressure. Measurements of particle motion and intensity will be necessary in the future if the full effects of these sounds are to be assessed.

3:40

2pAB6. Effects of background sound on fish. Michael E. Smith (Dept. of Biol., Western Kentucky Univ., Bowling Green, KY 42101, michael.smith1@wku.edu), Lidia E. Wysocki, and Arthur N. Popper (Univ. of Maryland, College Park, MD 20742)

There is increasing awareness that underwater anthropogenic sounds may be detrimental to marine organisms. While most of this work has focused on marine mammals, recent studies have shown that sounds higher than background can have detrimental effects on fish as well. This presentation is a review of the current data available on the effects of increased background ambient sound on fish. Loud continuous sounds can cause temporary hearing loss in fish, with the extent of hearing loss increasing with noise exposure duration and intensity, and recovery of hearing occurring within a few days or weeks. The extent of hearing loss is also species

specific—fish with more sensitive hearing thresholds are more prone to hearing loss, whereas nonsensitive fish are barely affected. The latter was shown in a long-term study on the effects of aquaculture noise in rainbow trout. A model termed the linear threshold shift hypothesis (LINTS) has been proposed to predict the extent of noise-induced hearing loss in fish, and this model should be beneficial in mitigating the effects of anthropogenic sound on fish. Other effects of noise include acoustical masking and physiological and behavioral stress responses, which also depend on species and noise type.

4:05

2pAB7. Noise exposure criteria for fish and turtles; lessons learned from criteria for marine mammals. Roger L. Gentry (ProScience Consulting, P.O. Box 177, Dickerson, MD 20842-0177, Roger.gentry@comcast.net)

A committee that is just finishing noise exposure criteria for marine mammals has learned the following lessons that may apply to the writing of similar criteria for fish and turtles. Writing criteria will require scientists from highly diverse backgrounds meeting multiple times over several years. Scientific discourse should prevail throughout; special interests will hinder the writing of science-based criteria. Because empirical data will undoubtedly be inadequate to the task, extrapolation procedures will be needed. Especially lacking will be animal data reporting metrics like SEL and particle motion. The wide diversity of sound types and of animal species will necessitate some grouping within each category. The most efficient format for the criteria will be a matrix of the two groupings. However, existing data will not support a matrix having too many cells. Some criteria will need to be expressed in more than one metric to account for all the relevant aspects of complex signatures. Frequency weighting functions will be needed. Criteria for injury will be easier to write than for behavioral responses due to data availability. Finally, several iterations of the criteria will be needed as science improves. The first version should be written to accommodate change.

4:30

2pAB8. Working group on "The effects of sound on fish and turtles": An update. Richard R. Fay (Parmly Hearing Inst., Loyola Univ. Chicago, IL 60626) and Arthur N. Popper (Univ. of Maryland, College Park, MD)

In order to develop acoustic exposure criteria for fish and marine turtles based on scientific evidence, an ASA Standards Working Group was formed with a membership that includes basic scientists expert on fish and turtle bioacoustics, physical acousticians with special expertise in marine bioacoustics, and several individuals with expertise on effects of anthropogenic sound in the marine environment. This presentation is a summary of the group's progress to date. One of the Working Group's goals is to publish several papers, one on what is known about damage risks due to exposure to underwater noise (e.g., from pile driving, seismic exploration, sonar systems), and one assessing the efficacy of various measures to mitigate adverse effects of noise exposure. The working group has tentatively decided that the fish potentially affected should be categorized with respect to their hearing sensitivity (potential for auditory system damage) and whether the species is known to detect sound pressure or acoustic particle motion. Over the next year to 18 months, the Working Group will be evaluating the known effects of sound sources on fish and turtles, identifying areas in which further research is needed, and beginning to develop noise exposure criteria for both turtles and fish.

2pBB1. Nanoacoustics: Towards imaging nanostructures using picosecond ultrasonics. T. B. Norris (Ctr. for Ultrafast Optical Sci., Univ. of Michigan, Flint, MI 48502, tnorris@eecs.umich.edu)

Coherent acoustic phonon pulses with a peak frequency and bandwidth of the order of 100 GHz can be generated by ultrafast optical excitation of a thin metal film on a crystalline substrate. We demonstrate submicron resolution imaging of surface-grown nanostructures using these picosecond ultrasonic pulses. Ultrafast optical pulses from a Ti:sapphire oscillator are used to thermoelas-

tically excite a patterned 15-nm-thick Al film on a Si substrate. The spatio-temporal diffracted acoustic strain field is measured by time-delayed optical probe pulses on the opposite side of the substrate, and this strain field is used in a time-reversal algorithm to reconstruct the Al pattern. The image resolution is characterized using lithographically defined 1-micron-period Al structures on Si. Straightforward technical improvements should lead to a resolution of at least 45 nm, which will significantly extend the resolution of acoustic microscopy and provide a novel contrast mechanism for nanoscale imaging. To assist the development of this imaging method, we have also made experimental and theoretical studies of the behavior of these coherent acoustic phonon pulses after propagation through millimeter-scale distances in crystalline Si.

1:55

2pBB2. Applying optics in surface wave laser ultrasonic microscopy. Michael Somekh, Stephen Sharples, and Matthew Clark (Univ. of Nottingham, NG7 2RD, UK, mike.somekh@nottingham.ac.uk)

Laser ultrasonics has many advantages compared to contacting ultrasonics, especially when both optical generation and detection are used. In addition to the obvious advantages of remote inspection there are several other benefits. In this paper we concentrate on the flexibility that can be conferred by employing both optical technology and optical concepts in our laser ultrasonic systems. The papers shows how spatial light modulators (SLMs) can be used to control the optical beam profile used to generate the ultrasonic waves. Initially, SLMs were introduced to improve the signal-to-noise ratio of the system. This is achieved by exciting the tone burst with a grating structure so that large signals can be generated without ablation. The SLMs can also be used to produce optical profiles that generate self-focusing surface waves; this also increases the ultrasonic amplitude. Our recent work has used SLM generation to overcome aberrations or distortions in the ultrasonic field during propagation. To this end an adaptive system using integrated electronics to overcome the phase aberrations during propagation has been developed. We also show how the SLM can be used to perform acoustic wavelength spectroscopy, which has proved invaluable in the characterization of texture in industrially important materials.

2:20

2pBB3. Laser generation and detection of zero-group velocity Lamb mode resonance in thin plates. Claire Prada, Dominique Clorennec, Daniel Royer (LOA, ESPCI, Universit Paris 7, CNRS UMR 7587, 10 rue Vauquelin, 75231 Paris, Cedex 05, France), Oluwaseyi Balogun, and Todd W. Murray (Boston Univ., Boston, MA 02215)

Some Lamb modes exhibit a resonant behavior at frequencies where the group velocity vanishes while the phase velocity remains finite. Such a zero group velocity point exists in most isotropic materials for the first-order symmetric mode. Laser sources couple efficiently into this resonance and a sharp peak is observed with source and receiver on epicenter. Moving the detection point away from the source allows us to establish the dispersion curves of the plate and observe the negative phase velocity. We used a modulated diode laser source and a Michelson interferometer to observe the resonance at high frequency. Measurements were made on different material of thickness down to 4μm. The resonance peak is sensitive to the thickness and mechanical properties of plates and may be suitable for the measurement and mapping of nanoscale thickness variations. We also observed this behavior with a 20-ns pulsed YAG laser source and a heterodyne interferometer. The low attenuation in duralumin allows the excitation of a very sharp resonance in a single shot. Thickness variations as small as 0.1μm have been measured in a 0.50-mm-thick duralumin plate. Furthermore, the time decay of the signal provides an estimation of the local attenuation.

2:45

2pBB4. Fabry Perot polymer film sensors for ultrasound field characterization and biomedical photoacoustic imaging. P. C. Beard (Dept. of Medical Phys. and Bioengineer., Univ. College London, Gower St., London WC1E 6BT, UK)

A contact ultrasound sensing technique based upon the detection of acoustically induced changes in the optical thickness of a Fabry Perot polymer film sensing interferometer has been developed for ultrasound measurement and imaging applications in medical and industrial fields. The technique provides a broadband ($>$50 MHz) response and excellent detection sensitivities ($<$1 kPa), comparable to those of piezoelectric PVDF transducers. A key feature is that the sensing geometry is defined by the area of the polymer sensing film that is optically addressed. As a consequence, very small element sizes (in principle down to the optical diffraction limit of a few μm) can be obtained without compromising detection sensitivity—a useful advantage over piezoelectric transducers. Additionally, by spatially sampling over a relatively large aperture, a high-density ultrasound receive array can readily be configured. These attributes lend the technique to a variety of applications such as mapping the output of broadband ultrasound sources, transmission ultrasound imaging, and biomedical photoacoustic imaging. The latter is particularly promising, offering the prospect of high-resolution imaging of optically absorbing soft tissue structures such as blood vessels for the study of tumors and other tissue abnormalities characterized by changes in the structure and oxygen status of the microvasculature.

3:10–3:25 Break

3:25

2pBB5. Playing with speckle in acousto-optic imaging. Albert-Claude Boccara, Benoit Forget, Francois Ramaz, Emmanuel Bossy (CNRS and Laboratoire Optique, ESPCI, 10 rue Vauquelin, F75005 Paris, France), Michel Gross (ENS Laboratoire, F75005 Paris, France), Pedro Santos, Florence Jean, and Michael Atlan (CNRS and Laboratoire Optique, F75005 Paris, France)

Using light to image in-depth structures and to quantify them in terms of optical (absorption, scattering) properties is a goal for physicists. We will recall the approaches which overcome the strong loss of the photons directional memory in scattering media and their limitations in terms of depth and resolution. Then we will consider hybrid methods which couple acoustics and optics to reach the optical contrast with the acoustic resolution: opto-acoustics, where a locally absorbed laser pulse generates an acoustic signal whose position and depth can be localized by an array of piezoelectric detectors, and acousto-optics (A.O.), where an ultrasonic beam

modulates the speckle. We will focus on the principle of A.O. signal generation for tagging spatially selected photons and describe various approaches based on numerical heterodyne holography or heterodyne holography using a photo-refractive beam splitter. To get enough signals through thick tissues (e.g., breast) in a short time we use these techniques at the shot noise limit. Finally we show images revealing optical contrasts in artificial structures or in tissues.

Contributed Papers

3:50

2pBB6. Characterization of nano-electro-mechanical systems (NEMS) using photoacoustic microscopy. A. SampathKumar, K. L. Ekinci, and T. W. Murray (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, twmurray@bu.edu)

A photoacoustic microscopy system has been developed for the non-contact characterization of materials at the micro- and nanometer scale. The system uses an electroabsoption modulated laser source for material excitation and a path-stabilized interferometer to detect the resulting displacements. Using this system, we describe the optical excitation and detection of high-frequency nanoelectromechanical systems (NEMS) at ambient temperature and pressure. Using a tightly focused modulated laser source, we have actuated the out-of-plane flexural resonances of bi-layered doubly clamped nanomechanical beams. The optically detected displacement profiles in these beams are consistent with a model where the absorbed laser power results in a local temperature rise and a subsequent thermally induced bending moment. The excitation technique allows probing and actuation of NEMS with excellent spatial and temporal resolution. From a device perspective, the technique offers immense frequency tunability and may enable future NEMS that can be remotely accessed thus obviating the need for electronic coupling. [The authors gratefully acknowledge funding from National Science Foundation under Grants ECS-0304446 and ECS-0210752.]

4:05

2pBB7. Focusing by use of time reversal of photoacoustic waves. Emmanuel Bossy (Laboratoire d'Optique Physique, ESPCI-CNRS UPR5, 10 rue Vauquelin 75005 Paris, France), Gabriel Montaldo, Jean-Francois Aubry, Michael Tanter, Mathias Fink (ESPCI-CNRS Universite Paris 7, 75005 Paris, France), and Claude Boccara (ESPCI-CNRS UPR5, 75005 Paris, France)

Time reversal of ultrasonic waves allows focusing of ultrasound through complex media, such as highly aberrating media. On one hand, focusing with time reversal can be performed by backpropagating detected ultrasonic waves generated by a localized ultrasound source. This source classically consists of high acoustic contrasts echoing ultrasonic waves generated by an incident ultrasonic field, or directly by pointlike transducers inserted in the medium. On the other hand, the photoacoustic effect consists of the emission of ultrasound caused by the absorption of light by an optical absorber. In particular, this effect can be used to ultrasonically image a distribution of optical absorbers simply by recording photoacoustic signals on an imaging transducers array. In this work, we perform time reversal of ultrasound generated by a pointlike photoacoustic source in order to automatically focus ultrasound back to an optical contrast. A Q-switched pulsed Nd:YAG laser was used to illuminate tissue phantom with nanosecond laser pulses. Conventional ultrasonic transducers arrays (in the MHz frequency range) and a time-reversal electronics were used to detect, record, and time reverse photoacoustic signals. We show that this allows focusing of ultrasound through highly aberrating medium, and perform acoustical imaging with good resolution within the isoplanetic region surrounding the optical contrast.

4:20

2pBB8. Laser pulse impact characterization using ultrasonic transducers. Subash B. Jayaraman, Mark A. Bohenick, Vladimir Semak, Bernhard R. Tittmann (The Penn State Univ., 212 Earth & Eng. Sci. Bldg., University Park, PA 16802), Jill R. Welsch, and Nicholas C. Nicholas (The Penn State Univ., University Park, PA 16802)

Experiments were conducted with an excimer laser (wavelength 248 nm) to cause damage to gelatinous materials, which have optical properties similar to skin tissue. The laser pulses, when they impact the specimen, generate an elastic wave that propagates through the material. A 150-MHz broadband ultrasonic transducer was placed underneath the specimen to observe the material response and the pressure generated by the laser pulse. Different incident laser energies and laser beam spot sizes were utilized to obtain a range of input parameters, and the corresponding transducer responses were recorded. Fourier analysis of the signals was performed to identify the frequency response from the laser pulse. Additional tests were carried out to observe the effects due to a train of laser pulses. Earlier tests were performed with 200-kHz hydrophone-calibrated transducer but due to the shortness of the laser pulses ($\sim$20 ns), a higher frequency transducer was used to accurately characterize the laser impact. The initial results indicate that there is a dominant frequency response around the 25–30-MHz regime.

2pEA1. Dr. Blue at the Underwater Sound Reference Division. Joseph F. Zalesak (2359 US Hwy. 70, SE #325, Hickory, NC 28602-8300)

At the Underwater Sound Reference Division Dr. Blue had many varied interests including acoustic metrology, acoustic materials research, enginering acoustics, underwater transducers, and bioacoustics. He performed the first thorough study on the reproducibility of calibrations of standard hydrophones. He supported the development of traveling-wave tubes and large pressure vessels for calibrating Navy sonar transducers and for the measurement of acoustic materials. The Acoustic Pressue Tank Facility is a 30 000-gal acoustic test vessel ideally suited for acoustic measurements at hydrostatic pressures up to 2700 psi and at frequencies as low as 1.0 kHz and can accommodate acoustic devices up to 6 ft in diameter. Dr. Blue supported research for improved measurement techniques for determining the properties of acoustic materials. Dr. Blue actively supported the development of new elastomeric materials used in the construction of underwater transducers. The Sonar Transducer Reliability Improvement Program was an extinsive program to properly specify a sonar transducer for Navy applications. He first suggested that coupler reciprocity might be used to perform ultra-precise calibrations of hydrophones. He also supported research in manatee vocalizations and dolphin echolocation clicks. Low-noise hydrophones with noise levels better than sea-state zero were developed for general use.

2pEA2. A perspective of Navy transducer calibration standards. Kirk Jenne (Office of Naval Res., Code 03D&I, 875 N. Randolph St., Arlington, VA 22203-1995)

Research and development efforts to establish underwater electroacoustic transducer standards for use in a variety of environmental conditions, performed concurrently with research on calibration methodologies, began nearly 60 years ago. This research and development effort successfully generated a series of standards now made available under the auspices of the U.S. Navy's Underwater Sound Reference Division in Newport, RI (a.k.a. USRD). Because of consistent and insightful investment of resources made over the years by Navy technical agents and advocates like Dr. Joseph Blue, scientists and engineers from government (U.S. and select foreign), academia, and industry can use Navy transducer calibration standards to perform accurate measurements of acoustic energy underwater. Definition and characteristics of a standard are considered. Performance characteristics of transducer standards currently used, along with some discussion of applications, are presented.

2pEA3. Development of 1-3 piezocomposites for U. S. Navy applications. Thomas R. Howarth and Kim C. Benjamin (Naval Sea Systems Command Div. Newport, 1176 Howell St., Newport, RI 02841, Howarthtr@npt.nuwc.navy.mil)

Efforts to develop 1-3 piezocomposite materials for U.S. Navy applications began in the early 1990s at the former Naval Research Laboratory's Underwater Sound Reference Detachment in Orlando, FL. These initial investigations concentrated on evaluating the materials properties and parameters from a number of different contractors and manufacturing techniques. This was followed by efforts to initially fabricate receiving devices to replace traditional piezoceramic sensor prototypes, followed by development of devices with both receiving and transmitting capabilities. The presentation will discuss the initial NRL-USRD efforts and follow the development of 1-3 piezocomposite materials from these humble beginnings to devices that are currently being used and further developed by the U.S. Navy. [Work supported by the NRL, ONR, DARPA, and NAVSEA.]

2:05

2pEA4. Use of complex source points to simplify numerical Gaussian beam synthesis. Stephen Forsythe (Naval Undersea Warfare Ctr., 1176 Howell Ave., Newport, RI 02841)

It is often desirable to generate the acoustic field due to a so-called Gaussian beam. One way to do this is to use the free-space Green's function for the acoustic field and to sum small area sources over a circular plate with the appropriate shading for the desired Gaussian beam. For very high frequencies and narrow beams, the computation time to give an accurate sum can be large when calculating the sum for many points in the acoustic field. An alternate approach comes from the use of a single point source with complex coordinates $R=(Xr+i^*Xi, Yr+i^*Yi, Zr+i^*Zi)$. When this complex source point is used in the free-space Green's function, the formal expressions for pressure and particle velocity can be used if careful attention is paid to the interpretation of the complex distance, r, that arises in the $\exp(ikr)/r$ term. The singularity is no longer a single point in the case of a complex source, but a circular disk. The far field of a complex source point is a good approximation to a Gaussian beam. Several computational uses of the technique will be demonstrated. Extension to the shear wave Green's function will be explored. [Work supported by ONR.]

2pEA5. Joe Blue and nonlinear acoustic transduction: Lessons learned and forgotten, some even ignored; and practical issues to revisit, anew. Thomas Muir (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, One Coliseum Dr., University, MS, 38677)

The 20th century was ripe with major advances in the understanding of nonlinear acoustics and its practical applications, in the American as well as the European and Soviet schools of thought. Some of us were privileged to study this art and contribute to its science, guided by the world's finest educators and mentors. The results originated in physics and were applied to aircraft acoustics and underwater sound, and later to biomedical acoustics, and other arenas, with great success. Joe Blue was a contributor and long-time advisor in many of these endeavors. Some early nonlinear acoustics topics will be reviewed, to refresh memories and introduce newcomers to the field. This includes parametric transmitters, the effects of shock formation and harmonic generation, parametric receivers, various theoretical models, classic experiments in air and water, as well as practical applications. In the early days, ideas for new nonlinear acoustic applications were often met with the comment, ''That's crazy.'' Perhaps many of these ideas were not crazy enough. At the present time, there appears to be some lack of boldness and innovation, coupled with abundant mistakes, in what is proposed and reported. Some comments on the state of the art are offered. [Work supported, throughout the years of the mid to late 20th century, by the U.S. Navy.]

3:10

2pEA6. Investigation of media with large, negative parameters of nonlinearity and their application to the enhancement of a compact, omnidirectional, parametric source. Peter H. Rogers, Etienne Dufour, and David H. Trivett (Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332)

This paper reports on two media whose acoustic properties are highly pressure dependent and, thus, have large nonlinear parameters ($B/A \sim -3000$ to -5000). One is Xanthan gelatin filled with, 10%, Expancel microspheres. The other is a polyurethane rubber, Polytek 74, with 20% Expancel microspheres. The microspheres have a high bulk modulus at ambient pressure due to the hoop stiffness of the spherical shell. As pressure is increased some of the microspheres buckle, leading to significantly decreased bulk modulus. The decreasing bulk modulus with increasing hydrostatic pressure (negative dc/dp) results in both negative B/A and low sound speed (150 m/s at the minimum), which further enhances nonlinear distortion. These media are used to enhance the efficiency of an underwater parametric source. Experiments on a spherical source with a thin layer (2 cm thick) of the Xanthan gelatin material resulted in a generated difference frequency source level 16 dB higher at 300 Hz, than would be obtained driving the transducer directly at the difference frequency. Experiments on the same source with a thin layer of the microvoided, polyurethane rubber are in progress. This material has a smaller coefficient of nonlinearity but operates over a broader range of hydrostatic pressures.

3:30

2pEA7. Nonlinear acoustic detection of buried landmines: A tribute to Joe Blue. Murray S. Korman (Phys. Dept., U. S. Naval Acad., Annapolis, MD 21402)

As a graduate student at Brown University ($\sim$1978), this researcher was very fortunate to have met Joe Blue at Acoustical Society meetings. As I had little knowledge of the members in the society and an extremely limited grasp of the practical technology behind nonlinear acoustics, Joe was extremely friendly and took the time to answer a long list of questions about nonlinear underwater transducer designs with applications to the parametric array [Muir, T.G. & Blue, J.E. ''Experiments on the acoustic modulation of large-amplitude waves,'' J. Acoust. Soc. Am. **46**, 227–232 (1969)]. This influenced this researcher's Ph.D. thesis involving experiments on the scattering of sound by sound in the presence of turbulence. Recently, experiments on the nonlinear acoustic detection of buried landmines [Korman, M.S. & Sabatier, J.M., ''Nonlinear acoustic techniques for landmine detection,'' J. Acoust. Soc. Am. **116**, 3354–3369 (2004)] has brought some attention to understanding the difference between classical and nonclassical nonlinearity. As a tribute to Joe Blue, the latest results will be presented involving the connections to mesoscopic nonlinear elasticity and slow dynamics in nonlinear buried landmine detection. Here, tuning curve behavior of the soil-surface vibration over a landmine exhibits a linear decrease in resonant frequency with increasing amplitude. Two-tone test excitation reveals a rich spectrum of combination frequency components useful in detection schemes.

3:50

2pEA8. The application of acoustic standards to sound sources and the subsequent levels in the ocean. William M. Carey (Aero and Mech. Eng., College of Eng., Boston Univ., Boston, MA 02215)

The American National Standards on Acoustics are applied to common sound sources used in both acoustics research and in naval sonar systems operation. Metrics are quantified for both continuous and transient sources of sound. The standard definitions are reviewed with theoretical sound source models and applied to examples of energy sources of sound such as transients from a small omni explosive, an air gun, a light bulb, and a dolphin. A qualitative model of a typical surface ship sonar system is discussed and active sonar transmissions are analyzed with the requisite quantitative metrics required to characterize these emissions. The relative role of peak pressure, time spread, intensity, and energy flux is discussed for deep- and shallow-water environments. These results should be useful in environmental assessments, biological experiments, and in the system design.

2pEA9. Calibrating parametric sonars for backscattering applications. Kenneth G. Foote (Woods Hole Oceanogr. Inst., 98 Water St., Woods Hole, MA 02543)

The status of parametric sonar calibration is reviewed. For backscattering applications, the standard-target method, which is widely used in calibrating ultrasonic scientific echo sounders and multibeam sonars that provide the water-column signal, can be adapted. Two problems generic to parametric sonars are addressed. (1) The virtual nature of the array may require controlled measurements at a number of ranges, spanning the near field in the general case. (2) Calibration at rather low difference frequencies requires a suitably powerful target. Both measurement protocols and target design are considered for a particular parametric sonar based on primary frequencies in the band 15–21 kHz, with difference frequencies in the band 0.5–6 kHz and sum frequencies in the band 30–42 kHz. Solid elastic spheres are specified for both frequency bands. For the lower band, this is an aluminum sphere of diameter 280 mm, with immersed weight of 190 N.

4:25

2pEA10. Evaluating the significance of interface nonlinearity for shallow-water parametric array sonar. Roger Waxler and Thomas G. Muir (NCPA, University, MS 38577)

Difference frequency generation in shallow water is considered for the case in which wave steepening in the primary beam is not significant. A general formula for the effective difference frequency source strength is presented. The Pekeris shallow water model, in which sound speeds and densities in both the water column and sediment are assumed to be constant and both interfaces are assumed to be planar, is considered. In this model, the propagating difference frequency pressure field is computed. Contributions from the interface nonlinearity are compared to those from nonlinearity in the water column.

4:40

2pEA11. High frequency acoustic wave propagation. Mohsen Badiey (Ocean Acoust. Lab., Univ. of Delaware, Newark, DE 19716)

A program studying high frequency acoustics was established in the mid-1990's by the Office of Naval Research that is still going on and has evolved into a substantial basic and applied research initiative to study many areas, including underwater communication. This abstract explains the genesis of that program, and Joe Blue's involvement in making it happen. During the course of the initial experiments under that program, a series of issues were raised dealing with the effects of acoustic transmissions on marine mammals. Again, Joe was a key person in resolving those issues, which could have brought the program to a halt. His insight into the technical problems, as well as, his calm nature helped to bring an excellent new program in acoustic research into being.

4:55

2pEA12. Ship strike acoustics: A paradox and parametric solution. Edmund Gerstein, Joseph Blue (Leviathan Legacy Inc., 1318 SW 14th St., Boca Raton, FL 33486), and Steve Forsythe (Naval Undersea Warfare Ctr., Newport, RI 02841)

Marine mammals are vulnerable to ship collisions when are near the surface. Here, acoustical laws of reflection and propagation can limit their ability to hear and locate the noise from approaching vessels. Defining the physics of near-surface acoustical propagation as it relates to ship noise and hearing is central to understanding and mitigating ship strikes. Field data from controlled ship passages through vertical hydrophone arrays demonstrate a confluence of acoustical factors that poses detection challenges including (i) downward refraction; (ii) spreading loss; (iii) Lloyd's mirror effect; (iv) acoustical shadowing; and (v) masking of approaching ship noise by ambient noise and distant ships. A highly directional, dual-frequency parametric sonar has been developed to mitigate these challenges and alert marine mammals of approaching vessels. The system projector is a planar array, comprised of 45 elements, band centered to transmit a high carrier frequency along with a lower sideband signal. The nonlinearity of water is used to demodulate the mixed high-frequency carrier into a lower-frequency waveform audible to both manatees and whales. The bow-mounted arrays project a narrow beam directly ahead of vessels, and fill in acoustical shadows in an effort to alert marine mammals of the approaching danger. [Research supported by DOD Navy Legacy Program.]

2pMU1. Mode studies in a triangular bell plate. Uwe J. Hansen, James Garner (Dept. of Phys., Indiana State Univ., Terre Haute, IN 47809), Thomas D. Rossing (Northern Illinois Univ., DeKalb, IL 60115), and Suzanne Hogg (Univ. of Technol., Sydney, Australia)

A triangular bell plate serves as a poor man's hand bell. A clapper affixed to the handle strikes the plate, resulting in a sound somewhat resembling the tone of a hand bell. A similar arrangement has been used with slotted Eames tubes. This paper will present a comparison of modes of vibration of a triangular bell plate as observed with holographic interferometry, modal analysis, and as calculated using finite element methods. The holographic interferometry studies were done in the Acoustics laboratory of NIU, the modal analysis work was carried out at ISU, and the FE calculations were done at the UT in Sydney. The similarity of mode shapes and mode frequencies lends credence to the validity of the techniques.

2:00

2pMU2. Finite-element calculation of a bass drum. Rolf Bader (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstrasse 13, 20354 Hamburg, Germany)

The bass drum of a drum kit used with rock or jazz music is modeled as a 3D geometry in a transient finite-element formulation. The geometry was taken from a Gretch drum set called ''Vinnie Colaiuta'' with no cushion damping within the drum or at the resonance membrane. The 12 cross layers or wood used for the drum body was assumed to result in an isotropical Young's modulus all over the wood. The drum was modeled with air enclosed, with the beating and resonating membranes being coupled to the air and to the wooden rim of the drum body. Also, as a starting point of the transient calculation, the strain of the wooden body caused by the tension of the membranes was taken into consideration. The transient model started with a beating on the front membrane and the radiation of the system was integrated over the radiating area. The results are compared to recordings of a real bass drum of this Gretch drum set.

2:30

2pMU3. Finite-element transient calculation of a bell struck by a clapper. Bjrn-Andre Lau, Peter Wriggers (Institut fr Baumechanik und Numerische Mechanik, Univ. of Hannover, Appelstrae 9a, 30167 Hannover, Germany), Albrecht Schneider, and Rolf Bader (Univ. of Hamburg, 20354 Hamburg, Germany)

A finite-element calculation of a bell struck by the bell clapper was performed as a transient contact problem. The geometry of the bell was taken from a real bell which was carved especially in behalf of this research. The eigenmodes and eigenfrequencies of the bell were calculated in advance, being in good agreement with the measured frequencies. The clapper/bell contact time and impulse shape show the expected behavior. The impulse shape is a Gaussian impulse with a tendency of a sharper attack slope and a softer decay slope. The periodical shape of the spectrum of this impulse caused by its finite width with zero values for some frequencies is shown. Nevertheless, this spectrum also drives the frequencies of the bell within the low-amplitude region of the driving impulse with expected and measured strength. The reason for this mode energy transfer is discussed. Furthermore, the sound of the bell is calculated as radiation from its surface and analyzed with signal-processing tools like wavelet transforms or autoregressive models.

2pMU4. Finite-difference modeling of the piano. N. Giordano (Dept. of Phys., Purdue Univ., 525 Northwestern Ave, West Lafayette, IN 47907, giordano@purdue.edu)

The construction of a complete computational model of the piano is described. This model treats the three major subsystems of the instrument: the hammers and strings, the soundboard, and the air (the sound radiation). Hammer nonlinearities and hysteresis are included, along with realistic stiff strings with frequency-dependent damping, following the work of Chaigne and Askenfelt. [Chaigne and A. Askenfelt, ''Numerical simulations of piano strings. I. A physical model for a struck string using finite difference methods,'' J. Acoust. Soc. Am. **95**, 1112–118 (1994); A. Chaigne, J. Acoust. **5**, 181 (1992)]. The strings are coupled to a soundboard model that includes the added thickness and stiffness of ribs and bridges. The vibrating soundboard drives the room air, with walls modeled through a complex acoustic impedance following Botteldooren. [D. Botteldooren, ''Acoustical finite-difference time-domain simulation in a quasi-Cartesian grid,'' J. Acoust. Soc. Am. **95** 2313–2319 (1994); **98**, 3302 (1995)]. All of the calculations take a finite difference approach, producing a time domain computation. Calculated tones are presented and future directions discussed. [Work supported in part by NSF grant PHY-9988562.]

3:45

2pMU5. Finite-element simulation of the acoustic guitar. Gregoire P. Derveaux, Eliane Becache, Patrick Joly (INRIA, domaine de Voluceau, BP105, 78153 Le Chesnay Cedex, France, gregoire.derveaux@inria.fr), and Antoine Chaigne (ENSTA, 91761 Palaiseau Cedex, France)

The purpose of this work is a 3-D time-domain numerical modeling of the acoustic guitar. The model involves the transverse displacement of the string excited by a force pulse, the flexural motion of the soundboard, and the sound radiation. A specific spectral method is used for solving the Kirchhoff-Love's dynamic plate model for a damped, heterogeneous orthotropic material. The airplate interaction is solved with a fictitious domain method, which allows for making a good approximation of the geometry of the instrument while using a regular mesh for the calculation of the 3-D sound radiation. A conservative scheme is used for the time discretization. Frequency analysis is performed on the simulated sound pressure and plate velocity waveforms in order to evaluate quantitatively the transfer of energy through the components of the coupled system. The effects of structural changes in soundboard thickness and cavity volume on the produced sounds are presented. Simulations of the same guitar in three different cases are also performed: ''*in vacuo*,'' in air with a perfectly rigid top plate, and in air with an lastic top plate. This allows comparisons between structural, acoustic, and structural acoustic modes of the instrument.

2pNSa1. Rationale for a new loudness standard. Rhona P. Hellman (Dept. of Speech-Lang. Path. and Audiol. and Inst. for Hearing, Speech, & Lang. (106A FR), Northeastern Univ., Boston, MA 02115, hellman@neu.edu)

In 2005, a new loudness standard was approved by ANSI for calculating the loudness of steady sounds. The new standard is based on a recent loudness model [Moore *et al.*, J. Audio Eng. Soc. **45**, 224–240 (1997)] derived from an earlier model devised by Zwicker [Acustica **8**, 237–258 (1958)]. It replaces and supersedes the more limited computational procedure used in the old ANSI S3.4-1980 standard that had its origins in the protocol developed by S.S. Stevens [J. Acoust. Soc. Am. **33**, 1577–1585 (1961)]. Unlike the old ANSI S3.4-1980 procedure, the newly adopted ANSI standard can be applied to sounds with sharp line spectral components as well as to broadband spectra. The new standard also extends the dynamic range for loudness calculations to loudness levels below 40 phons. Hence, it can be used to estimate loudness, or loudness level, with reasonable accuracy at levels close to threshold. Moreover, in accord with the revision of ISO 226 [International Organization for Standardization, Geneva (2003)], it enables the loudness of complex sounds containing spectral energy below 500 Hz to be determined. Empirical examples that illustrate the broader and more accurate scope of the new loudness standard are presented.

1:30

2pNSa2. The Cambridge loudness model: Design principles and predictions. Brian C. J. Moore, Brian R. Glasberg, and Tom Baer (Dept. of Exp. Psychol., Univ. of Cambridge, Downing St., Cambridge CB2 3EB, UK, bcjm@cam.ac.uk)

The Cambridge loudness model, which forms the basis for the new ANSI standard (ANSI S3.4-2005), is similar in structure to loudness models proposed earlier by Fletcher and by Zwicker, but differs in many of the details. The input signal to each ear is specified in terms of its spectrum, which may be defined in 1/3-octave bands, or as the sum of a series of sinusoidal components and one or more pink-or white-noise bands. The first stage of the model is a filter to account for the transfer of sound from the sound field or headphone to the eardrum. The second stage is a filter to account for the transfer of sound through the middle ear. The third stage transforms the effective spectrum reaching the cochlea to an excitation pattern, calculated as the output of an array of level-dependent auditory filters. In the final stage, the excitation at each center frequency is converted to specific loudness, by a nonlinear frequency-dependent transformation. The specific loudness is summed across frequency to give the loudness for each ear, and is summed across ears to give overall loudness. The model accounts well for the effects of level, frequency, and bandwidth on loudness.

1:55

2pNSa3. Reexamining loudness at and near threshold. Michael Epstein (Auditory Modeling and Processing Lab., Inst. for Hearing, Speech & Lang., Dept. of Speech-Lang. Pathol. and Audiol., Northeastern Univ. Boston, MA 02115) and Mary Florentine (Northeastern Univ. Boston, MA 02115)

This talk reviews two sets of data that support the contention that loudness at threshold is not zero, consistent with the new loudness standard. Both sets of data examine the form of the loudness function in normal listeners at low levels. The first set of data was derived from loudness-matching experiments between equally loud tones and tone complexes (i.e., spectral integration of loudness). Listeners matched the loudness of tone complexes comprised of subthreshold components with pure tones above threshold. Results show that a tone complex composed of components at threshold can easily be heard and can be relatively loud. This result is only possible if all tones had some probability of detection (some contribution to loudness), even those below threshold. The second set of data consists of the slopes of the loudness function at threshold, which average 1.3. These data are consistent with loudness functions obtained with a wide variety of methods that yield a slope close to unity. A slope close to unity indicates a positive loudness at threshold in accord with the new loudness standard. [Work supported by NIH/NIDCD Grant R01DC02241.]

2:20

2pNSa4. The new International Organization for Standardization (ISO) standard for the equal-loudness contours: Comparison to earlier contours and procedures. Yôiti Suzuki (Res. Inst. of Elec. Commun., Tohoku Univ., Katahira 2-1-1, Aoba-ku, Sendai 980-8577, Japan, yoh@riec.tohoku.ac.jp) and Hisashi Takeshima (Sendai Natl. College of Technol., Sendai 989-3128, Japan)

Equal-loudness contours exhibit the intensity-frequency characteristic of the auditory system. Since 1956 such contours based on the free-field measurements of Robinson and Dadson [Br. J. Appl. Phys. **7**, 166–181 (1956)] have been widely accepted as an international standard in ISO 226. However, in 1985 some questions about the general applicability of these standard contours were raised to ISO TC/43 WG1 by Fastl and Zwicker. Consequently, a new international effort to measure the equal-loudness contours was undertaken. In 2003, this effort produced a revision of ISO 226. The newer experimental data and their analyses were subsequently published by Suzuki and Takeshima, [J. Acoust. Soc. Am. **116**, 918–933 (2004)]. The revised contours more closely agree with the classic contours measured by Fletcher and Munson [J. Acoust. Soc. Am. **5**, 82–108 (1933)] than with those produced by Robinson and Dadson. This finding is especially true below 500 Hz at moderate loudness levels. Moreover, the revised contours are in good overall agreement with the contours calculated according to the procedure proposed by Moore *et al.* [J. Audio Eng. Soc. **45**, 224–240 (1997)]. In 2005, this procedure was adopted by ANSI for loudness calculations of steady sounds to replace ANSI S3.4-1980. Comparative examples are given.

2:45

2pNSa5. Future directions in loudness standardization: Time-varying loudness. Patricia Davies and Andrew Marshall (Purdue Univ., 140 S. Intramural Dr., West Lafayette, IN 47907-2031, daviesp@purdue.edu)

The loudness of many sounds varies with time and the temporal processing of the human hearing system affects loudness perception. Existing loudness algorithms that are standardized address loudness of stationary sounds. Two algorithms that predict time-varying loudness have been developed: Zwicker's, and Moore and Glasburg's time-varying loudness; variants of the former are available in most sound-quality analysis systems. For continuous sounds with repetitive impulses or beating tones loudness exceeded 5% of the time correlates well with perceptions of overall loudness. The focus here is on predictions of time-varying loudness algorithms for isolated impulsive sounds caused by supersonic aircraft, because recent developments in supersonic aircraft design could result in aircraft producing much quieter booms that may be more acceptable to the general public. Loudness is a major factor in community response; thus, the research focus is to understand how sound modifications (amplitude reduction, signal shaping) affect the loudness of transients. Also, playback systems involve signal filtering; how this may affect loudness perception is of interest. The predictions of the two algorithms are compared for a series of sonic-boom recordings and modified recordings to determine how filtering and signal modification affect loudness predictions.

2pPA1. Assessment of incipient material damage and remaining life prediction with nonlinear acoustics. Dimitri Donskoy (Intelligent Sensing Technologies, LLC, P.O. Box 6457, Fair Haven, NJ 07704-6457), Andrei Zagrai (Stevens Inst. of Technol., Hoboken, NJ 07030), Alexander Chudnovsky, Edward Golovin (Univ. of Illinois at Chicago, Chicago, IL 60607), and Vinod S. Agarwala (Naval Air Systems Command, Patuxent River, MD 20670)

Subjected to a wide spectrum of operational and environmental loads, engineering structures exhibit first signs of material deterioration at micro and meso scales. In contrast to nondestructive assessment of the macro-scale damage that resulted from material fracture, a limited number of technologies have tackled the complex task of detecting and monitoring the small-scale incipient damage. This paper discuses application of the nonlinear acoustic vibro-modulation technique for assessment of the micro/meso scale fatigue damage and remaining life prediction of metallic samples. A nonlinear acoustic damage index (DI), which indicates strength of the damage-induced nonlinear interaction of the high-frequency ultrasonic wave and the low-frequency structural vibration, was monitored during a set of strain-controlled fatigue tests. Stable growth of the damage index was observed at an increasing number of fatigue cycles showing correlation between DI and the micro/meso scale damage accumulation. This correlation allowed for introducing DI in the remaining life prediction methodology based on an entropy density criterion of local failure. Experimental testing confirmed the effectiveness of the proposed prediction approach. [Work supported by NAVAIR.]

1:45

2pPA2. Wave vector resonance in a nonlinear diffuse elastodynamic field. Alexei Akolzin and Richard L. Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, 104 S. Wright St., Urbana, IL 61801)

Nonlinear coupling within an elastic body leads to spectral energy redistribution. The coupling strength can exhibit sharp discontinuities as a function of frequencies, due to wave vector coincidences between constituent waves of different wave speeds. The phenomenon is investigated for an ensemble of weakly nonlinear elastic bodies of a generic ray-chaotic shape, with the elastodynamic field inside being treated as diffuse and described in a statistical fashion. Comparison is made between theoretical estimates of the average mode coupling strength and results of direct numerical simulations performed for an ensemble of 2D plane-strain elastic squares with rough boundaries and a model quadratic nonlinearity representative of elastodynamic waves. Existence of the wave vector resonance and its dependence upon frequency ratios is verified.

2:00

2pPA3. Dynamic characteristics of nonlinear interaction in elastic medium. Nikolai Zagrai (Taganrog State Univ. of Radio-Eng. GSP-17A, 44 Nekrasovsky St., Taganrog, 347928, Russia)

Traditionally, an acoustic wave process is analyzed in terms of sound pressure and/or sound velocity. The dynamic distortion of the wave profile, however, is complicated by contribution of both quadratic and cubic nonlinearities of the elastic medium. This condition necessitates expanding a range of variables to include particle and wave accelerations. As dynamic characteristics, particle and wave accelerations fully complement

analysis of dynamic and inert properties of the elastic medium. The Riemanns solution, in which the quadratic and cubic nonlinearities are accounted for through respective derivatives of the sound velocity, allows for a new and different perspective on the aforementioned properties. For a simple wave with contribution of the quadratic nonlinearity only, the acceleration profile describing dynamics of wave deformation varies symmetrically relative to the discontinuity region. The cubic nonlinearity leads to more complex acceleration profile with asymmetric properties, which can be discerned and assessed using a combination of numerical and graphical methods. Such an approach is quite effective and vivid in separating contributions of quadratic and cubic nonlinearities. An integral nonlinear parameter N, introduced on the basis of this analysis, is proposed for estimating ability of the fluidlike medium to support effective propagation and nonlinear interaction of acoustic waves.

2:15

2pPA4. A frequency-domain algorithm for the propagation of finite-amplitude acoustic signals. Lauren E. Falco (Grad. Prog. in Acoust., Penn State Univ., 217 Appl. Sci. Bldg., University Park, PA 16802, lfalco@psu.edu), Philip J. Morris, and Anthony A. Atchley (Penn State Univ., University Park, PA 16802)

It has been shown that the quantity Q_{p^2p}, the cross-spectral density of the square of the pressure and the pressure, is related to the strength of nonlinear effects in a propagating acoustic signal. Morfey and Howell [AIAA J. **19**, 986–992, (1981)] derive from the Burgers equation an expression that relates Q_{p^2p} to the rate of change of the power spectral density (PSD) of a signal. They suggest a propagation scheme based on this expression that makes assumptions about the Gaussian nature of the signal. These assumptions are invalid for many finite-amplitude signals, so a new propagation scheme is proposed and validated. This scheme uses an expression for the rate of change of the phase of the signal as well as its amplitude. These two expressions are combined into a finite-difference equation that is used to step the signal to the desired propagation distance. The method is shown to compare favorably with the Fubini solution for lossless plane waves. Comparisons are also made with a numerical split-step algorithm for the nonlinear propagation of a broadband source, and with experimental data obtained in a plane wave tube. [Work supported by ONR, GE.]

2:30

2pPA5. Thermal gradient effects on the propagation of nonlinear pressure waves in a gas. Nicholas DiZinno, George Vradis, and Volkan Otugen (Mech. & Aerosp. Eng., Polytechnic Univ., 6 Metrotech Ctr., Brooklyn, NY 11201, dizinno@yahoo.com)

A numerical study of wave propagation through gases with nonuniform temperature distributions will be presented. The main objective of this study is to determine the impact of temperature gradients on high-intensity, initially sinusoidal pressure waves. Particular emphasis is paid to wave reflection, transmission, and any influence a high-temperature region may have on nonlinear behavior. Ultimately, the performance of thermal barriers in attenuating nonlinear waves is evaluated. The concept of using regions of hot gas inside an ambient environment has potential in aeroacoustic applications, such as jet screech mitigation. This analysis considers one-dimensional compressible unsteady Euler equations with an ideal gas state equation, applied over a uniform domain. The domain is composed of two regions with uniform and equal gas properties (ambient conditions) separated by a third region with higher gas temperature and, accordingly, lower density. Pressure is uniform throughout the domain. We introduce a high-intensity sinusoidal wave into this medium. The shape and extent of the high-temperature zone is varied to study the effect of this region on wave propagation. Further, wave reflection and transmission are studied for a range of wave and thermal field parameters. Results for nonlinear pressure waves are compared to linear acoustic waves.

2:45

2pPA6. Evanescent time reversal: Super-resolution and communications applications. Stephane G. Conti, Philippe Roux, and William A. Kuperman (SIO/UCSD, Marine Physical Lab., 9500 Gilman Dr., La Jolla, CA 92093-0238)

The spatial resolution of the focused field with a classical time-reversal mirror in the far field has a wavelength-order diffraction limit. Previously reported results for super-resolution beyond the diffraction limit require either the full knowledge of the original source, or the evanescent waves in the near field. Here, we show that subwavelength focusing can be achieved without *a priori* knowledge of the original probe source. In the wave-number domain, the contributions for the spatial localization and for the resolution of the focus can be separated from each other in the time-reversed field recorded within one wavelength of the original source. The evanescent time-reversal field is then obtained from the combination of the spatial localization contribution from the far-field time reversed with the spatial resolution for a point source. Further, we show that different signals can be transmitted simultaneously with subwavelength separation. Super-resolution of the order of 1/20 of the wavelength is experimentally demonstrated with acoustic wave fields. Applications for communications are presented using multiple receivers a fraction of the wavelength apart.

2pPA7. Area oscillations of a bias-flow aperture, with application to phonation. Richard S. McGowan (CReSS LLC, 1 Seaborn Pl., Lexington, MA 02420, rsmcgowan@earthlink.net) and Michael S. Howe (Boston Univ., Boston, MA 02215)

A thin baffle plate in a mean flow duct partitions the tube into high- and low-pressure regions. The plate spans the whole cross section of the duct and is pierced by a small aperture, through which a nominally steady bias flow is maintained by the mean pressure differential. Sound is generated when the flow is disturbed by imposed, small amplitude cross-sectional area fluctuations of the aperture. For irrotational flow the radiation is determined by the input impedances of the tube on each side of the aperture, and energy flowing into the acoustic field is equal to the work done on the fluid by the suction force at the edge of the aperture. For high Reynolds number flow of a real fluid (modeled by the imposition of a Kutta condition) much of the work goes into the production of vorticity, the unsteady volume flow is greatly reduced, and at low frequencies there can be a substantial oscillating drag force on the plate [M. S. Howe, Proc. R. Soc. London, Ser. A **366**, 205–233 (1979)]. The application of these results to phonation indicates that the unsteady drag is most important in the lower harmonics of voice. [Work supported by NIDCD-004688 to UCLA.]

3:30

2pPA8. Simulation of fluid flow in and around a porous windscreen. D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., 72 Lyme Rd., Hanover, NH 03768, d.keith.wilson@erdc.usace.army.mil) and Michael J. White (U.S. Army Engineer Res. and Development Ctr., Champaign, IL 61826)

Fluid dynamic simulation of wind noise (turbulent pressure fluctuations) around porous microphone windscreens in an atmospheric flow is made difficult by the broad range of spatial scales, from large atmospheric eddies down to the pore size of the windscreen, that is involved. Here, we describe a simplified simulation approach that is based on two new insights: (1) the ability of linear fluid flow approximations to describe wind noise [Z.C. Zheng and B. K. Tan, J. Acoust. Soc. Am. **113**, 161–166 (2003)] and (2) a new set of macroscopic, time-domain relaxational equations for the linear interaction of a fluid flow with a porous material [D. K. Wilson, V. E. Ostashev, and S. L. Collier, J. Acoust. Soc. Am. **116**, 1889–1892 (2004)]. An upstream flow condition consisting of quasiwavelets

(analogous to turbulent eddies) is also used to create well-developed, realistic turbulence. This simulation approach is shown to provide detailed simulations of the production of pressure fluctuations in and around a porous windscreen.

3:45

2pPA9. Diffraction pattern of an axisymmetric aperture from axial measurements. Edward H. Pees (Dept. of Phys., Univ. of Rhode Island, 2 Lippitt Rd., Kingston, RI 02881-0817)

An axisymmetric aperture can be represented by a circular hole in an infinite rigid screen, a circular piston undergoing harmonic motion, or a more complicated source composed of annular ring transducers. Ordinarily, the radiation pattern for this type of aperture is measured by moving a sensor along a circular arc about the center of the aperture, measuring the intensity of the radiated field as a function of angle. In the present case, the angular spectrum of plane wave representation of the diffracted field is used to demonstrate that the diffraction effect leads to the presence of a wave number distribution, observable along the normal axis of the aperture, that can be used to reconstruct the far-field radiation pattern from measurements taken only along this angular view. Because this diffraction pattern has a direct relationship to the boundary condition on the aperture, it follows that measurements of the axial field can potentially provide useful information regarding the size and shape of the aperture.

4:00

2pPA10. Transient total reflection and transient evanescent wave. Hailan Zhang (Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080 China)

The total reflection of a steady plan wave is well known. The transmitted wave is an evanescent wave that propagates along one direction and evanesces along a direction perpendicular to the propagation direction. Evanescent waves also appear in many other acoustic problems, such as the surface wave along a free boundary of a solid medium. In this report, the total reflections with different incident waves are studied, including an incident beam with a limited width, an incident pulse wave with a limited duration, and an incident bulletlike wave package. These incident waves are represented by superposition of plane waves based on the angle spectrum synthesis. Their transmitted wave, therefore, can be synthesized from the transmitted waves of the plane incident wave. Snapshots of the acoustic field are presented that show the procedure of the interaction of the incident wave with the interface of the media. [Work supported by National Natural Science Fundation of China, No. 10534040.]

2pPP1. Spatial audio target acquisition in the frontal horizontal plane: Effects of feedback, mobility, and index of difficulty. Georgios Marentakis and Stephen Brewster (Dept. of Computing Sci., Univ. of Glasgow, 17 Lilybank Gardens, G12 8QQ UK)

The results of an empirical study investigating the effect of feedback, mobility, and index of difficulty on a deictic spatial audio target acquisition task in the horizontal plane in front of a user are presented. Audio feedback marked display elements are found to enable usable deictic interaction that is performed with high accuracy and can be described using Fitts' law. Feedback does not affect perceived workload or preferred walking speed compared to interaction without feedback. Without audio feedback, spatial audio is not found to support adequately the corrective submovements necessary for high selection accuracies. Interaction with the display becomes therefore highly inefficient. Mobility is found to degrade interaction speed and accuracy by 20%. Participants were able to perform deictic spatial audio target acquisition when mobile while walking at 73% of their preferred walking speed. The proposed feedback design is examined in detail and the effects of variable target widths are quantified. Deictic interaction with a spatial audio display is found to be a feasible solution for future interface designs.

4:05

2pPP2. Effect of roving on spatial release from masking for amplitude-modulated noise stimuli. Norbert Kopčo, Jaclyn J. Jacobson, and Barbara G. Shinn-Cunningham (Hearing Res. Ctr., Boston Univ., 677 Beacon St., Boston, MA 02215, kopco@bu.edu)

A previous study investigating detection of broadband signals embedded in broadband noise showed that detection thresholds depended both on the temporal structure of the target and masker and their simulated spatial locations [Kopco and Shinn-Cunningham, J. Acoust. Soc. Am. **117**, 2396 (2005)]. The current study extends this work by introducing a rove in overall intensity to reduce the reliability of overall intensity cues for detecting the target. Detection thresholds were measured for a broadband noise target spectrally and temporally centered within a broadband noise masker. Thresholds were measured for all combinations of six spatial configurations of target and masker and five modulation conditions (all combinations of target modulated and unmodulated and of masker modulated and unmodulated; when both target and masker were modulated, the modulation could either be equal or π out of phase). The amplitude modulation, if present, had a rate of 40 Hz and depth of 0.5. The masker level was roved by ± 5 dB between intervals within a trial. Results suggest that the cues underlying target detection depend on both the spatial configura-

tion of target and masker and their temporal structure, but that, when available, overall intensity cues also contribute to a target detection. [Work supported by NSF and ONR.]

4:20

2pPP3. Experiments in speech localization using headphones and loudspeakers. Casey Canfield, Michelle Vu (Garrison Forest School, 300 Garrison Forest Rd., Owings Mills, MD 21117), Ilene J. Busch-Vishniac, and James E. West (Johns Hopkins Univ., Baltimore, MD 21218)

This experiment studies the ability of humans to localize sound as recording and playback methods are varied. Further, because subjects are asked to indicate personal preference, we are able to determine the importance of localization in setting personal preference. The stimulus used in this experiment was speech (6 stanzas of a poem, each recorded at a different location). Three recording methods were used: monaural, stereo, and stereo through an artificial head. Two playback methods were used: stereo speakers and stereo headphones. Results of the work are applicable to the design of conference facilities and the design of headphones and speakers. [This work is a Wise Women project. Wise Women partners high school students from Garrison Forest School with Johns Hopkins engineering faculty.]

4:35

2pPP4. Evaluating the principal spectral components positioning a virtual sound source on a cone of confusion. David H. Benson and William L. Martens (CIRMMT, Faculty of Music, McGill Univ., 555 Sherbrooke St. West, Montreal, QC H3A-1E3, Canada, david.benson@mcgill.ca)

Although many studies have attempted to identify spectral cues to sound-source direction for the entire sphere of possible incidence angles, few studies have focused their attention on directional hearing for virtual sources positioned on cones of confusion. These regions of space, defined by relatively constant interaural time and intensity differences, provide an ideal subset of incidence angles for testing the importance of the spectral cues to direction allowing for up/down and front/rear distinctions between sources at constant angular distance from the median plane. In this study, head-related transfer functions (HRTFs) measured on a well-lateralized cone of confusion were decomposed into principal spectral components putatively responsible for positioning a virtual sound source, and their related angle-dependent scores that describe the relative contribution of each shape to the total spectral variation. The findings can be summarized as follows: For the set of ipsilateral HRTFs the most significant set of scores shows sinusoidal variation with angle, and could potentially encode a front-back cue, though with the extrema rotated by about 30 deg. The most significant score from an analysis of interaural spectral differences seems to capture a head-shadowing effect which is most extreme in the lower rear.

4:50

2pPP5. The effect of spectral differences on the ability to judge the laterality of a simulated source followed by a simulated echo. Joseph B. Boomer, Raymond H. Dye, Jr., Stanley Sheft, and William A. Yost (Parmly Hearing Inst., Loyola Univ., 6526 N. Sheridan Rd, Chicago, Chicago, IL 60626)

The purpose of this study was to examine listeners' abilities to lateralize a source click based on interaural difference of time (IDTs) when followed by a spectrally different echo click. The first click was centered at 3000 Hz and the second was centered at 1500, 2000, 3000, 4000, or 5000 Hz. A correlational analysis was carried out to assess the relative weight given to the IDTs of source and echo clicks for echo delays of 8–128 ms. Also measured were proportions correct and proportions of responses predicted from the weights. Listeners were instructed to indicate the laterality of the source click. The IDTs of the source and echo clicks were selected independently from Gaussian distributions ($=0$ s, $=100$ s). When the second click had energy in a spectral region above that of the first, source weights and proportions correct were higher than when the spectral region of the second was lower than the first click. For some observers, this low-frequency dominance was evident for echo delays as long as 128 ms. The effect of echo frequency was constant across all echo delays, although source weights and proportions correct were highest at an echo delay of 8 ms.

5:05

2pPP6. Learning of interaural-level-difference discrimination with a 0.5-kHz tone in human adults. Yuxuan Zhang and Beverly A. Wright (Dept. of Commun. Sci. and Disord., and Northwestern Univ. Inst. for Neurosci., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208)

Sound-source location on the horizontal plane is primarily determined by two cues: interaural time differences (ITDs) for low-frequency sounds and interaural level differences (ILDs) for high-frequency sounds. Though not available in natural listening environments, ILDs in low-frequency sounds, when artificially delivered to listeners through headphones, also can be used to lateralize sounds. Little is known about the neural processing of such low-frequency ILDs. Here, the modifiability of this processing was examined by training human adults on ILD discrimination with a 0.5-kHz tone on the midline. After nine 1-h daily training sessions, trained listeners ($n=6$) improved significantly more than untrained controls ($n=8$) on the trained condition. This learning generalized to a 4-kHz tone and a 0.5-kHz tone amplitude modulated at 30 Hz, but appeared not to generalize to a 1-kHz tone, an off-midline position, or ITD discrimination with the trained tone. This overall learning pattern differs from those previously obtained for ILD at 4 kHz and ITD at 0.5 kHz using the same training paradigm [Wright and Fitzgerald, Proc. Natl. Acad. Sci. U.S.A. **98**, 12307–12312 (2001)], suggesting that the processes involved in low-frequency ILD discrimination differ from those encoding high-frequency ILDs and low-frequency ITDs, at least at the neural site(s) affected by training. [Work supported by NIH/NIDCD.]

2pSAa1. Unsteady surface pressures on a ship hull. Michael Goody, Theodore Farabee, and Yu-Tai Lee (Signatures Directorate, Naval Surface Warfare Ctr., Carderock Div., 9500 MacArthur Blvd., West Bethesda, MD 20817-5700, Michael.Goody@navy.mil)

Unsteady surface pressure measurements at locations distributed on the surface of a ship model hull and flow visualization of the bow wave and free surface are discussed. The measurements were performed in the David Taylor Model Basin using a ship model that is approximately 40 ft. long and representative of a naval combatant at Froude numbers from 0.14 to 0.44. The pressure measurement locations are distributed over the hull surface from 15 surface pressure spectrum and limited spatial coherence measurements are discussed. Additionally, the measured surface pressure spectra are compared to predictions done using an RANS-based formulation and predictions done using an empirical formulation that is based on historical, flat-plate, surface pressure spectra. [Work sponsored by Office of Naval Research, Code 334.]

1:30

2pSAa2. Power flow and wave propagation characteristics of surface ship inner-bottom structure. Robert C. Haberman (BBN Technologies, Old Mystic Mill, 11 Main St., Mystic, CT 06355, rhaberman@bbn.com)

The construction of the inner bottom of a surface ship consists primarily of deck plating connected to hull plating by longitudinal vertical plates. Foundations supporting equipment typically line up with the vertical plates, thereby providing a direct path of mechanical excitation to the hull resulting in forced acoustic radiation. The purpose of this paper, therefore, is to provide an overview of the physics that controls wave propagation in surface ship inner-bottom structure along with a description of the power flow associated with direct force excitation of the vertical plating. Two theories will be presented: (1) an approximate theory based on the vertical plate modeled as a beam coupled to the deck and hull modeled as plates containing flexural waves and (2) an exact theory based on all three structures modeled as plates containing flexural, compressional, and shear waves. Numerical results will be presented that show the importance of full wave coupling along with some interesting phenomena associated with power flow and leakage of energy into deck and hull plating. The implication of these results in statistical energy analyses modeling will be briefly discussed. [Work partially funded by ONR, Code 334 Dr. S. Schreppler.]

1:45

2pSAa3. Radiated acoustic power of model ship hull sections estimated from scanning laser Doppler vibrometer vibration response measurements. Gerard P. Carroll (Naval Surface Warfare Ctr. Carderock Div., 9500 MacArthur Blvd., Bethesda, MD 20817)

This paper will present radiated acoustic power estimates for ship hull models which are based entirely on scanning laser Doppler vibrometer measurements of the underwater vibrating surface.The radiated power estimates are compared to direct measurements of the radiated acoustic power obtained using hydrophones in the reverberant tank. These radiation estimates are based on Rayleigh integral formulations, one for which the vibrating surface is assumed to be baffled, and the other for which it is unbaffled. For the latter case, the pressure in the plane of the vibrating surface is assumed to be zero outside the vibrating surface. This corresponds to a mixed boundary condition in which the velocity is known on the plate and the pressure is known off the plate. An iterative application of the Rayleigh integral is used to determine the velocity and the pressure over the entire plane. For the purposes of calculating the radiated power, this formulation is shown to iterate much more quickly by iteratively calculating the surface intensity. This is possible since the pressure and therefore the surface intensity is zero outside the plate boundary. Utilizing these surface radiation intensity calculations, it is possible to then investigate the sources and mechanisms of the hull radiation.

2:00

2pSAa4. Numerical investigation of small-scale surface ships by energy finite-element analysis. Kuangcheng Wu (Dept. of Signatures and Hydrodynamics, Northrop Grumman Newport News, 4101 Washington Ave., Newport News, VA 23607, kcwu@ngc.com) and Nick Vlahopoulos (Univ. of Michigan, MI 48109)

Experimental investigations have been performed to understand the structural acoustic characteristics of two small-scale surface ship models representing sections of conventional and advanced double-hull ship designs [Craun *et al.*, "Experimental and analytical investigation of surface shiphull structure acoustics using physical models," J. Acoust. Soc. Am. **116**, 2569 (2004)]. Recently, new developments have been added to the energy finite-element analysis (EFEA) for surface ships [Wu and Vlahopoulos, "Vibratory response of surface ships predicted by energy finite element approach," J. Acoust. Soc. Am. **116**, 2569 (2004)]. The presentation will compare hull responses from EFEA predictions to test data for the two small-scale models to validate the new development in EFEA. Furthermore, the impact of the hull responses due to the different model designs will be discussed. [Support for this research is provided by ONR code 334.]

2:15

2pSAa5. Application of a hybrid finite-element formulation for structure-borne vibration in an automotive vehicle structure. Sang-Bum Homg (Cummins, MC 50182, 1900 McKinley Ave., Columbus, IN 47201) and Nickolas Vlahopoulos (Univ. of Michigan, Ann Arbor, MI 48109)

The hybrid FEA method combines the conventional FEA method with energy FEA (EFEA) for analyzing systems that contain both flexible and stiff members. Conventional FEA models are employed for modeling the behavior of the stiff members in a system. Appropriate damping elements are introduced in the connections between stiff and flexible members in order to capture the presence of the flexible members during the analyses of the stiff ones. The component mode synthesis method is combined with

analytical solutions for determining the driving point conductance at joints between stiff and flexible members and for defining the properties of the damping elements which represent the flexible members when analyzing the stiff components. Once the vibration of the stiff members and the amount of power dissipated at the damping elements has been identified, an EFEA analysis is performed in order to determine the amount of vibrational energy in the flexible members. The new developments are validated by comparing results of the hybrid FEA with results from very dense conventional finite-element analyses for a typical body-in-white vehicle structure. [Work sponsored by the Automotive Research Center, supported by the U.S. Army NAC.]

2:30

2pSAa6. The role of structural acoustics in the space shuttle flowliner crack investigation. Michael J. Allen and Robert C. Haberman (BBN Technologies, Old Mystic Mill, 11 Main St., Mystic, CT 06355, mjallen@bbn.com)

During normal inspection of the Space Shuttle main propulsion fuel line system small cracks were identified in a slotted flowliner just upstream of the main propulsion engines. The cause is believed to be resonance excited by pressure fluctuations originating from the downstream fuel pump. This presentation highlights the analyses that were performed to characterize the structural acoustic environment surrounding the flowliner during waterflow and liquid hydrogen laboratory experiments, as well as in-flight conditions. Analyses employed a combination of analytical and finite-element methods to model fluid structure interaction and inverse methods to reconstruct equivalent acoustic sources representative of the fuel pump. Numerical results will be presented that compare experimental strain and pressure data with theoretical counterparts. Implications will be drawn regarding the applicability of the theory to the actual shuttle fuel line system. [Work was sponsored by NASA Marshall Flight Center.]

2:45

2pSAa7. Structural monitoring from noise cross correlation. Karim G. Sabra, William A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., U.C. San Diego, 9500 Gilman Dr., La Jolla, CA, 92093-0238, ksabra@mpl.ucsd.edu), Eric S. Winkel, Dwayne A. Bourgoyne, David R. Dowling, Steve L. Ceccio, and Marc Perlin (Univ. of Michigan, Ann Arbor, MI 48109-2133)

It has been demonstrated theoretically and experimentally that an estimate of the Green's function between two receivers can be obtained from the long-time average of the cross correlation of ambient noise at these two receivers in various environments and frequency ranges of interest: ultrasonics, underwater acoustics, and seismology. This result provides a means for structural monitoring using the ambient structure-borne noise only, without the use of active sources. The coherent wave-fronts emerge from a correlation process that accumulates contributions over time from noise sources whose propagation path passes through both receivers. We present experimental results using random vibration data collected on eight accelerometers mounted on a hydrofoil or plate at the Navy's William B. Morgan Large Cavitation Channel. The tests were conducted at high Reynolds number, with the primary excitation source being turbulent boundary-layer pressure fluctuations on the upper and lower surfaces of the plate or foil. Identical deterministic time signatures emerge from the noise cross-correlation function based on robust and simple signal processing between passive sensors. These time signatures can be used to estimate and monitor the structural response of the test models.

2pSAb1. A strain energy approach to the flexural damping of layered plates. Richard J. Deigan and Kin Ng (NSWCCD, 9500 MacArthur Blvd, W. Bethesda, MD 20817-5700)

The flexural damping factor of multilayered plates is developed using a strain energy approach. The derivation is based on the exact, steady-state solution for a plate subjected to boundary conditions that are harmonic in time and position along the plate. The distribution of elastic strain energy contained within the individual layers of the plate is developed, from which an effective, flexural damping factor is determined. Comparisons to the widely used RKU analysis [D. Ross, E. E. Ungar, and E. M. Kerwin Jr., ''Damping of Plate Flexural Vibrations by Means of Viscoelastic Laminae,'' ASME, Section 3, pp. 49–87 (1959)] are made for selected cases of constrained and unconstrained layer damping. Good agreement with RKU theory is demonstrated for the selected cases. Advantages of the present analytic approach include: (1) The ability to model the effect of fluid loading; (2) Unlimited number of plate layers; and (3) The handling of compressible layers and associated loss mechanisms. Analytical estimates of damping factors are compared with measurements made on steel bars treated with an unconstrained damping layer. Stress-state assumptions are shown to be a major factor affecting theory-data agreement.

3:30

2pSAb2. Dynamic modulus measurement using the Dynamic Mechanical Analyzer. Kin Ng, Richard Deigan, and Samedi Koch (Naval Surface Warfare Ctr., Carderock Div., 9500 MacArthur Blvd., West Bethesda, MD 20817-5700)

The Navy has used the Dynamic Mechanical Thermal Analyzer (DMTA) as a tool to characterize material properties over the last 20 years. It is now evaluating the Dynamical Mechanical Analyzer (DMA) as a replacement for the DMTA, with the goal to insert it into operation in 2006 with minimal disruption to current acquisition programs. This paper compares the two instruments with regard to their capabilities and looks at some of the transition issues.

3:45

2pSAb3. Space-dependent damping for reducing vibration of continuous systems. Mark H. Holdhusen (Univ. of Wisconsin—Marathon County, 518 S 7th Ave., Wausau, WI 54401)

Structural vibration in continuous systems is a common source of problems for many mechanical systems. Much research has considered ways to reduce the vibration in continuous systems. Some research uses passive techniques that are simple to implement, whereas other methods

implement active control that can be quite complex. The research presented here investigates the effect space-dependent damping has on the vibration of continuous systems. Specifically, the work at hand will focus on the flexural vibration of beams. In a distributed damping beam system, the damping is variable as a function of position along the length of the beam. Such a system could be physically realized through the use of magneto-rheological or electro-rheological fluids. Along its length, a beam could be divided into several isolated sections containing such a fluid. By controlling the magnetic or electric field across each section of the beam, the damping would vary along the length of the beam. The work presented here optimizes the damping as a function of beam position to reduce the broadband frequency response of the beam. A number of support conditions for the vibrating beam are considered.

4:00

2pSAb4. Multiple-particle tracking rheometry of gelling polymer solutions. Ryan Braun (NSWCCD, 9500 MacArthur Blvd, W. Bethesda, MD 20817-5700) and Dennis Wirtz (Johns Hopkins Univ., Baltimore, MD 21218)

Many polymer materials used for damping are generated utilizing polycondensation reactions. These polymer reactions may start in the liquid phase, undergo gelation, and then solidify. The microscopic, three-dimensional, heterogeneous network produced during the chemical reaction greatly affects the bulk material properties. The polymer architecture is mainly locked in at the point of gelation, when polymer mobility is drastically reduced. This study investigates the steady-state microstructure and micromechanics of gelling polymer materials using the recently developed method of multiple-particle tracking microrheometry (MPTM). Unlike existing methods, MPTM quantitates, in real time, the microrheology and microheterogeneity of complex fluids undergoing gelation. Brownian trajectories of probe particles are transformed into families of mean-squared displacements, from which distributions in local, frequency-dependent viscoelastic moduli or time-dependent creep compliance are readily extracted. To understand the effects the microscopic, three-dimensional architecture of a gel has on the macroscopic, bulk properties, a model polysaccharide gel system was studied. The steady-state properties of the polysaccharide gels were evaluated as a function of concentration.

4:15

2pSAb5. Metal-polymer-ceramic constrained layer damping system. Liya Bochkareva (UIIP Natl. Acad. of Sci. of Belarus, Filatova 7-28, Minsk 220026, Belarus) and Maksim Kireitseu (Univ. of Sheffield, UK)

The focus of this paper is directed toward the investigation into multilayered metal-polymer-ceramic damping coatings and their FEM-based computer modeling that can provide an alternative spacer material in a constrained layer damping configuration so as to enable design of three and more layered damping structures, but with controlled structure and mechanical properties of the gradient damping layers. An advanced measuring system for the analysis of vibrating structures is based on a laser scanning vibration interferometer. The position of a ceramic layer in a constrained layer configuration does matter. The outward position is most favorable for high strength by ceramic layer and damping by constrained aluminum-polymer layer. Modal loss factors obtained in the 60%–80% partial-coverage test cases of cylindrical shell are higher than the maximum modal damping obtained in the case of 100% coverage. The modal damping for the target modes is higher than in the complete-coverage case. An effective damping design involves selecting a proper combination of area coverage, relative thickness and stiffness values of the layers of the damped configuration. [Dr. Bochkareva is currently continuing her research work under 2-year EU INTAS 2005-2007 postdoctoral fellowship Ref. No. 04-83-3067.]

2pSAb6. Carbon nanotube-reinforced damping materials: Design and experiments. Maksim Kireitseu (INDMASH Natl. Acad. of Sci. of Belarus, Filatova 7-28, Minsk 220026, Belarus)

The CNT-reinforced material damping phenomenon is complex because of the variety of energy dissipation/fracture mechanisms involved, the complex nature of the nanoparticles themselves, etc. that affect damping/dynamics. The focus of this paper is directed toward the experimental validation of the next-generation vibration damping materials, providing a road map to experimental calibration and measurement of these materials. Modified modal strain energy method and FEM-based model created in MSC.visualNastran is employed to support an experiment. SWNT-reinforced polymeric matrix composites are prepared using an extrusion procedure. SWNT particles produced by Dynamic Enterprises, UK (2–5 nm in diameter and 70–90 vol % sample purity) are added in concentrations of 3%–6% by weight along with a surfactant (polyoxyethylene) to aid in dispersion. Resonance frequencies, the mode shape, and damping at each mode were determined by laser vibrometry at standard vibration shaker tests and Bruel & Kjaer vibration system. Data acquisition and control of the electro-dynamic system is based on the computer measurement dystem that is highlighted. Resonance frequency is determined from peaks on a frequency response curve for each of the experimental methods. [Work supported by Marie-Curie Fellowship Ref. No. 021298-Multiscale Damping 2006-2008 at University of Sheffield, UK with Prof. G.R. Tomlinson.]

Session 2pSC

Speech Communication: Speech Production (Poster Session)

Rajka Smiljanic, Chair
Northwestern Univ., Dept. of Linguistics, 2016 Sheridan Rd., Evanston, IL 60208

Contributed Papers

All posters will be on display from 1:30 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 4:30 p.m.

2pSC1. Finite-element simulations of self-oscillation mechanisms in human phonation. Douglas Cook, Luc Mongeau, and Paul Smith (Purdue Univ., 585 Purdue Mall, West Lafayette, IN 47907)

The fluid-structure interactions which occur during human phonation were investigated using a commercially available finite-element program. Both lumped mass and continuous structural models were coupled with viscous fluid flow. The simulated behavior was analyzed. The addition of viscous flow was not sufficient to induce self-oscillation of a single degree-of-freedom lumped mass model but did contribute to the steady vibration of the continuous model. This observation reinforces the conclusion that structural complexity is an essential mechanism of self-oscillation. The influence of false folds on the oscillation patterns of the continuous model was also examined.

2pSC2. Characteristics of phonation in women who produce voiced versus voiceless /h/. Laura L. Koenig (Haskins Labs., 300 George St., New Haven, CT 06511 & Long Island Univ., Brooklyn, NY 11201)

Production of the consonant /h/ typically involves a vocal-fold abduction gesture. Although /h/ is traditionally described as voiceless in English, voiced allophones also occur. Our recent work has described the phonatory behavior of women who produce a mixture of voiced and voiceless /h/; our results suggested speaker-specific patterns of the factors that lead to devoicing. This study characterizes the behavior of normal women who produce exclusively voiced /h/ and compares it to those who produced both voiced and voiceless /h/. Measures of baseline (dc) airflow are used as an index of abduction degree; peak intraoral pressures during adjacent /p/ closures provide a measure of subglottal pressure; and pulse-by-pulse measures are made of $f0$ and pulse amplitude (ac flow) around the /h/ abduction gesture. Multidimensional analyses are carried out within speakers to determine how these vocal parameters are related. We expect that women who produce only voiced /h/ will differ from those who devoice some /h/ productions in the parameters that facilitate phonation, such as higher subglottal pressures, smaller abduction degrees, and reduced vocal-fold tension as reflected in $f0$ measures. Based on our previous findings, however, we also expect individual variation in the phonatory settings that produce voiced /h/. [Work supported by NIH.]

2pSC3. Contextual effects on the continuancy of /ð/. Sherry Zhao (MIT, 77 Massachusetts Ave., Rm. 36-545, Cambridge, MA 02139)

This research examined the segmental-contextual effects on the continuancy of the voiced dental /ð/ in American-English and whether certain acoustic attributes were preserved despite possible modification. Word-initial /ð/ cases, extracted from continuous speech of 146 speakers from the TIMIT database, were frequently (averaging 65%) stoplike when it was in utterance-initial position or when its preceding phoneme was voiceless and/or [-continuant]. This stoplike modification occurred less frequently (averaging 39%) when /ð/ was preceded by a voiced fricative and rarely (averaging 13%) when preceded by a vowel or liquid consonant. A comparison of stoplike /ð/ and /d/ cases under similar contexts showed that the burst peak location, burst spectrum shape, and F2 at vowel onset averages were all statistically different between the two groups. In addition, the acoustic data suggested that the dental place of articulation was preserved for the modified /ð/. Preliminary automatic classification experiments involving salient acoustic attributes seemed to indicate that F2 at vowel onset may be a reliable cue for the dental place of articulation in /ð/. [Work supported by NIH DC02978 and T32DC00038.]

2pSC4. Modeling the influence of acoustic loading on laryngeal self-sustained oscillations. Matías Zañartu, Luc Mongeau, and George R. Wodicka (Ray W. Herrick Labs. Purdue Univ., West Lafayette, IN 47907)

Three-way interactions between sound waves in the subglottal and supraglottal tracts, the vibrations of the vocal folds, and laryngeal flow were investigated. Nonlinear coupling was investigated analytically, with a focus on the effects of a realistic acoustic loading on the self-sustained oscillation of the vocal folds. MRI-based shapes for the supraglottal tract [Story *et al.*, J. Acoust. Soc. Am. **100**, 537–554 (1996)] and an equivalent acoustical model for the subglottal tract [Harper *et al.*, IEEE Trans. Biomed. Eng. **48**, 543–550 (2001)] were considered. The model was based on the wave reflection analog technique, along with a novel single degree of freedom model of the vocal folds to describe the source. The effects of a mucosal wave on the vocal folds were incorporated through a time-varying discharge coefficient and a Bernoulli-type flow model. The relative importance of acoustic loading and time-varying flow resistance for fluid-structure energy transfer was compared for various configurations. [Work supported by NIH Grant RO1-DC05788.]

2pSC5. Patterns of interarticulator coordination within the syllable. Patrizia Bonaventura and Joseph Sand (Dept. of Commun. Sci., Case Western Reserve Univ., 11206 Euclid Ave, Cleveland, OH 44106, patrizia.bonaventura@case.edu)

Interarticulatory coordination patterns were observed in movements of the crucial articulator for the production of place in selected syllables containing labiodental and alveolar consonants. The coordination of the lower lip with upper lip and tongue tip, and the coordination of the tongue tip with tongue blade and lower lip have been observed. The goals of the study were (a) to verify whether stable patterns of speed with respect to excursion of movement [Fujimura, O., "Temporal organization of articulatory movements as a multidimensional phrase structure," Phonetica, **38**, 66–83 (1981a); "Icebergs revised," ASA meeting, 2aSC (1996b)], were

found in concurrent articulators to the crucial one for place, under different prosodic conditions; (b) whether such stable portions would vary proportionally to the increase in amplitude of the vertical jaw movement, selected as a measure of the magnitude of the syllable; (c) to observe relative timing at the iceberg thresholds in the selected consonantal movements with respect to the center of the syllable. Analyses were performed on articulatory recordings from cinefluorographic data, based on read dialogues [Erickson *et al.*, ''Articulatory correlates of prosodic control: Emotion and emphasis,'' Lang. Speech, **41**, 399–417 (1998)]. Iceberg patterns were found in the concurrent articulator movements, showing a linear dependence of slope on the total excursion of the demisyllabic movement. Timing of concurrent articulator movements with respect to the center of the syllable is shown to be relatively stable.

2pSC6. Modulation of frication noise in a dynamic mechanical model of the larynx and vocal tract. Anna Barney (ISVR, Univ. of Southampton, Southampton, SO17 1BJ, UK, ab3@soton.ac.uk) and Philip J. B. Jackson (Univ. of Surrey, Guildford, GU2 7XH, UK)

A dynamic mechanical model of the larynx and vocal tract was used to investigate the aerodynamics and acoustics of voiced fricatives. The model had typical dimensions for a human adult male. Glottal excitation arose from driven shutters representing the vocal folds; sinusoidal and square-wave driver functions were investigated. Glottal amplitude, fundamental frequency ($f0$), and volume velocity were independently controlled. Frication noise was produced by an orifice plate with a sharp-edged obstacle on its downstream side. Two different positions of constriction within the vocal tract, each coupled with a different constriction-obstacle distance, were investigated. Vocal-tract wall pressure was measured at three locations and a microphone at the vocal-tract exit measured radiated sound. The sound radiated from the open end of the vocal tract was found to have both harmonic and noise components. The noise was modulated by the $f0$ of the glottal vibration. The depth of modulation was independent of the shape of the glottal excitation. It showed an overall decreasing trend with increasing $f0$ in the range 20 to 150 Hz, but with a local maximum of modulation depth around 80 Hz. The noise bursts had maxima coincident with the middle of the glottal open phase.

2pSC7. Acoustic characteristics of clearly produced fricatives. Kazumi Maniwa, Allard Jongman (Linguist. Dept., Univ. of Kansas, 1541 Lilac Ln., Blake Hall, Rm. 427, Lawrence, KS 66044-3177), and Travis Wade (Posit Science Corp., San Francisco, CA 94104)

Research suggests that speakers can adopt a speaking style that allows them to be understood more easily when confronted with difficult communication situations, but few studies have examined the acoustic properties of clearly produced consonants in detail. This study attempts to characterize the type and magnitude of adaptations in the clear production of English fricatives in a carefully controlled range of communication situations. Ten female and ten male talkers produced nonsense syllables containing the eight English fricatives in VCV contexts, both in a conversational style and in a clear style (elicited by means of feedback consisting of simulated recognition errors received from an interactive computer program). Acoustic measurements were taken for spectral, amplitudinal, and temporal properties known to influence fricative recognition. Results illustrate that (1) there were some consistent overall clear speech effects, several of which (consonant duration, spectral peak location, spectral moments) were consistent with previous findings and a few (notably consonant-to-vowel intensity ratio) which were not; (2) ''contrastive'' differences related to eliciting prompts were observed in a few key comparisons; and (3) talkers differed widely in the types and magnitude of acoustic modifications.

2pSC8. Articulation of fricatives: Evidence from X-ray microbeam data. Christine H. Shadle, Khalil Iskarous, and Michael I. Proctor (Haskins Labs., 300 George St., New Haven, CT 06511)

Articulatory changes in /s/ over time give rise to the onset and offset of turbulence noise, but the small tolerances involved make it difficult to separately consider the effects of movement, phonetic context, and subject variation. Aerodynamic estimates of the constriction area have been shown to demonstrate a marked asymmetry, with the /s/ onset more rapid than offset [C. Scully, Speech Commun. **11**, 1992]. Previous articulatory studies led us to expect an invariant tongue tip position, with jaw raising dependent somewhat on the following vowel. In order to investigate the timing of the constriction formation in fricatives, X-ray microbeam data [Westbury *et al.*, 1994] for citation forms of /sVd/ for 15 vowels were studied. In fact, the tongue marker patterns during [s] vary both by following vowel and subject; subjects seem to have different apical-laminal strategies. The jaw reaches maximum height during [s] for each subject studied; that height does not appreciably vary with vowel. This indicates that jaw height is important specifically for /s/ production. One possibility is that the constriction is formed by the tongue, and turbulence noise is then maximized by the lower teeth being brought into position. [Work supported by NIH NIDCD R01 DC 006705.]

2pSC9. A range of intonation patterns produced in an elicitation task. Alejna Brugos, Jonathan Barnes (Program in Appl. Linguist., Boston Univ., 96 Cummington St. #246, Boston, MA 02215, abrugos@bu.edu), Stefanie Shattuck-Hufnagel (MIT, Cambridge, MA 02139), and Nanette Veilleux (Simmons College, Boston, MA 02115)

A production task was designed to elicit a specific intonation contour, characterized by an exaggerated rise-fall-rise in $f0$ ($L+H^*L-H\%$ in ToBI terms), conveying an attitude of ''dismayed surprise.'' Speakers were given models, a short practice period, and a preceding context for each utterance. A targetlike rise-fall-rise contour (including $H^*L-H\%$ variants) was successfully elicited for each of the contexts, but in less than half the utterances: Of 1134 utterances, 631 (56%) were judged by a panel of 3 experienced ToBI labelers as different from the intended contour, e.g., $L^*H-H\%$. Of these, 261 were produced with contours perceptually similar to the target, with a sustained flat or minimally rising $f0$ after the fall from the pitch accent, or with the rise occurring early in the next phrase. Alignment characteristics and individual speaker data may determine whether these are one contour with a continuum of realizations, or separate contours. These results (a) suggest that speakers have more than one way of signaling a given attitude and resist being limited to using only one, and (b) support the need for careful postexperiment transcription to characterize which contours subjects have actually produced. [Work supported by NSF 0345627 and NIH DC00075.]

2pSC10. Factors affecting phonetic variation of American English /k/. Stefanie Shattuck-Hufnagel (Speech Group, Res. Lab. of Electron., MIT, Cambridge, MA 02139) and Nanette Veilleux (Simmons College, Boston, MA 02115)

Word-final consonant reduction is commonly observed in American English, but variation in word-initial consonants is less thoroughly studied. Several considerations suggest that initial consonants might resist reduction; a more nuanced hypothesis is that initial consonants resist reduction in prosodically strong positions (i.e., at phrase edges and pitch accents) but may be reduced in weaker positions (e.g., phrase medially, in nonaccented syllables), particularly in un-self-conscious speech. A corpus of 16 spontaneous dialogues (8 speakers), prosodically labeled using the ToBI transcription system, provides a testbed for this view: the speakers were pairs of close friends engaged in an absorbing task which distracted them from paying close attention to their speech. Preliminary inspection of initial /k/'s from 3 speakers revealed a range of pronunciations (as described in earlier work), from normal prevocalic /k/ (with a silent closure period followed by release noise), to ''leaky'' /k/'s with some noise during the closure period and higher-amplitude release noise, to fricated /k/'s with

constant-amplitude noise throughout, and offered some support for reduction in weak prosodic contexts. Further analysis will compare prosodic context with other factors governing phonetic variation (e.g., word frequency); implications for speech recognition and production will be discussed. [Work supported by NIH DC00075 and DC02978.]

2pSC11. Errors and strategy shifts in speech production indicate multiple levels of representation. Bryan Gick (Dept. of Linguist., Univ. of BC, E270-1866 Main Mall, Vancouver, BC V6T1Z1 Canada)

An earlier pilot study [Gick, J. Acoust. Soc. Am. **112**, 2416 (2002)] observed that speakers producing challenging sequences of articulatory movements exhibit categorical shifts in production strategies. For example, a speaker may initiate all two-flap sequences with an upward tongue movement, then shift to a downward movement, then shift again. The present study attempts to determine how these strategy shifts can inform phonologists as to levels of representation. Ten subjects produced sequences of flap allophones of English /t/ and /d/ in an experimental paradigm similar to the pilot study. Results show strategy shifts in the speech of 7/10 subjects, such that: (1) shifts are more likely to occur following speech errors; (2) errors are more likely to occur in sequences with more flaps and more conflicts; (3) errors in response to articulatory conflicts occur at multiple levels of representation (segmental, lexical, etc.); (4) strategy shifts occur at multiple levels of representation (subsegmental, segmental, whole word); (5) word frequency does not affect strategy shifts. These results suggest that speech processing is active in parallel at multiple levels associated with phonological representation. [Work supported by NSERC.]

2pSC12. 3-D acoustic analysis based on magnetic resonance imaging of a "retroflex" and "bunched" American English rhotic sound. Xinhui Zhou, Carol Espy-Wilson (Dept. of Elec. and Comput. Eng., Univ. of Maryland, 2205 AV Williams Bldg., College Park, MD 20742, espy@glue.umd.edu), Mark Tiede (Haskins Labs, New Haven, CT 06511), and Suzanne Boyce (Univ. of Cincinnati, Cincinnati, OH 45202)

A variety of articulatory configurations can produce an American English /r/. Common across all configurations is a large front-cavity volume that results directly or indirectly in the characteristically low third formant. Earlier work [Zhang *et al.*, ICASSP2005 1, pp. 893–896] using 2-D finite-element modeling of the front cavity with stylized bunched and retroflexed shapes showed that, even at 2000 Hz, cross modes are generated in the front cavity. Thus, the front cavity should be modeled as a single tube with a side branch, regardless of whether there is space underneath the tongue. This paper extends the earlier work by (a) considering the full 3-D vocal tract geometry reconstructed from magnetic resonance images, (b) performing 3-D finite-element analysis, and (c) using contrasting tongue shapes from similar-sized subjects. Harmonic analysis showed the frequency response is comparable to the spectrum of the acoustic signal, suggesting good agreement between the actual and reconstructed vocal tracts. As before, wave propagation in the front cavity is not planar. 3-D vocal tract analysis shows that the cross modes have 3-D properties. Application of the 3-D wave propagation property to area function extraction and simple-tube modeling of the vocal tract will be discussed. [Research supported by NIH.]

2pSC13. Syllable structure effects on velum-oral coordination evaluated with real-time MRI. Stephen Tobin, Dani Byrd (USC Linguist., 3601 Watt Way, GFS 301, Los Angeles, CA 90089-1693, dbyrd@usc.edu), Erik Bresch, and Shrikanth Narayanan (USC Los Angeles, CA 90089)

Seminal work by Krakow (PhD. Diss., Yale University, 1989, Phonetics and Phonology **5**, 87–116, 1993) has indicated that intrasegmental coordination of articulatory gestures varies systematically as a function of syllable position. Specifically, onset and coda nasals display different lag times between the velum and oral gestural components. In onset nasals, velum lowering is achieved roughly synchronously with oral constriction, while in codas, velum lowering precedes oral constriction. However, Krakow's study was limited by its reliance on indirect measures of velum movement. Nor did her work examine nasals other than [m] or syllable organizations other than singleton onsets and codas. Our study employs real-time magnetic resonance imaging [Narayanan *et al.*, J. Acoust. Soc. Am. **115**, 1771–1776 (2004); Mathiak *et al.*, Int. J. of Lang. & Comm. Disorders **35**, 419–425 (2000)] to acquire direct information about the key vocal tract variables of velum aperture and oral constriction, thereby allowing the calculation of relative gestural timing. We investigate the effects of syllabification on interarticulatory timing in [n], and, in addition to examining codas and onsets, further consider juncture geminates spanning word boundaries. Preliminary real-time MRI results from one of three anticipated subjects do find the predicted timing difference for [n]. Further, we find that the relative timing in juncture geminates mirrors that of coda [n] but presents a velum aperture intermediate between coda and onset [n]. [Work supported by NIH.]

2pSC14. Adaptation of speech production to palatal perturbation: Kinematic analysis using electromagnetometry. Douglas M. Shiller (School of Commun. Sci. and Disord., McGill Univ., 1266 Pine Ave. West, Montreal, QC, Canada H3G 1A8, doug.shiller@mail.mcgill.ca), Mark K. Tiede (Haskins Labs., New Haven, CT), and Vincent L. Gracco (McGill Univ., Montreal, QC, Canada)

The extent to which adults are able to flexibly adapt their speech production to altered sensory-motor conditions has considerable implications for oral-motor rehabilitation, yet it remains poorly understood. Previous studies have explored the effects of different physical and perceptual perturbations on speech production, yielding mixed results with respect to the timecourse and extent of adaptation. A major limitation of these studies has been their reliance on acoustical measures as the sole index of motor adaptation. The difficulty with such an approach is the potentially complex relationship between acoustic changes and their underlying articulatory patterns. In the present study, speech adaptation to a palatal perturbation (5-mm thickened alveolar ridge) was investigated by directly measuring articulatory kinematics using electromagnetometry. In contrast to previous claims, subjects were found to produce a significant change in speech-related tongue movement immediately upon insertion and removal of the artificial palate. In addition, subjects gradually fine-tuned their tongue position with continued practice. The observed patterns are consistent with the idea of two independent adaptation processes: a rapid adaptation process that is driven by the mere presence of the false palate and a slower adaptation process driven by the continued presence of the palatal perturbation.

2pSC15. Production of American English word-initial stops in the vicinity of a voiceless stop. Elina Eydlin (Dept. of Speech-Lang. Pathol. and Audiol., New York Univ., 719 Broadway, Ste. 200, New York, NY 10003) and Nassima Abdelli-Beruh (New York Univ., New York, NY 10003)

This study examined how native-American English speakers produced the stop voicing distinction when word-initial stops were positioned before a voiceless stop (/t/) in the sentence repeat CVC ten times. Sentence durations, durations of vowel (/i/) before word-initial stops, number of produced stop closures (/t/, /c/), durations of voicing in closures and VOT were measured. Preliminary analyses on three speakers show that they produced only one closure in most cases. Speakers occasionally produced two closures when slowing down their speaking rate. Vowels preceding /b, d, g/ were barely longer than vowels before /p, t, k/. When speakers produced one closure, closures were occupied by voicing for both /b, d, g/ and /p, t, k/. However, the average durations of voicing in closure were consistently longer for /b, d, g/ than for /p, t, k/. In addition, /b, d, g/ were produced in most cases with short-lag VOT, except when there were two closures, in which case, /b, d, g/ were produced with lead VOT. All /p, t,

k/ were produced with VOT greater than 30 ms. Articulatory studies are needed to assess how the sequence of stops is produced and whether the gestures for /t/ are completely or partially eliminated.

2pSC16. Modeling the effects of the lower airway on vowel spectra. Steven M. Lulich (MIT Speech Commun. Group, 77 Massachusetts Ave., MIT Bldg. 36-511, Cambridge, MA 02139, lulich@mit.edu)

Computational models of the acoustics of the lower airway (below the glottis) have been implemented by researchers in the speech and respiratory sciences. In general, these models are symmetrical and are studied independent of acoustic coupling to the vocal tract. We have constructed a new model that is asymmetrical and based on human morphometric data. The acoustic properties of the model are explored and compared with symmetrical models, and the effects of the model on vowel spectra are studied for varying amounts of lower airway and vocal-tract coupling via the glottis. Cochlear excitation patterns are also computed for the vowel spectra, and the effects of the lower airway acoustics on these excitation patterns are discussed.

2pSC17. Effect of tone on voice onset time in laryngeal and esophageal speech of Mandarin. Manwa Ng (Commun. Sci. and Disord., Long Island Univ., Brookville, NY 11548-1300) and Hanjun Liu (Northwestern Univ., Evanston, IL 60208)

Defined as the time between the release of burst of a stop and the onset of the following vowel, voice onset time (VOT) directly indicates the interarticulator timing between the voicing source and the articulatory movement in the vocal tract. A number of studies have investigated the VOT characteristics of different languages. Yet, few have studied how VOT is affected by tone level in a tone language, and by the type of phonation. The present study investigated the possible effect of tone level and phonation type on such interarticulator timing characteristics. VOT values were measured from the syllables /p^ha/, /t^ha/, and /k^ha/ produced at four Mandarin tone levels by eight laryngeal (NL) and seven esophageal (SE) speakers who were native speakers of Mandarin. Results indicated that significant differences in VOT were found in the NL speaker group, but not in the SE speaker group. With respect to phonation type, SE speakers showed significantly shorter VOT values than NL speakers. Such differences may be related to the use of pharyngoesophageal (PE) segment as a new sound source. SE speakers appear to take a shorter time to start PE segment vibration as compared to NL speakers.

2pSC18. Intrinsic vowel pitch in tracheo-esophageal speech. Michael Kiefte, Natalie Didrachnik, and Jillian Roswell (School of Human Commun. Disord., Dalhousie Univ., 5599 Fenwick St., Halifax, NS B3H 1R2 Canada)

The tendency for high vowels to have higher fundamental frequency (f_0) than low vowels, or intrinsic vowel pitch (IF_0), has been found in both laryngeal and esophageal speech [e.g., Gandour and Weinberg, Phonetica **25**, 140–164 (1980)]. In the present study, eight tracheo-esophageal speakers were asked to produce five repetitions of each of the four point vowels and f_0 was measured. Results showed significantly higher f_0 for high vowels than for low vowels, consistent with previous findings for laryngeal and esophageal speakers. In addition, f_0 was measured from two laryngectomees over a period of 4 months immediately following surgery to determine whether IF_0 is produced automatically or whether it develops over time. Neither of these subjects produced differences in IF_0 at any time within the 4-month period. These preliminary data appear to indicate that IF_0 is not an automatic consequence of either speech physiology or acoustics. More data from additional subjects will be presented. [Work supported by SSHRC.]

2pSC19. Computational aeroacoustics of flow through static model of human vocal tract. Jungsoo Suh, Steven H. Frankel, Luc Mongeau, and Michael W. Plesniak (School of Mech. Eng., Purdue Univ., West Lafayette, IN 47907)

Computational aeroacoustics studies of flow through the human vocal tract, here modeled as a planar channel with an orifice, hence referred to as the glottis, were conducted using large-eddy simulation (LES). Comparisons were made between LES predictions and experimental wall pressure measurements and particle-imaging-velocimetry flow fields. Rigid models of both converging and diverging glottal passages, each featuring a 20-deg included angle and a minimal glottal width of 0.04 cm with transglottal pressure of 15 cm H_2O, were studied. The compressible Navier-Stokes equations were accurately and efficiently integrated for the low Mach number flow through the use of an additive semi-implicit Runge-Kutta method and high-order compact finite-difference schemes for spatial discretization. Characteristic-based nonreflecting boundary conditions were used together with an exit zone in the context of a multiblock approach. Asymmetry of the flow due to a Coanda effect, and transition to turbulence were observed. An acoustic analogy based on the Ffowcs Williams-Hawkings equation was applied to decompose the near-field acoustic source into its monopole, dipole, and quadrupole contributions to assess glottal geometry effects on far-field sound. The results showed that dipole sources due to the unsteady forces exerted on the duct wall are dominant. [Work funded by NIH Grant RO1 DC03577.]

2pSC20. Modal analysis of a time-varying vocal tract with losses: A comparison of left and right eigenfunctions. Gordon J. Ramsay (Haskins Labs., 300 George St., New Haven, CT 06511-6624)

Sound propagation during speech can be modeled by a linear wave operator describing the spatiotemporal evolution of acoustic pressure and velocity distributions on a bounded domain representing the interior of the vocal tract. The eigenvalues of the wave operator determine the formant frequencies and bandwidths. The right eigenfunctions describe the standing wave patterns associated with each formant, whereas the left eigenfunctions describe how an arbitrary source distribution projects onto each formant. In speech research, it has always been implicitly assumed that left and right eigenfunctions are identical. This only holds if the wave operator is self-adjoint, which cannot be true when losses due to viscous damping, radiation effects, and wall vibration are taken into account. To examine this issue, a time-domain finite-volume simulation of acoustic wave propagation in the vocal tract was developed, including the above loss mechanisms. Eigenvalues and eigenfunctions were calculated from the resulting state-space recursion, for time-varying geometries representing VCV sequences containing fricatives and stops. Left and right eigenfunctions are similar in shape, but there are differences in the zero-crossing points and the amplitudes of the different lobes. Predictions based on right eigenfunctions alone will be incorrect. [Work supported by NIH.]

2pSC21. The interaction of linguistic and affective prosody in a tone language. Chinar Dara and Marc D. Pell (Commun. Sci. and Disord., McGill Univ., 1266 Pine Ave. West, Montreal, PQ H3G 1A8, Canada, chinar.dara@mail.mcgill.ca)

To address how a common set of acoustic properties of speech prosody modulate to convey linguistic and affective meanings concurrently, this study investigated the influence of phonemic tones on the expression of emotion (happy, sad, angry) and linguistic modality (declarative, interrogative) in a tone language, Punjabi. Base stimuli consisted of neutral sentences with either of the three contrastive tones in Punjabi (falling, level, high-rising) varying at the object position of the sentence only. Each of these sentences was elicited as a statement or a question for each of the three emotions by 6 native Punjabi speakers. Utterances were validated for adequate representation of the target emotion, and reliable exemplars for each of the emotions and linguistic modality were subjected to detailed acoustic analysis. Fundamental frequency and duration measures were analyzed for the stressed vowel of the keywords (subject, object, verb) and

the whole utterance for each of the tokens. Results demonstrated ways that the acoustic correlates of tone at the word level interact with that of the intonation and emotion at the sentence level, which were further compared with previous results on the effect of focus on intonation and emotional prosody [M. D. Pell, J. Acoust. Soc. Am. **109**, 1668–1680 (2001)].

2pSC22. The scope of effect of prosodic boundaries in articulation. Jelena Krivokapic (Dept. of Linguist., USC, 3601 Watt Way, GFS 301, Los Angeles, CA 90089-1693)

An articulatory study of the scope of prosodic boundary effects across boundaries of varying strengths is presented. Sentences in each of three prosodic conditions contain the following string: C1VC2VC3#VC4VC5VC6, where C is an alveolar consonant, V is a vowel, and # is a prosodic boundary. The boundaries are of three degrees of strength. Using articulator movement-tracking data (EMA) for the tongue tip articulator, consonant constriction formation and release duration, acceleration duration, and spatial magnitude are measured. Leftward and rightward temporal effects of the boundary on the consonants are investigated. Based on earlier studies (e.g. Cambier-Langeveld, Linguistics in the Netherlands, 13–24, 1997; Shattuck-Hufnagel and Turk, Proceedings 16th International congress on Acoustics and 135th Meeting Acoustical Society of America, 1235–1236, 1998; Berkovits, J. of Phonetics **21**, 479–489, 1993) and predictions of the prosodic gestural model (Byrd and Saltzman, J. of Phonetics, **31**, 149–180, 2003), it is expected that (1) the amount of articulatory lengthening will increase with boundary strength and (2) the degree of lengthening will decrease with distance from the boundary. Three subjects participated. The results show that at the boundary, gestures have longer constriction and acceleration durations, and the effect of the boundary increases with boundary strength, distinguishing up to three levels of boundary strength. The effect is local and diminishes with distance from the boundary. These results support the initial hypotheses. [Work supported by NIH.]

2pSC23. Acoustic and fiberscopic studies of the voice characteristics of school teachers under vocal abuse conditions with the loud voices of children. Noriko Kobayashi (School of Allied Health Sci., Kitsato Univ., 1-15-1 Kitasato, Sagamihara 228-8555 Japan, noriko@ahs.kitasato-u.ac.jp, Takashi Masaki, and Koichiro Nishiyama (Kitasato Univ, Sagamihara 228-8555, Japan)

It has been known that the incidence of vocal pathology was high in school teachers as they had to use a great amount of voice and loud phonation in noisy school settings with the children's loud voices. A proper vocal hygiene program and voice therapy are effective treatments for these cases. The final goal of the treatment should be to obtain the skills to use effective and healthy phonation even in noisy environments. In our study, three school teachers with vocal nodules, three speech therapists who were trained to produce nonconstricted voice even in noisy environments, and ten college students with no laryngeal pathology (control group) spoke eight sentences with one target word in two environments: a quiet environment and one with meaningful multi-talker babble (MMB). Acoustic analyses and fiberscopic examination revealed higher sound pressure and F0 levels and laryngeal constriction in MMB for the teachers before therapy and the normal talkers, but two speech therapists kept similar F0 levels and laryngeal conditions in both environments. After voice therapy, teachers produced less constricted voice under noise. These results suggested the efficacy of voice therapy with MMB for teachers to obtain effective and healthy voice in their noisy work environments.

2pSC24. Realizing question intonation in Mandarin with neutral tone. Fang Liu (Dept. of Linguist., Univ. of Chicago, 1010 E. 59th St., Chicago, IL 60637, liufang@uchicago.edu) and Yi Xu (Univ. College London, London, NW1 2HE, UK)

Previous research has found that postfocus pitch range is lowered in Mandarin even in questions, although the amount of lowering is smaller than in statements. This study investigates whether postfocus pitch range is raised in questions where the postfocus words carry the neutral tone, which, being conventionally considered targetless, may be better suited for manifesting intonation. Eight native speakers of Mandarin each produced 80 statements and 80 questions. The sentences ended either with a sequence of 5 neutral tones or with 3 neutral tones followed by 2 high tones. The sentences had two alternative focus locations, one on the full tone (high, rising, low, or falling) immediately preceding the neutral tone sequence, and the other on the low tone before the full tone. Results show that (1) postfocus lowering occurred in the neutral-tone-final sentences in both statements and questions, just as in the full-tone-final sentences, and (2) sentence-final neutral tone had falling F0 even in questions, thus contrasting with sentence-final high tone, which had rising F0 in questions. The findings are interpreted as indication that the neutral tone, being associated with weak articulatory effort, is not as effective as full tones in realizing the statement/question contrast.

2pSC25. Acoustic and articulatory correlates of contrastive focus. Melanie Thibeault, Lucie Menard, Annie Leclerc, Anthony Calabrino (Laboratoire de phonetique, UQAM, Case postale 8888, succursale Ctr. ville, Montreal QC, Canada, H3C 3P8, thibeault.melanie.2@courrier.uqam.ca), and Annie Brasseur (UQAM, Montreal QC, Canada, H3C 3P8)

This paper aims at examining production of French speakers in marking focus-induced prominence at the articulatory and acoustic levels. The corpus consisted of CVC syllables, where C corresponds to one of the stops /p t k/ and V is one of the vowels /i a u/. Target words were embedded in carrier sentences elicited in two prosodic conditions: neutral (unfocused) and under contrastive focus. Four adult speakers (all native speakers of French) pronounced ten repetitions of each sequence. The audio signal and tongue shapes were recorded using a digital camera and a SONOSITE 180 ultrasound. Formant frequencies, rms values, duration, and tongue contours corresponding to each vowel were extracted. Analyses show that prosodic context has a significant effect on acoustic and articulatory data for all vowels, increasing F1 and F2 under contrastive focus, compared to the neutral context. However, this stable acoustic pattern is achieved by various articulatory strategies across subjects. For example, 2 subjects produced /u/ under focus with a lower tongue body than in the neutral context, whereas the remaining 2 subjects had a higher tongue body in focused syllables. Results are compared to previous studies on articulatory and acoustic correlates of prosodic structure in French and English.

2pSC26. Rhythm in English clear speech. Rajka Smiljanic, Josh Viau, and Ann Bradlow (Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, rajka@northwestern.edu)

This study investigates the effect of hyperarticulated, intelligibility-enhancing clear speech on English speech rhythm. Ramus *et al.* [Ramus *et al.*, "Correlates of linguistic rhythm in the speech signal," Cognition **72**, 265–292 (1999)] showed that temporal properties of a speech signal such as the percentage of vocalic intervals (%V) and variability of consonantal and vocalic intervals (C, V) can be related to phonological properties such as presence/absence of unstressed vowel reduction and syllable structure complexity, and are consequently quite successful at grouping languages into the traditional rhythmic classes (stress-, syllable-, and mora-timed). Here, we explore whether/how clear speech affects stress-timed characteristics of English sentences in terms of these measures. Results revealed that the proportion of vocalic intervals (%V) within sentences remained stable across speaking styles, i.e., consonants and vowels

were lengthened equally in clear speech. However, variability of both vocalic and consonantal intervals (V, C) was higher in clear than in conversational speech. The increase in V and C was achieved primarily through insertion/strengthening of short vocalic and consonantal segments that were dropped or coarticulated with surrounding sounds in conversational speech, making word and syllable boundaries more salient. These results suggest that increased intelligibility of clear speech can in part be attributed to prosodic structure enhancement by means of enhanced syllable and word boundaries demarcation.

2pSC27. Sensitivity of Mandarin speech to loudness-shifted voice feedback perturbation. Hanjun Liu, Qianru Zhang, Charles R. Larson (Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208), and Yi Xu (Univ. College London, London, NW1 2HE, UK)

Recent studies have demonstrated that loudness-shifted voice auditory feedback leads to compensatory adjustments in voice amplitude during production of vowels. In this study we asked the question of whether Mandarin-speaking subjects would respond to loudness-shifted voice feedback during speech. Twenty-two native-speaking subjects with normal hearing and neurological background served as subjects. They said the Mandarin phrase ba ma, with the high tone on both syllables, as answers to three randomized prerecorded questions. The questions induced focus on the first or the second syllable, or on both syllables. During each production a ± 3 dB, 200- or 400-ms perturbation in voice feedback was presented 250 ms following voice onset. Randomized control trials were intermixed with test trials. Digitized voice records were converted to an rms trace representing voice amplitude. Traces were aligned with stimulus onset for event-related averaging. Results demonstrated that subjects responded to the loudness perturbation with compensatory adjustments in voice amplitude. The data extend recent findings indicating that voice feedback is used to help control amplitude during speech. [This work was supported by NIH Grant No. DC006243-01A1.]

2pSC28. Gradient alternations and gradient attraction. Katherine Crosswhite (Dept. of Linguist., Rice Univ., 6100 Main St., Houston, TX 77005, crosswhi@rice.edu)

Many phonological alternations have been shown to be sensitive to lexical ''gradient attraction,'' defined by Burzio [''Surface-to-surface morphology: When your representations turn into constrainsts,'' Rutgers Optimality Archive #341-0999 (http://roa.rutgers.edu) (1998)] as follows: (A) The overall structure of a word W (in both phonological and semantic components) is influenced by that of other words in the lexicon to which W is independently similar, and which are thought of as ''attractors'' of W. (B) Attraction is stronger where independent similarity is greater. Since most strong attractors will be morphologically related to W, this results in a limitation on phonological alternations that would produce allomorphy. So far, gradient attraction has been studied for categorical alternations, such as stress placement in English (cf. compArable versus cOmparable). However, many alternations previously believed to be categorical are in fact gradient [as reviewed in, e.g., Port and Leary, ''Against formal phonology,'' Language **81**, 927–964 (2005)]. This study documents the influence of lexical attraction on two gradient phenomena of English: polysyllabic shortening and flapping. Attractor strength was varied in two manners. First, each base used in the study was paired with both derivational and inflectional derivatives (i.e., rose-roses-rosy for polysyllabic shortening, and wait-waiting-waiter for flapping), and second by analyzing the effect of between-item variation in semantic relatedness for the derivationally related forms (cf. ice-icy versus nose-nosy).

2pSC29. Resonance tuning in soprano singing and vocal tract shaping: Comparison of sung and spoken vowels. Shrikanth Narayanan, Erik Bresch (USC Viterbi School of Eng., 3710 S. McClintock Ave, RTH 320, Los Angeles, CA 90089, shri@sipi.usc.edu), Stephen Tobin, Dani Byrd, Krishna Nayak, and Jon Nielsen (USC, Los Angeles, CA 90089)

Singing at high pitches by sopranos involves complex orchestration of vocal-fold mechanisms and vocal-tract shaping. A specific phenomenon is the tuning of vocal-tract resonances to the fundamental at high pitches. Measurement of vocal-tract resonances has shown that this is particularly true for the first resonance [Joliveau *et al.* (2004)]. Higher resonances show some increase in their values perhaps reflecting incidental effects rather than active tuning. We investigate vocal-tract shaping in soprano singing using a real-time MRI technique [Narayanan *et al.* (2004)] with synchronized noise-cancelled audio recording. A professionally trained Western-classical singer spoke and sang the vowels /a, i, u, o, e/ preceded by the consonant /l/ over an ascending scale (from B-flat below middle C, rising two octaves). Acoustic analysis shows clear evidence of F1 tuning to F0 in the higher-octave singing of the vowels. The vocal-tract shape was distinctly different at the higher pitches compared to vowels spoken at normal pitch and those sung at the lower octave, with fairly large oral and pharyngeal cavities, created by a highly bunched and retracted tongue, and a raised larynx. At the highest pitch, the vocal-tract shape differences between the vowels are considerably lessened, although some vestigial canonical tongue shapes appear to remain. [Work supported by NIH, USC Annenberg Center.]

2pSP1. Short-term non-poissonian temporal clustering of magnitude 4+ earthquakes in california and western nevada. John E. Ebel (Weston Observatory, Boston College, 381 Concord Rd., Weston, MA 02493, ebel@bc.edu), Daniel W. Chambers, Alan L. Kafka, and Jenny A. Baglivo (Boston College, Chestnut Hill, MA 02467)

The M4+ mainshocks throughout California and western Nevada from 1932 to 2004 show non-Poissonian temporal clustering over time periods of a few days. The short-term clustering is independent of the distance between earthquake epicenters. It implies that some of the M4+ mainshocks are mutually triggered by some unknown regional cause. In southern California, more short-term clustering is found for M4+ earthquakes east of the San Andreas Fault. In central California, most M4+ mainshocks at Long Valley, CA have occurred within 10 days of M4+ mainshocks around the San Francisco Bay area. The clustering implies predictable behavior in the occurrences of M4+ mainshocks. We propose a hidden Markov model (HMM) as an earthquake forecast method for the region. Our HMM assumes a hidden sequence of interevent time states associated with observations of earthquake occurrences (times, locations, and magnitudes) with transition probabilities between states determined with the Baum-Welch algorithm and the past earthquake data. Given the seismic history up to the latest earthquake, the probability of another earthquake within the next few days is estimated. Tests of our HMM with two, three, and four temporal states show some modest success. We plan to extend the model to forecast magnitude and spatial parameters.

2pSP2. Trends in detection in earthquake seismology. David B. Harris (Lawrence Livermore Natl. Lab., P.O. Box 808 L-205, Livermore, CA 94551, harris2@llnl.gov)

Detection methods in earthquake seismology have been dominated in the past by simple energy detectors, often combined with array processing (beamforming) to detect at lower thresholds. Increasingly, correlation detectors now are being employed to exploit the additional gain possible with coherent detection methods. Coherent detection of transient seismic signals is complicated by the fact that earthquake signals generally cannot be predicted with certainty in advance, except for those cases where observations of previous events are available. One approach to solving this problem is to employ subspace detectors that allow variation in the correlation template to match the range of signals anticipated from a specific source region. Subspace templates have been produced empirically from past observations of repeating sources. The current challenge is to compute the templates in areas without past event observations. One approach to doing so calculates the target signal space by forward simulation through many earth realizations drawn from a stochastic earth model. In this talk, we present the results of empirical subspace detection with arrays of sensors (combining array gain with coherent matched-signal gain) and discuss preliminary results from the use of computed subspaces. [This work was performed under the auspices of the U.S. Department of Energy by the University of California, Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.]

2pSP3. Electromagnetic-to-seismic conversion: A new direct hydrocarbon indicator. A. H. Thompson (Retired, 13602 Peachwood Ct., Houston TX 77077)

In electroseismic (ES) exploration, electromagnetic (EM) energy converts to seismic energy at depth in the Earth. The amplitude of the converted seismic wave is large at porous, permeable, resistive bodies such as hydrocarbon reservoirs. ES is the only known exploration tool that, applied from the surface of the Earth, may discriminate between water, gas, and oil in the pores of reservoir rock. ES measures rock electrical properties with seismic resolution. The seismic conversion may be linear, at the same frequency as the EM stimulus. Electrokinetic effects, involving the relative motion of the rock solids and fluids, describe linear ES well. Nonlinear conversion may create all harmonics of the EM stimulus. Conventional descriptions of ES and SE conversion do not account for nonlinear conversions. New models, that couple EM and seismic energies through modulation of electrochemical potentials in the Earth, do explain the observations. ES field tests detected the hydrocarbon-sensitive, linear response to 1000 m and the nonlinear response to 1500 m deep. The results suggest that greater depth penetration, to 7000 m, is feasible.

2pSP4. Waveform design for electroseismic exploration. Scott C. Hornbostel, Arthur H. Thompson, and Warren S. Ross (ExxonMobil Upstream Res. Co., P.O. Box 2189, Houston, TX 77252-2189, scott.c.hornbostel@exxonmobil.com)

Electroseismic (ES) exploration remotely identifies the presence of hydrocarbons using the conversion of electromagnetic energy to seismic energy. These conversions are relatively larger in a porous, permeable resistive body (such as an oil or gas reservoir) when compared with background conversions. Typical ES signals, however, may be several orders of magnitude below the expected ambient noise levels, thus requiring repetitions of long source sequences. In addition, the ES signals may vary linearly or nonlinearly with the input current. Two classes of coded waveforms are presented for the detection of these linear and nonlinear conversions. The linear conversions are detected using a Golay sequence pair with side lobes that cancel when the correlated pair is summed. A set of pseudo-random binary sequences (PRBSs) can be modified to detect a nonlinear squared response with minimal side lobes while removing undesired linear conversions. These source waveforms are implemented in the power waveform synthesizer (PWS) that is capable of switching three-phase power to create the specified waveforms. The PWS is an important part of the overall electroseismic exploration system that includes source electrodes, pickup-free receivers, and acquisition and processing features aimed at effective detection of small ES signals.

2pSP5. Small-scale geophysics inversion using surface wave extracted from noise cross correlation. Pierre Gouedard, Philippe Roux, and Michel Campillo (LGIT—BP 53—38041 Grenoble cedex 9, France, pierre.gouedard@ujf-grenoble.fr)

Green's functions between receivers can be retrieved from the correlation of ambient noise or with an appropriate distribution of sources. We demonstrate this principle in geophysics at small scales. We used a 22.5-m-long line of 16 geophones and recorded noise signals in the bandwidth of 5 to 150 Hz. Noise was generated by human steps for a 10-min walk in the alignment of the geophones line (5 min on each side). The correlations of the records gave us the Green's functions associated with each pair of geophones, which exhibit two Rayleigh modes. We applied a frequency wave number transformation to separate those two modes and we measured the dispersion curve of each mode. We used these dispersion curves to perform an inversion and obtain the 1D velocity profile of the near surface (about 10 m deep).

2pSP6. Passive correlation imaging of a buried scatterer. Oleg I. Lobkis, Eric Larose, and Richard L. Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, 104 S. Wright St., Urbana, IL 61801)

Waveforms obtained by correlation of diffuse fields are now widely used to estimate times of flight and ballistic Green's functions. Theory, however, predicts that such passively obtained waveforms should equal the full Green's function of a medium, and thereby convey information on the details of a structure and the presence of isolated scatterers. Here, we investigate diffuse field correlations in a reverberant elastic body and demonstrate that their shear and Rayleigh waves allow to image internal and surface features. Resolution in the resulting images is comparable to standard echographic and seismic images. The experimental setup is analogous to a real seismic experiment.

2pSP7. Anisotropic seismic waves in systems with fluid-saturated fractures. James Berryman (Lawrence Livermore Natl. Lab., P.O. Box 808 L-200, Livermore, CA 94551-9900, berryman1@llnl.gov)

The seismic wave speeds observed in exploration reflection surveys of oil and/or gas reservoirs may be dominated by the elastic properties in the dry state of very flat cracks or fractures, containing relatively little porosity. In contrast, the majority of work on effective medium theories (both estimates and bounds) has concentrated on systems whose elastic behavior depends on the volume fractions of the fluid constituents. Although a considerable amount of work has already been done in this area, there remain controversies regarding the use of the differential and self-consistent schemes for property estimation in these systems, and these controversies are known and well documented. When the reservoirs contain vertical fractures, these systems exhibit anisotropic seismic wave speeds. Methods are known that permit relatively simple calculation of these anisotropic properties from theoretical estimates made on randomly isotropic systems of fractures. When these methods are appropriately combined with weak anisotropy approximations associated with the Thomsen seismic-wave parameters, it is possible (at least in principle) to estimate fracture orientations and densities. The relationships between these forward and inverse problems will be treated and discussed with special emphasis on the question of uniqueness of the resulting interpretations.

2pSP8. Finite-frequency seismic tomography. Yang Shen (Grad. School of Oceanogr., Univ. of Rhode Island, Narragansett, RI 02882)

The use of 3-D sensitivity kernels in tomographic inversions has received much attention in the seismological community. Conventional tomographic studies are based on ray theory, which assumes that the arrival time of a body wave depends only on the velocity along the ray path between the source and receiver. Observed seismic waves are finite frequency signals, and their travel times are sensitive to a 3-D volume around the geometrical ray and subjected to wavefront healing, scattering, and other diffractive effects. As a result, seismic waves passing through velocity heterogeneities with dimensions smaller than the width of the Fresnel zone undergo significant wave-front healing, which results in reduced travel-time shifts compared to the values predicted by ray theory. 3-D sensitivity kernels take into account the effects of wave diffraction and scattering. This presentation will provide a brief review of

finite-frequency tomography, which is in a stage of rapid development. With the advancement of computer technology, it has become increasingly practical to construct 3D sensitivity kernels based on 3D reference models using full waveform simulations. This holds the promise of a new level of the integration and joint interpretation of finite-frequency waves propagating in complex media.

3:50

2pSP9. High-resolution imaging of fault zone structures. Zhigang Peng and Yehuda Ben-Zion (Dept. of Earth and Space Sci., Univ. of California, 595 Charles E. Young Dr. East, Los Angeles, CA 90095, zpeng@ess.ucla.edu)

Damaged fault zone (FZ) rocks with high crack density are expected to produce several indicative wave propagation signals. These include scattering, anisotropy, nonlinearity, and FZ guided head and trapped waves. These signals can be used to obtain high-resolution imaging of the FZ structures and to track possible temporal evolution of FZ properties. Results associated with systematic analysis of such signals recorded at several large strike-slip FZs can be summarized as follows: The observed FZ trapped waves are generated by relatively shallow structures that extend only over the top $\sim 3--4km$ of the crust. The shallow trapping structure in the North Anatolian fault (NAF) is surrounded by broader anisotropic and scattering zones that are also confined primarily to the top 3 km. Systematic analyses of anisotropy and scattering around the NAF do not show precursory temporal evolution of properties. However, the scattering results show clear co-seismic changes and post-seismic logarithmic recovery. These effects are likely to reflect mostly changes in properties of the shallow crust in response to strong shakings of nearby major earthquakes. Analyses of FZ head waves along the San Andreas Fault point to the existence of material interfaces that extend to the bottom of the seismogenic zone.

2pSP10. Multichannel inversion of scattered teleseismic waves for migration imaging and separation of noise. Stephane Rondenay and Xander Campman (MIT, 77 Massachusetts Ave., 54-512, Cambridge, MA 02109, rondenay@mit.edu)

In recent years, a substantial increase in the availability and fidelity of broadband seismographs has led to new opportunities for multichannel processing of scattered teleseismic body waves, allowing for high-resolution imaging of subsurface structure. Here, we discuss the theoretical foundation and the implementation of such a technique. The problem is posed for forward- and back-scattered wave fields generated at discontinuities in a 2-D isotropic medium, with the backprojection operator cast as a generalized radon transform (GRT). The approach allows for the treatment of incident plane waves from arbitrary backazimuths, and recovers estimates of perturbations in material property (P and S wave velocities) about a smoothly varying reference model. In its current implementation, the method can be applied to low-pass filtered data (0.3-Hz cutoff) for imaging structure in the lower crust and lithospheric mantle. Examples from the Cascadia and Alaska subduction zones are shown. Ongoing work is being conducted to render the method applicable to higher frequency data by identifying and canceling noise generated by near-surface scatterers (e.g., mountains, sedimentary basins).

2pSP11. Multichannel near-array corrections for short-period teleseismic data. Xander Campman and Stephane Rondenay (Earth Resources Lab., Massachusetts Inst. of Technol., 42 Carleton St., Cambridge, MA 02142, xander@erl.mit.edu)

The increased availability of data from broadband and short-period seismometer arrays has stimulated the development of multichannel high-resolution imaging algorithms for scattered teleseismic waves. One of the main factors limiting the resolution of teleseismic images is the interference from unwanted phases at higher frequencies (0.3–1.5 Hz). These unwanted phases are generally associated to scattering at near-surface features. We describe initial results from a multichannel inversion-based method designed to suppress scattered waves from surface topography. Such an approach is possible because the dense spatial sampling of short-period arrays allows us to sample these phases well enough to characterize them. Using a subset of the data, we first estimate a model for the distribution of near-surface scatterers. Next, we predict scattered waves in the entire data set using this scatterer distribution model. Both the inversion and prediction steps are based on an integral representation of the scattered-wave field which takes into account the near-field character of body-to-surface wave scattering. Finally, we subtract the predicted scattered waves from the entire data set. Data from the LARSE93 experiment are used to illustrate and validate the present algorithm.

2pSP12. An earthquake detection, identification, and location system for the northeastern U.S. Based on the wavelet transform. John E. Ebel (Weston Observatory, Boston College, 381 Concord Rd., Weston, MA 02493)

In order to optimize the ability of the New England Seismic Network (NESN) to detect all local earthquakes to the smallest possible magnitude, Weston Observatory of Boston College has developed an automated event detection and identification system based on the wavelet transform. This software system performs a wavelet transform on the data from each station being received and uses the time, frequency content, and energy of the first arrival, the highest energy arrival, and the end of the detection to compute the Bayesian probability that the detection was a distant earthquake (teleseism), regional earthquake, local earthquake, quarry blast, Rg wave from a quarry blast, or transient noise. At each station, these measured parameters are used to estimate the origin time, epicentral distance, and magnitude for each detection. The systems attempts to associate the detections from different stations that have a common event identification as a teleseism, regional/local earthquake, or quarry blast. If three or more stations associate, an automatic event location and magnitude (if a regional or local earthquake) are computed. This wavelet-transform detector and identifier has greatly increased the sensitivity of detecting and locating small earthquakes and quarry blasts in the New England region.

2pUW1. Measurements and modeling of low-frequency air-sea-interface scattering. Roger C. Gauss, Joseph M. Fialkowski, and Daniel Wurmser (Naval Res. Lab., Code 7144, Washington, DC 20375-5350)

The acoustic scattering response of the undersea air-sea interface can be quite sensitive to ocean surface conditions, scattering geometry, and acoustic frequency. This paper presents both measurements and modeling of low-frequency (<1500 Hz) scattering strength. The modeling is based on a small slope approximation (SSA) that accounts for directional surface-wave roughness spectra with low-wave-number cutoffs. To provide an operationally useful predictive tool, a set of surface-wave spectral parameters (strength, exponent, and peak) are determined by nonlinear, multi-parameter fits to broadband, vertically bistatic surface backscattering strength data, leading to a semi-empirical bistatic model environmentally parameterized solely by the wind speed. The same SSA theory is also used to estimate the coherent-reflection loss given the frequency, angle, and wind speed. These broadband models are then used to explore the dependence of both incoherent and coherent sea-surface scattering on frequency, angle, and wind speed. [Work supported by ONR and PEO C4I & Space (PMW-180).]

2pUW2. How significant is the wave height of a moving surface on low-frequency propagation? Duncan P. Williams (Dstl. Winfrith, Winfrith Technol. Ctr., Rm. N11 Bldg. A32, Dorchester DT2 8WX, UK)

The ocean can carry low-frequency acoustic waves to surprisingly long range, but the ocean is ever changing and acoustic propagation is rarely unaffected by its interaction with the moving sea surface. The clarity of low-frequency acoustic communications at long range can be corrupted by this interaction. This is unsatisfactory for reliable communication and it is necessary to explain the effects introduced by the nature of the sea-surface scattering. This paper looks at the relationship between the power spectra of the received surface scattered signal and the sea surface. The surface can be conveniently characterized by its swell and wind-sea parts that can, in turn, be expressed as a function of their significant wave height and peak frequency. Basic properties of a surface spectral model are reviewed. A new model-based approach to computing the scattering from a moving sea surface is introduced. This approach is based on ray theory and a simple physical model for the response function of the surface. The model is compared with long-range experimental data and then results are shown to illustrate the effects of wave height and peak frequency on simple broadband waveforms.

2pUW3. Gravity wave focusing in the littoral zone. Grant Deane (Scripps Inst. of Oceanogr., Code 0238, UCSD, La Jolla, CA 93092-0238)

One of the unique environmental factors impacting acoustic propagation in the littoral zone is the presence of shoaling surf. Surface gravity waves act as acoustic mirrors, creating high-intensity cusps and caustics in the reflected sound field. The focal points of sound move through the water column as the gravity waves shoal, and can disrupt the performance of underwater communications systems and impact sonar performance. Analytical and numerical calculations of the focusing properties of shoaling gravity waves are described and used to predict the motion of the focal regions through time. [Work supported by ONR.]

2:05

2pUW4. A brief review of modeling in support of bubble-enhanced scattering from the air/sea interface. Richard Keiffer (NRL-SSC, Stennis Space Ctr., MS 39529)

By 1995 or so, the long-standing disparity (at low to moderate frequencies) between sea surface (backscatter) reverberation data and interface scattering models was solved by the incorporating a bubble cloud scattering mechanism into reverberation models. At that time (and still today), a comprehensive description of the spatially and temporally varying bubble population was lacking, so critical environmental parameters needed for the bubble cloud scattering models were inferred from the differences in the scattering levels predicted by interface scattering models and measured scattering strengths. This modeling development generally ignored another mechanism through which the bubbles may influence the reverberation: the bubbles will also cause upward refraction near the air/sea interface and this upward refraction may significantly increase the scattering from the air/sea boundary. In this presentation, a brief review of the published modeling supporting the bubble-enhanced interface scattering phenomenon will be presented. [Work supported by ONR/NRL.]

2:25

2pUW5. Wavefront modeling of scattering from surface waves. Chris Tindle (Phys. Dept., Univ. Auckland, Auckland, New Zealand)

The scattering of sound from any particular smooth realization of ocean surface waves can be calculated using wavefront modeling. The method uses ray tracing to locate the wavefronts and stationary phase analysis to determine the phase and amplitude of the sound field. Waveforms due to reflection of short pulses can be found directly and compare well with experimental results. Reflection at a curved surface leads to foci and caustics and the field is determined numerically from Pearcey and Airy functions, respectively. The method uses the time domain and is fast and accurate. [Work supported by ONR.]

2pUW6. Time domain modeling of acoustic Doppler from 2-D, developing, and swell-contaminated seas displaying a bimodal azimuthal dependence. Richard Keiffer (NRL-SSC, Stennis Space Ctr., MS 39529)

The typical sea-surface acoustic scattering experiment is often modeled invoking an environment and measurement scenario containing a number of idealizations. Almost universal is the assumption that the rough pressure-release air/sea boundary can be described using a roughness spectrum that belongs to spatially uniform, fully developed seas. Often this roughness spectrum is assumed to have a simple cosine-squared or some other canonical azimuthal dependence. The air/sea boundary is assumed to be an overly homogeneous isospeed ocean and the source and receiver are assumed stationary or in uniform rectilinear motion. Because the data collected at sea and the results from numerical simulations are often compared in order to infer the acoustic attributes of bubbles and bubble clouds, it is important to have a good understanding of the limitations that these common idealizations impose on the data/model comparison. In this paper, a newly developed and tested time domain model for acoustic scattering from moving 2-D surfaces [J. Acoust. Soc. Am. **118**(3), 1283–1299 (2005)] is used to examine the implications that wave growth, swell contamination of a bimodal azimuthal dependence, and near-surface upward refraction have on the Doppler of acoustic signals backscattered from the sea surface. [Work supported by ONR/NRL.]

2pUW7. Modeling of glints due to surface curvature using the virtual source technique. Ahmad T. Abawi, Michael B. Porter, and Martin Siderius (Heat, Light, and Sound Research, 12730 High Bluff Dr., San Diego, CA 92130)

The virtual source technique, also known as the method of superposition or the auxiliary source technique, has been widely used to model scattering from targets. In this technique the target is replaced by a collection of sources of unknown complex amplitudes. The source amplitudes are calculated by applying the appropriate boundary conditions at the surface of the target. In this paper, the virtual source technique is used to compute scattering from rough surfaces. For sound scattering from the rough ocean surface, this is done by solving the wave equation for a half-space ocean overlaying a bottom and forcing the solution to satisfy the pressure-release boundary condition at a desired surface. The method is applied to study the effect of focusing of energy (glints) due to reflection of sound from a gently sloping, but concave ocean surface for various ocean conditions. Additionally, the method is applied to the study of scattering of waves from an infinite periodic surface.

2pUW8. High-frequency limit under the Rayleigh hypothesis. Tanos Elfouhaily and Thomas Hahn (Univ. of Miami, RSMAS, 4600 Rickenbacker Cswy., Miami, FL 33149)

The Rayleigh hypothesis (RH) is traditionally invoked to compute the scattering amplitude in rough surface scattering. This hypothesis simplifies the analytic derivation of the scattering problem and has been proven to be accurate for the determination of the Volterra series for the small perturbation method (SPM). The SPM development physically corresponds to the scattering of low-frequency acoustical waves. In this study we focus on the high-frequency limit under the Rayleigh hypothesis (RH). We validate the consistency of the RH with the high-frequency limit to the order invoked in the approximation. This means that the first-order geometrical optics (GO1) is reached even though the Rayleigh hypothesis consists of the summation of solely upward scattered fields.

2pUW9. Scattering by surfaces with sub-Bragg structure. Frank Henyey and Dajun Tang (Appl. Phys. Lab., Univ of Washington, 1013 NE 40th St., Seattle, WA 92105)

The scattering from a rough pressure release surface, where the spectrum of the surface only contains wavelengths considerably shorter than half the acoustic wavelength, is considered. The amplitude of the surface may be larger than that for which perturbation theory would be appropriate. We show that the surface can be replaced by an effective surface containing waves longer than half the acoustic wavelength. This effective surface is close to the envelope of the actual surface; this effective problem is likely to be much easier to solve than the original problem. We investigate the relationship between the problems and adjust parameters of the effective surface, by solving both problems with the integral equation.

4:10

2pUW10. Finite-difference time-domain simulation of acoustic propagation through a dispersive oceanic bubble cloud. Guy Norton (Naval Res. Lab., Acoust. Div., Stennis Space Ctr., MS 39529, guy.norton@nrlssc.navy.mil)

Accurate modeling of pulse propagation and scattering is a problem in many disciplines. For the case of an acoustic wave propagating in a two-dimensional non dispersive medium, a routine second-order in time and space finite-difference-time-domain (FDTD) scheme representation of the linear wave equation can be used to solve for the acoustic pressure. However, when the medium is dispersive, one is required to take into account the frequency-dependent attenuation and phase speed. Until recently, to include the dispersive effects one typically solved the problem in the frequency domain and then Fourier transformed into the time domain. However, by using a theory proposed by Blackstock [D. T. Blackstock, J. Acoust. Soc. Am. **77**, 2050 (1985)], the linear wave equation has been modified by adding an additional term that takes into account the disper-

sive nature of the medium. In this work a fourth-order (in time and space) 2-D FDTD scheme, which includes attenuation and dispersion via the convolution operator, is used to model backscattering of broadband signals from a dispersive composite subsurface bubble cloud composed of two different plumes underlying a random rough sea surface. [Work supported by ONR/NRL.]

2pUW11. A time domain approach to sea-surface scattering. Martin Siderius, Michael B. Porter, and Ahmad T. Abawi (HLS Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130)

Solutions to scattering problems are often formulated in the frequency domain which, for ocean acoustics, implies the surface is frozen in time. This may be reasonable for short-duration signals but breaks down if the surface changes appreciably over the time of the transmission. Additionally, frequency-do-main solutions are impractical for source-receiver ranges and frequency bands typical for applications such as acoustic communications (e.g., several kilometers, 3–50-kHz band). The time-varying nature of the sea surface adds to the complexity, often leading to a statistical description for the variations in received signals. A purely statistical description likely limits the insight that modeling generally provides. In this presentation we describe a time-domain modeling approach to the sea-surface scattering problem. The Helmholtz integral equation is used with the Kirchhoff approximation. The Green's functions representing the impulse response from all scattering points on the surface to the receivers are computed in terms of arrival amplitudes and time delays. This time-domain framework allows for including both broadband signals and the time-varying sea surface. The method will be compared with exact solutions for a subset of problems (frozen, rough surfaces) to determine limitations. Further, scattering results will be compared with those using Gaussian beam tracing.

4:40

2pUW12. Further work on the relationship between the coherent-to-incoherent ratio (CTIR) and the sea surface wave height for one-way propagation in a shallow ocean channel. R. Lee Culver, David L. Bradley (Appl. Res. Lab and Acoust. Grad. Program, The Penn State Univ., P.O. Box 30, State College, PA 16804, rlc5@psu.edu), Philippe Roux (LGIT-Maison des Gosciences, Grenoble cedex 9, France), William A. Kuperman (Univ. of California at San Diego, La Jolla, CA 92093-0238), and Stevenson Mark (NATO Undersea Res. Ctr., La Spezia, Italy)

A 29-element source array and 32-element receiver array have been deployed 8.6 km apart in a 120-m-deep ocean channel. Both arrays spanned most of the water column. Linear frequency-modulated (LFM) pulses 150 ms long and 4 kHz wide centered at 3.5 kHz were transmitted from one source at a time and recorded at all receivers during a several day period. During the recordings, the sound speed profile was approximately iso-velocity and the significant wave height varied from 0.3 to 1.1 m. We average the received signal coherently and incoherently for each source-receiver pair, average over all pairs, and take the coherent-to-incoherent ratio (CTIR). Log (CTIR) is found to depend linearly on time after the initial arrival, with slope proportional to the significant wave height. An earlier talk showed that the average reflection coefficient times the number of surface bounces N was a good predictor of the slope, but subsequently we find that it alone is not sufficient. Here we report a more complete theory that combines N, the average reflection coefficient, and the density of the arrivals. A predictive model for slope versus surface wave height is presented and compared with the measurements. The method can incorporate ray tracing and be extended to non-iso-velocity environments.

4:55

2pUW13. Detection in a nonstationary waveguide using orthogonal codes to measure the invariants of the time reversal operator. Franck Philippe, Claire Prada, Dominique Clorennec, Julien De Rosny (LOA, ESPCI, 10 rue Vauquelin, 75005 Paris, France), and Mathias Fink (LOA, 75005 Paris, France)

In underwater acoustics, time reversal (TR) techniques using an array of acoustic sources are commonly known for their efficiency in applications such as communication and detection. However, as TR methods assume stationary conditions, they are clearly affected by fluctuations of the medium. Among them, the decomposition of the time reversal operator (DORT method), although highly efficient for separating the echo from two close targets through a complex medium, suffers from the long acquisition time required. Indeed the whole interelement responses are needed meaning that N signals are acquired for an N-transducer array. The measurement is then at least N times longer than travel time. To reduce the acquisition time, orthogonal codes can be used [Folgot *et al.*, J. Acoust. Soc. Am. **117**, 3757–3765 (2005)]. These codes are tested in a laboratory detection experiment: a small-scale model of a shallow-water wave guide in which we add artificial surface waves of different frequencies and different amplitudes. The perturbations induced by the surface waves on the invariant of the time reversal operator are analyzed. Different methods which greatly reduce the acquisition time like Kasami and AIRS codes are compared.

Meeting of Accredited Standards Committee (ASC) S1 Acoustics

J. P. Seiler, Chair S1
U.S. Dept. of Labor, Mine Safety and Health Admin., P.O. Box 18233, Bldg. 38, Cochrans Mill Road, Pittsburgh, PA 15236

G. S. K. Wong, Vice Chair S1
Inst. for National Measurement Standards, National Research Council, Montreal Road, Bldg. M36, Ottawa, Ontario K1A OR6, Canada

Accredited Standards Committee S1 on Acoustics. Working group chairs will report on the status of standards currently under development in the areas of physical acoustics, electroacoustics, sonics, ultrasonics, and underwater sound, etc. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note – those meetings will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 6 June 2006.

Scope of S1: Standards, specifications, methods of measurement and test, and terminology in the field of physical acoustics, including architectural acoustics, electroacoustics, sonics and ultrasonics, and underwater sound, but excluding those aspects which pertain to biological safety, tolerance and comfort.

Meeting of Accredited Standards Committee (ASC) S12 Noise

R. D. Hellweg, Chair S12
Hewlett Packard Co., Acoustics Lab., MR01-2/K15, 200 Forest St., Marlborough, MA 01752

W. J. Murphy, Vice Chair S12
NIOSH, 4676 Columbia Parkway, Mail Stop C27, Cincinnati, OH 45226

Accredited Standards Committee S12 on Noise. Working group chairs will report on the status of noise standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAG for ISO/TC 43/SC 1 Noise, take note – that meeting will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 6 June 2006.

Scope of S12: Standards, specifications and terminology in the field of acoustical noise pertaining to methods of measurement, evaluation and control, including biological safety, tolerance and comfort and physical acoustics as related to environmental and occupational noise.

3aAA1. "Flowers and Wreaths": Radio theater and surround. Ean White (15 Channel Ctr. St., #514, Boston, MA 02210-3426, ean@incendiaryarts.org)

Originally produced in late 1992, ''Flowers and Wreaths'' is a setting for poems by Jacques Prvert (*paroles* Prvert) in French and in English translations by Lawrence Ferlinghetti and me. Prvert's success in France after World War II was largely due to his unabashed use of street language and his staunch antiwar, antirational political stance. The performance featured much original instrumentation: an amplified skull-resonator dental floss violone, a 35-ft.-long infrasonic electric monochord, a naval signal lamp, mechanized moving audience seating, the amplified electrocution of vegetables, unconventional speaker placement, etc. Mari Novotny-Jones and I continued to perform the piece through 1993. ''Flowers and Wreaths'' was decidedly a kind of live radio theater, but far too contingent, too phenomenological to expect that it could actually be recorded and distributed in any satisfactory way. Nevertheless, this work continued to be pursued through the mid-nineties, finally producing *Radio Etudes* (with Sarah Hickler and technical help from the late Robert Moog), which addressed directly the issues of reproduction before being given up entirely. Now, on the brink of a new era in broadcast technology, imagine a radio theater renaissance.

8:20

3aAA2. "Passing Landscapes." James Moses (Music Dept., Brown Univ., Orwig Music Bldg., 1 Young Orchid Ave., Providence, RI 02806)

This 15-min piece is composed from five-channel surround sound environmental and naturalistic concert hall recordings of original music. Cross-synthesis and resonant filtering techniques are used to create harmonic and melodic content from the environmental recordings. The synthesized components move in the surround soundfield against the stable spatial image of the source recordings. The environmental recordings include bucolic settings, a downtown cityscape, a highway traffic scene, a public gathering, and a composed ambience/montage of sounds from our electronic media culture. The various environmental recordings are juxtaposed with each other and with concert hall material to create the form of the piece. The piece intends to provide a contextualized view of aspects of modern life and technology.

8:40

3aAA3. Vis-a-vis: Reading texts in real-time. Joseph Rovan (Music Dept., Brown Univ., 1 Young Orchard Ave., Providence, RI 02912, rovan@brown.edu)

This presentation addresses the formal and psychological aspects of Vis-a-vis as a way of framing the attitude of the technology itself. Based on a text by Rilke, the work situates a solo singer within a dense sonic landscape whose electronic sounds are based entirely on her voice. The interactive score, written in MaxMSP, makes the computer a virtual performer, listening and responding to the changing musical events in its own terms. In this new 5.1 mix a variety of real-time processes are used on the voice, shifting from scene to scene, according to the tone of the text. Among the real-time processes used are spectral analysis/resynthesis, granular sampling, harmonization, frequency shifting, and envelope tracking, among others. In Vis-a-vis the computer functions like a virtual performer, listening to the changing musical events phrasing, dynamics, and register of the singer, and responds accordingly, in its own terms. The point is to capture something of the improvisatory spirit that is part of any live performance, and to create an environment in which the singer and computer can interact as a duo, responding to each other's musical decisions in an immersive sonic environment.

9:00

3aAA4. Convergence. Andrew Carballeira (Driftwood Audio, 311 Concord Ave., Lexington, MA 02421)

convergence seeks to show the potential beauty of a world at peace through the manipulation of dissonance/consonance and spatial information. As a noncomposed experimental piece, the principal task is sifting through a wealth of improvised free music to gleam the sections most pertinent to the aims of the work. Thereby, convergence is, in many ways, a continuation of the concept adopted by Columbia editors on Miles Davis later works (''Bitches Brew'' and ''Live/Evil'' among them) which places the engineer/editor at the forefront of the creative process. In the spatial domain, this work draws heavily on the multi-channel spatialization techniques developed by IRCAM (*et al.*) and convolution with impulse responses, sampled and synthesized, to create the environment in which sound sources interact and ultimately join together with one voice.

9:20

3aAA5. Sparrows swarm and sing—a sonic collaboration. Eli D. Cohn, Robert M. Mallory, and Alexander U. Case (Sound Recording Tech., Dept. of Music, UMass Lowell, 35 Wilder St., Ste. 3, Lowell, MA 01854, alex_case@uml.edu)

Untitled Number 3 was written and performed by the Massachusetts-based sextet, Sparrows Swarm & Sing. The work combines orchestral string instruments and percussion, distorted guitars, rock drums, voices without words, and an array of handmade noisemakers. The first movement, ''Quartet'' (recorded live), begins with underlying chimes and noisemakers present throughout the piece. Acoustic cello and violin quietly emerge from the disciplined electric guitar line. Harmony and dissonance evolve into a lush reverberant noise created from each note played in the preceding string passage. The second movement, ''Come on Camaraderie,'' emerges from the reverberant decay into an uplifting dance song of which the climax is highlighted with a choral vocal line. This immediately propels itself into the brooding and relentless noise of guitar melodies/detunings. The quiet vocal melody introduces the third movement, ''The Processional.'' Electric guitar and bass beckon a distant cello melody followed by layers of bowed glockenspiel, cello/violin pizzicato, chimes, and snare drum.

9:40

3aAA6. Improvising with spaces. Pauline Oliveros (Rensselaer Polytechnic Inst., 110 Federal St., Troy, NY 12180, paulineo@deeplistening.org)

This paper explores qualitative changes that occur in voices and instruments in relationships with changing spaces that ordinarily are held in a stationary paradigm of performance practice, spatial transformations, and the effect on sounds in multi-channel speaker systems. Digital technology allows one to compose and improvise with acoustical characteristics and change the apparent space during a musical performance. Sounds can move in space, and space can morph and change, affecting the sounds. Space is an integral part of sound. One cannot exist without the other. Varieties of sounds and spaces combine in symbiotic relationships that range from very limited to very powerful for the interweaving expressions of the music, architectures, and audiences.

10:10

3aAA7. The creation of a surreal five-channel sound environment using human mobile microphone stands. Thomas Plsek (Berklee College of Music, MS-1140 Brass, 1140 Boyslton St., Boston, MA 02215, tplsek@berklee.edu)

The notion of creating a piece for a discrete five-channel audio environment calls for one to consider ways in which a piece could be created that could only exist in this environment, i.e., it would not be a documentation of a performance, nor could it even exist in the real acoustic world. Considering low-tech solutions to these problems led to the idea of doing a recording of solo trombone using human mobile microphone stands (or HMMS). This allows for real-time movement of both the source and the receivers during the recording process. This gives the possibility of creating a surreal audio environment that could only be created with extreme difficulty (if at all) any other way. As source material for composition, the poem, ''Rather the flight of the bird passing and leaving no trace,'' by Alberto Caeiro, who was one of many heteronyms of the Portuguese poet Fernando Pessoa, was chosen. Espcially notable is the line, ''What's past is nothing and remembering is not seeing.''

10:30

3aAA8. Temporal/spatial convergence in surround sound. Stephan Moore (Troy, NY 12180, stephan@oddnoise.com)

A discussion of the musical composition ''Thaw/Twist at Bailey's,'' in which a field recording of the 2004 spring thaw at Thomas Bailey's farmhouse in Richland, MI is used to explore the phenomena of temporal/spatial convergence and dispersal. This presentation will cover the creation of the piece, its initial installation for a site-specific 16-channel array of custom-built speakers, and the challenges and merits of adapting it for 5.1 surround sound.

10:50

3aAA9. The evolution of new counterpoint through electro-acoustic music. Eric Chasalow (Music Dept., Brandeis Univ., MS051, Waltham, MA 02454-9110)

It is widely believed that the advent of electronic music during the mid-20th century redefined music fundamentally. It may be shown, however, that a number of composers found rather more evolutionary ways of elevating basic acoustical elements to enrich the long tradition of music making. Examples from Davidovsky and the author demonstrate this history. Additional examples demonstrate the continuing evolution enabled by historical artifacts and surround technology.

11:10

3aAA10. Issues pertaining to the composing of "minimalist" loudspeaker music for home theater arrays. David Moulton (Moulton Labs., 39 Ames Rd., Groton, MA 01450, dmoulton@moultonlabs.com)

Loudspeaker music composed for home theater loudspeaker arrays is subject to a different set of aesthetic principles and production problems than is music (live or otherwise) prepared for concert presentation. Issues of scale, timing, dynamic range, spectral range, sonic materials, reverberance, the treatment of spatial issues, and listener expectations will all be discussed.

11:30

3aAA11. Spatial treatment of sound sources in John Mallia's "Anastasis." John Mallia (New England Conservatory of Music, 290 Huntington Ave., Boston, MA 02115)

This presentation will outline the spatial techniques and treatment of sounds in my five-channel acousmatic composition entitled ''Anastasis.'' The orchestration of sound objects in the field of five loudspeakers adheres to an elastic gravitational plan assigned to each point in space. Generally speaking, the field of five speakers is weighted so that rear point sources support sounds lower in pitch than those occurring in the front of the projection plane where frequencies are raised. The relationship between each point source and its corresponding interval of transposition is in constant flux and its size serves to emphasize the degree of spatial depth present at any given moment. No attempt is made to precisely emulate the way in which we hear sounds move in the real world, but, rather, sound sources are intuitively, and experimentally, decorrelated to support and exaggerate the listeners experience of space. The presentation of this working method will raise questions regarding the compositional effectiveness of experimental spatialization techniques informed by general observations of the physical properties of sound versus methods that attempt to model, more closely and accurately, the predictable behavior of sound in space.

11:50

3aAA12. Different space conceptions in two electroacoustic compositions: Rojo and human-space-factory. Hans Tutschku (Harvard Univ., Music Bldg., Cambridge, MA 02138, tutschku@fas.harvard.edu)

Having used multichannel speaker setups for my electroacoustic compositions since 1989, I have experimented with many approaches to compose different sound-space relationships over the years. In human-space-factory, composed in 1999, the movements of the sounds in space are directly correlated with spectromorphologic changes of the sounds themselves. The composition tends to create distinguishable different spaces, sometimes even simultaneously. Rojo, composed in 2004, evokes the aural image of rituals of different cultures. Voices come from all directions and create a musical happening, surrounding the audience to give the impression that the listener is actually participating in the performance. The paper will outline the different compositional approaches and some technical solutions encountered during the realization of both compositions. Sound examples will be played during the lecture.

3aAB1. The echolocating bat controls the direction and distance of its acoustic gaze. Cynthia Moss and Kaushik Ghose (Dept. of Psych., Inst. for Systems Res., Univ. of Maryland, College Park, MD 20742)

Adaptive vocal control by echolocating bats may serve to spatially filter acoustic information in a complex environment. It is well documented that FM bats actively adjust the duration of sonar vocalizations to avoid overlap of emissions and echoes. FM bats also control the direction of the sonar beam, which restricts the direction and volume of space sampled by the sonar system. Therefore, the temporal characteristics of the bat's sonar signals can be used to estimate its window of attention along the range axis, and the sonar beam aim as an index of the direction of its acoustic gaze. Here, we describe a series of studies that investigated adaptive sonar behavior of the big brown bat performing in a variety of echolocation tasks. We used high-speed infrared video to reconstruct the flight path of the bat and its insect prey. An array of ultrasonic microphones recorded the timing and spatial pattern of each sonar emission. Quantitative analyses of the data suggest that the bat's directional aim and temporal control of sonar signals may reduce information processing demands on its auditory system, enabling adaptive behaviors that must occur rapidly as the animal flies. [Work supported by NIMH and NIBIB.]

8:45

3aAB2. Strategies for bat echolocation estimated through characteristics of pulse and echo measured by a telemetry microphone. Hiroshi Riquimaroux (Doshisha Univ., 1-3 Tatara Miyakotani, Kyotanabe, Kyoto, Japan, hrikimar@mail.doshisha.ac.jp)

How echolocating bats extract important information from multiple targets during flight was investigated by a small and very light telemetry microphone system (Telemike) mounted on the head. A high-speed video camera system was also adopted together with Telemike to trace positions in space of the flying bat for analyzing spatio-temporal pulse emission patterns and flying velocity. With those devices, how the bats executed parallel time-sharing real-time processing during their flight could be examined. Taiwanese

leaf-nosed bats (Hipposideros terasensis), CF-FM bats, were used as subjects. The Doppler-shift compensation was confirmed during flight where the frequency of the dominant second harmonic of constant frequency component, CF2, of returning echoes was kept constant by adjusting CF2 frequency of emitting pulses. Estimated frequencies of CF2 of pulses from the bats flight speed strongly agreed with actually observed values. Pulse frequencies were also estimated using echoes returning directly ahead of the bat and from its sides for two different flight conditions: landing and U-turning. Temporal patterns for Doppler-shift compensation, interpulse interval, and echo delay showed that bats in flight alternately changed their attended direction from one to another. Bats were also observed to change the intensity and emission rate of pulses depending on the distance from the landing site. [Work partly supported by the Innovative Cluster Creation Project promoted by MEXT and by a grant to RCAST at Doshisha University from MEXT.]

9:00

3aAB3. Perception of object features by echolocating big brown bats. Caroline M. DeLong, Rebecca Bragg, and James A. Simmons (Dept. of Neurosci., Brown Univ., Box 1953, Providence, RI 02912, caroline_delong@brown.edu)

Big brown bats can discriminate among objects using wideband FM sonar sounds. They can perceive only the acoustic dimensions of echoes (e.g., delay, frequency, amplitude), or they can use those dimensions to reconstruct object features (e.g., distance, shape, size). To investigate this question, bats were presented with two-alternative (left/right) forced-choice sonar discrimination tasks. In experiment 1, the stimuli were a one-cylinder monopole target and a two-cylinder dipole target that were presented at all aspect angles. In experiment 2, the stimuli were multiple two-cylinder dipole targets presented at all aspect angles. In both experiments, the positive target was the dipole with a 5-cm separation (negative targets had separations of 1–7 cm). Acoustic dimensions of the dipole echoes change depending on the aspect angle. If the bats represent only acoustic dimensions, they should have difficulty selecting the positive target at many aspects. If the bats represent object features, they should be able to select the positive target independent of aspect angle. Bats perform well, suggesting that they reconstruct object features from echo acoustic dimensions. Errors appear due to masking of either the monopole glint with the dipole glints or the dipole glints with each other. [Work supported by NIH and ONR.]

9:15

3aAB4. How well does a whale hear its own biosonar pulses? Alexander Ya. Supin (Inst. of Ecology and Evolution of the Russian Acad. of Sci., 33 Leninsky Prospect, Moscow, Russia), Paul E. Nachtigall, and Marlee Breese (Univ. of Hawaii, HI)

During echolocation, whales and dolphins perceive faint echoes shortly after emitting loud outgoing sound pulses. Why do the outgoing sounds not mask the faint echoes? Is it because the sound energy is effectively concentrated in the transmitted sonar beam and isolated from the animal's own ears? To answer this question, we recorded a false killer whale's emitted echolocation pulses and auditory-evoked potentials provoked by its pulses and compared them to similar responses produced by external acoustic signals of known intensities. A few thousand of the individual AEP records were sorted according to the spontaneously varied amplitude of the synchronously recorded biosonar pulses. In each of the sorting bins (in 5-dB steps), AEP records were averaged to extract AEPs from the noise. For comparison, AEPs were recorded to external sound pulses with waveforms, spectra, and amplitudes similar to those of the whale's biosonar pulses. A comparison has shown that, depending on the target presence or absence, the sensitivity of the whale's hearing to its own transmitted biosonar pulse was 30 to 45 dB lower than might be expected in a free acoustic field

9:30

3aAB5. Detection and discrimination of fish prey by echolocating odontocetes. Whitlow W. L. Au (Hawaii Inst. of Marine Biol., Univ. of Hawaii, P.O. Box 1106, Kailua, HI 96734), Kelly J. Benoit-Bird (Oregon State Univ., Corvallis, OR 97331) and Ronald Kastelein SEAMARCO, 3843 CC Harderwijk, the Netherlands)

The echolocation detection range of the Atlantic bottlenose dolphin *Tursiops truncates* and the harbor porpoise *Phocoena phocoena* have been either measured or estimated in nonmasking and noise-masking environments using human-made targets. These experiments provide little information on the detection range for fish prey in a natural environment. Backscatter and corresponding target strength measurements were performed on four species of fish, Atlantic cod, gray mullet, pollock, and sea bass, using simulated dolphin and harbor porpoise echolocation signals. Backscatter measurements were also performed on several species of snappers using simulated bottlenose dolphin echolocation signals. The fish subject was anesthetized and placed in a monofilament net bag which was attached to a monofilament curtain attached to a rotor. The target strength and backscatter characteristics were determined as a function of angle in the lateral plane. The results of detection experiments using real targets were used to estimate echolocation detection range for the different fish species. In a nonmasking environment, a bottlenose dolphin should be able to detect a cod between 84 and 135 m and a porpoise detection range should be between 12 and 23 m. We also examined the cues echolocating animals could use to discriminate fish species.

9:45

3aAB6. Numerical insights into the mechanisms of biosonar beamforming. Rolf Müller (School of Phys. & Microelectronics, Shandong Univ., 5 Hongjia Lou, 250100 Jinan, China)

The pronounced interspecific variability in the outer ear and nose shapes of bats suggests that the beamforming action of these structures is functionally important to the animals' biosonar systems. Numerical methods bring three major advantages to the study of the underlying mechanisms: efficiency in producing high-resolution directivity estimates, exploration of wave properties in the near field, and integration with digital shape manipulations. High-resolution directivity estimates reveal the shape of main- and sidelobes as well as their interplay over frequency. In two case studies, sidelobes were found to be prominent directivity features with significant sensitivity. In one case, they were even part of a dynamic pattern in which the maximum sensitivity alternates between mainlobe and sidelobes over frequency. Shape manipulations can be applied to the study of such features as the tragus or antitragus and prominent ledges around the pinna rim. These features can either be digitally removed or continuously transformed (e.g., rotated or scaled). The effects of multiple features can be studied by generating all combinations of presence or absence of the individual features. All prominent morphological features studied so far were found to have an effect mainly on sidelobes.

3aAB7. Cepstral processing for bat biosonar. John R. Buck (Dept. of Elec. and Comput. Eng. & School for Marine Sci. and Technol., Univ. of Massachusetts Dartmouth, 285 Old Westport Rd., North Dartmouth, MA 02747), James A. Simmons, and Caroline M. DeLong (Brown Univ., Providence, RI 02912)

Bats routinely discriminate multiple glint targets whose interglint time spacings are much less than the integration time of the bat auditory system. This suggests that the bats are exploiting spectral cues in the received echos to resolve the glints. Closely spaced glints cause notches and peaks in the received signal spectrum with frequency spacings characteristic of the glint separations. A biologically inspired signal processing algorithm for resolving these echos into target images is described. The algorithm combines a coarse energy detector to locate targets with a windowed short-time cepstral analysis, or cepstrogram, to resolve the fine structure of the detected targets. The algorithm's performance is demonstrated using data recorded in a laboratory experiment. The experiments transmit an ultrasonic chirp and record the echos from a target consisting of a pair of cylinders spaced 5 cm apart, presented at aspect angles ranging from 0 to 90 deg. These recordings are processed with the cepstrogram algorithm using parameter choices commensurate with the performance of the bat auditory system. The cepstrogram algorithm accurately estimates the spacing of the cylinders. Combining the results from the left and right receiver channels produces a binaural image of the target. 3aAB8. Evaluation of performance of the echolocation model for the restoration of an acoustic image from a single-emission echo. Ikuo Matsuo (Faculty of Liberal Arts, Tohoku Gakuin Univ., 2-1-1 Tenjinzawa, Izumi-ku, Sendai 981-3193, Japan), Takashi Magara, and Masafumi Yano (Tohoku Univ., Sendai 980-8577, Japan)

Using frequency-modulated echolocation sound, bats can form a fine acoustic image of an object. The acoustic image is an impulse response, known as a reflected-intensity distribution, which is composed of amplitude and phase spectra over a range of frequencies. However, bats detect only the amplitude spectrum due to the low-time resolution of their peripheral auditory system, and the frequency range of emission is restricted. The amplitude spectrum varies with the changes in the configuration of the reflected-intensity distribution, while the phase spectrum varies with the changes in its configuration and location. By introducing some reasonable constraints, we previously proposed a method for restoring an acoustic image from the echo produced by a single emission. The configuration is extrapolated from the amplitude spectrum of the restricted frequency range by using the continuity condition of the amplitude spectrum at the minimum frequency of the emission and the minimum phase condition. The location is estimated from the temporal changes of the amplitude spectra computed by the convolution of the Gaussian chirplet with a carrier frequency compatible with bat emission sweep rates. In this paper, the performance of this model is evaluated by measuring and analyzing the echo reflected from the object.

3aAB9. A computational model of bottlenose dolphin sonar: Feature-extracting method. Tengiz V. Zorikov (Inst. of Cybernetics, 5 S. Euli, 0186, Tbilisi, Georgia, zorikov@hotmail.com)

A process of echo-image formation in bottlenose dolphin perception was investigated in our experiments, in which animals were trained to differentiate passive actual echoes recorded beforehand purposely, as well as echo-like simulated impulses. The results suggest that dolphin, processing echoes within critical interval of time ($\sim$0.2 ms), utilizes the string of three independent, hierarchically organized features (echoes subjective characteristics) being defined by different scales of spectral density oscillation, and energy. Herewith, dolphin is capable to assess features average value over a series of echoes. Distinguishing stimuli, dolphin estimates successively features values from senior to minor, terminating the process at the feature, which contains detectable differences in compared stimuli (the distinctive feature). A procedure of subsequent identification of the reference stimulus can be described by the following decision rule: If the dolphin utilizes some feature as the distinctive one, then in order to preserve the image of the reference stimulus in the animal's perception, it is necessary and sufficient to preserve the same values of the distinctive feature and all higher ones in order of hierarchy. These data were formalized mathematically and used in our computational model, comparative testing of which has revealed critical capabilities comparable with those of bottlenose dolphins.

3aAB10. A spike burst coding scheme for environment representation by FM bats. Herbert Peremans and Bertrand Fontaine (Dept. Environment, Tech. and Tech. Management, Universiteit Antwerpen, Prinsstraat, 13, 2000 Antwerpen, Belgium, herbert.peremans@ua.ac.be)

All environmental features of interest to bats, i.e., spatial arrangement of reflectors as well as reflector type, are coded into the patterns of spikes that travel up the auditory nerve into the bat's brain. Realistic scenes containing multiple, closely spaced reflectors give rise to complex echo signals consisting of multiple, highly overlapping filtered copies of the bat's own vocalization. Some of this filtering is self-induced, i.e., directivity of the bat sonar system, and some of it is beyond the control of the bat, i.e., sound absorption and reflection process. This analysis concentrates on the conspicuous ridges these filter operations give rise to in the time-frequency representation of the echo as produced by the FM bat's inner ear. Assuming multiple threshold detecting neurons for each frequency channel, it is shown how the time dispersion of the generated spike bursts is linked to the presence and characteristics of these notches. A neural network decoding the spike bursts in terms of notch locations and types is described. After separating the notches due to the HRTF from the reflector generated ones, they are separately interpreted in terms of the environmental features of interest, i.e., target location and target structure. [Work funded by the EC, IST-FET Initiative.]

3aAB11. Simulating neural responses to biosonar signals. David C. Mountain (Boston Univ. Hearing Res. Ctr., 44 Cummington St., Boston, MA 02215)

The mammalian auditory system is a highly evolved acoustic signal-processing system that performs well even in highly reverberant and cluttered acoustic environments. In echolocating species, the auditory system is even more highly evolved and is generally more important than vision for navigation and foraging. Since invasive physiological experiments using echolocating species is challenging at best and is illegal for protected species, other methods must be sought if we are to understand how biosonar systems function. Biophysically based computer models provide a method by which we can extrapolate from physiological experiments performed on species that can be used for invasive experiments to those species that cannot be used. Results will be presented for simulations of physiological responses in the auditory nerve and brainstem to biosonar signals for several species. The simulations were done using the EARLAB (http://earlab.bu.edu) desktop simulation environment. Model parameters for species of interest were estimated from behavioral audiograms and from other available data. The models can be used to predict how different types of biosonar signals are represented in neural firing patterns and how the neural representation degrades in the presence of anthropogenic noise. 3aAB12. Bat sonar and the role of frequency diversity. Kenneth G. Foote (Woods Hole Oceanogr. Inst., 98 Water St., Woods Hole, MA 02543) and James A. Simmons (Brown Univ., Providence, RI 02912)

Species of echolocating bats that forage in foliage, in the presence of clutter with attendant multiple, often overlapping echoes, use 3–5 simultaneous harmonic sweeps to cover a broad bandwidth, whereas species of bats that hunt only in the open use a single sweep to cover the same broad bandwidth. It is hypothesized that the frequency diversity evident in the presence of several harmonically related frequencies is vital to success in clutter. It is additionally hypothesized that the bat processes harmonic FM echoes in a manner tantamount to split-beam processing. Simultaneous determination of phase at several related frequencies enables the bat to distinguish between single and multiple targets, as in the theory of coincidence echoes [K. G. Foote, J. Acoust. Soc. Am. **99**, 266–271 (1996)]. The plausibility of the second hypothesis is gauged by computations based on empirical knowledge of the signal parameters and timing acuity of the big brown bat (*Eptesicus fuscus*).

3aAB13. Echolocating big brown bats shorten interpulse intervals when flying in high-clutter environments. Anthony E. Petrites (Ecology & Evolutionary Biol., Brown Univ., 80 Waterman St., Box G-W, Providence, RI, 02912), Donald S. Mowlds, Oliver S. Eng, James A. Simmons, and Caroline M. DeLong (Brown Univ., Providence, RI, 02912)

Insectivorous big brown bats (*Eptesicus fuscus*) use frequency-modulated ultrasonic echolocation calls to locate and capture prey, often while navigating through highly cluttered areas of vegetation. To test how their calls change while flying through different clutter densities, a matrix of vertically hanging chain links was constructed in a 4.5-m-wide, 10.5-m-long, and 2.6-m-high flight room. Three different clutter densities (low, medium, and high) were created by varying the number of chains in the matrix (9, 114, and 150, respectively). Four wild-born bats were trained to fly through curved gaps in the chain network. These flights were recorded in the dark with a stereoscopic pair of thermal imaging cameras and a heterodyne bat detector. The bats were flown first through the high-, then the low-, and finally the medium-density configuration over a period of 40 days. Preliminary analysis of the pulse intervals of the bats sounds during flight reveals that the interpulse intervals shorten considerably under high-clutter conditions as compared to medium or low clutter. The data suggest that bats flying through high clutter become limited to shorter interpulse intervals in order to ensonify their immediate environment at the expense of larger-scale navigation. 3aAO1. Acoustic species identification: When biology collides with physics. John K. Horne (UW School of Aquatic and Fishery Sci., P.O. Box 355020, Seattle, WA 98195)

Acoustic species identification remains a long-term goal of fishers, researchers, and resource managers that use sound to locate, map, and count aquatic organisms. Interpreting acoustic data from aquatic organisms requires an understanding of how pressure waves interact with biological targets to produce single or multiple echoes. Intensity and variability of backscattered energy is influenced by physical factors associated with energy propagation through a dense medium, and biological factors including the morphology,

ontogeny, physiology, and behavior of targets. Efforts to quantify relative magnitudes and importance of biological factors have resulted in an approach that integrates field and laboratory measurements, numeric backscatter models, and computer visualizations. Acoustic visualizations are used to incorporate representations of the acoustic beam; the shape and composition of targets; target orientation (tilt, yaw, roll) and behavior (individuals and aggregations); and the resulting frequency-dependent backscatter. Exclusive use of acoustics to identify aquatic organisms requires metrics that discriminate among species with similar body types and implementing these metrics in routine data processing. Increased frequency bandwidth and angle-dependent backscatter measurements increase the information content of acoustic data to help achieve this goal. [Work supported by ONR and NOAA Fisheries.]

3aBB1. Nonlinear Rayleigh waves in soft tissue. Evgenia A. Zabolotskaya, Yurii A. Ilinskii, and Mark F. Hamilton (Appl. Res. Labs., Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

Linear and nonlinear Rayleigh waves in soft elastic, tissuelike media are investigated theoretically. When the shear modulus is much smaller than the bulk modulus, as it is for soft tissue, the medium can be modeled as being incompressible provided shear stress alone is sufficient to support a particular mode of propagation. Such is the case for Rayleigh waves. Propagation speeds and penetration depths of the transverse and longitudinal components of Rayleigh waves are evaluated under these conditions. Differences between Rayleigh waves in ordinary solids and in soft elastic media are discussed. In tissuelike media, the transverse component obeys a wave equation, and the longitudinal counterpart obeys the Laplace equation. It is also shown that Rayleigh waves in soft elastic media are degenerate in the sense that the potential and solenoidal components cannot be separated. The analysis is based on Hamiltonian mechanics, following an approach developed by the authors for modeling nonlinear surface acoustic waves in both isotropic and anisotropic solids. Nonlinearity coefficients are estimated that characterize the rate of waveform distortion and harmonic generation. Numerical simulations of nonlinear propagation effects in soft elastic incompressible media are simulated in the quadratic approximation. [Work supported by NIH Grant EB004336.]

3aBB2. Coupling between elastic strain and interstitial fluid flow: Ramifications for poroelastic imaging. Ricardo Leiderman, Paul E. Barbone (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215), and Assad Oberai (Rensselaer Polytechnic Inst., Troy, NY 12180-3590)

Elastography refers to a host of imaging techniques that enables the quantitative measurement of tissue displacement and strain *in vivo*. In its most common modality, ultrasound is used to map the displacement, and an inverse problem to find the tissue biomechanical properties results, based on the tissue's constitutive equation, and the law of conservation of momentum. In most previous applications, the constitutive model for the tissue is assumed to be elastic or viscoelastic. It is well recognized, however, that soft tissues contain both fluid and solid phases. Furthermore, the fluid may flow within and between several different compartments. This paper addresses the question: Can ultrasound be used to image and quantify interstitial fluid flow in soft tissues from spatio-temporal patterns of elastic strain? To answer this, we use the mathematical model of vascularized soft tissue, which includes the effects of fluid flow and the possibility of exchange between fluid compartments in conjunction with finite-element modeling to predict the effects of fluid fluid flow on the spatio-temporal patterns of soft-tissue elastic strain.

3aBB3. Transcranial longitudinal and shear sound speeds in animal models. P. J. White, G. T. Clement, and K. Hynynen (Dept. of Radiol., Harvard Med. School, Brigham and Women's Hospital, Boston, MA 02115)

For nearly every experimental procedure or device developed for clinical application, animal models are vigorously pursued to not only ensure efficacy and safety of the tool, but as research models for the sequential observation of phenomena arising from simple systems to the complex. When novel procedures are introduced or proposed for study, it is imperative to ensure that effects observed in animal models are congruous to the expected effects in humans. In the case of transcranial ultrasound, the recently proposed application of ultrasound through the skull bone at incident angles to induce shear mode transmission required the quantitative assessment of shear sound speeds in human and animal skull bone. Using time-of-flight measurement methods with fresh and formalin-fixed skulls, measurements of longitudinal and shear sound speed were performed on pig, sheep, rabbit, and rat skull bone specimens. Discrepancies were observed in some cases between sound speeds in animal skull bone and those obtained from earlier studies of human skull bone. Results from these measurements will give indication as to whether certain animal models are sufficiently suited for transcranial longitudinal and shear mode ultrasound studies. [Work supported by NIH: R01EB003268 and R21EB004353.]

9:15

3aBB4. Ultrasonically determined thickness of long cortical bones. Petro Moilanen, Maryline Talmant, and Pascal Laugier (Laboratoire d'Imagerie Paramtrique, CNRS UMR 7623, Univ. Paris 6, 15 Rue de l'Ecole de Medecine, 75006 Paris, France, pemoilan@cc.jyu.fi)

Recent experimental studies have shown that an ultrasonically determined thickness (U-Th), based on a fit between measured and theoretical velocity of a fundamental flexural guided wave, correlated significantly with the cortical thickness (C-Th) of human radius bones. In this study, suitability of the theoretical model for fitting with experimental results for bones was evaluated. Numerical model, based on 3-D x-ray reconstructions of human radii ($n=29$), was developed, and wave propagation was simulated using the finite-difference method. In spite of variations in cortical thickness along the propagation path, a wave mode consistent with A0 Lamb mode was identified, and U-Th (2.7 ± 0.6 mm) was indeed strongly correlated ($r^2=0.90$, $p<0.001$) with C-Th (3.0 ± 0.6 mm) (2D

results). Three-dimensional simulations were then performed yielding similar results. These results were in good accordance with the previous *in vitro* experiments. Particularly, slight variation in geometry of bone did not affect too strongly the dispersion of fundamental guided waves, and simple analytical theory can be used as a satisfactory model for the average geometrical properties of cortical bone.

9:30

3aBB5. Sensitivity of 1-MHz ultrasound compression and shear waves propagating on cortical bone porosity: A numerical study. Cecile Baron, Maryline Talmant, and Pascal Laugier (Laboratoire d'Imagerie Parametrique, UMR 7623, 15 rue de l'Ecole de Medecine, 75006 Paris, France)

The objective of this study was to describe how the porosity of cortical bone affects ultrasound propagation (wavelength: mm scale). The bulk compression and shear velocities were determined for 40 specimens of human radius using finite-difference computation of transient ultrasound bulk waves in axial and transverse directions. The 3D microstructure of the specimens were obtained using high-resolution synchrotron radiation micro-computed tomography (voxel size $=10\mu$m). The pores were filled with a nonviscous fluid and the model assumed the bone material to be elastic and transversely isotropic or isotropic. All bulk wave velocities decreased quasi-linearly with increasing porosity, e.g., typically 28 m/s/%por for the axial compressional wave velocity. For the radial compressional wave velocity, the rate depended on the assumption on the bone material (for isotropy 56 m/s/%por and for transverse isotropy 19 m/s/%por). In case of transversely isotropic bone matrix, cortical bone tended to become more acoustically isotropic when its porosity increases in agreement with previous experimental studies. This study may help to develop more accurate models of cortical bone used to design improved ultrasound devices and to provide guidelines for establishing methods for the ultrasonic determination of bone properties.

9:45

3aBB6. A constrained optimization technique for the design of a uniformly excited $N\times N$ ultrasonic transducer micro-array. James Whitney, III and Ralph Etienne-Cummings[a] (Morgan State Univ., 1500 E. Coldspring Ln., Baltimore, MD 21251)

A method for obtaining the optimal and specific sensor parameters for an ultrasonic transducer micro-array is presented. The ultrasonic transducer array sensor parameters, such as frequency of operation, element size, interelement spacing, number of elements, and transducer geometry, are adjusted using a quadratic programming method to obtain maximum directivity while being constrained by MEMS design rules, a total array size of 4 mm^2, and the required resolution for microsurgery. The technique is used to determine whether a uniformly spaced $N\times N$ transducer array is capable of resolving structures as small as 2 μm. The parameters extracted from the proposed technique will be used in the development of tool-mounted sensors for imaging and robotic guidance for retinal microsurgery. [a] Presently at Johns Hopkins Univ.

3aBB7. A single-channel low-frequency method for ultrasound imaging. P. J. White and G. T. Clement (Dept. of Radiol., Harvard Med. School, Brigham and Women's Hospital, Boston MA 02115)

Transcranial ultrasound imaging of brain structures and pathologies have traditionally suffered from compromised signal-to-noise ratios due to the bone-mediated increase in signal attenuation with increasing frequency. Yet, established modalities of image reconstruction with ultrasound measurements rely on higher frequencies for radial resolution and large temporal bandwidths for axial resolution. A new method that substantially reduces the dependency of image resolution on ultrasound frequency is proposed. Using an asymmetric transducer design, an unfocused, broadband, and frequency-separated ultrasound field is created in a region-of-interest (ROI). In this fashion, a unique complex spectral label can be assigned to each point in the ROI with a spatial resolution independent of source frequency. Ultrasound scattering sites within the ROI are then spatially localized by identifying the unique frequency-phase signature detected by either a point receiver or by the transmitting transducer. A cross-correlation method is used to reconstruct the echogenic profile of the ROI using *a priori* measurements of the field. Since the method's axial and radial resolutions are dependent on bandwidth rather than frequency, deeper penetration into tissues and application in highly attenuation tissues is feasible. Also, the prospect of multiple-dimension imaging with a single channel will allow for reduced emitter and electronic complexity. [Work supported by NIH: R21EB004353 and U41RR019703.]

10:30

3aBB8. Three-dimensional ultrasound image registration and shear elastic modulus reconstruction. Michael S. Richards (Dept. of Biomed. Eng., Boston Univ., 44 Cummington St., Boston, MA 02215, msrich@bu.edu), Nachiket H. Gokhale, Paul E. Barbone (Boston Univ., Boston, MA 02215), and Assad A. Oberai (Rensselaer Polytechnic Inst., Troy, NY 12180)

It is widely recognized that tissue pathologies often change biomechanical properties. For instance, neoplastic tissue is typically highly vascularized, contains abnormal concentrations of extracellular proteins (i.e., collagen, proteoglycans) and has a high interstitial fluid pressure compared to most normal tissues. The aim of this work is to develop and evaluate an ultrasound technique to quantitatively measure and image the mechanical properties of soft tissues in three dimensions. The intended application of our work is in the detection and diagnosis of breast cancer and other soft tissue pathologies. The specific goal of this project is the accurate measurement of the elastic shear modulus distribution of a tissue-mimicking ultrasound phantom, using a 3-D ultrasound imaging system. This requires the design and characterization of algorithms to provide three-dimensional motion estimates from ultrasound images and to solve the three-dimensional inverse problem to recover shear elastic modulus. Modulus images, reconstructed using our algorithms, are presented and compared to values determined by independent mechanical testing. The effect of the boundary conditions and regularization methods on the reconstructed modulus images and the uniqueness of the solution is also discussed.

10:45

3aBB9. Motion detection for vibro-acoustography. Matthew Urban and James Greenleaf (Dept. of Physiol. and Biomed. Eng., Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905)

Vibro-acoustography is a method that uses ultrasound radiation force to investigate the mechanical response of an object [Fatemi and Greenleaf, ''Ultrasound-stimulated vibro-acoustic spectrography,'' Science, **280**, 82–85 (1998)]. The dynamic radiation force causes the object to vibrate within the focal region of the transducer, which creates a sound field called acoustic emission measured by a hydrophone. To gain a better understanding of the objects investigated with vibro-acoustography, a method is proposed that measures the displacement of the local vibration. A pulse-echo ultrasound method is implemented with the same transducer used to create the radiation force to measure the displacement of the object. A Kalman filter approach is used to process the pulse-echo data to obtain estimates of the local displacement [Zheng *et al.*, ''Kalman filter motion detection for vibroacoustography using pulse-echo ultrasond,'' 2003 IEEE Ultrasonics Symposium, pp. 1812–1815 (2003)]. Results using this ultrasound method to measure vibration of a metal beam compare well with laser vibrometer results. This method can reliably measure displacements with amplitudes of 120–2000 nm with error less than 9%. A pulse-echo method is described that provides displacement detection with simultaneous radiation force generation for vibro-acoustography applications using a single transducer. [Work supported by Grants EB002640 and EB002167 from NIH.]

3aBB10. Simulation of B-mode image synthesis with the fast near-field method and time-space decomposition. James F. Kelly and Robert J. McGough (Dept. of Elec. and Comput. Eng., Michigan State Univ., 2120 Eng. Bldg., East Lansing, MI 48824)

Rapid calculations of scattered and pulse-echo acoustic fields are required for simulations of ultrasonic imaging systems. Due to the large computational grids, broadband pulses, and complex scattering geometries, these simulations are computationally intensive with traditional tools. A new computational framework, based on the fast near-field method and a time-space decomposition technique, is developed for transient acoustic scattering problems. By analytically decomposing the temporal and spatial dependence of the pulse-echo field, this time-space decomposition method computes the first-order scattered field in an efficient and flexible manner. Due to the bandlimited nature of the time-space decomposition approach, sampling frequencies commensurate with the bandwidth of the excitation pulse are used in the scattering simulations. B-mode imaging is simulated by computing the scattered fields due to a collection of scatterers for multiple steering angles. The pulse echo field generated by a 128-element phased array of rectangular elements is derived and numerically evaluated. The computed transient fields are validated and compared with the FIELD II software in terms of computation time. Preliminary results show that the combination of the fast near-field method and time-space decomposition is significantly faster than FIELD II for numerical simulations of diagnostic imaging systems.

11:15

3aBB11. Transcranial ultrasound tracking of brain shift. Anthony B. Ross and Greg T. Clement (Brigham and Women's Hospital, Harvard Med. School, 221 Longwood Ave., Rm. 514, Boston, MA 02115)

Transcranial ultrasound provides a portable, inexpensive, rapid, and nonionizing technique to measure brain shift and structural changes. This technique may have important implications in neurosurgery, emergency room diagnosis, and long-term or frequent patient monitoring. The ability of transcranial ultrasound to measure motion inside the skull was investigated in *ex vivo* human skulls. The skulls were submerged in degassed water and a 2-D velmax positioning system was used to position a small needle within the skull. An array of low-frequency transducers (0.5–2 MHz) was positioned in a frame around the skull. Ultrasound pulses were sent in longitudinal and shear wave modes through the skull. The digitized receive signals of all transducers were then analyzed with Matlab. Using geometric and time-of-flight analysis the magnitude and direction of the needle shifts were determined. The transcranial ultrasound tracking system was able to accurately (within 0.2 mm) detect the needle motion in the skull. Overall, transcranial ultrasound using both shear and longitudinal waves was shown to be an effective method to track motion in the skull and may be a useful real time method to correct for misregistration of presurgical images. [Work supported by NIH Grants R21EB004353 and U41RR019703.]

3aBB12. Singular spectrum analysis applied to ultrasonic imaging of brachytherapy seeds. Jonathan Mamou and Ernest Feleppa (F. L. Lizzi Ctr. for Biomed. Eng., Riverside Res. Inst., 156 William St., 9th Fl., New York, NY 10038)

Singular spectrum analysis (SSA) shows promise for reliably imaging radioactive seeds implanted in the prostate gland. Brachytherapy using small titanium-shelled radioactive seeds is proving to be a well-accepted means of treating prostate cancer. Unfortunately, implantation using needles inserted transperineally causes gland movement, and the resulting distortion may cause seed misplacement and dosimetry errors. If actual seed locations can be determined during the brachytherapy procedure, then dosimetry errors can be corrected immediately in the operating room. SSA utilizes pairs of eigenvalues derived from the autocorrelation matrix of envelope-detected radiofrequency echo signals to identify seed-specific signal repetitions. The power spectrum associated with a repetition signal is computed to derive a P-value indicative of the likelihood of the presence of a seed at the location of that repetitive signal. Simulations to assess performance as a function of different levels of white and speckle noise and the presence of signals at repetition periods not associated with seeds. Experiments in an ideal scattering environment were performed, using seeds implanted in beef. Results show an encouraging potential of SSA for seed detection and imaging, and illustrate the basic trade-off considerations for optimization of SSA for clinical applications. [Work supported by NIH Grant R01 CA098465.]

11:45

3aBB13. Cavitation and acoustic streaming in ultrasonic fields: Applications in bio-, leather-, and chemical processing. R. Nagarajan, N. P. Dhanalakshmi, A. Krishnan (Dept. of Chemical Eng., IIT Madras, Chennai, India 600036, nag@iitm.ac.in), V. Sivakumar, G. Swaminathan (Central Leather Res. Inst., Adyar, Chennai, India 600036), and M. Goodson (Crest Ultrasonic Corp., Trenton, NJ 08628)

High-frequency, high-intensity ultrasound influences chemical reactions and transport phenomena via two principal mechanisms, acoustic streaming and cavitation. Bubble implosions associated with acoustic cavitation generate very high temperatures (1000s of Kelvin) and pressures (100s of atmospheres) which can accelerate many biochemical reaction rates by several orders of magnitude; acoustic streaming unidirectional high-velocity flow induced by the pressure gradient can substantially enhance heat-, mass-, and momentum fluxes. These aspects of acoustically driven process intensification are investigated here for three different applications: (1) growth characteristics, enzyme production, and ROS (reactive oxygen species) of *Bacillus subtilis* under varying conditions of ultrasonic frequency (58–192 KHz) and input power (maximum 500 W, variable between 40% to 100%); (2) dynamics of dye uptake by leather under these conditions; and (3) sono-chemical production of a fluorescent product from the reaction of two nonfluorescing species. Experimental data indicate that a combination of cavitation and acoustic streaming, e.g., by using dual-frequency systems that combine a low frequency (e.g., 58 kHz) with a higher frequency (e.g., 192 kHz), is optimal for accelerating processes that involve simultaneous heat-, mass-, and momentum transfer; purely kinetically limited processes, however, are most sensitively affected by cavitation characteristics of the applied field.

3aED1. Quantifying rain noise on three different roof structures. Sunil Patel and Lily M. Wang (Architectural Eng. Prog., Univ. of Nebraska-Lincoln, 1110 S. 67th St., Omaha, NE 68182-0681)

A system for measuring rain noise has been constructed, consisting of a 3.4-m^3 structure with a slanted roof and an artificial rain generation apparatus using PVC pipes and an appropriate spray nozzle. Three different roof structures have been tested for the level of rain noise generated within the structure: a shingle roof, one made with an EPDM membrane, and a corrugated metal panel roof system. Measurements show that the shingle and EPDM membrane roofs perform approximately the same and outperform the corrugated metal panel system by at least 13 dB across the frequency bands of 250 to 5000 Hz. The test system and detailed results are presented, as well as compared to guidelines provided in a draft ISO standard on measuring rain noise. [Work supported by UNL UCARE Grant.]

3aED2. Quantitative evaluation of architectural acoustics computer models. Christopher J. Beers and Robert D. Celmer (Acoust. Program & Lab., Mech. Eng. Dept., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117)

Computer modeling has enhanced many professional fields, including that of architectural acoustics. The accuracies of these models should be known if they are to be used in the design process. While some calculations in architectural acoustics software have been well established (such as the Sabine and Eyring reverberation time), the development of other higher-order algorithms is more recent. The purpose of this investigation is to examine possible methods for evaluating accuracy in architectural acoustics computer models. Recordings were made in an existing space, and analogous audio files were generated through one such software package. The recorded and calculated audio files were then compared via multiple means. The effectiveness and appropriateness of each metric was analyzed. Conclusions were drawn regarding the metrics and subsequent research implications were explored. [Work supported by ASA Robert W. Young Award for Undergraduate Student Research in Acoustics.]

3aED3. Wavelet analysis of active cavitation detector output. Kofi A. Anguah and E. Carr Everbach (Eng. Dept., Swarthmore College, Swarthmore, PA 19081)

Active cavitation detectors (ACDs) have provided useful information concerning the dynamics of microbubbles exposed to intense pulsed ultrasound. In an examination of the effects of nearby solid surfaces on the asymmetrical collapse of bubbles, ACD signals consisting of 60-cycle 30-MHz tone bursts of <0.1 MPa peak negative pressure returned complex echoes for individual bubbles and groups of bubbles. The Gauss-Harmite wavelet transform was used to analyze these signals to differentiate between symmetrical and asymmetrical collapse signatures, with the goal of identifying the percentage of asymmetrical bubble collapses in a cavitation field. [Work supported by NIH R-15 EB004630-01.]

Invited Paper

Chair's Introduction—10:25

10:30

3aID1. Status of acoustics in Russia. Nikolay A. Dubrovskiy (Andreyev Acoust. Inst., Shvernika Ul, 4, Moscow 117036, Russia)

Acoustics is developed mainly in Moscow, Saint Petersburg, Nizhny Novgorod, and Vladivostok. Studies are performed in different directions including both fundamental studies and applied research connected with the needs of Russian industry and the developing Russian market. Coordination of works on acoustics and dissemination of knowledge are implemented mainly by the Russian Acoustic Society (RAO), East European Association of the acousticians (EEAA), and the Council for Acoustics of the Russian Academy of Sciences. RAO carries out 1 or 2 scientific sessions yearly. This year RAO conducted two sessions. The basic periodical of Russian acousticians is *Acoustical Physics*. Science (and acoustics, in particular) in Russia is slowly reviving after a crisis happened after the collapse of the Soviet Union. This crisis manifests itself in significant reduction in funding; loss of prestige in being a scientist; young people leaving science and the aging of personnel; capable acousticians leaving the country; lack of demand for scientific innovations by Russian industry; lack of experience to work within the market economy; and absence of adequate tools for financing R&D. Wide international collaboration has become a positive factor for Russian acoustics. ASA provided valuable financial support for young Russian acousticians in recent years. [This lecture is supported by the ASA.]

9:00

3aMU1. Contact problems with friction applied to musical sound synthesis. Joel Bensoam (Acoust. Instrumental Team, Ircam, 1, place Igor Stravinsky, 75004 Paris, France)

Modalys, a sound synthesis software developed at Ircam for research and musical applications, allows one to build virtual instruments based on physical models to obtain the most entire range of expressive variations in the instrument in response to intuitive controls. An instrument, as a complex structure, is described by the mechanical/acoustical interaction of its components (strings, tubes, resonators, soundboard, . . .). Some new research has been done recently to extend the sound prediction to three-dimensional objects with the help of numerical methods. In particular, theoretical and numerical treatment of the unilateral dynamic contact with friction between two arbitrary elastic bodies is studied. In addition to the classical variational statement that arises from static problems, a dynamic contact condition is needed and found by adjusting the energy balance law to the impenetrability condition. In the context of infinitesimal deformation, a reciprocal formulation is then used to reduce this well-posed problem to one involving Green functions

defined only on contact surfaces. This allows us to use considerably fewer unknowns compared to finite difference algorithms. The ability of the method to predict the contact interaction between two elastic bodies, irrespective of the material constitution and geometry, is highlighted by analytical and numerical simulations.

9:30

3aMU2. Whole-body finite-difference formulation of the violin. Rolf Bader (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstrasse 13, 20354 Hamburg, Germany, R_Bader@t-online.de)

The whole body of a violin was modeled with the finite-difference method in terms of a transient calculation. The model, like a previous guitar body model, takes bending or transversal and longitudinal or in-plane motion of the wooden body into consideration and couples these two kinds of vibrations. Here, the curvature of the violin body also enhances this coupling according to the amount of curvature. The string/bow mechanism was modeled in terms of sticking/slipping, depending on the displacement difference of the bowing point to a point next to this bowing point. The different parts of the violin show different behavior within the steady state of one bowing cycle. Most noticeable, the ribs showed a chaotic motion, causing it to be quite small and greatly influenced by the surrounding parts. As this is practically the only part with noisy components, we can say the violin bowing noise comes from the ribs. Additionally, initial transients were modeled by changing the bowing pressure and velocity over the intial transient phase for a soft and a hard attack, resulting in reasonable descriptions of the violin playing attack.

9:45

3aMU3. A 3D finite-element method (FEM) of the body of a classical guitar. Jan Richter (Jan Richter, Gefionstrasse. 11, 22769 Hamburg, Germany)

A 3D finite-element method (FEM) of a body of a classical guitar is performed. It consists of the rib, back plate, top plate with bridge, soundhole and fan bracing, and wooden block. The idea of this project is to compare the eigenfrequencies of different body shapes and make assumptions about the way the elements of the body influence the sound of a classic guitar. The aim is to calculate the influence of the thickness of the bottom, the amount of bracing, and the appearance of the block. As a submittal a real guitar was taken and the geometrical pararmeters are precisesly modeled in the computer. These solutions are found by using the finite-element method, which allows calculation of the different eigenfrequencies and mode shapes of the guitar body.

10:00–10:15 Break

10:15

3aMU4. Modeling of steeldrum sounds using finite element and finite difference methods. Michael Steppat (Institut fr Musikwissenschaft, Universitt Halle, Kleine Marktstr. 7, 06099 Halle(Saale), steppat@cs.tu-berlin.de)

The Caribbean steeldrum, which was developed over 60 years ago in Trinidad, is one of the most novel music instruments. It is made of leftover oil drums. On the bottom of these drums, dents can be formed with a specialized technique, to get playing areas with a definite pitch. The tonal range of a whole orchestra can be reached with different models, covering a tonal range from bass to soprano. Despite the usage of the same material and even if they are made by the same tuner, the instrument can sound very different. Good instruments can be played in various striking strengths, without producing interfering noise. Instruments of weaker quality tend to produce interfering noice, even at small striking strengths. The sound of the instrument can be simulated with the finite difference method and finite element method . With the finite element method, a model of the vibration system can be formed by small rectangular plate elements. To simulate the sound of a note, a transient response analysis can be calculated. The simulation takes various production techniques into account, e.g., different shapes of the dent.

10:30

3aMU5. Tuning parameters of a Nigerian slit gong. Jacob Skubal, Nathan Hall, and Thomas Moore (Dept. of Phys., Rollins College, Winter Park, FL 32789, tmoore@rollins.edu)

The Nigerian slit gong is a wooden idiophone, hand-carved from a single log, that is characterized by its ability to produce two distinct notes when struck. The resonant modes of the gong have been studied using a finite-element analysis model, which was validated by comparing the predicted mode shapes to those observed by electronic speckle pattern interferometry. Using this model, the effects of changing the parameters available to the artisan when carving the instrument have been studied. Results of the model are compared with a simple theory, and the physics of tuning the Nigerian slit gong is discussed.

10:45

3aMU6. A three-dimensional, time-dependent simulation of a Turkish cymbal using the finite element method. Malte Muenster (Mansteinstr. 46, 2053 Hamburg, Germany, m.muenster@arcor.de)

We built computer-aided simulations of several musical instruments to study microstructural behavior of initial transients and eigenvalues. Our finite element model (FEM) of a cymbal is an example for the possibilities of this method. Proceeding from a three-dimensional mindlin plate model, we discovered some former unknown, sometimes moving fundamentals, depending on striking positions, hammering during production process, sizes, forms, and alloys. Special movements of the bell of the cymbal have been investigated. Moreover, experimental studies and simulation are able to be compared directly concerning their variety of dynamic behavior. This leads to more and more precise formulation of requirements of musical instruments. Cymbals are among the oldest instruments. The production techniques, some were real secrets, were given from father to son to the next generations of instrument builders. But only recent developments in musical acoustic research include computational modeling and signal processing power to show that most parts of musical sounds of a cymbal are caused by the features mentioned above, in regard to styles, expression, and instrument qualities important to musicians. Our studies try to give an idea of formulating and influencing sound parameters of musical instruments using FEM simulations. The target is to describe how to build a cymbal fulfilling any condition of sound.

11:00

3aMU7. Turbulent finite difference model of simplified musical geometries. David Linke and Berit Janssen (Lohkoppelstrasse 32c, 22083 Hamburg, Germany, david_linke@web.de)

A turbulent flow in a two-dimensional space is modeled using a finite difference method of the Navier-Stokes equation taking the k-epsilon turbulence model into account. In this formulation the flow is divided into a laminar and an averaged turbulent part. Mathematically this changes the normal Navier-Stokes equation into the Reynolds averaged Navier-Stokes equation. Kolmogorov's idea was that the energy of the laminar flow is transverted into eddies which get smaller down to the smallest eddy size, where this enery is completely dissipated. This introduces two new parameters, the turbulent energy k and the turbulent dissipation epsilon. Generally this turbulence model adds additional damping through the Reynolds stress tensor. This investigation compares turbulent and nonturbulent flows using different musical relevant geometries, like surfaces and edges.

11:15

3aMU8. Conservative numerical methods for sound synthesis. Stefan Bilbao (Univ. of Edinburgh, Rm. 7306B, James Clerk Maxwell Bldg., King's Bldg., Mayfield Rd., Edinburgh, EH9 3JZ UK)

Direct numerical simulation techniques, such as finite difference and finite element methods, are playing an increasingly important role in sound synthesis based on physical models of musical instruments. While they can lead to enormous improvements in sound quality over existing methods, a problem of mounting importance is that of maintaining numerical stability when the system to be simulated is strongly nonlinear, as is the case for many musical instruments. This problem is especially acute if real-time synthesis is to be an eventual goal. Standard stability checking machinery, such as frequency domain (von Neumann) analysis, does not immediately apply, and, often, the most straightforward numerical methods may exhibit such instabilities in an unpredictable manner. In this paper, various techniques for the construction and analysis of numerical methods for strongly nonlinear musical systems are presented; they are based on the translation of the principle of conservation or dissipation of energy to discrete time and can lead directly to sufficient nonlinear stability conditions, without invoking frequency domain concepts. Special attention is paid to the nonlinear string, bar, and plate models. Numerical results and sound examples will be presented.

3aNS1. From articulation index to speech privacy: A review. Leo L. Beranek (975 Memorial Dr., Ste. 804, Cambridge, MA 02138, beranekleo@ieee.org)

Communication by voice over wired and radio systems is ever more important. Voice recognition by machine is commonplace today, whether it involves a person telephoning into an organization or the government spying on international communications. In these examples, context is not yet highly developed, so that the advantage a person has in understanding a sentence even if all words are not perceived does not ordinarily exist. Thus, correct understanding of isolated words is crucial. Two papers pioneered in establishing a metric for determining the degree of understanding of words in the presence of noise [French and Steinberg, ''Factors governing the intelligibility of speech sounds,'' J. Acoust. Soc. Am. **19**, 90–119 (1947); Beranek, Proc. I.R.E., **35**, 880–890 (1947)]. This paper will review the basic principles taught in those papers. Very low values of AI (i.e., little or no intelligibility) proved critical in studies on speech privacy in buildings by BBN scientists some 50 years ago. Those early studies also confirmed the relative importance of masking sounds in offices and other spaces, sometimes referred to as acoustic perfume, in achieving desired degrees of speech privacy.

8:40

3aNS2. Speech privacy in buildings: A review. William Cavanaugh (Cavanaugh Tocci Associates, Inc., 327F Boston Post Rd., Sudbury, MA 01776) and Parker Hirtle (Acentech Inc., Cambridge, MA 02138)

Studies on speech privacy problems in buildings at Bolt Beranek and Newman begun in the mid 1950s showed convincingly that a person's sense of acoustical privacy was directly related to the intelligibility of the intruding speech over the continuous ambient sound present [Cavanaugh *et. al.*, J. Acoust. Soc. Am. **34**, 475–492 (1962)]. Both in laboratory and in real-world settings people feel they have confidential privacy when the articulation index (AI) of the intruding speech is 0.05 or less. Higher values of AI are acceptable for less demanding tasks, i.e., normal privacy. The method quantifies each of the significant variables involved and compares a summary of these metrics with response data for prior case histories both to predict, and, in the case of existing situations, to evaluate speech privacy conditions. R. W. Young reviewed the analysis method and showed that sufficient accuracy was preserved if simple, commonly used A-scale sound levels were used in place of more cumbersome frequency-based metrics [R. W. Young, J. Acoust. Soc. Am. *38*, 524–533 (1965)]. Later in the 1960s the method was successfully applied to open plan offices which were becoming more prevalent [Hirtle *et. al.*, J. Acoust. Soc. Am. **46**. 91A (1969)]. The lessons learned in applying the speech privacy calculation over the years are discussed.

9:00

3aNS3. Postoccupancy assessment of speech privacy in offices. Charles Salter, Randy Waldeck (Charles M. Salter Associates, 130 Sutter St., Ste. 500, San Francisco, CA 94104), and Kevin Powell (General Service Administration, San Francisco, CA 94111)

The General Services Administration (GSA) Workplace 20.20 initiative includes acoustical design analysis for offices. Internet questionnaires about acoustics and occupant satisfaction have been filled out by hundreds of GSA office workers. These results have been correlated with acoustical testing that our firm, Charles M. Salter Associates, Inc., has conducted during the last 4 years around the country. Survey responses, which are correlated with the results of our acoustical testing, will be presented.

9:20

3aNS4. New developments in speech privacy design. Kenneth P. Roy (Armstrong World Industries, 2500 Columbia Ave., Lancaster, PA 17604)

The design of architectural spaces for the purpose of speech privacy attainment has been quietly practiced over many years. In the late 1960s and 70s, with the introduction of open-plan office layouts, the need for speech privacy became an issue of productivity, as well as one of confidentiality. Today, with the introduction of government regulations such as HIPAA, the need for confidential speech privacy in the healthcare industry has hit the mainstream of our consciousness, even as individuals. And, in this day of (in)security the issues of espionage and terrorism have implications for architectural acoustic design of spaces for speech security. This paper considers both the architectural design trends and issues, and the measurement and evaluation methods being developed in response to these needs for speech privacy, as we move boldly forward into the next 50 years.

9:40

3aNS5. Open-plan privacy revisited. Rein Pirn (Acentech Inc., 33 Moulton St., Cambridge, MA 02138)

Driven by a desire for economy, the open office has been with us since before World War II. However, it was not until the 1960s that largely through the work of a Quickborn (Germany)-based team of space planners it became an art form, touting all manner of organizational benefits, and flexibility. Though speech privacy was recognized as an issue, there was no systematic approach to resolve it. Against this backdrop, five variables that would affect speech privacy in an open plan were identified and their relative contributions quantified [R. Pirn, ''Acoustic variables in open planning,'' J. Acoust. Soc. Am. **49**, 1339–1345 (1971)]. This work and its impact on acoustical design of the 1970s is reviewed, as are the trends in and the failings of current open-plan design practices.

10:00–10:20 Break

10:20

3aNS6. The speech intelligibility index standard and its relationship to the articulation index, and the speech transmission index. Chaslav Pavlovic (Sound ID, 3040 West Bayshore Rd., Palo Alto, CA 94301)

The history of the Speech Intelligibility Index (SII) Standard (ANSI S3.5-1997) and its relationship to the Articulation Index (AI) and the Speech Transmission Index (STI) are reviewed. The SII Standard defines a method for computing a physical measure (SII) that is highly correlated with the intelligibility of speech. The SII is calculated from acoustical measurements of speech and noise. The standard is a revision of the ANSI S3.5-1969, ''American National Standard Methods for the Calculation of the Articulation Index.'' In that sense the AI and the SII are one and the same thing. In addition, however, SII incorporates the Speech Transmission Index procedures appropriate for many conditions of use where the traditional AI does not apply [H. J. M. Steeneken, and T. Houtgast, ''A physical method for measuring speech-transmission quality.'' J. Acoust. Soc. Am. **67**, 318–326 (1980)]. Other changes of the Standard are due to new data which have been accumulated since 1969 for various parameters and procedures used in the calculations. These include spread of masking, standard speech spectrum level, and relative importance of various frequencies to speech intelligibility. In addition, the SII calculation details have been adapted to computer implementation rather than to manual chart-type computations.

10:40

3aNS7. Speech privacy: What's new? What's next? John S. Bradley and Bradford N. Gover (Inst. for Res. in Construction, Natl. Res. Council, Montreal Rd., Ottawa, K1A 0R6 Canada)

This paper will review recent work that has considered speech privacy criteria in open-plan offices and the development of new procedures to assess the architectural speech security of closed offices and meeting rooms. For open-plan offices, new subjective studies have confirmed the validity of a speech privacy design goal of SII no more than 0.20 (AI 0.15) and that an ideal masking noise level is ~45 dBA. For the speech security of closed meeting rooms, subjective studies have developed new weighted signal-to-noise ratio measures for rating the privacy of meeting rooms and a new measurement procedure has been developed to assess conditions close to the outside boundaries of a meeting room. While much progress has been made, further work is still required. For example, it is now clear that in many situations, privacy is significantly influenced by both signal-to-noise and reverberation in the rooms. Both factors must be included when assessing the privacy of situations with significant amounts of reverberation.

11:00

3aNS8. Speech privacy: New laws require changes in professional practice. David Sykes Remington Partners, 23 Buckingham St., Cambridge, MA 02138)

We take privacy for granted but changing technology and heightened government security concerns have altered the landscape, putting privacy back in the headlines. Privacy laws like HIPAA, GLBA, and PIPEDA compete against tech-based crimes like identify theft as well as security, laws like the Patriot Act, Homeland Security, and FISA. What constructive role can acoustics professionals play? Speech privacy is covered by most privacy laws, explicitly or implicitly—though enforcement procedures remain unclear. But, thanks to 50 years of research and standards development, a basis for objective, measurable enforcement of speech privacy exists and will soon be integrated into professional practice by the AIA. New policies and improved understanding by architects as well as legislators, regulators, judges, lawyers, and juries are beginning to stimulate demand for speech privacy engineering services including research, measurement, design, monitoring, site certification, expert testimony, and training. The TCAAN joint subcommittee on speech privacy (soon to be an S.12 Work Group) was set up in November 2005 to lead this work. Subcommittee members are addressing two issues: Writing new Guidelines for Acoustics in Healthcare Facilities for the AIA and American Hospital Association, and developing a uniform speech privacy enforcement guideline for use in healthcare environments.

11:20

3aNS9. Noise in hospitals redux. Lewis S. Goodfriend (Lewis S. Goodfriend & Assoc., 760 Rte. 10, Whippany, NJ 07981, lsg@lsga.com)

A major result of the patient survey, conducted as part of the study, Noise in Hospitals, published in 1963, and funded by the U.S. Public Health Service, was that patients in private and semi-private rooms could hear conversations from the corridor and, on occasion, discussions of their diagnosis and condition by hospital staff. Also noted was the audibility of conversations from adjacent rooms. The study covered eight eastern hospitals of varied size. The results showed background ambient sound kevels in patient rooms, in the low-to-mid 40 dB(A) range. In general, the spectra, with low mid- and high-frequency levels, show why speech in the corridor, at normal levels, was highly intelligible in patient rooms in a number of hospitals. Much of the noise in hospitals is not continuous and that which was continuous, often had undesirable spectral or cyclic characteristics that added to the annoyance of the patients, but did not interfere with speech intelligibility, even with high, annoying, low-frequency levels. More recent information from one of the original hospitals and work by others indicates that the problem of noise in hospitals has not yet been well addressed.

11:40

3aNS10. Quieting Weinberg 5C: A case study in reducing hospital noise on a patient ward. Mark MacLeod, James E. West, Ilene J. Busch-Vishniac, Jeffrey Dunn (Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218), and Anita Reedy (Johns Hopkins Hospital, Baltimore, MD 21218)

Although noise in hospitals is among the top complaints of patients, visitors, and staff, little has been done to address the problem. Further, hospitals have become increasingly worried about using materials that might harbor bacteria, shunning traditional sound absorbers and making the problem even more acute. In this study, we investigated an oncology unit in a relatively new building at Johns Hopkins Hospital, with the aim of demonstrating a noise reduction. We found a series of problems at Weinberg 5C, including architectural design that focuses sound at the nurses station, hallways that create an effective waveguide around the unit, and the total absence of sound-absorbing materials. We were able to mitigate these problems through judicious placement of sound-absorbing panels on the ceiling and high on hallway walls. The panels were constructed of noncompressed fiberglass insulation wrapped in an antibacterial fabric and suspended with Velcro. Results show a drop in sound level of about 5 dB(A), a drop in reverberation time of roughly a factor of 3. A survey of patients and staff before and after the intervention shows a remarkable shift from the perception that the unit is noisy to a perception that it is reasonably quiet.

3aPA1. Characterization of elasticity, friction, anelasticity, and adhesion with nm lateral resolution, using the ultrasonic vibration modes of atomic force microscope cantilevers. W. Arnold, A. Caron, D. Rupp, K. Schwarz, H. Hirsekorn, and U. Rabe (Fraunhofer Inst. for Non-Destructive Testing (IZFP), Saarbrcken, Germany)

Ultrasound is combined with atomic force microscopy to achieve the lateral resolution of scanning probes for imaging. Atomic force acoustic microscopy (AFAM) and ultrasonic friction force microscopy (UFFM) exploit the vibrational modes of AFM cantilevers which extend from 10 kHz to several MHz. In the AFAM mode the cantilever vibrates in contact mode in one of its flexural resonances. Images can be obtained with the contrast depending on the local indentation modulus, which can be obtained quantitatively from the contact resonance frequencies. The lateral resolution is defined by the tip-sample contact radius and is 10 nm. At large ultrasonic amplitudes nonlinear effects that are related to adhesion become important. In UFFM shear stiffness and friction phenomena can be examined by evaluating the torsional cantilever resonances. At low lateral surface amplitudes, the sensor tip remains in elastic contact and the cantilever behaves like a linear torsional oscillator with damping. If the amplitude exceeds a critical value, the resonance develops a plateau due to stip-slick in the tip-sample contact, allowing one to monitor friction. Ultrasonic C-scan images and the corresponding contact resonance spectra will be shown and compared to theory. Applications of the AFAM techniques to measure local piezoelectricity and anelasticity will be discussed as well.

8:25

3aPA2. Quantitative nanomechanical measurements and imaging with atomic force microscopy methods. D. C. Hurley, M. Kopycinska-Mueller, R. H. Geiss, E. D. Langlois (NIST Mtls. Reliability Div., 325 Broadway, Boulder, CO 80305, hurley@boulder.nist.gov), and A. B. Kos (NIST Electromagnetics Div., Boulder, CO 80305)

We describe our work to evaluate the nanomechanical properties of surfaces, thin films, and nanostructures using the atomic force microscope (AFM). Our approach is based on atomic force acoustic microscopy (AFAM) and involves the resonant vibrations of an AFM cantilever in contact with a sample. We first describe the basic principles of AFAM, in which local elastic-property values are determined from the contact-resonance frequencies using models for the cantilever dynamics and for the tip-sample contact mechanics. Quantitative results for a variety of thin supported films ranging in stiffness from 50 to 250 GPa and as thin as 50 nm are given to illustrate our methods. Studies related to measurement accuracy involving the effects of film thickness and tip shape are also presented. Finally, we discuss new frequency-tracking electronics for rapid (typically 20 min per image), quantitative imaging of nanoscale elastic properties. We describe how such methods not only provide modulus mapping capabilities, but also have enabled us to detect variations in adhesion between a thin film and substrate.

8:50

3aPA3. Nanoscale acoustical imaging—deep or superficial? Andrzej J. Kulik, Gerard Gremaud, Laszlo Forro (Ecole Polytechnique Federale de Lausanne, IPMC-Station 3, CH-1015 Lausanne, Switzerland), Robert Szoszkiewicz (Georgia Inst. of Technol., Atlanta, GA 30332), and Nancy A. Burnham (Worcester Polytechnic Inst., Worcester, MA 01609-2280)

Several ideas of near-field detection of ultrasonic vibrations of the sample surface using atomic force microscopy (AFM) have been developed. Two major techniques are used: contact and nonlinear detection (intermittent contact). Most of the experiments were performed using low-MHz frequencies, meaning that wave propagation can be neglected in thin and small samples. In this talk we will analyze and present data obtained using two techniques: (a) contact measurements, where surface vibrations are sensed by the AFM tip, mapping local stiffness of the sample [Burnham *et al.*, J. Vac. Sci. Technol. B **14**, 794–796 (1996)], and (b) ''mechanical diode'' measurements, where high-amplitude surface vibrations are detected through nonlinearity of tip-sample interactions. This method gave access to local adhesion hysteresis [Szoszkiewicz *et al.*, Appl. Surf. Sci. **210**, 54–60 (2003); J. Appl. Phys. **99**, 014310 (2006)].

9:15

3aPA4. High-resolution ultrasound: A survey. Bernhard R. Tittmann (Penn State Univ., 212 Earth & Eng. Sci. Bldg., University Park, PA 16802)

This presentation provides a survey of high-resolution ultrasonic techniques and examples. With the discovery by Baranski, followed by the work of Boemmel and Dransfeld, the field of hypersonic wave propagation began to come into its own. The measurements over a range of frequencies from 100 MHz to 2 GHz, first in superconducting lead and then in type-II superconductors by Tittmann, took place under cryogenic temperatures. These and other results provided impetus for the development of a room temperature scanning acoustic microscope (SAM) by Quate. The licensing to three organizations for manufacturing the SAM led to the sale of many instruments which have since been used by many researchers around the world for materials characterization. This work was enhanced by Weglein with the interpretation of the $V(z)$ signature of materials. The room temperature SAM requires fluid for ultrasonic coupling and provides about 1 micron resolution at 1 GHz. With the onset of nanotechnology even finer resolution was required and the atomic force microscope was adapted by several groups around the world for use with ultrasound with the development of U-AFM and AFAM. This presentation will provide several examples of methods and results throughout the development of high-resolution measurement capability.

9:40

3aPA5. Recent advances in nanoindentation-based nanoscale dynamic mechanical analysis. Oden L. Warren and S. A. Syed Asif (Hysitron, Inc., 10025 Valley View Rd., Minneapolis, MN 55344)

Nanoindentation-based nanoscale dynamic mechanical analysis is rapidly gaining popularity as a quantitative small-volume characterization technique for soft matter such as polymers. In addition, the so-called nanoDMA technique can be coupled to scanning probe microscopy to quickly generate images showing the spatial distribution of storage and loss moduli, a time-saving advantage for the study of heterogeneous materials such as phase-segregated polymer blends. This presentation will address recent advances in nanoDMA, including instrumentation improvements, new measurement/analysis techniques, and efforts to push beyond the widely used linearized equation of motion to begin accounting for sources of nonlinearity not previously appreciated. If time permits, this presentation will also address the use of nanoDMA in combination with scanning probe microscopy for rapid screening of combinatorial polymer libraries.

10:05–10:20 Break

10:20

3aPA6. Resonance ultrasound microscopy for quantitative determination of local stiffness and local damping of solids. Hirotsugu Ogi and Masahiko Hirao (Grad. School of Eng. Sci., Osaka Univ., Toyonaka, Osaka, Japan 560-8531)

Home-built resonance ultrasound microscopy is presented for quantitatively determining local Young's modulus and local internal friction of materials. It evaluates the elastic properties from resonance frequencies and attenuation of an isolated langasite oscillator, touching the examined material. Noncontacting measurement (wireless and electrodeless) of the resonance frequency and attenuation of the oscillator has been achieved with a line antenna by the piezoelectric effect. The oscillator is supported by a fixture exactly at nodal points, and it touches the material at an antinodal point. Thus, acoustical contact on the oscillator surfaces occurs only at one point with the material, providing high sensitivity to the modulus and damping in the local area. Formulation of relationships between material's stiffness and internal friction, and oscillator's resonance frequency and attenuation is proposed using the generalized Hertzian-contact model. Results for polycrystalline copper, dual-phase stainless steel, and NbTi/Cu superconducting wire are shown, giving important knowledge including stiffness distribution within a crystallite. The results are compared by electron-backscattering-pattern measurements.

3aPA7. Acoustic microscopy inspection of layered structures. Jikai Du and Benhard R. Tittmann (Dept. of Eng. Sci. and Mech., The Pennsylvania State Univ., Univeristy Park, PA 16802, jxd338@psu.edu)

Thin films are widely applied in a variety of fields and, for example, are utilized in semiconductor devices, biological measurements, optical components, and micro-electro-mechanical-structures (MEMS). Thin films can serve for conductive and capacitive effects, tissue elastic properties evaluation, and control of optical properties. Therefore, the evaluation of thin film integrity is necessary and important. A thin film component is a layered structure and usually referred to as a film-substrate system. Acoustic microscopy is a nondestructive technique, which can generate surface acoustic waves (SAWs) in the thin film/substrate system. The energy of these SAWs is confined to the system surface and thus suitable for the evaluation of film properties. In our research, theoretical modeling of wave propagation in soft thin film/substrate system with different material properties and bond strength is established. A relationship between dispersive wave propagation and film integrity is discussed. A new experimental system is reported for measuring dispersion curves up to 1 GHz. Preliminary data are presented and compared to the theory. Good agreement was observed.

11:00

3aPA8. Correlation between elastic constant and perpendicular magnetic anisotropy in cobalt/platinum superlattice thin films studied by picosecond ultrasounds. Nobutomo Nakamura, Hirotsugu Ogi, Takeshi Yasui, and Masahiko Hirao (Grad. School of Eng. Sci., Osaka Univ., Machikaneyama 1-3, Toyonaka, Osaka 560-8531, Japan)

The easy magnetization direction of a Co monolayer thin film is always parallel to the film surface, but it can be perpendicular to the film surface for Co/Pt multilayer thin films when the Co layer consists of a few atomic layers. This property is called perpendicular magnetic anisotropy (PMA), achieving ultrahigh-density magnetic recording media. PMA occurs because of the large lattice misfit (near 10%) at the Co-Pt interfaces, and large elastic strains must affect the elastic constants through lattice anharmonicity. Thus, elastic constants and magnetic properties of Co/Pt superlattice thin film should show a correlation, which was investigated by picosecond ultrasound. The pulse-echo signals of the longitudinal wave

traveling in the thickness direction were detected by the laser pump-probe technique, which gave the elastic constant C33. The film thickness was determined by the X-ray reflectivity measurement. Co/Pt superlattice thin films were prepared by the magnetron-sputtering method, changing the Pt-layer thickness between 0.2–2 nm and keeping the Co-layer thickness to be 0.4 nm. Total film thickness was near 80 nm. C33 showed good correlation with the degree of PMA and it differed from the modulus predicted from the elastic constants of bulk materials.

11:15

3aPA9. Comparison of atomic force acoustic microscopy and dynamic nanoindentation methods for compliant polymer systems. Matthew Stagemeyer, Joseph A. Turner (Dept. of Eng. Mech., Univ. of Nebraska-Lincoln, Lincoln, NE 68588), and Mark R. VanLandingham (US Army Res. Lab., Aberdeen Proving Ground, MD 21005-5069)

Nanomechanical characterization of soft materials such as polymers and polymer composites represents a unique and challenging research topic of current interest. In this presentation, two characterization methods are compared directly using a set of model PDMS polymer systems. Experiments were conducted using both nanoindentation and atomic force acoustic microscopy (AFAM) to determine the dynamic mechanical properties. The experiments were conducted to determine reduced elastic modulus E^* via AFAM measurement and storage modulus E via nanoindentation. The AFAM analysis was done using both a Hertzian contact model and a flat punch model. While the two methods showed marginal agreement, the resulting AFAM moduli were dependent on the model used in the analysis. Further investigation is needed to improve the accuracy of these measurements. In addition, further modeling is needed to improve the understanding of the tip-sample interaction in such systems. The results are anticipated to lead to the development of improved characterization methods for compliant materials. [Work supported by ARL.]

11:30

3aPA10. Capture of *in vivo* biological images below the surface of aqueous media with ultrasound atomic force microscopy. Sahar Maghsoudy-Louyeh, Jikai Du, and Bernhard R. Tittmann (Dept. of Eng. Sci. & Mech., The Penn State Univ., University Park, PA 16802, sum179@psu.edu)

Atomic force microscopy (AFM) is a useful tool for measuring sample topography and has been widely applied to imaging of biological cells. The Park Scientific M5 AFM in our laboratory, in addition to measuring sample topography, can also give images of spatial distributions of sample elastic properties through applying an ultrasonic AFM (U-AFM) technique. But the M5 AFM is normally a dry operation AFM, and this makes it unsuitable for imaging *in vivo* biological cells in aqueous media. To modify the M5 AFM for imaging in aqueous media, both mathematical modeling and physical experimentation were established. A modified AFM system was built based on the theory. As a result, both topography and elastic property images are obtained on biological samples in aqueous media. The details of the modification will be described and examples of under-liquid imaging will be presented.

11:45

3aPA11. Dissipation mechanisms associated with atomic force acoustic microscopy. Joseph A. Turner, Matthew Stagemeyer, and Kangzhi Shen (Dept. of Eng. Mech., Univ. of Nebraska-Lincoln, Lincoln, NE 68588)

The impact of tip-sample dissipation mechanisms in atomic force acoustic microscopy (AFAM) and other techniques is evident in the width (and corresponding Q-factor) of the resonances observed. The Q-factors of resonances while in contact are often several orders of magnitude lower than those for air alone. Dependence on applied load, humidity, and vibration mode have also been observed. Here, two dissipation mechanisms are discussed with application to AFAM. First, frictional losses associated with the tip-sample oscillations are examined. The cyclic energy loss that accompanies tip vibrations is calculated for the combined normal and shear forces present during AFAM measurements using an extension of a Mindlin contact model. The dependence on mode, applied load and friction coefficient, and other parameters is seen explicitly. Second, the dissipation associated with losses from viscoelastic contact is calculated using simple viscoelastic materials models that are coupled with the vibrating-beam boundary value problem. In this case, the dependence of the dissipation on sample properties and tip geometry is determined. The role of each of these mechanisms for specific tip-sample systems is discussed. The results are expected to impact quantitative aspects of nanomechanical characterization techniques. [Work supported by ARL.]

3aPP1. An auditory perceptual change with repeating noise bursts. Patrick M. Zurek (Sensimetrics Corp., 48 Grove St., Somerville, MA 02144, pat@sens.com)

This talk describes a change in perception that is experienced when listening to repeating noise bursts. When a brief (10–20 ms) frozen noise burst is presented repeatedly at a rate of about 1/s, the perceived quality of the bursts changes. Initially, the noise bursts have the expected perceptual texture of white noise (like the consonant ''ch'' spoken in isolation). At some later time, usually 10–30 s after the start, that noise texture disappears and the perceptual quality becomes that of a dull click or thump. Initial observations of this perceptual change under a variety of stimulus manipulations will be described. Unlike perceptual changes involving repeated speech (e.g., semantic satiation and the verbal transformation effect), which are usually labile and involve multiple transitions among multiple perceptual forms, the observed change with noise bursts appears (thus far) to be only a two-state, one-way change with constant stimulus repetition.

7:55

3aPP2. Two types of learning revealed by evaluation of the best and worst daily performance during auditory-discrimination training. Beverly A. Wright, Yuxuan Zhang, and Christopher C. Stewart (Dept. of Commun. Sci. and Disord., Hugh Knowles Ctr., and Inst. for Neurosci., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208-3550)

Performance on many auditory discrimination tasks improves with practice. This learning could result from improvements in fundamental processing capacity (as is implicitly assumed), from improvements in the ability to consistently access already existing capacities, or from a combination of the two. To help distinguish among these types of improvement, we reanalyzed learning data on three basic auditory tasks, examining the best and worst, rather than the mean, thresholds on each of 6–10 days of training. On one task (interaural-level discrimination), the best and worst thresholds decreased in parallel, indicating an improvement in fundamental processing capacity. On another task (interaural-time discrimination), the best thresholds remained unchanged but the worst thresholds decreased, suggesting an increased consistency in accessing already existing capacities. Demonstrating a combination of these two types of improvement, on the third task (duration discrimination), both the best and worst thresholds improved, but the worst thresholds improved more. These results indicate that learning on auditory tasks can result not only from refinements in fundamental stimulus encoding, but also from increases in the ability to use the best information that was already available before training. [Work supported by NIH/NIDCD.]

3aPP3. Different developmental patterns for average performance and performance consistency on basic auditory tasks during adolescence. Julia Jones Huyck and Beverly A. Wright (Dept. of Commun. Sci. and Disord., 2240 Campus Dr., Northwestern Univ., Evanston, IL 60208-3550)

Learning patterns on auditory discrimination tasks have been observed to differ markedly between average performance (average threshold) and performance consistency (within-subject standard deviation), suggesting that these two measures of performance may be governed by different processes [Wright *et al.*, ARO Abstr. **27**, 274 (2004)]. Further supporting this idea, different developmental patterns for average performance and performance consistency are reported here. Naive 8- to 10-year-olds ($n=6$), 11- to 14-year-olds ($n=16$), and adults (≥ 18 years old; $n=17$) were tested on four auditory detection conditions in which a 10-ms 1-kHz tone was presented (1) immediately before a 300-ms broadband noise, (2) at noise onset, (3) 200 ms after noise onset, or (4) immediately after noise offset. On two of the four conditions (conditions 1 and 4), both average performance and performance consistency improved with increasing age. However, on the remaining two conditions, either average performance improved significantly with increasing age while performance consistency did not (condition 2) or vice versa (condition 3). These results suggest that, in development, the processes underlying average performance may differ from those underlying performance consistency, and, more generally, that different processes may underlie these two measures of performance in many aspects of behavior. [Work supported by NIH/NIDCD.]

3aPP4. Estimating the rate of response growth using above characteristic-frequency maskers. Magdalena Wojtczak and Neal F. Viemeister (Dept. of Psych., Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455, wojtc001@umn.edu)

Growth of forward masking was measured to determine the relative rate of basilar-membrane (BM) response growth at the characteristic-frequency (CF) place that was stimulated with a higher-frequency tone. Two signal frequencies (f_s) were used, 1 and 4 kHz. The masker frequency was $1.1f_s$ or $1.2f_s$. A lower-frequency masker ($0.6f_s$) was also used to replicate previously published data. Previous data obtained using a method for deriving the BM input-output function based on temporal masking curves suggested a linear growth of the BM response to a tone with a frequency equal or higher than $1.1f_s$ and a compressive growth for the CF tone. This study demonstrates that the growth-of-masking method for deriving the BM response provides a similar result (indicating a compressive growth for the CF tone) when a low-frequency masker is used but leads to a fundamentally different result (indicating an expansive response growth) when a higher-frequency masker is used. The expansive growth is observed even when a low-pass noise is used to limit potential off-frequency listening. The data will be related to mechanical BM data and the equivalence of the two psychophysical methods for deriving BM compression will be discussed. [Supported by NIH Grants DC00683 and DC006804.]

3aPP5. Forward masking of spectral modulation. Elizabeth M. O. Borchert, Magdalena Wojtczak, and Neal F. Viemeister (Univ. of Minnesota, 75 E. River Rd., Minneapolis MN 55455)

Some physiological and psychophysical evidence indicates that spectral shape is processed by means of a Fourier-like analysis of the spectral envelope. A forward masking paradigm in the spectral envelope domain was used to further investigate the properties of such spectral analysis. Detectability of a 50-ms sinusoidal modulation (ripple) in the amplitude spectrum of a broadband noise was measured when it was preceded by either uniform-spectrum noise, or by a noise with a same-frequency ripple (the forward masker). Data showed considerable forward masking of ripple detection when the phase of the masker and that of the signal were the same, but little or no masking when the masker and signal ripples were out of phase. Such results could be explained either by perceptual confusion between the signal and masker or by the adaptation of phase-sensitive, tuned ripple channels. In a follow-up study, the masker consisted of a broadband noise with both an on-frequency and an off-frequency (nonmasking) ripple. Little or no masking was observed in this study, which is consistent with an explanation based on the perceptual similarity between signal and masker. [Work supported by NIH Grant DC00683.]

8:55

3aPP6. Temporal integration functions of AM detection and AM depth discrimination. Jungmee Lee (Dept. of Speech, Lang., and Hearing Sci., Univ. of Arizona, P.O. Box. 210071, Tucson, AZ 85721-0071, jmlee6@email.arizona.edu), Glenis Long, and Changmo Jeung (CUNY, New York, NY 10016)

Previous studies (Lee, 1994; Lee and Bacon, 1997) suggested that both AM rate and AM depth discrimination were influenced by the number of AM cycles, instead of by the duration of stimulus. AM detection and AM depth discrimination were measured as a function of the number of AM cycles for the modulation rates of 10, 20, 40, 80, 125, 160, and 320 Hz. The carrier was a broadband noise (10 kHz low pass), and the carrier was either gated with the modulator (gated carrier) or presented 250 ms earlier and 250 ms later than the modulator (continuous carrier). The overall level of each presentation was randomized within 6-dB range from 65 dB SPL. For the lower modulation rates (10, 20, 40, and 80 Hz), there was a significant improvement with the continuous carrier at smaller number of cycles (two and four modulation cycles) as compared to the gated carrier condition. For the higher modulation rates (125, 160, and 320 Hz), however, the thresholds were not affected by carrier type. These results suggest that there might be a different temporal integration process for lower and higher modulation rates. [This work was supported by NIDCD Grant No. R03 DC06605-02.]

3aPP7. Response-related patterns in discrimination of FM narrow-band noise. Jinyu Qian and Virginia Richards (Dept. of Psych., Univ. of Pennsylvania, 3401 Walnut St., Ste. 302C, Philadelphia, PA 19104)

Noise stimuli were used to investigate weighting patterns for detecting dynamic frequency changes. For one stimulus set, a tonal glide was modulated by a narrow band of noise (gliding narrow-band noise, GNBN, condition). For the second set, the glide was preceded and followed by steady-state tones before modulation (SS condition). The task was to indicate whether the stimulus had a frequency glide or not. Weighting patterns (as a function of time) were derived for each subject based on a linear classification model. First, the deviation of the instantaneous carrier for each stimulus was calculated and then weighted by the squared envelope of the stimulus. This was followed by the linear classifications of the squared-envelope-weighted deviation of instantaneous carrier (SEWDOIC) according to the subjects responses [A. Ahumada, J. Vis., **2**, 121–131 (2002)]. The weighting patterns were consistent across subjects although individual differences in pattern details were observed. The comparison between the patterns from the GNBN and SS conditions indicates the use of dynamic information rather than only comparing the beginning and ending frequencies, consistent with Lyzenga *et al.* [J. Acoust. Soc. Am. **116**, 491–501 (2004)]. Similar weighting patterns were also estimated when the center frequency of the stimuli was random.

3aPP8. Revisiting psychometric functions for frequency discrimination. Huanping Dai (Div. of Commun. Disord., Univ. of Wyoming, Laramie, WY 82071)

In studies of auditory detection and discrimination, psychometric functions not only describe listeners sensitivity to changes in the stimulus, but often provide information regarding the auditory neural coding mechanisms involved in these tasks. In the present study, psychometric functions for frequency discrimination were systematically measured with a group of normal-hearing young adults. Frequency difference limens were in agreement with previous reports in their dependence on frequency. On the other hand, unlike that implied in previous analyses, the slopes of the psychometric functions, expressed in $\log(d)$ versus $\log(\Delta F)$, were found to be consistently shallower than unity at frequencies below 4 kHz. Only at higher frequencies did the slopes average around unity. These results will be discussed in light of auditory neural computational models based on either place or temporal coding. [Work supported by the Division of Communication Disorders, University of Wyoming.]

3aPP9. Suppression of sports chants through delayed feedback of sound. Sander J. van Wijngaarden and Johan S. van Balken (TNO Human Factors, P.O. Box 23, 3769 ZG Soesterberg, The Netherlands)

A novel approach for disrupting offending chants at sporting events is proposed, based on attacking synchronization between individuals. Since timing is crucial for coordination between chanters, disruption of timing is expected to be effective against chants. Delayed auditory feedback is known to disrupt timing in individuals; hence, delayed feedback may also be effective in a group context. It is shown that the timing of individuals joining in with sports chants can be severely disrupted by also presenting an artificially delayed version of this chant. This effect is reduced if the individual is given more cues (direction, fidelity) to differentiate between original chant and distracter. Unsurprisingly, the effectiveness also depends on delay time and the target-to-distracter ratio. The feedback signal has to be at least as loud as the original chant, and the delay should be greater than 200 ms. Conventional auditory feedback shows a pronounced peak in effectiveness around 300 ms. Such a peak does not occur here; up to approximately 1 s, effectiveness increases monotonically with delay time. Field experiments show that it may be hard to implement the approach suggested here in practice, since the required feedback signal levels tend to lead to instability of the feedback loop.

3aPP10. Testing the role of harmonic number in the contribution of a nonsimultaneous mistuned harmonic to residue pitch. Hedwig E. Gockel, Robert P. Carlyon (MRC Cognition and Brain Sci. Unit, 15 Chaucer Rd., Cambridge CB2 2EF, UK, hedwig.gockel@mrc-cbu.cam.ac.uk), and Christopher J. Plack (Lancaster Univ., Lancaster LA1 4YF, UK)

Ciocca and Darwin [J. Acoust. Soc. Am. **105**, 2421–2430 (1999)] reported a surprising finding: Mistuning the fourth harmonic produced the same residue pitch shift when presented after the remainder of the complex as when it was simultaneous. They concluded that partials are integrated over a period of 170–250 ms for the calculation of pitch. Gockel *et al.* [J. Acoust. Soc. Am. **118**, 3783–3793 (2005)] failed to replicate this result, but mistuned the third harmonic. Here, subjects adjusted a matching sound (harmonic complex) so that its pitch equaled that of a subsequent 90-ms complex tone (12 harmonics of a 155-Hz $F0$) containing a mistuned ($\pm 3\%$) third or fourth harmonic. Pitch shifts were significantly

larger when: (i) the mistuned harmonic was presented simultaneously with, rather than after, the remainder of the target complex; (ii) the fourth rather than the third harmonic was mistuned; (iii) the nominally mistuned harmonic was present in, rather than absent from, the matching sound. The results again contrast with Ciocca and Darwin's findings and contradict the idea of obligatory integration over a long time period for the formation of residue pitch. [Work supported by EPSRC Grant EP/D501571/1.]

10:25

3aPP11. Onset transient significance in listener identification of pipe organ stops. Alastair C. Disley and David M. Howard (Dept. of Electron., Univ. of York, Heslington, York, YO10 5DD, UK, acd500@ohm.york.ac.uk)

Pipe organs typically contain many ranks of pipes, but it is uncertain whether listeners can discern the often subtle differences between different ranks. The importance of onset transients in timbral identification is well established, but in many pipe organ listening situations, the transient is obscured. This paper explores the significance of organ pipe onset transients in an experiment based on Berger's work on orchestral timbre (K. W. Berger, J. Acoust. Soc. Am. **36**, part II, 1888 (1963)] Listeners familiar with the pipe organ attempted to identify recordings of single organ pipes, representing commonly found types of organ stop. Each pipe was presented on different occasions with its own transient and with artificial transients created by amplitude ramps. The results demonstrate that when onset transients are present, expert listeners are adept at identifying the general tonal nature of a stop, but are less adept at precise identification. Replacement of transients with amplitude ramps resulted in a decrease in both precise and general correct identification. The subjective mapping demonstrated between pipe names and their spectral features is explored. Onset transients are shown to be important in listener identification of pipe organ stops.

10:40

3aPP12. Spectral correlation of timbral adjectives used by musicians. Alastair C. Disley, David M. Howard, and Andrew D. Hunt (Dept. of Electron., Univ. of York, Heslington, York, YO10 5DD, UK, acd500@ohm.york.ac.uk)

As part of a project to develop a synthesis interface which nontechnical musicians should find intuitive, the adjectives musicians use to describe timbre have been studied in a large-scale listening test. Timbral adjectives were gathered from both musicians and previous studies and refined in a pilot experiment to a set of 15 (bright, clear, dull, evolving, gentle, harsh, metallic, nasal, percussive, pure, rich, ringing, thin, warm, and wooden). Fifty-nine English-speaking musicians used these words as rating scales (e.g., bright to not bright) in a listening experiment involving 12 single-note samples chosen to explore the timbre space of Western musical instruments. Twenty-three of those listeners were in a control group who took the test ten times, showing good consistency in their answers. The results demonstrate a good common understanding of adjectives between listeners, and multivariate data analysis techniques were used to exclude poorly understood or highly correlated adjectives. The relationship between the consistently understood adjectives and the spectral features they describe is explored by looking for correlation with a large number of time and frequency domain analyses of the 12 instrument samples. Significant correlation is found between some timbral adjectives and spectral features.

10:55

3aPP13. Speeded detection of sound signals based on temporal differences. Clara Suied, Laurent Pruvost, Patrick Susini, Nicolas Misdariis (IRCAM-CNRS, 1 place Igor Stravinsky, 75004 Paris, France, clara.suied@ircam.fr), Sabine Langlois (Renault, 78288 Guyancourt, France), and Stephen McAdams (McGill Univ., Montreal, QC, Canada H3A 1E3)

Previous research has identified acoustic parameters modulating the perceived urgency of alarms. Such approaches have focused mainly on the subjective relationship between characteristics of the alarms and the perception of urgency. We suggest that an objective measurement will ensure with more certainty the effectiveness of the acoustic parameters and will help us to understand more precisely the underlying processes. We have to the improve the ability of warning signals to increase the probability of a faster reaction under emergency conditions. Thus, we performed two experiments using a speeded reaction-time (RT) paradigm, under two tracking task conditions: motor and visual. Experiment 1 studied the influence of the tempo of the sequences. RT decreased as tempo became faster. Experiment 2 studied the influence of temporal irregularity. Outlier analyses show that RT decreased with the irregularity of the sequences. A scaled judgment of urgency was also given by subjects. Two underlying processes seem to be involved: experiment 1 highlights expectancy effects (temporal regularities provide a temporal reference frame), whereas experiment 2 emphasizes capture effects (a temporally perturbed event is more salient than a temporally expected one) [Jones, M.R., ''Attention and timing,'' in *Ecological Psyhoacoustics*, edited by J. Neuhoff (Elsevier Acadamic Press, San Diego, 2004) pp. 49–88 (2004)]. Moreover, comparisons between RT measurements and subjective judgments improve the validity of our approach.

11:10

3aPP14. Investigating auditory induction without complete continuity. Justin Aronoff (Neurosci. Program, Univ. of Southern California, HNB 27, Los Angeles, CA 90089, aronoff@usc.edu)

Auditory induction, the process of restoring missing auditory information, plays a crucial role in perception. A number of researchers have examined the characteristics of this phenomenon when there is a signal anchoring both sides of the induced sound (i.e., complete anchoring). However, the characteristics of partially anchored induced sounds (i.e., anchoring on only one side of the induced sound) are largely unknown, although prior research suggests that such partially anchored induction can occur [Wrightson and Warren, J. Acoust. Soc. Am. **69**, S105–S106 (1981)]. To examine the characteristics of this latter type of induced sound, synthetic stop-initial syllables were used in a forced-choice task, allowing easy assessment of the type and amount of induced information. The first 25 ms of each transition was removed, and noise (used to elicit the induced sound) was added to the truncated transition in small segments, replacing the removed transition. Accuracy increased with increasing amounts of noise, indicating that induction was occurring with partial anchoring. However, this induction was strongly limited, extending only 15 ms into the noise. This suggests that complete anchoring plays an important role in extending the induced sound, although it is not necessary for its creation.

11:25

3aPP15. Using psychometric functions to determine auditory perception of the size and speed of a rolling ball. Christophe Stoelinga, Dik Hermes (Technische Universiteit Eindhoven, Den Dolech 2, P.O. Box 513, 5600MB Eindhoven, The Netherlands), and Armin Kohlrausch (Philips Res. Labs. Eindhoven, 5656AA Eindhoven, The Netherlands)

The purpose of the presented experiments is to quantify exactly how precise listeners can judge certain mechanical parameters of a system by listening to the sounds generated by this system. We used sounds generated by a ball rolling over a plate. In the recording of these sounds, the ball diameter, rolling speed, and plate thickness were varied. Subjects were asked to judge each of these three parameters in the sound in two different ways; in a paired comparison, two alternative forced choice, and using absolute magnitude estimation. Both methods were used to calculate psychometric functions which estimate the probability that a listener correctly identifies the difference in one of the physical parameters. Both paired comparison and absolute magnitude estimation lead essentially to the same psychometric functions. For each pair of sounds the percentage of correct responses is plotted against the fraction of their sizes. These datapoints are then fitted to a cumulative normal distribution. The good fit of the results, using this logaritmic scale for the estimated parameter, is in close agreement with Steven's law. This method was used to test whether if discrimination capabilities decrease when two parameters, eg. speed and size, are changed simultaneously.

11:40

3aPP16. Effect of context on identification of environmental sounds. Brian Gygi (Acoust. Res. Inst. of the Austrian Acad. of Sci., Reichratsstrasse 17, Vienna 1010 Austria) and Valeriy Shafiro (Rush Univ. Medical Ctr., Chicago, IL)

This study investigated the role of auditory context in identifying individual environmental sounds. Limited previous research has not demonstrated a facilitatory influence of context on sound identification comparable to the benefits grammatical context provides for identifying speech sounds. Unlike some previous studies, in which context was determined by sound presented sequentially before and after the target environmental sound, in the present experiments the sounds to be identified were mixed in with a background of naturally occurring auditory scenes, such as the ambience of a beach or a street. Thirty-one familiar environmental sounds from previous environmental sounds studies were presented mixed either with congruent scenes (such as hammering at a construction site) or incongruent scenes (such as a horse galloping in a restaurant). The sounds were presented at signal-to-background ratios of −12 and −16 dB and trained listeners identified them using three-letter codes. Results indicate auditory context had a small but significant effect on identification performance. However, contrary to expectations, the sounds were identified more accurately in incongruent scenes (55% correct) rather than congruent ones (46% correct). The differential effects of auditory attention in determining foreground and background sounds will be discussed in connection with the results.

11:55

3aPP17. Relationships of performance accuracy, target call sign sensitivity, and response bias on the Coordinated Response Measure task. Valeriy Shafiro (Commun. Disord. & Sci., Rush Univ. Medical Ctr., 1653 W. Congress Pkwy., Chicago, IL 60612), Brian Gygi (Acoust. Res. Inst., Vienna, Austria), and Hillary Snapp (Rush Univ. Medical Ctr., Chicago, IL 60612)

Coordinated Response Measure tasks evaluate attentional processing by requiring the listener to mark the color-number response contained in a phrase that starts with a specific call sign. However, when a target call sign is present on every trial, it is not known whether subjects must perceive the call sign in order to respond correctly. The present experiment examined the relationships among sensitivity to the target call sign, response bias, and performance accuracy in 6 normal-hearing subjects over 4 testing sessions. The number of talkers (2–4) and talker sex configuration were manipulated in 9 stimulus conditions. In session 1, a target call sign was present on every trial. During sessions 2 and 4, 10% of the trials were foils with no target call sign, while the stimuli in the third session had an equal number of trials with and without the target call sign. Results indicate significant main effects of test session and sex configuration for all 3 experimental parameters. High correlations were observed between sensitivity and accuracy for all sessions. However, a significant improvement in sensitivity was not accompanied by a similar improvement in accuracy, suggesting that better call sign detection does not necessarily lead to better task performance.

3aSA1. Monitoring of bulk materials using ultrasonic waveguides. Michael Lowe, Peter Cawley, and Francesco Simonetti (Dept. of Mech. Eng., Imperial College, London SW7 2AZ, UK)

Much progress has been made in the use of guided waves for the detection of cracks and corrosion in structures such as pipelines, railway lines, and steel reinforcing tendons. The challenge with those ideas is to use waves which are sensitive to the defects and insensitive to any materials in contact with the structure. However, a complementary approach is to identify waves which are particularly sensitive to materials in contact with the waveguide and thus to identify their presence and properties. The authors have worked on a number of interesting applications of this kind, including the characterization of sludge and detection of blockages in pipelines, the *in situ* measurement of the material properties of soil, the monitoring of the cure of adhesives, and the measurement of the properties of complex fluids. The paper will discuss the physical phenomena which determine how the guided waves in bars, pipes, and plates are affected by materials with which they are in contact, and give examples of how these phenomena can be exploited.

8:30

3aSA2. Guided waves for stress corrosion crack detection in pipelines—feature selection and classification. Austin P. Albright, Venugopal K. Varma, Raymond W. Tucker, and Philip R. Bingham (Oak Ridge Natl. Lab., 1 Bethel Valley Rd., Bldg. 3500, Rm. C028, Oak Ridge, TN 37831-6010, albrightap@ornl.gov)

This paper describes a wavelet-based analysis of electromagnetic acoustic transducer (EMAT) signals for in-line inspection of flaws in natural gas pipeline. The main objective of the project has been to implement the use of EMATs for pipe flaw detection, specifically the ability to detect stress corrosion cracks (SCCs) that are undetectable by current techniques. In this approach, two EMATs are used; one is the transmitter, while the second one, located a few inches away from the first, is used to receive the induced signal. Using a four-level wavelet decomposition, the EMAT data are filtered based on frequency. The features used to classify are derived from the coefficients representing each level of the four-level decomposition of the signature. The objective of the project was

to detect SCC with minimal false positive even if smaller SCCs (shallow) are not identified. Although many features could be used, selecting the right features that results in maximum separation between the classes (SCC flaw, other pipe artifacts, and no flaw) was a challenge. This paper describes the process of down-selecting the feature sets and separating the classes. The results using this approach have shown promise.

3aSA3. Decay curvature due to "losses" into a waveguide from a reverberant body. Richard Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, 216 Talbot Lab., 104 S. Wright, Urbana, IL 61801)

We study the dissipation of diffuse ultrasonic energy in a reverberant body coupled to an effectively infinite elastic waveguide. A simple model predicts a distribution of complex eigenfrequencies and a corresponding nonexponential (''curved'') dissipation. This behavior was predicted in its broad outlines by Manfred Schoeder and is largely confirmed by measurements. For the case of fully open channels, however, measurements deviate from the simple model to a statistically significant degree. A random matrix supersymmetric calculation is found to accurately model the observed behaviors at all coupling strengths. We discuss implications for modeling losses in large complex systems and, in particular, for modeling decay curvature.

3aSA4. Waveguide scattering from flanges, ribs, and defects in fluid-loaded, laminated cylinders. Ann Stokes, Charles Corrado (Appl. Physical Sci., 4 Muzzey St., Lexington, MA 02421), and Gregory McDaniel (Boston Univ., Boston, MA)

The vibration of laminated, fluid-loaded cylinders is efficiently predicted with a wave transmission line analysis. The transmission line approach expresses the motion of homogeneous cylinder sections in terms of propagating and evanescent waves. The full set of wave dispersion relationships is computed with a semi-analytic technique, which uses a finite element radial discretization of the laminated shell and interior fluid. External fluid is represented using a state-space representation of the rational function approximation (RFA). Scattering of waves from discontinuities, including flanges, delamination, and pitting, is predicted through coupling a two-port admittance of the structure or defect to the semi-infinite admittance of the cylinder waveguide. Issues regarding the measurement of scattered and reflected waves, and identification of structural wave numbers, are discussed. The use of causality and reciprocity constraints substantially reduces measurement requirements and noise. By exciting and measuring a mixture of structural waves, defects may be classified and located. An example of predicting and measuring scattering of a defect beyond a flange is presented. 3aSA5. Leaky wave excitation on concave surfaces and hyperbolic Fresnel zones. Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814)

Leaky waves are waves guided by elastic structures having phase velocities exceeding the speed of sound in the surrounding fluid. When analyzing the excitation of leaky waves on smoothly curved elastic structures it is often helpful to determine the Fermat paths. Those paths satisfy Fermat's principle for the combined acoustic propagation in the fluid and guided propagation on the structure. It is also helpful to determine the shape of the Fresnel zones associated with deviations from Fermat paths. That information is directly useful for calculating guided leaky wave amplitudes [P. L. Marston, ''Spatial approximation of leaky wave surface amplitudes for three-dimensional high-frequency scattering: Fresnel patches and applications to edge-excited and regular helical waves on cylinders,'' J. Acoust. Soc. Am. **102**, 1628–1638 (1997)]. The Fresnel zones associated with the external excitation of helical leaky waves on submerged circular pipes or cylinders were previously shown to be elliptical. The resulting leaky wave amplitudes are in agreement with amplitudes derivable by other methods and with experiments. In the present work, the analysis is generalized to excitation of leaky waves by ultrasound incident from the concave side of cylindrical shells or pipes. Even though the resulting Fresnel zones are approximately hyperbolic in shape, ray approximations for the amplitude are applicable when expressed using the Hessian of the phase deviation. 3aSA6. Selective modal excitation using phase-shifted ultrasound radiation force. Thomas M. Huber (Phys. Dept., Gustavus Adolphus College, 800 College Ave., St. Peter, MN 5608), Mostafa Fatemi, Randall R. Kinnick, and James F. Greenleaf (Mayo Clinic College of Medicine, Rochester, MN 55905)

The ultrasound radiation force can be used as a noncontact method for exciting vibrational modes. In one implementation, an audio-range modulation signal is combined with a 40-kHz carrier to form a double-sideband suppressed-carrier (DSSC) waveform that is emitted from an ultrasound transducer. The frequency of the ultrasound radiation force is the difference between the frequencies of the sidebands, therefore at twice the modulation frequency. We describe a method for selective mode excitation using a transducer pair, each emitting a DSSC signal. The modulation signal for one transducer was phase shifted relative to the other transducer. When the two modulation signals were in phase, the radiation stress field was uniform. For devices studied, this excited transverse modes while suppressing torsional modes. Similarly, if the modulation signals were out of phase, torsional modes were excited while suppressing transverse modes. This technique has been demonstrated for devices including an MEMS mirror, hard-drive suspension, and brass cantilever. For a cantilever, the ratio of the amplitudes of 180-Hz transverse over 1.3-kHz torsional modes was varied by over two orders of magnitude by shifting the phase difference between the two beams over a range of 90 deg. This noncontact technique allows control over the types of vibration excited.

3aSA7. Ultrasonic nondestructive evaluation in thin-walled concrete for flaw detection. Michael K. Pedrick, Bernhard R. Tittmann (Dept. of Eng. Sci. and Mech., The Penn State Univ., 212 EES Bldg., University Park, PA 16802, mkp136@psu.edu), and Shivprakash Iyer (The Penn State Univ., University Park, PA 16802)

Accurate inspection techniques for today's infrastructure have become an area of great interest. Several ultrasonic techniques for testing and evaluating concrete have been established and show great promise. However, much of the work is concerned with concrete piles or thick-walled specimen (greater than 500 mm). Vast amounts of concrete piping in sewer systems and water mains require testing techniques applicable to thinner-walled systems (less than 100 mm). This work aims to extend ultrasonic inspection techniques to thin-walled systems. Impact-echo and resonant ultrasonic spectroscopy (RUS) techniques are explored. Finite-element models have been developed to describe the propagation characteristics in different specimen. Several specimens have been tested experimentally to determine the effects of steel reinforcements, pipe curvature, and simulated defects. The influence of sensor configuration, transducer characterization, and data capture on measurement accuracy and inspection time is examined. The potential for wavelet analysis is explored for isolation of wave propagation modes and defect characterization.

3aSA8. Nondestructive inspection of in-service pipelines by guided ultrasonic waves. Hasson M. Tavossi (Dept. of Physical and Environ. Sci., Mesa State College, 1100 North Ave., Grand Junction, CO 81501)

Ultrasonic techniques for inspection of pipelines are investigated, using them as channels for guided ultrasonic waves. The current standard method for pipe inspection requires sending a rotating probe inside the pipe and measuring the wall thickness by pulse-echo technique. The inside wall of the pipe should therefore be accessible, clean, and smooth. These requirements limit the applicability of this method. The inconvenience of the above method can be removed by the guided wave technique that uses the pipe itself as a waveguide. In the guided wave technique the waves are not reflected from the inside surface of the pipe and they do not have the restrictions mentioned above. It is well known that dispersion of ultrasonic guided waves occurs in the wall of the pipe. As the waves propagate along the length of the pipe, different modes travel at different speeds. Selection of an appropriate mode for the transmitted waves is used to detect various flows in the pipelines. These flaws include wall thinning, pitting by corrosion, or cracks. High-frequency ultrasonic transducers in the range of 10 to 20 MHz are used for this purpose. Theoretical results are discussed and compared with the experimental findings on the ultrasonic nondestructive in-service pipe inspections.

3aSA9. Time-reversal imaging for structural monitoring. Gregoire P. Derveaux (INRIA, domaine de Voluceau, BP105, 78153 Le Chesnay Cedex. France, gregoire.derveaux@inria.fr), George Papanicolaou (Stanford Univ., Standford, CA 94305), and Chrysoula Tsogka (Univ. of Chicago, Chicago, IL 60637)

We investigate time-reversal imaging with distributed sensors in order to locate localized damage in a structure. Given a configuration of transducers, we assume that a full response matrix for the healthy structure is known. It is used as a basis for comparison with the response matrix that is recorded when there is damage. We have carried out a numerical experiment with the wave equation in two dimensions. The healthy structure is a domain containing many scatterers. We want to image two pointlike defects with the help of 12 sensors regularly distributed. Because of the complexity of the environment, the traces have a lot of delay spread and travel time migration does not work well. Instead the traces are back-propagated numerically in the medium, assuming that we have some knowledge of the background. Since the time at which the back-propagated field will focus on the targets is unknown, we compute the Shannon entropy of the image and pick the time where it is minimal. The TV norm proves also a good indicator. Thanks to the superfocusing property of time reversal in a highly scattering medium, this algorithm works well: it gives reliable and stable results.

3aSA10. High-frequency thermoviscoelastic vibration of functionally graded thin beams. M. Cengiz Dkmeci (Istanbul Tech. Univ., P.K.9, Gmssuyu, 34430 Istanbul, Turkey, dkmeci@itu.edu.tr) and Glay Altay (Bogazii Univ., 34342 Istanbul, Turkey)

The paper presents the system of 1D equations so as to analyze the thermoviscoelastic behavior of an axially functionally graded beam of rectangular cross section at high-frequency vibration. First, the 3D fundamental equations of a hyperbolic thermoviscoelasticity are expressed by a unified variational principle in terms of the Laplace transformed field variables [cf., Dkmeci and Altay, Acta Mechanica **143**, 91–11 (2000)]. Next, the temperature increment and the displacement field as well as the material density and elasticities [e.g., Sankar and Tzeng, AIAA J. **40**, 1228–1232 (2002)] are expressed by the power series expansions in the thickness coordinate of the beam. A variational averaging procedure [e.g., Dkmeci and Altay, Int. J. Non-linear Mech. **37**, 225–243 (2002)], together with the series expansions, is used in deriving the system of 1D beam equations in both differential and fully variational forms. The system of 1D equations governs the extensional, flexural, torsional, and thickness shear and also the coupled vibrations of the beam at high frequency. Special cases are indicated involving the material properties and/or the vibration of the beam. Also, the uniqueness is investigated in solutions of the system of beam equations. [Work supported by TUBA.]

Speech Communication: Speech Processing and Special Populations (Poster Session)

Janet L. Slifka, Chair
Massachusetts Inst. of Technology, Research Lab. of Electronics, 55 Vassar St., Cambridge, MA 02139

Contributed Papers

All posters will be on display from 8:45 a.m. to 11:45 a.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:45 a.m. to 10:15 a.m. and contributors of even-numbered papers will be at their posters from 10:15 a.m. to 11:45 a.m.

3aSC1. Recording and environmental effects in sociolinguistic interviews: Implications for sociophonetic analysis. Tyler Kendall (English Dept., Duke Univ., Box 90017, Durham, NC 27708, tsk3@duke.edu)

Sociophonetians are often interested in examining speech that has been recorded in acoustically diverse conditions. Sociolinguistic methodology is centrally concerned with combating the observer's paradox, finding ways to minimize informant's awareness that they are under investigation, and often the requirements needed to ensure high-quality recordings conflict with this theoretical focus. While sociophoneticians are aware of some potential problems when comparing different speakers, with only rare exceptions have they examined the potential problems on both inter- and intraspeaker analyses due to recording and environmental effects. Meanwhile, other fields (especially computer speech recognition) have investigated the acoustic effects of environmental noise and recording equipment and have demonstrated that these factors impact the resulting speech signals in ways that are possibly significant for sociophonetics. This study emulates a number of traditional sociolinguistic interview recording techniques by taking an array of recordings for single interviews. Each interview is simultaneously recorded with a wired lavalier microphone connected to an audiocassette recorder, a unidirectional vocal microphone placed 2 ft from the speaker connected to an audiocassette recorder, and a wireless lavalier to a digital video camera. The results of phonetic analyses of these recordings, along with the implications for sociophonetic analysis, are explored.

3aSC2. Acceptable noise levels with intelligible and unintelligible primary discourse. Susan G. Hickey and Robert E. Moore (Dept. of Speech Pathol. and Audiol., Univ. of South Alabama, 2000 UCOM, Mobile, AL 36688-0002)

Acceptable noise levels (ANL) were assessed for 30 adult, normal-hearing listeners in sound field in three conditions. The three conditions were primary signal of (1) intelligible discourse (Arizona Travelogue); (2) unintelligible backwards discourse (Arizona Travelogue recorded backwards); and (3) unintelligible Chinese discourse. In each condition the primary speaker was male. ANL was determined for each of three conditions by having participants select their most comfortable level (MCL) for the primary discourse. Next, for each condition, speech babble was added and adjusted to find the participant's maximum background noise level (BNL) that was acceptable while listening to the primary discourse. The ANL was determined by subtracting the BNL from the MCL. The group mean ANLs for the intelligible discourse, the backwards discourse, and the Chinese discourse were 7.16, 8.64, and 9.31 dB, respectively. An ANOVA for repeated measures indicated a significant main effect for primary discourse type ($F=5.54$, $p=0.006$). *Posthoc* paired samples t-tests indicated a significant difference between the intelligible and unintelligible backwards discourse condition ($t=-2.47$, $p=0.020$) and the intelligible and unintelligible Chinese discourse condition ($t=-3.17$, $p=0.004$).

3aSC3. Using the reassigned spectrogram to obtain a voiceprint. Sean A. Fulop (Dept. of Linguist., California State Univ. Fresno, 5245 N. Backer Ave. PB92, Fresno, CA 93740-8001) and Kelly Fitz (Washington State Univ., Pullman, WA 99164-2752)

While established methods for imaging the time-frequency content of speech—such as the spectrogram—have frequently been christened ''voiceprinting,'' it is well-known that it and other currently popular imaging techniques cannot identify an individual's voice to more than a suggestive extent. The reassigned spectrogram (also known by other names) is a relatively little-known method [S. A. Fulop and K. Fitz, ''Algorithms for computing the time-corrected instantaneous frequency (reassigned) spectrogram, with applications,'' J. Acoust. Soc. Am. **119**, 360–377 (2006)] for imaging the time-frequency spectral information contained in a signal, which is able to show the instantaneous frequencies of signal components as well as the occurrence of impulses with dramatically increased precision compared to the spectrogram (magnitude of the short-time Fourier transform) or any other energy density time-frequency representation. It is shown here that it is possible to obtain a reassigned spectrogram image from a person's voice that appears to be sufficiently individuating and consistent so as to serve as a true voiceprint identifying that person and excluding all other persons to a high degree of confidence. This is achieved by focusing on just a few phonatory pulsations, thereby revealing the vocal-fold vibrational signature unique to each person.

3aSC4. A spike-based computational model for noise robust vowel classification. Ismail Uysal, Harsha Sathyendra, and John G. Harris (Computational Neuro Eng. Lab., The Univ. of Florida, Gainesville, FL 32611)

The human ability to recognize speech drastically outperforms that of commercial ASR systems especially in noisy environments. Presently, there is limited knowledge of the auditory system dynamics, however it is known that coding and processing of information is carried out via action potentials. This research aims to better understand the coding mechanisms along the auditory pathway, while devising a noise robust system for speech recognition. A biologically plausible algorithm for vowel classification is proposed, which solely uses spikes for both the feature extraction and the classification stages. The algorithm uses an improved and adaptive model of the inner-hair cell [Sumner *et al.*, J. Acoust. Soc. Am. **113**, 893–901 (2003)] to generate spike trains at different characteristic frequencies. The synchrony among the hair cells is used as a noise robust means for feature extraction. Detected features are then classified using a

spike-based rank order coder, which uses the spike arrival times to the postsynaptic neuron to encode information [Delorme and Thorpe, Neural Networks. **14**, 795–803 (2001)]. Experiments on a noisy vowel dataset (5 dB SNR) show an average of 15% increase in the recognition rate for the prototype system when compared to a nearest-neighbor classifier employing Mel frequency cepstral coefficients.

3aSC5. Noise robust bandwidth extension of telephone speech for mobile and landline communications. Harsha M. Sathyendra, Ismail Uysal, and John G. Harris (Computational Neuro Eng. Lab., Univ. of Florida, Gainesville, FL 32611)

The present day telephone infrastructure limits the bandwidth of telephone speech to 300–3400 Hz, whereby conversational speech falls mostly within 50–8000 Hz. The ensuing band-limited narrow-band (NB) speech has a considerable loss in sound quality, in terms of naturalness and intelligibility. The purpose of bandwidth extension (BWE) is to utilize the receiver end NB speech and to add relevant frequency information to the missing low and high frequencies. This novel BWE algorithm utilizes the linear source filter model, which separates NB speech into two roughly independent components, the excitation and the spectral envelope. These components are then extended and convolved together to attain reconstructed wideband (RWB) speech. Excitation extension involves harmonic reconstruction for voiced frames and some modulations and filtering steps for unvoiced frames. Spectral envelope extension utilizes a Gaussian mixture model trained via the expectation maximization algorithm, which is involved in the mapping of NB noise robust features to the corresponding RWB features. Noise analysis is used to isolate the best feature set for real world applications. Results from a subjective listening test indicate this algorithm has an improvement in sound quality, while having the lowest known distortion metric among other speaker independent bandwidth extension algorithms.

3aSC6. Acoustic parameters for nasality based on a model of the auditory cortex. Tarun Pruthi and Carol Y. Espy-Wilson (Dept. of Elec. Eng. and Inst. of Systems Res., Univ. of Maryland, College Park, MD 20742, tpruthi@umd.edu)

Due to the longer length of the nasal tract as compared to the oral cavity, the asymmetry of the left and right nasal passages, and the coupling of the nasal tract to the sinuses, nasal sounds generally have more formants than oral sounds. However, all of the formants may not be prominent in the acoustic spectrum due to close-lying antiresonances. The net effect of the nasal peaks can be an increase in frequency modulation. In this work, we study the effectiveness of two new acoustic parameters (APs) that capture this increase in frequency modulation based on the ''scale'' dimension of a model of the auditory cortex [Chi *et al.*, J. Acoust. Soc. Am. **118**(2), 887–906 (2005)]. The new APs, mean center of gravity of scales and mean ratio of high scales to low scales, were used along with a previous set of four APs for the discrimination of nasal consonants and semivowels. Overall accuracy of 93.10% was obtained for this task. This corresponds to an 18.63% reduction in error rate over previously reported results. It remains to be seen if these APs are also useful in detecting nasalization in vowels. [Work supported by NSF Grant No. BCS0236707.]

3aSC7. Automated measurement of nasality over time in vowels. Michael A. Berger, Meghan Clayards, Neil Bardhan, and Joyce McDonough (Dept. Linguist., Univ. of Rochester, Rochester, NY 14627, berger@ling.rochester.edu)

Nasalized vowels have acoustic characteristics that allow the degree of nasality to be quantified from the acoustic signal. These characteristics include decreased first-formant amplitude ($A1$) and increased amplitudes of two extra peaks ($P0$ and $P1$). Chen (1995, 1997, 2000) used the parameters $A1-P1$ and $A1-P0$ (dB) to quantify nasality in vowels. These two measures are complementary in that different vowel types may be more accessible to one or the other. This research attempts to extend Chen's measures in several ways: (1) normalize the two parameters so that they are comparable; (2) integrate them into a single composite measure by a weighted average; (3) measure nasality over the time domain of each vowel token, resulting in nasality contours with high temporal resolution; and (4) automate the process of measuring nasality in vowels, so that large amounts of speech data can be processed rapidly by computer. Nasality measurement in this framework, whether manual or automated, requires a solution to the problem of tracking the three relevant peaks over time: $F1$, $N0$, and $N1$. A deterministic peak-tracking algorithm is proposed, but alternative statistical approaches are also considered. The validity of a peak-based approach for female speech is examined.

3aSC8. Detection of vowels in long-term speech-shaped noise. Chang Liu (Dept. of Commun. Sci. and Disord., Wichita State Univ., Wichita, KS 67260) and David A. Eddins (Univ. of Rochester, Rochester, NY, 14616)

The method of calibration is a critical issue in studies of vowel identification in noise, especially when manipulating speech-to-noise ratio. Common methods focus on stable estimates of the intensity or sound pressure level for specific speech sounds. However, vowels with the same sound pressure level often differ in both loudness, when presented at supra-threshold levels, and audibility, when masked detection thresholds for the vowel stimuli are measured. In the present study, detection thresholds for 12 isolated American-English vowels naturally spoken by three male and three female talkers were measured for young normal-hearing listeners in the presence of a long-term speech shaped (LTSS) noise. The duration of the vowels was equalized to 170 ms. The spectrum of the LTSS noise was identical to the long-term average spectrum of a 12-talker babble. The LTSS noise was present at 70 dB SPL. Thresholds for vowel detection showed distinct pattern as a function of the vowel category that was similar across listeners and talkers. This indicates that certain vowels were more audible than others, regardless of listeners and talkers. To account for the vowel-detection thresholds in noise, various analyses including comparisons of excitation patterns and estimates of specific loudness will be considered.

3aSC9. Enhancement of spectral modulation frequency in acoustics and identification of vowels. David A. Eddins (Dept. of Otolaryngolgy, Univ. of Rochester, Rochester, NY, 14616 and Intl. Ctr. for Hear. and Speech Res., RIT, Rochester, NY 14623) and Chang Liu (Wichita State Univ., Wichita, KS 67260)

The pattern of intensity variations across audio frequency can be represented as a series of spectral modulation frequencies. Selectivity for spectral modulation frequency in the auditory system has been demonstrated by physiological and psychophysical studies, suggesting that auditory perception of complex sounds might be based on spectral envelope channels. The present study investigated the effects of enhancing spectral modulation frequency on vowel acoustics and vowel identification. Twelve naturally spoken American-English vowels by three female talkers served as the standard stimuli. Various spectral modulation frequency regions of the standard vowels combined with a long-term speech-shaped (LTSS) noise were enhanced. Identification performance for the vowels presented in LTSS noise with and without spectral modulation frequency enhancement was estimated for seven young normal-hearing listeners. Vowels were presented at a sensation level of 3 dB in the LTSS noise (70 dB SPL). Results indicated that vowel identification performance was improved on average by 4%–6% over the 12-vowel categories for spectral modulation enhancement between 1.0 and 2.5 cycles/octave. Acoustic analysis suggested that the improved vowel identification as a result of the global spectral modulation enhancement may be due to increases in the spectral contrast of individual formants.

3aSC10. Information conveyed by *f*0 for vowel identification. Terrance M. Nearey (Dept. of Linguist., Univ. of Alberta, Edmonton, AB, T6G 2E7, Canada) and Peter F. Assmann (The Univ. of Texas at Dallas, Richardson, TX, 75083)

Our recent experiments with vocoded natural speech, wherein the spectral envelope and fundamental frequency are manipulated independently, have confirmed that some coordination of *f*0 and formant patterns are beneficial to vowel identification by humans. In an effort to model the perceptual dependency more precisely, we have investigated the performance of several alternative pattern recognition models on natural speech samples. This paper reports on several quite distinct methods of exploiting statistical relations between formant frequencies and *f*0 for recognition. Many of these methods yield quite similar results on the classic Peterson and Barney data and on larger, more recently collected data sets. Methods involving indirect normalization whereby the *f*0 of a single token is restricted to the role of estimating the formant frequency average of a speaker's entire vowel system perform well. Indeed, they are often better than a method where the role of *f*0 is unconstrained, thus accommodating inherent pitch differences among vowels. The indirect use of *f*0 also allows for methods of combining *f*0 and formant range information in ways that preliminary results suggest to be more effective for modeling perceptual effects with modified stimuli. More formal evaluation against perceptual data will be presented.

3aSC11. Recurrence quantification analysis of speech. Aaron Schultz (Deptartment of Psych., Univ. of Connecticut, 406 Babbidge Rd., Unit1020, Storrs, CT 06269-1020)

A time-series analysis technique known as recurrence quantification analysis (RQA) holds promise as a new method for investigating the dynamical properties of the acoustic speech signal. RQA was created to deal with complex time series generated by high-dimensional, nonlinear dynamical systems. While RQA has most frequently been used for physiological studies and investigations into nonlinear dynamics, it has not been widely applied to the acoustic analysis of speech. Recurrence quantification analysis is free of many key assumptions involved in Fourier-type analyses such as data set size, stationarity, and linearity, which are routinely violated in the speech stream. This study offers some preliminary findings on the dynamic nature of speech and characteristics of speaker variability obtained by using recurrence quantification analysis. Future directions for the use of RQA in speech perception and production studies, including shadowing and imitation studies, are discussed.

3aSC12. Predicting changes in breathiness resulting from variations in aspiration noise and open quotient using a loudness model. Arturo Camacho (Comput. and Information Sci. and Eng., Univ. of Florida, Gainesville, FL 32611) and Rahul Shrivastav (Univ. of Florida, Gainesville, FL 32611)

Previous studies have reported that increases in high-frequency aspiration noise (AH) and open quotient (OQ) are correlated with an increase in the perception of breathiness in vowels [Klatt and Klatt, J. Acoust. Soc. Am. **87**, 820–857 (1990)]. However, a system based on psychoacoustic loudness models has been shown to predict the level of breathiness in vowels to a greater extent than AH and OQ themselves [Shrivastav and Sapienza, J. Acoust. Soc. Am. **114**, 2217–2224 (2003)]. The goal of this experiment was to verify the significance of AH and OQ in the perception of breathiness and to determine how each of these influences the output of the loudness model, individually and in combination. Ten vowels, five male and five female, were synthesized using a Klatt synthesizer. Each vowel was used to generate three continua varying in terms of their OQ and/or AH. Ten listeners rated breathiness for each continuum using a magnitude estimation task. Results show that normalized partial loudness as well as the loudness of aspiration noise predicted changes in breathiness resulting from an increase in AH. Increase in OQ resulted in very small changes in perceived breathiness, resulting in poor correlation with loudness measures. [Research supported by NIH/R21DC006690.]

3aSC13. Towards a probabilistic system for estimation of acoustic landmarks for speech recognition. Chiyoun Park and Janet Slifka (Speech Commun. Group, RLE, MIT, Cambridge, MA 02139, goodie@mit.edu)

Algorithms for consonant landmark detection, such as Liu [S. Liu, J. Acoust. Soc. Am. **100**, 3417–3430 (1996)], extract cues to specific types of abruptnesses in the acoustics. The abruptnesses indicate occurences of closure and release for obstruent and sonorant consonants, and burst release for stop consonants. In Liu's algorithm, fixed thresholds are used to filter out abruptnesses that are unlikely to be true landmarks. The resulting set of landmarks does not retain any information regarding these filtered-out instances. However, such information may be useful later in the lexical access process, especially given the range of contextual variation in the speech signal. In this work, the landmark detection process is reformulated as a probabilistic system. First, thresholds are lowered to include more candidates, and then a probability value is calculated for each candidate. An *N*-best search is used to pick the most likely sequences of obstruent landmarks based on the calculated probabilities. Experiments with 80 sentences from the TIMIT database detect corresponding landmarks within 40-ms windows of 96% of hand-labeled obstruent landmarks, 98% of burst-release landmarks, and 76% of sonorant landmarks. Applying 5-best search results in 9% deletion and 4% insertion rate. [Work supported by NIH DC02978.]

3aSC14. Evaluation of token-based acoustic measures for classification of irregular phonation in normal speech. Janet Slifka and Kushan Surana (Speech Commun. Group, Res. Lab. of Elec., MIT, Cambridge, MA 02139, slifka@speech.mit.edu)

Quantification of the acoustic characteristics of irregular phonation provides a foundation for automatic detection of regions of irregular phonation in continuous speech. Recent results for automatic classification of regions of phonation as either regular or irregular demonstrate classification rates greater than 90% (false positive $<10\%$) [K. Surana, M.Eng. thesis, MIT, Cambridge, MA 2006]. Similar acoustic cues may be useful in separating subtypes of irregular phonation. Two types of irregular phonation are examined: (1) regions characterized by reduced airflow, assumed to correspond to tightly adducted vocal folds with brief regions of separation, and (2) regions characterized by increased airflow, assumed to correspond to a spread or spreading vocal-fold configuration [J. Slifka, J.Voice (in press)]. Reduced-airflow tokens are extracted, using airflow, audio, and electroglottography signals, from utterance-medial locations, and increased-airflow tokens are all utterance final (20 tokens/speaker, 4 speakers). Surana's cue set was evaluated for the ability to separate these subtypes of irregular phonation. Preliminary results indicate that an energy difference measure (between tokens smoothed at 6 vs 16 ms) and normalized rms amplitude yield statistically separable populations. Limitations on the use of these cues are discussed including intra- and interspeaker variation and the effect of token duration. [Work supported by NIH DC02978.]

3aSC15. Effects of spectral slope on perceived breathiness in vowels. Mario A. Landera and Rahul Shrivastav (Dept. of Commun. Sci. and Disord., Univ. of Florida, P.O. Box 117420, Gainesville, FL 32611)

Previous studies have indicated that breathiness is correlated with changes in spectral slope as well as aspiration noise [Klatt & Klatt, "Analysis, synthesis, and perception of voice quality variations among female and male talkers," J. Acoust. Soc. Am. **87**, 820–857 (1990)]. In a recent study, Shrivastav and Pinero [Shrivastav & Pinero "Effect of aspiration noise and spectral slope on perceived breathiness in vowels," J. Acoust. Soc. Am. **117**, 2622 (2005)] observed that varying spectral slope resulted in minimal changes on the perceived breathiness for synthetic vowels. However, the stimuli tested in this experiment included a relatively narrow range of spectral slope variation. The goal of the present experiment was to verify the role of spectral slope on the perception of breathiness by testing stimuli that had a wider range of variation in spec-

tral slope. Ten voices (5 male and 5 female) were synthesized using a Klatt synthesizer. Each of these was manipulated to generate two continua varying in their spectral slope from −3 to −30 dB/octave. One continuum had a constant cutoff frequency of 500 Hz, while the other continuum had a cutoff frequency between the second harmonic (H2) and the third harmonic (H3). Ten listeners judged the degree of breathiness using a 7-point rating scale. Preliminary results suggest that spectral slope has minimal effect on the perception of breathiness in synthetic vowels. [Research supported by NIH/R21 DC006690.]

3aSC16. Perceptual judgments of breathy voice quality using rating scale, magnitude estimation, and matching tasks. Sona Patel, Rahul Shrivastav (Dept. of Commun. Sci. and Disord., Univ. of Florida, Gainesville FL 32611), and David A. Eddins (Univ. of Rochester, Rochester, NY)

Experiments to study voice quality have typically used rating scales to obtain listener judgments. Recent research has questioned the validity of this data due to poor agreement between listeners [Kreiman *et al.*, J. Acoust. Soc. Am. **87**, 820–857 (1993)]. However, Shrivastav *et al.*, J. Acoust. Soc. Am. **117**, 2622 (2005) showed that such variability was partly related to the experimental methodology and could be minimized by multiple presentations of each stimulus to each listener. The nature of this averaged data, whether ordinal or interval, needs to be determined since it is necessary to develop appropriate perceptual scales for voice quality. The present experiment used three different psychophysical methods to obtain perceptual estimates of voice quality. These include a rating scale (with single and multiple presentations of stimuli to each listener), a direct magnitude estimation task, and a matching task. The experiment sought to determine if these three methods provided equivalent information. Perceptual judgments of breathiness were obtained for ten synthetic vowel continua that varied in terms of their aspiration noise, open quotient, or both. Preliminary results show that perceptual judgments using the magnitude estimation task and rating scale task (with multiple presentations of each stimulus) give very similar information. Results of the matching task will also be discussed. [Research supported by NIH/R21DC006690.]

3aSC17. Acoustic source measures for documenting outcomes of combined modality treatment of adductor spasmodic dysphonia. Erin Silverman, Rahul Shrivastav, and Christine Sapienza (Dept. of Commun. Sci. and Disord., Univ. of Florida, 335 Dauer Hall, Gainesville, FL 32608, ejpear@hotmail.com)

Spasmodic dysphonia (SD) is a voice disorder of neurogenic origin, wherein one or more intrinsic laryngeal muscles exhibit irregular and uncontrollable spasms. These spasms interfere with the production of perceptually normal voice. This paper presents a prospective, randomized, and placebo-controlled study to examine the effects of phonatory retraining (voice therapy) following Botox injections for ADSD. Thirty subjects were randomly assigned to 1 of 3 experimental groups: Botox only, Botox plus voice therapy, and Botox plus sham therapy. The sham therapy group was included in order to examine nonspecific treatment effects which may emerge as a result of close patient-therapist interaction during voice therapy for ADSD. Dependent variables of interest include acoustic source measures as well as voice-related quality of life, subject self-rating of voice, and duration of benefit between initial and repeat Botox injections. Source measures were typed according to National Center for Voice and Speech and signal typed into type 1, 2, and 3 signals. Voice breaks and frequency shifts were also measured. Preliminary results indicate that the combined modality treatment of voice therapy plus Botox has the more significant positive effect on source measures with trend toward more normal phonation or type 1 signal.

3aSC18. Minimizing occlusion: An evaluation of open-fit versus deep-canal fit hearing aids. Kristin A. Vasil and Kathleen M. Cienkowski (Dept. of Commun. Sci., Univ. of Connecticut, 850 Bolton Rd., Storrs, CT 06269, kristin.vasil@uconn.edu)

Individuals with good low-frequency hearing and poor high-frequency hearing may complain that when wearing hearing aids, their voice sounds boomy or hollow [B. C. Grover and M. C. Martin, Audiology **18**, 335–350 (1979)]. This is known as the occlusion effect. This effect occurs due to an improvement of bone-conduction responses when the ear canal is covered or blocked [D. P. Goldstein and C. S. Hayes, J. Speech Hear. Res. **8**, 137–148 (1965)]. The purpose of this study was to determine the degree of measured and self-rated occlusion for hearing aids that attempt to minimize occlusion by utilizing open-fit or deep-canal fit designs. Measured occlusion was calculated from aided and unaided real ear responses obtained while subjects vocalized [i]. Self-ratings were acquired using an occlusion effect scale. Results showed that open-fit and deep-canal fit hearing aids differ in degree of measured and self-rated occlusion. Hearing aids with open-canal characteristics had less measured occlusion, according to real ear measures, than the deep-canal fit device. Self-ratings of occlusion were correlated with objective real ear measures. For deep-fitting devices, optimum insertion depth had to be reached in order for maximum occlusion reduction to be achieved. [Work supported by a grant from Vivatone LLC.]

3aSC19. Acoustical differences in mothers' speech to children with cochlear implants versus normal-hearing children. Rose Bradley (Commun. Disord., Butler Univ., 4600 Sunset Ave., Indianapolis, IN 46208-3485), Tonya R. Bergeson (Indiana Univ. Med. School, Indianapolis, IN 46202), and Carolyn Richie (Butler Univ., Indianapolis, IN 46208-3485)

Infant-directed speech includes higher pitch overall and more exaggerated pitch contours compared to adult-directed speech. Clear speech is characterized by increased duration and expanded vowel space compared to conversational speech. This study investigated the differences between mothers' speech to children with cochlear implants versus normal-hearing children in terms of acoustic characteristics associated with infant-directed speech and clear speech. Ten mothers of children with cochlear implants, 12- months postimplantation, and 25 mothers of normal-hearing, 12-month-old children were recorded during a 5-min play session between mother and child. Pitch range, vowel duration, and vowel space in mothers' speech to children with cochlear implants and normal-hearing children were examined. Results are discussed in terms of differences between groups depending upon the hearing status of the child, and in terms of the acoustic characteristics of infant-directed speech and clear speech directed toward hearing-impaired listeners. [Work supported by NIH-NIDCD Training Grant T32DC00012 to Indiana University and NIH-NIDCD Research Grant R21DC06682 to the Indiana University School of Medicine, HUG grant Butler University.]

3aSC20. Sentence comprehension when formant transitions are present or absent by normal-hearing and hearing-impaired listeners. Jae Hee Lee and Diane Kewley-Port (Dept. of Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405)

Burkle et al. [''Contribution of consonant versus vowel information to sentence intelligibility by normal and hearing-impaired listeners,'' J. Acoust. Soc. Am. **115**, 2601 (2004)] reported that young normal-hearing (YNH) and elderly hearing-impaired (EHI) listeners recognized sentences better with only vowels compared to only consonants in a noise replacement paradigm. Using the same paradigm, this experiment examines whether the 2:1 benefit was due to the type of information presented in whole segments or to the proportion of total sentence duration. Forty-two sentences were processed to present only steady-state or dynamic transition information, rather than whole segmental information. YNH and EHI listened to sentences with 50% and 70% proportion of total sentence du-

ration, and the number of words that listeners correctly repeated in sentences was scored. There was no effect of processing conditions. For sentences with 50% and 70% proportions, YNH recognized 60% and 84% of the words across conditions, while EHI recognized only 16% and 45%. The benefit ratio for the 70% proportion compared to 50% was 0.4 for YNH and 3.7 for EHI. YNH improved linearly with increases in proportional duration regardless of the type of information presented. EHI improved with proportional duration, but less systematically, and were more affected by the type of information. [Supported by NIHDCD-02229.]

3aSC21. Infant's perception of speech in noise: Effect of the number of background talkers. Rochelle S. Newman (Univ. of Maryland, 0100 Lefrak Hall, College Park, MD 20742, rnewman@hesp.umd.edu)

A number of recent studies have investigated infants' abilities to hear speech in noise [Newman & Jusczyk, ''The cocktail party effect in infants,'' Percep. Psychophs. **58**, 1145–1156 (1996); Newman, R. S., ''The cocktail party effect in infants revisited: Listening to one's name in noise,'' Develop. Psychol. **41**, 352–362 (2005); Barker & Newman, ''Listen to your mother! The role of talker familiarity in infant streaming,'' Cognition, **94**, B45–B53 (2004); Hollich, *et al.*, ''Infants' use of synchronized visual information to seperate streams of speech,'' Child Develop. **76**, 598–613 (2005)]. In the current study, we examine how the type of background noise influences infants' ability to understand speech. Infants aged 5 months heard a talker repeat either their own name or another infant's name in the presence of one of 3 types of background noise: multitalker babble, a single background talker, or a single talker reversed in time. With multitalker babble, infants could recognize their name (shown by longer listening to own-name than other-name test trials) only when the target speech was at least 10 dB more intense than the background. However, even at this high SNR, infants fail to recognize their name when the background consists of a single talker. This difficulty is not the result of semantic information or speechlike properties from the single talker; infants likewise fail when the single talker is temporally reversed. Rather, infants appear to be distracted by signals containing the time-varying amplitude patterns of a human voice, and do not appear to benefit from the dips in noise amplitude that occur with a single voice.

3aSC22. Acoustics of clear speech from children with normal hearing and cochlear implants. Andrew J. Lotto (Univ. of Texas at Austin, 1 University Ave. A8000, Austin, TX 78712-0187, andrew@mail.cps.utexas.edu), Dana L. Ide-Helvie, Elizabeth A. McCleary, and Maureen B. Higgins (Boys Town Natl. Res. Hospital, Omaha, NE 68131)

It is common among clinicians to ask children to produce their best speech during intervention. However, it is unclear whether children know how to respond to these directions and whether any contingent changes in their production actually result in better speech. Normal and best speech for children with normal hearing (NH) and cochlear implants (CI) were compared on a variety of acoustic measures. The children (7 to 14 years of age) were asked to read ten simple sentences to train up a fictional automatic speech recognizer for children. They subsequently produced the same sentences with their best and then very best, very clearest speech (ostensibly to test the recognizer). Sentence, pause, and vowel duration were calculated for all sentences as well as vowel intensity and fundamental frequency. Additionally, phonetic distinctiveness was evaluated through vowel space size and voice onset time differences between voiced and voiceless stops. NH children demonstrated patterns of best speech that resemble adult clear speech productions. CI children's speech resembled NH best speech in all elicitation conditions, except that they slowed (their already slower) speaking rate for best speech. The results indicate that clear speech can be produced by children. [Work supported by NIH.]

3aSC23. Vowel production with and without auditory feedback in children with cochlear implants. Sneha V. Bharadwaj and Amanda G. Graves (Callier Ctr. for Commun. Disord., Univ. of Texas at Dallas, 811 Synergy Park Blvd., Richardson, TX 75080, snehab@utdallas.edu)

The effects of auditory feedback on vowel formant frequencies were investigated in the speech produced by three early-implanted (received cochlear implants before the age of 3 years) and three late-implanted children (after 5 years). The syllables /heed/, /hid/, /had/, /whod/, /hood/, and /hod/ were produced in a carrier sentence 12 times, each in both implant processor ON (auditory feedback present) and OFF (feedback absent) conditions. Comparisons of the vowel formant frequencies in processor ON versus OFF conditions revealed primarily second formant frequency ($F2$) shifts for a majority of the vowels, while showing minimal changes in the first formant frequencies ($F1$). In addition, a majority of the $F2$ shifts was towards the middle of the vowel space, suggesting centralization of vowels in the absence of auditory feedback. Further, most of the formant frequency changes were present in the vowels produced by late- compared to early-implanted children. These findings suggest that the late-implanted children may rely on auditory feedback to a greater extent than early-implanted children for speech production. Implications of the short-term effects of auditory feedback on speech production will be discussed in reference to the feedback and feed-forward models for speech production. [Work supported by NIH/NIDCD R03DC007052-01.]

3aSC24. Normalizing pitch variability in intoxicated speech. Ryan Hanke and Thomas Purnell (Dept. of Linguist., Univ. of Wisconsin, Madison, 1168 Van Hise, 1220 Linden Dr., Madison, WI 53706)

Intoxicated speech studies have shown mixed results with respect to prosodic characteristics. Both an overall $F0$ rise [Hollien *et al.*, J. Acoust. Soc. Am. **110**, 3198–3206 (2001)] and $F0$ lowering [Johnson *et al.*, Phonetica **47**, 215–237 (1990)] have been observed under intoxication. These conflicting findings may be due to increased $F0$ fluctuations at various levels of intoxication and use of inconsistent prosodic domains, such as averaging over entire sentences or utterances. If phonetic analysis takes into account prosodic boundaries, then models will account for appropriate prosodic rises and falls [Taylor, J. Acoust. Soc. Am **107**, 1697–1714 (2000)]. This paper reports an analysis of recordings of both intoxicated and control subjects. Speech samples are analyzed at sober and three levels of intoxication. Of particular interest are the prosodic patterns at the often unreported descending limb of intoxication, which displays the widest range of variability in behavior. Use of $F0$ parameter extraction, stylization, and rotation methods over appropriate prosodic domains factors out spurious variation at different intoxication levels. Evaluation of this normalization procedure is reported with respect to both within- and across-subject variation. Implications for the analysis of normal, intoxicated, and disordered speech are discussed.

3aSP1. Overview of signal processing in uncertain and random environments. Leon H. Sibul (Appl. Res. Lab. and Grad. Program in Acoust., Penn State Univ., P.O. Box 30, State College, PA, 16804, lhs2@psu.edu)

This paper is an overview of optimum and/or robust signal-processing approaches for detecting signals in random and uncertain propagation and interference environments, a topic that is intertwined with statistical modeling of the medium and signals. The classical approach to processing of signals that have propagated through randomly fluctuating media is based on the concepts of randomly time-varying impulse responses, spreading functions, and scattering functions. This approach uses second-order statistics and gives insight into performance of active sonar. Implementation of maximum likelihood (ML) detectors for signals that have propagated through random environments requires knowledge of the probability density functions (pdf's) of the random signal and noise parameters. Random signal parameters that are typically affected by medium randomness are amplitude, phase, and arrival time; pulse and Doppler spread; arrival angle bias and spread. Signal pdf's can be derived from ocean acoustic models using the maximum entropy (ME) principle, which exploits what is known but is maximally noncommittal of what is uncertain. The ME method can be used to generate densities that belong to the exponential class, and for this class, ML detectors can be implemented as an estimator-correlator and estimator-noise canceler structure. 3aSP2. Bayesian geoacoustic inversion of time-averaged horizontal-array data. Stan E. Dosso (Univ. of Victoria, Victoria, BC V8W 3P6 Canada) and Dag Tollefsen (Norwegian Defence Res. Establishment, 3191 Horten, Norway)

This paper considers quantifying data errors in Bayesian geoacoustic inversion applied to time-averaged data. Cross-spectral density matrices are formed by averaging spectra from a sequence of time-series segments (data snapshots). Error estimation for snapshot-averaged data has typically assumed either that averaging reduces errors as if they are fully independent between snapshots (an optimistic assumption), or that averaging does not reduce errors at all (a pessimistic assumption). Data errors are quantified here assuming that averaging reduces measurement error (dominated by ambient noise, which can be reasonably assumed independent), but does not reduce theory (modeling) error. This provides a physically reasonable intermediate result between the optimistic and pessimistic assumptions. Bayesian inversion is applied to data collected by FFI with a bottom-mounted horizontal array at a shallow-water site in the Barents Sea. Supporting geophysical measurements (seismic reflection and refraction, bottom-penetrating sonar, gravity core) provide independent information on seabed properties. A towed acoustic source transmitted multiple low-frequency tones at levels comparable to those of a merchant ship. Inversion results in the form of marginal posterior probability distributions are compared for the different approaches to data error estimation, and for data collected for several source ranges and bearings.

9:30

3aSP3. Use of prior information in acoustic inference. Kevin H. Knuth (Dept. of Phys., Univ. at Albany, Albany, NY 12222, kknuth@albany.edu)

Often in scientific and engineering applications, we possess prior information about the specific problem under investigation. In acoustics, this prior information may consist of knowledge about the design and arrangement of our detectors, the behavior of the sound sources, and the laws of physics describing sound propagation through an intervening medium. In this talk I explore the use of prior information for use in Bayesian inference in acoustic applications. This prior information can be either encoded in the signal model, which is represented in the Bayesian formulation by the likelihood function, or in the prior probabilities, which weight the particular values of the signal model parameters. I give examples of the use of such prior information by focusing on the specific problems of source separation and localization. By choosing to focus on the appropriate model parameters one can change a source separation problem into a source localization problem and vice versa, thus changing the very nature of the acoustic inference.

9:50

3aSP4. Bayesian model comparison and selection in energy decay analysis of acoustically coupled spaces. Tomislav Jasa and Ning Xiang (Grad. Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst. Troy. NY 12180)

The use of Bayesian inference in problems of parameter estimation from noisy data and in uncertain environments has been well discussed in the acoustical signal processing literature. In many acoustical problems where it is uncertain which suitable model among a set of competing ones should be used, the model comparison and selection become crucial prior to the actual parameter estimation. However, tools for model selection in Bayesian inference have received less attention. In problems of model comparison and selection, the Bayesian methodology is most different from orthodox statistical methods. We present several methods for model comparison and selection from a Bayesian viewpoint and demonstrate their application to the problem of estimating the number of decay rates present in acoustically coupled spaces.

3aSP5. Applications of Markov chain Monte Carlo methods in ocean acoustics. David Battle (MIT Ctr. for Ocean Eng., 77 Massachusetts Ave., Cambridge, MA 02139, dbattle@mit.edu)

Markov chain Monte Carlo (MCMC) methods have recently been applied to ocean-acoustic parameter estimation problems, as well as to model selection, wherein different parametrizations can be compared to assess which model most efficiently describes acoustic field measurements at a given signal-to-noise ratio. This talk will deal with some ocean-acoustic applications of Monte Carlo parameter estimation, including approaches to calculating Bayesian evidence integrals for model selection. The talk will conclude with a discussion of known defects in algorithms currently available and some possible future directions for algorithm development.

10:45

3aSP6. Optimal source localization in the presence of interfering sources. Zoi-Heleni Michalopoulou (Dept. of Mathematical Sci., New Jersey Inst. of Technol., Newark, NJ 07102, michalop@njit.edu)

Source localization in shallow-water ocean environments is hindered by the presence of loud interfering sound sources. To remediate these nuisance sources, one needs to back out the true signal from the received mixed acoustic field by estimating a most likely interference scheme. In this work the focus is on resolving problems introduced by an unknown number of interfering signal sources. A statistical model for the sensed acoustic field is estimated using Gibbs sampling in which one obtains through iteration an approximation to the full joint posterior probability description of the model and data. From this joint probability description, the impact of canceling undesirable field components is readily seen on the estimated uncertainty that characterizes the localization process. [Work supported by ONR.]

3aSP7. Using the maximum entropy method to estimate probability density functions for oceanographic and acoustic parameters. H. John Camin, R. Lee Culver, Leon H. Sibul, Jeffrey A. Ballard, and Colin W. Jemmott (Appl. Res. Lab. and Grad. Program in Acoust., P.O. Box 30, State College, PA 16804)

The maximum entropy (MaxEnt) method offers a powerful means of estimating the probability density functions (pdf's) of measured data. Traditionally, pdf's have been estimated by fitting data to particular distributions (e.g., Gaussian, log-normal, Rayleigh, chi-squared, etc.). This approach can lead to misleading results, especially if the data are highly skewed or kurtotic. First published in 1957 by Jaynes [E. T. Jaynes, Phys. Rev., **106**, 620–630 (1957)], MaxEnt has gained wide use in recent years. The method uses Lagrangian multipliers to maximize the *entropy*, a measure of uncertainty, subject to specified constraints. The result is a pdf that Jaynes describes as being the ''least biased estimate possible on the given information; i.e., it is maximally noncommittal with regard to missing information.'' In other words, all possibilities under the given constraints are considered equally. This method is particularly useful in determining prior pdf's based on limited measurements. MaxEnt pdf's, which belong in the exponential class of distributions, can also be used to derive optimum processors in the maximum likelihood sense. This talk will discuss the theory and implementation of the MaxEnt method and emphasize its utility for modeling acoustic propagation in uncertain environments. [Work supported by The Undersea Signal Processing Program, Office of Naval Research.]

3aUW1. Polynomial chaos expansions for coupled mode amplitude and phase uncertainty in the presence of oceanographic uncertainty. Kevin D. LePage (Naval Res. Lab., Code 7144, 4555 Overlook Ave. SW, Washington, DC 20375)

Polynomial chaos (PC) techniques have recently been introduced to the field of underwater acoustics for modeling the nonlinear transfer of probabilistic measures of the propagation environment into measures of acoustic propagation uncertainty [Finette, J. Acoust. Soc. Am. **117**, 997–1000 (2005)]. Recently we have proposed and implemented a PC method for modeling this process for coupled mode propagation through internal waves (IWs) [LePage, J. Acoust. Soc. Am. **118**, 1903–1904 (2005)]. While showing promise, the approach was implemented for a single empirical orthogonal function (EOF) component of the IW field only and was derived for small PC coefficients. In this paper the restriction of small coefficients is removed for the first two terms of the PC expansion, and results for uncertainty caused by more than one uncorrelated EOF component are also presented. [Work supported by ONR.]

7:55

3aUW2. Stochastic differential equation analysis for ocean acoustic energy scattering by internal waves. Andrey K. Morozov (Woods Hole Oceanograph. Inst., Woods Hole, MA, 02543) and John A. Colosi (Naval Postgrad. School, Monterey, CA 93943)

Stochastic coupled mode theory is used to study acoustical scattering of a narrow-angle, low-frequency acoustical beam. Random index of refraction perturbation fields are described using the Garrett-Munk internal wave spectrum. The stochastic differential equations for the first- and second-order statistical moments of the acoustical field are derived using the Markov approach similar to Dozier, Tappert, and Chernov theories. The main objective of the research is to account for cross-mode correlations and to show that the method can be used for a calculation of the detailed structure of the mean acoustic field intensity distribution. For this purpose a narrow finite-frequency beam was taken as an example, and the intensity of the scattering field was calculated as a function of frequency and sound source depth. The coefficients of the matrix differential equation were obtained analytically, and an efficient numerical computation was obtained. Comparisons to Monte Carlo simulation show that the method can be used for detailed statistical sound field analysis in long-range propagation.

8:10

3aUW3. Mean, variance, and temporal coherence of the 3D field forward propagated through random internal waves in deep-ocean waveguides. Tianrun Chen (MIT, 77 Massachusetts Ave., Cambridge, MA 02139), Purnima Ratilal (Northeastern Univ., Boston, MA 02115), and Nicholas Makris (MIT, Cambridge, MA 02139)

An analytical expression for the temporal coherence of an acoustic signal propagated through a 3D random internal-wave field in a deep-ocean waveguide is derived. The modeled coherence time scale of the acoustic fluctuations at 3000-km range is on the order of 10 min and matches the ATOC experimental measurement. It is found that the 3D scattering effects on the forward field become pronounced when the Fresnel width exceeds the cross-range coherence length of the internal-wave field. The depth-integrated intensity losses due to internal waves first increase then decrease as frequency decreases from 75 to 10 Hz. These results are derived by applying a general modal solution for the statistical moments of an acoustic field propagating through 3D random inhomogeneities [Ratilal and Makris, ''Mean and covariance of the forward field propagated through a stratified ocean waveguide with three-dimensional random inhomogeneities,'' J. Acoust. Soc. Am. **118**, 3532–3559 (2005)] to the acoustic propagation through a random internal-wave field. The mean and variance of the forward field are expressed in terms of the stochastic moments of the inhomogeneous medium's scatter function density. This is derived by applying the Rayleigh-Born approximation to Green's theorem in terms of the medium's compressibility and density fluctuations, which are related to the displacement of internal waves. The statistical properties of the displacement of internal waves are formulated with the Garret-Munk spectrum.

8:25

3aUW4. The vertical structure of shadow-zone arrivals at long range in the ocean. Lora J. Van Uffelen, Peter F. Worcester, Matthew A. Dzieciuch, Daniel L. Rudnick, Bruce D. Cornuelle, and Walter H. Munk (Scripps Inst. of Oceanogr., Univ. of California at San Diego, 9500 Gilman Dr., Mail Code 0238, La Jolla, CA 92093, lvanuffe@ucsd.edu)

Multimegameter-range acoustic data obtained by bottom-mounted SOSUS receivers show significant acoustic energy penetrating several hundred meters into the geometric shadow zones below cusps in the predicted acoustic time fronts, much further than can be accounted for by diffraction [Dushaw *et al.*, IEEE J. Oceanic Eng. **24**, 202–214 (1999)]. Acoustic data from two vertical line array receivers deployed in close proximity in the North Pacific Ocean, together virtually spanning the water column, show similar shadow-zone arrivals for transmissions from broadband 250-Hz sources moored at the sound-channel axis (750 m) and at surface conjugate depth (3000 m) at ranges of 500 and 1000 km. The vertical structure of the receptions will be compared to parabolic equation propagation simulations for sound-speed fields constructed from high-resolution underway conductivity-temperature-depth (UCTD) data in the upper 400 m, widely spaced deep CTD casts, and climatological data. Predictions will be made (i) for the observed field; (ii) for a smoothed field, and (iii) for fields that include sound-speed fines structure due to density variations (internal waves) or due to density-compensated sound-speed variations (spice).

8:40

3aUW5. Propagation in highly range-dependent shallow-water waveguides with elastic sediments and beach interactions. Jon M. Collis, William L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180, collisj@rpi.edu), and Michael D. Collins (Naval Res. Lab., Washington, DC 20375)

Accurate and efficient prediction of propagation over realistic models of elastic sediments has been achieved recently using parabolic equations. A major advance is the variable rotated parabolic equation solution [Outing *et al.*, J. Acoust. Soc. Am. **115**, 2579 (2004)], which allows treatment of variable bathymetry. The bathymetry is modeled as a series of constant slopes, and within each region the parabolic equation is solved in a coor-

dinate system aligned with the interface. This approach has been benchmarked against analytic solutions and laboratory data. The variable rotated parabolic equation has been extended recently to solve problems involving variable topography (when the elastic sediment rises above the surface of the ocean). For these problems the surface boundary is modeled by a series of constant slopes. In this presentation we show how the transition from air-water to air-sediment surface boundary conditions, such as in beach environments, can be handled to high accuracy. In addition, an improved treatment of the boundary conditions at the air-sediment interface is described. Finally, procedures for handling elastic sediment interfaces of nonconstant thickness, along with range-dependent bathymetry, are developed and benchmarked. [Work supported by the Office of Naval Research.]

8:55

3aUW6. Effect of nonlinear internal waves on midfrequency acoustic propagation on the continental shelf. Frank S. Henyey, Dajun Tang, Kevin L. Williams, Ren-Chieh Lien (Appl. Phys. Lab., Univ of Washington, 1013 NE 40th St., Seattle, WA 92105), Kyle M. Becker, R. Lee Culver, Paul C. Gabel, Joy E. Lyons (The Penn State Univ., State College, PA 16804), and Tom C. Weber (The Penn State Univ., State College, PA 16804)

Packets of nonlinear internal waves and strong sound-speed variability due to neutrally buoyant intrusions were measured in detail using a towed conductivity, salinity, pressure (CTD) chain. The measurements were taken in October 2005, on the continental shelf south of Rhode Island. Acoustic propagation through the measured sound-speed field is modeled. The waves in October are qualitatively different from the more familiar summertime nonlinear waves. Further measurements using the CTD chain will be made in the summer of 2006, in association with acoustic propagation measurements.

9:10

3aUW7. Downslope propagation of adiabatic and stepwise coupled modes. Richard B. Evans (Scientific Applications International Corp., 23 Clara Dr., Mystic, CT 06355, richard.b.evans@saic.com)

Downslope propagation, from a shallow source, redirects steeply propagating modes toward the horizontal. Slope conversion is of particular interest for noise sources near the shelf break. Noise modeling procedures may rely on adiabatic modes for efficiency, but their ability to accurately handle downslope conversion is not well tested. The adiabatic approximation is derived from continuously coupled modes by assuming the coupling matrices are the identity matrix and by using an asymptotic approximation to solve the uncoupled ordinary differential equations for the modal coefficients. A simpler interpretation of the twofold adiabatic approximation is obtained in the context of stepwise coupled modes when the continuous differential equations are replaced by a single matrix recursion. The stepwise interpretation of the adiabatic approximation is used to evaluate its validity, for a shelf-break environment, in a side-by-side comparison with stepwise coupled modes. The adiabatic approximation partially accounts for downslope conversion, but vertical directivity, computed in with adiabatic modes and stepwise coupled modes, is not comparable. Parabolic equation calculations, which corroborate the stepwise coupled mode results, provide a practical alternative to adiabatic modes for ambient noise modeling in shelf-break environments.

9:25

3aUW8. Regions where transient signals are influenced between a source and receiver. John Spiesberger (Dept. of Earth and Environ. Sci., Univ. of Pennsylvania, 240 S. 33rd St., Philadelphia, PA 19104-6316, johnsr@sas.upenn.edu)

At infinite frequency, a medium only influences the waveform of a received signal emitted from a source along one or more infinitesimally thin rays. For transient signals at finite frequencies, an exact method is developed to compute the regions in a medium that significantly influence the received signal for any specified window of signal travel time. Results are (1) in homogeneous media, a significant portion of the signal originates from waves that traverse paths that are approximately integer and half-integer numbers of cycles greater than the straight path between source and receiver. Called ''constructive and destructive paths of influence,'' they do not obey Fermat's principle of path stationarity. (2) For reflection from a flat interface in a homogeneous medium, the received signal is significantly influenced by constructive and destructive paths of influence whose angles of incidence and reflection differ. (3) Near 100 Hz in an oceanic waveguide, the region of influence markedly departs from a ray. Near upper turning points, the influential region is flat for O(10) km instead of O(1) km for a ray. (4) The first Fresnel zone is an inappropriate scale to characterize the region of influence for transient signals near a steep ray in inhomogeneous media.

9:40

3aUW9. A near-field solution for underwater acoustics; a finite-difference solution to the Helmholtz equation. Catherine de Groot-Hedlin (Scripps Inst. of Oceanogr., 9500 Gilman Dr., UCSD, La Jolla, CA 92093)

A finite-difference method is derived for the frequency-domain acoustic wave equation as expressed in cylindrical coordinates. L'Hopital's rule is used to transform the singularity at $r=0$ into a determinate form. The resulting finite difference frequency domain (FDFD) algorithm can be used to solve for sound intensities in complex models that may include high material contrasts and arbitrary bathymetry. Solutions obtained using this method are presented and compared to wide-angle parabolic equation solutions and analytic solutions, where available. Four models are examined: a uniform half-space, a waveguide with a rigid bottom boundary, an upslope wedge with a source in the ocean column, and a downslope wedge with a source below the seafloor. Comparison with analytic results indicates that the FDFD method accurately solves for the acoustic wave-field at all propagation angles and is more accurate than the wide-angle parabolic equation method at low radial distances from the source. The FDFD method is more accurate in situations where high angle scattering occurs near the source.

10:10

3aUW10. Bistatic invariance principle for multi-static active geometries. Lisa Zurk, Jorge Quijano (Portland State Univ., 1900 SW Fourth Ave., Ste. 160-17, Portland OR 97207, zurkl@cecs.pdx.edu), and Dan Rouseff (Univ. of Washington, Seattle, Washington)

The invariance principle describes the spatial interference patterns resulting from the coherent addition of propagating normal modes in the ocean channel. The relationship simplifies propagation structure into a scalar invariant which is approximately unity for many shallow-water environments. For passive sonar geometries (i.e., source to receiver) this valuable relationship has been extensively explored and applied to the interpretation of passive lofargrams. In active bistatic geometries, a transmitted pulse travels over two distinct propagation pathways (i.e., source-to-target and target-to-receiver). Assuming a distributed network (i.e., long-range propagation), each of these paths in isolation would produce interference patterns as dictated by the invariance principle. However, for bistatic active applications, the received pulse is a product of both propagation paths and a target-dependent scattering matrix which introduces mode coupling. For broadband waveforms, the question arises as to whether there is an observable interference pattern for a moving source. In this presentation, a derivation of the bistatic invariance principle is presented and discussed. Simulation results for the predicted time-frequency structure in a shallow-water channel are presented for specific sensor geometries and choices of target scattering matrix. Implications for application to multi-static active target tracking are presented in a companion paper.

10:25

3aUW11. Effect of shelf break front on acoustic propagation. James H. Miller, Gopu R. Potty, Kristy A. Moore (Dept. of Ocean Eng., Univ. of Rhode Island, 217 Sheets Bldg., Narragansett Bay Campus, Narragansett, RI 02882), and James F. Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

The effect of a shelf break front on acoustic propagation is discussed in the context of the Shallow Water Experiment (SW-06) in the New Jersey Shelf. The primary effect is a horizontal analog to the classical horizontal Lloyd's mirror effect, produced by the fact that fronts can totally internally reflect sound incident upon them at low grazing angles. The direct and reflected modal rays add up to produce an interference pattern in range. It has been shown [Lynch *et al.*, ''Consideration of finescale oceanography and 3D acoustics effects for the ESME sound exposure models,'' IEEE JOE (in press)] based on simple calculations that this frontal effect has the potential to increase the maximum insonification level up to 6 dB. Noise measurements analyzed using the SWARM -95 data also provide some evidence to this effect. The present study explores this effect in more detail using a horizontal ray-vertical mode approach. Calculations were made using environmental parameters corresponding to the New Jersey Shelf area, where field measurements will be made in 2006 to explore this effect. [Work supported by Office of Naval Research.]

10:40

3aUW12. Shallow-water waveguide characterization using an autonomous underwater vehicle-towed hydrophone array. Jason D. Holmes, William M. Carey (Boston Univ., 110 Cummington St., Boston, MA 02215), and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Sound transmission results are reported for frequencies of 220, 415, 635, 823, 1031, and 1228 Hz in an iso-velocity waveguide 13 m deep with known bottom properties. The experiments were conducted in Nantucket Sound in proximity to the Lynch-Frisk (1982) experiment in an area surveyed prior to the experiments. A fixed source and an autonomous underwater vehicle six-element towed hydrophone array were used. The experimental track consisted of two 2–4-km straight legs with measurement of the bathymetry and currents performed by the vehicle. Transmission results show stable modal-multipath interference effects with predictable phase rate variations. Coherent processing using vehicle estimates of ground speed and position yields results close to theoretical expectations and indicates a constant depth stable tow was realized. Horizontal wavenumber spectra using coherent synthetic aperture Hankel transforms are presented and shown to be calculable and comparable to the previous work. The demonstration of this measurement capability provides for cost effective measurements of the sound field at sea.

10:55

3aUW13. Effect of wind-generated surface waves on vertical coherence of sound propagation in the East China Sea. Jie Yang, Ji-Xun Zhou, and Peter H. Rogers (School of Mech. Eng., Georgia Inst. of Technol., MS 209, Atlanta, GA 30339-0405, gte036y@mail.gatech.edu)

Literature has shown that wind-generated surface waves are an important factor in determining the spatial coherence of long-range sound propagation [Kuperman and Ingenito, J. Acoust. Soc. Am. **113**, 1178–1187 (1977); Zhou *et al.*, J. Acout. Soc. Am. **115**, 2550 (2004)]. During the ASIAEX in the East China Sea, wind speed and the rms waveheight were recorded between 29 May and 7 June along with acoustic measurements of broadband explosive sources. The rms surface waveheight varied between 0.1–0.6 m during the acoustic measurements. This paper analyzes the characteristics of vertical coherence of sound propagation under the influence of these surface waves. A model is built to explain observed characteristics of vertical coherence which incorporates coring analysis in the ASIAEX area. [Work supported by ONR.]

11:10

3aUW14. Propagation of modulated pulses in shallow water. Aijun Song, Mohsen Badiey, (Ocean Acoust. Lab., Univ. of Delaware, Newark, DE 19716), Boris Katsnelson, and Alexander Tshoidze (Voronezh State Univ., Voronezh 394006, Russia)

In this paper propagation of low-frequency pulses, carrying information in shallow water, is studied. Different types of information-carrying pulses are analyzed and compared. These include phase shift keying (PSK) signals, frequency shift keying (FSK) signals, and noncoherent signals with respect to their ability to information transfer. Numerical modeling of pulses propagation is carried out. Basic attention is paid to studying the influence of dispersive characteristics of a shallow water channel (boundary conditions, variation of properties along the track, internal waves, etc.) on the waveguide capacity for different types of pulses and frequencies. Complex space-frequency and time-frequency intensity fluctuations of a propagating signal allow us to consider shallow water as the unique information channel (medium). A model for numerical calculations is constructed on the basis of the SWARM95 experimental data. [Work was supported by ONR and RFBR.]

11:25

3aUW15. The effect of turbulence and acoustic waves on underwater acoustic propagation. Stefanie E. Wojcik, William W. Durgin, and Tatiana A. Andreeva (WPI, 100 Institute Rd., Worcester, MA 01609, stefanie@wpi.edu)

The primary objective of this study was to develop a predictive methodology for received signal variation as a function of ocean perturbations using a ray-based analysis of the effects of internal waves and ocean turbulence on underwater acoustic propagation. In the present formulation the eikonal equations are considered in the form of a second-order, nonlinear ordinary differential equation with harmonic excitation due to an internal wave. The harmonic excitation is taken imperfect, i.e., with a random phase modulation due to Gaussian white noise, accounting for both chaotic and stochastic behavior. Small scale and geostrophic turbulence are represented using the potential theory two-wave-number model for a vortex array. The focus is to numerically study the influence of these fluid velocity and sound speed fluctuations and the role of initial ray angle on underwater acoustic propagation to provide a realistic characterization of acoustic arrivals. Predicted arrival behavior is analyzed using ray trace, time-front, and phase plots for varying initial conditions. Regions of instability are identified using bifurcation and phase diagrams. This work leads to understanding how turbulence and internal waves affect sound transmission and utilizes the statistics of received signals to identify fluid mechanic phenomena that occurred along the sound channel.

11:40

3aUW16. Multiple frequency acoustic propagation through clusters of bubbles. Thomas C. Weber (Ctr. for Coastal and Ocean Mapping, Univ. of New Hampshire, 24 Colovos Rd., Durham, NH 03824), Anthony P. Lyons, and David L. Bradley (Penn State, State College, PA 16804)

A numerical study has been conducted in order to examine the effect of bubble clustering on acoustic propagation through bubble clouds. Commonly used effective medium theories make the assumption that the positions of bubbles are statistically independent from each other. It is plausible, however, that there are some scenarios in which this assumption does not apply. For example, bubbles may become preferentially concentrated or clustered as they cross fluid flow streamlines due to their density difference from that of the surrounding liquid. In order to help understand the acoustic implications of bubble clustering, propagation through two types of bubble clouds was investigated numerically. In the first type of bubble cloud the positions of the bubbles were statistically independent from each other. In the second type the bubbles were clustered. Both the average attenuation and the variance in the acoustic pressure amplitude were recorded at nine different frequencies for each type of bubble cloud. It was found that clustering has the effect of reducing the average attenu-

ation from that observed in the nonclustered bubble cloud while increasing the variance. This contrasting behavior suggests a method for detecting the presence of bubble clustering using multiple frequency acoustic propagation measurements.

11:55

3aUW17. Geometrical dispersion of broadband sound pulse in a three-dimensional shallow-water environment with a corrugated bottom. Frédéric Sturm (LMFA, UMR CNRS 5509, Ecole Centrale de Lyon, 36, avenue Guy de Collongue, FR-69 134 Ecully Cedex, France)

Numerical results of sound propagation in a three-dimensional oceanic waveguide with a sinusoidal (corrugated) bottom are reported. A broadband sound pulse with a center frequency of 25 Hz and a bandwith of 30 Hz is considered. This acoustic problem was studied by others considering a harmonic point source [M. D. Collins and S. A. Ching-Bing, J. Acoust. Soc. Am. **87**(3), 1104–1109 (1990)]. The numerical method used to solve the 4-D acoustic problem is based on a Fourier synthesis of frequency-domain solutions. The calculations in 3-D are carried out using the fully 3-D parabolic equation based model 3DWAPE. To analyze the acoustic problem, we follow closely the methodology used in previous works to investigate the 3-D ASA wedge and the 3-D Gaussian canyon [F. Sturm, J. Acoust. Soc. Am. **117**(3), 1058–1079 (2005)]. Results corresponding to a 25-Hz cw point source are first presented and compared with predictions by other models. Then, the acoustic problem is solved considering the broadband source pulse. The modal structure of the received signals on several distinct vertical arrays is analyzed and clearly exhibits mode arrivals of the propagating signal not predicted by pseudo-3-D or 2-D models.

WEDNESDAY MORNING, 7 JUNE 2006 PROVIDENCE BALLROOM I (WESTIN), 8:30 TO 10:00 A.M.

Meeting of Accredited Standards Committee (ASC) S2 Mechanical Vibration and Shock

R. J. Peppin, Chair S2
5012 Macon Road, Rockville, MD 20852

D. J. Evans, Vice Chair S2
National Institute of Standards and Technology (NIST), 100 Bureau Dr., Stop 8220, Gaithersburg, MD 20899

Accredited Standards Committee S2 on Mechanical Vibration and Shock. Working group chairs will report on the status of various shock and vibration standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAG for ISO/TC 108, Mechanical vibration and shock, and its five subcommittees, take note – that meeting will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 6 June 2006.

Scope of S2: Standards, specifications, methods of measurement and test, and terminology in the field of mechanical vibration and shock, and condition monitoring and diagnostics of machines, including the effects of exposure to mechanical vibration and shock on humans, including those aspects which pertain to biological safety, tolerance and comfort.

WEDNESDAY MORNING, 7 JUNE 2006 PROVIDENCE BALLROOM I (WESTIN), 10:30 A.M. TO 12:00 NOON

Meeting of Accredited Standards Committee (ASC) S3 Bioacoustics

R. F. Burkard, Chair S3
Hearing Research Lab., State Univ. of New York at Buffalo, 215 Parker Hall, Buffalo, NY 14214

C. A. Champlin, Vice Chair S3
Univ. of Texas, Dept. of Communication Sciences & Disorders, CMA 2-200, Austin, TX 78712

Accredited Standards Committee S3 on Bioacoustics. Working group chairs will report on the status of standards under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note – those meetings will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 6 June 2006.

Scope of S3: Standards, specifications, methods of measurement and test, and terminology in the fields of psychological and physiological acoustics, including aspects of general acoustics, which pertain to biological safety, tolerance and comfort.

Session 3pAA

Architectural Acoustics: Session in Honor of John Kopec

David L. Moyer, Chair
Riverbank Acoustical Labs., 1512 S. Batavia Ave., Geneva, IL 60134-3300

Chair's Introduction—1:00

Invited Papers

1:05

3pAA1. John Kopec and the papers of Wallace C. Sabine. Leo L. Beranek (975 Memorial Dr., Ste. 804, Cambridge, MA 02138, beranekleo@ieee.org)

In April 1975, the Illinois Institute of Technology called the author saying that some notebooks had been found that appeared to be those of Wallace Clement Sabine. It was thought previous to this find that Sabine had destroyed all of his notebooks and papers because none was found when Professor Theodore Lyman was collecting Sabine's papers for publication. Those notebooks were studied, a paper was published [J. Acoust. Soc. Am. **61**, 355–365 (1977)], and they were deposited in the Harvard University Archives. Imagine the surprise when John Kopec called in early 1979, saying that at another location at the Riverbank Acoustical Laboratory, a pile of folders that contained some of Sabine's consulting experiences had been discovered. John said that he had copied Sabine's faded pages into typescript, and he invited the author to join with him in studying them and perhaps publishing a paper jointly with him. Discussed here is our work together and our publication of the results [J. Acoust. Soc. Am. **69**, 367–382 (1981)]. Through this effort readers can judge Sabine's breadth of activity and his depth of understanding in the field of applied acoustics.

1:35

3pAA2. John W. Kopec and *The Sabines at Riverbank*. William Cavanaugh (Cavanaugh Tocci Assoc., Inc., 327F Boston Post Rd., Sudbury, MA 01776)

I first became acquainted with John Kopec at a meeting of the Greater Boston Chapter of ASA in the late 1970s. He told a delightful story of his discovery of papers of Wallace Sabine, long thought to be lost, at the IITRI Riverbank Acoustical Laboratories in Geneva, IL, where John had been an employee since 1961. John was working with Leo Beranek to have these papers donated to the Harvard Rare Books Library for safekeeping [L. L. Beranek, "The Notebooks of Wallace C. Sabine," J. Acoust. Soc. Am. **61**(3), (1977) L. L. Beranek and J. W. Kopec, "Wallace C. Sabine, acoustical consultant," J. Acoust. Soc. Am. **59**(1), (1981)]. I quickly learned that John had been collecting historical information on not only Wallace Sabine, but his cousin Paul Sabine, who was called upon to direct the laboratory in 1919 after Wallace's untimely death, and Paul's son Hale who also became director of the laboratory after Paul. It became obvious to all of us who heard John's tales of Riverbank that he had to put these into print. Hence, at the urging of his abundant friends and colleagues, the Acoustical Society published *The Sabines at Riverbank* in 1997. This book is John's legacy to all of us interested in the science of architectural acoustics and the part played by the Sabines at Riverbank.

Contributed Paper

2:05

3pAA3. John W. Kopec at Riverbank. David Moyer (Riverbank Acoust. Labs. 1512 Batavia Ave., Geneva, IL 60134)

John Kopec's tenure at Riverbank as manager, supervisor, and chief liaison engineer during an active time of architectural and noise control related testing by manufacturers as well as trade associations made for some interesting challenges and client interactions. The author hopes to collect material from a broad range of interested parties to contribute to both aspects. A brief review of some of the 20-plus publications and presentation attributed to Kopec will also be provided.

Session 3pAB

Animal Bioacoustics: Animal Psychophysics

Peter M. Scheifele, Chair
Univ. of Connecticut, Dept. of Animal Science, 850 Bolton Rd., Storrs, CT 06269-1085

3pAB1. Impaired frequency resolution in canaries with hereditary high-frequency hearing loss. Amanda Lauer, Robert Dooling (Dept. of Psych., Univ. of Maryland, College Park, MD 20742), and Marjorie Leek (Natl. Ctr. for Rehabilitative Auditory Res., Portland, OR 97207)

Belgian Waterslager canaries (BWS), bred for a distinct low-pitched song, have an inherited high-frequency hearing loss related to hair cell abnormalities. Many hair cells are missing or damaged, and many of the remaining hair cells have abnormal stereocilia bundles. To investigate how the hair cell abnormalities affect frequency tuning along the BWS basilar papilla, we measured psychophysical tuning curves (PTCs) in BWS and normal-hearing non-BWS canaries using operant conditioning procedures. Non-BWS canaries showed relatively symmetrical tuning curves that became more narrowly tuned with increasing center frequency. Despite near-normal hearing at low frequencies, PTCs in BWS were elevated for all center frequencies tested. The sharpness of tuning was normal in BWS for PTCs with a center frequency of 1000 Hz and broader than normal at higher frequencies. The shapes of the PTCs were abnormal in BWS, particularly at higher frequencies. The abnormal tuning properties in the BWS are consistent with changes in the impedance characteristics of the basilar papilla due to structural damage. [Work supported by NIH DC01372 and DC04664.]

1:15

3pAB2. Spatial release from aerial masking in a harbor seal. Marla M. Holt and Ronald J. Schusterman (UCSC Long Marine Lab., 100 Shaffer Rd., Santa Cruz, CA 95060)

Spatial release from masking (SRM) occurs when a signal and masker are spatially separated, resulting in improvement of signal detection relative to when they are spatially coincident. Harbor seals feed in the water but haul out on land for a variety of activities. There have been no SRM investigations conducted on harbor seals in air. In this study, SRM was measured at 1, 8, and 16 kHz in a harbor seal (*Phoca vitulina*) who had to detect an aerial tone in the presence of an octave band of white noise centered at the tone frequency. While the masker always occurred in front of the subject (0 deg), the tone occurred at 0, 45, or 90 deg in the horizontal plane. Absolute thresholds were also measured at these angles to account for differences in hearing sensitivity based on source azimuth. Current data show that the largest masking level differences (MLDs) of 7 dB occurred at 1 kHz when the signal was projected at 90 deg. MLDs reported here on an amphibious carnivore are larger than those measured under water, are consistent with measurements collected on terrestrial animals, and have important implications for noise effects on free-ranging animals.

1:30

3pAB3. A comparison of behavioral and auditory brainstem response measurements of absolute and masked auditory thresholds in three species of birds. Isabelle C. Noirot (Dept of Psyc., Univ. of Maryland, College Park, MD 20742, and Univ. of Liege, Bat B6c, 4000 Liege, Belgium, inoirot@psyc.umd.edu), Elizabeth F. Brittan-Powell, Robert J. Dooling, and Lindsay Montgomery (Univ. of Maryland, College Park, MD 20742)

Auditory brainstem responses (ABRs) were used to measure auditory thresholds for pure tone in quiet and in noise for three species of birds: budgerigars (*Melopsittacus undulatus*), canaries (*Serinus canarius*), and zebra finches (*Taeniopygia guttata*). ABRs were recorded in response to 5-ms pure tones at frequencies between 500 and 8000 Hz. Results showed that the shape of ABR audiograms generally paralleled the shape of behavioral audiograms but ABR thresholds were generally 20 to 40 dB higher than those obtained behaviorally. ABR thresholds in noise were also measured at frequencies between 1000 and 4000 Hz. Three different levels of broadband white noise were used and critical ratios (CR; signal-to-noise ratio at masked threshold) were calculated. In general, CRs were independent of the level of the masking noise, in good correspondence with behavioral data. While CRs across a wide variety of vertebrates show a 3-dB/octave increase, CRs in these birds were similar or better at 2860 Hz than 2000 Hz, and worse at 4000 Hz. To the extent that these relationships between behavioral and ABR thresholds are generalizable across species, ABR measurements can be used to calculate audiograms and CRs in species that cannot be tested behaviorally. [Work supported by DC00198, DC04664 to R.J.D.]

1:45

3pAB4. Comparative analyses of canine hearing using event-related potentials. Peter M. Scheifele, Michael Darre, Michelle G. Pinto, Frank E. Musiek (Univ. of Connecticut, Unit 4040, 3636 Horsebarn Hill Rd. Ext., Storrs, CT 06269-4040), and John Preece (NYU, New York, NY 10010)

The hearing of three dogs was tested using auditory brainstem response (ABR) and distortion product oto-acoustic emissions (DPOAE) tests. The three subject dogs included one with known normal hearing, one congenitally deaf dog, and one dog with presbycusis. ABRs were run using a 100-s click stimulus at a repetition rate of 19.7 Hz at 90, 60, and 40 dB nHL. Based on the combined analysis of ABR and DPOAE, differences in canine hearing of dogs with presbycusis and congenital (Waardenburg syndrome) are evident. These results continue to be compared with those of other dogs of known otology and audiology in an effort to develop canine norms for ABR and to readily detect these pathologies in companion animals to assist veterinarians in the diagnosis and treatment of hearing loss in dogs.

2:00

3pAB5. Auditory feedback of vocal production in budgerigars using earphones. Michael Osmanski and Robert Dooling (Dept. of Psych., Univ. of Maryland, Biol.-Psych. Bldg., College Park, MD, 20742, mosmanski@psyc.umd.edu)

There is considerable interest in understanding the mechanisms whereby auditory feedback (AF) enables a bird to learn and to produce a stable vocal repertoire. In the free field, budgerigars (*Melopsittacus undulatus*) show evidence of a Lombard effect, an increase in the intensity of their contact calls in the presence of background noise. They also adjust the frequency of their calls to compensate for pitch-altered AF. Here, we extend these findings using earphones to more precisely determine the role of AF in vocal production. Budgerigars were fitted with small head-mounted earphones and were trained to produce contact calls for food reinforcement in the presence of altered AF; alterations included noise and changes in call amplitude, frequency, and spectrotemporal structure (e.g., reversed calls). Results show that budgerigars produce compensatory changes to perturbations in AF. For example, these birds increase the amplitude of their vocal productions in the presence of noise (Lombard effect). They also reduce the level of vocal output when provided with amplified feedback of their own vocalizations. [Work supported by NIH Grant DC-00198 to R.J.D., NIH grant DC-04664 to R.J.D., and NIH Grant DC-006766 to MSO.]

WEDNESDAY AFTERNOON, 7 JUNE 2006 BALLROOM D, 1:30 TO 2:35 P.M.

Session 3pID

Interdisciplinary: Hot Topics in Acoustics

David R. Dowling, Chair
Univ. of Michigan, Dept. of Mechanical Eng., 2019 Automotive Lab. 2133, 1231 Beal Ave., Ann Arbor, MI 48109-2133

Chair's Introduction—1:30

Invited Papers

1:35

3pID1. Vector sensors—over 40 and still hot. Paul C. Hines (Defence R&D Canada-Atlantic, P.O. Box 1012, Dartmouth, NS, B2Y 3Z7, Canada, paul.hines@drdc-rddc.gc.ca)

Acoustic vector sensors and gradient arrays have been in use in underwater acoustics for more than 4 decades, so one may wonder why they are featured in a session entitled ''Hot Topics.'' The reason lies in the recent resurgence in their use. This, in turn, is due primarily to major advances in engineering and signal processing that have been applied to these devices. Historically, theoretical gains have been difficult to achieve with these sensors due to their susceptibility to uncorrelated noise. That is to say, the very process of making a localized measurement of the vector acoustic field lowers the signal-to-noise ratio, relative to a simple pressure measurement. However, with today's advances in design, manufacturing, and digital signal processing, high-quality performance can be achieved in a very small package size. Moreover, the current interest in these devices is not limited to underwater acoustic applications; rather, it extends across a number of technical areas within the acoustics community. This presentation will begin with a brief introduction to the theoretical foundation and history of these devices. Then, some current applications in both underwater and airborne acoustics will be highlighted.

1:55

3pID2. Extracting coherent information from cross correlations of random wave fields. Karim G. Sabra (Marine Phys. Lab, Scripps Inst. of Oceanogr., U.C. San Diego, 9500 Gilman Dr., La Jolla, CA 92093-0238, ksabra@mpl.ucsd.edu)

The random nature of noise and scattered fields tends to suggest limited utility. Indeed, seismic or acoustic fields from random sources or scatterers are often considered to be incoherent. Nevertheless, it has been shown that it is possible to extract information from random noise fields of a type that would typically be associated with a coherent process. An estimate of the Green's function (or impulse response) between two points can be obtained from the cross correlation of ambient noise recorded at these two points. Recent theoretical and experimental studies in ultrasonics, underwater acoustics, and seismology have investigated this technique in various environments and frequency ranges. These results provide a means for passive imaging using only the ambient noise field, without the use of active sources. The coherent wave-fronts emerge from a correlation process that accumulates contributions over time from noise sources whose propagation paths pass through both receivers. Results will be presented from experiments using ambient noise cross correlations for the following applications: (1) localization and synchronization of unconnected acoustic receivers; (2) passive tomography of the seismoacoustic environment; and (3) studies of marine and airborne structures embedded in turbulent flow.

2:15

3pID3. Demonstrations and experiments: The life-blood of acoustics education. Uwe J. Hansen (Dept. of Phys., Indiana State Univ., Terre Haute, IN 47809)

You hear: You forget; You see: You remember; You do: You understand. Acoustics represents a science discipline with very broad appeal. It is essential, both for the well being of the field, as well as the influence of science at large, to generate enthusiasm for science in general and acoustics in particular in our young people. Thus educational outreach is vital. The effectiveness of that

outreach is closely related to the direct involvement of the students. A number of examples of demonstrations and hands-on experiments will be shown. They include acoustic levitation, mode studies, Dan Russell's web site, and video animations of modal analysis studies in several musical instruments.

WEDNESDAY AFTERNOON, 7 JUNE 2006 ROOM 557, 1:00 TO 3:00 P.M.

Session 3pNS

Noise, Architectural Acoustics, and Speech Communication: Fifty Years of Speech Privacy II

Gregory C. Tocci, Chair
Cavanaugh Tocci Associates, 327F Boston Post Rd., Sudbury, MA 01776

Contributed Papers

1:00

3pNS1. Measurements of sound leaks or "hot spots" and their effect on the architectural speech security of closed rooms. Bradford N. Gover and John S. Bradley (Inst. for Res. in Construction, Natl. Res. Council, Ottawa, ON, K1A 0R6, Canada)

A new measurement procedure has been developed that accurately indicates the degree of speech security (speech privacy) of a closed office or meeting room. The procedure first determines the attenuation from an average sound-pressure field within a source room to single receiving points outside the room. These average-to-spot attenuations are used to predict transmitted speech levels outside of meeting rooms, which along with the background noise levels are used to derive a reliable indicator of the audibility or intelligibility of speech at the receiving points. A key aspect of the approach is that a localized weak spot in an otherwise highly insulating partition can be identified and assessed. Investigations were carried out as to the severity and detectability of different types of sound leaks intentionally introduced into an otherwise ''good'' wall separating two reverberation chambers. Steady-state and impulse response measurements of received pressure were made at a distance of 0.25 m from the wall. In addition, a highly directional beamforming microphone array was used in an effort to quickly locate the position of potential leaks. An overview of the measurement procedures will be presented, including discussion of the severity of several types of ''hot spots,'' such as holes, penetrations, and electrical boxes.

3pNS2. Speech privacy in design: A cost-privacy analysis. Tim Lavallee (LPES, Inc., 14053 Lawnes Creek Rd., Smithfield, VA 23430) and Kenneth Good (Acoust. Privacy Enterprises, LLC, Mount Joy, PA 17552)

With the development of new standards in the health care industry, design professionals will soon have additional construction criteria to ensure speech privacy in new facilities. There are currently sound transmission class (STC) ratings required for partitions in a healthcare setting outlined in the Guidelines for Design and Construction of Hospital and Healthcare Facilities. These currently implemented criteria have traditionally focused on patient personal privacy and not speech privacy. This effort will be a general analysis to determine the shortcomings of these standards with respect to speech privacy and a cost-privacy analysis for commonly used wall constructions. Wall constructions included in the analysis will be suitable for a healthcare setting. Commonly referenced published, modeled, and measured transmission loss across partitions will be shown. The privacy indices will be evaluated for each configuration. The talk will highlight that, in most cases, no extraordinary measures will be needed to ensure reasonable safeguards have been implemented.

3pNS3. The performance of a newly developed mobile hands-free context-aware communications system in a hospital environment. Joshua D. Atkins (Dept. of Elec. Eng., Johns Hopkins Univ., 3400 North Charles St., Baltimore, MD 21218, joshatkins@jhu.edu), Michael J. Sammon, and Lynne S. Brotman (Avaya Labs Res., Basking Ridge, NJ 07920)

This paper characterizes the effect of hospital noise conditions on a mobile communications system developed for a research trial in a Johns Hopkins Hospital nursing unit. The system provides an alternative to telephones and overhead paging in hopes of reducing the amount of noise on the hospital unit. Benefits of this system over current similar solutions include a completely hands free approach using a computerized voice agent and a design that addresses privacy concerns to comply with HIPAA requirements. The nurses were happy with the system and bypassed the phones and overhead paging in preference of their headsets. However, during the system trial, the effect of noise on the automatic speech recognition (ASR) engine from sources like alarms, medical equipment, and wind noise from mobile users was an issue. Utterance tests were run using a variety of different Bluetooth headsets to measure the impact of various noise sources, S/N, and noise reduction algorithms on ASR performance. Common noise reduction methods were not helpful for the type of noise encountered, suggesting that solutions such as noise robust speech systems and noise reduction with adaptive microphone arrays currently being researched will be of great importance to future systems of this kind.

3pNS4. The role of sound masking treatment in the value engineering of office designs. Thomas Horrall and Carl Rosenberg (Acentech, 33 Moulton St., Cambridge, MA 02138)

For over 50 years sound masking systems have often been included in the design and planning of office spaces because the owner understood that they are required to provide adequate speech privacy, or because he believed they can create a more pleasing and private acoustic environment. However, installations have rarely been considered on the basis of project value engineering or return on investment. In this paper, we argue that sound masking systems should in fact be considered not only as a stand-alone cost component of the office design, but evaluated along with ceiling tile, private office wall construction, and workstation design for their mutual impact on the overall project budget, instead of solely on their contribution to acoustical performance. With over 70 years of combined experience dealing with speech privacy issues and masking systems of all kinds, we provide typical project data to demonstrate that contemporary systems often can result in substantial overall project cost savings.

3pSP1. Comparison of extended Kalman filtering with split-aperture processing for angle of arrival estimation in multibeam echo-sounding. Daniel S. Brogan and Christian P. de Moustier (Ctr. for Coastal and Ocean Mapping, Univ. of New Hampshire, 24 Colovos Rd., Durham, NH 03824-3525, daniel.brogan@unh.edu)

Echo angle of arrival estimates may be obtained from the FFT beamformed output of a multibeam sonar system at each successive time sample. Whether tracking disparate targets in the water column or tracking a mostly continuous surface such as the seafloor, the sequence of angles of arrival versus time is inherently nonlinear and nonstationary, and lends itself to processing with an extended Kalman filter. This filter provides both an approximation of the optimum (in a least squares sense) angles of arrival estimation and a measure of the associated errors. This technique is applied to quadrature-sampled field data collected with the 26-element hydrophone array of a 160-kHz multibeam sonar system. Results are compared to arrival angle estimates obtained with a conventional split-aperture processor. [Work supported by NOAA Grant 111833.]

3pSP2. Universal properties of the channel Q function: Applications to underwater acoustic communications. T. C. Yang (Naval Res. Lab., Code 7120, Washington, DC 20375)

Channel Q function is, for a time-invariant channel, the sum of autocorrelation functions of the channel impulse response functions over multiple receivers [T. C. Yang, IEEE J. Oceanic Eng. **28**, 229–245 (2003)]. It can be used to characterize the performance (output SNR) of acoustic communications using either passive-phase conjugation or decision feedback equalizer [T. C. Yang, IEEE J. Oceanic Eng. **29**, 472–487 (2004)]. Channel Q function also determines the channel capacity for a single source and multiple receivers (SIMO). We analyze in this paper the properties of the channel Q function and show that it possesses universal and stable properties for underwater acoustic waveguides, irrespective of the channel sound-speed profiles, source and receiver range/depths. This property is examined with real data collected in various oceans with significant temporal variations in the propagation conditions and/or source-receiver range. Applications to underwater acoustic communications are discussed. [Work supported by the Office of Naval Research.]

3pSP3. Error performance of equalizers based on sparse and dynamic channel estimation. Weichang Li and James C. Preisig (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

For broadband communications in the very shallow water environment, it has been shown that both model-based dynamic channel estimation and sparse channel estimation are capable of reducing the signal prediction error by several dB [W. Li and J. C. Preisig, J. Acoust. Soc. Am. **118**, 2014 (2005)]. Dynamic channel estimation is based on explicit modeling of the rapid channel variations; sparse channel estimation exploits the channel structure formed by the resolved multipath arrivals. In this paper, the error performance of the equalizer based on these channel estimators are analyzed, demonstrated through experimental results and compared with the performance of equalizers that do not explicitly model and exploit the channel dynamics and structure. [Work supported by ONR Ocean Acoustics.]

3pSP4. Adaptive predictive-error optimal gridding. Lisa A. Pflug and Donald R. DelBalzo (Planning Systems, Inc., 40201 Hwy. 190 E., Slidell, LA 70461, lpflug@plansys.com)

Transmission loss computations in littoral areas often require a dense spatial and azimuthal grid to achieve acceptable accuracy and detail. The computational cost of accurate predictions in complex areas can be unacceptable for some naval applications. EAGLE (Efficient Adaptive Gridder for Littoral Environments) was developed to reduce the computational requirements by adapting the fundamental calculation grid to the natural environmental structure. EAGLE produces a nonuniform grid structure within which the underlying data have approximately constant spatial uncertainty, or iso-deviance. The EAGLE point-selection approach is based on a predictive-error metric and least-squares polynomial curve fitting with arbitrary order. This research indicates the degree to which EAGLE grids are related to the underlying coherence properties of the natural environment. The results show significant efficiency enhancements compared to uniform grids of the same accuracy, when the environmental coherence properties are used to control the polynomial order. [Work sponsored by NAVAIR.]

3pSP5. Quantifying ocean acoustic environmental sensitivity. Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria BC, Canada), Peter Giles, Gary H. Brooke (General Dynam. Canada, Dartmouth NS, Canada), Diana F. McCammon (McCammon Acoust. Consulting, Waterville NS, Canada), Sean Pecknold, and Paul C. Hines (Defence Res. and Development Canada—Altantic, Dartmouth NS Canada)

This paper examines the sensitivity of acoustic propagation data required for sonar performance predictions to physical parameters of the ocean environment. Sensitivity is quantified here by an appropriate measure of the relative uncertainty of the acoustic data due to realistic uncertainties in environmental parameters. Within a linear approximation, Gaussian-distributed environmental parameter uncertainties lead directly to Gaussian data uncertainties which scale linearly with the parameter uncertainties. However, the actual data uncertainties, which can be esti-

mated numerically via Monte Carlo methods, do not necessarily possess these desirable linear properties. The applicability of the linearized approximation and the relative magnitude of acoustic sensitivities are examined for realistic uncertainties in seabed geoacoustic parameters and oceanographic features of the water-column sound-speed profile. Sensitivities are considered as a function of source and receiver depth, range, and source frequency for various shallow-water environments. [Funding provided by DRDC-Atlantic Rapid Environmental Assessment Project.]

2:20

3pSP6. Approximating acoustic field uncertainty in underwater sound channels. Kevin R. James and David R. Dowling (Dept. of Mech. Eng., Univ. of Michigan, 2019 Lay Auto Lab., 1231 Beal Ave., Ann Arbor, MI 48109, drd@umich.edu)

Precise acoustic field prediction relies on accurate knowledge of many environmental parameters. Uncertainty in any of the inputs to a propagation routine leads to uncertainty in the predicted field. The most accurate but time-consuming method of assessing the resulting field uncertainty is Monte Carlo simulation, which requires calculating the field with many possible combinations of inputs. This presentation covers a method to approximately determine the uncertainty in the predicted field, using only one additional field calculation for each uncertain parameter, when the input uncertainties are relatively small. The method relies on identifying how variations in uncertain input parameters can be mapped into spatial displacements in the original field calculation. Simultaneous uncertainty in multiple input parameters is handled using a net effective spatial displacement. In addition to expected values and standard deviations, the method allows for the generation of complete probability density functions for the uncertain predicted field. Calculated field amplitude results for both ideal and more realistic range-independent sound channels having small depth and sound speed uncertainty are shown and compared to Monte Carlo simulations at several source-receiver ranges. [Work sponsored by the Office of Naval Research, Code 321OA.]

2:35

3pSP7. Adaptive sampling based on the waveguide invariant for determining environmental provinces. James H. Leclere and George B. Smith (Code 7183, Bldg. 1005, Naval Res. Lab., Stennis Space Ctr., MS 39529, gsmith@nrlssc.navy.mil)

The waveguide invariant (related to the striations seen in range-frequency plots of sonar data) can be used as a tool to determine provinces in adaptive sampling schemes used to plan the placement of environmental measurements. The quantity from which the waveguide invariant is derived is used to demark spatial regions over which the environment can be considered to be range and bearing independent from an acoustic point of view. This allows significant speedup in acoustic propagation calculations. It also provides guidance for the placement of environmental measurements—particularly water column sound speed profile measurements. Results from the application of this technique to simulated data and to data from the Sea of Japan are shown and are compared to results of another method based on the adiabatic condition. [This work was supported by ONR with technical guidance provided by the Naval Research Laboratory, Stennis Space Center, MS.]

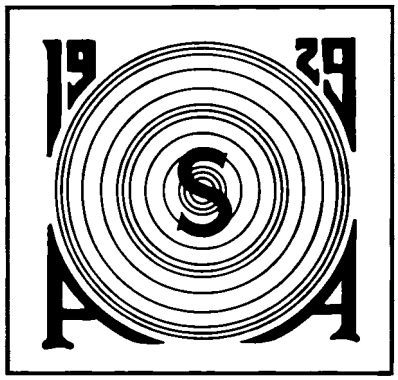
Gold Medal to James E. West

ACOUSTICAL SOCIETY OF AMERICA

R. BRUCE LINDSAY AWARD



Purnima Ratilal

2006

The R. Bruce Lindsay Award (formerly the Biennial Award) is presented in the Spring to a member of the Society who is under 35 years of age on 1 January of the year of the Award and who, during a period of two or more years immediately preceding the award, has been active in the affairs of the Society and has contributed substantially, through published papers, to the advancement of theoretical or applied acoustics, or both. The award was presented biennially until 1986. It is now an annual award.

CITATION FOR PURNIMA RATILAL

. . . for contributions to the theory of wave propagation and scattering through a waveguide, and to the acoustic remote sensing of marine life

PROVIDENCE, RHODE ISLAND • 7 JUNE 2006

''Dancing helps against seasickness,'' said Purnima Ratilal, this year's recipient of the R. Bruce Lindsay Award, as she demonstrated on the helicopter deck, to the beat of the waves in a raging mid-spring squall at the edge of the continental shelf, a day's sail from the nearest landfall. Not all of us were in a condition to follow. At sea, exhausted after a long day's work, we'd sometimes discover her dancing on the fore deck in the twilight, hidden behind the bridge, full of energy, . . . the professor who dances with the ocean.

Purnima was born in Singapore, the youngest of five children, to her parents Ratilal and Pushpaben. She graduated with honors from the Physics Department of the National University of Singapore, where she is fondly remembered by her bachelor's thesis adviser, the astrophysicist Chia Tzu Tit, as one of his best undergraduate students. After graduation, she became a research physicist at Singapore's DSO National Laboratories, where she quickly established herself as a rising young star. She performed at a level well beyond her years by designing and directing a series of offshore oceanographic experiments in the seas near Singapore. From what can be gathered now, this bit of ocean apparently served as a personal laboratory for Purnima to develop her remarkable intuition about the physics of remote sensing. She did this by investigating such phenomena as transmission through a fluctuating medium, as well as the causes and effects of reverberation and ambient noise in a waveguide. It also began her career in characterizing the marine environment with sound, here using matched field inversion and headwave analysis to determine local oceanographic and seabed properties. After presentations at a number of international conferences, including the Office of Naval Research (ONR) Ocean Acoustic Inverse-Methods Workshop where her work found its way to the top, she was heavily recruited by many leading graduate schools, including the Massachusetts Institute of Technology (MIT), which was fortunate enough to sign her on for study.

As a graduate student, Purnima flew through her initial doctoral qualifying exams, easily passing them after only four months at MIT. Almost all students wait 16 months. Unlike most students, she always seemed to pick professors with the toughest reputations from around the institute to be on her exam and thesis committees. Her enthusiasm for learning seemed to short-circuit the usual fear. In the second part of her qualifying exams, years later, she was grilled mercilessly by Jin Au Kong, author of the well-known volumes ''Scattering of Electromagnetic Waves,'' and leading theoretical hydrodynamicist Dick Yue, the Associate Dean of the School of Engineering, who often joked that ''acoustics is just a subset of hydrodynamics.'' Kong left the exam very impressed, but exhausted after two hours, the blackboard densely covered with Purnima's latest derivations in acoustic waveguide-scattering theory. Purnima, on the other hand, was still energetic and hoping for more fun. Yue supplied this ''fun,'' taking another couple of hours from a busy schedule. Recently he commented that her research and thesis work is of the caliber we get only every few years at MIT. As a graduate student Purnima also engaged in many philanthropic undertakings with extreme generosity, serving at homeless shelters, regularly contributing with nothing more than her meager graduate-student stipend to various charities. She pulled many other students, undergraduate and graduate alike, out of the fire by giving them hours and hours of extra tutoring and guidance. She did the same for her research group time and time again by jumping in and tackling the most difficult outstanding problems with amazing creativity, efficiency, sophistication and common sense.

Purnima's most important theoretical contributions began early in her career as a graduate student when she derived the Extinction Theorem for object scattering in a waveguide, and so generalized the classical free-space Extinction Theorem, also known as the optical theorem or Forward Scatter Theorem, one of the most fundamental results in scattering theory. (The free-space version was derived in various forms by such well-known investigators as Rayleigh, Heisenberg and Van du Hulst.) She showed extinction in a waveguide, or removal of power from the forward propagated field by the object, to be far more complicated than in free-space, and to involve intuitive mode-coupling effects arising from subtle interference structures inherent in a waveguide.

Later as an ONR Post-Doctoral Fellow at MIT, and as Assistant Professor of Electrical Engineering and Computer Science at Northeastern University, she returned to what became one of her

favorite topics, forward scattering. In what ASA Associate Editor Bill Siegmann has called a ''theoretical tour de force that for the first time provides mean and covariance expressions for three-dimensional scattering effects from virtually any mechanism of interest in the ocean,'' she derived compact analytic expressions for these field moments after multiple forward scattering in a waveguide, and showed when three-dimensional effects become important, without the need for laborious Monte-Carlo simulations. Michael Collins of the Naval Research Laboratory in Washington, DC, and a previous recipient of the Lindsay Award, whose propagation models are in standard use by the US Fleet, notes that ''Achieving this goal has long been the Holy Grail in this area, and Purnima has done it.'' For the essential inspiration, she went back deeply, citing Rayleigh's 1899 derivation explaining why the sky is blue and the sunset red. As many of us know, it was R. Bruce Lindsay who wrote the introduction to Lord Rayleigh's classic book, which is well referenced in her papers.

In her recent experimental work, appearing both in our Society's journal as well as the journal *Science*, Purnima co-invented a method for instantaneously detecting and imaging fish populations over continental-shelf-scale areas (thousands of square kilometers) and then continuously monitoring these populations with Ocean Acoustic Waveguide Remote Sensing (OAWRS). There she used OAWRS to make a number of fundamental new discoveries about animal group behavior by revealing the instantaneous horizontal structural characteristics, volatile short term behavior and propagation of information in very large fish shoals, containing tens of millions of fish and stretching for tens of kilometers. Colleagues in a wide variety of disciplines expect the impact of her work to the Census of Marine Life, the study of marine ecology, and the management of marine fisheries to be pronounced.

With the same series of experiments, Purnima also played an enormous role in helping to solve one of the Navy's primary problems in active sonar operations by showing that the presence of strong inexplicable ''clutter'' returns in continental shelf environments are often caused by dynamically moving fish groups rather than geology. Jeff Simmen, the ONR Program Manager in Underwater Acoustics at the time, noted this was ''a very important and unexpected finding,'' since the original goal of the experimental program was to seek geologic correlates.

Purnima has made scores of presentations at ASA meetings and has been awarded Best Student Paper Awards on three occasions. She presented one of the Young Investigator Keynote Addresses at the ASA 75th Anniversary Celebration in New York. Purnima is the author or co-author of several papers published in the *Journal of the Acoustical Society of America* and is a member of the Technical Committee on Underwater Acoustics. With Purnima, the best is always yet to come. We will no doubt see many fascinating new discoveries from her and the vibrant research group she has put together at Northeastern University.

NICHOLAS C. MAKRIS

ACOUSTICAL SOCIETY OF AMERICA

Silver Medal in

Biomedical Ultrasound/Bioresponse to Vibration
and
Acoustical Oceanography

Mathias Fink

2006

The Silver Medal is presented to individuals, without age limitation, for contributions to the advancement of science, engineering, or human welfare through the application of acoustic principles, or through research accomplishment in acoustics.

ENCOMIUM FOR MATHIAS FINK

. . . for contributions to the understanding of time reversal acoustics

PROVIDENCE, RHODE ISLAND • 7 JUNE 2006

The common threads of Mathias Fink's activities have been his exceptional diversity and energy. He has made seminal contributions in physical and medical acoustics, wave propagation in simple or complex solids or fluids that often employed analogies between acoustics, optics, quantum mechanics, and has also applied basic physics to accomplish self-adaptive signal processing. All this while being a devoted teacher of a generation of acousticians and also playing an important role in the development of a new, acoustic-based industry.

Mathias A. Fink was born in Grenoble (France) in October 1945. He received the B.S degree in Mathematics from the University of Paris (1967) and M.S. (1968) and Ph.D. (1970) degrees in Solid State Physics, at the Groupe de Physique du Solide de l'Ecole Normale Superieure in Paris. His Ph.D. research was in the area of electron-phonon interaction in semiconductors. Because he was a strong diver and interested in Underwater Archeology, Mathias decided to pursue a research career in Underwater Acoustics. In1972, he joined Pierre Alais at the Pierre et Marie Curie University (Paris). However, with no significant funding in his chosen field, he began working in the new field of Ultrasonic Medical Imaging. In 1978 he received the Doctorat es-Sciences from Paris University for his research in the area of ultrasonic focusing that included building the first real-time ultrasonic imaging system with electronic focusing capability. He developed various coded aperture techniques to achieve high-resolution imaging based on broadband diffraction theory. His water skills, though, were put to use years later when he rescued a colleague from a sinking boat off the coast of Corsica during one of the Cargese Summer Physics Schools.

In 1983 he joined Strasbourg University as a full Professor in Physics, where he conducted research in ultrasonic medical imaging and non-destructive testing. After a sabbatical at the University of California, Irvine, he joined Paris University (Denis Diderot) in 1984 and in 1990, he founded the now world famous Laboratoire Ondes et Acoustique at the Ecole Supérieure de Physique et de Chimie Industrielles de la Ville de Paris (ESPCI). He was elected a Senior Member of the Institut Universitaire de France in 1994; in1996 he was awarded the Grand Prix, by the New Economist and the Centre National de la Recherche Scientifque (CNRS) for his collaboration with SNECMA (French aircraft engine society) in nondestructive testing. He was elected a Member of the Académie des Technologies (National Academy of Engineering of France) in 2002 and at the French Académie of Science in 2003.

Mathias is most well known for pioneering the development of the Ultrasonic Time Reversal Mirror (TRM) from his basic physics experiments to the development of ultrasonic medical and nondestructive testing techniques. He first demonstrated the high degree of focus one obtains with time reversal (TR) and, more interestingly, showed (with Derode and Roux) that multiscatter media reveal the TR focal properties thereby providing significant opportunities for acoustic and wireless communication through complex environments. His research included an explanation of this phenomenon in terms of basic statistical mechanical quantities such as the mean free scattering path. On a basic research level I mention only three (of many) extremely elegant experiments with associated theory. He studied with Carsten Draeger single channel TR in a chaotic cavity finding an analogy with Anderson localization. With student Roux, he studied the basic nature of time reversal in reciprocity breaking media such as a fluid with vortices showing a beautiful analogy with the electromagnetic Bohm-Aharonov effect. In another elegant set of TR based vibration experiments, he and his student, Julien DeRosny showed how one can go past the diffraction limit by adding the missing evanescent spectrum using an ''anti-sink'' source function. In signal processing, his work with Claire Prada led to the ''DORT'' method—a decomposition of the Time Reversal Operator that has a fundamental relation with nonlinear adaptive processing methods. Further this procedure reveals the properties of elastic objects and other complex targets from scattering measurements. Getting more applied, the *Economist* magazine recently reported on a startup company based on his work in developing a TR-based keyboard without moving parts. Always dancing between applications and basic science, two other interesting research areas in which he has worked with students are on the application of a Time Reversal Mirror to sonoluminescence for the purpose of creating a more highly compressed bubble and to room acoustics using Lamb waves to focus sound from one room to another.

Much of Mathias' work has been in medical ultrasonics. ''Supersonic Imagine,'' which is also the name of a startup company, is an incredibly clever method to image (the rigidity of) human

tissue. Since the shear speed of human tissue is of the order of only a few m/s, he developed (with Mickael Tanter) a way to acoustically create a focus spot in tissue that could move faster than the shear speed. The resulting Mach cone is imaged ultrasonically and the large shear speed variations associated with the rigidity of a tumor, for example, are identified from variations in the Mach cone apex-angle. Further, his group has made important progress in TR based methods to place an acoustic focus past the highly absorbing skull into the brain. Experiments are now being conducted together with medical facilities in Paris. Another example of his work in medical ultrasonics is the study of nonlinear TR and the preshock conditions that still permit TR focusing; this work is leading to a compact lithotripsy system based on the ''acoustic bazooka'' he developed in his lab. Mathias mentioned to me that this latter device might also be used an acoustic paint remover or ''sand blaster'' type device.

In France, Mathias is very active in the politics and the popularization of science. I remember seeing him on the cover of *Le Monde* during one of my first visits to his lab: it was a picture of an ominous looking bald man in a black background with the article entitled ''Master of Time.'' He is constantly embroiled in the politics of not only promoting scientific research in France, but also in promoting an entrepreneurial friendly environment to enhance technology-based startups. Very recently, the French Minister of Industry organized a press conference that featured Mathias explaining his successful efforts in convincing some French scientists to return from the U.S. to start up the new French company Supersonic Imagine.

I have attended many of his lectures and even co-lectured with him during some tutorials; he is not an easy act to follow. He is in great demand as a lecturer and typically circumnavigates the globe more than once a year. But the true measure of his effectiveness is his students—many of whom I have the pleasure of knowing and some of whom I have been lucky enough to have as post docs. Together they make up a rather spectacular collection of scientists—too many to mention here.

An avid experimentalist, in his early days Mathias used to bring equipment home for various fluid experiments—once placing sensors (hooked up to an oscilloscope) in milk and excitedly making, what he thought, a world shattering discovery on the change of the milk after three days as seen through his electro-hydro-acoustic measurements. In this instance, however, his wife, Minelle, who has not only tolerated his jet-set tendencies, has also kept Mathias grounded in reality while he operated at the elevated heights of the most erudite science, pointed out that the milk had simply curdled. His two daughters, Emmanuelle and Julia, also provide a very lively family life; and one of them also provided a concrete example that time *also* goes forward: his new grandson Antoine.

But Fink is not only well known within the acoustics community; his more popular articles on Time Reversal Mirrors in *Scientific American* and *Physics Today* have also served as a beacon of the excitement of contemporary acoustics to those outside the field. With over twenty-five patents and an extensive publication record, dozens of Ph.D. students, Mathias has been a major, interdisciplinary contributor to both basic and applied acoustics. He is truly deserving of the Helmhlotz-Rayleigh Interdisciplinary Silver Medal.

W.A. KUPERMAN

GOLD MEDAL
of the
Acoustical Society of America

James E. West

2006

The Gold Medal is presented in the spring to a member of the Society, without age limitation, for contributions to acoustics. The first Gold Medal was presented in 1954 on the occasion of the Society's Twenty-Fifth Anniversary Celebration and biennially until 1981. It is now an annual award.

CITATION FOR JAMES E. WEST

. . . for development of polymer electret transducers, and for leadership in acoustics and the Society

PROVIDENCE, RHODE ISLAND • 7 JUNE 2006

James Edward West is a consummate acoustician, inventor and an extraordinary human being. In his lifetime of professional activities in acoustics, he has created a large number of distinctly unique microphones and loudspeakers and made important contributions in architectural acoustics and noise control. He has also mentored a number of current ASA members and dedicated enormous time and effort to encouraging students to consider careers in science.

Born on February 10, 1931 in rural Virginia, Jim West is the son of Matilda and Samuel West. Matilda West was a school teacher and during World War II was employed at Langley Air Force Base working with wind tunnel data until she lost her job because she was a leader in the National Association for the Advancement of Colored People, a group that Senator Joseph McCarthy had labeled as communist. Samuel West worked, at various points, as a funeral home owner, B & O Railroad porter, and insurance salesman.

Jim's interest in electrical phenomena began at an early age when he found an old radio and plugged it in to see if it still worked. His lab skills not yet perfectly honed, the resulting electrical shock immobilized him until his brother knocked him over. From that moment he was hooked. In the 1940s Jim's cousin, Edward B. Allen, a school teacher, worked part time wiring homes and Jim, aged 12, went to work for him crawling under houses and carrying the wire from one place to another. Thus began his lifelong habit of tinkering and seeking to understand how things work —in his own words, ''A screwdriver and pliers were very dangerous. Anything that had screws in it, I could open up.''

After graduating from high school, Jim enrolled at Hampton University as a premedical student —honoring the desire of his parents that he pursue one of the careers open to black people of that time (lawyer, doctor, teacher, and preacher). But before completing his degree, Jim was drafted to serve in the Korean War, where he was awarded a Purple Heart. Upon returning to college Jim switched to Temple University and solid-state physics.

Jim's contributions to acoustics largely define the advances in transduction in the last 50 years. He, along with Gerhard Sessler, invented the modern electret microphone found in virtually all telephones and voice recorders, and now produced worldwide at a rate well in excess of 2 billion units annually. He also was involved in the production of adaptive close-talking microphones, first- and second-order differential microphones, blood pressure monitoring transducers, wideband telephone receivers, and microphone arrays of various sorts. For his work on electroacoustic devices, he has been inducted into the National Inventors Hall of Fame and the National Academy of Engineering and honored with too many awards to name. Jim's name is on 47 US and over 200 foreign patents. He has authored over 100 scientific articles.

In addition to his work on transducers, Jim has made important contributions to architectural acoustics. He defined the ''seat effect'' in a 1964 paper and was the first to publish the importance of early reflection arrivals in the subjective quality assessment of concert halls (in an ASA abstract). Jim was also instrumental in the measurement of the performance of a number of halls, including Philharmonic Hall.

More recently, Jim has focused his attention on new piezoelectric materials, new multi-channel tele-collaboration techniques, and noise control in hospitals. The work on piezoelectric material uses previously unexploited mechanisms for generating dipole moments in the design of polymer composites in which the mechanical performance is determined by one polymer and the electroacoustic coupling by a second. This ability to separately control mechanical and electrical performance will make it possible to custom design piezoelectric materials with specified performance measures. Multi-channel tele-collaboration is a joint project with Fred Juang at Georgia Institute of Technology that aims at making more effective use of stereo hearing in tele-collaboration venues. In the hospital noise area, Jim has worked to characterize the noise at Johns Hopkins Hospital and to demonstrate noise interventions that will work long term. This work has generated an enormous positive response from medical caregivers and the lay public.

Jim has also been very active in the Acoustical Society of America. He regularly delivers talks at our biennial meetings and participates in the engineering acoustics, noise, and architectural acoustics technical committee meetings. He has been a member of the Acoustical Society of America (ASA) since 1962 and has served as chair and member of many committees and in several elected positions including Member of the Executive Council (1989-92), President-Elect

(1997-98) and President (1998-99). Jim was instrumental in the establishment of the Society's minority fellowship and the educational programs for local high-school students that are conducted at Society meetings. During his tenure as President of the Society, the ASA held its first meeting outside of North America jointly with the European Acoustics Association. Jim worked to further broaden our reach by fostering a lasting relationship with South American and Mexican acousticians, culminating in the joint meeting in Cancun for which he served as Cochair. The Acoustical Society is clearly core to Jim's administrative work, and his effectiveness in this as in other arenas is defined by his focus on building personal relationships.

To define Jim by his copious and important work in acoustics is to miss his most important aspect–his warmth and generosity of spirit. As anyone who has interacted with Jim already knows, he enjoys forging deep relationships with people and encouraging their success. Jim is at his best when interacting with students at all levels and helping them understand how to learn by trying and how to challenge themselves. He was one of the founders of the AT&T Corporate Research Fellowship Program, the most significant corporate funding program for minority PhD students in the world. He is also one of the premier advisors for a new program in which high school junior and senior women spend a term working in a lab at the Johns Hopkins University campus. This program, called Wise Women, is now serving as a model for academic institutions across the country.

James Edward West has been a sterling colleague, collaborator, friend, and mentor to many of us. He is also a loving spouse to Marlene and a father to four children.

Session 4aAAa

Architectural Acoustics, Musical Acoustics, and Engineering Acoustics: Composed Spaces Loudspeaker Concert I (Performance Session)

Alexander U. Case, Chair
Fermata Audio + Acoustics, P.O. Box 1161, Portsmouth, NH 03802

Works of music and sound art will be presented as a concert in this session. No lecture papers will be presented. A repeat performance of the compositions will be held in Session 4pAAb from 1:00 p.m. to 6:00 p.m. Attendees from all disciplines are invited to attend.

Invited Papers

8:00

4aAAa1. "Flowers and Wreaths": Radio theater and surround. Ean White (15 Channel Ctr. St., #514, Boston, MA 02210-3426, ean@incendiaryarts.org)

Originally produced in late 1992, ''Flowers and Wreaths'' is a setting for poems by Jacques Prvert (*paroles* Prvert) in French and in English translations by Lawrence Ferlinghetti and me. Prvert's success in France after World War II was largely due to his unabashed use of street language and his staunch antiwar, antirational political stance. The performance featured much original instrumentation: an amplified skull-resonator dental floss violone, a 35-ft.-long infrasonic electric monochord, a naval signal lamp, mechanized moving audience seating, the amplified electrocution of vegetables, unconventional speaker placement, etc. Mari Novotny-Jones and I continued to perform the piece through 1993. This new, surround recording is of only the title poem in the suite, ''Flowers and Wreaths,'' with a few elements which were originally used with other texts. It was a relatively quiet passage in an otherwise fairly raucous performance but was also a kind of spiritual center for the piece. The point of view for the listener during this extracted section is that of a corpse laying in a ditch by the side of a road. My intent is to explore the possibility of new, surround broadcast technology and its suitability for a resurgence of radio theater.

8:15

4aAAa2. "Passing Landscapes." James Moses (Music Dept., Brown Univ., Orwig Music Bldg., 1 Young Orchid Ave., Providence, RI, 02806)

This work was created through experimentation with surround recording and manipulation techniques. A variety of coincident and spaced microphone recording techniques are used to create realistic and immersive recordings of everyday environments. Processing and manipulation are then applied to these recordings to create musical material that plays against the recordings and guides us on a contextualized journey through the landscapes many of us pass though everyday.

8:30

4aAAa3. Vis-a-vis (2002), Katherine Bergeron, voice. Joseph Rovan (Music Dept., Brown Univ., 1 Young Orchard Ave., Providence, RI 02912, rovan@brown.edu)

What is the cause, and the cost, of insight? What does it mean to see the world face to face? These questions were raised by the young Rainer Maria Rilke in a passage from his Notebooks of Malte Laurids Brigge, a journal he kept in 1904 while serving as secretary to the sculptor Rodin. They also lie at the heart of Vis-a-vis, a multimedia work for voice and computer music soundscape, which takes Rilkes words as a dramatic point of departure. Recalling an encounter with a nameless woman in the streets of Paris, Rilke's text is a meditation on the nature of faces. It reads like a drama, a story in five virtual scenes told from multiple points of view and in several voices, alternately droll, philosophical, ironic, pathetic. In this new 5.1 mix the multivocal and multilingual aspects of Vis-a-vis are highlighted through the use of acousmatic space; the aim is to suggest the shifting psychological relationship between the woman who sings and the nameless woman who is the subject of Rilkes narration.

9:00

4aAAa4. Convergence. Andrew Carballeira (Driftwood Audio, 311 Concord Ave., Lexington, MA 02421)

In the words of Mahatma Gandhi, ''We must become the change we wish to see in the world.'' Exploitation, racism, violence, and militarism are all the rage in our world today. Persons of conscience opposed to this intoxicating madness are charged with envisioning something better. This piece is one in a series of attempts to draw a ray from our current predicament to a world free of war and racism. It opens with highly disjointed, atonal interactions physically separated in space. As the piece evolves, the voices begin to move together and speak more consonantly with each other: an aural simulation of the world uniting around the principles of peace, justice, and equality.

9:30

4aAAa5. Untitled Number 3. Andrew Clifford, Eli D. Cohn, Robert M. Mallory, and Alexander U. Case (Sound Recording Technol., Dept. of Music, UMass Lowell, 35 Wilder St., Ste. 3, Lowell, MA 01854, alex_case@uml.edu)

Untitled Number 3 was written and performed by Sparrows Swarm & Sing in 2005 and 2006. The work is a postrock instrumental for cello, violin, percussion, distorted electric guitar, rock drums, voices, handmade noisemakers, and digital signal processors. Composition is a collaborative process that occurs through both live improvisation among the six-piece ensemble and deliberate experimentation, rehearsal, and overdubbing.

9:45

4aAAa6. Moving Space. Pauline Oliveros (Rensselaer Polytechnic Inst., 110 Federal St., Troy, NY 12180, paulineo@deeplistening.org)

Moving Space (2006) is a composition for 5.1 surround sound system. Sustained sounds morph in quality as space changes and space changes as sounds move. The piece uses vector based amplitude panning (VBAP) and Monoverb mono implementation of the Schroeder/Moorer reverb model (mono version of freeverb~) to achieve these changes. Sounds are improvised and processed by the expanded instrument system (EIS), a MAX program designed by the composer consisting of multiple delays and processing algorithms.

10:00

4aAAa7. Rather the flight of the bird passing . . . . Thomas Plsek (Berklee College of Music, MS-1140 Brass, 1140 Boyslton St., Boston, MA 02215, tplsek@berklee.edu)

Rather the flight of the bird passing . . . is a five-channel composition created to produce a surreal sound environment that could only exist in a recorded, multichannel version. The solo trombonist in the piece (the composer) performs and is recorded by 5 human mobile microphone stands, i.e., people holding microphones and moving around the recording space searching for sounds. The sounds and the movements are influenced by a poem by Alberto Caeiro (1889–1915), a poet who did not actually physically exist. He was a heteronym created by the great Portuguese poet Fernando Pessoa (1888–1935). Pessoa created numerous heteronyms, each with their own styles and subject matter. The line of the poem, ''What's past is nothing and remembering is not seeing,'' is central to the practices used by all the performers to create the work.

10:30

4aAAa8. "Thaw/Twist at Bailey's." Stephan Moore (Troy, NY 12180, stephan@oddnoise.com)

A field recording of the 2004 spring thaw at Thomas Bailey's farmhouse in Richland, MI is used to explore the phenomena of temporal/spatial convergence and dispersal, as it can be used to manipulate and disorient our perception of location. Originally composed for a site-specific 16-channel array of custom-built speakers, this piece has been adapted to standard 5.1 surround sound. Duration: approximately 9 min.

11:00

4aAAa9. Two surround compositions: *Crossing Boundaries* and *The Puzzle Revealed*. Eric Chasalow (Music Dept., Brandeis Univ., MS051, Waltham, MA 02454-9110)

Crossing Boundaries (composed in 2000), was commissioned by Bates College to celebrate the millennium. The text aphorisms and reminiscences make a counterpoint of different spaces and moments to give different senses of the passage of historical and musical time. Musically, the piece moves from one large moment to the next one, usually reinforcing the phrasing of the text. Throughout, there is a shifting perception of just how fast we are moving. Musical sources include a Hebrew chant (which maintains a ghostly presence throughout the piece), Beethoven's piano music, improvised jazz, analog synthesized electronic music, and distorted electric guitar. *The Puzzle Revealed* (2006) is a maquette for an evening-long intermedia work, *The Puzzle Master*, a retelling of the Icarus myth by poet F. D. Reeve. This piece was conceived to specifically exploit the BeoLab 5 loudspeakers in 5.1 configuration. Material in the piece derives from vocal sources and explores morphing techniques that may become prominent in the larger work. The envelopment provided by full-range 5.1 playback is used to test ideas about the range of possibilities for spectral fusion or disintegration as a dynamic feature of different sound objects.

11:30

4aAAa10. Power chords, polyphonic trains, and plain old phase. David Moulton (Moulton Labs., 39 Ames Rd., Groton, MA 01450, dmoulton@moultonlabs.com)

Power chords, polyphonic trains, and plain old phase is a 36-min work of music composed directly for a six-channel array of loudspeakers (reduced to 5 channels for this performance). This piece draws on the work of minimalist sculptors such as Donald Judd and Michael Heizer, and explores the evolving nature of slowly shifting phase, reverberation, and the sonic continuum, using extremely simple sonic materials.

12:00

4aAAa11. "Anastasis." John Mallia (New England Conservatory of Music, 290 Huntington Ave., Boston, MA 02115)

"Anastasis" is a five-channel composition realized at the Institut de Musique Electroacoustique de Bourges (IMEB). The work is programmatic in its representation of Christ's "Descent into Limbo," a frequently treated subject in Medieval art. The majority of sounds used are derived from concrete sources, some of which carry conceptual weight. For example, the recurring sound of wax being scraped away from the metal surface of the candle trays at Bourges Cathedral St. Etienne: the residue of prayer . . . its removal, a daily chore (or performance ritual) captured in sound. Also, the emergence of a field recording of windmills at the work's close: transformation, by man, of nature's breath into energy as a storm blows in on the mountainside. The piece itself is a stormy, transformative descent. Sounds of friction and resistance represent the interpenetration of spheres of existence. Long intense strokes of sound such as the dragging of wood along wood, glass on glass, and the grinding and scraping of metals are fractured by abrupt, pointed declamations. Highly spatialized, bristling electronic textures occur as interruptions of the long descent and represent the accumulation of a mysterious, electrical energy in the empty tomb above; static glimpses of that middle sphere.

12:30

4aAAa12. Thirty-minute concert: Human-space-factory and Rojo. Hans Tutschku (Harvard Univ., Music Bldg., Cambridge, MA 02138, tutschku@fas.harvard.edu)

Human space-factory: The sound sources for this composition are derived from sung and spoken human sounds and from recordings in factories. Piano sounds serve as a pitched connection between the two sound worlds. The eight-channel space is used not only to place and to move the sounds, but to form a link between the sound families; by changing their position in space, the sound qualities transfer from one source to another. The three parts of the composition describe different densities: human sounds in an energetic space. The eight-channel electroacoustic composition is presented in a 5.1 mix; production: studio Musiques et Recherches Ohain; duration: 11.49 min; year: 1999; dedicated to Annette vande Gorne. Rojo plays with the imagination of simultaneous musical activities throughout the world. Recorded memories from several trips combine and exchange their qualities. Sometimes they change into huge sound masses, and occasionally their original environment is preserved. The composition creates an imaginary ritual, sourrounding the listeners, in which many sources meet and play together. The eight-channel electroacoustic composition is presented in a 5.1 mix; production: KlangProjekteWeimar (2004); commissioned by Radio Berlin Brandenburg; duration: 15.06 min; year: 2004; dedicated to Jonty Harrison.

THURSDAY MORNING, 8 JUNE 2006 BALLROOM B/C, 8:00 A.M. TO 12:00 NOON

Session 4aAAb

Architectural Acoustics: Spaces of Worship—Another Quarter Century of Experience (1984-Present) I (Poster Session)

Rose Mary Su, Chair
Acentech, 33 Moulton St., Cambridge, MA 02138

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

4aAO1. How toothed whales echolocate to find and capture prey. Peter L. Tyack, Mark Johnson (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Peter T. Madsen (Univ. of Aarhus, Aarhus C, Denmark), Walter M. X. Zimmer (NATO Undersea Res. Ctr., I-19138 La Spezia, Italy), and Natacha Aguilar de Soto (La Laguna Univ., Tenerife, Canary Islands, Spain)

Sperm and beaked whales are deep-diving toothed whales whose echolocation behavior has been studied using tags that record sound and whale orientation. Combining orientation data from tagged clicking whales with acoustic localization data from a towed hydrophone array allowed measurement of the three-dimensional beam pattern of regular clicks from sperm whales. These data confirm Mohl's bent horn hypothesis for sound production in sperm whales. During deep foraging dives, beaked whales produce several thousand regular clicks with interclick intervals (ICI) between 0.2 and 0.4 s. These search clicks have a distinctive FM upsweep from 25 to 55 kHz and a pulse length of 200–250 μs. The process of echolocating on prey can be divided into search, approach, and capture phases. The approach phase starts when a series of echoes from prey is detected. The capture phase starts when the target is about 2–5 m away, with a terminal buzz with click rates to ICIs of about 0.01 s. Tagged whales do not adjust their ICI to match range to target, nor do they adjust click level to maintain a constant echo level, but rather have a bimodal echolocation pattern using two kinds of clicks each with a typical ICI.

8:50

4aAO2. Exploitation of sound during predator-prey interactions: Killer whales and herring. Lee A. Miller (Inst. of Biol., Univ. of Southern Denmark, Campusvej 55, DK-5230 Odense M, Denmark), Malene Simon (Greenland Inst. of Natural Resources, DK-3900 Nuuk, Greenland), Fernando Ugarte (Ministry of Fisheries & Hunting, DK-3900 Nuuk, Greenland), and Magnus Wahlberg (Aarhus Univ., 8000 Aarhus C, Denmark)

The majority of killer whales (*Orcinus orca*) in Norway and Iceland feed cooperatively on schools of herring (*Clupea harengus*). The whales swim towards the school and, at short distances, perform underwater tail slaps that produce thudlike sounds containing impulses resembling cavitation pulses in duration, frequencies, and amplitude. Herring are debilitated by the underwater tail slaps, probably due to a combination of factors like sound pressure gradients, particle movements, hydrodynamic effects, and physical contact with the tail or other fish. Following the underwater tail slaps, killer whales can easily capture individual flaccid herring [Simon *et al.*, J. Exp. Biol. **208**, 2459–2466 (2005); a video will be shown]. Icelandic killer whales have another strategy not shown by their Norwegian relatives. A whale can emit a 3-s, 680-Hz call that ends 1 s before the tail slap. The frequency of the call falls within the herring audiogram, but outside that of killer whales. This call seems suited for herding the herring into tighter groups, making it possible to debilitate more fish [Simon *et al.*, Behav. Ecol. Sociobiol. (submitted)]. Herring are not defenseless. The school can produce a flatulent bubble net that could hinder detection by killer whale biosonar [Wahlberg Westerberg, Aquatic Living Resources **16**, 271–275 (2003)].

9:10

4aAO3. Hyper-directionality in clicks from the sperm whale (*Physeter macrocephalus*). Bertel Moehl, Magnus Wahlberg, and Anders Heerfordt (Inst. of Biological Sci., Zoophysiology, Bygn. 1131, C. F. Moellers Alle 133, DK-8000 Aarhus C, Denmark, bertel.moehl@biology.au.dk)

Directivity is an important determinant of animal sonar performance but difficult to assess for large, free-ranging species. Recent field studies of sperm whales indicate usual clicks to be quite directional [directivity index: 27 dB at a transmitting cross section to wavelength ratio ($2a/wl$) of 8], with indications of even narrower beams. To obtain better measures of directivity, a fiber-optically linked, linear hydrophone array with up to ten receivers, spaced 50 m apart, has been designed. The array can be deployed to depths of 1 km and incorporates a transmitting transducer. The array was deployed off Andenes, Norway, in July 2003, 2004, and 2005. On five occasions, transmissions of short broadband pulses (peaking at 14 kHz, SL 135 dB *re*: 1 Pa) apparently induced sperm whales at

ranges of about 2 km to train their sound beams towards the transmitter and lock them there. This implies beam-steering from the whales' auditory system, having a high auditory directionality, and detection capability of signals at 65 dB *re*: 1 Pa. It resulted in a high yield of on-axis recordings with maximum directivity indices of 39 dB, incompatible with plane piston radiation at $2a/wl$ ratio of 8.

9:30

4aAO4. The Humpback Whale Acoustic Research Collaboration studies on the use of sound by humpback whales. Douglas H. Cato (Defence Sci. & Tech Org., and Univ. of Sydney, P.O. Box 44, Pyrmont, NSW 2009 Australia), Michael J. Noad (Univ. of Queensland, St. Lucia, QLD 4072 Australia), Dale Stokes (Scripps Inst. of Oceanogr., La Jolla, CA 92093), Rebecca A. Dunlop, Joshua N. Smith (Univ. of Queensland, St. Lucia, QLD 4072 Australia), Patrick J.O. Miller (Univ. St. Andrews, Scotland, KY168LB, UK), Nicoletta Biassoni (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), Eric T. Kniest (Univ. of Newcastle, Callaghan, NSW 2038, Australia), John Noad (100 Monash Rd., Tarragindi, Queensland 4121, Australia), Aaron M. Thode, and Grant B. Deane (Scripps Inst. of Oceanogr., La Jolla, CA 92093)

Humpback whales produce two different types of vocalizations with apparent difference functions: songs and social sounds. There is also the potential to use the sounds of their environment, such as surf noise during migration along coasts, though this has not been demonstrated. The Humpback Whale Acoustic Research Collaboration (HARC) is a series of well-controlled, multiplatform experiments designed to improve our understanding of how humpback whales use sound, both vocalizations and sounds of their environment. There have been two major experiments with humpback whales migrating along the east coast of Australia. Whales passing within 10 km were tracked acoustically and visually during daylight hours in conjunction with behavioral observations, and DTAGs were used on some whales to record their 3D movements and the sound field to which they were exposed. There was also playback of social sounds and full characterization of the acoustics of the environment, including the ambient noise exposure. Preliminary results of interactions between singing and nonsinging whales, the use of song as a spacing mechanism, responses to playback, and context of social sounds will be discussed. [Research supported by ONR and DSTO.]

Contributed Papers

9:50

4aAO5. Do humpback whales exploit bioacoustic absorption spectroscopy to detect and classify fish schools? Orest Diachok (Appl. Phys. Lab., Johns Hopkins Univ., Laurel, MD 20723)

Humpback whales employ bubble nets for catching fish. In the Gulf of Alaska the method involves acoustic communication between whales: one whale, situated below the school, transmits sounds and drives the fish toward the surface; a second whale, situated above the school, deploys a bubble net (as wide as 30 m), which encircles the school as it approaches the surface. Before and during this process one (or more) humpback emits signals, called trumpet sounds, which consists of a series of cw tones, which are harmonics of ~300 Hz. The target species in the Gulf of Alaska is adult, 22-cm-long herring. These signals cover the resonance frequency of the target species swim bladders, which is about 1.5 kHz at 30 m. Resonance frequencies of individual fish are determined by the radius and depth of the swim bladder; significantly lower bubble cloud resonance frequencies of schools are determined by the void ratio and the dimensions of the school. One of the functions of these vocalizations may be detection and classification: the listening whale, near the surface, may be capable of interpreting the high absorption losses at resonance frequencies [Diachok, O. ''Effects of absorptivity due to fish on transmission loss in shallow water,'' J. Acoust. Soc. Am. **105**, 2105–2128 (1999)] to infer fish length, species, and size of school.

10:05–10:20 Break

10:20

4aAO6. The role of the spectral characteristics of discrete calls in killer whale (*Orcinus orca*) communication. Filipa Samarra (CREEM, The Observatory, Buchanan Gardens, Univ. of St. Andrews, St. Andrews, Fife KY16 9LZ, UK, fips2@st-andrews.ac.uk) and Patrick Miller (Univ. of St. Andrews, St. Andrews, Fife KY16 8LB, UK)

Many studies of killer whale calling have focused on group-specific time-frequency contours. This study investigated variation in the spectral structure of calls recorded from identified individuals and sought to identify factors that influence call spectral structure. The energy level of the first two harmonics was measured at each 0.01-s interval and linear mixed effects models used to test the sources of variation in the relative level of the first and second harmonics. Within a call, spectral structure changes according to the frequency of the fundamental ($p<0.001$), but not time since call start. Between calls, variation seems related to body size. Adult males had a stronger second harmonic, whereas for females the opposite tended to be true. Size class was a significant factor in the model ($p=0.0108$), while duration of calls or orientation and range of the signaller were not. Further analysis indicates different energy patterns between males and females up to the fifth harmonic. These results are consistent with a source-filter model of sound production, with formants arising from filtering effects of the sound-production apparatus. However, more research is clearly needed on the sound production mechanism of this species.

10:35

4aAO7. Whistle characteristics of bottlenose dolphins (*Tursiops truncatus*) are conserved independently of whistle quality. Carmen Bazúa-Durán (Lab. Acústica, Facultad de Ciencias, UNAM, Circuito Exterior s/n, Ciudad Universitaria, 04510 México, D.F., Mexico, bazua@servidor.unam.mx)

Bottlenose dolphins use their acoustic sense (whistles and pulses) to communicate and inspect their environment. One of these environments is a coastal lagoon in the southern Gulf of Mexico, the Laguna de Términos, where bottlenose dolphins inhabit all year round in herds varying from 1–120 individuals, with a yearly population of about 600 dolphins. Several characteristics of dolphin whistles were measured: quality (whistles with a signal-to-noise ratio, SNR, greater or less than 3 dB), repertoire (by classifying contours as either constant, ascending, descending, concave, convex, or multiple), and time-frequency parameters (duration, average frequency, medium frequency, and frequency range) to investigate how the overall whistle structure varied. Results show that regardless of their quality (SNR), whistles were not significantly different in their parameters and repertoire. Additionally, in this area dolphins produce more whistles/min/dolphin during traveling than during social interactions and feeding (whistle production was lowest during resting). Dolphins are presumed to use whistles to maintain group cohesion and to broadcast identity, thus being important in determining dolphin social structure. The results of this work support these hypotheses, suggesting that faint (whispered and/or far range) or strong (loud and/or close range) whistles broadcast, overall, similar information. [Work supported by CONACyT-Campeche, PAPIIT-UNAM, and ICMyL-UNAM.]

10:50

4aAO8. Differences in whistles of bottlenose dolphins between two populations in southeastern Australia. Michelle Lemon (Marine Mammal Res. Group, Macquarie Univ., NSW, 2109, Australia), Douglas H. Cato (Defence Sci. and Technol. Organisation, Pyrmont, NSW, 2009, Australia), and Robert Harcourt (Macquarie Univ., NSW, 2109, Australia)

The acoustic repertoires of two populations of Indo-Pacific bottlenose dolphins, *Tursiops aduncus*, have been studied in comparison with surface behaviors in southeast Australia. These populations are largely genetically differentiated and geographically isolated, one being in Port Stephens and the other in Jervis Bay about 300 km to the south. Ten variables were measured from the fundamental frequency of 200 whistle contours from each population, recorded in various behavioral contexts. Principal component analysis revealed significant differences between the populations. The Port Stephens dolphin population have less complex whistles of a higher frequency than those in Jervis Bay. Although significant differences were observed in phonation rates between behaviors at either site, there was no interaction between site and behavior. The genetic difference and degree of isolation of the populations suggest that cultural drift may play a part in the differences in whistles between sites. Ambient noise measured during observations showed significant differences between sites, but the measurements did not fully sample the range of ambient noise and differences are small compared to the expected temporal variation.

11:05

4aAO9. Verified passive acoustic detection of beaked whales (*Mesoplodon densirostris*) using distributed bottom-mounted hydrophones in the tongue of the ocean, Bahamas. David Moretti, Ronald Morrissey, Nancy DiMarzio, and Jessica Ward (Naval Undersea Warfare Ctr. (NUWC), Code 71, Bldg. 1351, Newport, RI 02841)

Passive detection of beaked whales has become increasingly important as at least two species, Blainville's beaked whales (*Mesoplodon densirostris*) and Cuvier's beaked whales (*Ziphius cavorostris*) have stranded in events associated with sonar. Passive acoustic detection and localization algorithms develop as part of the Office of Naval Research (ONR) Marine Mammal Monitoring on Navy Range (M3R) program will be presented along with results from a series of tests that demonstrate the efficacy of passive acoustic detection of vocalizing *M. densirostris*. Ninety-two bottom-mounted sensors at the Atlantic Undersea Test and Evaluation Center (AUTEC) were monitored for vocalizations. M3R systems were used to detect and localize vocalizing animals. Based on these real-time data, trained observers were vectored to the animals and verified the species. Focal follows coordinated with passive acoustics were completed. Observer photos along with raw sensor, detection and localization data were collected.

4aBB1. Tissue-ultrasound interactions: Absorption to imaging artifacts. Frederick Kremkau (Ctr. for Medical Ultrasound, Wake Forest Univ. School of Medicine, Winston-Salem, NC 27157-1039, fkremkau@wfubmc.edu)

Attenuation determines fundamental limitations in sonography. It directly limits the imaging depth (penetration) and indirectly limits the detail, contrast, and temporal resolutions by limiting the frequency. These resolutions improve with increasing frequency but penetration requirements determine the upper limit on frequency in each imaging situation because attenuation (and therefore penetration) is frequency dependent. Attenuation in soft tissue is dominated by absorption (typically about 90%). Absorption occurs primarily at the molecular level. Sonographic artifacts occur when one of the pulse-echo imaging assumptions is violated. These assumptions are that sound travels in straight lines, that echoes originate only from objects located on the beam axis, that the amplitude of returning echoes is related directly to the reflecting or scattering properties of distant objects, and that the distance to these objects is proportional to the round-trip travel time (13 μs/cm of depth). If scattering strength of an object is high but its absorption is low, a hyperechoic presentation will occur with distal enhancement. A more common occurrence is hyperechoic with distal shadow indicating high echogenicity and attenuation, therefore high absorption. Examples of several imaging artifacts will be shown with discussion of the propagation assumptions violated.

8:25

4aBB2. Phased arrays for high-intensity focused ultrasound therapy. Leon A. Frizzell (Bioacoustics Res. Lab., Univ. of Illinois, 405 N. Mathews Ave., Urbana, IL 61801)

Several groups have examined the design of ultrasound phased array probes for transrectal treatment of the prostate. An effective design must use the entire aperture of the array and maintain relatively low grating lobe intensities, ideally while minimizing the number of elements and associated phasing circuitry. A new approach to the design of a cylindrical array was developed. The cylindrical aperture of the array was divided into six columns of elements oriented along its length. Because of the symmetry when focus formation and scanning are limited to a plane oriented along the length of the array and perpendicular to it, the six columns are really three column pairs such that each column in a pair has the same phasing applied to its elements. The unique feature of this new design is that a different center-to-center spacing (different widths) for the elements was applied to each column pair. This results in a different location for the grating lobes for each of the three column pairs. This leads to much better performance when looking at grating lobe intensity levels compared to the intensity at the focus. [Work supported by NIH and NCSA.]

4aBB3. Thresholds for sound-induced lung hemorrhage for frequencies from 100 Hz to 1 MHz. Diane Dalecki, Sally Z. Child, and Carol H. Raeman (Dept. of Biomed. Eng., Hopeman 309, Box 270168, and the Rochester Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627)

Edwin L. Carstensen has made outstanding and wide-ranging contributions to the field of biomedical ultrasound. His many achievements span the areas of bioeffects of ultrasound, acoustic cavitation, lithotripsy, thermal and mechanical mechanisms, and nonlinear acoustics. In 1990, Carstensen first reported that pulsed ultrasound at diagnostic exposure conditions could produce mammalian lung hemorrhage [Child *et al.*, Ultrasound Med. and Biol. **16**, 817–825 (1990)]. Recent work from our lab has quantified the thresholds for murine lung hemorrhage over a range of acoustic frequencies from approximately 100 Hz to 1 MHz. Various exposure systems were used to generate acoustic fields over this broad frequency range in the laboratory. Through several different investigations, we have shown that murine lung responds to low-frequency underwater sound as a resonant structure. The resonance frequency of adult murine lung is approximately 325 Hz, and the pressure threshold for lung hemorrhage is lowest at the resonance frequency. The threshold increases for frequencies above lung resonance. The equation $P_{th}=0.01f^{0.64}$, where P_{th} is the threshold pressure in MPa and f is the acoustic exposure frequency in kHz, approximates our experimental lung threshold data, for long pulse durations, over the 2.5–1000-kHz range.

9:05

4aBB4. Nonlinear acoustics in E. L. Carstensen's career. David T. Blackstock (Appl. Res. Labs and Dept. of Mech. Eng., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

HIFU and harmonic imaging are hallmarks of present day biomedical ultrasound. But it wasn't always this way. At one time linear theory ruled supreme. Although by the early 1970s nonlinear acoustics had made its way into many areas of acoustics, e.g., physical acoustics, underwater sound, and aeroacoustics, biomedical ultrasound remained a safe haven for small-signalists. Ed Carstensen changed all that. By the mid-1970s he realized that linear theory could not account for certain phenomena he observed. At the 1978 Allerton Conference his invited talk entitled ''Nonlinear Aspects of Ultrasonic Absorption'' may have been the first public disclosure that nonlinear effects are important in biomedical ultrasound. His first archival work appeared as two papers in 1980; Tom Muir was a coauthor for both. During the next decade Ed and a series of colleagues showed that absorption could easily be dominated by nonlinear propagation effects. In turn the increased absorption causes increased heating, an important practical application. Ed's pioneering work paved the way for many of the well-known applications today.

9:25

4aBB5. Medical imaging using nonlinear ultrasound and the role of Edwin Carstensen. Kevin J. Parker (Univ. of Rochester, Dept. of Elec. and Comput. Eng., P.O. Box 270126, Rochester, NY 14627)

In the 1960s, with the development of weak shock theory by Blackstock and other advances, nonlinear acoustics found growing importance and applications in the atmosphere and underwater. By comparison, during this time frame the field of medical ultrasound remained largely focused on linear mechanisms. Three major subfields within medical ultrasound eventually developed major nonlinear theory and applications: cavitation, lithotripsy, and imaging. Edwin Carstensen's collaborative research and directorship of the Rochester Center for Biomedical Ultrasound played an important role in these developments. This talk focuses on the development of nonlinear acoustics to clinical imaging, tracing benchmark developments from the 1960s to the early 2000s, under the guiding influence of Ed Carstensen.

9:45

4aBB6. Stress, strain, and flow produced by a vibrator in, or on the surface of, a soft solid. Wesley L. Nyborg and Harold M. Frost (Phys. Dept., Univ. of Vermont, Burlington, VT 05405)

The field of biomedical ultrasound is greatly indebted to Edwin Carstensen for important contributions, without number, that he and his associates have made to understanding of the subject. These contributions have dealt not only with linear and nonlinear propagation of ultrasound in biological materials, but also with effects produced by ultrasound through various thermal and nonthermal mechanisms. Such understanding is important for advancing benefits and minimizing risks in applications of ultrasound. Many therapeutic applications discussed in the literature utilize focused beams of megahertz frequency, while others employ lower frequencies. In this talk, some findings will be presented from experiments in which a vibrating source of frequency in the range 20–90 kHz is brought into contact with the surface of a soft viscoelastic solid and information is obtained on resulting fields of strain. Under some

conditions the mechanical properties of the solid are altered by an exposure, in an apparent change of internal structure, and the change is maintained (recorded) until erased by a later sonication. The role of radiation force and other mechanisms in producing such effects will be discussed, as well as their possible relevance to ultrasonic angioplasty and other applications.

10:05–10:20 Break

10:20

4aBB7. Statistical estimation of ultrasonic propagation path parameters for aberration correction. Robert C. Waag and Jeffrey P. Astheimer (Dept. of Elec. and Comput. Eng., Univ. of Rochester, Rochester, NY 14627)

Parameters in a linear filter model for ultrasonic propagation are found using statistical estimation. The model employs an inhomogeneous-medium Green's function that is decomposed into a homogeneous-transmission term and a path-dependent aberration term. Power and cross-power spectra of random-medium scattering are estimated over the frequency band of the transmit-receive system by using closely situated scattering volumes. The frequency-domain magnitude of the aberration is obtained from a normalization of the power spectrum. The corresponding phase is reconstructed from cross-power spectra of subaperture signals at adjacent receive positions by a recursion. The subapertures constrain the receive sensitivity pattern to eliminate measurement system phase contributions. The recursion uses a Laplacian-based algorithm to obtain phase from phase differences. Pulse-echo waveforms were acquired from a point reflector and a tissuelike scattering phantom through a tissue-mimicking aberration path from neighboring volumes having essentially the same aberration path. Propagation path aberration parameters calculated from the measurements of random scattering through the aberration phantom agree with corresponding parameters calculated for the same aberrator and array position by using echoes from the point reflector. The results indicate the approach describes, in addition to time shifts, waveform amplitude and shape changes produced by propagation through distributed aberration under realistic conditions.

10:40

4aBB8. Thermal dose and the probability of adverse effects from biomedical ultrasound. Charles C. Church (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

Absorption of biomedical ultrasound heats tissue. Moderate heating to a few degrees above normal physiological temperatures can perturb biological systems, e.g., by altering normal metabolic processes, while brief, intense heating can kill cells, tissues, or entire organisms. Of particular concern for diagnostic ultrasound is thermally induced teratogenesis, which has been demonstrated in many animal species (chicken, mouse, rat, guinea pig, monkey) and apparently also occurs in humans. The nature and interpretation of such studies will be discussed. In therapeutic ultrasound, e.g., HIFU, the interest is in assuring the destruction of diseased tissue while sparing adjacent, healthy tissue. The concept of thermal dose will be described and used to quantify the probability and extent of biological effects expected from both diagnostic and therapeutic exposures. Additional factors relevant to thermal effects will also be considered, including the nature of the acoustic field *in situ*, as well as the state of perfusion and the variation in thermal sensitivity of the exposed tissue. It is concluded that adverse thermal events following diagnostic exposure are usually extremely rare, although there may be some reason for concern in a few special cases, while HIFU may induce significant collateral damage to proliferating cells pre- and postfocal zone.

Contributed Papers

11:00

4aBB9. The relation between lung damage induced by acoustic excitation and the subharmonic response of bubbles. Jonathan Young, Sheryl M. Gracewski (Dept. of Mech. Eng. and the Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627, grace@me.rochester.edu), Stephen McAleavy, and Diane Dalecki (Univ. of Rochester, Rochester, NY 14627)

Edwin L. Carstensen has made significant contributions to determining thresholds for and understanding mechanisms of mammalian lung hemorrhage caused by both ultrasound and lithotripter shock waves. The work presented here extends this knowledge base to investigate mechanisms of lung damage caused by acoustic excitation at the lung resonance frequency. This situation is relevant to divers exposed to high-amplitude, low-frequency sonar. Based on preliminary experiments, it was hypothesized that the threshold for lung hemorrhage at resonance occurs when lung surface oscillations at the subharmonic frequency of order one-half become unstable, producing significantly larger lung displacements. A balloon model was developed to approximate the behavior of small mammalian lung. The theoretical model for surface mode oscillations of a bubble was modified to account for the initial tension in the balloon membrane and used to investigate the stability of subharmonic oscillations. Reasonable agreement between the theoretical model and experimental measurements of the balloon surface displacements were obtained. In addition, a sharp pressure threshold for the presence of subharmonic oscillations was observed in the displacement data for the balloon model. The relevance of these simulations and measurements to murine lung hemorrhage will be discussed.

11:15

4aBB10. Some relationships among phase cancellation at a phase-sensitive receiving transducer, phase aberration in diagnostic medical imaging, and nonlinear imaging. James G. Miller, Kirk D. Wallace, and Mark R. Holland (Dept. of Phys., Washington Univ., St. Louis, MO, 63130, james.g.miller@wustl.edu)

A 1975 J. Acoust. Soc. Am. article by Marcus and Carstensen [Marcus & Carstensen, ''Problems with absorption measurements of inhomogeneous solids,'' J. Acoust. Soc. Am. **52**, 1334–1335 (1975)] reported perhaps the earliest study of potential artifacts in medical ultrasonics arising from phase-cancellation effects at the face of a phase-sensitive receiving transducer. This paper recognized the insights offered in a 1966 paper by Southgate [Southgate, ''Use of power-sensitive detector in pulse-attenuation measurements,'' J. Acoust Soc. Am. **39**, 480–483 (1966)] proposing a phase-insensitive receiver based on the acousto-electric effect to reduce phase-cancellation effects. Also in the 1970s, the Thurston lab at Duke and our lab in St. Louis examined consequences of propagating an ultrasonic field through the intrinsically inhomogeneous medium of soft tissue. Subsequently, several laboratories developed and implemented sophisticated algorithms applied to signals from receiving transducer arrays to provide some improvement. One of the most significant strides in reducing aberration artifacts came about serendipitously with harmonic mode (nonlinear) imaging. We will present experimental studies from our laboratory that examine approaches for reducing the profound effects arising from phase cancellation at the face of a phase-sensitive receiving transducer on measurements of ultrasonic attenuation and backscatter. Measurements utilizing phase-insensitive receiving transducers based on

the acoustoelectric effect and measurement using two-dimensional arrays of pointlike receivers to characterize tissue-mimicking materials and intrinsically anisotropic hearts will be discussed. [Work supported by NIH R37-HL40302 and R01-HL72761.]

11:30

4aBB11. Ultrasound hyperthermia in clotted blood and *ex vivo* cranial bone. Volodymyr M. Nahirnyak (Dept. of Phys., Univ. of Cincinnati, 231 Albert Sabin Way, Cincinnati, OH 45221-0511) and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH 45267-0586)

Ultrasound thermal effects have been hypothesized to contribute moderately to ultrasound-assisted thrombolysis. Transcranial ultrasound adjuvant to thrombolytic treatment of ischemic stroke requires a detailed investigation of the heating produced by ultrasound exposure to the skull bone, brain, and blood clots. Thermocouple measurements of *ex vivo* cranial bone and blood clot heating were compared to theoretical predictions of ultrasound hyperthermia, which assumed adiabatic conditions and provided an estimate for the worst-case scenario. The *in vitro* experiments were conducted at two temperatures, 20 °C and 37 °C. *Ex vivo* human skull, and porcine or human blood clots were exposed to 120 kHz, 1 MHz, or 3.5 MHz pulsed ultrasound with an 80% duty cycle and an acoustic spatial peak intensity of 0.5 W/cm^2. The thermal elevation in human cranial temporal bone was below 1 °C for all three frequencies. The ultrasound hyperthermia in porcine and human clots increased with an increase in center frequency, but did not exceed (0.33 ± 0.06) °C. These results provide the information necessary to quantify the contribution of a thermal mechanism for ultrasound-enhanced thrombolysis.

11:45

4aBB12. Acoustic radiation force imaging of prostate: Initial results. Stephen McAleavey, Menoj Menon (BME Dept., Univ. of Rochester, 308 Hopeman, Rochester, NY), and Deborah Rubens (Univ. of Rochester Med. Ctr., Rochester, NY)

Dr. Edwin Carstensen has contributed significantly to the understanding of the mechanical forces produced by acoustic waves in biological tissues, including work on cavitation and tactile perception of acoustic radiation force. This work presents some initial results in using radiation force for remote palpation of prostate tissue. Acoustic radiation force impulse (ARFI) images of excised human prostates are presented. Fresh prostates obtained immediately after surgery were scanned in an isotonic saline bath at room temperature. Scanning was performed with a Siemens Antares scanner and VF10-5 linear array. Tissue displacement was induced by pushing pulses of 30 to 75/μ s duration at 6.67 MHz and an I_{sppa} on the order of 1 kW. Observed peak displacements in healthy tissue were in the range of 6–12/μ m. Most prostates were scanned free-hand. One specimen was scanned with a transducer mounted to a single axis stage and imaged at 1-mm steps. The resulting images are presented with matching histology images and show good correspondence. [Work supported by the Wallace H. Coulter Foundation Early Career Award for Translational Research program.]

THURSDAY MORNING, 8 JUNE 2006 ROOM 552B, 8:00 TO 11:30 A.M.

Session 4aEA

Engineering Acoustics: Microphones and Loudspeakers

Daniel M. Warren, Chair

Contributed Papers

8:00

4aEA1. Acoustic noise in microphones from the thermal boundary layer resistance in enclosures. Stephen C. Thompson (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804) and Janice L. LoPresti (Knowles Electronics LLC, 1151 Maplewood Dr., Itasca, IL 60143)

Many types of acoustic sensors include a small enclosure as an integral part of the device. For example, a condenser microphone has a volume enclosed behind its diaphragm so that the acoustic pressure drives only the front of the diaphragm. In other sensors the enclosure may exist mainly to protect the sensitive components or to provide electrostatic shielding to the high impedance parts of the electrical circuitry. Whatever their reason, these volumes can play a significant role in the performance of the sensor. The adiabatic compliance of the enclosure is commonly included in device models. However, these enclosures are often small enough that the thermal boundary layer thickness can consume a substantial fraction of the enclosed volume at low frequencies. Thermal effects modify both the real and imaginary parts of the cavity impedance in ways that may be important in determining the sensitivity and internal noise of the device. This paper examines these effects. One interesting consequence is a thermal noise source that has a power spectral density proportional to 1/*f* throughout a substantial frequency band.

8:15

4aEA2. A ladder network impedance model for lossy wave phenomena. Daniel M. Warren and Janice L. LoPresti (Knowles Electronics, 1151 Maplewood Dr., Itasca, IL 60143, daniel.warren@knowles.com)

The ratio of Bessel functions $J_1(z)/J_0(z)$ often occurs in the calculation of impedance of lossy components in electroacoustic devices. In particular, the electric impedance of hearing aid receivers or loudspeakers has a term proportional to a Bessel function ratio of this form when losses due to eddy currents are taken into account. This so-called *semi-inductance* has been notoriously difficult to model in simple lumped-parameter circuit calculation tools such as SPICE. This paper presents a simple ladder network derived from the Bessel function ratio expressed as a continuous fraction. The same transformation has been used to model the acoustic impedance of small cavities with losses at the thermal boundary layer.

8:30

4aEA3. Contribution of cross talk to the uncertainty of microphone calibrations by the electrostatic actuator method. Allan J. Zuckerwar (Analytical Services and Mater., 107 Resrearch Dr., Hampton, VA 23666, ajzuckerwar@yahoo.com) and Richard M. Faison (Simco Electronics, Newport News, VA 23606)

Cross talk in electrostatic actuator calibrations is defined as the response of a test microphone to the actuator excitation voltage when the

microphone membrane is frozen, i.e., when the actuator polarization voltage is zero—an unavoidable nuisance effect that contributes to the calibration uncertainty. Two models for the cross talk are considered. In the first, the actuator excitation voltage is coupled to the microphone output through the stray capacitance between the actuator electrode and the microphone backplate; in the second, it is coupled through the ground resistance, which provides a common element between the input and output loops. In the stray capacitance model, at frequencies below the membrane resonance, the cross talk is independent of frequency, but in the ground resistance model it varies inversely with frequency. The frequency dependence of the cross talk thus serves as a discriminator between the two models. Measurements on condenser microphones of various sizes yield results that favor the stray capacitance model. The ratio of cross-talk signal to actuator pressure signal (at 94 dB *re*: 20 mPa) is found experimentally to be −74 dB for a 1-in. condenser microphone and nearly the same for 1/2-in. and 1/4-in. microphones.

8:45

4aEA4. Microphone bandwidth extension by digital correction of low-frequency roll-off. Timothy Marston and Thomas Gabrielson (Grad. Program in Acoust., Penn State Univ., 217 Appl. Sci. Bldg., University Park, PA 16802, tmm357@psu.edu)

When the low-frequency roll-off of a condenser microphone needs to be extended, the standard method of achieving extra bandwidth is to place a shunt capacitor in parallel with the input capacitance of the preamplifier. The result increases the bandwidth in the desired region, but sacrifices dynamic range across the entire bandwidth. It is possible to digitally extend the useful bandwidth of a microphone and only compromise dynamic range in the extended region. A technique for doing this has been developed and applied to microphones used to record sonic boom data. Microphones that have an insufficiently low-frequency response to capture the characteristic *N*-wave shape of sonic booms are corrected using the developed methods, and the results are compared to data captured by microphones with adequate low-frequency response. During the development of the filtering technique, it was found that phase response is critical in the correction process and its importance is demonstrated. [Research funded by the Applied Research Laboratory Educational and Foundational Fund.]

9:00

4aEA5. Infrasonic pistonphone calibration of acoustic transducers. Timothy Marston and Thomas Gabrielson (Grad. Program in Acoust., Penn State Univ., 217 Appl. Sci. Bldg., University Park, PA 16802, tmm357@psu.edu)

A simple infrasonic pistonphone was developed for the low-frequency calibration of acoustic sensors. The pistonphone, which utilizes a variable speed dc motor and a crank-driven piston, has a frequency range of 20 mHz to 20 Hz. Digital techniques have been implemented to correct for the inherent distortion in the crank-driven piston design, enabling simpler mechanical construction without significant loss in calibration accuracy. As in similar design geometries [H. E. Dahlke and John J. Van Houten, J. Acoust. Soc. Am. **37**, 1209 (1965)], the transition from an adiabatic to an isothermal pressure-volume relation is readily observed within the specified frequency range and results in a 0.5-dB reduction in calibration signal amplitude. A digital model for this transition is compared to data acquired using the pistonphone, and possibilities for increasing the calibration accuracy by use of this digital model are presented. [Research funded by the Applied Research Laboratory Educational and Foundational Fund.]

9:15

4aEA6. Multimicrophone method for measurement of acoustic absorption. Charles H. Oppenheimer (DSA, 4900 SW Griffith Dr., Ste. 216, Beaverton, OR 97005)

A multimicrophone method for measurement of the acoustic absorption of small material samples using impedance tubes is presented. The multimicrophone method may be implemented with actual or synthetic microphone arrays, the latter involving successive measurements and a roving microphone, and is an alternative to the two-microphone method of ASTM E 1050. The effects of absorption measurement inaccuracy due to microphone response (magnitude and phase) bias and measurement noise are determined by simulation. Simulation results indicate that the multimicrophone method is more robust against microphone bias and noise and is therefore more accurate than the standard method, especially as microphone counts increase, while requiring minimal additional effort and cost.

9:30

4aEA7. Impulse response of a spherical microphone array (eigenmike). Colin Barnhill, James West, and Ilene Busch-Vishniac (Johns Hopkins Univ., 3100 Wyman Park Dr., Rm. 157, Baltimore, MD 21211, shaolin_cb@yahoo.com)

Spherical microphone arrays are capable of complete three-dimensional sound field capture and robust noise cancellation [J. Meyer & G.W. Elko, ''A Highly Scalable Spherical Microphone Array Based on an Orthonormal Decomposition of the Soundfield,'' in Proc. IEEE Int. Conf. Acoust., Speech, Signal Processing, 2002, Vol. II, pp. 1781–1784]. The spherical array tested has 24 omni-directional pressure microphones arranged on a rigid sphere. The sound pressure from each sensor is decomposed into spherical harmonics (standard eigen analysis) which results in rotationally symmetric output along any axis (three dimensionally) through the center of the sphere. An accurate impulse response of this system is important to sound localization and tracking methods. Time history can also be used to enhance the prediction model for source movement. The impulse measurements on this array were made in a semi-anechoic chamber and are in good agreement with expected results. The three main characteristics of the impulse response that will be discussed are the delay times, amplitude differences, and frequency response.

9:45

4aEA8. Development of microelectromechanical systems capacitive microphone for high-frequency applications. Michael Pedersen (Novusonic Corp., P.O. Box 183, Ashton, MD 20861, info@novusonic.com)

In this paper the development is described of a new high-frequency capacitive microphone based on the Knowles SiSonic MEMS microphone technology. The intended application for these microphones is aeroacoustic testing, which requires a transducer bandwidth of 80–100 kHz and the ability to measure sound pressures to 150 dB SPL without excessive distortion. The MEMS microphone structure was modified to meet these requirements and still be manufactured using the Knowles SiSonic production process. In addition, the microphone package was modified to eliminate the front port resonance, at approximately 12 kHz, associated with the standard SiSonic device. Specifically, the microphone package was modified with a lid that has lower acoustic inertance, thereby increasing the resonance frequency of the Helmholtz resonator formed by the front port and the microphone interior cavity. Details of the design process and the theoretical behavior of the microphones are presented, and it is shown that a microphone sensitivity of 0.5–1 mV/Pa can be achieved for a 100-kHz bandwidth. Preliminary results from fabricated microphones indicate a sensitivity around 0.5 mV/Pa and an A-weighted noise level of approximately 61.5-dB SPL. A more detailed analysis of the microphone noise spectrum and frequency response is presented.

4aEA9. Multiphysics analysis of a loudspeaker. Marcellin Zahui (Univ. of North Dakota, Grand Forks, ND 58202)

A coupled physics analysis of a loudspeaker is presented. This finite-element analysis of a theoretical loudspeaker is performed using a commercial finite-element package installed on a Window-based personal

computer. The objective is to use multiphysics modeling to analyze the loudspeaker coupled fields (electric, magnetic, structural, fluid, and acoustic) that are solved in a single step. All the components of the electro-acoustic transducer, i.e., the rear plate, the magnet, the voice coil, the pole piece, the spider, the frame, the cone, and the dust cap are incorporated in a single finite-element model. The system is then analyzed using an electrical input circuit also modeled using finite element to evaluate the acoustic radiation from the cone. Even though the solution is obtained in a single analysis, each physics field is separately validated with known and well-established data. First the magnetic field is validated, then the resulting structural displacement of the cone, and finally the fluid field, followed by the acoustic field. The work is an attempt to provide a global design and optimization environment for electro-acoustic transducers and other acoustic multiphysics systems such as active noise control.

10:30

4aEA10. Acoustic impedance matching for axial wave radiation from cylindrical polyvinylidene fluoride film air ultrasonic transducer mounted inside of concentric hollow cylinder. Mionoru Toda (Measurement Specialties Inc., 460 E. Swedesford Rd., Ste. 3005, Wayne, PA)

It is well known that radial vibration of cylindrical polyvinylidene fluoride (PVDF) film excites acoustic waves towards radial direction in 360-deg range. When the length of cylindrical film is equal to or less than half the wavelength, the excited wave towards the axial direction becomes stronger than the radial wave. In this work, a cylindrical PVDF transducer was concentrically mounted inside of a hollow cylinder, and it was observed that the smaller the gap between film surface and inner wall surface of the pipe, the more the axial wave was excited. In order to explain this phenomenon, radiation impedance for axial wave excitation was calculated, and it was found that (1) radiation impedance increases with decreasing gap; (2) energy flow from transducer to axial wave increases with decreasing gap and becomes maximum at impedance matched condition; and (3) for the radiation impedance larger than optimum matched condition, the output decreases with increasing radiation impedance (decreasing gap) and the resonance frequency of cylindrical transducer shifts to the higher side due to loading of imaginary part of too high radiation impedance. All these results were successfully observed by experiments at 85-kHz burst mode. This principle can be applied to a new class of ultrasonic air transducer.

10:45

4aEA11. Microelectromechanical-systems-based parametric transmitting array in air—Application to the ultrasonic ranging transducer with high directionality. Haksue Lee and Wonkyu Moon (Dept. of Mech. Eng., POSTECH, Pohang, Kyungbuk 790-784, South Korea, wkmoon@postech.ac.kr)

Reduction of the transducer size decreases the efficiency of the secondary wave generation in the parametric transmitting array. To overcome this problem, MEMS-based transducer radiating high intensity sound is required in the parametric array. A high-performance PZT MEMS ultrasonic transducer composed of many small membrane-type radiator units was designed and fabricated by bulk micro-machining, and the secondary wave generated by the transducer was observed. This experiment proves that a MEMS-based parametric transmitting array is possible and applicable to some devices. A new ranging ultrasonic transducer with high directionality as an application was proposed because ultrasonic transducers generally need to be designed for high directionality to enhance the spatial resolution in the pulse-echo measurement in air. The 40-kHz difference tone, the measuring signal, was generated using 100- and 140-kHz primary tones by the PZT MEMS ultrasonic transducer. The difference tone had a half-power beam width of around 5 deg and a sound pressure level of over 85 dB at the peak. For the real application, higher sound pressure level should be achieved, and this will be included in the future work. [Research supported by MIC.]

11:00

4aEA12. A stepped plate transducer as an ultrasonic loudspeaker. Dong Hoon Yi, Hak-sue Lee, and Wonkyu Moon (POSTECH, San 31, Hyoja-dong, Nam Gu, Pohang, Gyungbuk, Korea, maneuvre@postech.ac.kr)

Research on the ultrasonic loudspeaker has been under way since Mary Beth Bennett and Blackstock verified the existence of parametric array phenomenon in air experimentally. Although several transducers that make use of piezoelectric films have been proposed, an ultrasonic loudspeaker system is not developed enough to be practical due to its high cost and high power consumption. In the 1970s, Gallego-Juarez *et al.* developed an ultrasonic transducer exploiting flexural modes of circular radiating plate, which shows highly efficient and directional performance. The feasibility of this type of transducer as ultrasonic loudspeakers, however, has not been investigated. Thus, a transducer with a stepped radiating plate of 283 mm diameter and a resonance at 40 kHz was designed, manufactured, and tested. In order to maximize the pressure radiated, piezoelectric ceramics were placed at the nodal point of the structure. The features of the transducer manufactured are over 130 dB of maximum primary wave at resonance on the acoustic axis, half-power beamwidth of primary ultrasound less than 10 deg, 40 to 60 dB of secondary waves from 1.5 to 20 kHz at 1m, and half-power beamwidth of secondary sound less than 10 deg.

11:15

4aEA13. Electrostatic negative stiffness and coupling factor of micromachined capacitive ultrasonic transducers. Li-Feng Ge (School of Electron. Sci. and Technol., Anhui Univ., Hefei 230039, China)

A theoretical model for micromachined capacitive or electrostatic ultrasonic transducers (mCUT or cMUT) was presented [L.-F. Ge, Theoretical and Computational Acoustic 2001, edited by E.-C. Shang *et al.*, *World Sci.*, 459–469, 2002; *Proc. 18th Intl. Conf. Acoustics, Vol. III*, 2255–2258, 2004]. The model takes into account the bending stiffness of diaphragm tension in diaphragm, compressibility of air within air-gaps, the effects of the metal electrode coated on diaphragm, and a negative stiffness caused by electrostatic attraction, providing a comprehensive and accurate description of the behavior of mCUTs. The electrostatic negative stiffness is derived from the electrostatic force based on the parallel plate capacitor assumption and is expressed as $K_{neg} = -\varepsilon_0 V_0^2 / x_0^3$, where ε_0 is the permittivity of air, V_0 the bias voltage, and x_0 the effective separation between two electrodes. It corresponds to a negative capacitance C_{neg} or negative impedance $\mathbf{Z_{neg}}$ at the mechanical port in the equivalent electrical circuit for mCUTs. Thus, the electromechanical coupling factor $\mathbf{K}$ can be defined by $\mathbf{K}^2 = (-\mathbf{Z_{neg}})/\mathbf{Z_{MO}}$, which is a ratio of the electrostatic negative impedance to the open-circuit mechanical impedance of the mCUT. The definition may give a new view for the coupling factor of electromechanical transducers. [Work supported by NSFC (60374044).]

4aEDa1. Ultrasound imaging instruction for veterinary students at Colorado State University. Robert H. Wrigley (Veterinary Medical Ctr., Colorado State Univ., Fort Collins, CO 80523)

Didactic ultrasonography instruction to the veterinary students begins with the physical principles of sonography, machine selection, and operating controls. Subsequently, image artifacts and normal sonograms of the heart and abdominal organs are presented. Sonograms of pregnancy and abnormal sonograms of common diseases are discussed. In the final-year practicum course, small groups of students (2–4) spend a week in the echocardiography lab and the soft-tissue imaging lab. Here, students acquire hands-on sonography skills and become proficient in sonography of small animals and horses. An Internet-based interactive instruction module on the equine limb was developed to enable veterinary students to better learn ultrasonography of tendons/ligaments of the metacarpus. Interactivity was achieved by creating clickable zones on the tendons and ligaments. Students are challenged to apply the knowledge gained studying normal ultrasound anatomy to clinical patients affected with tendon/ligament injuries. Students are asked to identify (by clicking on) the location of the sonographic lesions. The program provides immediate feedback on their ability to recognize the site of the injury. In addition, having the program web-based allows students to review the instructional material on a time schedule that best fits their needs and from remote locations.

8:35

4aEDa2. Education in medical acoustics. Tyrone Porter (Dept. of Biomed. Eng., Univ. of Cincinnati, 231 Albert Sabin Way, 6166 Medical Sci. Bldg., Cincinnati, OH 45267-0586)

The field of medical acoustics has grown tremendously in the last 30 years. Sophisticated ultrasound scanners are utilized to image a developing fetus in the womb or blood flow in the vessels. High-pressure acoustic pulses travel through muscle, fat, and capillary beds to pulverize kidney stones with minimal damage to the intervening tissue. Gas-based microbubbles stabilized with polymeric or liposomal shells are injected into the vasculature to enhance the contrast in ultrasound images or to deliver life-saving drugs. Due to the interdisciplinary nature of medical acoustics, educating the next generation of clinicians, engineers, and researchers within the field has become more challenging. Students must gain some understanding of a variety of concepts, including the derivation of the wave equation, the effect of biological media on the propagation of ultrasound (attenuation, scatter, etc.), signal-processing techniques for converting scattered sound into images, and the effect of viscoelastic shells on the forced oscillation of microbubbles. Armed with this knowledge, medical acousticians will continue to develop innovative diagnostic and therapeutic applications for ultrasound.

4aEDa3. Teaching ultrasound instrumentation in medical and dental schools. Maureen Stone (Dept. of Biomed. Sci. and Dept. of Orthodontics, Univ. of Maryland Dental School, 666 W. Baltimore St., Baltimore, MD 21201, mstone@umaryland.edu)

This presentation will describe teaching strategies for applying ultrasound, a commonly used instrument in medical schools, to studying a novel application, the tongue. These methods have been used with students in otolaryngology and dentistry as well as linguistics, engineering, and speech and hearing. Four areas are considered important for students to know. (1) Introduction to ultrasound principles and use of commercial machines. Students are taught basic principles of sound propagation including focused versus nondirectional sound waves, scan types, and tissue properties. Commercial machine features are explained, such as gain control, depth setting, and calibration. (2) Data collection for research versus clinical purposes. Students are taught procedural requirements for research studies, including the importance of choice of task, positioning of transducer, and head stabilization to allow normalization across subjects. (3) Reduction and analysis of the high-dimensional ultrasound images. Data conditioning includes understanding how to interpret images, identify structures of interest, determine artifacts, find and use references, and extract tongue surface contours from the images. (4) Interpretation of data. It is easy to see tongue differences, but harder to capture them numerically. Students learn tools to reduce contour dimensionality, average and compare contours and contour sequences. [Research supported by R01 DC01758 NIDCD.]

4aEDa4. Use of ultrasound as educational tool in medicine. E. Carr Everbach (Eng. Dept., Swarthmore College, Swarthmore, PA 19081)

Ultrasound is an imaging and therapy technology that is becoming increasingly important in modern medicine. Though only a fraction of physicians nationwide uses ultrasound in their practices, most medical students and many technicians receive an overview of the principles of ultrasound as part of their training. Often this overview is the only introduction to acoustics, and can be used as an educational tool to raise broader issues. This talk will describe the basic education in biomedical ultrasound obtained by most physicians and healthcare workers, and will discuss what is left out that should be part of medical education.

10:20

4aEDa5. Teaching acoustics in the medical and related fields. Daniel R. Raichel (CUNY Grad. Ctr. and Eilar Assoc., 2727 Moore Ln., Fort Collins, CO 80526)

Acoustics is playing an ever-increasing role in the medical and related fields. Besides the more obvious applications such as otology, audiometry, stethoscope usage, effects of sound on hearing, and psychological well-being, more modern applications include ultrasound diagnostics and therapeutics, fetal monitoring, surgical applications, removal of dental plaque, musical therapy, etc. This gives rise to the question: how much acoustical theory needs to be taught to future practitioners, many of whom were not science or engineering majors during their undergraduate years? A motor vehicle operator, for example, does not need to understand the fundamentals of internal combustion and mechanics of power transmission in order to develop the skill to handle a vehicle; he/she needs to learn applicable motor vehicle laws. In the same vein, a prospective medical practitioner does not need to learn solutions to the wave equation and understand the basis of how frequency analyzers function, but he/she needs to develop the skills to use applicable acoustic technology, interpret the results with understanding of their ramifications, and be aware of technical limitations such as permissible ultrasound dosages. Acoustic education requirements in a number of medical subfields are discussed in terms of depth and breadth of coverage.

4aEDb1. Acoustic education and the Bolognan process in Russia. Nikolai Zagrai and Vladislav Zakharevich (Taganrog State Univ. of Radio-Eng., GSP-17A, 44 Nekrasovsky St., Taganrog, 347928, Russia)

Acoustic education in Russia is traditionally based on a solid natural-sciences curriculum with core classes in higher mathematics, physics, continuum mechanics, and electronics. However, parallel to the so-called specialist qualification encompassing a standard 5-years engineering training, a new education trajectory of bachelor (4 years) and master (6 years) qualifications has emerged as a result of the international Bolognan Agreement recently signed by the Russian Federation. Students willing to pursue the master qualification may enroll in this program after completing either bachelor or specialist training. Aimed at making Russian educational programs more easily understood, we are implementing a smooth transition from traditional academic hours used for weighting program content and value in the Russian educational system to internationally recognized credit hours. Nowadays, mainstream technical universities include individual creative thinking approach in their modulus-rating systems with the multilevel assessment. The latter is related to direct rating educational technologies. In general, the content of Russian education programs in acoustic is equivalent to similar foreign programs.

11:15

4aEDb2. Optical table with embedded active vibration dampers (smart table) as an educational tool in structural acoustics and vibration. Vyacheslav M. Ryaboy (Newport Corp., 1791 Deere Ave., Irvine, CA 92606, vyacheslav.ryaboy@newport.com)

The actively damped optical table contains two sensor-actuator assemblies connected to a digital feedback controller. The controller is programed to damp resonant flexural vibrations of the table. The controller can auto-tune to accommodate changes in the payload. It has a software interface that allows one to switch the damping on and off, to regulate the amount of active damping manually, to analyze the signals from embedded vibration sensors, and to display the results in both time and frequency domains. For an advanced user it is possible to completely reprogram the controller. Besides its main purpose of vibration control, the smart table can be used for laboratory demonstrations of various phenomena in structural acoustics without additional equipment or with minimal additional technical means. Among these effects: structural response in the frequency domain (resonance peaks versus forced operational peaks, damped versus undamped system); time response of damped versus undamped system; tonal sound emission in response to random excitation (damped versus

undamped system); open-loop response of the control system and mechanical impedance of the structure versus closed-loop response. More experiments and demonstrations can be devised as educators and students become more familiar with the system.

11:30

4aEDb3. Development of an acoustics program at Morgan State University. M. Roman Serbyn (Dept. of Phys. and Eng. Phys., Morgan State Univ., 1700 E. Cold Spring Ln., Baltimore, MD 21251, rserbyn@jewel.morgan.edu)

This report describes the gradual implementation of one educator's plan to introduce acoustics into the curriculum of a medium-size university. Rooted in the physics department, the program from its inception has emphasized the interdisciplinary nature of the discipline. The first course, consisting of a series of lectures within an existing format of ''Great Issues,'' was offered to seniors of the university in 1998. Subsequently one graduate and two undergraduate courses were developed and approved. The undergraduate course, Acoustics and You, has been particularly popular because of the diversity of topics. The graduate course is a typical presentation of the fundamentals of acoustics with discussion of selected applications. Acoustical research has been limited to the author's areas of interest and subject to time and funding constraints. Recent collaboration with the departments of biology and psychology have been very beneficial to the growth of the program. The narrative will be illustrated with course syllabi, student data, as well as lessons learned, and plans for the future.

11:45

4aEDb4. A Portable device to illustrate two methods for vibration reduction namely tuned dynamic absorber and isolation mounting. Samuel Koretas and M. G. Prasad (Dept. of Mech. Eng., Stevens Inst. of Technol., Hoboken, NJ 07030, mprasad@stevens.edu)

Mechanical vibrations can be harmful to structures as well as to humans. It is important to understand the principles of design that are used in developing various methods for reducing vibration. There are several tools at our disposal to reduce the vibrations transmitted from a vibration machine to the building structure. Two commonly available methods of vibration control are using passive vibration isolation mountings and tuned mass absorbers. This paper presents the design and working of a portable device to illustrate both methods of vibration reduction. We can examine the performance of both mounting and absorber using this physical device. The analytical and experimental work shows that such a device can effectively illustrate the principles involved in the design of mountings and absorbers. Also, the device can be used to show the influence of various physical parameters on performance. The presentation will also include the discussion on the role of such devices in enhancing the understanding of design principles in acoustics, noise, and vibration.

4aMU1. Real-time measurement/viewing of vocal-tract influence during wind instrument performance. Gary P. Scavone (Music Technol., Schulich School of Music, McGill Univ., 555 Sherbrooke St. West, Montreal, QC, H3A 1E3 Canada)

Since the early 1980s, there have been a number of investigations into the role and influence of a player's vocal tract on the sound production of wind instruments. While the underlying acoustic principles are relatively well understood, a general lack of agreement remains within both the music acoustics and performance communities with regard to the importance of this mechanism during playing conditions. Disparities arise in part because subtle manipulations of the oral cavity can affect the response of the instrument without necessarily producing effects audible to an observer. A real-time measurement system is demonstrated that provides a visual comparison of the relative strengths of the ''upstream'' windway and ''downstream'' air column impedances under playing conditions. The system assumes continuity of volume flow on either side of the ''reed,'' which leads to a direct proportionality between the upstream and downstream pressures and impedances. Playing experiments clearly demonstrate many instances in which vocal-tract manipulations can cause impedance peak magnitudes in the mouth cavity to exceed those in the downstream air column. In addition to providing visual ''proof'' of such manipulations, the system is expected to offer a pedagogical tool to help performers better learn how to make use of this control mechanism.

9:15

4aMU2. Amplitude fluctuations within musical instrument sounds because of impulse reflections. Rolf Bader (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstrasse 13, 20354 Hamburg, R_Bader@t-online.de)

Musical instrument sounds nearly always show amplitude fluctuations in their overtones within the quasisteady state of the sound.These fluctuations make the sound more lively and are found in blown instruments like the saxophone or clarinet, in string instruments like the guitar or the violin, or in percussion instruments. The reason for this can be found within a feature common to all musical instruments, their impulse-driven behavior. Not only do the blown instruments work with impulses; the string forces of plucked, strucked, or bowed instruments of the top plate are also an impulse train. So, when looking at the system during the steady state not like one of standing waves but of impulses being reflected at different inhomogeneties within the structure, these reflections can be shown to be the reason for the amplitude fluctuations. The mechanism is caused by the fact that the energy within an impulse is split into potential and kinetic energy, where only the kinetic energy is radiated. When traveling along a

homogeneous region, the energies are more or less conserved. But, during reflections, these energies get larger and smaller and cause a fluctuation in the kinetic energy and so in the radiation of sound.

9:30

4aMU3. Acoustical effects of reed cells in the American reed organ. Benjamin A. Franta and James P. Cottingham (Phys. Dept., Coe College, 1220 First Ave. NE, Cedar Rapids, IA 52402)

In a reed organ the free reed is mounted above the windchest and is typically surrounded by a reed cell cavity. The length of this tubelike cavity varies from just slightly longer than the reed in some instruments to several centimeters longer in others. Earlier research on effects of the reed cell focused mainly on the lowering of sounding frequency due to the presence of the cell [J. Cottingham, ''Effects of reed cell geometry on the vibration frequency and spectrum of a free reed,'' J. Acoust. Soc. Am. **101**, 3143 (1997)]. Reed cells are shown to have a significant effect on the radiated waveform and spectrum. The length and interior geometry of the cell are significant factors in determining this effect. Changes in reed cell dimensions have a greater effect on the sound spectrum than changes in reed dimensions. It is shown that the presence of a reed cell considerably enhances the upper harmonics of the spectrum. Higher vibrational modes in air-driven free reeds have recently been observed [A. Paquette, J. Vines, and J. Cottingham, ''Modes of vibration of air-driven free reeds in transient and steady state oscillation,'' J. Acoust. Soc. Am. **114**, 2348 (2003)]. The current measurements indicate that the reed cell substantially affects the higher vibrational modes of the reed, particularly enhancing the second and third transverse modes. [Research supported by the Carver Summer Scholar Program.]

9:45

4aMU4. Experimental and calculated frequencies of the Southeast Asian naw. Eric A. Dieckman (Truman State Univ., Kirksville, MO 63501, ead603@truman.edu) and James P. Cottingham (Coe College, Cedar Rapids, IA 52402)

The naw, an Asian free-reed gourd pipe, is constructed of pipes open at both ends with a free reed in the side of each pipe near one end. The pipes of the naw are cylindrical over a significant portion of their length but have a slightly tapered bore near the reed end. The bottom end of the pipe can be covered with the player's thumb to bend the pitch. Previous research on the khaen, a similar instrument with a cylindrical bore, found that the sounding frequencies of the khaen are well approximated using the simple equation for an open cylindrical pipe. This is not possible for the naw. A method of transmission matrices has been used to calculate the theoretical resonant frequencies of the naw pipes, both open and closed. The calculated values agree well with the resonant frequencies determined experimentally by measuring the input impedance of the pipe. When blown normally, the open pipe sounds near its calculated frequency, while the closed pipe sounds slightly lower than the open pipe frequency. By underblowing the reed, however, the closed pipe can be made to sound near its predicted resonant frequency. [Research supported by NSF REU Grant PHY-0354058.]

10:15

4aMU5. Benchmarking the lattice Boltzmann method for the determination of acoustic impedances of axisymmetric waveguides. Andrey Ricardo da Silva, Philippe Depalle, and Gary Scavone (Music Technol. Area, Faculty of Music, McGill Univ., 555 Sherbrooke St. West, Montreal, Canada H3A 1E3, andrey.dasilva@mail.mcgill.ca)

A numerical technique for determining the acoustic impedance of axisymmetric waveguides based on the lattice Boltzmann method (LBM) is proposed here. This approach presents some desirable characteristics, namely, the possibility of explicitly considering the propagation of waves at low Mach number conditions with a relative low computational cost when compared to traditional continuum methods. The validation of the method is achieved by simulating the radiation of an open unflanged pipe using LBM and comparing the results with those obtained through a finite-element model and through the analytic solution derived by Levine and Schwinger. Finally, the results and the discussion of the method in terms of its computational efficiency and applicability to the simulation of wind instruments at more realistic conditions are presented. [The first author was supported by CAPES (Brazil).]

4aMU6. Keyboard characterization using spiral and Cartesian mappings of the harmonic series. Palmyra Catravas (ECE Dept., Union College, Schenectady, NY 12308, catravap@union.edu)

Spatial transformations of functions of frequency can facilitate the analysis of frequency spectra and the identification of characteristic spectral patterns. Here, spiral and Cartesian mappings of the harmonic series are applied to frequency spectra from several keyboard instruments (modern grand piano, modern upright piano, fortepiano). Their utility in comparing properties of the instruments, including inharmonicity, coupling between strings, tuning errors, and beat frequencies, and simply identifying a fundamental frequency will be described. An update on a previous application of the transformations (identification of the B-A-C-H motif in music) will also be presented.

4aNS1. Development of artificial neural network classifier to identify military impulse noise. Brian A. Bucci and Jeffrey S. Vipperman (Dept. of Mech. Eng., Univ. of Pittsburgh, 648 Benedum Hall, Pittsburgh, PA 15261)

Civilian noise complaints from urban encroachment have curtailed military exercises that produce high levels of impulse noise. Currently, monitoring stations are in place around many military installations to monitor noise levels. However, these monitoring stations do not provide real-time data and suffer from false positive detections. This project sought to develop algorithms with improved noise classification accuracy. Various types of military impulse noise and nonimpulse noise were measured and processed. Approximately 1000 waveforms were field collected (670 nonimpulse and 330 military impulse). Although several metrics were examined, the conventional time domain metrics of kurtosis and crest factor as well as two novel frequency domain metrics, weighted square error and spectral slope, were found to work best. The computed metric values were used to train and verify the performance of the artificial neural network (ANN), which was able to achieve 100% accuracy on training data and 100% accuracy on verification data. [This research was supported wholly by the U.S. Department of Defense, through the Strategic Environmental Research and Development Program (SERDP).]

4aNS2. Analysis of high-amplitude jet noise using nonlinearity indicators. Kent L. Gee, Micah R. Shepherd (Dept. of Phys. and Astron., N283 ESC, Brigham Young Univ., Provo, UT 84602, kentgee@byu.edu), Lauren E. Falco, Anthony A. Atchley (The Penn State Univ., University Park, PA, 16802), Lawrence S. Ukeiley, and Bernard J. Jansen (The Univ. of Mississippi, University, MS 38677)

Nonlinear effects in high-amplitude jet noise are often characterized by examining spectral changes over some propagation range. However, in the case of typical laboratory-based measurements with model-scale nozzles, the study of nonlinearity via spectral changes is made difficult by both limited measurement bandwidth and short propagation distances. One analysis technique that potentially can overcome these difficulties is a single-point measurement of nonlinearity that has been studied most recently by Falco *et al.* [J. Acoust. Soc. Am. **117**, 2596 (2005)]. Another potential solution is bispectral analysis, which has been used in the past as an indicator of nonlinearity for a wide variety of applications. Both of these analysis methods have been applied to data from recent laboratory measurements at the National Center for Physical Acoustics. Observed trends for a variety of source conditions, measurement angles, and propagation distances are discussed. [Work supported in part by the Office of Naval Research.]

4aNS3. A comparison of differences in highway noise barrier design using TNM 2.5 and STAMINA. Ning Shu, Louis Cohn, Rowell Harris, and Teak Kim (Univ. of Louisville, Louisville, KY 40292)

In April 2004, the FHWA TNM 2.5 was released; all state transportation agencies are required to use it for all Federal funded projects by FHWA. TNM 2.5 has been modified from the previous versions to update the noise energy back to the source, and therefore influence the predicted insertion loss and absolute noise levels. The study was designed to compare the noise barrier design by both TNM 2.5 and TNM 2.0, as well as STAMINA 2.0. All these models were used to design noise barriers on the I-64 St. Louis, MO project with the length for the mainline of 11 mile.

9:30

4aNS4. Analysis of brake squeal noise using the finite-element method: A parametric study. Samir N. Y. Gerges, Mrio Trichs, Jr., and Alessandro M. Balvedi (Dept. of Mech. Eng., Federal Univ. of Santa Catarina, Trindade, Florianopolis, SC, Brazil)

Brake squeal noise has been under investigation by the automotive manufacturers for decades due to consistent customer complaints and high warranty costs. Brake squeal is a problem that has been faced by several numerical and analytical methods in the last decade. Among then, finite-element analysis is proving to be a useful tool to predict the noise occurrence of a particular brake system during the design stage. The finite-element method (FEM) has been employed to analyze the squeal propensity of the disc brake systems. The complex eigenvalue analysis conjugated with FEM has been widely used to detect unstable frequencies in numerical brake systems models. These unstable frequencies are related, in most cases, with high sound pressure levels generated during the brake system operation. This paper summarizes the application of the complex eigenvalue analysis in a finite element model. The effects of the operating parameters (friction coefficient, braking pressure, brake temperature) and wear on the dynamic stability of the brake system are examined. After identifying unstable frequencies and the behavior under different conditions, the performance of some control methods are tested. Changes in material properties and the application of brake noise insulators are presented and its effect discussed.

9:45

4aNS5. NOIDESc: A novel traffic noise description scheme. Brian Gygi, Werner Deutsch, Holger Waubke, and Anton Noll (Acoust. Res. Inst. of the Austrian Acad. of Sci., Reichratsstrasse 17, Vienna 1010 Austria)

A novel framework for the acoustic and psychoacoustic description of noise signals (railway and road) has been proposed in order to extend and improve traditional noise classification schemes. In addition to measures of averaged sound-pressure level and noise exposure duration, the description scheme includes psychoacoustic parameters such as spectral centroid, spectral spread, modulation spectrum, and further dynamic aspects of the sound events corresponding in part to the MPEG-7/4 standard. The dynamic changes between foreground and background are addressed in the model. The approach assumes the evaluation of several low-level acoustic parameters of the noise, to be integrated into few high-level features by means of statistical methods, such as Gaussian mixture models and cluster analysis. As the usage of noise monitoring systems is expected to increase in the near future, the cumulative collection of calibrated sound recordings will provide comprehensive regional and supraregional sound databases to serve as input for automated noise classification. [The work in progress is performed in cooperation with the division of Acoustics of the TGM Vienna and is supported by the Austrian FFG.]

4aNS6. New approach to studying traffic noise nuisance. Cobis Rabah Derbal and Hamza Zeghlache (BP 12 SMK, Constantine 25003, Algeria, cobis.derbal@free.fr)

More often the problem of noise and sonic pollution particularly in urban sites, is studied by different disciplines such as physics, acoustics, psychoacoustics, medicine, and others. Some studies are carried out in laboratories taking noise and sonic phenomena as samples cut off from their realistic context. Urban noise is studied as well by making abstraction of the different contextual parameters by idealizing a rather complex sonic environment. This derives often on incompatible results that can hardly be used in real situations of urban noise problems. The noise, according to this present approach, is supposed to react with the surrounding space, and it takes the form and the quality of the place by defining and requalifying it. It is found that the contextual aspects such as social, cultural, or even symbolic dimensions modulate the listening and the perception quality of the noise. The multiparameter dimension study of the noise in urban context is necessary. The small number of studies already done based on such multidisciplinary approach and the results that came out of such studies comfort well our effort and are very encouraging to go ahead with this methodological approach.

4aNS7. Predicting acoustic and seismic pulses from outdoor explosions. Keith Attenborough, Patrice Boulanger (Dept. of Eng., The Univ. of Hull, Cottingham Rd., Hull HU6 7RX, UK), and Donald Albert (U.S. Army ERDC Cold Regions Res. and Eng. Lab., Hanover NH 03755-1290)

To support the formulation of a simple model that can be used for assessment and prediction of ground vibration levels due to above-ground explosions, a fast field program for layered air ground systems (FFLAGS), developed originally for continuous sound sources, has been extended to enable predictions of propagation from impulsive sound sources in a refracting atmosphere above layered porous and elastic ground. Using a mixture of measured and best-fit parameters, the pulse version of the code (PFFLAGS) has been found to give predictions of the air pressure spectrum above ground and the vertical component of solid particle velocity near the ground surface that compare tolerably well with published data for the spectra and waveforms of acoustic and seismic pulses at short range (60 m) in grass- and snow-covered ground and at longer range (3 km) in forested terrain. The predicted seismic pulses in the presence of the snow cover explain a phenomenon frequently observed for shallow snow covers whereby a high-frequency ground vibration is modulated by a lower-frequency layer resonance [Work supported in part by SERDP SEED Project SI-1410 and Contract Number W90C2K9887EN010001 through the European Research Office of the U.S. Army.]

10:45

4aNS8. Noise in the adult emergency department of Johns Hopkins Hospital. Douglas Orellana, Ilene J. Busch-Vishniac, and James E. West (Mech. Engr. Dept., Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218)

While hospitals are generally noisy environments, nowhere is the pandemonium greater than in an emergency department, where there is constant flow of patients, doctors, nurses, and moving equipment. In this noise study we collected 24-h measurements throughout the Adult Emergency Department of Johns Hopkins Hospital, the top-ranked hospital in the U.S. for 15 years running. The emergency department is structured into pods, each of which specializes in particular types of treatment. We obtained measurements in each pod. Compared to data collected at other locations of the hospital, the average L_{eq} throughout the emergency department is about 5 dB (A) higher. Within the emergency department the triage area has the highest L_{eq}, ranging from 65 to 73 dB (A), primarily due to being at the entrance to the department. Sound levels in the emergency department are sufficiently high [on average between 62 to 67 dB(A)] to raise concerns regarding the communication of speech without errors, an important issue everywhere in a hospital and a critical issue in emergency departments because doctors and nurses frequently need to work at an urgent pace and to rely on oral communication.

11:00

4aNS9. Reducing the occlusion effect with active noise control. James G. Ryan (Gennum Corp., 232 Herzberg Rd., Kanata, ON, Canada K2K 2A1), Betty Rule, and Stephen W Armstrong (Gennum Corp., Burlington, ON, Canada L7L 5P5)

The occlusion effect refers to the build-up of low-frequency sound pressure in the ear canal when it is sealed by a hearing aid. Hearing aid wearers experiencing the occlusion effect often complain about the sound of their own voice. The traditional solution to this problem is to introduce a vent or opening through the hearing aid from the canal end to the faceplate. Unfortunately, the use of large vents, which is required for reducing occlusion, can result in significant feedback problems. This paper describes a solution for the occlusion problem that is based on active noise control techniques. This approach allows occlusion reduction without the feedback problems caused by large vents.

11:15

4aNS10. Operating room noise at Johns Hopkins Hospital. Jonathan Kracht, Ilene J. Busch-Vishniac, and James E. West (Mech. Engr. Dept., Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218)

Very little reliable information exists on the sound levels present in an operating room environment. In an attempt to remedy this situation, rigorous acoustic testing of the operating rooms in Johns Hopkins Hospital was conducted. Sound levels in each of the operating rooms was recorded for a period of 24 h. The data were analyzed to determine background sound levels, average equivalent sound levels (L_{eq}'s), and frequency distribution. With the assistance of Johns Hopkins Hospital, we were able to match each surgery to the period of noise it produced and to associate sound levels with particular types of surgeries. This data was used to determine the average sound-pressure level for classes of surgery (e.g., orthopedic, neurological, etc.). Averaging over many surgeries, orthopedic surgery was found to have the highest L_{eq} at approximately 66 dB(A). Urology, cardiology, gastrointestinal, and neurosurgery followed closely, ranging from 62 to 65 dB(A).

11:30

4aNS11. Dynamic behavior analysis of a switched reluctance motor. Juan Llado, Beatriz Sanchez, Jesus Ortiz (Mech. Eng. Dept., Univ. of Zaragoza, Spain), Aberlardo Martinez, Francisco Perez, Bonifacio Martin del Rio, Tomas Pollan, Eduardo Laloya (Univ. of Zaragoza, Spain), and Javier Vicuna (Univ. of la Rioja, Spain)

Within the home appliances sector, the series motor practically shares most applications. However, no further progress in cost reduction or control performances is envisaged. But, the switched reluctance motor, SRM, shows fairly good characteristics such as robustness, easy assembly, and low manufacturing costs. Besides, it allows accomplishment of integrated designs with the product, and an improvement of efficiency up to 90% when compared to about 45% reached by series motors used for home appliances. However, two specific drawbacks of this machine are control complexity and acoustic noise. As a first step, with respect to the acoustic noise, the target of this work is to develop a theoretical modal model of an SRM of four phases with 24 poles in an external stator and 18 poles rotor placed inside. This requires a theoretical simulation by means of an FEM software and an experimental work in a test bench to analyze the motor structure. The comparison of the results obtained by both methods will validate the theoretical model analyzed with the FEM software, and introduce structural modifications that can be used to design quiet SRMs from the knowledge of mode shapes and mode frequencies.

11:45

4aNS12. Sound power emission of a washing-machine cabinet. Beatriz Sanchez and Juan Llado (Mech. Eng. Dept., Univ. of Zaragoza, Spain)

The noise emitted by a washing machine can be divided into airborne noise produced mainly by the electric motor, and structural-borne noise caused by the cabinet vibration. The aim of this work is to determine the contribution of the structural radiation of the cabinet to the total sound power emitted by a washing machine, and to know which element is the noisiest. The total sound power was measured according to ISO 3744, and in order to know which panel of the cabinet is the noisiest, the standard ISO TR 7849 was applied. This experimental procedure relates the noise radiated by a structure with its vibration velocity, and it was found that the front and lateral left panels were the most relevant. Once the noise transmission paths were characterized, the proposal to reduce noise was focused on reducing the excitation force transmitted by the shock absorbers. As the modification of the force applied by the shock absorber is initially not feasible because it would imply changing the dynamic of the oscillating group, as a first step the panels which support these elements were modified to make them more flexible. A sound power reduction of about 5 dBA was obtained.

8:00

4aPA1. Excitation techniques for nonlinear acoustic landmine detection. Douglas Fenneman and Brad Libbey (U.S. Army RDECOM CERDEC NVESD, 10221 Burbeck Rd., Fort Belvoir, VA 22060)

Nonlinear acoustic landmine detection techniques are currently being investigated. These detection methods employ two tones broadcast in the vicinity of a buried mine. Measurement of the resultant surface velocity yields a spectrum rich in nonlinearly generated combination frequencies. The nonlinear mechanism governing the mine/soil interface is not completely understood. Donskoy *et al.* have proposed that a discontinuity occurs when the mine/soil system is subjected to acoustic excitation. [Donskay *etal*, J. Acoust. Soc. Am. **111**, 2705–2714 (2002)] In this case, the mine and soil remain in contact during compression, but separate in tension. Concurrently, Korman and Sabatier have documented nonclassical nonlinear effects in conjunction with acoustic mine detection [Korman *etal*, J. Acoust. Soc. Am. **116**, 3354–3369 (2004)]. Specifically, they have observed conditioning, soil dynamics, and hysteresis. These results are consistent with those of geomaterials which exhibit mesoscopic elasticity. It is likely that the nonlinear response above a buried mine is a function of both classical and nonclassical effects. These experiments investigate the amplitude dependence of nonlinear effects above a buried mine as a function of linear velocity. A comparison of the nonlinear amplitude dependence in the presence of a mine versus soil alone is intended to provide insights into the nature of the mine/soil interface.

8:15

4aPA2. Laboratory experiments on nonlinear acoustic detection of buried objects. Keith Attenborough, Qin Qin (Dept. of Eng., The Univ. of Hull, Cottingham Rd., Hull HU6 7RX, UK), Jonathan Jefferis, and Gary Heald (DSTL, Kent, TN14 7BP, UK)

The surface velocity response to acoustic excitation of sand contained within a thick-walled PVC tank in the shape of a truncated cone has been investigated with and without buried objects. The excitation was provided by either tonal or white-noise spectra from a large loudspeaker, and the sound field was localized above the buried objects by means of an inverted cone and pipe arrangement. The surface velocity of the sand has been measured with an accelerometer. The loading effects of the accelerometer have been found to be minor. The surface admittance spectra above a buried plastic container are found to have uniquely resonant structures, the nature of which has been investigated. It has been found that if the surface of a granular medium, containing buried objects, is subject to high levels of sound using either a single frequency or two separate frequencies, then, as well as an enhanced linear surface velocity response at the excitation frequencies, increased quadratic and cubic nonlinear responses may be observed. The nonlinear response at a sand surface is found to be highly sensitive to the moisture content and the degree of compaction. [Work supported by DSTL (UK) Contract Number RD029 06495.]

8:30

4aPA3. Saturation of burial-induced resonance frequency shift in acoustic landmine detection experiments. W. C. Kirkpatrick Alberts, II, Roger Waxler, and James M. Sabatier (Univ. of Mississippi, NCPA, 1 Coliseum Dr., University, MS 38677)

Modes in landmines have become a topic of recent interest in acoustic landmine detection. Of equal importance is the effect of burial on the experimentally observed resonances of landmines. Complicated dependence of resonance frequency on depth has been observed in field measurements and has been, thus, the topic of experimental and theoretical study. As such, further burial simulation experiments have been performed on a landmine and an acoustic landmine simulant. Burial simulation in water shows a saturation of downward modal frequency shift that rapidly deviates from the shift predicted by simple mass loading theory. This saturation agrees with that predicted by Velea *et al.* [J. Acoust. Soc. Am. **115**, 1993–2002 (2004)]. Burial simulations performed in sand reveal resonance frequency depth dependence that saturates following a rapid downward frequency shift and a small resonance frequency increase. [This work was sponsored by US Army Research, Development, and Engineering Command, Night Vision and Electronic Sensors Directorate under Contract DAAB15-02-C-0024.]

8:45

4aPA4. Wide-bandwidth time-reversal techniques for landmine detection. Brad Libbey, Douglas Fenneman (U.S. Army RDECOM CERDEC NVESD, 10221 Burbeck Rd., Fort Belvoir, VA 22060, brad.libbey@nvl.army.mil), Alexander Sutin, Victor Kurtenoks, and Armen Sarvazyan (Artann Labs., Inc., Trenton, NJ 08618)

Detection of landmines using acoustic to seismic wave propagation has shown that accurate landmine localization is possible by sensing vibrations of a soil surface above the mine. Time-reversal acoustic (TRA) focusing allows concentration of elastic energy at a location in the soil that increases landmine vibration and improves signal/noise levels. Previous experiments with TRA landmine detection utilized narrow-band signals, but in the most recent experiments wide-bandwidth signals provide clear excitation of the mine resonant frequencies. A loudspeaker array broadcasts these signals and the resulting soil vibration is measured by a laser Doppler vibrometer. The experiment utilizes linear frequency sweeps and orthogonal signals with frequency content between 50 and 500 Hz. Using the orthogonal signals, the suggested TRA procedure can be implemented simultaneously with multiple transmitters to increase the scanning speed. The spatial distribution of energy on and off mine demonstrates that the TRA system concentrates elastic wave energy in the desired area with the focal spot dimension comparable to a wavelength. The spectral density of the TRA focused signal increases in the area near the resonant frequency of the landmine.

9:00

4aPA5. Performance of the scanning ultrasound vibrometer for sensing displacements of a randomly rough vibrating surface. Ameya Galinde, Mark Andrews, Ninos Donabed, Carey Rappaport (Northeastern Univ., 409 Dana Res. Ctr., Boston, MA 02115-5000, ameya.g@gmail.com), Douglas Fenneman (U.S. Army RDECOM CERDEC Night Vision and Electron. Sensors Directorate; Fort Belvoir, VA 22060), and Purnima Ratilal (Northeastern Univ., Boston, MA-02115-5000)

An analytic model is developed for the ultrasound field reflected off a randomly rough vibrating surface for a scanning ultrasound vibrometer system in bistatic configuration. Kirchhoff's approximation to Green's theorem is applied to model reflection and scattering from the vibrating rough surface. The model incorporates the beampattern of both the transmitting and receiving ultrasound transducers and the statistical properties of the rough surface. Conventional approaches for estimating surface displacement and velocity based on the laser vibrometer, such as incoherent Doppler shift spectra and coherent interferometry, are applied to the ultrasound system. Simulations with the model indicate that surface displacement and velocity estimation is highly dependent upon scan velocity and operating frequency of the ultrasound vibrometer relative to the roughness height and correlation length scales of the rough surface. The model is applied to determine optimal sonar design parameters and measurement geometry for the scanning ultrasound vibrometer for measuring ground displacements from acoustic/seismic excitation in land-mine detection.

9:15

4aPA6. Effect of particle friction on the vibrations of a plate loaded with granular media. Wonmo Kang, Liyong Yang, Joseph A. Turner, Kitti Rattanadit, and Florin Bobaru (Dept. of Eng. Mech., Univ. of Nebraska-Lincoln, Lincoln, NE 68588-0526)

Acoustic methods have recently been shown to hold promise for detection of nonmetallic mines. These methods rely on the vibration response of the soil-plate system. The influence of particle size on the frequency response was previously illustrated using sieved sand as the loading material. Here, the influence of particle friction is studied using spherical glass beads. The first resonance of a plate was measured as a function of layer mass for a layer of monodispersed glass beads of various sizes (from 38 μm to 2.5 mm). The plate exhibited the same qualitative behavior as with sand loading but the response was quantitatively different. In particular, the minimum frequency attained for the glass bead layer was consistently higher than that for sand. However, the dependence on particle size followed the similar trends. Mechanisms related to both interparticle friction and layer-plate interface friction were explored. Experimental results with a roughened plate indicate that the resonance behavior is not dependent on the interaction between the layer-plate interface. Finally, numerical results based on dynamic simulations of discrete, interacting particles are discussed as applied to the experiments. The results are expected to impact quantitative aspects of mine detection by acoustic methods. [Work supported by ARL.]

9:30

4aPA7. Comparisons between predicted and measured acoustic scattering from a wedge. Ronald Hughes, Jan Niemiec (NSWCCD, 9500 MacArthur Blvd., West Bethesda, MD 20817), and Herbert Uberall (Catholic Univ. of America, Washington, DC)

Our earlier work has mainly dealt with developing a mathematical approach for predicting acoustc scattering from a wedge for various boundary conditions and wedge material properties. We initially reported scattering for wedge surfaces that satisfy a Dirichlet or a Neumann boundary condition. Recently, our approach was extended to include wedge boundary conditions that can be characterized by an impedance, including absorption. Numerical predictions are found using the Kontorovich-Lebedev transform [A. Erdelyi, *Higher Transcendental Functions* (McGraw-Hill, New York, 1953)] based upon MacDonald functions, requiring very high precision numerical techniques. We now apply this numerical approach to calculate the monostatic scattering amplitude for a fabricated wedge structure that has been measured in a nonlaboratory environment. Comparisons will be presented and discussed of the results obtained from the predicted and measured monostatic scattering pressures for a range of insonification frequencies at selected offset distances and angles relative to the edge of the wedge.

9:45

4aPA8. Scattering of sound by a cylinder above an absorbing boundary. Kai Ming Li and Wai Keung Lui (The Ray W. Herrick Labs., Purdue Univ., 140 S. Intramural Dr., West Lafayette, IN 47907-2031)

The problem of acoustic scattering by an impedance infinite cylinder irradiated by a point source is investigated. A theoretical model has been developed to consider the case of the sound scattered by an impedance cylinder above an outdoor ground surface of finite impedance. The formulation is based on the use of the appropriate wave-field expansions, the classical image source method, and the translational addition theorem for cylindrical wave function. The solutions can be expressed in the form of a multiscattering interaction between the cylinder and the image cylinder near a flat boundary. The effect of boundary impedance on the reflected sound fields is incorporated in the numerical model by using the well-known Weyl–van der Pol formula. The numerical results are compared with the published data. The effects of various source and receiver locations around the cylinder above the impedance boundary on the sound field are also studied.

10:00–10:15 Break

10:15

4aPA9. A ray/diffraction model of high-frequency backscattering for the study of caustic merging in simple targets. Benjamin R. Dzikowicz (NSWC-Panama City, Code HS-11, 110 Vernon Ave., Panama City, FL 32407)

The backscattering from certain finite geometric targets can be enhanced due to caustic merging when a geometric parameter, such as aspect, is varied. For example, Blonigen and Marston [Blonigen & Marston, ''Backscattering enhancements for tilted solid plastic cylinders in water due to the caustic merging transition: Observations and theory,'' J. Acoust. Soc. Am. **107**, 689–698 (2000)] have shown that there occurs an enhancement for doubly reflected shear waves within a finite plastic cylinder at certain tilt angles. Here, the contributions of single ray classes, such as the doubly reflected shear waves in the example above, are numerically

summed by following ray patches on an incoming reference plane through the target and back, forming a patch on an outgoing diffraction plane. The phase and magnitude of the returning patch depend on reflection and refraction coefficients and attenuation in the target material. When integrated, these patches can form singularities when rays merge at the screen and the patch sizes become infinitesimal. To solve this problem, a change in variables is made and the integration performed over the incoming, rather than the outgoing, patches. By studying the contribution of a single class of rays, individual caustic merging transitions can be studied. The total scattering at steady state can be written as an infinite sum of all classes of rays. [Work supported by ONR.]

10:30

4aPA10. Coherent backscattering without a source. Eric Larose, Oleg I. Lobkis, and Richard L. Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, 104 S. Wright St., Urbana, IL 61801)

Coherent backscattering is due to constructive interferences of reciprocal paths and leads to an enhancement of the intensity (by factors of up to 2 or 3, typically) of a multiply scattered field near its source. To observe this enhancement an array of receivers must be placed close to the source, within one or two wavelengths. It has been proposed that the effect may be used for the assessment of mean free paths against scattering. Here, we propose and demonstrate a passive technique that allows observation of the enhancement without need of sources. It is performed using time correlation of diffuse fields [Weaver and Lobkis, Phys. Rev. Lett. **87**, 134301 (2001)] obtained by receive-only transducers. It is shown that this passive enhancement cone has an excellent spatial resolution, comparable to active cones previously obtained by others [Tourin *et al.*, Phys. Rev. Lett. **79**, 3637–3639 (1997), Lobkis and Weaver, Phys. Rev. Lett. **90**, 254302 (2003)].

10:45

4aPA11. Determination of effective properties and effective thickness of resonant acoustic metamaterial. Vladimir Fokin, Muralidhar Ambati, Cheng Sun, and Xiang Zhang (NSF Nanoscale Sci. and Eng. Ctr. (NSEC), Univ. of California, 5130 EtcheVerry Hall, Berkeley, CA 94720-1740, xiang@berkeley.edu)

Multiple scattering in periodic structures with strong modulation of elastic constants leads to phononic band structures. According to the Bragg's theory, the spatial modulation of the periodic structure must be of the same order as the wavelength of considered elastic waves. A resonant acoustic metamaterial's respective wavelength is about two orders of magnitude larger than the lattice constant. Each unit cell consists of a locally resonant structural unit in contrast to simple acoustic scatterers in phononic crystals. In this report, we will address the design of locally resonant sonic materials. These materials may offer dynamic effective negative material properties around resonance frequency. Locally resonant sonic crystals, such as an array of Helmholtz resonators and cylinders or spheres coated with acoustically soft material, were analyzed in the literature. However, existing literature lacks a systematic study of the dependence of effective properties for a finite slab of these metamaterials both on the geometry and the properties of its constituent materials. In this report, we present a method for obtaining effective properties and effective thickness of a slab of acoustic metamaterial. The dependence of effective acoustic properties of a metamaterial on the geometrical and acoustic properties of constituent materials will be discussed.

11:00

4aPA12. Homogenization of two-dimensional clusters of rigid rods in air. Daniel Torrent, Andreas Håkansson, Francisco Cervera, and José Sánchez-Dehesa (Wave Phenomena Group, Nanophotonics Technol. Ctr., Universidad Politecnica de Valencia, C/Camino de Vera s/n, E-46022 Valencia, Spain)

The scattering of sound by finite-size clusters consisting of two-dimensional distributions of rigid cylinders in air is studied in the low-frequency limit (homogenization), both theoretically and experimentally. First will be reported analytical expressions for the effective density and sound speed obtained, in the framework of multiple scattering theory, for a circular-shaped cluster. Homogenization is theoretically analyzed as a function of the filling fraction, the type of arrangement of the cylinders in the cluster (hexagonal and square lattice), and the dimension of the cluster. Finally, experiments will be presented for the case of a circular-shaped cluster of 151 wooden cylinders in air. It is demonstrated that, in the long-wavelength limit, this cluster acoustically behaves as a cylinder of argon gas. Moreover, it is shown that homogenization works for frequencies lower than 3 kHz, which corresponds to a wavelength that is four times the parameter of the embedded lattice and is only a quarter of cluster's diameter.

11:15

4aPA13. Wigner distribution of ultrasonic transducers applied to scattering in polycrystalline media. Goutam Ghoshal, Joseph A. Turner (Dept. of Eng. Mech., Univ. of Nebraska—Lincoln, W317.4 Nebraska Hall, Lincoln, NE 68588-0526), and Richard L. Weaver (Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801)

Diffuse ultrasonic backscatter measurements have been especially useful for extracting microstructural information and for detecting flaws in materials. Accurate interpretation of experimental data requires robust scattering models. Quantitative ultrasonic scattering models include components of both transducer beams as well as microstructural scattering information. Here, the Wigner distribution is used in conjunction with a radiative transfer equation (RTE) to model this scattering problem. The Wigner distribution represents a distribution in space and time of spectral energy density as a function of wave vector and frequency. An RTE is derived within the context of the Wigner distribution of various transducer beam models of common interest such that the source and receiver distributions are included in the analysis in a rigorous fashion. The resulting RTE is then simplified in the single-scattering limit typical of many diffuse backscatter experiments. Such experiments, usually done using a modified pulse-echo technique, utilize the variance of the signals in space as the primary measure of microstructure. The resulting backscatter model derived here is compared with previous derivations and experimental backscatter results for materials of common interest. These results are anticipated to impact ultrasonic nondestructive evaluation of polycrystalline media. [Work supported by U.S. DOE.]

4aPA14. Theoretical prediction of super-radiant modes in ideal and distorted hexagonal clusters of two-dimensional sonic crystals. José Sánchez-Dehesa, Yuriy A. Kosevich, and Daniel Torrent (Wave Phenomena Group, Nanophotonics Technol. Ctr., Polytechnic Univ. of Valencia, E-46022 Valencia, Spain)

Resonance modes confined in hexagonal and threefold symmetry clusters consisting of two-dimensional arrays of rigid cylinders in air have been studied analytically and numerically using a multiple scattering method. It is shown that in the low-frequency (homogenization) limit the triangular modes play a fundamental role in the radiation behavior of the cluster. Analytical formulas are found to predict the frequencies of weakly confined resonance modes, whose pressure patterns have triangular symmetry. In the case of ideal hexagonal cluster, there are two degenerate triangular modes, which result in sixfold symmetry of the far-field radiation. In the case of distorted hexagonal clusters with threefold symmetry, two triangular modes with different frequencies are predicted. These modes have the property of being strongly radiating along three normals to the sides of the distorted hexagonal cluster, having their radiation properties not equivalent. Multiple scattering simulations confirm our analytical formulas and show the predicted threefold symmetry of the far-field radiation from the distorted hexagonal cluster. 4aSAa1. Perturbation theory of resonance amplification for skewed fan blades. R. Martinez and A. Stokes (Anteon Corp., 84 Sherman St., Cambridge, MA 02140, and Applied Physical Sciences Inc., 4 Muzzey St., Lexington, MA 02421)

The vibrational response of generic turbomachinery blades has been analyzed via a Timoshenko-Mindlin theory of flexure for thick beams formally extended to include torsion due to 3D skew. An alternate interpretation is the generalization of the governing equations of the special case of a radially stiff rib of prismatic cross section to include thick-beam flexure for displacements in the axial direction. The development identifies an artificially small parameter for the coupling of bending and torsion. A subsequent perturbation analysis yields an expression for the system's resonance-amplification envelope in terms of its material loss factor and flexural modal density as affected by torsion. The asymptotic theory reveals how a blade's skew could be exploited to transfer vibrational energy from flexure to torsion and thereby maximize a turbomachine's overall damping for bending. The greatest benefits are found for a band of high frequencies straddling the point at which the dispersive phase speed for thick flexure matches the prismatic member's effective torsional wave speed. Comparisons are made between the closed-form predictions of the perturbation analysis and exact calculations that do not rely on a presumed smallness of the coupling between flexure and torsion.

4aSAa2. Solution of the 3-D equations of elasticity in prolate spheroidal coordinates. Jeffrey E. Boisvert (NAVSEA Newport, Code 1514 Bldg 1258, Newport, RI 02841) and A. L. Van Buren (Cary, NC 27519)

The 3-D equations of elasticity in prolate spheroidal coordinates are solved using a Helmholtz decomposition for the displacement vector. The displacement vector is written in terms of a scalar potential (dependent on the dilatational wave number) and a vector potential (dependent on the shear wave number). These wave potentials are solutions, respectively, of the scalar and vector wave equations cast in prolate spheroidal coordinates. An eigenfunction expansion of spheroidal wave functions is employed to solve the scalar wave equation. The solution of the vector wave equation is facilitated using expansions of prolate spheroidal vector wave functions. These vector wave functions are constructed by applying certain vector differential operators to the scalar wave functions. The canonical problem of free vibration of a traction-free confocal elastic layer (shell) is considered. The shape of the prolate spheroid is defined by the major-axis length L and minor-axis length D. Since the sphere is a limiting form of the prolate spheroid, the analytical approach is validated by comparing the frequency spectra of a prolate spheroidal shell with $L/D \sim 1$ to those of a spherical shell using a 3-D solution in spherical coordinates. 4aSAa3. Energy finite-element analysis of the NASA aluminum test-bed cylinder. Aimin Wang, Nickolas Vlahopoulos (NA&ME Dept., Univ. of Michigan, 2600 Draper Rd., Ann Arbor, MI 48109), Ralph Buehrle, and Jacob Klos (NASA Langley Res. Ctr., Hampton, VA 23681)

A formulation was developed in the energy finite-element analysis (EFEA) for modeling the vibration of cylindrical structures with periodic axial and circumferential stiffeners. Appropriate power transfer coefficients are computed from the values of the propagation constants. The joint matrices of the EFEA formulation are computed based on the power transfer coefficients derived from periodic structure theory. EFEA analyses are performed for the NASA aluminum test-bed cylinder and simulations are compared to experiments. Excitation is applied on the test-bed cylinder by four shakers and the vibration is measured at 40 bays formed by axial and circumferential stiffeners. The EFEA results are compared successfully to test data between the $\frac{1}{3}$ octave bands of 315 and 6300 Hz. [Work sponsored by NASA Langley Structural Acoustics Branch.]

4aSAa4. Detecting and classifying adhesive flaws between bonded elastic plate: The inverse problem. Ricardo Leiderman and Paul E. Barbone (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

A time-harmonic inverse scattering problem to reconstruct the effective stiffness distribution of an adhesive bond in a layered elastic plate was formulated and solved. The motivation is based on the assumption that localized adhesion flaws that diminish bond stiffness also tend to diminish bond strength. The formulation and solution are based on the invariant embedding method, apply to isotropic and anisotropic elastic layers, and are essentially that of identifying embedded acoustic sources in elastic layered structures. Two solutions of the inverse problem are presented: the Born approximation and the exact solution. In the example calculations we compare the two solutions and show that when imperfections are too large the accuracy of the Born approximation breaks down. The impact of noise and uncertainties in the background properties in the inversion is also investigated.

9:30

4aSAa5. Using a scanning laser Doppler vibrometer to measure acoustic intensity. Andrew J. Boone, Jonathan Blotter, Scott D. Sommerfeldt, and Timothy W. Leishman (Dept. of Mech Eng., BYU, 435 CTB, Provo, UT 84602, boone.andrew@gmail.com)

Two different scanning methods were compared to see if acoustic intensity can be accurately measured using a scanning laser Doppler vibrometer (SLDV). Both intensity scans were performed on the same vibrating object, the side panel of a diesel generator enclosure. The first scan was done the traditional way using an intensity probe and scanning grid. The second scan was done using an SLDV. The results from each intensity scan were compared and analyzed. From these results it appears that the SLDV scan is measuring intensity contributed by the vibrating panel alone, while the traditional scan is measuring intensity contributions from both the vibrating panel and the enclosed generator.

4aSAa6. Simulation of the propagation of the first antisymmetric Lamb mode in the audible range. Guillemette Ribay, Stefan Catheline, Didier Cassereau, and Mathias Fink (Laboratoire Ondes et Acoustique, 10 rue Vauquelin, 75005 Paris, France)

When somebody knocks on a plate-shaped object, the first antisymmetric Lamb wave is created, propagates, and is reflected a lot before vanishing. It has been recently shown [Appl. Phys. Lett. **87**, 204104 (2005)] that if the wave is recorded by an accelerometer, it is possible to deduce the knock position thanks to a cross-correlation technique. Now it is of interest to be able to simulate the wave field created in such experiments, for example in order to study the influence of various parameters, or possibly to try to replace the learning phase of this localization technique by a numerical prediction of the impulse responses. Therefore, in this talk, a finite difference code is presented, simulating the A0 wave in the frequency range excited by a knock on a plate, i.e., [0, 10 kHz]. It is based on a new wave equation of the flexural wave, which takes into account shear correction. Experiments on plates have been carried out to validate the simulation. It is shown that the spectrum of the experimental waves of this reverberant cavity is the same as the simulated one. [This work was financially supported by the TAICHI European project.]

4aSAb1. Adaptive mechanical model of human footsteps. Alexander Ekimov and James M. Sabatier (The Univ. of Mississippi, NCPA, 1 Coliseum Dr., University, MS 38677, aekimov@olemiss.edu)

The vibration signature from footsteps can be exploited for human characterization and recognition. Footsteps are repeatable cycles of supported surface loading by a dynamic force. This force produces the vibration response of the ground/floor in a broadband frequency range. The vibration response at the distance R from the applied force is proportional to the dynamic force and results from the product of the footstep force and the ground/floor specific transfer function. The transfer function describes the propagation of vibration between the force location and the location of the detector. It was experimentally shown that walkers could vary the dynamic force of footsteps by controlling leg stiffness. An adaptive model of a walking person as a mass-spring system with controlled leg-spring stiffness was developed. This model was tested indoors and outdoors. Three distinct types of walking styles (regular, soft, and stealthy) with the same speed of motion were described and investigated. These styles result in different vibration magnitudes in the low-frequency range (below 100 Hz) due to differences in the walker's leg stiffness. The transfer functions in the building and outdoors were measured and results are presented. [Work supported by Department of the Army, Army Research Office Contract W911NF-04-1-0190.]

4aSAb2. Elastic and vibrational properties of a regular tensegrity structure. Anthony R. Smith and Andrew A. Piacsek (Central Washington Univ., 400 E. University Way, Ellensburg, WA 98926-7422)

Invented by R. Buckminster Fuller and Kenneth Snelson between 1948 and 1961, tensegrity structures consist of stiff rods connected to flexible strings such that no rod is joined to any other rod. A prestressed tensegrity structure, in which all the strings are under tension, maintains a distinct shape, deforming slightly under a load. For the present study, tensegrity masts consisting of repeated layers of three-, four-, or five-rod patterns were constructed. With 15-cm rods, an eight-layer mast is 50 cm long and has a diameter of 20 cm. All masts exhibited a hysteretic nonlinear elastic response to applied stress along the major axis. Young's modulus for the eight-layer mast ranged from 2500 to 5000 Pa at 8% strain. Increasing the tension in the strings by a factor of 2 resulted in a 14% increase in the Young's modulus at small strains. Implications of this nonlinear behavior for wave propagation along the axis of a tensegrity mast is currently being investigated. Results will be shown for resonance frequencies as a function of drive amplitude. [Work supported by the Murdock Charitable Trust and Central Washington University.]

4aSAb3. Models of rattling objects for a moving base excitation. Daniel H. Robinson, Robert J. Bernhard, and Luc G. Mongeau (Ray W. Herrick Labs., Purdue Univ., 140 S. Intramural Dr., West Lafayette, IN 47906)

Rattle noise is of particular concern in housing structures near airports. This secondary noise source is often related to large-amplitude low-frequency noise excitation of floors and walls and their interaction with loosely supported objects such as windows, wall hangings, and bric-a-brac. Simple theoretical models were developed to describe interactions between rigid bodies and vibrating surfaces. Rattle models were divided into two classes to describe resonant and nonresonant systems. The models allow a better understanding of the causes of rattle and help identify suitable criteria to mitigate rattle noise. In this presentation, thresholds of rattle onset are discussed and mitigation strategies to reduce and possibly eliminate rattle noise are identified. [Work supported by the Federal Aviation Administration.]

4aSAb4. Spatial statistics of diffuse elastodynamic modes. Alexei Akolzin and Richard L. Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, 104 S. Wright St., Urbana, IL 61801)

Spatial statistics of the modes in an elastic body plays a useful role in predicting certain average elastodynamic responses of complex structures, such as transmitted power or nonlinear spectral energy redistribution. For single wave-speed fields, extensive evidence exists that high-frequency modes in the interior of a generic ray-chaotic body resemble a superposition of plane waves with random amplitudes and phases. This implies centered Gaussian statistics for the field amplitude and a specific form for the two-point correlation function. The former can also be linked to the imaginary part of the Green's function averaged over a frequency band or over a characteristic ensemble of body realizations, which allows extension to the boundaries and inclusion of effects of finite body size. In the present study we analyze and compare theoretical expressions for a num-

ber of spatial statistics, such as intensity distribution, wave-type energy equipartition, and two-point correlation function, with numerical results for an ensemble of 2D plane-strain elastic bodies with rough boundaries.

11:15

4aSAb5. Transmission and localization in connected ergodic reverberation rooms. Igor Rozhkov and Oleksandr Zelyak (Dept. of Phys. and Astron., Univ. of Kentucky, 177 Chem.-Phys. Bldg., 600 Rose St., Lexington, KY 40506-0055, irozh2@uky.edu)

The wave power redistribution in two connected reverberant structures represents a paradigm problem in studies of transmission through a complex structure consisting of several reverberant substructures. We analyze randomly coupled ergodic reverberation rooms with the goal to extend such analysis to a more general situation. The two-room problem is, however, quite challenging on its own [R. L. Weaver and O. I. Lobkis, J. Sound Vibr. **231**, 1111–1134 (2000)]. Although the ergodicity assumption allows one to use random matrix theory (RMT), by describing both subsystems with random Gaussian Hamiltonians, the nonperturbative calculations of power transmission and localization have not yet been done. The only attempt made in this direction was the corresponding study of two coupled quantum dots [A. Tschersich and K. B. Efetov, Physi. Rev. E **62**, 2042–2045 (2000)], which used the supersymmetry technique to calculate the joint distribution of local densities of electron wavefunctions and found spatial correlations absent in a single chaotic system. Here, we present both perturbative and nonperturbative (in ensemble averaging) RMT calculations of simplest nontrivial characteristics of power transmission and localization, and compare it with numerics.

11:30

4aSAb6. Free vibrations of a polar elastic body. Glay Altay (Dept. of Civil Eng., Faculty of Eng., Bogazii Univ., Bebek, 34342 Istanbul, Turkey, askarg@boun.edu.tr) and M. Cengiz Dokmeci (Istanbul Tech. Univ., 34430 Istanbul, Turkey)

This paper concerns certain features of the equations governing the time-harmonic free vibrations of a polar elastic body. The governing equations of micropolar elasticity are expressed in differential form; then, the uniqueness in their solutions is investigated. The conditions sufficient for the uniqueness are enumerated using the logarithmic convexity argument without any positive-definiteness assumptions of material elasticity. Applying a general principle of physics and modifying it through an involutory transformation, a unified variational principle is obtained for the free vibrations. The principle leads to all the governing equations of the free vibrations, as its Euler-Lagrange equations. The governing equations are alternatively expressed in terms of the operators related to the kinetic and potential energies of the body. The basic properties of vibrations are studied and a variational principle in Rayleigh's quotient is given, and the high-frequency vibrations of a micropolar plate [cf., Altay and Dkmeci, Int. J. Solids Struct. (2006)] are likewise treated. [Work supported by TUBA.]

4aSAb7. Progress towards a diffusion theory of wave energy transport in large irregular structures. Richard Weaver and Nicholas Wolff (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, 216 Talbot Lab., 104 So. Wright, Urbana, IL 61801)

We address the problem of constructing predictions for mean-square bandlimited displacement (''energy'') at points in a complex structure, and doing so with information gleaned from short-time cost-effective direct numerical simulations (DNS). Past work has shown that a DNS over short times subsequent to the action of a transient force allows good estimates of band-averaged admittances and therefore also of sensitivity to local energy density. (A further assumption of equipartition and no damping then permits estimates of response levels at infinite time.) We note that short-time DNSs also reveal a degree of transport and find that the transport operator observed to govern flow over short times may be iterated to predict energy distributions at later times. When carefully constructed, this iteration does a good job of predicting actual energies—at least for the special cases studied so far.

4aSC1. Context matters!—The influence of listening materials on L2 speakers' performance of devoiced liquids in English. Sally Chen and Janice Fon (Grad. Inst. of Linguist., Natl. Taiwan Univ., 1 Roosevelt Rd., Sec. 4, Taipei 106, Taiwan)

For previous L2 studies, the influence of context could be categorized either as the duration speakers live in an environment with their L2 as the official language or as the retaining effect after a certain amount of training. This study aims to investigate the variations on L2 learners' production of English devoiced liquids with contexts of different degrees of directness provided. Sixteen subjects are divided into three groups. They are given an equal length of story (indirect context), wordlist (direct context), or music (control) in the listening task between two recordings of their production of a wordlist consisting of 14 monosyllabic English words containing a voiceless stop in the first position and a liquid in the second (e.g., play). Duration and ratio of the consonant clusters are measured and so is the voiceless portion of the clusters. Preliminary results showed that after the listening task, participants had a significantly longer duration for both cluster length and voiceless parts. Cluster duration of the two experimental groups was also lengthened. Furthermore, the wordlist group had their cluster/word and voiceless/cluster ratio closer to the native speakers in the second recording. Thus, practice effect, context effect, and directness effect were all supported.

8:45

4aSC2. The hybrid system of voice onset time in French/English bilinguals. Claire Gurski (Univ. of Western Ontario, 509-880 Kipps Ln., London, ON N5Y 5K4, Canada, mchough@uwo.ca)

This study will look at the production of occlusive consonants by bilinguals in both their first and second languages, namely French and English. Due to the inherent differences in the voice onset times (VOTs) of these two languages, do second language speakers acquire a native-like voice onset time when speaking in their second language or do traces of their first language remain? It will be shown that although French and English have categorical distinctions in their VOT systems [Keating ''Phonetic and phonological representation of stop consonant voicing,'' Language, **60**, 286–319 (1984) Lisker & Abramson, ''A cross-language study of voicing in initial stops: Acoustic measurements,'' Word. **20**, 384–422 (1964)] a hybrid system of the two languages is produced regardless of first language. This research is part of a larger continuing study looking at speaker identification of bilinguals. Due to the right to a trial in either of the official languages of Canada, French or English, it is impossible to force a bilingual suspect to supply a voice sample that can be compared with an incriminating recording in one of the two languages. In such a situation, is it possible to base an identification (or a nonidentification) on the comparison of samples in the two languages of the suspect?

9:00

4aSC3. The language interference of pitch accent language on tone language—A case study of Mandarin and Swedish. Yi-Chen Tung (NCTU Dept. of Foreign Lang. and Lit.s, 1001, Ta-Hsueh Rd., Hsinchu, Taiwan, 300)

The study aims to find how pitch accent language influences learning of tone language. The target language is Mandarin which has three contour lexical tones and one level lexical tone. The source language is Swedish which has two contour accents. It is assumed that Swedish cannot produce a Mandarin words with contour tone applied on single syllable since Swedish always exerts contour tone over two or more syllables. In experiment 1, it was found that the Swedish could produce a Mandarin contour tone completely. On the other hand, it was found that the Swedish subject used accent 1 to produce FR (falling+rising) and RL (rising +falling-rising) tonal combinations and accent 2 to produce RF (rising + falling) and LR (falling-rising+rising) tonal combinations. To further investigate the learning pattern of tone language, all the possible tonal combinations in Mandarin were tested in experiment 2. It was found that the Swedish subject applied accent 1 to produce all the tonal combinations. The result revealed that the language interference of pitch accent on tone language could be illustrated on the manipulation of direction of F0 movement.

9:15

4aSC4. Comprehension of envelope-only sentences by English-speaking adults and children and Mandarin-speaking adults. Susan Nittrouer (Speech and Hearing Sci., Ohio State Univ., 1070 Carmack Rd., Columbus, OH 43210) and Robert Packer (Washington State Univ., Pullman, WA 99164)

Listeners comprehend sentences when only amplitude envelope information for a few bandlimited channels is available, but there is variability in their abilities to do so. This experiment asked whether the variability in listeners' abilities to comprehend these signals is best explained by variability in magnitude of linguistic context effects, in auditory processing, or in sensitivity to structural organization at a global level. Stimuli were 30 four-word syntactically appropriate, semantically anomalous sentences, processed to preserve envelope information in 4 or 8 channels. Listeners were two groups of native English speakers (adults and 7-year-old children) and one group of native Mandarin speakers (adults) who were proficient enough in English to be graduate students at an American university. The sentences provided linguistic context that should affect comprehension equally for all these listeners, so that possible outcomes were (1) All three groups would perform similarly if abilities to use linguistic context best explained previously reported variability; (2) both adult groups would perform similarly and better than children if age-related differences in auditory processing best explained variability; and (3) English-speaking children and Mandarin-speaking adults would perform similarly and poorer than English-speaking adults if sensitivity to global structure best explained variability. Results matched possible outcome #3. [Work supported by NIDCD Grant No. DC-00633.]

9:30

4aSC5. The error patterns of different nonword repetition tasks in 3-year-old Mandarin-speaking children. Naihsin Li, Joanna Lee, Janice Fon, and Hintat Cheung (Grad. Inst. of Linguist., Natt. Taiwan Univ., No. 1, Sec. 4, Roosevelt Rd., Taipei, 10617 Taiwan, r93142004@ntu.edu.tw)

This study investigates qualitatively and quantitatively 3-year-old Mandarin-speaking children's error patterns in two nonword repetition tasks which differ in their degrees of wordlikeness, i.e., the nonce word and the gap word sets. Their performances in the two tasks were transcribed and analyzed from two respects: (1) the rate of a specific unit retaining the target structure and (2) the cross comparison between linguistic units and error processes. Results showed that tones and syllable structures of the target forms were easier to retain than the contents. And even though children's error patterns approximated the adults patterns in gap word repetition task, they had strategic difference in dealing the weight decay in memory: while the children used syllable and rhyme substitutions, the adults used syllable omissions. Our study has implied that children have the same processing mechanism with adults in learning novel words. However, their strategic difference may have an implication for language learning. In addition, the present study also contributes the processing of tone to the linguistically constrained model (Hartley & Houghton, ''A linguistically constrained model of short-term memory for nonwords,'' J. Mem. Lang. **35**, 1–31 1996), so that it can become a more complete model in demonstrating how novel sound sequences are learned and recalled in Mandarin-speaking young children.

9:45

4aSC6. Response to subthalamic deep brain stimulation on speech intelligibility in Parkinson's disease. Emily Wang (Dept. of Commun. Disord. and Sci., Rush Univ. Medical Ctr., 1653 West Congress Pkwy., Ste. 203 SENN, Chicago, IL 60612), Leo Verhagen Metman (Rush Univ. Medical Ctr., Chicago, IL 60612), Roy Bakay (The Chicago Inst. of Neurosurgery and Neuroresearch), and Bryan Bernard (Rush Univ. Medical Ctr., Chicago, IL 60612)

The study reports on intelligibility of reading and monologues produced by Parkinsonian patients who underwent unilateral subthalamic deep brain stimulation (STN DBS). Twenty right-handed individuals with advanced Parkinson's disease (PD) and dysarthria underwent unilateral STN DBS. Ten were operated on the right hemisphere and ten on the left hemisphere. The side receiving STN DBS had more affected motor function. Speech was evaluated before surgery and three-to-six months after surgery with stimulator-off and with stimulator-on; all were off anti-Parkinsonian medication for 12 h before evaluation. Evaluators and subjects were blinded to the subjects stimulator status at the postsurgery evaluations. Nonspeech motor performance was assessed with UPDRS-III. Each subject read a standard passage and produced a monologue on a preselected topic. The readings and monologues were rated for intelligibility using UPDRS-III item 18. Sixteen student clinicians in speech pathology served as judges. Each speech sample was repeated three times. The reading and monologue samples were presented in two blocks. Within each block, the samples were randomly presented to each judge over headphones. Presentation and response collection were completed using a computer procedure written in Praat. The results are discussed with regard to speech and nonspeech motor response and to hemisphere-specific response on speech intelligibility.

10:00–10:15 Break

10:15

4aSC7. Vowel imitation of 4-year-old children. Richard S. McGowan (Haskins Labs. and CReSS LLC, 1 Seaborn Pl., Lexington MA 02420, rsmcgowan@earthlink.net)

Published formant scalings for vowels of American 4-year-olds who were imitating adult production are used along with published data of American adult male vowel production to synthesize /ah, ae, uu, ii/. Perturbations to these vowels were also synthesized. Adult listeners were asked to categorize these synthetic vowels in a forced-choice task. Except for a preference for slightly more extreme first formant frequencies and higher second formant for /ae/, the formant frequencies preferred for the vowels /ah, ae, uu, ii/ were close to the values used for synthesis. A five-tube model was used in an algorithm to infer vocal-tract shape from the first three formant frequencies of the adult productions, the children's synthesized /ah, ae, uu, ii/, and the formant frequencies derived for these vowels based on the listening experiments. It was found that the rear tube length for the children, in proportionate terms, was nearly always greater than that of the adult. In proportionate terms the rear tube length was twice as long in children compared to adults for the vowel /uu/. Tongue root flexibility may be more important than pharynx length in determining formant scalings for young children. [Work supported by NIHD-003782 to Haskins Laboratories.]

10:30

4aSC8. Pitch and voice quality in Burmese vowels. James F. Gruber and Zhaleh Feizollahi (Georgetown Univ., Washington, DC 20057, jfg27@georgetown.edu)

Burmese vowels are pronounced with a four-way contrast in laryngeal configuration, described as high, low, creaky, and killed registers [Bradley, Tonation, Pacific Linguistics Series A-62 117–132 (1982)]. However, acoustic descriptions differ as to whether the registers should be defined in terms of pitch or voice quality [Watkins SOAS Working Papers in Linguistics: **10**, 139–149 (2000)]. This study investigates whether voice quality or pitch is the more consistent carrier of contrast across the four registers. Four speakers pronounced 20 words (5 vowels $\times 4$ registers) inside a frame sentence surrounded by syllables of low register. Each sentence was repeated five times consecutively. For each syllable, F0 measures were taken at each quartile, as well as peaks and valleys. Voice quality was quantified in terms of spectral slope [Gordon and Ladefoged, J. Phonetics **29**, 383–406 (2001)], specifically the difference in dB between the first and second harmonics in an FFT spectrum over a 50-ms window. Results indicate that pitch more reliably indicates register than voice quality. While there was no significant difference in spectral slope between registers, the four registers differed consistently in height and timing of pitch peaks.

10:45

4aSC9. Initial pitch informs sentence duration. Johanna Tan, Joel Dunham, Caleb Lee, and Eric Vatikiotis-Bateson (Dept. of Linguist., Univ. of British Columbia, E270-1866 Main Mall, Vancouver, Britsh Columbia V6T 1Z1, Canada)

This study re-examines the potential relation between sentence duration and sentence-initial fundamental frequency ($F0$), in both speech production and perception, and provides perceptual evidence for speech planning. Liberman and Pierrehumbert [in *Language Sound Structure*, edited by Aronoff & Oerhle (MIT Press, Cambridge, 1984)] argued that a correspondence between sentence length and initial $F0$ would accommodate declination and could be evidence for speech planning. Unfortunately, their study did not provide strong evidence either for or against this intriguing possibility. The present study has two parts: First, read sentences were recorded for native English speakers and the relation between sentence length and $F0$ was analyzed. With a few exceptions, longer sentences had higher initial $F0$. Second, 24 listeners were presented with initial portions (300 and 700 ms) of the recorded sentences and asked to make both relative and absolute predictions of total sentence duration. Subjects consistently associated sentence fragments containing higher initial $F0$ with longer sentences. [Research supported by NSERC and CFI.]

11:00

4aSC10. Position variability in stop and fricative production. Anders Lofqvist (Haskins Labs., 300 George St., New Haven, CT 06511, lofquist@haskins.yale.edu)

This study analyzed position variability in stop and fricative consonants, examining potential differences related to precision requirements. It has often been claimed that fricatives require more precision in their production than stops due to the management of airflow. However, there is very little, if any, empirical evidence for this claim which is mostly based on different developmental trends. Tongue movements were recorded using a magnetometer system. Measurements were made of tongue position at the onset of the consonant, defined in the acoustic signal. The results do not show any consistent pattern within or across subjects for stops and fricatives. Thus, there is not less position variability for fricatives than for stops. Taken together with results showing that the tongue movement during the closure is no less constrained for a fricative than for a stop, the present results thus indicate that the precision requirements for stops and fricatives do not differ. These results most likely reflect the fact that speech is an overlearned skill, so that any differences related to precision are very small, or nonexistent, in adults, and might only be seen in the early stages of speech development or second language learning. 4aSC11. $F0$ and the voicing states of initial consonants in Mandarin. Chunling Zhang and Terrance M. Nearey (Dept. of Linguist., Univ. of Alberta, 4-32, Assiniboia Hall, Edmonton, AB, T6G 2E7 Canada, chunling@ualberta.ca)

Studies have shown inconsistent $F0$ changes following the plain voiceless stops ($F0_{\mathrm{PLAIN}}$) compared to (1) voiced stops ($F0_{\mathrm{VOICED}}$) and (2) aspirated voiceless stops ($F0_{\mathrm{ASPIRATE}}$). Aerodynamic, laryngeal setting and auditory enhancement models of [$\pm$voice] have all been implicated in $F0$ variations [J. Kingston and R. L. Diehl, Language **70**, 419–454 (1994)], but each explains only certain aspects of the prevocalic voicing effects on $F0$. Studies in English show that $F0$ of a vowel is simultaneously affected by multiple phonetic factors, such as voicing state, vowel identity, intonation, and place of articulation. Previous small-scale experiments in Mandarin also exhibit interactions of the phonetic distinctions on $F0$, but only certain aspects of the contextual variations of $F0$ have been examined. This study carries out a large-scale recording of Mandarin CV syllables in isolation, examining the interactive patterns of acoustic correlates of the voicing states of initial consonants. Preliminary results show dramatically different $F0$ changes from previous studies in Mandarin [C. X. Xu and Y. Xu, JIPA, **33**, 165–181 (2003)] but show similar patterns to English, such that $F0_{\mathrm{PLAIN}}$ is similar to $F0_{\mathrm{VOICED}}$ (nasals), with $F0_{\mathrm{ASPIRATE}}$ significantly higher. This study provides a better understanding of the cross-linguistic phonetic realization of voicing distinctions.

11:30

4aSC12. The nature of aspiration in stop consonants in English. Helen M. Hanson and Kenneth N. Stevens (Speech Commun. Group, Res. Lab. of Electron., MIT, 77 Massachusetts Ave., Cambridge, MA 02139, hanson@speech.mit.edu)

The releases of aspirated stops in English are typically modeled as having three consecutive phases, which overlap somewhat in time: (1) transient, (2) frication, and (3) aspiration. Close examination reveals that the noise spectrum in the aspiration phase is sometimes dominated by one spectral prominence, rather than several prominences as expected with a glottal source. In this work, the possibility that frication noise generated during the third phase may sometimes dominate the aspiration noise is explored. The nature of the radiated sound during the production of both voiced and unvoiced stop consonants is examined for the three places of

articulation in English and with several different following vowels. Data from eight subjects are observed. Results suggest that some subjects follow the classical model, but other subjects produce a mix of frication and aspiration during the third phase. There is considerable variability in these acoustic attributes, both within a speaker and across speakers. It is suggested that speakers can choose between using (1) an extended burst or (2) formant transitions to provide enhancing cues to place of articulation. The relation of these data to acoustic theories of sound production and to perceptual saliency is discussed. [Work supported by NIH Grant No. DC00045.]

9:05

4aSP1. Perception and cognition of acoustic signals. Laurie M. Heller (Dept. of Cognit. and Linguist. Sci., Brown Univ., Providence, RI 02912)

Sonar operators may distinguish the sound of a submarine from the sound of a fishing trawler amidst a background of snapping shrimp. This accomplishment requires integrating auditory sensation and perception with auditory cognition, experience, and the ability to adapt to context. The fundamentals of auditory perception and cognition required for this task will be reviewed in this talk. I will cover a range of levels in the auditory system: from the ability to detect a signal in a background of noise, to the ability to distinguish a complex pattern from a complex background, to the ability to analyze the physical properties of an event. This review of both empirical data and research will cover a variety of psychoacoustic testing methods that is appropriate for different situations that are likely to be encountered in underwater signal processing, such as detection, discrimination, and identification.

9:25

4aSP2. Active listening in passive-sonar soundscapes. Gregory Wakefield (Elec. Eng. and Comput. Sci. Dept., Univ. of Michigan, 1301 Beal Ave., Ann Arbor, MI 48109, ghw@umich.edu) and Thomas Santoro (Naval Submarine Medical Res. Lab., Groton, CT)

Listening tasks differ across a variety of dimensions. Tasks that are characteristic of competing channels are those in which command and control signals are delivered simultaneously. Such signals are typically highly uncertain, statistically independent, and nonredundant. Tasks that are characteristic of cooperative channels are those in which sources vary in some coordinated or collaborative fashion. Such signals are typically of much greater certainty, statistically correlated in several of their parameters, and highly redundant. We report on results from several types of cooperative-channel tasks in which listeners attend to targets in multiple-source soundscapes that resemble the passive sonar listening environment. Several levels of rendering are considered ranging from monaural to individualized binaural auditory displays with head motion. As the number of sources increases, performance degrades but at a slower rate than observed for competing channels. The fidelity of the binaural auditory display also affects performance, with greater performance gains being realized by more accurate realization of the listener's head-related transfer functions. Finally, we introduce results concerning the perceptual asymmetry between source and head rotation and discuss the importance of head rotation in cooperative-channel tasks. [Research supported by a grant from the Office of Naval Research.]

9:45

4aSP3. Aural classification of impulsive-source active sonar echoes. James Pitton (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698), Scott Philips, Les Atlas (Univ. of Washington, Seattle, WA 98195-2500), James Ballas, Derek Brock, Brian McClimens (Naval Res. Lab., Washington, DC 20375-5337), and Maxwell Miller (ARCON Corp., Washington, DC 20375-5337)

The goal of this effort is to develop automatic target classification technology for active sonar systems by exploiting knowledge of signal processing methods and human auditory processing. Using impulsive-source active sonar data, formal listening experiments were conducted to determine if and how human subjects can discriminate between sonar target and clutter echoes using aural cues alone. Both trained sonar operators and naive listeners at APL-UW were examined to determine a baseline performance level. This level was found to be well above chance for multiple subjects in both groups, validating the accepted wisdom that there are inherent aural cues separating targets from clutter. In a subsequent experiment, feedback was provided to the naive listeners and classification

performance dramatically improved, demonstrating that naive listeners can be trained to a level on par with experts. Using these trained listeners at APL-UW, a multidimensional scaling (MDS) listening experiment was designed and conducted. The results of these experiments and an analysis of the data, particularly its correlation with the physical attributes of target and clutter echoes (i.e., signal features), will be presented.

10:05–10:20 Break

Contributed Paper

10:20

4aSP4. Study on the human ability to aurally discriminate between target echoes and environmental clutter in recordings of incoherent broadband sonar. Nancy Allen, Paul C. Hines, Victor W. Young, and Douglas A. Caldwell (Defence R&D Canada Atlantic, P.O. Box 1012, Dartmouth, NS, Canada B2Y 3Z7, nancy.allen@drdc-rddc.gc.ca)

Unacceptably high false-alarm rates due to the inability to discriminate between target echoes and environmental clutter are an issue for existing low-frequency active sonar systems operating in coastal environments. A research project at Defence R&D Canada—Atlantic is investigating the potential use of aural cues to tackle this challenge. One aspect of the project is to evaluate the human ability to aurally discriminate between target echoes and environmental clutter. The design and preliminary results from the study are presented here. Human subjects are presented with a series of sounds containing target echoes and clutter obtained from recordings of an incoherent broadband sonar experiment. The quantitative data collected in the study are the subjects' decisions as to whether the echo heard was a target echo or clutter and their level of confidence associated with the decisions. Receiver-operating characteristic (ROC) analysis is used to produce a statistical model of the subjects' performance. The study also includes a questionnaire: answers may prove useful in supporting the quantitative results and in providing a better understanding of the cues and decision techniques used by the subjects.

Invited Papers

10:35

4aSP5. Generalizing timbre space data across stimulus contexts: The meta-analytic approach. Stephen McAdams (CIRMMT, Schulich School of Music, McGill Univ., 555 Sherbrooke St. W., Montréal, QC, H3A 1E3, Canada, smc@music.mcgill.ca) and Bruno L. Giordano (McGill Univ., Montréal, QC, H3A 1E3, Canada)

Studies of the multidimensionality of the complex auditory attribute called timbre often represent the perceptual structure in terms of a spatial model in which distance has a monotonic relation to perceived dissimilarity. Acoustical correlates are sought for the dimensions of these timbre spaces in order to quantify them psychophysically. An important question concerns the extent to which the results obtained with one stimulus set generalize to other stimulus sets. A meta-analytic study of data from several timbre spaces using musical tones was performed with the same multidimensional scaling algorithm. The effect of changing a subset of the sounds on the perceptual relations among common sounds was evaluated in conditions where the degree of variation along perceptual dimensions across sets was similar or different (new salient dimensions added). A change in the sounds present in the stimulus set, keeping salient dimensions constant, had little effect on perceptual structure of the common sounds in the two sets. Changing salient acoustical correlates present, while resulting in new dimensions, did not strongly affect the perceptual structure of the common sounds. Results demonstrate that, while a change in stimulus set may introduce new perceptual dimensions, the perceptual structure among sounds common to two sets remains similar.

10:55

4aSP6. Active sonar classification using perceptual signal features from musical acoustics. Victor W. Young, Paul C. Hines, and Sean Pecknold (Defence R&D Canada-Atlantic, Box 1012, Dartmouth, NS B2Y 3Z7, Canada, victor.young@drdc-rddc.gc.ca)

Because of the relatively low frequencies at which they operate, navy active sonars are often plagued by false-alarm returns resulting from geological structures. In the lexicon of sonar operators these false returns are referred to as geoclutter or simply clutter. Despite mounting evidence that human operators can aurally discriminate target returns from clutter, attempts to develop robust automatic classification algorithms have, as yet, met with limited success. This paper investigates the possibility of improving the performance of automatic classifiers by exploiting the signal processing employed in the human auditory system. This amounts to replacing the statistical signal features used by conventional automatic classifiers with perceptual signal features that reflect the way a human listener would perceive a given return. Drawing an analogy between active sonar returns and percussive musical timbre, this paper considers perceptual signal features—like loudness centroid, sub-band attack/decay, and sub-band correlation—that have previously been identified as underlying the perception of timbre. Values for each of these timbre features are measured for a series of target and clutter returns recorded during an experimental sea trial. The effectiveness of these perceptual features as target-clutter discriminators is then evaluated using a Gaussian linear discriminant classifier.

Contributed Papers

11:15

4aSP7. Automatic feature identification using multidimensional scaling data. Scott Philips, Les Atlas (Elec. Eng. Dept, Univ. of Washington, Campus Box 352500, Seattle, WA 98195-2500), and James Pitton (Univ. of Washngton, Seattle, WA 98105-6698)

Multidimensional scaling (MDS) listening experiments have long been used to better understand the perceptual cues human use when distinguishing between sounds in a given dataset. By collecting aural similarity measures between sound pairings, one can find the position of each sound in a D-dimensional perceptual space. The space allows the researcher to explore the perceptual attributes used to distinguish sounds. Typically, candidate signal features are correlated to each dimension to find which features accurately predict the signal positions in the perceptual space. Signal features generally exhibit varying degrees of correlation, with the optimal (highest correlated) feature declared to be the one used in perception. This method is not only ambiguous as to which feature (or combination of feature) is important to perception, but also is limited to previously defined signal processing features. Instead of optimizing over a limited set of features, one can optimize over a function which maps our signals to the

perceptual MDS results. This approach allows one to find a transform of the data that better represents the complicated perceptual space. A number of solutions to the problem will be presented based on the results of an MDS experiment using active sonar echoes.

11:30

4aSP8. Information-theoretic limits on spatial auditory display of sonar beam data. Jason E. Summers and Charles F. Gaumond (Acoust. Div., Code 7142, Naval Res. Lab., Washington, DC 20375-5350, jason.summers@nrl.navy.mil)

A signal-processing-based method that determines the number of independent channels in a set of head-related impulse responses (HRIRs) [B. Gardner and K. Martin, http://sound.media.mit.edu/KEMAR.html] is presented. The HRIRs in the horizontal plane are analyzed using information-theoretic methods and the resulting number of independent channels is shown as a function of noise level. These results are compared to previous psychophysical measurements of absolute and relative localization thresholds as a function of signal spectrum and target angle. This comparison leads to a noise level related to human perception. Additionally, the information-theoretic treatment is shown to yield a representation of the HRIR in the horizontal plane as a one-dimensional manifold in multidimensional coefficient space. An interpolation method is presented that is based on a distance measure on this manifold and is related to previous work [R. Duraiswami and V. C. Raykar, Proc. ICASSP **3**, 285–288 (2005)]. Different distance measures are compared. Finally, these results are discussed in context of presenting beamformed sonar data via a spatial auditory display using a mapping of beams to sources in a virtual auditory space [G. R. Arrabito *et al.*, Appl. Acoust. **66**, 986–1005 (2005).] [Work supported by ONR.]

4aUW1. Internal and surface wave effects on inverted echo sounder measurements. David M. Farmer (Grad. School of Oceanogr., Univ. of Rhode Island, Narragansett, RI 02882) and Timothy F. Duda (Woods Hole Oceanographi Inst., Woods Hole, MA 02543)

Inverted echo-sounders operating at 10 kHz, long used to observe mesoscale synoptic variability from the sea-floor through changes in acoustic travel time and pressure, were recently deployed in the South China Sea to explore their potential for detecting nonlinear internal waves. The observations, based on a 6-s transmission rate, reveal both the internal tide and high-frequency nonlinear internal wave packets and are consistent with remotely sensed images and nearby temperature time series. The results motivate exploration of a refinement in instrument operation in which the raw signal is digitized and stored at the full transducer bandwidth, rather than the present scheme of narrow band filtering and threshold detection. If the raw signal is available, it will be related to the surface wave field, leading to the prospect of ocean surface environmental measurements from the sea-floor. An intriguing possibility is that internal wave modulation of the surface wave field, so evident in remotely sensed images, including the consequence of surface wave breaking in convergence zones, might be detectable in this way from the ocean floor, thus linking internal wave observations directly with surface wave modulation. Model calculations of surface scatter are used to gain insight on this approach.

8:50

4aUW2. HF propagation in the ocean waveguide: Progress and open issues. Michael Porter (Heat, Light, and Sound Research, 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130, mikeporter@hlsresearch.com)

The HF band, defined for this talk as 5–50 kHz, has become of interest to us for many reasons. This operating band includes the musical chords and less-musical hisses of acoustic modems, the whistles and clicks of the common dolphin, and the newly recorded sounds of beaked whales. This band is of interest for mine hunting and torpedoes. Further, new HF tomography systems are emerging that exploit this band to produce lightweight systems to image the ocean weather, including both thermal fronts and currents. In turn, the latter are particularly important to lightly powered autonomous vehicles and gliders. To the surprise of many used to lower-frequency systems, sound in this band can produce identifiable echoes involving many reflections from a sea surface broken by waves and quite rough ocean bottom. Thus, the role of both dynamic and static boundaries is important, as well as refractive effects of the ocean volume. We review recent progress and discuss open issues in this area.

9:10

4aUW3. The coupled oceanographic-tomographic analysis and prediction system: A practical means for utilizing high-frequency tomography in the world's oceans. Peter J. Stein (Sci. Solutions, Inc., 99 Perimeter Rd., Nashua, NH 03063), James K. Lewis (Sci. Solutions, Inc., Kalaheo, HI 96741), and Subramaniam D. Rajan (Sci. Solutions, Inc., Nashua, NH, 03063)

Over the last several years, technology has been developed to transition ocean tomography out of the laboratory and into practical use. This technology, the coupled oceanographic-tomographic analysis and prediction system (COTAPS), couples an ocean circulation model in a region with travel time information from a network of high-frequency acoustic nodes in the same region. A data assimilation technique is used to impose corrections to the ocean model temperatures and salinities based on observed arrival time anomalies and a Kalman gain matrix. Details of the features of COTAPS are presented and discussed. This includes the technique and associated software for assessing ray path information in the area in which the network of nodes is deployed, an automated method for calculating the Kalman gain, and a suggested design of the acoustic nodes. We also discuss a few issues that remain to be researched. These include significant variability of observed arrival times over short time intervals (less than 5 min) and how to mitigate the impact of such variability, the use of observed arrival times to account for errors in the locations of the nodes in a network, and the effect of assimilating arrival time information from multiple source-receiver pairs.

9:30

4aUW4. Modeling of the intensity channel impulse response for the East China Sea. Jee Woong Choi and Peter H. Dahl (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, choijw@apl.washington.edu)

Results of modeling the intensity channel impulse response in shallow and comparison with measurements are presented. The measurements were made in the East China Sea (depth 100 m, range ~ 500 m) as part of the Asian Seas International Acoustics Experiment (ASIAEX). The intensity channel impulse response is obtained by incoherent summation of separate impulse response functions for each path (eigenray); the latter are modeled using ray and bistatic scattering methods. Measured sea surface spectral information and inverted seabed properties (from previously published works) are incorporated in the modeling. The modeled channel impulse response is convolved with representations of the CW (center frequency 8 and 16 kHz) or FM (frequency range 8–16 kHz) waveforms that were transmitted for comparison with observations. This talk will discuss (1) the influence of two-dimensional (out-of-plane) scattering including near-surface bubbles and the volume inhomogeneities in the sediment, on the intrapath time spread, and (2) the contribution of each arrival (up to the sixth path) to the channel impulse response. [Work supported by Office of Naval Research.]

9:50

4aUW5. Environmental effects on high-frequency propagation during the Makai experiment. Thomas Folegot (NATO Undersea Res. Ctr., MILOC, Viale S. Bartolomeo 400, 19138 La Spezia, Italy), Vincent K. McDonald (Space and Naval Warfare Res. Systems Ctr., San Diego, CA), Sergio M. Jesus (Univ. of Algarve, Faro, Portugal), Mohsen Badiey (Univ. of Delaware, Newark, DE 19711), Paul Hursky, and Michael B. Porter (Heat, Light, and Sound Res., Inc., San Diego, CA)

The Makai experiment was conducted from 15 September to 2 October 2005 off Kauai Island to provide a comprehensive study of acoustic propagation in the 8–14-kHz band for diverse applications. Thermistor string measurements show how the interaction between the barotropic tides and the bathymetry generates a highly dynamic environment. Strong variability in the sound-speed profile has been observed, with diurnal and semidiurnal thermocline depth changes up to 50 m. Acoustic waves have been propagated at several ranges between two sources and receiver arrays, using fixed and drifted setup. The structure of the received impulse functions shows strong variability, although resolved arrivals are persistent.

10:05–10:20 Break

10:20

4aUW6. Modeling Doppler effects for acoustic communications. Martin Siderius, Michael B. Porter, Paul Hursky (HLS Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130), and Vincent McDonald (SPAWAR Systems Ctr., San Diego, CA 92152)

Performance of high-data-rate, bandwidth-efficient communications signals can be significantly degraded by failing to compensate for Doppler effects. Significant Doppler spread can be introduced simply from the sound interacting with the moving sea surface; however, the effects can be much greater when the source and receiver are also in motion. Numerical modeling that accurately accounts for Doppler effects can be used to develop and test communications algorithms. In this presentation, a simple technique will be presented for modeling communication signals in the ocean that includes Doppler effects. The challenge for modeling is due, in part, to the broad band and high frequencies (e.g., 3–50 kHz) typically used in underwater communications. The frequency band suggests using Gaussian beam tracing to determine the field. In addition, the Gaussian beams are conveniently interpolated and extrapolated to allow for the treatment of Doppler effects due to environmental and platform motion. The technique will be tested using simulations and experimental data from Doppler-sensitive transmissions.

10:35

4aUW7. Scattering by a set of sediment rough layers from a normal incident beam. Dajun Tang (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

The seabed can often be modeled as layers, which are in general not flat. The ability to model scattering from such rough layers is important for interpreting data from acoustics systems such as chirp sonar and echo sounders. The goal of this work is to investigate this scattering problem for a normal incidence scenario. A set of one-dimensional fluid rough interface realizations was generated using Monte Carlo method. Integral equations for the problem are solved, which include all multiple scattering effects. The solution is simplified when scattering matrices for each individual rough interface are pre-calculated. Based on the exact solution, the applicability of Kirchhoff approximation under various conditions is evaluated. The approximated method can then be applied to two-dimensional rough interfaces. [Work supported by ONR.]

10:50

4aUW8. Accurate imaging of the current and temperature structures in coastal oceans by acoustic data assimilation. Tokuo Yamamoto (Appl. Marine Phys. Div., RSMAS, Univ. of Miami, Miami, FL 33149) and Arata Kaneko (Hiroshima Univ., Hiroshima, Japan)

Both ocean observations and models have limitations. To eliminate the limitations, the idea of data assimilation has been tried in recent years but the results still have been very limited. We have made reciprocal transmissions of 2.5-kHz sound signals along six paths in the Japanese Inland Sea. An extensive ADCP survey was made during this acoustic transmission experiment for the ground truth. The acoustic data were directly inverted for imaging the current and temperature structures. The acoustic data were also assimilated into a Princeton ocean model (POM) using a Kalman filter. The acoustic data assimilation produced very accurate structures of current and temperature, while the direct inversions produced inaccurate and distorted structures. The time interval of data assimilation controls the accuracy of data assimilation technique.

11:05

4aUW9. M-ary frequency-shift-keying bit error rate analysis for a high-frequency underwater acoustic fading channel. Wen-Bin Yang and T. C. Yang (Naval Res. Lab., Code 7120, 4555 Overlook Ave., SW, Washington, DC, 20375, wyang@wave.nrl.navy.mil)

One of the prime advantages of M-ary frequency-shift-keying (MFSK) modulation is its ability to use an incoherent receiver. The incoherent receiver does not need precise frequency and phase estimates so that it can perform well, particularly in a significantly faded underwater acoustic communications channel. MFSK bit error rate (BER) performance using an incoherent receiver is determined by fading statistics of received signal amplitude. From our recent study in high-frequency underwater acoustic channel characterization, we found the fading statistics has a non-Rayleigh behavior and may be modeled as a K-distribution. In this paper, the MFSK BER is derived in terms of the parameters of the K-distribution. The theoretical BER is compared with measured BER of frequency-hopping (FH) FSK signaling data collected off the coast of New Jersey during the TREX04 experiment. The FH-FSK signal is a modified version of MFSK signals and was centered at 17 kHz with 4-kHz bandwidth. [Work supported by the Office of Naval Research.]

Architectural Acoustics: Acoustics of Libraries

Benjamin E. Markham, Chair
Acentech Inc., 33 Moulton St., Cambridge, MA 02138-1118

Chair's Introduction—1:00

Invited Papers

1:05

4pAAc1. Fine-tuning the acoustics of libraries at colleges and universities. Joyce E. Rosenbaum, Carol L. Krumhansl, and Michael J. Hove (Dept. of Phys., Cornell Univ., Ithaca, NY 14853, jer42@cornell.edu)

New technology and changing student work habits challenge academic libraries to accommodate different types of study by designing different rooms for distinct purposes. This requires not only a variety of technologies, room setups, and seating, but also acoustic conditions that stimulate efficient and comfortable productivity—whether with computers, textbooks, or interactive study groups. Acoustic recordings were taken in 13 different ''favorite'' rooms, with diverse characteristics and personalities, within the two main libraries at Cornell University. The acoustic measurements were compared with observations of student activity within these spaces to determine relationships between acoustic measurements and student behavior. Factor analysis revealed three types of student-activity categories: quiet concentration, relaxing and socializing, and computer use. The analysis also revealed three categories of room type: quiet study rooms, rooms with computer use, and cafés. These categories of activities and room types correlate with acoustic measurements, pointing to the existence of distinct niches within the library system. Examining the acoustic conditions conducive to certain activities may help future designers of academic libraries to optimize the acoustics of study spaces for different purposes.

1:25

4pAAc2. Rethinking the library for the 21st century? Peter Nobile (Shepley Bulfinch Richardson and Abbott, 2 Seaport Ln., Boston, MA 02210)

In the past few decades, the evolution of libraries has been increasingly dramatic and complex. Technology has fundamentally revolutionized information access, manipulation, and utilization. This transformation has challenged librarians and architects to evaluate the implications of these changes and their impact on the core mission of the library, its architecture, and the institution as a whole. Shepley Bulfinch is often engaged by our clients to help usher in the library for the 21st century. Such a facility is expected to fully integrate the digital and print worlds and introduce new spaces for media access, cyber cafs, 24/7 use, seminar and general instruction, faculty development labs, and GIS services. Additionally, such projects create flexible spaces that can be easily transformed to meet changing needs and uses. These projects bring with them significant acoustical isolation and technological access problems. However, such challenges are to be expected as these projects redefine the research and learning environment by integrating library resources, services, and users in spaces that reflect the overall evolution of the library.

1:45

4pAAc3. The digital preservation facility. Elizabeth Cohen (Consulting Professor of Elec. Eng., Stanford Univ., 161 Packard Bldg., 350 Serra Mall, Stanford, CA 94305)

Critical listening should be an essential part of all archiving and restoration facilities quality control. We review the priorities and requirements for listening spaces ranging from the individual collector and small community archives to large-scale facilities. Examples discussed include the Library of Congress Culpepper facility, university libraries, and commercial facilities. Adapting listening rooms to the requirements of n-channel audio are discussed. Public recommendations of the Sound Preservation Board of the Library of Congress will be reviewed.

2:05

4pAAc4. Acoustical design issues for library facility planners. Cristina L. Miyar, Elaine Y. Hsieh, and Charles M. Salter (Charles M. Salter Associates, Inc., 130 Sutter St., 5th Fl., San Francisco, CA 94104, cristina.miyar@cmsalter.com)

Acting under the provisions of the Library Services and Technology Act, the U.S. Institute of Museum and Library Services retained Charles M. Salter Associates, Inc. to provide a document explaining acoustical and audio/visual requirements for libraries to library planners, architects, and lay people. Acoustical design issues for libraries discussed on the website include site noise considerations, noise standards for each use space, room acoustics considerations, sound isolation between various use spaces, vibration control for mechanical equipment, and audio/visual system considerations. The completed document forms a part of the Libris Design library facility planning information system, which includes a website, <Librisdesign.org>, with recent information on facility planning topics and a database of recently constructed California public libraries.

2:25

4pAAc5. Wireless technology and library acoustics. Benjamin Markham (Acentech Inc., 33 Moulton St., Cambridge, MA 02138, bmarkham@acentech.com)

The modern library cannot function without modern technology. Printers, copiers, wireless computers, and espresso machines all contribute to the soundscape of the typical municipal library (and many academic libraries, too). While some of these noise sources are stationary and can be isolated acoustically, wireless computing has transformed the acoustic experience for the typical library patron. Study carrels and desks used to define the boundaries of study and work areas in libraries, and architects could design spaces accordingly. With wireless technology, every space is a study space. This paper will discuss the implications of wireless technology on library acoustics. Measurement results at a variety of case study libraries will be presented.

2:45

4pAAc6. Modern library design—architectural directions. Isaac Franco (Moshe Safdie and Associates, 100 Properzi Way, Somerville, MA 02143) and Carl Rosenberg (Acentech, Inc., Cambridge, MA 02138)

The architectural practice of Moshe Safdie and Associates in Boston has been challenged by numerous clients recently to design major public libraries. The clients have stated an interest in making the library a major civic focal point and a place for community activities and identity. Moshe Safdie has responded to these challenges in Philadelphia, Vancouver, and Salt Lake City by designing buildings that encourage community interaction with large light-filled gathering spaces to support public congregating venues, shops and eateries, music recitals, meetings, electronic technologies, and even book club gatherings. This presentation will discuss the architectural context of contemporary library design. As a coda to the presentation, there will be a discussion about the acoustical implications of these new directions in civic library design.

THURSDAY AFTERNOON, 8 JUNE 2006 ROOM 552B, 1:00 TO 5:05 P.M.

Session 4pAO

Acoustical Oceanography and Animal Bioacoustics: Exploitation of Sound by Marine Mammals II

David L. Bradley, Cochair
Pennsylvania State Univ., Applied Research Lab., P.O. Box 30, State College, PA 16804

Whitlow W. L. Au, Cochair
Hawaii Inst. of Marine Biology, P.O. Box 1106, Kailua, HI 96734

Chair's Introduction—1:00

Invited Papers

1:05

4pAO1. Anthropogenic noise and baleen whales: A perspective from humpback whale acoustics. Whitlow W. L. Au and Marc O. Lammers (Marine Mammal Res. Program, Hawaii Inst. of Marine Biol., Univ. of Hawaii, P.O. Box 1106, Kailua, HI 96734)

The effects of anthropogenic noise on baleen whales is a topic of intense interest not only to marine mammalogists but also to a variety of commercial interests, the military, oceanographers, and researchers that use sounds in the ocean. One of the major difficulties in setting standards for exposure levels and the effective use of anthropogenic sounds is a lack of knowledge of the auditory properties of whales. The auditory sensitivity and frequency range of hearing (audiogram) are not known, as well as how anthropogenic sounds physically affect the auditory system, the psychological well being, and the use of sounds by whales. One approach to gain some insight in this area is to study the acoustics of a baleen whale species, the humpback whale. The source levels and frequency range of humpback whale song units have been measured and can provide insights into what these whales expose each other to. The highest rms source level was 173 dB for a specific unit. The average sound pressure levels of chorusing have been measured and can provide insights into the long-term acoustic environment of humpback whales. The highest daily average of sound pressure level for chorusing sounds was 130 dB.

1:25

4pAO2. Right whales—Social sound production. Susan E. Parks (Bioacoust. Res. Program, Cornell Univ. 159 Sapsucker Woods Rd., Ithaca, NY 14850, sep6@cornell.edu), Douglas P. Nowacek (Florida State Univ., Tallahassee, FL 32306-4320), Mark P. Johnson, and Peter L. Tyack (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Right whales use sound to mediate many social interactions. Examples include females producing screams to initiate the formation of surface active groups, adult males producing gunshot displays in agonistic contexts, and mothers producing contact calls when reuniting with their calves. We are just beginning to understand the more sophisticated abilities of right whales to utilize sound. Playback experiments demonstrate that right whales are capable of precise sound localization over long ranges and can remember these locations after the sound source ends. Further evidence suggests that individual recognition may play an important role in

acoustic communication, from the simple examples from mothers and calves, to more complex evidence that some males preferentially approached playbacks of calls from specific females. Future research investigating the complexity of baleen whale sound use will include studies of individual recognition and the localization and spatial memory abilities of these whales. New technological developments are making it possible to answer these more complex questions and will reveal more details of how baleen whales to use sound to survive.

1:45

4pAO3. Sound production and detection by pinnipeds. Brandon L. Southall (NOAA Ocean Acoust. Program, NMFS Office of Sci. and Technol., 1315 East-West Hwy., Silver Spring, MD 20910), David Kastak, Colleen Reichmuth Kastak, Steven J. Insley, Marla M. Holt, Jason Mulsow, and Ronald J. Schusterman (Univ. of California, Santa Cruz CA 95060)

Pinnipeds (seals, sea lions, and walruses) emit and receive sounds both in air and water. Their amphibious natural history has resulted in a number of fascinating sensory capabilities, including but not limited to hearing, but has apparently precluded the evolution of sophisticated biosonar systems. Pinnipeds produce vocalizations in a variety of social contexts, notably reproduction and aggression. Attraction calls in many species serve to retain or re-establish contact between females and offspring and to draw the attention of potential mates. Repulsion vocalizations warn adversaries and can advertise strength and intent. Cognitive processes, including conditioned learning, are an essential foundation of the sophisticated acoustic communication systems of pinnipeds. Recent advances in understanding these systems and passive listening in the context of predator and prey detection and spatial orientation will be discussed.

2:05

4pAO4. Imaging acoustic centers of the dolphin brain with positron emission tomography. Sam Ridgway, Dorian Houser, Don Carder (SPAWAR Systems Ctr. San Diego, Div. D235, 53560 Hull St., San Diego, CA 92152-5001), and Carl Hoh (Univ. of California, San Diego, CA 92093)

In human subjects, positron emission tomography (PET) has been used in diagnosis of disease, in studies of complex cognitive tasks, and in localizing areas of sensory activation, motor movement, and attention. Now, brain physiology of bottlenose dolphins, *Tursiops truncatus*, has been studied with PET. The dolphin brain is in the human size range but is more highly convoluted. The known acoustic centers of the dolphin brain are greatly enlarged compared with human brains. However, dolphins have a multi-tiered cortex with an extensive extra lobe, the paralimbic lobe, which does not occur in mammals or other animals outside the Order Cetacea. Because of its inaccessible location, there are no functional studies of the paralimbic cortex. PET offers an opportunity to study activity in this unique part of the dolphin brain during various stimulus conditions that may help to reveal functional aspects of the paralimbic cortex. For experimental scans, the dolphin was exposed to acoustic stimuli (tones or pulses) to reveal areas of relative brain metabolism after 18-F-FDG administration. These scans have revealed interesting features of the living dolphin brain including the paralimbic lobe as well as known acoustic areas in the cortex, midbrain, and acoustic nuclei.

4pAO5. Dolphin pods of the Southern California Offshore Range: Localization and behavior. Katherine H. Kim, Paul Hursky, Michael B. Porter (Heat, Light, and Sound Research, Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130, katherine.kim@hlsresearch.com), John A. Hildebrand, E. Elizabeth Henderson, and Sean M. Wiggins (Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0205)

The Southern California Offshore Range, a U.S. Navy training area located near San Clemente Island, is rich in odontocete activity. Pods of dolphins, numbering as many as several hundred individuals, regularly transited the area and frequently vocalized during the 2004 SCORE 23F experiment. Such acoustic data were collected on a high-frequency, four-element, horizontal line array as well as on a high-frequency, single-element buoy. The copious dolphin vocalizations were then processed using automated whistle and click detection techniques and various localization methods which utilized time-of-arrival differences, frequency-domain beamforming, and multipath arrival structure. Combining the acoustic tracking results with concurrent visual observations provides a unique look at large numbers of free-ranging dolphins at and below the sea surface and suggests certain group behavioral patterns.

2:40

4pAO6. Depth/range localization of diving sperm whales using passive acoustics on a single hydrophone disregarding seafloor reflections. Christophe Laplanche, Olivier Adam, Maciej Lopatka, and Jean-François Motsch (Université Paris 12, 61 av. du Gal de Gaulle, 94000 Créteil, France)

Depth and range of sound sources can be estimated using a single hydrophone. Such a passive acoustic technique requires the detection of direct path transmitted, sea surface, and seafloor reflected source signals, so as to measure their time of arrival differences (TOADs). Sperm whales almost continuously emit powerful, directional echolocation sounds (usual clicks) when diving. Sperm whales often dive in deep water, and click seafloor reflections are usually well detected only at the beginning of the dive. Surface echoes may be detected during the entire dive. If the measurement of the surface reflection TOAD of a single click is not enough for estimating the depth/range of the sperm whale at the time when this click was emitted, the joint consideration of delays emitted during the whole dive may provide this estimation. Such delays are indeed the measurements of a single phenomenon: the underwater movements of a single-clicking sperm whale. One can merge such data using a Bayesian technique, as well as use prior information (e.g., range when fluking-up). Such

a method could make the single-hydrophone localization technique usable regardless of the properties of the sea bottom, e.g., in deep or high relief areas.

2:55–3:05 Break

3:05

4pAO7. Linking sound production and dive behavior in feeding humpback whales. Alison K. Stimpert, Whitlow W. L. Au (MMRP/Hawaii Inst. of Marine Biol., P.O. Box 1106, Kailua, HI 96734, stimpert@hawaii.edu), David N. Wiley (Stellwagen Bank Natl. Marine Sanctuary, Scituate, MA 02066), Kenneth A. Shorter, Kira L. Barton, Mark P. Johnson (Woods Hole Oceanogr. Inst., Woods Hole, MA, 02543), Colin Ware, and Roland Arsenault (Univ. of New Hampshire, Durham, NH, 03824)

Acoustic studies of baleen whales are becoming increasingly common. However, a minority of studies combines acoustic data with technologies that allow sound production to be placed in a detailed behavioral context. Noninvasive digital acoustic recording tags (DTAGS) were attached to humpback whales (*Megaptera novaeangliae*) on the western North Atlantic's Great South Channel feeding grounds to study foraging and acoustic behavior. Acoustic records totaling 48.4 data hours from four attachments were aurally and automatically analyzed, and occurrences of several sound types were correlated with body orientation and dive behavior of the tagged subject. Whales produced a wide variety of sound types, which differed in depth and context of production. Long, tonal groans and moans (3-s average duration, 500-Hz peak frequency) occurred more frequently in upper portions of the water column, in contrast to broadband paired bursts (50-ms average duration, 300-Hz peak frequency), which appeared associated with bottom feeding. Virtual behavioral study using GEOZUI4D is used to visualize how sounds may be associated with foraging behavior. Overall results indicate sophisticated, situation-dependent use of sound. Behavioral implications of masking effects by surrounding vessel traffic noise are discussed.

3:20

4pAO8. Naval sonar, marine mammal strandings, and the bubble hypothesis. Mark W. Muller (Marine Mammal Res. Program, Hawaii Inst. of Marine Biol., 46-007 Lilipuna Rd., Kaneohe, HI 96744 and Dept. of Mech. Eng., Univ. of Hawaii, 2540 Dole St., Honolulu, HI 96822), Whitlow W. L. Au (Hawaii Inst. of Marine Biol., Kaneohe, HI 96744), John S. Allen (Univ. of Hawaii, Honolulu, HI 96822), Eryn M. Wezensky (Naval Undersea Warfare Ctr. Newport, RI 02841), and Michael R. Barkley (Bates Creative Group, Silver Spring, MD 20910)

Although spatio–temporal links exist between some military active sonar testing and cetacean mass stranding events, the underlying causal mechanism(s) of the strandings are not well understood. It has been demonstrated that cetaceans may experience *in vivo* gas bubble/emboli development; however, the basis for cavitation formation remains unknown. Acoustically mediated *in vivo* cavitation formation in cetaceans exposed to high-intensity sound sources has been proposed. The distance of these exposure effects from midfrequency sound sources can be influenced by a combination of factors affecting underwater acoustic propagation. To investigate these issues, this experiment considered rectified diffusion as a possible mechanism for acoustically mediated *in vivo* cavitation formation in cetaceans. Gelatin samples were placed under water and exposed to an SPL of 205 dB *re*: 1 μ Pa at 4.5 kHz for up to 1000 s. The sound field was generated by a Massa transducer similar to the transducer element used in the United States Navy AN/SQS–23 shipboard high–power sonar system. Exposure time threshold of cavitation formation was determined to be 600 s for the given sound field. Experimental results were compared with previously developed theoretical models for acoustically enhanced cavitation growth. The applicability and limitations of this approach as well as future research direction are discussed.

3:35

4pAO9. Acoustic analysis for the Haro Strait on 5 May 2003. David M. Fromm (Naval Res. Lab., 4555 Overlook Ave. SW, Washington, DC 20375-5320)

On 5 May 2003, USS SHOUP conducted sonar training for 4 h while transiting through the Strait of Juan de Fuca and the Haro Strait. During the time period when the sonar was configured for long-range operations, the transmissions were alleged by some observers to have influenced the behavior of the resident J-pod of orcas. Additionally, the transmissions were received and recorded on various hydrophones deployed for monitoring marine mammal vocalizations. The U.S.-Navy-commissioned detailed reconstruction of the event that relates the location of SHOUP, the J-pod, and the monitoring hydrophones during the time period of SHOUP's long-range sonar operations is presented. By combining high-fidelity predictions of the acoustic field with the *in situ* acoustic recordings, the reconstruction provides a detailed, moment-to-moment picture of the worst case estimates of the sonar sound levels experienced by the J-pod. [Work supported by the U.S. Navy Pacific Fleet.]

3:50

4pAO10. Are manatees modifying their vocalizations to compensate for noise? Jennifer L. Miksis-Olds (Univ. of Massachusetts SMAST, 706 South Rodney French Blvd., New Bedford, MA 02744, jmiksis@umassd.edu)

Elevated environmental noise levels have the potential to interfere with the acoustic communication system of manatees by masking signals containing biologically important information. Communication theory recognizes several ways a sender can modify its acoustic signal to compensate for noise. These include increasing the source level of a signal, its repetition, its duration, or shifting frequency outside of the noise band. To test whether manatees can modify their vocalizations to compensate for noise, vocalization usage and structure were examined in terms of vocalization rate, duration, frequency, and source level. Results imply that manatees do increase their vocalization energy expenditure, or vocalization effort, as a function of behavior and calf presence. Increases in vocalization rate, duration, and source level were most pronounced when calves were present and during behaviors whereby animals tended to be more dispersed, which may suggest a cohesion function. In conditions of elevated noise levels, manatees increased call duration during feeding and milling behaviors when calves were present, suggesting that ambient noise levels do have a detectable effect on manatee communication and that manatees modify their vocalizations as a function of noise.

4:05

4pAO11. Wavelet-based denoising of manatee vocalizations. Christopher Niezrecki and Berke M. Gur (Dept. of Mech. Eng., Univ. of Massachusetts Lowell, One University Ave., Lowell, MA 01854, christopher_niezrecki@uml.edu)

In the last decade, novel research on the wavelet transform has led to its recognition as a promising tool for denoising signals. Wavelet-coefficient-shrinkage-based denoising algorithms have been applied in various fields of science and engineering and successful results have been reported in Raman spectroscopy and medical imagery. Within this study, the wavelet transform is used to denoise manatee vocalization recordings corrupted with typical underwater noise such as boat, snapping shrimp, and water movement noise. The detection range and performance of acoustically based detection systems depends greatly on the SNR of the acoustic signal. A selective thresholding is performed on the wavelet coefficients and the denoised vocalizations are obtained through the reconstruction of these coefficients. The performance of the method presented is benchmarked against the well-known wavelet-coefficient-shrinkage-based denoising algorithms using the same underwater acoustic data obtained in prior studies. Preliminary results indicate that the suggested wavelet-transform-based denoising algorithm outperforms the shrinkage-based methods by an average of 5 dB.

4:20

4pAO12. Locating manatee position with an acoustic array. Paulin Buaka Muanke and Christopher Niezrecki (Dept. of Mech. Eng., Univ. of Massachusetts Lowell, One University Ave., Lowell, MA 01854, christopher_niezrecki@uml.edu)

This paper presents the effort conducted in determining a manatee's position by using acoustic methods. The time difference of arrival (TDOA) technique developed for the position location is used with the Hilbert envelope peak technique to estimate the time difference of arrival. The time differences obtained are converted into nonlinear hyperbolic equations which are solved using the least square method to perform the manatee localization. To improve the position location accuracy, with four hydrophones, six pairs of time delays are estimated and then combined (three by three) to give 20 calculated locations for each individual vocalization. To get a more accurate location, a statistical analysis test to remove the time delays combinations, which generate outliers, is applied on these 20 location results. Simulated results using the dSpace system for data acquisition and signal processing are presented for the case of an artificial tone signal. This method is applied to a variety of experimental data to test the systems performance.

4:35

4pAO13. Background noise reduction of manatee vocalizations. Zheng Yan, Louis N. Cattafesta, III (Dept. of Mech. and Aerosp. Eng., Univ. of Florida, Gainesville, FL 32611-6250), Christopher Niezrecki (Univ. of Massachusetts Lowell, Lowell, MA 01854), and Diedrich O. Beusse (Univ. of Florida, Gainesville, FL, 32610-0126)

The West Indian manatee (*Trichechus manatus latirostris*) has become an endangered species in the United States partly because of an increase in the number of collisions with boats. A device to alert boaters of the presence of manatees is desired. Previous research has shown that background noise limits the detection range (which is critical for practical implementation). By improving the signal-to-noise ratio of the vocalization signal, it is possible to extend the detection range. The finite impulse response (FIR) structure of the adaptive line enhancer (ALE) can detect and track narrowband signals buried in broadband noise. In this paper, a constrained infinite impulse response (IIR) ALE, called a feedback ALE (FALE), is implemented to reduce the background noise. In addition, a bandpass filter is used as a baseline for comparison. A library consisting of 100 manatee calls spanning ten different signal categories is used to evaluate the performance of the bandpass filter, FIR-ALE, and FALE. The results show that the FALE is capable of reducing background noise by about 6.0 and 21.4 dB better than that of the FIR-ALE and bandpass filter, respectively, when the signal-to-noise ratio (SNR) of the original manatee call is -5 dB.

4:50

4pAO14. Simulation of ranges for acoustic-based manatee detection. Christopher Niezrecki, Berke M. Gur (Dept. of Mech. Eng., Univ. of Massachusetts Lowell, Lowell, MA 01854, christopher_niezrecki@uml.edu), James Cramer (Univ. of Massachusetts Lowell, Lowell, MA, 01854), and Diedrich O. Beusse (Univ. of Florida, Gainesville, FL 32610-0126)

One aspect of the feasibility of an acoustically based manatee detection system relies upon the distance in which a manatee vocalization is detectable. The magnitude of environmental noise, manatee vocalizations, as well as the acoustic spreading properties of the habitat need to be considered to estimate the detection range of a vocalizing manatee. The simulation presented combines measured source levels of manatee vocalizations with the modeled acoustic properties of manatee habitats to illustrate the effective ranges in which manatees are detectable. The simulation indicates that background noise significantly affects the detectable range.

4pBB1. The role of cavitation in therapeutic ultrasound. L. Crum, M. Bailey, V. Khokhlova, O. Sapozhnikov (Ctr. for Industrial and Med. Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), B. Rabkin (Univ. of Washington, Seattle, WA 98105), A. Evan, J. McAteer, Y. Pishchalnikov, J. Williams (Indiana School of Medicine, Indianapolis, IN), and R. Cleveland (Boston Univ., Boston, MA 02215)

Ed Carstensen has made many contributions to biomedical ultrasound but among those that are becoming more and more relevant to current clinical practice are those that determine the conditions under which cavitation is induced *in vivo*. For many years, it was assumed that the medical ultrasound devices were unable to induce cavitation in living tissue because either the acoustic conditions were not sufficient or the nucleation sites that are required were too small. With the advent of lithotripters and high-intensity focused ultrasound (HIFU) devices, cavitation generation *in vivo* is commonplace. Our current research at the University of Washington has focused on the role that cavitation plays in stone comminution and tissue damage during lithotripsy, as well as the enhancement or reduction of desirable coagulative necrosis during HIFU application. During HIFU application, we find enhanced heating that results

from nonlinear acoustic wave propagation (a key Carstensen contribution) leads to vapor bubble formation. This presentation will review our recent studies in this area. [Work supported in part by the NIH under CA109557 and DK43881, and the NSBRI SMS00402 under NCC9-58-50.]

4pBB2. Vessel damage mechanisms by ultrasound or shock wave pulses. Sheryl M. Gracewski, Hongyu Miao (Dept. of Mech. Eng. and the Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627, grace@me.rochester.edu), and Diane Dalecki (Univ. of Rochester, Rochester, NY 14627)

Edwin L. Carstensen has been one of the pioneers investigating not only the thresholds for bioeffects of ultrasound, but also determining mechanisms for these bioeffects, especially when air cavities are involved. Previous studies have demonstrated that hemorrhage or endothelial layer damage can occur when the blood vessels are exposed to lithotripter shock waves or to ultrasound in the presence of echo contrast agents. The presence of bubbles is often necessary for the damage to occur. Two main hypotheses describing the mechanism of vessel damage by acoustically excited microbubbles have been proposed. The vessel could be damaged by the high pressures and/or temperatures generated by the violent collapse of cavitation bubbles. Alternatively, the vessel could rupture upon bubble expansion. Here, a simple model is presented for vessel rupture upon bubble expansion and calculations are presented for parameters corresponding to two recently published experimental observations of vessel rupture and of endothelial cell damage to try to distinguish between these two mechanisms.

1:40

4pBB3. Risk factors for tissue injury induced by shock wave lithotripsy (SWL). Andrew P. Evan, Lynn R. Willis, Bret A. Connors, Philip M. Blomgren (School of Medicine, Indiana Univ., Indianapolis, IN 46223), Rajash Handa, Youshi Shao, James A. McAteer, Yuri A. Pishchalnikov (Indiana Univ., Indianapolis, IN 46223), and James E. Lingeman (Methodist Hospital Inst. for Kidney Stone Disease, Indianapolis, IN 46220)

A clinical dose of SWL consistently and specifically disrupts the cellular layers of renal veins and arteries, first in the medulla, but progressing into the cortex with an associated inflammatory response. The resulting hemorrhage within the focal zone produces regions of intraparenchymal and subcapsular hematomas of varying size. Renal blood flow and glomerular filtration rate fall acutely by 50% in the treated kidney and by 20% in the untreated kidney. The sites of acute injury form scars with a permanent loss of renal function and have been associated with apatite/brushite stone formation and hypertension. Our team has shown that the size of the SWL-induced lesion can be dramatically reduced by lowering the kV level, applying fewer shock waves, slowing the shock wave rate, and by pretreating the kidney with 100–500 shock waves at 12 kV prior to standard SWL. The mechanism of tissue injury caused by SWL has not been defined; however, protocols that reduce cavitation activity also reduce the size of the SWL-induced lesion, and injection of bubbles into the renal vasculature, which support cavitation, intensifies and broadens the regions of the SWL-induced injury.

4pBB4. A possible noncavitational mechanism of ultrasound-accelerated thrombolysis in fibrin clots. E. Carr Everbach (Eng. Dept., Swarthmore College, Swarthmore, PA 19081), Irina N. Chernysh, and John W. Weisel (Univ. of Pennsylvania, Philadelphia, PA 19104)

Blood clots made of human plasma or purified fibrin with and without the addition of rt-PA were insonified with 1-MHz pulsed ultrasound on a microscope slide placed in a spectrophotometer. Clot dissolution times were measured by absorption of light at 350-nm wavelength passing through the clot. Dissolution times were halved for ultrasound-exposed clots versus shams. Clots with no rt-PA present showed a small but significant thrombolysis effect in the presence of ultrasound which could be prevented by the addition of factor XIII, which effectively binds the fibrin. Ultrasound pulse parameter variations showed a broad maximum effectiveness at 0.5-MPa peak negative pressure, 1-ms duration, and 50-Hz PRF. Concentration of protein in solution was elevated as much as a factor of 10 following insonification of clots without rt-PA, suggesting that ultrasound affects the kinetics of fibrin remodeling. A possible explanation that does not involve bubble activity is relative motion between the clot fibers and the interstitial fluid.

2:20

4pBB5. Nonviral gene transfer to murine liver *in vivo* is enhanced by exposure to high-amplitude, 1-MHz ultrasound with Optison®. Andrew A. Brayman (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698), Zhenping Shen, Liping Chen (Children's Hospital and Regional Medical Ctr., Seattle, WA 98109), and Carol Miao (Univ. of Washington, Seattle, WA 98195)

High-amplitude, 1-MHz ultrasound applied in pulse or burst mode at low duty factor, in conjunction with the injection of a mixture of gas-filled microspheres (Optison®) and plasmid, enhances nonviral gene transfer to surgically exposed murine liver *in vivo*. In this system, neither plasmid + ultrasound, nor plasmid + Optison produced significant gene expression relative to plasmid-only controls. The combination of plasmid + ultrasound + Optison produced a large enhancement of gene expression. The effect has a strong dependence on acoustic pressure. Together with the dependence of the effect on gas bodies, these results suggest that cavitation-induced permeability changes to hepatocytes are involved. Parametrization studies, the goal of which has been to further enhance gene transfer, will be discussed. At this writing, ultrasound treatments comprised by relatively brief pulses (20–40 cycles) at relatively high pulse repetition frequency (50 Hz) have produced nearly an order of magnitude greater gene expression than produced by tone bursts of several hundred cycles at low pulse repetition frequency (3 Hz) when plasmid and Optison are injected into the portal vein. [Project supported by NIH Grant R01 HL69049.]

4pBB6. Measuring bubble dynamics in lithotripsy using a high-speed camera. Parag V. Chitnis and Robin O. Cleveland (Dept of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215, pchitnis@bu.edu)

The primary goal of this study was to examine bubble dynamics in shock wave lithotripsy and experimentally obtain the radius-time (r-t) profile. A piezoelectric array was employed as a shock wave (SW) source. The focal waveform (as measured with a fiber optic probe hydrophone) was double-peaked with two shocks: leading peak pressure 65 ± 3 MPa and second peak 30 ± 3 MPa. The negative phase in between had a peak $p-=-16\pm2$ MPa. The cavitation field was monitored using a dual passive cavitation detector consisting of two 1-MHz focused transducers. The second peak of the SW inhibited cavitation limiting the characteristic time to less than 60 μs. A high-speed camera (up to 10 million frames per second) with a spatial resolution of 2 μm/pixel was used to measure bubble dynamics. The camera could record 14 frames that were timed to measure the growth and collapse phases of the bubbles. The bubbles were initially spherical but became aspherical and exhibited jetting as they collapsed. The bubble radius was estimated from the area of bubble in each snapshot from which r-t curves were constructed and compared to calculations using the Gilmore formulation. The maximum radius ranged from 150 to 300 μm. [Work supported by NIH.]

2:55

4pBB7. Cavitation-induced saturation of the negative-pressure phase of lithotripter shock pulses. Yuri A. Pishchalnikov, James A. McAteer (Dept. of Anatomy and Cell Biol., Indiana Univ., School of Medicine, 635 Barnhill Dr., Indianapolis, IN, 46202-5120, yura@anatomy.iupui.edu), Michael R. Bailey (Univ. of Washington, Seattle, WA 98105-6698), Oleg A. Sapozhnikov (Moscow State Univ., Moscow, Russia, 119899), Irina V. Pishchalnikova, and James C. Williams, Jr. (Indiana Univ., School of Medicine, Indianapolis, IN, 46202-5120)

The tensile stress imposed by the negative-pressure phase of lithotripter shock pulses can cause cavitation. Bubbles continue to grow after the passage of the acoustic pulse; thus, some of the pulse energy is transformed to the kinetic and potential energy of the liquid surrounding the cavitation bubbles and, therefore, no longer belongs to the acoustic field. One might predict that this energy loss should be more pronounced for strong pulses that produce more cavitation. To investigate this, acoustic pulses were measured at the geometric focus of a Dornier HM-3 electrohydraulic lithotripter (water 39°C, dissolved gas ~8% saturation) using a fiber-optic probe hydrophone FOPH-500. Measurements showed that, while the amplitude and duration of the leading positive-pressure phase increased dramatically as charging potential was increased from 12 to 24 kV, the trailing negative-pressure phase of the pulse remained unchanged. This stabilization of the negative-pressure phase could be due to cavitation restricting the amplitude of the negative pressure that can be transmitted through the liquid, such that further increase of the amplitude at the source would not increase the negative amplitude at the target but would only result in stronger cavitation along the acoustic path. [Work supported by NIH-DK43881.]

4pBB8. Mapping stone breakage to the acoustic field of the low-amplitude, broad-focal-zone lithotripter. Yuri A. Pishchalnikov, James A. McAteer, R. Jason VonDerHaar, Irina V. Pishchalnikova, and James C. Williams, Jr. (Dept. of Anatomy and Cell Biol., Indiana Univ., School of Medicine, 635 Barnhill Dr., Indianapolis, IN 46202, yura@anatomy.iupui.edu)

Recent reports describe the design, initial clinical experience, and mechanisms of stone breakage of a wide-focal-zone, low-pressure, self-focusing lithotripter [UMB **27**, 638 (2001); **28**, 769 (2002)]. We undertook mapping of the acoustic field of this device (Xixin lithotripter) using a fiber-optic hydrophone FOPH-500, and looked for correlation between features of the shock pulse, and breakage of gypsum stones at different locations within the field. The efficiency of stone breakage did not correlate with peak positive pressure, shock rise time, duration of the pulse, or positive area under the waveform, but did correlate with energy density and peak negative pressure. Breakage was significantly better at the target point of the imaging system and along the axis 20 mm proximal and distal to this point compared to the geometric focus, located ~4 cm distally. Measured dimensions of focal width (~15 mm) differed only slightly from the published value (18 mm), and stones up to 20 mm off-axis could be broken to completion although it took half as many pulses for breakage at 20 mm than at 15 mm. Thus, stone breakage was most efficient prefocally, and there appears to be considerable latitude for targeting with effective breakage both on-axis and lateral to the acoustic axis with this lithotripter. [Work supported by NIH-DK43881.]

3:40

4pBB9. Customization of acoustic output in lithotripsy using a piezoelectric transducer array. Parag V. Chitnis and Robin O. Cleveland (Dept of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215, pchitnis@bu.edu)

A piezoelectric array was employed to examine the role of waveform shaping on stone fragmentation in lithotripsy. The array consisted of 170 elements placed on the inner surface of a 15-cm-radius spherical cap. Each element was driven independently using 170 individual pulsers—each capable of generating 1.2 kV. The acoustic field was characterized using a fiber optic probe hydrophone with a bandwidth of 30 MHz and a spatial resolution of 100 μm. When all elements were driven simultaneously, the focal waveform was a shock wave with peak pressures $p+=65\pm3$ MPa and $p-=-16\pm2$ MPa and the focal region was cigar shaped: 13 mm long and 2 mm wide. The firing of group of elements was adjusted so that each groups focused to different locations in the geometric focal plane. This method allowed the width of the focal region to be broadened albeit with decrease in peak pressure: for a 3-mm-wide region $p+=32$ MPa and for a 4-mm focal region $p+=25$ MPa. Waveform shaping was used to enhance or suppress cavitation effects where cavitation activity was observed using a dual passive cavitation detector consisting of two 1-MHz focused transducers. Stone fragmentation was assessed by treating artificial stones with fixed number of shock waves. [Work supported by NIH.]

4pBB10. Experimental investigation of linear resonant bubble behavior between parallel plates. Theodore F. Argo, IV and Preston S. Wilson (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

Recent findings suggest that bubble clouds play an active role in the breakup of kidney stones in patients undergoing shock-wave lithotripsy treatment. Understanding the dynamic behavior of the bubble cloud and its component bubbles within confined spaces will increase the efficacy of the treatment, but to date, even idealized model systems are not well understood. The behavior of a single bubble near a rigid plane has been verified; the study of this configuration is one of a bubble and a single bubble image source. A model recently set forth [Cui *et al.*, J. Acoust. Soc. Am. **119** (in press)] gives a description of the dynamics of a bubble between rigid parallel planes by using an infinite string of bubble image sources. This represents a step toward understanding the dynamics of fully enclosed bubble clouds. Experimental measurements of the resonance frequency and quality factor of air bubbles suspended between two parallel stainless-steel plates are presented and compared to the new model. An acoustic spectral subtraction technique was used to isolate the bubble response from that of the experimental tank. The bubbles were independently sized using diffuse backlighting and video microscopy. [Work supported by ARL:UT.]

4:10

4pBB11. Measurement of pressure produced at a solid surface by an acoustically driven cavitation bubble cloud. Teiichiro Ikeda, Shin Yoshizawa, Yoichiro Matsumoto (Dept of Mech. Eng., The Univ. of Tokyo, 113-8656 Tokyo, Japan), Michael R. Bailey, Lawrence A. Crum (Univ. of Washington, Seatte WA, 98105), and John S. Allen (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

A cavitation bubble cloud typically acts as a strong acoustic scatterer; however, at certain frequencies and amplitudes waves transmitted by a cloud are amplified. A long-term goal is to break up kidney stones by using a two-frequency ultrasound forcing method with one frequency that generates the cloud followed by a lower second frequency that excites its violent collapse. The goal of this study is to determine the frequency and pressure amplitudes which produce the largest pressures as measured by a PVDF membrane on the stone surface. Reflection was also measured by a concave PVDF sensor placed 40 mm from the surface, and cloud sizes were determined by high-speed camera images. Transmission is quantified by the force. Reflection and transmission showed a reciprocal relation: peak in transmission corresponded to a minimum in reflection. The largest cloud observed created the largest reflection, whereas the smallest clouds created the largest transmitted signals. Forces generated by the small clouds were five times larger than the amplitude without a cloud. Thus, in using a two-frequency excitation combination, the pressures generated by the cloud cavitation might be optimized for lithotripsy applications. [Work supported in part by NIH DK43881 and NSBRI SMS00402.]

4:25

4pBB12. Numerical study on nonlinear behavior of a collapsing bubble cloud in an ultrasound field. Shin Yoshizawa, Teiichiro Ikeda, Shu Takagi, and Yoichiro Matsumoto (Dept. of Mech. Eng., The Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan)

Cloud cavitation is known well as one of the most destructive cavitations. High pressure generated by the violent collapse of a bubble cloud causes severe erosion, noise, and vibration in hydraulic machines. In the medical field, many researchers have investigated the behavior of the collapsing bubble cloud to effectively use the highly concentrated energy for HIFU (high-intensity focused ultrasound) applications. In this study, it is assumed that the acoustic cavitation forms a spherical bubble cloud which consists of many microbubbles, and ultrasound focusing in the spherically symmetric cloud is numerically investigated. The compressibility of the liquid, the evaporation and condensation of the liquid at the bubble wall, and heat transfer through the bubble wall are considered in the simulation. The pressure wave focuses to the center of the cloud and the pressure inside bubbles extremely increases when the frequency is near the first mode natural frequency of the cloud. Especially in the cases of relatively high-pressure amplitudes, a shock wave is formed in the cloud and it generates high pressure fluctuation near the center of the cloud even when the frequency is much lower than the first mode frequency.

4:40

4pBB13. Lagrangian description of the interaction of a bubble with a particle. Todd A. Hay and Mark F. Hamilton (Appl. Res. Labs., Univ. of Texas at Austin, Austin, TX 78713-8029, haymaker@mail.utexas.edu)

The Lagrangian formalism used previously to describe pulsations and translations of interacting bubbles [Ilinskii *et al.*, Proc. 17th ISNA, Penn State, edited by Atchley and Sparrow (AIP, New York, 2006)] has been extended to model interactions of bubbles and elastic particles. The bubbles and particles are assumed to be spherical. Of eventual interest is interaction of a cavitation bubble cluster with fragments of kidney stones produced during shock-wave lithotripsy. Here, we discuss only the interaction of a single gas bubble with a single rigid particle. Numerical simulations illustrate change in separation distance in the presence of an applied sound field. Using the averaging procedure employed by Harkin *et al.* [J. Fluid Mech. **445**, 377 (2001)] for two bubbles, we develop approximate equations for the translation under the conditions of weak excitation and weak interaction. Radiation force between the bubble and particle is fifth order in terms of the separation distance, as found previously by Coakley and Nyborg [in *Ultrasound: Its Applications in Medicine and Biology*, edited by F. Fry (Elsevier, Amsterdam, 1978), pp. 77–159]. Numerical and analytical results are compared with results obtained by others using different approaches. [T.A.H was supported by an NSF Graduate Research Fellowship.]

4pBB14. On the impact of vessel size on the threshold of bubble collapse. Elisabetta Sassaroli and Kullervo Hynynen (Dept. of Radiol., Brigham and Women's Hospital, 75 Francis St., Boston, MA 02115)

Most of the studies investigating the physical properties of ultrasound contrast agents have addressed situations in which the microbubbles are contained in vessels much larger than the bubble size. Since contrast agents are normally injected into blood vessels, the investigation of their behavior in a confined environment may reveal useful information for the optimization of diagnostic and therapeutic applications of ultrasound. A series of experiments involving an ultrasound contrast agent in different sized silica and polyester tubes ranging from 50 to 400 microns in internal radius is presented. It is shown that the threshold for bubble collapse, as recorded by broadband acoustic emission, is not only dependent on the applied pressure amplitude but also on the tube size with an increase for smaller vessels. These data are interpreted and rationalized on the basis of a simple physical model. These findings may have implications for the evaluation of the risk of inertial cavitation in blood vessels. [Work supported by NIH RO1-EB003268 and by the Brigham Radiology Research and Education grant.]

4pEA1. Broadband barrel-stave flextensional transducers. Dennis F. Jones (Defence R&D Canada - Atlantic, P.O. Box 1012, Dartmouth, NS, Canada B2Y 3Z7, dennis.jones@drdc-rddc.gc.ca)

The last time I discussed underwater transduction technologies with Joe Blue was at the 125th Meeting of the Acoustical Society of America in May 1993. As we enjoyed lunch on the patio of a downtown Ottawa bistro under a sunny spring sky, the discussion touched on broadband transducers for naval applications. His ideas were insightful, motivating me to redesign and improve my original 1989 broadband barrel-stave flextensional transducer the following year. Over the last decade 30 experimental units were built at DRDC Atlantic, most of them used in marine mammal and coastal surveillance applications [D.F. Jones, J. Acoust. Soc. Am. **117**, 2447 (2005); **118**, 2038–2039 (2005)]. This paper will present electroacoustic measurements made at both the DRDC Atlantic Acoustic Calibration Barge on Bedford Basin near Halifax, Nova Scotia and the NAVSEA Seneca Lake Sonar Test Facility near Dresden in upstate New York. The performance parameters of interest include resonance frequencies, mechanical quality factors, transmitting voltage response versus water depth, and directivity patterns. [Work supported in part by the Office of Naval Research.]

2:25

4pEA2. Piezocomposite array technology for commercial and military sonar applications. Barry J. Doust and Brian G. Pazol (Material Systems Inc., 543 Great Rd., Littleton, MA 01460, bdoust@matsysinc.com)

Piezocomposites are a widely known form of piezoceramic with proven advantages over conventional monolithic piezoelectric ceramics providing improved efficiency and bandwidth. Unique manufacturing processes such as injection molding, curved structures, and layered array assembly provide creative solutions to complex, state-of-the-art designs. In addition, recent advances in piezocomposite technology have addressed the optimization of materials and electroacoustic design to provide devices with improvements in bandwidth and transmit power capability. Several state-of-the-art designs will be presented showing capability of producing complex-shaped transducers and arrays for transmit only, receive only, and two-way (transmit/receive) applications. These commercial and military systems will be presented showing the unique operational capability achieved using curved array structures, unique aperture patterns, and precisely matched phased arrays. Application examples will be presented highlighting communication and navigation, imaging, and parametric systems.

4pEA3. Modal acoustic transducer array. John L. Butler and Alexander L. Butler (Image Acoustics, Inc., 97 Elm St., Cohasset, MA 02025)

An acoustic system composed of an array of transducers, which generates multiple acoustic radiation modes, is presented and shown to yield directional steered beam patterns when the modes are appropriately combined together. A single ring array which uses eight piston transducers with a common tail mass and a cylindrical array of five of these rings are used to illustrate the performance of such a modal acoustic array. A discussion of the operation of the transducer array with a common tail mass as well as the means for combining the modes is presented. Monopole, dipole, and quadrupole array modes are illustrated with finite-element models. These modes are then combined together to generate a true cardioid, a new very wide cardioid type, and a low sidelobe narrow caridioid-type beam pattern. Calculated and FEA results are compared with measurements. [Work supported by ONR.]

4pEA4. Characterization of an underwater electroacoustic transmit system and the use of real electrical equivalents circuits for approximating loaded projectors. Corey L. Bachand and David A. Brown (BTech Acoust., Acoust. Res. Lab., and ATMC & Dept. of Elect. Eng., Univ. of Massachusetts Dartmouth, 151 Martine St., Fall River, MA 02723)

Many underwater applications using acoustic communication rely upon an effective and efficient system of transmit hardware for adequate signal strength, bandwidth, and long-term sustainability. The focus of this work is to outline a procedure for investigating and optimizing the performance of transmit hardware intended for broadband underwater communication. The transmit hardware considered in this discussion consists of a power supply, power amplifier, matching (step-up) transformer, tuning inductor, and loaded piezoelectric projector. The use of an electrical equivalent circuit of a piezoelectric projector is adopted for performing complex power measurements throughout the transmit hardware for system characterization. Parameters for constructing an electrical projector circuit can be

obtained analytically or experimentally. The complex power measurements are automated with a digital function generator and digitizing oscilloscope under software control. This method allows developers to evaluate the performance of the transmit hardware under realistic operating conditions in an engineering laboratory with standard equipment. One particular transmit hardware configuration, the WHOI Micro-modem, will be used to demonstrate the testing method.

3:15

4pEA5. Electrokinetic acoustic transducer. Nicholas P. Chotiros (Appl. Res. Labs., Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

An electrokinetic (EK) transducer consists of a liquid-saturated porous solid with electrodes at each end. It converts a pressure difference into electrical potential by means of the naturally occurring electrical charge that exists at the interface between certain liquids and solids. In 1964, Collins and Ellis [''Electrokinetic, acoustic pressure transducer,'' J. Acoust. Soc. Am. **36**, 1858–1860 (1964)] published a paper describing a prototype EK acoustic pressure transducer, based on a very simple formula for the EK potential. In 1965, Rice and Whitehead [J. Phys. Chem. **69**(11), 4017–4024 (1965)] published a more elaborate theoretical model of EK flow in a narrow capillary. Although the EK transducer had been presented as a pressure transducer, it is essentially a pressure difference transducer. This paper explores its potential in the light of Rice and Whitehead and later publications. [Work supported by the Office of Naval Research, Ocean Acoustics.]

4pEA6. Investigation of magnetostrictive materials and transducers for the generation of ultrasonic waves. Matthew M. Kropf and B. R. Tittmann (The Penn State Univ., 212 EES Bldg., University Park, PA 16802, mmk230@psu.edu)

The magnetostrictive effect is commonly exploited to generate ultrasonic waves for many applications. A better understanding of the physical mechanism of magnetostriction in terms of material and transducer characteristics could expand its utilization to many new sensor applications. Maximizing the ustable frequency bandwidth for ultrasonic wave generation alone allows for various choices of modes that are individually suitable for different applications. Several different materials were analyzed and compared in terms of theoretically expected magnetostrictive efficiency. Frequency content of ultrasonic waves generated via magnetostriction was examined with reference to the geometry and configuration of a magnetic coil transducer. Static measurements were made and extended in an attempt to quantify magnetostriction in the dynamic sense. A survey of current applications and direction for future research is included.

4:00

4pEA7. An innovative piezoelectric force sensor to determine the integrity of electrical sockets. Elizabeth Blickley and Bernhard Tittmann (The Penn State Univ., 212 EES Bldg., University Park, PA 16802, eab223@psu.edu)

An ultrasonic force sensor was designed to calculate the socket contact force in a cable connector assembly. The force sensor operates through measuring the relationship between the mechanical force and change in resonance frequency in a piezoelectric tube. The sensor's aim is to assess the effectiveness of aging electric sockets to ensure their replacement before failure. A network analyzer was used to perform tests on the repeatability and sensitivity of the resonance change in two sets of piezoelectric tubes of different thickness. The hoop mode proved to be the most consistent as well as most sensitive resonance mode. The results show an increase in the change in resonance frequency corresponding to an increase in applied socket contact force. Socket contact forces are measured through a friction-based method. To refine the testing technique, the 3-D modeling software SolidWorks was used to design a prototype socket testing device to hold the tubes for insertion into the socket. The piezoelectric tubes were adapted to perform in the tube holder and the prototype socket testing device was created out of aluminum.

4:15

4pEA8. Wave propagation in liquid-filled tubes: Measurements and model predictions. Aaron M. Kyle, George R. Wodicka (Weldon School of Biomed. Eng., Purdue Univ., 500 Central Dr., West Lafayette, IN 47907-2022), Sandra L. Ordóñez, Eduardo J. Juan (Univ. of Puerto Rico-Mayaguez, Mayaguez, PR 00681-9042), and J. Stuart Bolton (Purdue Univ., West Lafayette, IN 47907-2088)

Wave propagation in liquid-filled pipes was investigated using time- and frequency-domain techniques. Water- and ethanol-filled copper and PVC pipes having inner diameters of 1.44 and 1.19 cm, and wall thicknesses of 0.0686 and 0.208 cm, respectively, were driven with tone bursts from a submerged hydrophone, and the resultant acoustic pressures in the liquid were measured. Group velocities in the copper pipe were observed to decrease with increasing frequency: velocities were 1124 m/s at 10 kHz and 1039 m/s at 50 kHz in water and 1052 m/s at 10 kHz and 902 m/s at 40 kHz in ethanol. Propagation in the PVC pipe was significantly slower, e.g., the estimated water group velocity at 10 kHz was 593 m/s. The estimated group velocities were then compared to those predicted by an acoustic transmission line model of the pipes. The predicted group velocities were within 13% of the estimated values for the copper tube for both liquids. The pipe systems were also excited with Gaussian noise, and exhibited bands of low spectral energy that could be attributed to the transverse resonances of the tube walls. The model predicted the upper frequency limit of these bands to within 5% of measured values.

4:30

4pEA9. Sonic demultiplexing by inverse designed scattering acoustical elements: An experimental demonstration. José Sánchez-Dehesa, Andreas Håkansson, and Francisco Cervera (Wave Phenomena Group, Nanophotonics Technol. Ctr., Polytechnic Univ., E-46022 Valencia, Spain)

Experiments demonstrating sonic demultiplex devices able to spatially separate several wavelengths will be reported. The devices are based on clusters of cylindrical scatterers of circular section whose positions and sizes are determined by an inverse design approach. Two devices are reported, a first device that spatially separates two wavelengths, 20.0 and 22.7 cm, and a second that separates three wavelengths: 20.0, 21.3, and 22.7 cm. Both prototypes are typical examples of acoustic scattering elements, a name here introduced to define inverse designed devices characterized by their great adaptability in controlling the scattering image, including both the reflected and transmitted wave. [Work supported by MEC of Spain.]

4:45

4pEA10. Band-gap creation using quasiordered structures based on sonic crystals. Vicent Romero Garcia, Elies Fuster Garcia, Juan V. Sanchez-Perez (ACARMA and Dep. de Fisica Aplicada, ETSICCP, UPV, Cno. de Vera s/n, 46022 Valencia, Spain, jusanc@fis.upv.es), Luis M. Garcia-Raffi, and Enrique A. Sanchez-Perez (ETSICCP, UPV, 46020 Valencia, Spain)

It is well known that sonic crystals are periodic structures that present acoustic band-gap attenuation centered at frequencies related with the lattice constant of the structure. In this work we present a new approach based on genetic algorithms to create band gaps in a predetermined range of frequencies. The mechanism used by genetic algorithms to achieve this

objective is the creation of vacancies in a starting sonic crystal, built with air-embedded rigid scatterers. As a result of the optimization process we obtain quasiordered structures whose acoustic properties are based in the multiple scattering theory. [This work has been supported by Universidad Politcnica de Valencia (Interdisciplinary Projects (P.I.I.Ref. 4114 2003), Comision Interministerial de Ciencia y Tecnologia of Spain (Contract N. MAT 2003-04993-03), and by Generalitat Valenciana (Spain) under Grant GV04B-371.]

4pNS1. Cooling tower noise control. Thomas S. Paige (Kinetics Noise Control, Inc.—Vibron Products Group, 1720 Meyerside Dr., Mississauga, ON, L5T 1A3 Canada, tpaige@kineticsnoise.com)

Cooling towers are typically provided with multiple large-diameter propeller fans mounted on top of the unit and discharging upward. These fans generate a significant level of low-frequency noise. The induced-draft intakes for these fans are typically located on the sides of the unit, so fan noise is also radiated horizontally from these openings. Traditional methods for noise control include sound-barrier walls, silencers, or complete noise enclosures. Barrier walls usually have no adverse effect on the performance of the cooling towers. However, silencers and close-fitting noise enclosures must be carefully designed to minimize resistance to the airflow that is required to maintain proper operation of the cooling tower. This paper discusses the current techniques used to reduce outdoor noise propagation from cooling towers. Some case studies are presented to illustrate successful implementation of these noise-control methods.

4pNS2. Global active control of broadband noise from small axial cooling fans, Part 2. Matthew Green and Scott Sommerfeldt (Dept. Phys. and Astron., Brigham Young Univ., N283 ESC, Provo, UT 84602)

The multi-channel filtered-x LMS algorithm has previously been used for feed-forward control of the tonal noise of a small axial cooling fan [Gee and Sommerfeldt, ''Application of theoretical modeling to multi-channel active control of cooling fan noise,'' J. Acoust. Soc. Am. **115**, 228–236 (2004)]. With much of the tonal noise content removed it becomes desirable to reduce the broadband fan noise. A previous study demonstrated the feasibility of achieving desirable broadband attenuation by means of active feedback control. Measurements will be presented and discussed that have an impact on the control achievable. Experimental control results will be presented.

4pNS3. Numerical prediction of aerodynamic noise radiated from a cross-flow fan. Song Li, Anbang Chen, and Dongtao Huang (Dept. Eng. Mech., Tsinghua Univ., Beijing 100084, PROC, lisong@tsinghua.edu.cn)

The surface pressure fluctuations of blades, vortex wall, and the rear wall of a cross-flow fan are commonly considered as the aerodynamic noise sources of an air conditioning unit. In order to predict the noise, these pressure fluctuations were at first obtained by solving the 2D unsteady Reynolds-averaged Navier-Stokes (RANS) equations using a computational fluid dynamics software. It was validated by the fan performance experiments that the prediction of static pressure in the channel agreed well with the test data. It means the results of the pressure fluctuations obtained from the numerical simulation are correct. Then, the Ffowcs Williams-Hawkings (FW-H) equation was used to predict the far-field noise caused by these sources. The errors of the prediction of the sound-pressure levels of the blade passing frequency (BPF) and total noise are within 4 and 3 dB, respectively, comparing with the corresponding measured data. It is shown from the numerical prediction that only the surface pressure fluctuations of the rear wall and the vortex wall are main sources, and that the method of numerical prediction of aerodynamic noise radiated from a cross-flow fan is successful.

4pNS4. An analytical study of the effectiveness in noise control due to combination of mufflers in design of duct systems. B. S. Sridhara (Dept. of Eng. Technol. and Industrial Studies, Middle State Tennessee State Univ., Murfreesboro, TN 37132) and M. G. Prasad (Stevens Inst. of Technol., Hoboken, NJ 07030, mprasad@stevens.edu)

Mufflers are effective noise control devices used in acoustical design of duct systems. The performance evaluation of a single muffler in terms of four-pole matrix approach is well known. The performance evaluated in terms of four-pole parameters and insertion loss describes the system using various components namely source, muffler, and termination. The performance of a reactive muffler is known to be frequency dependent based on its internal geometrical details. This paper presents analytical studies on the effectiveness of combining mufflers on the noise control. The studies deal with both series and parallel arrangement of the reactive mufflers.

The effects of various parameters such as number of mufflers, the length of ducts associated with the system, and the muffler geometry are presented. For a given source model, simple expansion chamber-type mufflers are studied in detail in order to understand the nature of interaction in different types of arrangements. Applications of this study would be to increase the noise reduction by combining mufflers in systems such as automotive, HVAC, etc.

4pNS5. Subjective and objective evaluation of air-conditioning noise. Jin Yong Jeon, Jin You, and Su Yeon Kim (School of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea)

Noise from an air-conditioning system installed in the ceiling of classrooms was evaluated to investigate the subjective responses to air-conditioning noise. Harmonics of air-conditioning noise was removed and the sound-pressure levels of the frequency bands from 250 to 630 Hz were varied to control sound quality. Evaluation for air-conditioning noise sensation was conducted using a paired comparison method and the results showed that noise without harmonics was preferred to noise with harmonics. The noises which have larger level increases to the noise at 250 to 630 Hz were evaluated better in both of the noises with and without harmonics. Results of multiple regression analysis on psychoacoustic parameters and subjective preferences showed sharpness as a major factor in describing the sound quality of air-conditioning noise. A semantic differential test was also conducted to evaluate the sound-quality characteristics of air-conditioning noise.

4pNS6. Acoustic performance of sound-attenuating ducts utilizing spatially periodic area changes with absorbing material. Donald Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708) and Pavel Danilov (Continuum-Dynam., Inc., Ewing, NJ 08618)

Sound propagation of one-dimensional waves through a duct with spatially periodic area changes has been studied theoretically and experimentally. The resulting wave behavior is similar to that observed for periodic structures, with Bloch waves, passbands, and stopbands. This configuration substantially reduces sound transmission from noise sources having harmonics that fall in the stop bands, while having little effect in passbands. The present study adapts this concept to configurations with dissipative sound-absorbing material. The periodically spaced regions of the duct with larger cross-sectional area are partially filled with porous material, so that the open cross-sectional area remains constant throughout the duct. The duct is analyzed as a quasi-one-dimensional system using an approach based on periodic structure theory. The porous material makes the propagation wave number in the porous/open subsections complex, thereby changing the nature of the stop- and passbands, and providing significant attenuation even in passbands. Results demonstrate that the best attenuation strategy may be to distribute the porous material in periodically spaced subregions rather than in either a single larger volume, or in a uniform distribution all along the duct, particularly if cancellation of discrete harmonics is desirable.

3:40

4pNS7. Acoustic impedance of perforations in contact with absorbing material. Iljae Lee, Ahmet Selamet (The Ohio State Univ., 930 Kinnear Rd., Columbus, OH 43212, selamet.1@osu.edu), and Norman Huff (Owens Corning, Novi, MI 48377)

Acoustic impedance of perforations in contact with fibrous material is experimentally determined for various hole geometries and filling densities in the absence of mean flow. Two setups are developed to measure the perforation impedance and the acoustic properties of the absorbent, while yielding empirical expressions for both. The experimental results show that both real and imaginary components of the perforation impedance substantially increase as a result of the contact with the fibrous material, whereas they generally decrease with increasing porosity for a given filling density. The empirical expressions developed in this study are implemented in a boundary element method to predict the transmission loss of dissipative silencers, which is then compared with the experimental results.

3:55

4pNS8. Numerical prediction of vortex shedding noise radiated by a centrifugal impeller. Weixiong Wang and Dongtao Huang (Dept. of Eng. Mech., Tsinghua Univ., Beijing PROC, 100084)

Numerical prediction of fan noise is very difficult work because of the restriction of the computer technology. The fluctuating blade force caused by the vortex shedding from a centrifugal impeller is a main noise source but no paper has been published so far to predict this kind of noise. Vortex flow models to predict low-pressure axial flow fans were developed by several researchers since 1964. In this paper a study of numerical prediction of vortex shedding noise radiated by a commercial centrifugal impeller is reported, which is based on a vortex flow model developed by Lee in 1993. Three main research works are carried out by the authors. First, using FLUENT software a numerical simulation of 3D turbulent flow field of the impeller in order to predict the aerodynamic performance is completed and well validated by the experiment. Then, the velocity profile near the wall at the trailing edge of the blade is analyzed in detail to determine the boundary layer thickness both on the pressure and suction sides. Finally, the total SPL of the noise is predicted and the results agree with the experimental data within 3 dB near the design operation.

4pPA1. An ultrasonic analog for a laser. Richard Weaver, Oleg Lobkis (Dept. of Theoret. and Appl. Mech., Univ. of Illinois, 216 Talbot Lab., 104 So. Wright, Urbana, IL 61801), and Alexey Yamilov (Univ. of Missouri at Rolla, Rolla, MI 65409)

We report measurements on two simple ultrasonic systems analogous to random lasers. One system entails unstable ultrasonic feedback between distinct piezoelectric transducers on an irregularly shaped high-Q solid; another involves a spontaneously emitting piezoelectric device that can also emit by stimulation. Both are found to exhibit some of the behaviors of lasers. Over a wide range of parameters we observe narrow single-emission lines (natural width is estimated at about 0.000 000 000 1 Hz), sensitivity to linear cavity properties, complex multimode emissions, and line narrowing.

2:00

4pPA2. Time-reversal acoustic focusing system based on the liquid-filled acoustic resonator. Alexander Sutin (Artann Labs., 1459 Lower Ferry Rd., West Trenton, NJ 08618, asutin@artannlabs.com), Yegor Sinelnikov (ProRhythm, Ronkonkoma, NY 11779), and Armen Sarvazyan (Artann Labs., West Trenton, NJ 08618)

Numerous time-reversal acoustic focusing systems (TRA FS) based on the use of solid acoustic resonators (acoustic cavities) capable of accumulating acoustic energy in time are described in the literature. We experimentally demonstrated that the liquid-filled resonators can be superior to solid resonators in efficient focusing, especially in applications related to focusing of ultrasound in waterlike media, such as biological tissues. To understand the mechanisms of the observed effects and optimally design the water-filled resonators for biomedical applications, we developed a theoretical model and explored the factors defining the efficiency of TRA FS. The model allows evaluation of the spatial and temporal characteristics of TRA focused field formed as a result of numerous reflections of ultrasound within the resonator. The focused field structure and its dependence on the shape and size of the resonator, ultrasound frequency, and attenuation, and the coefficient of ultrasound reflection from the resonator walls were investigated. Principles of optimization of the resonator shape and size are developed. It is shown that for the resonator filled with an attenuating liquid TRA focusing in binary mode of radiation provides narrower focal spot than conventional analog signals. The experiments confirmed the predictions of developed theory.

2:15

4pPA3. Synchronized-piezoelectric auto-oscillators, a classical analog laser. Richard Weaver and Oleg Lobkis (Dept. of Theoret. and Appl. Mech., Univ. of Illinois, 216 Talbot Lab., 104 So. Wright, Urbana, IL 61801)

We report the behavior of two ultrasonic transducers, each part of an auto-oscillating Wein bridge, in contact with a high-Q elastic body. In particular, we compare the behavior of the one- and two-transducer cases. Each transducer oscillates erratically, and at its own frequency, when isolated and not in contact with the elastic body. When placed in contact with an elastic body, each transducer then stabilizes at a frequency close to the range of the original erratic oscillation, where it excites a "mode" (not necessarily a normal mode of the body) of the system. When both are in contact with the elastic body, a new mode is excited, and both transducers oscillate at the same frequency. They are locked to themselves and to each other by virtue of their mutual access to the same acoustic system, and the power output of the pair is, presumably, approximately 4 times as great as that of either transducer by itself.

4pPA4. Band gap engineering for two-dimensional periodic systems of fluids. Manvir S. Kushwaha (Inst. of Phys., Univ. of Puebla, P.O. Box J-45, Puebla 72570, Mexico) and Bahram Djafari-Rouhani (Univ. of Sci. and Technol. of Lille I, Lille, France)

Periodic binary systems can give rise to genuine acoustic stop bands within which sound and vibrations remain forbidden. Extensive band structures have been computed for two-dimensional (2D) periodic arrays of air cylinders in water background. Complete, multiple, huge stop bands are found for both square and triangular lattice arrangements. The lowest stop bands are largest for a range of filling fraction $10\% \leqslant f \leqslant 55\%$, with a gap/midgap ratio of 1.8. The most interesting finding of the present investigation is that the low-frequency, flat passbands for a perfectly periodic system correspond to the discrete modes of a *single* airy cylinder. This is attributed to the low-filling fraction and huge density contrast in air and water. It is stressed that such a simple inhomogeneous system as made up of air and water exhibits the largest stop bands ever repoprted for 2D and/or 3D phononic as well as photonic crystals.

2:45

4pPA5. Transmission effects of flexural shell vibration modes in sonic band-gap crystals made of hollow cylinders in air: A theoretical analysis. Yuriy A. Kosevich, José Sánchez-Dehesa (Wave Phenomena Group, Nanophotonics Technol. Ctr., Polytechnic Univ., E-46022 Valencia, Spain), and Cecile Goffaux (CENAERO, B-6041 Gosselies, Belgium)

The transmission properties of periodic arrays of hollow cylinders in air are studied analytically and numerically using a finite-difference–time-domain method. Particularly, transmission spectra across slabs of a few layers of cylinders arranged in a square lattice will be reported. It is shown that $n=2$ and $n=3$ flexural shell vibration modes [A. Leissa, *Vibrations of Shells* (Acoustical Society of America, New York, 1993)] associated with the hollow cylinders play a fundamental role in the band-gap transmission properties of this two-dimensional sonic composite medium. The parameters of the hollow cylinders (thickness and elastic parameters of the material) are chosen in order to have the frequencies of the $n=2$ and $n=3$ flexural shell vibration modes inside, correspondingly, the first and third band gaps of the sonic crystal. In comparison with corresponding sonic crystal made of full cylinders, the transmission properties of this new composite medium present two main physical features: (i) huge transmission resonances with asymmetric Fano-type shape appear in the band gaps; and (ii) widening of the band gap widths occurs and increases with filling fraction of cylinders in the sonic crystal. Analytical expressions for the resonance frequencies and physical picture of both phenomena will be presented. [Work supported by MEC of Spain.]

3:00

4pPA6. Band gap engineering for three-dimensional periodic systems of air bubbles in water. Manvir S. Kushwaha (Inst. of Phys., Univ. of Puebla, P.O. Box J-45, Puebla 72570, Mexico), Bahram Djafari-Rouhani, and Leonard Dobrzynski (Univ. of Sci. and Technol. of Lille I, Lille, France)

Systematic and extensive evidence for the existence of multiple, complete, huge stop bands in the band structure for three-dimensional (3D) cubic arrays of air bubbles in water is reported. A Fourier series expansion method, which does not require matching of the messy boundary conditions, is used to investigate all three important 3D geometries such as face-centered cubic (fcc), body-centered cubic (bcc), and simple-cubic (sc) arrangements. The lowest stop bands are largest for a volume fraction $f \leqslant 10\%$, with a gap/midgap ratio of ≈ 1.8 for all three geometries. Surprising but rigorously justifiable is the fact that the low-frequency flat passbands for the perfectly periodic systems correspond to the discrete modes of a *single* bubble. This is an artifact of the low-filling fraction and huge density contrast in air and water. It is emphasized that such a simple inhomogeneous system made up of air bubbles in water can exhibit the widest stop bands ever reported for elastic and/or dielectric periodic composites.

4pPA7. History effects on the motion of particles subject to acoustic fields. John S. Allen, III, Carlos F. M. Coimbra, and Marcelo H. Kobayashi (Dept. of Mech. Eng., Univ. of Hawaii—Manoa, 2540 Dole St., Honolulu, HI 96822)

Acoustic fields have been used to trap, manipulate, and separate particles suspended in fluids. The separation of solid and gas particles is possible since the acoustic radiation force depends on the particle's size, density, and compressibility. Moreover, numerous devices using acoustic standing waves have been developed for this purpose. The ability to model and accurately predict the particles' trajectories and distributions resulting from these applied acoustic fields is of great importance for a wide range of biomedical and industrial applications. However, limited previous theoretical efforts have been made to account for the unsteady viscous effects on a particle's motion in an acoustic field. We examine these unsteady history effects on a particle in the vicinity of a nodal point in an acoustic standing wave field. The relative importance of the history (Basset) force, which has a fractional derivative dependence of the order 3/2, is demonstrated for acoustic separation device conditions. The inclusion of the history force has the net effect of changing the eigenfunctions of the problem from exponential to Mittag-Leffler functions in time, thus influencing the overall acoustic force balance.

3:45

4pPA8. Possibilities of thin-film bulk acoustic resonators as punctual mass sensors. Humberto Campanella, Jaume Esteve, Josep Montserrat (Centro Nacional de Microelectrnica, Campus UAB, 08193 Bellaterra Barcelona, Spain, humberto.campanella@cnm.es), Arantxa Uranga, Gabriel Abadal, Nuria Barniol (Universitat Autnoma de Barcelona, Barcelona, Spain), and Albert Romano (Universitat de Barcelona, Barcelona, Spain)

In this work, thin-film bulk acoustic resonators (FBARs) are implemented as punctual mass sensors, with the purpose of future integration in biomolecular sensing systems, where selective spatial detection is required. The piezoelectric thin film is a (002)AlN membrane, sputtered over Ti/Pt on a (001)Si wafer, and released by surface micromachining of silicon. The effective lateral area of resonator is $50\times 50\mu$m, and the thicknesses of AlN and Ti/Pt layers are 1000 and 180 nm, respectively. A punctual mass of a C/Pt/Ga composite with a contact surface much smaller compared to that of the resonator's electrode is deposited on the top electrode of the resonators, by means of a focused ion beam. Selected areas of the electrode, especially near the center of the resonator, were chosen to growth the composite with lateral dimensions in the units of micrometers, and thickness on the order of several nanometers. Based on the mass-loading principle, the sensor changed its resonance frequency in a proportional manner to the added mass, achieving an average sensitivity of 2.4^{-22} g/Hz and a mass resolution an the order of femtograms. Regarding these results, FBAR is proposed as a candidate to measure localized particles and, in general, to be applied as biological mass sensor.

4:00

4pPA9. Unconventional thermoacoustic heat engines. Matthew G. Hilt, K. A. Pestka, II, G. D. Mahan, J. D. Maynard (The Penn State Univ., University Park, PA 16802), D. Pickrell, B. Na, and J. Tamburini (Omega Piezo, State College, PA 16801)

During 1988 to 1994, John Strachen and Harold Aspden demonstrated an all-solid-state thermoelastic cooler which was 0.5 cm thick and a few centimeters in length. With 7.2 V dc applied across the device, it drew 6.3 W of electrical power and produced 13.7 W of cooling power with a 20 °C temperature drop. The coefficient of performance was 2.2, or 21% of the maximum possible (Carnot) efficiency. The device operated reversibily; 3.7 W of heat throughput generated 0.15 W of electrical power, for an efficiency of 47% of Carnot. The device operated at a frequency of about 500 KHz. To date, no one has found an explanation for the effect. Recently we have begun a program to develop a theory and to reproduce a working device. This research, as well as some research with other unconventional thermoacoustic devices, will be presented. [Research supported by DARPA and the Aviation and Missle Command.]

4:15

4pPA10. An open-air infrasonic thermoacoustic engine. William Slaton (Dept. of Phys. & Astron., The Univ. of Central Arkansas, Conway, AR 72035)

Wind noise at infrasound monitoring stations is a significant problem especially at the low frequencies of interest. Noise-reducing filters, typically consisting of radial arrays of porous hose, effectively area average the infrasonic pressure wave over a large space. The resulting area-averaged sound wave is then measured by a microbarometer. However, the only method to calibrate both the microbarometer and wind-noise filter is to use atmospheric or land-based man-made explosion. Thus, an infrasound source is needed that can calibrate both the microbarometer and the wind-noise filters in a safe way. A lowfrequency open-air thermoacoustic prime mover in a Helmholtz resonator has been constructed to fulfill this purpose. The system resonates at 10 Hz, is portable, compact, and safe to operate. The engine's experimental and theoretical performance will be presented. [Work supported by a subcontract with the National Center for Physical Acoustics and a grant from the University Research Council at the University of Central Arkansas.]

4:30

4pPA11. Optimizing miniature thermoacoustic coolers. H. El-Gendy, Y. Kwon, L. Lyard, and O. G. Symko (Dept. of Phys., Univ. of Utah, 115 South 1400 East #201, Salt Lake City, UT 84121)

Because of limited sound intensity output from commercial drivers at midaudio and ultrasonic frequency ranges used in thermoacoustic coolers, it is important to optimize their performance. To achieve this, studies were conducted on heat transfer at the cold heat exchanger and at the hot heat exchanger. Measurements were taken on stray heat influx to the cooler by mechanisms of convection, conduction, radiation, and streaming, and from the driver. PIV studies show the contributions of streaming, both from the driver and other parts of the devices. A special 4-layer copper mesh heat exchanger was designed and tested to cope with heat pumped acoustically from the cold heat reservoir as well as the streaming from the piezoelectric driver. For typical sound levels of 155–160 dB achieved inside the resonator by commercial bimorph piezoelectric drivers, a cooling power density of 0.5 watts/cm^2 was achieved with air at 1 atm. Pressurizing the working gas to 17 atm raises the cooling density. The choice of working gas provides a increase in power density. With the above optimizing approaches, a cooling power density of over 50 watts/cm^2 appears feasible for the frequency range of 4 to 24 kHz. [Work supported by a grant from the ONR and the State of Utah.]

4:45

4pPA12. Hot wire anemometry for the measurement of temperature and velocity fluctuations inside a thermoacoustic cooler. Arganthaël Berson, Philippe Blanc-Benon (Ctr. Acoustique, LMFA, UMR CNRS 5509, Ecole Centrale de Lyon, 36 avenue Guy de Collongues, 69134 Ecully Cedex, France), Luc Mongeau, and Insu Paek (Purdue Univ., West Lafayette, IN 47907-2031)

Hot wire anemometry was used to measure velocity and temperature fluctuations inside a thermoacoustic refrigerator. In an oscillating flow with zero-mean velocity, such as in an acoustic standing wave, heat transfer is different from heat transfer in a steady flow. A dynamic calibration of the system is required. This calibration was done inside the resonator of the cooler, with no stack and no heat exchangers. Two thermoacoustic systems were studied to calibrate the anemometer in air at atmospheric pressure and in He/Ar mixtures at a mean pressure of 6 bars. Measurements of temperature and velocity were done at the end of the stack and heat exchangers. Correlations between temperature and velocity fluctuations were obtained, and the enthalpy convective flux was computed. These results were compared with results obtained from numerical simulations recently done at Ecole Centrale de Lyon [D. Marx, AIAA J. **42**(7) (2004)].

Psychological and Physiological Acoustics: Characterizing Auditory Attention

Frederick J. Gallun, Chair
Boston Univ., Speech, Language and Hearing Science, 635 Commonwealth Ave., Boston, MA 02215

Invited Papers

1:00

4pPP1. Auditory attention: One term for several concepts? Frederick J. Gallun (Dept. of Speech, Lang. and Hearing Sci. and Hearing Res. Ctr., Boston Univ., 635 Commonwealth Ave., Boston, MA 02215)

The recent rise in the use of spectrally and temporally complex stimuli appears to be responsible for the increasingly frequent use of the term attention as an explanation of results in auditory experiments. It seems timely, therefore, to provide a broad examination of the various meanings often associated with this term. The goal of this session is to explore the ways in which the concept of auditory attention has been applied and perhaps suggest ways in which its application could be refined. An essential first question then is whether auditory attention refers to one concept or many. This talk will begin by examining the historical uses of this term and then proceed to outline some of the contemporary uses of the term, relating them back to the theoretical concepts the term is meant to represent. A specific example will be provided by reviewing a recent series of experiments in which the experimental designs were intended to manipulate listener attention and which were interpreted as providing insight into the mechanisms available for performing a variety of auditory tasks. [Work supported by NIH/NIDCD.]

1:25

4pPP2. Cuing in auditory detection. E. R. Hafter (Dept. of Psych., Univ. of California, Berkeley, CA 94720)

A traditional theory of auditory attention describes it metaphorically as the beam of an attentional searchlight. It underlies, for example, the logic of the auditory critical ratio, where subjects detect a tonal signal in a wideband masker, where the extent to which processing is restricted to a specific frequency-region is inferred through calculation of the critical ratio between signal level at threshold and the spectrum level of the masker. Values so found correlate well with results from other techniques such as restriction of the masker by notched noise and presentation of unexpected probe signals that are presumably attenuated by the skirts of the listening band. Lower performance in response to subjective uncertainty about the signal's frequency has been modeled by assumptions of a wider attentional searchlight, i.e., listening band, an idea supported by alleviation of uncertainty effects by cues that inform the subject about where to listen. The plan here is to review experiments in which various kinds of cues have been used to focus attentional searchlights, including a discussion of the potential for use of this method for examining filters at higher levels of auditory analysis where the effective signal is an emergent property of the basic stimulus.

1:50

4pPP3. Attending to auditory events "takes" time . . . event time. Mari R. Jones (Dept. of Psych., The Ohio State Univ., Columbus, OH 43210)

Commonplace acoustic stimuli in our environment unfold in time over many time scales, ranging from milliseconds to seconds to minutes. At each time level, there is some ability to perceive and/or ignore stimulation. What does this mean for the role of attention? I suggest that auditory attention takes time, but not necessarily processing time. Instead, moment-to-moment attending literally takes hold of (i.e., locks into) event time spans by entraining to event time at one or more levels. Efficient attending involves an internal

activity (a pulse of attentional energy?) that is capable of coordinating in time with an unfolding sound pattern such that attending energy coincides with to-be-attended elements. My main hypothesis is that, to attend efficiently at any time scale, synchronicity of attending with constituent sound elements is a necessary, but possibly not a sufficient, condition. I unpack this idea using illustrative dynamical models that assume an entrainment approach to attending. Several experiments use auditory sequences in which the time structure of constituent tones is systematically varied. In some tasks, listeners judge standard and comparison time intervals in different rhythmic contexts; in others, they identify the pitch of probe tones in sequences where both pitch and time structure vary.

2:15

4pPP4. Multiple mechanisms of auditory attention. Elyse S. Sussman (Dept. of Neurosci., Albert Einstein College of Medicine, 1410 Pelham Pkwy. S., Bronx, NY 10461, esussman@aecom.yu.edu)

Selective attention limits processing so we can handle the vast amount of information that we encounter daily. Actively selecting a subset of sensory information has been shown to bias response properties of neurons within sensory cortices, generally seen as an enhancement of the neural activity associated with the attended stimuli. This talk will present another type of attention effect on neural activity, affecting the representation of sequential sounds in memory. Event-related brain potentials were used to identify the timing of various cognitive processes, the subjects' perception of the sounds, and to assess the stages at which attention interacted with sensory input in perception. In one study, attention modified the grouping and storage of sequential sounds, reflected by the absence or presence of specific ERP components. In another study neural representations were biased by stimulus-driven factors without attentional control. In a third study, attention increased accuracy for discriminating stimulus information but did not change the way the information was organized in auditory memory. These results indicate that there is more than one mechanism of auditory attention operating at different processing stages depending on the listeners task, and supports the view that attention interacts with stimulus-driven processes to facilitate behavioral goals. [Research supported by NIH.]

2:40–2:55 Break

2:55

4pPP5. Spatial auditory attention. Barbara G. Shinn-Cunningham (Hearing Res. Ctr., Boston Univ., 677 Beacon St., Boston, MA 02215)

Historically, most psychoacoustic studies measured performance on tasks limited by bottom-up, sensory factors. However, in the everyday world, sensory sensitivity does not always determine performance. The problem in many everyday settings is not that components of an important sound source cannot be heard, but rather that they are not noticed amidst the clutter caused by competing sound sources. In particular, recent evidence suggests that competition for central resources is often the primary limitation on performance in tasks in complex, uncertain environments. This talk will review results of recent studies demonstrating that spatial cues are one important feature that can enable a listener to focus attention on a sound source of interest and mediate competition for central resources. Psychophysical results will be interpreted in light of physiological measures from visual and auditory tasks illustrating the importance of top-down factors on neural activity. Parallels and differences in the role of spatial attention for visual and auditory tasks will be discussed. Speculations about these similarities and differences will be offered, driven by the hypothesis that similarities derive from common control circuitry, while differences arise from differences in peripheral neural coding. [Work supported by AFOSR, ONR, and NIDCD.]

Contributed Papers

3:20

4pPP6. Selective attention with ambiguous dichotic-pitch images. Frans A. Bilsen (Delft Univ. of Technol. Delft, The Netherlands)

Experiments in the past have shown that several types of dichotic pitch arise from dichotic white noise stimuli having a particular interaural phase relation [e.g., F.A. Bilsen and J. Raatgever, compact disc "Demonstrations of Dichotic Pitch," Delft University of Technology (2002)]. Often such stimuli generate two or more ambiguous images inside the head at different places along the lateralization axis, each image having the same or a significantly different pitch value. Which pitch at which place is heard is a matter of selective attention. Typically, only one image can be heard at a time (ambiguity of place coupled with pitch). New experiments on dichotic repetition pitch will be reported that show the existence of a continuum of different pitches for one parameter setting of the stimulus. Which pitch is perceived depends on the lateralized position of the focus point of attention by the listener. Implications for the organization of the binaural auditory scene and the process of selective attention will be reviewed.

3:35

4pPP7. Frequency-band importance functions for auditory and auditory-visual speech by hearing-impaired adults. Ken W. Grant (Walter Reed Army Medical Ctr., Army Audiol. and Speech Ctr., Washington, DC 20307-5001)

How we listen to speech appears to be fundamentally different in a number of respects when we can simultaneously see the face of the speaker while listening to his or her speech. Not only is our ability to recognize and understand speech far better when we can see as well as hear, as compared to hearing alone, but the way we hear is also different. This is evident in the patterns of activity in primary auditory cortex, which are different for auditory versus auditory-visual speech inputs, as well as data from normal-hearing subjects suggesting that auditory attention is focused on different spectral regions depending on whether visual speech cues are available. The present study examines whether frequency band-importance functions are different for auditory and auditory-visual speech recognition in a group of hearing-impaired listeners. Results show that hearing-impaired listeners perform much like normal-hearing subjects in attending to primarily low-frequency speech cues under auditory-visual conditions. In contrast, under auditory-alone conditions, hearing-impaired

listeners place more importance on mid-to-high-frequency acoustic information, presumably to better recognize place of articulation cues.

4pPP8. Spatial uncertainty reduces the benefit of spatial separation in selective and divided listening. Antje Ihlefeld, Shawn J. Sarwar, and Barbara G. Shinn-Cunningham (Hearing Res. Ctr., Boston Univ., 677 Beacon St., Boston, MA 02215)

Spatial separation between two talkers can improve speech intelligibility (i.e., cause spatial unmasking) when attending to either one talker (selective listening) or both talkers (divided listening). Such spatial unmasking occurs by (1) allowing listeners to hear otherwise inaudible portions of the signal(s) (energetic masking) and (2) reducing central competition between similar talkers (informational masking, IM). Here, we examine how *a priori* knowledge affects spatial unmasking in selective and divided listening in IM-dominated stimulus conditions. Performance was measured in blocks where the locations of the talkers were either constant (fixed) or varied from trial to trial (spatially randomized). Spatial separation improves performance in both selective and divided tasks when locations are fixed. In the fixed conditions, the acoustic signal-to-noise ratio at the better ear for the less-intense talker partially accounts for the spatial unmasking; however, there is also a large residual spatial unmasking, similar to that seen in previous studies. In the spatially randomized conditions, spatial unmasking is much reduced. In addition, in the divided listening, randomized conditions there is little evidence for any better-acoustic-ear effect. Results suggest that the way in which subjects utilize spatial cues depends on their knowledge of the source locations. [Work supported by ONR Grant No. N00014-04-1-0131.]

4:05

4pPP9. Spatial cues are used differently for localizing and identifying the same attended auditory object. Adrian K.C. Lee (Div. of Health Sci. and Technol., Speech and Hearing Biosci. and Technol. Prog., Harvard-MIT, 77 Massachusetts Ave, Cambridge, MA 02139), Ade Deane-Pratt, David McAlpine (Univ. College of London, London WC1X 8EE, UK), and Barbara Shinn-Cunningham (Hearing Res. Ctr., Boston, MA 02215)

Spatial cues not only affect localization of auditory stimuli, they also influence the formation of perceptual objects (streams). Previous experiments demonstrate that spatial cues influence the grouping of an ambiguous target tone that logically could be part of two different objects in the auditory scene. For such ambiguous stimuli, spatial cues affect how the target tone is grouped, changing the perceived rhythm of a repeating tone stream and the perceived identity of a slowly repeating vowel [Lee *et al.*, ''The missing target: Evidence of tone's inlability to contribute to the auditory foreground'' Proc. Mid-Winter Meeting of the ARO, New Orleans (2005)]. Here, we investigate whether perceived location of tone and vowel streams can be predicted by the grouping results of these previous identification experiments. Results show that the perceived location of the attended object (the repeating tones or vowels) depends on (1) interactions between the perceived locations of the two objects comprising the stimuli and; (2) the spatial cues contained in the target tone. Moreover, the degree to which the target tone affects perceived object location is not predicted by the degree to which the target is perceived as part of the attended object. This suggests that spatial cues affect object formation and object location, but in ways that are independent of one another.

4pSA1. Visualization of the energy flow for guided waves near the surface of an ensonified fluid-loaded elastic cylindrical shell via the Poynting vector field. Cleon E. Dean (Phys. Dept., P.O.B. 8031, Georgia Southern Univ., Statesboro, GA 30460-8031, cdean@georgiasouthern.edu) and James P. Braselton (Georgia Southern Univ., Statesboro, GA 30460-8093)

The Poynting vector field is used to show the energy flow in the near-surface region of an ensonified fluid-loaded elastic cylindrical shell for both forward and backward propagating waves. The present work uses a method adapted from a simpler technique due to Kaduchak and Marston [Kaduchak & Marston, ''Traveling-wave decomposition of surface displacements associated with scattering by a cylindrical shell: Numerical evaluation displaying guided forward and backward wave properties,'' J. Acoust. Soc. Am. **98**, 3501–3507 (1995)] to isolate unidirectional energy flows.

1:45

4pSA2. Nonaxisymmetric acoustic scattering from submerged prolate spheroidal shells. Jeffrey E. Boisvert (NAVSEA Newport, Code 1514 Bldg 1258, Newport, RI 02841) and Sabih I. Hayek (Penn State Univ., University Park, PA 16802)

The equations of motion for nonaxisymmetric vibration of prolate spheroidal shells of constant thickness were derived using Hamiltons principle [S. I. Hayek and J. E. Boisvert, J. Acoust. Soc. Am. **114**, 2799–2811 (2003)]. The shell theory used in this derivation includes shear deformations and rotatory inertias. The shell displacements and rotations were expanded in infinite series of comparison functions. These include associated Legendre functions in terms of the prolate spheroidal angular coordinate and circular functions in the azimuthal angle coordinate. The shell is insonified by a plane wave with arbitrary incident angle. The external (heavy) fluid-loading impedance was computed using an eigenfunction expansion of prolate spheroidal wavefunctions. Far-field backscattered acoustic pressure spectra are presented as a function of incident angle for several shell thickness-to-half-length ratios ranging from .005 to 0.1, and

for various shape parameters, a, ranging from an elongated spheroidal shell ($a=1.01$) to a spherical shell ($a\sim100$). The far-field directivity of acoustic scattering is presented at selected frequencies and plane wave incident angles. [Work supported by the ONR/ASEE Summer Faculty Research Program and the NAVSEA Newport ILIR Program.]

4pSA3. Acoustic scattering of fluid-filled spheres: Modeled and experimental results. David Deveau (Naval Undersea Warfare Ctr., 801 Clematis St., West Palm Beach, FL 33401, david.deveau@autec.navy.mil)

Investigation into the scattering nature of surfaces or other physical objects often requires the use of measurement systems which cannot always be well controlled. This lack of control can be compensated for by calibrating the resulting measurements against a known target. While these targets can be any object, the goal is to use a target that has a stable scattering response and is independent of angle. The ideal shape is that of a sphere but even this can be improved with the addition of internal fluids that focus and temperature stabilize the scattering response. A scatter response model of a sphere has been developed and used to design four thin-walled spheres, each with a different diameter and filled with a focusing fill fluid (Fluorolube). One pair of spheres was measured in an ocean environment while the second pair was tested in a controlled test tank from 5–120 kHz but using shorter continuous wave pulses. While the ocean-measured spheres closely matched the model, the test tank measurements provided insight to the model's near-field limitation and low-frequency noncontinuous wave effects.

4pSA4. Liquid-filled focusing cylinders and the caustic merging transition. Christopher Dudley and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ. Pullman, WA 99164-2814)

Thin spherical shells filled with a liquid having a sound speed significantly less than the speed of sound in water are widely used for targets having enhanced backscattering. This enhancement has been analyzed using quantitative ray theory [P. L. Marston, Phys. Acoust. **21**, 1–234 (1992)]. Backscattering enhancements are investigated here for a liquid-filled flat-ended thin fiberglass circular cylindrical shell in water. In addition to partially focused enhanced backscattering for near-broadside illumination, this target exhibits enhancements for specific ranges of tilt angles associated with caustic merging transitions previously demonstrated for blunt plastic cylinders [F. J. Blonigen and P. L. Marston, J. Acoust. Soc. Am. **107**, 689–698 (2000)]. The refractive properties for the tilted cylinder depend on the effective refractive index N that is a function of the tilt angle and the actual acoustic refractive index of 1.68 (relative to water) for the enclosed liquid. Backscattering enhancements are visible from the tilted cylinder associated with two- and four-chord transmitted internally reflected rays when the tilts are such that N is close to 2 and is close to 4, respectively, as predicted by ray theory. The wave-number-radius product was as small as 16. [Work supported by the Office of Naval Research.]

2:30

4pSA5. Combining an energy boundary element analysis with an energy finite element analysis for computing airborne noise inside a flexible structure due to an exterior acoustic source. Geng Zhang (Michigan Eng. Services, 3916 Trade Ctr. Dr., Ann Arbor, MI 48108) and Nickolas Vlahopoulos (Univ. of Michigan, Ann Arbor, MI 48109)

The energy boundary element analysis (EBEA) has been utilized in the past for computing the exterior acoustic field at high frequencies (above ~400 Hz) around vehicle structures and numerical results have been compared successfully to test data [Wang *et. al.*, J. Sound Vib. **126**, 278–283 (2004); Internoise (2002)]. The EFEA has been developed for computing the structural vibration of complex structures at high frequencies and validation has been presented [Zhang *et. al.*, J. Sound Vib. **282**, 679–700 (2005); **41**, 11–12 (2005); Finite Elements Anal. Des. **41**(11-12) (2005); Wang *et. al.*, SAE Paper No. 2005-01-2372]. In this presentation the EBEA is utilized for computing the acoustic field around a cylindrical structure (similar to the NASA aluminum test-bed cylinder) from an external acoustic noise source. The computed exterior acoustic field comprises the excitation for the EFEA analysis. The structural vibration and the interior noise levels are computed, demonstrating how the EBEA and the EFEA can be combined in airborne noise applications for performing a complete vibro-acoustic analysis. [Work supported by ONR Code 334, SBIR program.]

2:45

4pSA6. Scattering of an obliquely incident plane wave from an immersed transversely isotropic rod covered by an isotropic cladding. Sina Sodagar, Farhang Honarvar (NDT Lab, Faculty of Mech. Eng., K. N. Toosi Univ. of Tech, P.O. Box 16765-3381, Tehran, Iran, honarvar@mie.utoronto.ca), and Anthony N. Sinclair (Univ. of Toronto, Toronto, ON M5S 1A4, Canada)

Valuable information is contained within the scattered pressure field from a submerged elastic cylinder. Many theoretical and experimental investigations on the scattering from elastic cylinders have been carried out during the past few years. This includes recent work of the authors on modeling of the scattered pressure field from immersed transversely isotropic cylinders and immersed isotropic clad rods. In the current paper, an analytical solution to the problem of acoustic wave scattering from an immersed transversely isotropic cylinder covered by an isotropic cladding is presented. The mathematical expressions are derived for the far-field backscattered amplitude spectrum, normal modes, frequency spectrum, and phase diagrams resulting from oblique insonification of an infinite, transversely isotropic cylinder covered by an isotropic cladding. The validity of the mathematical model is verified by comparing the results with data available in the literature for simpler cases, such as transversely isotropic rods and isotropic clad rods. The results are also consistent with elasticity theory.

4pSA7. The effect of in-plane forces on sound radiation from convected fluid-loaded plates. Peter L. Schmidt and Kenneth D. Frampton (Vanderbilt Univ., 2400 Highland Ave., Nashville, TN 37212)

It is well established that fluid flow can have significant effects on structural acoustic behavior, along with the fact that induced coupling between discrete modes of vibration becomes significant as flow velocity increases. Work in this area has been confined to flows in air, over unloaded structures, with the effects on sound radiation efficiency, kinetic energy, and sound power radiation quantified and compared for various flow speeds. The purpose of this work is to study the effects that plane stress has on these structural acoustic phenomena. Theoretical development of the equations governing the vibration of a simply supported plate subjected to in-plane forces in an infinite baffle and an aerodynamic system that models a semi-infinite flowing medium along with the method for coupling these systems is included. Computational results are presented illustrating the behavior of the uncoupled coupled effects on the sound power radiation from the plate in both subsonic and supersonic flows, for a variety of loading cases.

3:30

4pSA8. An approximate method for the computation of the response of a line-driven, fluid-loaded plate with edges. Daniel DiPerna and Xingguang DiPerna (Naval Surface Warfare Ctr., 4500 MacArthur Blvd., West Bethesda, MD 20817)

An approximate method for predicting the response of a line-driven, fluid-loaded plate will be presented. The method is based on the free space Green's function using the rational function approximation developed by DiPerna and Feit. The approximte representations of the Green's function and pressure and velocity fields will be shown to satisfy the Helmholtz integral equation for the infinite plate. The Helmholtz integral equation

will then be used in conjunction with these approximate representations to solve the problem of a finit length plate. Results from the approximate solution will be compared to results from finite-element analysis.

3:45

4pSA9. Active control of vibration of fluid-loaded plates at moderately large amplitudes. Chiruvai P. Vendhan and A. N. Suryanarayana Prasad (Dept. of Ocean Eng., IIT Madras, Chennai, Tamilnadu-600036, India)

The problem of active control of vibrations has been studied by many in recent years. Gu and Fuller [J. Acoust. Soc. Am. **93**, 337–345 (1993)] considered the linear vibrations of a simply supported rectangular plate in a fluid half-space following the analysis of Sandman [J. Acoust. Soc. Am. **61**, 1502–1510 (1977)] and studied active control strategies to minimize the far-field sound-pressure levels. They evaluated the fluid loading using the classical solution for a baffled point source. Following a similar approach, Prasad *et al.* [Prasad *et al.*, J. Acoust. Soc. Ind. **33**, 535–540 (2005)] developed a Rayleigh-Ritz analysis capability for the linear vibration of fluid-loaded rectangular plates with a variety of boundary conditions. The present article is concerned with the nonlinear vibration of a simply supported isotropic square plate. The Duffing-type modal equation based on a single transverse mode approximation [AIAA J. **13**, 1092–1094 (1975)] has been chosen. The fluid loading is calculated using the procedure mentioned above. The equivalent linearization technique has been employed to reduce the nonlinear equation and solution in the form of frequency response function (FRF) obtained using an iterative procedure. The effect of piezoelectric patches mounted at the center of the plate is studied.

4:00

4pSA10. Study on the acoustic similitude of the underwater complex shell structure. Sande Wang, Jr. (Dalian Sci. Test & Technol. Inst., P.O. Box 67 Dalian, 116013, China)

The underwater noise that is produced by the underwater complex shell structure is a basic question to be solved for the noise control of an underwater structure. One way to study and control the underwater noise of the underwater complex shell structure is the experiment of vibration and sound radiation of all kinds of scaled-down models for its prototype. This method can predict vibration and sound radiation of an underwater complex shell structure, and provides the necessary parameters for the design of noise control. Using the finite-element method and the spherical function spread method, this paper investigates the similitude of coupled vibration and acoustic radiation for the typical structure of an underwater vehicle (elastic ring-stiffened cylindrical shell with hemispherical caps on the ends), and presents acoustic similitude conditions and relationships of the structures. At the same time, the acoustic scale effect and boundary effect, which are influenced by loss factors, shear and rotatory inertia, and surface sound reflection are investigated in detail. The results show that these effects can be controlled with similitude model designing and experiment design.

4:15

4pSA11. High-frequency broadband radiation from panels and periodic structures including the effect of structural power flow on directivity. Donald Bliss, Linda Franzoni (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708), and Pavel Danilov (Continuum Dynam., Inc., Ewing, NJ 08618)

In the high-frequency limit, a vibrating panel subject to spatially random temporally broadband forcing is shown to have broadband power and directivity properties that can be expressed analytically by a limited set of parameters. The radiated pressure-field power and directivity are characterized in terms of the structural power flow direction, wave-speed ratio, panel damping, and dimensionless frequency. The role of boundary conditions at the panel edge is illustrated, as are the effects of other types of forcing. Corresponding behaviors for panels coupled to form a periodic structure are also shown by approximate analytical solutions and numerical simulation. Overall, relatively simple broadband behaviors are revealed. For a single panel the analytical characterization is shown to be particularly straightforward in the high-frequency broadband limit. The relationship between radiation and structural power flow is potentially useful in energy-intensity-based prediction methods with application to aircraft interior noise prediction.

Session 4pSC

Speech Communication: Acquisition of Speech and Cross-Linguistic Studies (Poster Session)

Cynthia G. Clopper, Chair
Northwestern Univ., Dept. of Linguistics, 2016 Sheridan Rd., Evanston, IL 60208

Contributed Papers

All posters will be on display from 1:30 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 4:30 p.m.

4pSC1. Rudimentary phrasal parsing in preverbal French-learning infants. David-Etienne Bouchard (Dept. of Linguistics, Univ. of Montreal, Montreal, QC H3T 1N8 Canada) and Rushen Shi (Univ. of Quebec at Montreal, Montreal, QC H3C 3P8 Canada)

The present study examines the initial parsing of noun phrases in infants. Participants were 8-month-old Quebec-French-learning infants. During Familiarization, infants heard two types of trials, one presenting a noun phrase sliced from a sentence (NP trial) and the other presenting the same word sequence (as in the NP trial) but sliced from another sentence in which these words were a part of a noun phrase and a part of a verb phrase, i.e., a non-unit trial. During Test, infants heard the original sentence containing the sliced NP and that containing the sliced non-unit. Two pairs of noun phrases and non-units were used in the experiment across two groups of infants. We predicted that if infants encoded the sliced stimuli in the NP trial as more coherent than those in the non-unit trial during Familiarization, they should listen longer to the sentences containing the NPs than those containing the same words but constituting non-units. Preliminary results show that infants listened significantly longer to the sentences containing the sliced noun phrases, even though the NP trial and non-unit trial during Familiarization involved exactly the same words. This finding suggests that salient prosodic markings enable French-learning infants to parse noun phrases from sentences.

4pSC2. Frequency factor in the segmentation of function words in French-learning infants. Rushen Shi, Melanie Lepage, Bruno Gauthier, and Alexandra Marquis (Dept. of Psychol., Univ. of Quebec at Montreal, Montreal, QC H3C 3P8, Canada)

Previous work showed that 8-month-old French-learning infants segment both highly and moderately frequent function words from continuous speech [Shi and Gauthier, J. Acoust. Soc. Am. **117**, 2426 (2005)]. In the present study we examine if high-frequency function words are segmented by even younger infants. Participants were 6-month-old Quebec-French-learning infants. As in the previous study, infants in the high-frequency condition were familiarized with a target functor (des or la) and were then tested with phrases containing the target versus those containing the nontarget. Thus, for infants familiarized to la, la-phrases were the target phrases and des-phrases were the nontarget phrases during Test. The reverse was the case when des was the familiarization target. The lower-frequency condition included a target functor mes versus ta (prosodically analogous to the functors in the high-frequency condition). The results show that 6-month-olds listened significantly longer to phrases containing the familiarized target than those containing the nontarget during Test, suggesting that they segmented the target. No difference was observed in the lower-frequency condition. Thus, while 8-month-olds segmented both high- and lower-frequency functors [Shi and Gauthier, J. Acoust. Soc. Am. **117**, 2426 (2005)], 6-month-olds showed evidence of segmentation only for high-frequency functors. These findings suggest that frequency is a determining factor in the development of the segmentation of function words.

4pSC3. Learning to categorize lexical tones in sentences with variable narrow focus: A neural network approach. Bruno Gauthier, Rushen Shi (Dept. of Psych., Univ. of Quebec in Montreal, C.P. 8888, Succ. Ctr. ville, Montreal, QC, Canada, H3C 3P8, gauthier.bruno@courrier.uqam.ca), and Yi Xu (Univ. College London, London, UK, NW1 2HE)

The surface F0 patterns of lexical tones contain variability from many different sources, which raises questions as to how infants can learn tones based on such highly variable input. A recent modeling study showed that the velocity profiles of F0 (i.e., first derivatives, or D1) enable naive learners to successfully categorize the four Mandarin tones despite cross-speaker and contextual variations [Gauthier, *etal.* ''Recognising tones by tracking moments—How infants may develop tonal catagories from adult speech input,'' in *Proceedings ISCA workshop on plasticity in Speech Perception*, edited by V. Dellwo (UCL Publications, London, UK, 2005) pp. 72–75]. The present study explores the robustness of D1 for categorizing Mandarin tones in sentences said with different focus conditions. As a contrastive communicative function, narrow focus within a multi-word utterance introduces extensive variability to F0, making tone learning a more challenging task. Using multi-speaker productions of utterances with systematically varied tones and focus [Xu, ''Effects of tone and focus on the formation and alignment of contours. J. Phonet. **27**, 55–105 (1999)], self-organizing neural networks were trained with both syllable-sized D1 and F0 as input, with no special treatment for different focus conditions. In the testing phase, novel tokens were tested for tonal categorization. The results revealed that D1 yielded overall excellent categorization, far superior than F0. Detailed analyses showed that with D1, performance of tonal recognition dropped only in post-focus regions. These findings indicate that successful tone learning can be achieved with velocity profiles as input despite variability introduced by focus.

4pSC4. The effect of concurrent serial digit recall on speech processing in children. Sangsook Choi, Dawna Lewis, Brenda Hoover, and Pat Stelmachowicz (Boys Town Natl. Res. Hospital, 555 N 30th St., Omaha, NE 68131, chois@boystown.org)

Developmental changes in speech perception in a dual task paradigm were investigated in 32 children (7–14 years). Monosyllabic words were presented in noise with or without the concurrent serial recall of visually presented digits (3 or 5). Children were instructed to focus primarily on the listening task, placing secondary effort on digit recall. In both single and dual tasks, word recognition and digit recall improved with age. However, word recognition improved and digit recall decreased in the dual task

condition (*re*: the single task) regardless of age. Greater improvements in word recognition were found for younger children during the dual task in the 3 digit condition. Consequently, the age differences in word recognition observed in the single task diminished during the dual task. Results suggest that the competing digit task might have helped children to optimize attention resulting in improved speech processing. In a follow-up experiment, children will be asked to focus attention on the digit task to determine if the instructions were responsible for observed improvements in word recognition in the first experiment. Results of these studies may have clinical implications for perceptual training methods for children with language delays or hearing loss.

4pSC5. Children's production of prosody: Disambiguating sets of compound nouns. Michiko Yoshida and William F. Katz (Univ. Texas—Dallas, Callier Ctr. for Commun. Disord., 1966 Inwood Rd., Dallas, TX 75235)

Studies have suggested that although young children may perceive prosodic patterns marking structural boundaries in ambiguous sentences (e.g., distinguishing ''pink and green, and white'' from ''pink, and green and white''), children do not necessarily produce these prosodic patterns. However, most of these studies did not test perception and production in the same group of subjects. Therefore, the relation between perception and production for a given linguistic structure could not be clearly established. Yoshida and Katz [''Children's use of prosody to identify ambiguous sets of compound nouns,'' J. Acoust. Soc. Am. **116**, 2645 (2004)] had young children and adults listen to resynthesized speech versions of ''sun/flower/pot.'' F0 and duration patterns were parametrically manipulated to provide a continuum of interpretations between ''sun, flowerpot'' and ''sunflower, pot.'' Results indicated that children showed adultlike processing of duration and F0 cues. The current study reports acoustic data for productions made by these same subjects (elicited prior to the perceptual experiment). Subjects played a naming game with pictures that depicted either (a) a sunflower and a pot or (b) a sun and a flowerpot. Acoustic analyses support the idea that children and adults control both duration and F0 to disambiguate their utterances. Results suggest that previous studies may have underestimated young children's capacity for producing prosodic structures.

4pSC6. Consonant-vowel place linkages in the babbling of 6-, 9- and 12-month-old learners of French, English, and Mandarin. Sara Giulivi (Haskins Labs., 300 George St., New Haven, CT 06511 and Univ. of Florence), D. H. Whalen, Louis M. Goldstein (Haskins Labs., New Haven, CT 06511), and Andrea G. Levitt (Haskins Labs., 300 George St., New Haven, CT 06511)

The place of articulation of consonants and vowels in CV syllables in babbling has been claimed to be linked, such that front vowels predominantly occur with labial consonants, mid-vowels with coronals, and back vowels with velars[P. F. MacNeilage, Behav. Brain Sci. **21**, 499–546 (1998)]. Support for this claim has come from a variety of languages, but a further implication has not been tested: If children depend on this frame/content approach less as they develop, there should be a trend away from it as language mastery increases. Here, we examined the babbling of six English-learning, five French-learning, and five Mandarin-learning infants, sampled at 6, 9, and 12 months of age. There was only moderate support for the frame/content account in the overall ratios, with velars occurring noticeably less often than predicted with back vowels. Further, there was no pattern toward a decrease in evidence for frame/content organization across these 6 months. Together with other theoretical considerations, these results cast doubt on the utility of the frame/content account for language acquisition.

4pSC7. Fricative development in English-learning children. Joanna H. Lowenstein and Susan Nittrouer (Dept. of Speech and Hearing, Ohio State Univ., 1070 Carmack Rd., 110 Pressey Hall, Columbus, OH 43210)

Acoustic studies of school-aged children's fricatives have demonstrated that those gestures are not as precisely specified as in adult speech [e.g., S. Nittrouer, J. Acoust. Soc. Am. **97**, 520–530 (1995)]. The current study examined the development of English fricatives at younger ages by audiotaping seven children at 2-month intervals from the onset of first words (around 14 months) to the onset of three-word sentences (around 30 months). Two measures were made: the numbers of words produced with intended /s/ and /sh/ in initial and final word positions were counted, and first through fourth spectral moments were derived for each /s/ and /sh/ noise at each recording session. Fricatives were rare until after 24 months of age. /s/ was produced earlier than /sh/, and /s/ was produced in word-final before word-initial position. The first moments of /s/ and /sh/ were similar, and both resembled those of /sh/ spectra produced by slightly older children. Spectral skewness and kurtosis were produced with the same degree of separation for /s/ and /sh/ as those of adults, but values were more negative. Results suggest that these children were starting to develop mature spectral shapes for /s/ and /sh/. [Work supported by NIDCD Grant No. DC-00633.]

4pSC8. Developmental changes in the acoustic vowel space of Mandarin-learning children before 2 years of age. Li-mei Chen (Dept. of Foreign Lang., Natl. Cheng Kung Univ., 1 Univ. Rd., Tainan City 701, Taiwan)

Vocalic productions of Mandarin-learning infants aged 0–24 months were audiotaped and analyzed. Major findings in this longitudinal study are (1) There is no obvious change in the range of $F1$ and $F2$ values during these 2 years; (2) Midcentral vowels occurs most frequently for infants younger than 6 months. Vowel /a/occurs most frequently in infants 7 to 24 months old; (3) The frequently occurring vowel categories show steadier pattern of vowel formant frequencies in the second year; (4) Other vowels develop rapidly from 18 months on. However, the newly developed /i, u/ are difficult to identify because of the low amplitude and short duration at this stage of development; (5) Diphthongs, triphthongs, and vowels with nasal endings appear. However, they are unstable, weak, abrupt, and incomplete in the transition. These cause great difficulty in perceptual judgment and acoustic analysis. (6) The individual differences found in the first year became less obvious in the second year. [Investigation supported through funds from National Science Council in Taiwan, Republic of China (NSC 90-2411-H-006-015) (NSC 92-2411-H-006-021) (NSC 93-2411-H-006-024) and a faculty grant from National Cheng Kung University.]

4pSC9. Development of phrase boundary effects. Sara Zepralka and Betty Kollia (Commun. Disord., William Paterson Univ., Wayne, NJ 07470)

In this study we investigate the acquisition and development of phrase-final lengthening in children ages 3 to 7 years of age. Fifteen subjects participated in the study. Preliminary data indicate that subjects produced more adultlike phrase-final lengthening at younger ages, with phrase-final

lengthening duration decreasing with increasing age. Statistically significant phrase-final lengthening was observed in 9 of the 15 subjects. Suggestions for this pattern of acquisition and future research are discussed.

4pSC10. Effects of experience on speech perception in noise. Ratree Wayland, Bin Li, LaTosha Csonka (Program in Linguist., Univ. of Florida, Gainesville, FL 32611-5454), and James Harnsberger (Univ. of Florida, Gainesville, FL)

This study will report on an experiment designed to test the hypothesis that the benefit derived from naturally clear speech is commensurate with listeners' increased exposure to the target language. Research participants were 37 native Chinese speakers, 15 native Spanish speakers, 16 native Thai speakers, and 30 native speakers of English served as control subjects. All participants were asked to listen to four lists of English sentences identical to those used in Bradlow and Bent (2002). These sentences were produced in a conversational and a clear speaking style by a male speaker. All sentences were then normalized for their rms amplitude and mixed with white noise to generate two sets of stimuli (for each speaking style) with a signal-to-noise ratio of -4 and -8 dB, respectively. The number of key words ($N=50$ for each of the four lists) correctly identified by each listener were obtained. The statistical analyses to be performed on the data will focus on comparing the performance of subjects, both within and across language group, whose experience with English differs significantly.

4pSC11. Perceptual assimilation in context and isolation. James Harnsberger, Ratree Wayland, and Jenna Silver (Univ. of Florida-Gainesville, 356 Dauer Hall, P.O. Box 117420, Gainesville, FL 32611)

A study was conducted to examine the effects of sentence context and speaking rate in the perceptual assimilation of non-native speech sounds. Native speakers of American English were presented with two voicing contrasts, [k]-[g] and [t\sh]-[d\yog], produced by two Hindi speakers. They appeared word-initially before [a] and within a short sentence frame. These sentences were produced at three speaking rates (slow, normal, and fast). Listeners were administered a categorial AXB discrimination test and a forced-choice identification test. The results were compared to those collected in a previous study that employed the same contrasts appearing in isolated words and produced by the same talkers. The results showed that the discrimination of these speech sounds in a sentence frame was significantly poorer relative to the isolation context. Moreover, the modal native consonant used to classify the Hindi stops varied depending upon the sentence context variable: in isolation, more discriminable uncategorizable assimilation types were elicited, while in a sentence frame, Hindi contrasts tended to be classified using a single English (voiced) consonant. Speaking rate only showed modest effects on proportion of responses represented by the modal native consonants. These results highlight the sensitivity of perceptual patterns elicited in the laboratory to experimental variables.

4pSC12. Temporal aspects of voicing in Russian and English. Roza Zak and Carole Gelfer (William Paterson Univ., 300 Pompton Rd., Wayne, NJ, 07470, zakr@student.wpunj.edu)

The study compares temporal aspects of voicing in Russian and English. Specifically, it examines whether Russian-English bilinguals who have learned English as a second language (L2) in early childhood are able to differentiate Russian and English consonants /p/, /b/, /t/, /d/, /k/, /g/ according to voice onset time (VOT). Monolingual Russian-speaking 3-year-old children's VOTs will be compared to those of monolingual Russian-speaking adults. Bilingual (Russian and English) 9-year-old children's VOTs will be compared to monolingual 9-year-old children's VOTs. It is predicted that 9-year-old bilingual children will demonstrate appropriate voicing boundaries in English; however, their production of Russian VOTs will differ from the Russian monolingual production.

4pSC13. Voice onset time of bilingual English and French-speaking Canadians. Carol Fowler, Sarah Rowland, David Ostry (Haskins Labs. 300 George St., New Haven, CT 06511, sarah.rowland@uconn.edu), Valery Sramko (McGill Univ. Montreal, QC, H3A 1B1 Canada), and Pierre Halle (CNRS/Sorbonne-Nouvelle Paris, France)

There is evidence of voice onset drift when bilinguals are submerged in cultures that are dominated by their second language (L2). Sancier and Fowler [Gestural drift in a bilingual speaker of Brazilian Portuguese and English," J. Phonet. **4**, 421-436 (1997)] found that voiceless stop voice onset times (VOTs) of a bilingual speaker of Brazilian Portuguese and English were longer after months spent in the US than after time spent in the speaker's first language (L1) context. Flege ["The production of "new" and "similar" phones in a foreign language: Evidence for the effect of equivalence classification," J. Phonet. **15**, 47–65 (1987)] studied French L1 English L2 bilinguals and English L1 French L2 bilinguals who had spent about 12 years living in the L2 dominant culture. The French L1 English L2 bilinguals VOTs were longer than the VOTs of French monolinguals. The English L1 French L2 bilinguals VOTs were shorter than the VOTs of English monolinguals. In the present study the nature of the experience underlying VOT drift was investigated. Specifically, the aim of the current study was to see whether exposure to another language with different VOTs affects VOT production in the first (or only) language or if VOT production drift is dependent on speaking the non-native language. Productions from English and French monolinguals and from English-French bilinguals were compared across varying linguistic contexts and order of acquisition.

4pSC14. Perception of French stops by French and American English speakers. Nassima Abdelli-Beruh (Dept. of Speech-Lang. Pathol. and Audiol., and Dept. of Speech and Hearing, New York Univ., 719 Broadway, Ste. 200, New York, NY 10003) and Steve Chartan (John L. Miller Great Neck North High School, Great Neck, NY)

This study examined how native French and native American English speakers perceive edited and unedited word-initial stops produced by two monolingual Parisian speakers. Most words used in this study exist in both languages, yet are produced differently. Listeners were asked to identify the initial stops of French monosyllabic words recorded in isolation. The words were unedited (condition A), edited (condition B), and whispered (condition C). In condition A, words were produced in isolation at modal vocal intensity. In condition B, voicing lead was removed from words beginning with /b, d, g/, and in condition C, words were naturally whispered. Participants were asked to listen to each stimulus and then identify the initial consonant (b, d, g, p, t, k). Statistical analyses show that native French speakers performed significantly better than native American English speakers on identification of the word initial consonant in condition A (unedited words spoken at modal vocal intensity). In condition B (voicing lead removed from words produced at modal vocal intensity), native American English speakers performed significantly better than the native French speakers. Finally, both language groups were equally impaired in condition C (whispered speech). Errors were analyzed as a function of the listener's language phonetic inventory.

4pSC15. The perception of Mandarin tone contrasts: A cross-linguistic study. Yueh-chin Chang (Grad. Inst. of Linguist., Natl. Tsing Hua Univ., Hsinchu, Taiwan, ycchang@mx.nthu.edu.tw), Pierre Halle (CNRS-Paris V (UMR 8581), Boulogne-Billancourt, France), and Catherine T. Best (Univ. of Western Sydney, Milperra NSW, Australia)

Previous studies of the perception of tone continua found that Mandarin listeners perceive tones more categorically than French listeners, whose performance is essentially psychophysically motivated. In this study, we examined native-language effects on the perception of Mandarin

tone continua by Cantonese, Thai, and Japanese listeners. Cantonese distinguishes six tones: high-rising, low-rising, low-falling, and high-, mid-, and low level. Thai has five tones: rising, falling, and high-, mid-, and low level. Standard Japanese has a word pitch accent with at most one LH and one HL pitch movement per word. Listeners of these languages were tested on three Mandarin tone continua constructed from natural utterances within carrier sentences. Listeners were run on AXB identification and discrimination tests on isolated syllables. Japanese, Thai, and Cantonese listeners, in that order, perceived tones increasingly categorically. Cantonese and Thai listeners were more sensitive to tone-contour differences than Japanese listeners, although less than Mandarin listeners. The Cantonese and Thai data show that both phonological and phonetic properties of the native language affect the perception of the non-native Mandarin tones. The findings are compared with prior cross-linguistic research, and discussed with reference to the suprasegmental phonological differences across languages.

4pSC16. Return of the weckud wetch: Rapid adaptation to a new accent. Neil P. Bardhan, Richard N. Aslin, and Michael K. Tanenhaus (Brain & Cognit. Sci., Univ. of Rochester, Meliora Hall, Rochester, NY 14627)

This study investigated listeners' adaptation to a new accent within a portion of the vowel space of their native language. Previous work has shown that such adaptation requires only brief exposure [Maye *et al.*, "In search of the weckud wetch: Online adaptation to speaker accent," CUNY Conference on Sentence Processing, Cambridge, MA (2003); Clarke & Garrett, "Rapid adaptation to foreign-accented English," J. Acoust. Soc. Am. **116**, 3647–3658 (2004)]. However, neither adaptation involved visual referents and the postadaptation assessment involved either a lexical decision task or a cross-modal lexical matching task. In the present study, English-speaking listeners were exposed to a list of lexical items in which front vowels were lowered (e.g., "witch" became "wetch") but back vowels were not (e.g., moon). During adaptation, subjects selected an object from a visual array after hearing a naturally produced, accented form of the object's name. In a postadaptation lexical decision task subjects were more likely to accept the accented form as a word than before training. Also examined were the effects of generalization across the lexicon to untrained words and throughout the vowel space to include back vowels. This paradigm of lexical adaptation lends itself to further studies using an eye-tracking measure to assess dialect influences on lexical access in spoken word recognition. [Work was supported by NIH 5R01DC005071-05 and NIH 5T32DC000035-12.]

4pSC17. Sequential contrast versus compensation for coarticulation in Japanese versus English. Daniel Mash and Shigeto Kawahara (Ling. Dept., Univ. of Massachusetts, Amherst, MA 01003-9274)

English listeners identify a stop ambiguous between /t/ and /k/ more often as "k" after [s] than after [sh] (Mann and Repp, J. Acous. Soc. Am. **69**, 548–558, 1981). This bias could reflect compensation for coarticulation, which undoes the fronting of a stop expected next to [s], or instead sequential contrast, in which an intermediate F3 value sounds lower and more "k"-like after [s]'s high-frequency energy concentration. Japanese may distinguish these accounts' predictions. The Japanese sibilant fricative is pronounced [s] before [u] but [sh] before [i]. These vowels delete between two voiceless consonants, so [s] or [sh] can occur before [t] or [k] in surface forms. If Japanese listeners treat [s] followed by a stop from a [t-k] continuum as containing an intervening [u] and [sh]-[t-k] as containing an intervening [i], sequential contrast but not compensation for coarticulation predicts that they should identify more of the continuum as "t" after [s] because [u] concentrates energy at lower frequencies than [i]. However, if they instead judge the stop in terms of the fricative that occurs next to it on the surface, then they should respond like English listeners, and their behavior is predicted equally well by sequential constrast and compensation for coarticulation. [Work supported by NIH.]

4pSC18. Perception and production of English vowels by native speakers of Mandarin. Karece Lopez (Dept. Speech, Commun. Sci., & Theatre, St. John's Univeristy, Queens, NY 11439), Yan Helen Yu (CUNY Grad. School, New York, NY), and Fredericka Bell-Berti (St. Johns Univ., Jamaica, NY 11439)

This study examines the relationship between the identification of English vowels by 48 Mandarin ESL speakers and their production of these same vowels, and how factors of AoA, LoR, general and English education, and language spoken at work and home influence that relation. The Mandarin ESL speakers produced eight repetitions of the following words, heed, hid, head, had, hod, hawed, hood, who'd, hud, and heard, and then identified tokens of each of these words produced by two native speakers of Greater Metropolitan New York City English. Native speakers of American English identified the productions of the Mandarin ESL speakers to provide a measure of their ability to produce these vowels. We hypothesize that general and English educational background and language use influence the L2 English speakers' perception and production of English vowels, and that the more accurately the L2 listener distinguishes a vowel contrast, the more distinctly he/she produces that contrast.

4pSC19. Pronunciation of English vowels of native Turkish speakers. Janine Sadaka and Manwa Ng (Commun. Sci. and Disord., Long Island Univ., Brookville, NY 11548-1300)

Foreign accent can be defined as the allophonic variations in the target language (L2) under the influence of the first language (L1). This is mainly caused by the incorrect placement of articulators during production of the vowels and consonants of L2. As direct acoustic correlates of articulatory gestures, formants can be a valuable tool to indicate the amount of misarticulation, and thus amount of accent traits. The present study attempts to investigate the amount of accent in Turkish-English bilingual individuals producing English vowels. The first two formant frequencies (F1 and F2) of eight English monophthongs produced by ten male and ten female native Turkish will be analyzed. The bilingual speakers have been using English and Turkish in their daily communication. All English vowels are produced three times in the /hVd/ context. Five data points will be selected evenly along each vowel segment, and the average F1 and F2 values will be measured. The average F1 and F2 values thus measured will be compared with those of native English speakers as reported by Peterson and Barney (1952). It is hypothesized that the F1 and F2 values of the accented English vowels will be slightly different from those produced by native English speakers.

4pSC20. Vowel errors and sentence intelligibility in Spanish-accented English speech. Jonathan Dalby (Dept. of Audiol. and Speech Sci., Indiana Univ.—Purdue Univ., Fort Wayne, 2101 E. Coliseum Blvd., Ft. Wayne, IN 46805, dalbyj@ipfw.edu)

It has been shown that foreign-accented speech is more difficult for listeners to process than native speech when presented under noisy listening conditions. It has also been shown that errors in vowel productions are more damaging to connected speech intelligibility than are errors or distortions in consonant production. This study compared the intelligibility of Spanish-accented English vowels in isolated words with that of short samples of connected speech. Five native Spanish speakers who had learned English as adults read a list of 42 monosyllabic English words selected so that 14 Spanish-accented English monophthongs could be presented to native listeners in a three-alternative forced-choice identification task. In each trial the target and two nearby (in the vowel space) distracters were presented. Talkers also read a set of 20 phonetically balanced sentences. Ten native English listeners identified the vowels in the isolated word task and judged the intelligibility of the sentences in a simple write-down procedure. While overall sentence intelligibility scores are not very well predicted by word intelligibility scores when the full set of vowel contrasts is included, predictability improves when a subset of the vowels is chosen. [Work supported by Purdue Research Foundation.]

4pSC21. Formant movement and duration in second-language vowel learning. Paul Iverson and Bronwen G. Evans (Dept. of Phonet. and Linguist., Univ. College London, 4 Stephenson Way, London NW1 2HE, UK)

This study tested native speakers of Norwegian, German, French, and Spanish on their recognition and production of L2 English vowels. A goodness-optimization method was used to construct phonetically detailed perceptual vowel space maps for each listener's L1 and L2 (English). These maps comprised best exemplar locations in a multidimensional stimulus space that included $F1$ and $F2$ target frequencies, $F1$ and $F2$ movement, and duration. The maps were then compared to assessments of each individual's recognition accuracy for naturally spoken English vowels and their degree of accent for spoken English. The results demonstrated that all four language groups used phonetic detail to recognize English vowels; individuals had higher recognition accuracy for natural English vowels when their best exemplars had formant movement and duration contrast that were more like those of L1 English speakers. However, their use of phonetic detail was not entirely predictable by their L1 background. It thus appears that individuals with a range of L1 backgrounds form phonetically detailed category representations during L2 learning, and that their representation of phonetic detail has practical implications for recognizing natural L2 speech.

4pSC22. Training Chinese dialect listeners to perceive English /n/ and /l/. Bin Li and Ratree Wayland (Linguist. Program, Univ. of Florida, 4131 Turlington Hall, P.O. Box 115454, Gainesville, FL 32611-5454, bli@ufl.edu)

Dialects and Mandarin subdialects in certain areas of southern China do not distinguish between /n/ and /l/. Native speakers of these dialects usually have difficulty distinguishing these two sounds when learning English, even after years of experience with the language. The goal of the present research is to develop a set of procedures that would be effective in training these speakers to learn this non-native speech contrast in English. Forty listeners were recruited from 3 dialect areas (6 Gan, 11 Jianghuai, and 23 Xinan). Listeners were instructed to identify the initial consonant in an English word spoken by 3 native speakers of American English. A pre- and a post-test design were used to assess the effect of a 4-day training. A generalization test containing the same stimuli spoken by 2 new talkers was also carried out on the same day of the post-test. Overall, subjects' performance improved significantly from the pre-test to the post-test and there was no significant group difference. Additionally, there was no significant difference between their performance of /n/ and /l/ either before or after training. Vowel contexts and syllable structures are also found to have affected listeners' perception in the post-test.

4pSC23. Effects of dialect variation on speech intelligibility in noise. Cynthia G. Clopper and Ann R. Bradlow (Dept. of Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, c-clopper@northwestern.edu)

Recent research has shown that listeners can classify talkers based on their regional dialect of American English (AE). The present experiment explored the effects of regional dialect variation on speech intelligibility. Participants from various AE dialects transcribed meaningful English sentences mixed with noise. The sentences were produced by male and female talkers from four different AE regional dialects. At a favorable signal-to-noise ratio (-2 dB), intelligibility of General American and Southern talkers was significantly better than Northern and Mid-Atlantic talkers, and was significantly better for the Northern than the Mid-Atlantic talkers. At a more difficult signal-to-noise ratio (-6 dB), intelligibility was equally poor for the Southern, Northern, and Mid-Atlantic talkers, but remained significantly better for the General American talkers. No effects of listener dialect were observed. Thus, speech intelligibility in noise was generally poorer for more phonologically marked dialects (e.g., North, Mid-Atlantic) than less-marked dialects (e.g., General American). However, noise had differential effects on dialect interference; intelligibility of marked dialects was graded at easier signal-to-noise ratios, but marked dialects were equally difficult to transcribe at unfavorable signal-to-noise ratios, suggesting that dialect information may be conveyed by aspects of the signal that are relatively vulnerable to perceptual disruption by noise.

4pSC24. Consonantal context and experience effects on American L2-learners' perception of French vowels. Erika S. Levy (Teachers College, Columbia Univ., Biobehavioral Sci., Box 180, 525 W. 120th St., New York, NY 10027)

According to Best's [Best, C. T. (**1994**). "The emergence of native-language phonological influence in infants: A perceptual assimilation model," in *The Development of Speech Perception: The Transition from Speech Sounds to Spoken Words*, edited by J. Goodman & H. C. Nusbaum (MIT Press, Cambridge, MA); Best, C. T. (**1995**) "A direct realist view of cross-language speech perception," in *Speech Perception and Linquistic Experience Issues in Cross-Language Research*, edited by W. Strange (York Press, Baltimore, MD)] Perceptual Assimilation Model (PAM), listeners' perceptual assimilation of unfamiliar speech sounds predicts their discrimination accuracy of these sounds. This study applied the PAM to second-language (L2) learners. Three groups of American English (AE) listeners performed a perceptual assimilation (PA) task involving Parisian French (PF) vowels /y-œ -u-o-i-ɛ-a/ and a categorial discrimination task involving French front versus back rounded pairs /y-u/, /y-o/, /œ -o/, /œ -u/, front rounded versus front unrounded /y-i/, /y-ɛ/, /œ -ɛ/, /œ -i/, and front rounded /y-œ /. Vowels were in bilabial /rabVp/ and alveolar /radVt/ contexts. PF front-rounded vowels were perceptually assimilated overwhelmingly to back AE vowels, resulting in more discrimination errors for front-versus back-rounded PF pairs than for front-unrounded versus rounded pairs. Listeners with formal French instruction fared similarly to listeners with no experience. Extensive immersion correlated with fewer errors than formal experience, although /u-y/ discrimination remained relatively poor for this group. More errors occurred in alveolar than bilabial context. Thus, native-language allophonic variation may explain context-specific L2 perception. Using a percent overlap method, a significant correlation was found between PA overlap and discrimination errors for all groups, suggesting that the PAM may be extended to L2-vowel learning. 4pSP1. Estimating mutual information for the underwater acoustic channel. Paul Gendron (Naval Res. Lab., Acoust. Div., 4555 Overlook Ave. SW, Washington, DC 20375)

Estimates of the upper and lower bounds on the information rates attainable for acoustic communication systems with white Gaussian sources under uncertain channel conditions are provided that account for finite duration signaling and finite coherence time. For the case where the coherence time of the channel exceeds that of the packet duration the estimators are computationally efficient with the Levinson recursion and provide a means of tuning the accuracy of the estimates to fit a given computational budget. The reduction in the information rate relative to the known channel case is quantified in terms associated with the duration of signaling, the posterior covariance of the channel, and the prior covariance of the channel. For scenarios where the prior channel covariance is known exact bounds on the information rates are computable else the estimators provide confidence intervals for these rates. The estimators are tested on 18 kHz at sea data collected in shallow water north of Elba Italy on a 1.8-m aperture vertical array and on very shallow water sites at Keyport Washington. The effects of temporal coherence degradation as well as multi-path spread are quantified. [Work supported by the Office of Naval Research.]

4pSP2. Robust processing against uncertain reverberation spectra in shallow-water broadband active sonars. Peter G. Cable (BBN Technologies, Old Mystic Mill, 11 Main St., Mystic, CT 06355)

Broadband low-frequency active sonars operating in shallow water must work against reverberation having uncertain spectral color. Under these conditions prewhitening of the background is appropriate for detection and estimation processing. To assess the importance of prefiltering, in this talk signal-to-background performances of energy detected data subjected to no prewhitening, prewhitening, and Eckart filtering are compared for typical observed shallow-water reverberation spectral shapes. Adaptive prewhitening algorithms are described and their performances analyzed in terms of loss associated with spectral estimation errors. Modeled detection performance is compared with measured results obtained from Area Characterization Test III performed in the Korea Strait. Finally, the relevance of adaptive prewhitening to estimation for classification is also described. [Work supported by ONR and DARPA.]

4pSP3. Measured and modeled multirank signals in a range-dependent environment. Kevin D. Heaney (OASIS, Inc., 11006 Clara Barton Dr., Fairfax Station, VA 22039, oceansound04@yahoo.com)

Environmental variability can take the form of sound-speed fluctuations, range- and azimuthally dependent geoacoustics, and strong bathymetric gradients. In this paper we examine the rank of strong broadband tones in a strongly range-dependent environment and the subsequent effect on adaptive processing. Range-dependent transmissions off the coast of Kauai were recorded during the Basin Acoustic Seamount Scattering EXperiment (BASSEX04) in September of 2004. Broadband transmissions (27-s M-sequence, 75-Hz center frequency) of the North Pacific Acoustic Laboratory (NPAL) source-mounted bottom in 900 m of water off the coast of Kauai were recorded using a 200-m towed line array. The single-element signal-to-noise ratio (SNR) is on the order of 15 dB before matched filtering, so there are no issues of adequate SNR for adaptive beamforming. With such a strong single source, the spread in eigenvalues will be studied as an indication of the effect of motion, environmental variability, and multipath propagation. In this environment, the rank of the CSDM is significantly higher than can be modeled using 2D range-dependent parabolic equation modeling, indicating that environmental variability (scattering, 3D acoustics) dominates over motion and multipath effects (which are well handled in the PE modeling).

2:35

4pSP4. Full-field likelihood ratio detection for multistatic sensors in uncertain environments. Lawrence Stone and Bryan Osborn (Metron, Inc., 11911 Freedom Dr., Ste. 800, Reston, VA 20190, osborn@metsci.com)

As small networked sonobuoys become cheaper and more viable in the submarine warfare community, there is a growing demand for techniques to automatically process detection data from dense fields containing O(100) or more sonobuoys. The presentation describes a Bayesian framework for the incoherent integration of automatic detections from these dense sonobuoy fields. This framework recursively integrates likelihood ratio functions to form a cumulative posterior over a target state space. To be most effective, these methods exploit either empirical sensor performance models or physics-based signal excess sensor performance models. The presentation describes the use of each type of performance model and presents one method for handling uncertainties associated with signal excess predictions. The method presented starts with a prior on a set of possible environmental conditions. When a target is present in the detection data, the cumulative likelihood ratio will peak in the environment most consistent with the true environment.

4pSP5. The estimated ocean detector (EOD) for Gaussian signal and noise. Jeffrey A. Ballard, Colin W. Jemmott, Leon H. Sibul, R. Lee Culver, H. John Camin, and David L. Bradley (Appl. Res. Lab. and Grad. Program in Acoust., The Penn State Univ., P.O. Box 30, State College, PA 16804, jab795@psu.edu)

Our overall goal is to develop a method for incorporating knowledge of the environment, and in particular, environmental variability, into the signal processor. This talk begins with the assumption that all available information about the environment has been used to compute the probability density functions (pdfs) of relevant received signal parameters (e.g., amplitude or time spread). For the exponential class of pdfs that arises from applying the maximum entropy method to random signal parameters, the maximum likelihood detectors (MLD) can be implemented as an estimator-correlator [Schwartz, "The estimator-correlation for discrete-time problems," IEEE Trans. on Information Theory. **23**, 93–100 (1977)]. The MLD detector correlates received data with the conditional mean estimate of the signal; hence we have named it the estimated ocean detector (EOD). Here, we present the general structure of the EOD and explore EOD performance for Gaussian signals and noise, which are members of the exponential class. The resulting implementation produces a detection statistic that is the weighted sum of an energy detector and a correlation receiver, with the weights calculated from the variances of the noise and signal. EOD performance bounds are calculated using completely known and completely unknown oceans. [Work supported by The Undersea Signal Processing Program, Office of Naval Research.]

3:15

4pSP6. Performance of the estimated ocean detector (EOD) against non-Gaussian signal and noise. Colin W. Jemmott, Jeffrey A. Ballard, Leon H. Sibul, R. Lee Culver, H. John Camin, and David L. Bradley (ARL and Grad. Program in Acoust., The Penn State Univ., P.O. Box 30, State College, PA 16804, cwj112@psu.edu)

Our overall goal is to develop a method for incorporating knowledge of environmental variability into a passive sonar detector. An earlier talk presented the derivation of the estimated ocean detector (EOD), which is the maximum-likelihood detector for the exponential class of received signal parameter probability density functions (pdfs). A particular implementation of the EOD for Gaussian signal and noise (members of the exponential class) was shown and performance bounded. This talk evaluates the performance of the Gaussian EOD under nonideal conditions, including inaccuracies in the estimates of signal and noise variance, and examines robustness under received signal distributions that contain nonzero skew and kurtosis. To assess detection performance for non-Gaussian signals, receiver operating characteristics are computed for received signal pdfs obtained by applying the maximum entropy method to fit an exponential class pdf to experimental data. Gaussian EOD performance for non-Gaussian signal and noise conditions is compared to the classical envelope and correlation detectors, which form the limiting cases of the EOD. [Work supported by The Undersea Signal Processing Program, Office of Naval Research.]

4pSP7. A method to predict active sonar detection range in uncertain shallow water environments. Peter G. Cable (BBN Technologies, Old Mystic Mill, 11 Main St., Mystic, CT 06355)

Knowledge of maximum detection range is important for the appropriate operation of search sonar. For example, effective spacing of multistatic sonar sources and receivers will be influenced by good estimates of achievable detection range. But predicting detection range for low-frequency active sonar in shallow water can be problematic in the face of inadequate environmental characterization. Thus, incomplete knowledge of bottom sediment geoacoustics and bottom scattering strength, and absence of a good understanding of bottom reverberation mechanisms, will greatly hamper the accurate prediction of dependable detection ranges. Given a bistatic sonar configuration in shallow water, a method is proposed and described that exploits the observed transition time from reverberation to noise-limited conditions to simply and robustly predict maximum detection range for specified target strength. Modeling and analysis suggest that estimates of maximum detection range within 25% accuracy can be readily achieved.

4pUW1. Spatial diversity in passive time reversal communications. H. C. Song, W. S. Hodgkiss, W. A. Kuperman, T. Akal (MPL/SIO, UCSD, La Jolla, CA 92093-0238), and M. Stevenson (NATO Undersea Res. Ctr., La Spezia, Italy)

A time reversal mirror exploits spatial diversity to achieve spatial and temporal focusing, a useful property for communications in an environment with significant multipath. This paper presents the impact of spatial diversity on passive time reversal communications between a single probe source and a vertical receive array using at-sea experimental data, while the probe source is either fixed or moving at about 4 knots. The performances of two different approaches are compared: (1) time reversal alone and (2) time reversal combined with adaptive channel equalization. In the presence of source motion, the motion-induced Doppler shift is coarsely estimated using a decision-feedback phase-locked loop with a training sequence and then the received time series is resampled prior to the demodulation process. The time-varying channel responses due to source motion require an adaptive channel equalizer such that time reversal combined with the equalizer outperforms time reversal alone by up to 13 dB as compared to 5 dB for a fixed source case. The experimental results around 3 kHz with a 1-kHz bandwidth illustrate that even two or three receivers (i.e., 2- or 4-m aperture) can provide resonable performance at 4.2- and 10-km ranges in a 118-m deep water.

4pUW2. Surface reflection caustics and their impact on communications in the littoral zone. Grant Deane (Code 0238, Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238)

Gravity waves with wavelengths longer than a Fresnel zone create cusps and caustics in the surface-reflected acoustic field. The properties of these coherent focal regions have been measured in the surf zone and the 20-m-deep littoral waters off Martha's Vineyard. The time-dependent scattering function shows features consistent with a theoretical analysis of the focal region micro-path structure. The rapid amplitude, phase, and Doppler shifts associated with individual micro-paths present challenges to the reliable operation of phase-coherent underwater communications systems that must implicitly or explicitly track the fluctuations in the impulse response. Data from the experiments will be presented and the implications for underwater communications systems will be discussed. [This work has been undertaken in close collaboration with Dr. James Preisig at the Woods Hole Oceanographic Institution and Dr. Chris Tindle at the Auckland University Physics Department, New Zealand, and supported by the Office of Naval Research.]

4pUW3. High-resolution shallow water tomography using an array of sources and receivers. Philippe Roux, Bruce D. Cornuelle, Jit Sarkar, Tuncay Akal, W. S. Hodgkiss, W. A. Kuperman, Karim G. Sabra, Hee Chun Song (Scripps Inst. of Oceanogr., UC San Diego, 9500 Gilman Dr., La Jolla, CA 92093-0230), and Mark Stevenson (NATO Undersea Res. Ctr., La Spezia, Italy)

During the FAF05 experiment, two vertical arrays of 29 sources and 32 receivers both covering a large part of the shallow water ocean were located 5 km from each other. A complete acquisition of the waveguide impulse responses between each source and each receiver was performed every 20 s during several hours using broadband pulses at 3.5 kHz. Using time-delay beamforming on both the source and receiver arrays, each ray path was isolated and matched to a ray code based on an *a priori* model of the environment. Following this approach, the impulse responses data matrices were then inverted over time to obtain a movie of the range- and depth-dependent fluctuations of the sound speed between the two arrays. Spatial resolution is discussed as a function of the number of rays used in the inversion. [Work supported by ONR.]

2:05

4pUW4. Amplitude statistics for high-frequency underwater acoustic communications. Wen-Bin Yang and T. C. Yang (Naval Res. Lab., Code 7120, 4555 Overlook Ave., SW, Washington, DC 20375, wyang@wave.nrl.navy.mil)

Amplitude statistics is one major channel characteristic of a communication system, particularly when an energy detector is used as an incoherent receiver. The amplitude statistics is usually modeled as a Rayleigh or a Rician distribution for an rf channel. From our recent study, the amplitude statistics of high-frequency underwater acoustic communications channel is found to be a K-distribution based on M-sequence data collected during the TREX04 experiment. The TREX04 experiment was conducted in shallow water ($\sim$70-m depth) off the coast of New Jersey. The source and receivers were located about 35 m deep. The M-sequence signal was operated at 17 kHz with a 5-kHz bandwidth. The K-distribution is one of non-Rayleigh family and may be approximated by a combination of a long-term fading and a short-term fading statistics. The long-term and short-term fading statistics are close to a lognormal distribution and a Rayleigh distribution, respectively. [Work supported by the Office of Naval Research.]

2:20

4pUW5. Single- and multi-channel underwater acoustic communication channel capacity: A computational study. Thomas J. Hayward and T. C. Yang (Naval Res. Lab., Washington, DC 20375, hayward@wave.nrl.navy.mil)

Acoustic communication channel capacity determines the maximum data rate that can be supported (theoretically) by an acoustic channel for a given source power and source/receiver configuration. In this paper, results reported previously [Hayward & Yang, *High Frequency Ocean Acoustics Conference*, AIP Conference Proceedings (American Institute of Physics, New York, 2004) for single-input, single-output (SISO) systems are reviewed. Then, channel capacities of single-input, multi-output (SIMO) and multi-input, multi-output (MIMO) systems are investigated, first in the limit of a dense receiver array spanning the entire acoustic environment and then for arrays consisting of a small number of sensors. For the dense array, the computed values of the MIMO channel capacities for a modeled shallow-water environment are found to be over 2 orders of magnitude higher than for the SISO channel. Channel capacities for smaller arrays are computed using an exact formula and then compared with approximations based on previously published results. Noise modeling issues and implications for underwater acoustic communication systems are discussed. [Work supported by the Office of Naval Research.]

4pUW6. A low-complexity fading simulator for underwater acoustic communication channels. Y. Rosa Zheng (Dept. of ECE, Univ. of Missouri-Rolla 1870 Miner Circle, Rolla, MO 65401)

Shallow water is an extremely complicated place for communications, and realistic channel models can provide an effective tool for system design. This paper proposes a low-complexity simulator that generates channel impulse responses for broadband frequency-selective acoustic channels. It uses a sum-of-sinusoids (SoS) method to generate Doppler fading impulse responses for wide-sense stationary correlated scattering (WSSCS) Ricean fading channels. The line-of-sight component is obtained by $G_0(t,\tau_0)=A_0\exp[2\pi(1+\epsilon_0)ft\cos\alpha_0+\phi_0\delta(\tau-\tau_0)$ and the scatterers by $G_s(t,\tau)=\Sigma_{n=1}^{N}A_n\exp\{j[2\pi ft\Sigma_{m=1}^{M}(1+\epsilon_m)\cos\alpha_{m,n}+\psi_n\delta(\tau-\tau_n)$, where the random parameters A_n, $\alpha_{m,n}$, ψ_n, and τ_n are, respectively, the attenuation coefficients, impinging angles, initial phases, and path delays. The Doppler scaling is $(1+\epsilon_m)f$, where f is the carrier frequency and ϵ_m depends on the speed of sound propagation in water and the velocities of the transmitter, receiver, and wind. Nonuniform probability density functions are selected for impinging angles $\alpha_{m,n}$ to account for the nonisotropic waveguide effect in shallow-water channels. The proposed simulator is a general stochastic model that does not require site-specific information. It only uses $6N+4$ random variables and requires $O(N)$ multiplications and additions, where N is on the order of several tens. This low-complexity simulator can be easily implemented by real-time digital signal processors.

3:05

4pUW7. Ocean variability effects on underwater communication channel. Aijun Song and Mohsen Badiey (College of Marine Studies, Univ. of Delaware, 114 Robinson Hall, Newark, DE 19711)

In the recent high-frequency acoustics experiments KauaiEx and MakaiEx, it is shown that the variability of the oceanographic parameters has direct impacts on the acoustic signal propagation. For example, the variability of the sea surface condition is highly correlated with the changes of energy in the surface bounces. The coherence of the communication channel is also affected by the sea surface wave. To design an efficient communication system, the relevant ocean variability effects should be investigated. Such investigation will also lead to the prediction of the communication performance at dynamic environment. In the presented work, oceanographic parameters, including sound speed profile and sea surface condition, will be correlated with a series of channel property. Their impacts on the communication receiver, especially maximum-likelihood (ML) receivers, will be also presented. [Work supported by the ONR.]

3:20

4pUW8. The effect of medium variability on acoustic variability: Internal waves and thermohaline intrusions (spice). Joy E. Lyons, David L. Bradley, R. Lee Culver, and Kyle M. Becker (Grad. Program in Acoust., The Penn State Univ., P.O. Box 30, State College, PA 16804, jel246@psu.edu)

In July 2002, an experiment was conducted off the coast of southern California in which the two-dimensional temperature and salinity field were measured directly using a towed conductivity, temperature, and depth chain. The spatial scales are approximately 3500 m long by 80 m deep, with a horizontal resolution of 1–2 m. The resulting sound-speed field has been decomposed into fields of internal waves and density-compensated, thermohaline intrusions. The medium variability in these two fields covers many spatial scales. High-frequency acoustic propagation (1–5 kHz) through the derived fields, as well as through the original field, was computed using the PE-based model RAM and the ray-trace model RAY. Using the metric of scintillation index, the contributions of internal waves and thermohaline intrusions to the acoustic variability are examined, and their relative contributions to the total acoustic variability quantified.

3:35

4pUW9. Decompostion of the time reversal operator applied to detection and focusing in a 12-m-deep channel in Brest Bay. Claire Prada, Julien De Rosny, Dominique Clorennec, Jean-Gabriel Minonzio, Mathias Fink (LOA, ESPCI, Universit Paris 7, CNRS UMR 7587, 10 rue Vauquelin, 75231 Paris, France), Lothar Bernire, Sidonie Hibral, Philippe Billant, and Thomas Folgot (Technople Brest Iroise, Brest, France)

We have developed a 12-kHz, 24-element rigid source receiver array [J. Acoust. Soc. Am. **117**, 2462 (2005)]. During sea trials in spring 2005, the array has been deployed in the Brest Bay, in a 12-m-deep channel. Backscattered data from a variety of submerged objects have been recorded for distances up to 1 km. After the description of the experimental setup and the acoustic propagation conditions, results from detection experiments using the DORT method will be presented. In particular, we will focus on separation of target echo from bottom reverberation as well as separation of two targets. Resolution and sensitivity aspects of the method

will be discussed and compared with results obtained with conventional beamforming. Furthermore, selective focusing by transmission of the eigenvectors of the time reversal operator will be shown. [Work supported by the French DGA/SPN under Contract No. 02 77 154 00 470 75 53.]

3:50

4pUW10. Source localization in deep ocean using matched double-path delay method. Yudong Liu (P.O. Box 67, Bin Hai St. No. 16, Dalian City, Liaoning Province, Post Code 116013, PROC, Liu_yudong@tom.com)

The relationship of matched-field processing (MFP) and multipath delay localization (MDL) is described in this paper. MDL is a kind of simplification of MFP. A method of analyzing multipath structure is presented in this paper. The coincidence between the theory prediction and experiment data shows that the method and program could be used to determine multipath time-delay structure. A realistic method called L2 norm match algorithm for MDL is developed. The depth-range ambiguous figures are pretty good. Comparison between the match method of absolute delay and relative delay shows that the performance of the latter is better. In the case of known source depth, a double-path match plan is given here. It is easy to determine the source distance from the range-delay curves. Many experiments have shown that the error is less than 6% within the range of 30 km and less than 10% within the range of 40 km. The influence caused by mismatch of ocean environment parameters and receiver configuration on double-path ranging is analyzed.

Session 4eAB

Animal Bioacoustics: Urban Bioacoustics

Andrea M. Simmons, Chair
Brown Univ., Dept. Psychology and Neuroscience, Box 1853, Providence, RI 02912

China Blue is an artist and innovator who works in a variety of media that focuses on sound and how it shapes space. Her current works are based on what she terms ''urban bioacoustics,'' recording activities from day-to-day life to examine sonic flow and energy. The current show includes two sound pieces: ''4 Ball Corner Pocket,'' uses spatial recording and post-production processing to capture and manipulate the acoustic element of a billiard game. The manipulated sound fields are presented through a 7.1 surround sound system to segregate the sounds in space. This creates a highly active sound environment that impresses on the viewer both the physicality and the dynamics of the game in a very primal manner. ''Mikey vs. Fabio,'' is a study of the acoustics of a ping-pong game presented in discrete stereo and mimicking the linearity of the two player game. It also immerses the listeners in both the spatialized dynamics of the ball and the human conversations punctuated by the play. She will also display a number of paintings of her visual interpretation of acoustic flow in different environments.

Session 5aAA

Architectural Acoustics: Current Topics in Measurement and Modeling

William M. Hartmann, Chair
Michigan State Univ., Dept. of Physics and Astronomy, East Lansing, MI 48824

Contributed Papers

8:00

5aAA1. An experimental study of how paint affects the specific airflow resistance and visual appearance of nonwoven scrims on acoustical ceiling tiles. William Frantz and Anthony Wiker (Armstrong World Industries Inc., 2500 Columbia Ave., Lancaster, PA 17604, whfrantz@armstrong.com)

This study explores how paint affects the specific airflow resistance and visual appearance of nonwoven scrims used on acoustical ceiling tile. Nine different scrims are included. Each scrim is finished with two application rates of paint. The specific airflow resistance is measured by the ASTM C522 method. The painted samples are also scanned and the images processed by ImagePro software to characterize visual aspects such as number of features, area of features, and roundness. It is found that specific airflow resistance and visual responses can be correlated to the resistance of the unpainted scrim, the surface tension characteristics of the scrim and paint, and the application rate of the paint. The resulting empirical models can be used to understand design tradeoffs between airflow resistance and visual impact.

8:15

5aAA2. Maximum length sequences versus random telegraph noise in measuring impulse responses and transfer functions. Neil L. Aaronson and William M. Hartmann (Dept. of Phys. and Astron., Michigan State Univ., 4230 BPS Bldg., East Lansing, MI, 48824)

Maximum length sequences (MLS) are commonly used to measure impulse responses and transfer functions of linear systems. The remarkable utility of the MLS comes from the property that its autocorrelation is approximately a delta function, and this approximation becomes more valid for higher orders (lengths) of MLS. However, the autocorrelation of a random telegraph noise (RTN) sequence also approaches a delta function in the long-sequence limit. Advances in computer hardware make it possible to use long sequences of RTN. Consequently one wonders if the MLS still confers an advantage. This study presents a quantitative analysis of the accuracy of MLS and RTN for all lengths up to $2^N-1=262{,}143$. RTN sequences were generated by scrambling the elements of an MLS. A special case wherein the approximate length of the impulse response is prior knowledge allows the measured impulse response to be windowed. Even with this advantage applied to RTN (but not to MLS), MLS measurements are clearly more accurate. The numerical experiments conclude than any MLS sequence longer than the impulse response outperforms a RTN of any practical order by an order of magnitude. [Work supported by the NIDCD grant DC 00181.]

8:30

5aAA3. Simulations of head-related transfer functions in wideband acoustics. Eira T. Seppälä, Ole Kirkeby, Asta Kärkkäinen, Leo Kärkkäinen (Nokia Res. Ctr., Itämerenkatu 11-13, FI-00180 Helsinki, Finland), and Tomi Huttunen (Univ. of Kuopio, Kuopio, Finland)

Head-related transfer functions (HRTFs) have been simulated in three dimensions for a head-and-torso model for the entire audio frequency range, from 20 Hz to 20 kHz. As opposed to data acquired through measurements, the results derived from computer simulations are free from the effects of noise and imperfections in the electro-acoustic chain. In addition, the spatial resolution can easily be made better than in any practical experiment. The simulations have been performed using an ultraweak variational formulation method for solving Helmholtz equation. The numerical method with its parallel computing capability is efficient, enabling numerical calculations of large physical systems, e.g., of size $0.4\times0.5\times0.8$ m, at high frequencies. The method uses plane-wave basis functions instead of polynomial basis as in standard finite-element methods (FEM), resulting in the need of much sparser volume mesh than in FEM. For HRTF calculations, a so-called perfectly matched layer has been utilized and the solutions are derived in the far field. Thus, exterior problems often solved using boundary-element method are dealt with. The specific HRTF simulations have been performed using fully reflecting, sound hard, boundaries on the head and torso, and also with complex impedance boundaries on the torso such as clothing.

8:45

5aAA4. Reverberation time, mean-free-path, and sound absorption in concert halls—Numerical examination by computer simulation. Takayuki Hidaka and Noriko Nishihara (Takenaka R&D Inst., 1-5-1, Otsuka, Inzai, Chiba 270-1395, Japan)

Sabine and Eyring equations are commonly used to estimate the reverberation time (RT) in concert halls. Derivations of the two equations are based on well-defined and different physical assumptions, and they are both slightly different from the realistic situation in halls. In many researches so far, comparatively simple room shape has been utilized to study the question of which equation is preferable. In this study, the sound fields in rooms with more complex or wide-ranging shape are numerically analyzed by applying the computer simulation technique and CAD models for architecture. Focusing on the fundamental relation between the mean free path as a physical measure of the room and the RT, validity of the two equations in actual halls is discussed. Next, the influence of the room shape or the choice of the RT equation on the effective sound absorption is examined.

9:00

5aAA5. A high-frequency broadband energy-intensity boundary element method for specular reflection in three-dimensional reverberant enclosures. Jerry W. Rouse, Linda P. Franzoni, and Donald B. Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708, linda.franzoni@duke.edu)

A new method is presented for predicting the spatial variation of mean-square pressure within three-dimensional enclosures having steady-state, high-frequency broadband sound fields. The enclosure boundaries are replaced by a continuous distribution of uncorrelated broadband directional sources, which provide constituent fields expressed in terms of mean-square pressure and time-averaged intensity variables. Boundary conditions for radiating and absorbing surfaces are recast in energy and intensity variables. Superposition of these source fields in a numerical boundary element formulation leads to the prediction of overall mean-square pressure and time-averaged intensity as a function of position. Both specular and diffuse reflection boundaries can be accommodated. In contrast to the traditional boundary element approach, this method is independent of frequency, and each element has multiple unknowns, namely the strengths of directivity harmonics. For verification, exact analytical solu-

tions for the mean-square pressure distribution in several model problem enclosures were obtained by modal sums and frequency integration and compared to the new method. The comparisons show the method is very accurate, and it is extremely computationally efficient in comparison to classical modal and boundary element approaches. Results also show that diffuse field methods do not provide an accurate simulation for specular reflection cases.

9:15

5aAA6. Energy-based field quantities in reverberation chamber measurements. David Nutter, Timothy Leishman, and JohnPaul Abbott (Brigham Young Univ., N247 ESC, Provo, UT 84602, dave_nutter@hotmail.com)

Traditional reverberation chamber measurements, such as sound power and sound absorption measurements, rely on the evaluation of acoustic pressure at many field positions. Other field quantities could be better suited for these applications if they had greater spatial uniformity and required fewer source-receiver positions to produce accurate measurement results. This paper explores the possibility of using energy-based field quantities for this purpose and provides several analytical and experimental results to show their benefits.

9:30

5aAA7. Analysis method for temporal decay of diffuse broadband sound fields in enclosures. Donald Bliss, Ben Manning, and Linda Franzoni (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708)

An analysis method to predict the behavior of time-dependent broadband diffuse sound fields in enclosures is described. A formulation utilizing time-dependent broadband energy-intensity boundary sources, including propagation time delays, is developed as a numerical boundary element method. An interpolation method is used to re-express the actual delays in terms of a discrete set of integer-multiple delays, thereby facilitating the numerical solution. The method is demonstrated for the prediction of temporal decay in interconnected one-dimensional channels and in two-dimensional enclosures. Temporal behavior is expressed in terms of a higher-dimensional eigenvalue/eigenmode problem, with boundary source strength distributions expressed as eigenmodes. In temporal decay from steady state, solutions exhibit rapid short-time spatial redistribution of energy, followed by long-time decay of a predominant spatial eigenmode. Long-time decay depends on behavior of the most slowly decaying eigenmode and the relative source-panel strengths do not depend on initial conditions. Short-time adjustment and decay depends on initial source characteristics and the relative distribution of absorbing material. An interesting feature of the short-time behavior is that the time-decaying eigenmodes are primarily a manifestation of energy redistribution rather than absorption.

9:45

5aAA8. Absorption-based scaling method to predict steady-state broadband sound fields in enclosures. Donald Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708), Jerry Rouse (Sandia Natl. Labs., Albuquerque, NM 87185-0847), and Linda Franzoni (Duke Univ., Durham, NC 27708)

An absorption-based analysis method is developed for steady-state broadband sound fields in enclosures having diffuse or specular reflection boundaries. The wall absorption is expressed as an overall spatially averaged value, with spatial variations around this mean. Interior pressures and intensities are expressed in a power series of the overall absorption, treated as a small parameter, thereby giving a separate problem at each order. The first problem has a uniform mean-square pressure level proportional to the reciprocal of the absorption parameter, as expected. The second problem gives a mean-square pressure and intensity distribution that is independent of the absorption parameter and is primarily responsible for the spatial variation of the reverberant field. This problem depends on the location of sources and the spatial distribution of absorption, but not absorption level. Higher-order problems proceed at powers of the absorption parameter, but are essentially small corrections to the primary spatial variation. The primary spatial variation problem is solved using two different methods. Although formally developed based on treating absorption as a small parameter, the method is demonstrated to work remarkably well in practice up to large absorptions, and to provide insight into the behavior and design of acoustic spaces.

Animal Bioacoustics and Psychological and Physiological Acoustics: Is Hearing All Cochlear?

Neil P. McAngus Todd, Chair

Univ. of Manchester, Psychology Dept., Oxford Rd., Manchester, M60 1QD, UK

Chair's Introduction—7:55

Invited Papers

8:00

5aABa1. Is all hearing cochlear?—revisited (again). Neil P. McAngus Todd (Faculty of Life Sci., Univ. of Manchester, M60 1QD, UK, neil.todd@manchester.ac.uk)

Over 70 years ago John Tait raised a question with regards to the certainty that the line of division between the hearing and vestibular portions of the VIIIth cranial nerve had been drawn at the proper place [J. Tait, Ann. Otol. Rhinol. Laryngol. **41**, 681–704 (1932)]. His reason for raising this question was the evidence which existed at that time that the otolith organs of anamniotes (fish and amphibians), most commonly the sacculus, were demonstrably organs of hearing in many species. He went on to speculate about a possible auditory role for the otolith organs in amniotes (reptiles, birds, and mammals), including in humans, although at this time there was no direct evidence for this. Since this time, however, there has developed a significant literature documenting evidence, not only for anamniote otolithic hearing, but also for a conserved acoustic sensitivity for the amniote otoliths. In the case of humans, this

5a FRI. AM

sensitivity has been exploited for the development of new acoustic tests of vestibular function. The time is ripe 70 years on, therefore, for us to revisit John Tait's question and explore the possibility that the sacculus may indeed contribute to human hearing. [Work supported by the Royal Society.]

8:25

5aABa2. Structure/function relationships in the saccule of fishes. Arthur N. Popper, Xiaohong Deng, David Zeddies (Dept. of Biol., Univ. of Maryland, College Park, MD 20742, apopper@umd.edu), and Mardi C. Hastings (Office of Naval Res., Arlington, VA 22203)

The saccule is morphologically the most diverse of the otolithic end organs among fish. Each otolithic end organ contains a sensory epithelium with numerous hair cells. The apical ends of the hair cell ciliary bundles contact a solid dense otolith. Relative motion between the sensory epithelium and otolith results in stimulation of the hair cells. Diversity in the saccule includes the overall shape and size of the end organ, the number of hair cells, the length of the ciliary bundles, and the shape and size of the otolith. Functionally, the saccule subserves both hearing and vestibular senses. There is some correlation between the orientation pattern of the sensory hair cells with whether fish are specialized for hearing or not. Yet, there is no real understanding of the relationship between structural diversity and functional differences. In effect, it is not known whether the structural diversity indicates adaptations for different auditory and/or vestibular functions, or whether the structural diversity reflects different ways for taxonomically and ecologically diverse fish to do similar ear functions. This talk will explore these issues using data from highly diverse deep-sea fish and direct measures of responses of the inner ear to sound.

8:50

5aABa3. Acoustically responsive fibers in the mammalian vestibular nerve. John J. Guinan, Jr. (Eaton Peabody Lab., Massachusetts Eye & Ear Infirmary, Harvard Med. School, 243 Charles St., Boston, MA 02114)

There are afferent fibers in the vestibular nerve of cats and guinea pigs that respond to sound at levels within the normal range of hearing. Most acoustically responsive fibers are in the inferior vestibular nerve and have irregular spontaneous activity, although not as irregular as cochlear afferents. Single-fiber labeling shows that acoustically responsive, irregularly discharging (ARID) fibers originate in the saccule. ARID fibers traced centrally arborized extensively in vestibular nuclei and ventromedial to the cochlear nucleus. ARID fibers had broad, V-shaped tuning curves with best frequencies between 500 and 1000 Hz, thresholds of 90 dB SPL or more, and shapes comparable with tuning-curve tails of cochlear afferents. ARID fibers synchronized to a preferred phase of the tone cycle at levels approximately 10 dB lower than their firing-rate threshold. ARID spike rates increased monotonically with sound level without saturating at 115 dB SPL. Acoustic clicks evoked spikes in ARID fibers with minimum latencies less than 1.0 ms. Contraction of the middle-ear muscles decreased responses to sound, consistent with the sound transmission path being through the middle ear. In summary, there is strong evidence that the mammalian saccule responds to sound and sends acoustic information to the central nervous system. [Work supported by NIDCD RO1DC00235.]

9:15

5aABa4. Assessing saccular (otolith) function in man. James G. Colebatch (Dept. of Neurol., Prince of Wales Hospital, Randwick Sydney, NSW 2031 Australia)

Scattered observations have suggest that the vestibular apparatus may have retained sound sensitivity in man and primates [e.g., Young *et al.*, Acta Otolaryngol. **84**, 352–360 (1977)]. In 1964 Bickford *et al.* [Ann. N.Y. Acad. Sci. **112**, 204–218 (1964)] reported the properties of the ''inion response,'' evoked by clicks and which in subsequent publications they deduced was likely to be arising from the saccule. Colebatch *et al.* [Colebatch, *et al.* J. Neurol. Neurosurg. Psychiatry **57**, 190–197 (1994)] reported a new method which reliably demonstrated a short latency vestibulocollic reflex evoked by clicks and recorded from sternocleidomastoid EMG. Consistent with previous evidence, the saccule was thought to be the most likely receptor to mediate the response, a conclusion for which there has been further experimental support. Bone-conducted acoustic stimulation can also evoke a similar reflex and, although saccular receptors are probably excited, this may not be the sole vestibular receptor activated under these conditions. The vestibular apparatus is relatively more sensitive to bone-conducted sound than to air-conducted sound, when compared to the cochlea. [Work supported by NH&MRC Australia.]

9:40

5aABa5. Central connections of anamniote auditory otolith endorgans. Catherine A. McCormick (Dept. Biol. and Dept. Neurosci., Oberlin College, Oberlin, OH, catherine.mccormick@oberlin.edu)

The ascending auditory pathways of anamniotes (fish and amphibians) are organized similarly to those of amniotes (reptiles, birds, and mammals). A common pattern for the flow of acoustic information—inner ear to first-order nuclei to higher-order auditory nuclei in the medulla, midbrain, thalamus, and cerebrum—probably evolved early in vertebrate history and was retained in extant fish and in terrestrial vertebrates (with taxon-specific modifications) despite variability in inner-ear acoustic receptors. Otolith endorgans subserve hearing in jawed fish; auditory fibers segregate from otolith endorgan vestibular fibers and supply auditory divisions of functionally mixed (auditory-vestibular) first-order nuclei. Amphibian auditory otolith endorgans are primarily seismic detectors complementing new sound-pressure receptors of the amphibian and basilar papillae. Otolithic and papillar auditory endorgans supply common areas within functionally mixed (auditory-vestibular) first-order nuclei. Uniquely in anurans, they also supply a discrete first-order auditory nucleus analogous to the amniote cochlear nuclei. Discrete first-order auditory nuclei are correlated with the evolution of a tympanic ear, an independently evolved condition in anurans and among amniotes. Thus, at the first-order level, the amphibian auditory pathway retains primitive organizational features present in fish auditory pathways. Convergent neuroanatomical specializations in anurans and amniotes may reflect common functional requirements.

10:05–10:20 Break

10:20

5aABa6. Evidence for near-field hearing in crocodilian vocal communication: Intensity of the American alligator (*Alligator mississippiensis*) vocal display. Neil P. McAngus Todd (Faculty of Life Sci., Univ. of Manchester, M60 1QD, UK, neil.todd@manchester.ac.uk)

The aim of this study was to carry out an acoustic analysis of alligator vocal displays recorded simultaneously in air and water in order to estimate the role of the sacculus in crocodilian acoustic communication. Crocodilians are interesting animals to study as they are aquatic, highly vocal, and morphologically have a large sacculus. Alligators, in particular, are known to be one of the most vocal species. Previous studies of alligator hearing in air and water have indicated a maximum sensitivity between 800 and 1000 Hz [Higgs *et al.*, J. Comp. Physiol. **188**, 217–223 (2002)]. Analysis of alligator vocalizations, however, indicates that most of the power in adult vocalizations in water is typically between 30–50 Hz. These results leave the very real possibility that the basilar papilla may not be the primary receptor during crocodilian water-borne communication. At 1-m distance peak SPLs of 140 dB can be obtained in water and, in conjunction with existing threshold data, the effective radius of saccular acoustic sensing of the above source can be estimated to be approximately 30 m, which is easily greater than the typical distance between performer and receiver animals during a display.

10:45

5aABa7. Saccular hearing in anurans. Seth S. Horowitz and Andrea M. Simmons (Dept Psych. & Neurosci., Brown Univ., Providence RI 02912)

Acoustic sensing in anurans is mediated by several inner ear organs, including the amphibian papilla, basillar papilla, and lagena. The contribution of the saccule to hearing in adult ranids tends to be constrained to vibration sensitivity and gravity sensing, although there has been some evidence for low-frequency hearing sensitivity as well. The organs that mediate hearing in larval ranids are less well understood. Several studies have postulated a strong role for saccular-mediated hearing in tadpoles, operating by the sensing of particle motion mediated by direct kinetic effects on otolithic organs (the fenestral pathway). Physiological studies show that, in tadpoles, the medial and lateral vestibular nuclei are sensitive to particle motion stimulation, while the dorsal medullary nucleus is more sensitive to pressure stimulation. Anatomical tract tracing with lipophilic cyanocarbanine dyes placed in the saccular branch of the eighth nerve show projections to both auditory and vestibular medullary nuclei, suggesting that input from the saccule may play a role in both particle and pressure sensation.

11:10

5aABa8. The sense of hearing mediated by the saccule in goldfish. Richard R. Fay (Dept. Psychol. and Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

The saccule mediates the sense of hearing for many fish species, goldfish (*Carassius auratus*) in particular. Motions of the swim bladder in response to pressure fluctuations impinge on the saccule of each ear, where auditory-nerve fibers project to medullar, midbrain, and forebrain nuclei in a circuit analogous to the ascending auditory system of tetrapods. It has been repeatedly shown over the past 40 years that the sense of hearing mediated by the saccule has many fundamental features in common with the sense of hearing of tetrapods. Detection and discrimination thresholds for goldfish are in the vertebrate range quantitatively, and are of the same sorts of simple and complex discriminations that mammals and other tetrapods can perform. Furthermore, goldfish behave as if the perceptual dimensions of spectral pitch, complex musical pitch, timbre, and roughness exist for them. Although goldfish do not vocalize, many fish species that hear using saccular input do vocalize (e.g., mormyrids), and have special adaptations for responding to vocalizations, like many tetrapods. Finally, goldfish have been shown capable of simultaneous stream segregation based on the same principles known for humans and other species. Thus, otolith organs can participate in a sense of hearing that is typical for vertebrates.

5aABa9. Are acoustically induced flows relevant in fish hearing? Charlotte W. Kotas, Peter H. Rogers, and Minami Yoda (Mech. Eng. Dept., Georgia Inst. of Technol., Atlanta, GA 30332-0405, charlotte.kotas@gatech.edu)

The fluid-filled fish ear contains an irregularly shaped, dense, bony otolith that influences the acoustically induced motion of the adjacent hair cells and thus what fish "hear." Because incident sound causes the otolith to oscillate with respect to its surroundings, acoustically induced fluid flows are generated near the otolith. A series of experiments was performed using oscillating spheroids as model otoliths to study the induced steady streaming and periodic flows. The studies focused on how the flows change with spheroid (or otolith) geometry and orientation, as well as oscillation (or sound) frequency ω and amplitude s. Experiments were conducted for Reynolds numbers $\mathrm{Re} \equiv \omega L^2/\nu < 10^2$ and amplitude ratios $\epsilon \equiv s/L = 0.05-0.2$, where L is the product of the spheroid aspect ratio and equivalent radius. Results will be presented for oblate and prolate spheroids oscillating at angles up to 45° relative to the spheroid's axis of symmetry and for flows induced by spheroids driven simultaneously at different frequencies. Understanding these flows may give insight into how fish localize sound sources and lead to new acoustic sensor designs. [Work supported by ONR.]

5aABa10. Saccular hearing; turtle model for a human prosthesis. Martin L. Lenhardt (Dept. of Biomed. Eng., Otolaryngol., and Emergency Medicine, Virginia Commonwealth Univ., Box 980168 MCV, Richmond, VA 23298-0168)

The saccule is a hearing organ is some vertebrates thought to be responsive to substrate vibration (bone conduction) or low-frequency aerial sound. There was likely some overlap in these functions in the course of evolution after the sensory area to become the cochlea migrated from the saccule. That overlap is preserved in extant turtles by columella (stapes) saccular coupling via fibroelastic strands; thus both organs can respond to air conduction and bone conduction stimulation. Evoked potential data, however, reflect differential AC/BC drive to the inner ear. The columellas inertia provides the force to displace the saccular wall with the tympanum

providing damping. Intense AC stimulation likely stimulates the human saccule. A proprietary stapedial saccular strut is described that serves as a surgically implanted coupling device for humans, allowing more efficient use of AC saccular hearing in clinical deafness. The human saccular resonance is about 350 Hz, which should allow for sufficient speech coding for intelligibility assuming connectivity to the auditory neuraxis. BC stimulation through audible ultrasound also likely activates the saccule in individuals with profound deafness. A stand-alone stapedio-saccular strut or one used in combination with an ultrasonic hearing aid offers the potential of communication through saccular hearing.

5aABb1. Online acoustic parameter extraction and annotation for a marine sound collection. Shelagh A. Smith and Jack W. Bradbury (Macaulay Library, Cornell Lab of Ornithology, Ithaca, NY 14850)

After 3 years of archival and with the collaboration of more than 20 researchers and institutions, the online marine sound collection at the Macaulay Library, Cornell Lab of Ornithology, is now in a proof of concept phase. This presentation introduces the new annotation and acoustic parameter extraction and retrieval tools. It is further explained how these tools are used for fine-grain searches and recovery of specific sounds within long recordings while online. Also included is a description of the online open access model and delivery mechanism. [Work supported by ONR and NSDL.]

8:15

5aABb2. Dynamic time warping for automatic classification of killer whale vocalizations. Judith C. Brown (Phys. Dept., Wellesley College, Wellesley, MA 02481 and Media Lab., MIT, Cambridge, MA 02139) and Patrick J. O. Miller (Univ. of St. Andrews, St. Andrews, Fife KY16 9QQ UK)

A large number of sounds from the captive killer whale population at Marineland of Antibes, France have been classified perceptually into call types. [A. Hodgins-Davis, thesis, Wellesley College (2004)]. The repetition rate of the pulsed component of five or more examples of each call type was calculated to give a set of melodic contours. These were compared pairwise using dynamic time warping to give a dissimilarity or distance matrix. The distances were then transformed into a component space using multidimensional scaling, and the resulting points clustered with a *k*-means algorithm. In grouping 57 sounds into 9 call types, there was a single discrepancy between the perceptual and automated methods. Preliminary measurements on a second set of 74 sounds from northern resident killer whales have been made. Both the high-frequency and low-frequency contours have been measured and classified perceptually into 7 groups. Errors for the automatic classification of this group are over 10%. [Sound recording supported by grants from WHOI's Ocean Life Institute and the Royal Society to Patrick J. O. Miller.]

8:30

5aABb3. Probability distributions for locations of calling animals, receivers, sound speeds, winds, and data from travel time differences. John Spiesberger (Dept. of Earth and Environ. Sci., Univ. of Pennsylvania, 240 S. 33rd St., Philadelphia, PA 19104-6316, johnsr@sas.upenn.edu)

A new, nonlinear sequential Monte Carlo technique is used to estimate *posterior* probability distributions for the location of a calling animal, the locations of acoustic receivers, sound speeds, winds, and the differences in sonic travel time between pairs of receivers from measurements of those differences, while adopting realistic *prior* distributions of the variables. Other algorithms in the literature appear to be too inefficient to yield distributions for this large number of variables (up to 41) without recourse to a linear approximation. The new technique overcomes the computational inefficiency of other algorithms because it does not sequentially propagate the joint probability distribution of the variables between adjacent data. Instead, the lower and upper bounds of the distributions are propagated. The technique is applied to commonly encountered problems that were previously intractable, such as estimating how accurately sound speed and poorly known initial locations of receivers can be estimated from the differences in sonic travel time from calling animals, while explicitly modeling distributions of *all* the variables in the problem. In both cases, the new technique yields one or two orders of magnitude improvement compared with initial uncertainties. The technique is suitable for accurately estimating receiver locations from animal calls.

8:45

5aABb4. Automatic call recognition of cricket songs using image processing. T. Scott Brandes (Tropical Ecology Assessment and Monitoring (TEAM) Initiative, Conservation Intl., 1919 M St., NW, Washington, DC 20036), Piotr Naskrecki (Harvard Univ., Cambridge, MA 02138), and Harold K. Figueroa (Cornell Lab. of Ornithology, Ithaca, NY 14850)

An automatic call recognition (ACR) process is described that uses image processing techniques on spectrogram images to detect constant-frequency cricket calls recorded amidst a background of evening sounds found in a lowland Costa Rican rainforest. This process involves using image blur filters along with binary filters to isolate calling events. The binary filters are used to isolate potential calls from background noise, and the blur filters are used to unite discrete call fragments as a single continuous call. Features of these events, notably the events central frequency, duration, and bandwidth, along with the type of blur filter applied, are used with a Bayesian classifier to make identifications of the different calls. Of the 22 distinct sonotypes (calls presumed to be species specific)

recorded in the study site, 17 of them are recorded in high enough numbers to both train and test the classifier. The classifier approaches 100% true-positive accuracy for these 17 sonotypes. The high true-positive accuracy of this process enables its use for monitoring singing crickets in tropical forests.

5aABb5. Feature normalization for robust individual identification of the ortolan bunting (*emberiza hortulana L*). Kuntoro Adi and Michael T. Johnson (Dept. of Elec. and Comput. Eng., Marquette Univ., Milwaukee, WI 53201, kuntoro.adi@marquette.edu)

This paper presents the use of cepstral moment normalization for the purpose of improving the accuracy of individual identification in the ortolan bunting (*emberiza hortulana L*). The underlying classification algorithm is based on hidden markov models (HMMs) using Greenwood function cepstral coefficients (GFCCs), and the proposed feature normalization is implemented via a combination of cepstral mean subtraction and cepstral variance normalization, which are equivalent to a statistical z-score normalization across each example utterance. Results indicate a significant reduction in error on the individual identification task, improving accuracy from 89% to 96% in initial experiments, using a single call type over a small population of 6 individuals.

9:15

5aABb6. Characteristics of nonlinear phenomena in the tonal vocalizations of a North American canid, *Canis rufus*. Jennifer N. Schneider (Dept. of Psych., Univ. of Buffalo, Park Hall Rm. 206, Buffalo, NY, 14260), Rita E. Anderson, and Edward H. Miller (Memorial Univ. of NF, St. Johns, NF, A1B 3X9 Canada)

This study examines the structure and frequency of occurrence of nonlinear phenomena found in tonal vocalizations produced by red wolves. Spectrograms were obtained from audio tracks of digital video recordings of captive wolves from a breeding facility in Graham, WA. Tonal vocalizations were determined to be composed of 1–30 sound units, arranged in 1–5 phrases. Linear units included squeaks (2600–9600 Hz) and wuhs (100–1600 Hz); nonlinear units accounted for 22% of sounds and included between-type frequency jumps, harmonic and pure-tone biphonations, squeaks with sidebands, and squeak jumps. Five tonal vocalization types were identified based on unit composition: squeaks (48.4%), wuhs (19.3%), and three mixed vocalizations: banded squeaks (13.2%), complex squeaks (6.4%), and squeak-wuhs (12.2%). Unit order within a squeak-wuh vocalization was not random; transitions between units following a structural gradient most likely begin with higher frequency units and end with mixed or lower frequency units. The production of nonlinear sounds varied within and between individuals. The linear and nonlinear structure of red wolf tonal vocalizations are similar to that which has been reported in dholes and African wild dogs, and which have been indicated in reviews of published sonograms of gray wolf vocalizations.

5aABb7. Equine acoustics: Further analysis of a whinny—The expressive component. David G. Browning (Dept. of Phys., Univ. of Rhode Island, Kingston, RI 02881, decibeldb@aol.com) and Peter M. Scheifele (Univ. of Connecticut, Storrs, CT 06269)

A horse's whinny appears to be a very interesting vocalization. Initial acoustic analysis suggested two principal components, one ''emotional'' and the other ''expressive.'' The first seems to follow Morton's criterion: increasing frequency with emotional state. The second component, since many suggest that a whinny is not a threatening gesture, has the potential for a number of specific expressions for such situations as ''calling'' or ''greeting.'' This paper describes the present indications as the data base slowly increases.

9:45

5aABb8. Discovery of Sound in the Sea website: An educational resource. Kathleen J. Vigness Raposa (Marine Acoust., Inc., 809 Aquidneck Ave., Middletown, RI 02842, kvigness@aol.com), Gail Scowcroft, Jill Johnen, Chris Knowlton (Univ. of Rhode Island, Narragansett, RI 02882), and Peter F. Worcester (Univ. of California—San Diego, La Jolla, CA 92093-0225)

The scientific community and the public have become increasingly aware of, and concerned about, underwater sound. There is increasing interest in learning about sources and uses of sound, and potential effects of sound on the marine environment. The Discovery of Sound in the Sea website (http://www.dosits.org) provides scientific information for the general public and K–16 educators and students. It also includes advanced level content appropriate for high school physics or undergraduate classes. The website has three major sections, (1) Science of Sound in the Sea, (2) People and Sound in the Sea, and (3) Animals and Sound in the Sea, introducing the physical science of underwater sound and how people and animals use sound to accomplish various tasks. The Animals and Sound section also summarizes the current state of knowledge of the effects of underwater sound on marine mammals and fishes. Three galleries contain a collection of underwater sounds (Audio Gallery), video interviews with researchers (Scientist Gallery), and descriptions of acoustic equipment (Technology Gallery). Additions to the website are ongoing. Scientists with recordings and/or equipment that have not been included are encouraged to contact the authors. A limited number of free CDs of the website will be available.

Animal Bioacoustics: Acoustic Sensing of Animals

Jennifer L. Miksis-Olds, Chair

Univ. of Rhode Island, Graduate School of Ocean Biology, Narragansett, RI 02882

10:15

5aABc1. Tracking fish motion and behavior with acoustic flow. Srinivasan Jagannathan, Deanelle Symonds, Sunwoong Lee, Nicholas C. Makris (MIT, Cambridge, MA 02139), Ninos Donabed, and Purnima Ratilal (Northeastern Univ., Boston, MA 02115)

Fish populations in the New Jersey continental shelf have been continuously monitored over thousands of square kilometers using acoustic waveguide remote sensing techniques [Makris *et al.*, ''Fish population and behavior revealed by instantaneous continental-shelf-scale imaging,'' Science **311**, 660–663 (2006)]. Here, we explore the approaches for tracking both large shoals and smaller isolated fish groups over space and time from images of fish population density. One method uses density thresholds to segment coherent population centers and track their centroids. These data are then used to compute differential velocities between population centers and to determine the rate at which information may be transmitted across a population center. We also examine the possibility of applying optical flow concepts from machine vision [Horn, B. *Robot Vi-*

5a FRI. AM

sion, MIT Press, 1986], as a global approach for estimating fish velocity at every pixel in the fish density image. The analogous acoustic flow is computed based on changes in acoustic intensity over space and time. Acoustic flow automatically tracks fish motion within a school or shoal and migration across fish bridges connecting shoals segments. We also investigate the possibility of using acoustic flow for navigating the ocean environment and correcting for errors in charting acoustic returns, for instance caused by array-heading sensor.

10:30

5aABc2. The roles of density, geometry, and short-range positional order in low-frequency acoustic scattering from fish schools. Thomas R. Hahn and Tanos Elfouhaily (RSMAS, AMP, Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149)

Fish can be efficient scatterers of low-frequency underwater sound. This results from the large response of their swim bladders to incoming acoustic waves at frequencies close to their natural resonance frequencies. For large and densely packed fish schools the scattering returns deviate significantly from what could be expected by adding the individual fish returns. These deviations are caused by multiple scattering between the individual fish in the school and concern the target strength as well as the spectral and directional characteristics of the scattering cross sections. Acoustically, a fish school can be viewed as a single object with acoustic bulk parameters determined from the properties of the individual fish and their positional arrangement in the school. This effective medium approach incorporates the acoustic coupling of all fish due to multiple scattering and works for a wide range of fish sizes, -numbers, and -densities. In this study, the effective medium approach as well as numerical computations from first physical principles are employed to investigate the coherent and diffusive low-frequency scattering cross sections of large and dense fish schools as a function of fish density, school geometry, and positional order among the individual fish. Inversions for these parameters are explored.

10:45

5aABc3. Assessing fish populations and enhancing biological detection in continental shelf environments with range-dependent scattering and reverberation models. Mark Andrews, Ameya Galinde, Ninos Donabed, Purnima Ratilal (Northeastern Univ., 360 Huntington Ave, Boston, MA 02115), Tianrun Chen, Deanelle Symonds, Sunwoong Lee, and Nick Makris (MIT, Cambridge, MA 02139)

Fish populations in continental shelf environments can be continuously imaged over thousands of square kilometers using acoustic waveguide remote sensing techniques [Makris *et al.*, Science, Feb. (2006)]. A calibrated range-dependent scattering and reverberation model [Ratilal *et al.*, J. Acoust. Soc. Am. **114**, 2302 (2003)] based on the parabolic equation has been applied to assess population densities of fish by inverting long-range acoustic data collected on the New Jersey continental shelf. This model is now applied to predict the types of fish species and zooplankton that are detectable in a general range-dependent continental shelf environment, including the resolution and accuracy that can be expected in estimating fish population densities and for differentiating fish species. We consider different geometries of the source and receiving array to enhance biological detection and reduce background reverberation in highly range-dependent environments. Using multiple source frequencies, the possibility of distinguishing fish species based on their differing scattering characteristics and resonance frequencies will be examined.

11:00

5aABc4. Integrated marine mammal monitoring and protection system: Gray whale target strength measurements. Irena Lucifredi, Amy Vandiver, and Peter Stein (Scientific Solutions Inc., 99 Perimeter Rd., Nashua, NH 03063)

With a broader objective of establishing a global solution for systematic assessment and protection of the marine environment, one of the central objectives of this work is to distinguish whale backscattered responses from the ones generated by the environmental clutter in a waveguide. Furthermore, it aims to identify and analyze the target signature features that are necessary for enhanced active sonar detection and classification of marine mammals. Over the years there have been very few documented attempts to capture and analyze the backscattering response of whales using an active sonar system. Nevertheless, whales, mostly owing to their size, their motion, and the aspect dependence of their backscattered field, possess desirable properties that help distinguish their scattered response from clutter and other environment related false alarms. As an initial step, data collected during the Marine Mammal Active Sonar Test (MAST04) is presented, and long-range gray whale target strength measurements are obtained. Results are compared to the previously published whale target strengths. Additionally, an investigation is conducted in an effort to provide whale feature identification points suitable for automated detection and classification, as a means of relating gray whale active acoustic signatures to their inherent characteristics and motion. [Work supported by ONR.]

11:15

5aABc5. Initial application of spectrogram-based cross correlation to the localization of Orcas. Martin C. Renken (Naval Undersea Warfare Ctr. Div. Keyport, 610 Dowell St., Keyport, WA 98345-7610, renkenmc@kpt.nuwc.navy.mil)

Localization and tracking of sperm whales (*Physeter macrocephalus*) and pilot whales (*Globicephala macrorhynchus*) has been demonstrated using the widely spaced bottom-mounted hydrophone arrays located at the Atlantic Undersea Testing and Evaluation Center (AUTEC), Andros Island, Bahamas [Moretti *et al.*, US Navy J. Und. Acoustics **52**, 651–668 (2002)]. The marine mammal monitoring utilizes a cross correlation of the spectrogram calculated from acoustic calls received at each hydrophone. The spectrogram information is combined with time of arrival pattern estimates to identify specific animals in order to estimate the animal's position through triangulation. This paper explores the initial application of these techniques to the wide variety of acoustic vocalizations recorded from transient killer whales (*Orcinus Orca*) in Dabob Bay of Washington state's inland waters in February of 2005. The recordings were made from a bottom-mounted linear array of hydrophones during a period of low acoustic interference. While this recording was obtained by Naval Undersea Warfare Center Keyport, active operations are not conducted in the presence of whales according to standard operating policy. Monitoring in the Dabob Bay Naval Operating Area is carried out both visually and acoustically by range operators trained in marine mammal identification by NOAA.

11:30

5aABc6. Modeling of acoustically enhanced bubble growth in supersaturated biological media. Yurii A. Ilinskii, Mark F. Hamilton, and Preston S. Wilson (Appl. Res. Labs., Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

Recent measurements and predictions of dissolved nitrogen concentration in tissues of dolphins and whales following repeated dives have indicated that the gas concentration may reach 300% of saturation [Houser *et al.*, "Can diving-induced tissue nitrogen supersaturation increase the chance of acoustically driven bubble growth in marine mammals?," J. Theor. Biol. **213**, 183–195 (2001)]. This has generated renewed interest in whether underwater sound may increase the likelihood of decompression sickness in these cetaceans. One potential mechanism is bubble growth due to rectified diffusion. Eller and Flynn ["Rectified diffusion during nonlinear pulsations of cavitation bubbles," J. Acoust. Soc. Am. **37**, 493–503 (1965)] modeled rectified diffusion by solving a Rayleigh-Plesset equation for the acoustically driven bubble dynamics, coupled to a quasi-analytical diffusion model that accounts for increase of the equilibrium bubble radius. Crum and Mao ["Acoustically enhanced bubble growth at low frequencies and its implications for human diver and marine mammal," J. Acoust. Soc. Am. **99**, 2898–2907 (1996)] used similar models to consider dissolved gas saturations up to 223% and demonstrated significantly enhanced bubble growth at sound-pressure levels above 210 dB (re: 1 μPa). We are revisiting this problem by extending these models and considering wider ranges of parameters. A principal difference is that the gas diffusion is modeled by solving the full partial differential equation

numerically. Not only does this approach circumvent analytical approximations, it permits taking into account variations in gas concentration associated with dive-profile-dependent hydrostatic pressure variations. [Work supported by ONR.]

11:45

5aABc7. Physics-based volume clutter from GeoClutter biological distributions. Adam Frankel (Marine Acoustics Inc., 706 Giddings Ave., Ste. 1C, Annapolis, MD 21401), Richard H. Love (12315 Fairway Meadows Dr., Fort Worth, TX 76179), Charles Monjo, Bruce Newhall, Juan I. Arvelo, Jr. (Johns Hopkins Univ., Laurel, MD 20723-6099), and William T. Ellison (Marine Acoustics Inc., Litchfield, CT 06759)

Empirical fish species composition and distribution data obtained during a GeoClutter survey were input into scattering models for marine mammals [Love, J. Acoust. Soc. Am. **49**, 816–823 (1971)] and for schools of fish [Feuillade *et al.*, J. Acoust. Soc. Am. 99, 196–208 (1996)]. These scattering models drew additional inputs from a database of biological parameters to generate volume clutter simulations. Model inputs included distribution of fish size, school population size, depth, orientation, and location. The volume clutter model treated each fish school and individual marine mammal as discrete acoustic targets. Motion of the dominant marine organisms (in addition to source and receiver motion) was taken into account to observe clutter map variability during a series of pings. The volume clutter distribution from this physics-based approach was compared against bottom clutter and against measured clutter-rich reverberation from the GeoClutter experiment. [The Office of Naval Research (ONR) is sponsoring this effort.]

FRIDAY MORNING, 9 JUNE 2006 ROOM 553AB, 9:00 TO 11:30 A.M.

Biomedical Ultrasound/Bioresponse to Vibration: Targeted Contrast Agents

Tyrone M. Porter, Chair

Univ. of Cincinnati, Biomedical Engineering, Medical Sciences, 231 Albert Sabin Way, Cincinnati, OH 45267-0586

Invited Papers

9:00

5aBB1. Treatment of ischemic stroke with nanobubbles and ultrasound. Evan C. Unger (ImaRx Therapeutics, Inc., 1635 E. 18th St., Tucson, AZ 85719)

The use of perfluorocarbon-filled microbubbles for ultrasound contrast imaging is well known. Now, the next generation of perfluorocarbon-filled bubbles has reached nanoscale and will be evaluated in clinical trials for the dissolution of blood clots in ischemic stroke and other vascular occlusions. MRX-815 nanobubbles are submicron, lipid coated, perfluorocarbon nanobubbles. Due to their small size they are able to penetrate a thrombus. Since they share a lineage with ultrasound contrast agents, their progress can be monitored on diagnostic ultrasound and once they have reached the site of thrombosis ultrasound can be applied externally to activate the bubbles. This activation consists of the bubbles oscillating in the field of ultrasound and cavitating. This mechanical energy works to dissolve the clot and restore blood flow to the ischemic tissues beyond. This process, SonoLysis® therapy, can be used in tandem with lytic agents or can be used alone in cases where lytic agents are contraindicated. A multicenter, Phase II clinical trial is currently evaluating SonoLysisregistered in the treatment of acute ischemic stroke. Preliminary findings have been encouraging and additional studies are planned.

9:30

5aBB2. Echogenic targeted liposomes for transfection and drug delivery. David D. McPherson (Northwestern Univ., 251 East Huron, Galter 8-230, Chicago, IL 60611, d-mcpherson@northwestern.edu)

We have developed targeted, echogenic immunoliposomes. These agents are lipid based, can be targeted to cells, and have encapsulated air bubbles that render them echogenic, and the air bubbles can also be used as cavitation agents. They have the ability to encapsulate drugs and genes. We have developed stable formulations and optimized attachment of antibodies and peptides for targeted molecular imaging using ultrasound. We are determining the pharmacokinetics of drug and gene entrapment and the ultrasonic destruction threshold for therapeutic delivery. With the enclosed cavitation agent, therapeutic ultrasound (sonoporation) potentiates cellular drug and gene delivery. This presentation will focus on optimizing the liposomes for stability, targeting, drug entrapment and release, destruction threshold, and the additive sonoporation effect of the encapsulated cavitation nucleii. Tissue plasminogen activator and papaverine are prototype drugs and beta-galactosidase is the prototype gene for encapsulation. The objective of this work is to use modifications of our echogenic immunoliposomes to better entrap and release drugs and genes, while utilizing the enclosed cavitation nucleii, which allows ultrasound to not only release the drug/gene, but also improve its delivery.

10:00–10:15 Break

10:15

5aBB3. Gas-filled microbubbles—Contrast agents for targeted molecular imaging. Alexander L. Klibanov, John Hossack, Yun K. Cho, William C. Yang, Joshua J. Rychak, and Klaus F. Ley (Univ. of Virginia, Charlottesville, VA 22908)

Microbubble contrast agents suitable for targeted molecular imaging have been described. Commonly used agents are gas-filled micron-size bubbles. Targeting ligands (antibodies, peptides, or proteoglycans) are coupled to the contrast particles and ensure firm attachment of microbubbles to intravascular regions of interest. Targeting is directed to selectins or integrins upregulated on vascular endothelium in the areas of pathology (inflammation, ischemia-reperfusion injury, or angiogenesis). Real-time imaging has been performed in animal models with sub-millimeter spatial resolution. Detection sensitivity for targeted microbubble contrast is superb: single bubbles (pg mass) can be visualized by ultrasound. Successful retention of microbubbles on the target is dependent on the target receptor surface density as well as targeting ligand surface density on the bubbles. To improve targeting efficacy, microbubbles can be outfitted with fast-binding ligands (such as P-selectin glycoprotein ligand-1 analogs) in addition to slow but firmly binding ligands (such as antibodies). Ultrasound irradiation also improves efficacy of targeting, especially in high shear conditions. In addition to imaging, microbubbles can be applied for drug and gene delivery purposes: interaction of ultrasound and bubbles can be used for in situ targeted deposition, activation and release of pharmaceutical agents [Disclosures: ALK, JJR, and KFL: Targeson stock ownership. ALK: Philips Research grant.]

10:45

5aBB4. Nonlinear oscillation of microbubble in microtubes for ultrasound imaging and drug delivery. Shengping Qin and Katherine Ferrara (Dept. of Biomed. Eng., Univ. of California, 451 East Health Sci. Dr., Davis, CA 95616)

Ultrasound-assisted microbubble drug delivery is under intensive investigation due to the potential for enhanced local delivery without systemic adverse effects. The efforts in modeling bubble oscillation have been largely focused on using various modified forms of the Rayleigh-Plesset bubble dynamics equation, of which the cornerstone assumption is that a bubble oscillates in an unbounded liquid field and remains spherical until it collapses. Here, nonlinear oscillation of a bubble confined inside a microtube with diameters comparable with capillaries is studied numerically and experimentally. In numerical simulation, the liquid is treated as incompressible viscid fluid and contrast agent is treated as gas bubble obeying the polytropic law. Microbubble oscillation is shown to decrease in a small vessel as compared with oscillation in an infinite fluid or a larger vessel diameter. For the same bubble size, the natural oscillation frequency of a bubble deceases with the decrease of tube size. The natural frequency of a bubble with an equilibrium diameter of 2.5 μm decreases from 3.56 MHz, in unbounded liquid field, to 1.16 MHz in an 8-μm tube. Decreasing the ultrasound center frequency can increase the amplitude of bubble oscillation and thereby produce a higher pressure on the tube.

11:00

5aBB5. *In vitro* and *in vivo* high-frequency ultrasound response of microbubbles. Orlando Aristizábal, Daniel H. Turnbull (Skirball Inst. of Biomolecular Medicine, New York Univ. School of Medicine, 540 First Ave., New York, NY 10016, oarist@saturn.med.nyu.edu), and Jeffrey A. Ketterling (Riverside Res. Inst., New York, NY 10038)

Recently, there has been a growing interest in utilizing contrast agents with high-frequency ultrasound (HFU $>$ 20 MHz). As a first step to using contrast agents *in vivo* with HFU, the acoustic response of several agents was examined using a 40-MHz ultrasound biomicroscope (UBM, Vevo 770, VisualSonics). Optison, Definity, and near-micron and submicron agents from Point Biomedical were investigated. A small volume of the agents was injected into a petri dish of saline solution, and radio-frequency (rf) backscatter data from the UBM were digitized with a digital oscilloscope. Agents were also injected into the cardiovascular system of mouse embryos and rf data were acquired *in vivo*. The echo signals from individual bubbles were windowed in the rf data and the spectra were calculated. The resulting spectra revealed an increasing harmonic content for each of the agents as the acoustic drive amplitude and number of excitation wavelengths increased. Harmonic generation appeared to be due mainly to nonlinear propagation in the water bath and not from a nonlinear response of the contrast agent because reflected spectra without contrast agent showed similar harmonics. Using a modified parameter imaging method, fundamental (40 MHz) and first-harmonic (80 MHz) images were generated.

11:15

5aBB6. Molecular imaging and therapy with perfluorocarbon-based site targeted contrast nanoparticles. Kirk D. Wallace, Michael S. Hughes, Jon N. Marsh, Kathryn C. Crowder, Huiying Zhang, Samuel A. Wickline, and Gregory M. Lanza (Dept. of Medicine, Washington Univ. St. Louis, MO 63130, kirk.wallace@wustl.edu)

Advances in molecular biology and cellular biochemistry are providing new opportunities for diagnostic medical imaging to ''see'' beyond the anatomical manifestations of disease to the earliest biochemical signatures of disease. The emerging field of ''molecular imaging'' encompasses the noninvasive *in vivo* diagnosis of complex pathological processes by detection of unique molecular signatures. Localization of specific biochemical epitopes with targeted contrast agents affords the unique opportunity for both targeted delivery and deposition of therapeutics. Liquid perfluorooctylbromide nanoparticles (approximately 250 nm mean diameter) elicit little acoustic reflectivity in suspension and strong acoustic contrast when bound and concentrated on a surface (e.g., fibrin deposits in a thrombus). This nanoparticle platform may be functionalized with homing ligands, like anti-$\alpha v \beta 3$ integrins, and therapeutic agents. Acoustic imaging of densely distributed biomarkers (e.g., fibrin epitopes) is readily accommodated with fundamental imaging, but for sparse biomarkers (e.g., integrins) we have developed and implemented complementary, nonlinear imaging techniques based upon information-theoretic receivers. Moreover, perfluorocarbon nanoparticles also offer targeted drug delivery, based on contact facilitated lipid exchange, which can be further augmented by ultrasonic insonification.

Invited Papers

8:00

5aMU1. Musical coffee mugs, singing machines, and laptop orchestras: New paradigms for musical expression. Perry Cook (Comput. Sci., Princeton Univ., 35 Olden St., Princeton, NJ 08544)

Advances in algorithms, hardware, and sensors now allow us to build new types of expressive musical devices based around small computer systems. These new ''instruments'' can leverage and extend the expertise of virtuoso performers, expand the palette of sounds available to composers, and encourage new ideas and participation from the young or the musically untrained. New musical instuments can take the form of augmentations of traditional musical instruments, whimsical objects made by augmenting everyday nonmusical objects, or entirely new paradigms for making and controlling sound. Wired and wireless networking can provide opportunities, yet pose significant challenges, for new forms of ''orchestral'' expression. This talk will look at a variety of musical technologies, devices, systems, compositions, and performances we have created at Princeton in the last 10 years or so. Lots of audio/video examples, as well as actual live demonstratons, will be presented.

8:30

5aMU2. Mapping strategies for sound synthesis, digital audio effects, and sonification of performer gestures. Vincent Verfaille and Marcelo M. Wanderley (SPCL & IDMIL, Music Technol. Area, McGill Univ., 555 Sherbrooke St. West, Montreal, Canada, H3A 1E3)

Mapping strategies are an essential step when designing realtime musical performance systems, as well as offline digital sound processing. These strategies define how we relate input device parameters to sound synthesis or audio effect parameters. This implies the ability to combine input parameters among themselves (parameter combination) and valid control signals in terms of range, variation type, etc. (signal conditioning). Recent works highlighted the interest of multi-layer mapping strategies in the context of digital musical instruments, which can also be applied in the context digital audio effects. In this presentation, three strategies will be discussed in order to illustrate the role of mapping strategies in various contexts. The first example concerns an additive synthesizer called *Ssynth*, a further development of *Escher*, a prototyping system aiming at studying the effect of mapping strategy in instrument design. The second example is a general mapping strategy for digital audio effects, allowing for both adaptive and gestural control. The final example concerns sonification of gestures, used to provide cues about ancillary movements of performers. For each example, mapping strategies will be explained in terms of their structure and functionality. [Work supported by FQRNT and MDEIE PSR-SIIRI (Québec, Canada), CNRS and PACA (France).]

9:00

5aMU3. On the evolution of controllers for sound spatialization. Jonas Braasch (Program in Architectural Acoust., Rensselaer Polytechnic Inst., Troy, NY 12180)

Dynamic changes in spatial sound attributes have played a role in classical Western music for a long time. It is known that choreographic movements of opera singers were sometimes made for acoustic considerations. Probably the first mechanical spatial sound controller is the so-called wind swell that is found in pipe organs. Already in 1712, Renatus Harris mentions how *swelling* enables the player to project the sound of the pipes *ad libitum* to nearby or further distances. With the invention of electroacoustic music, a number of electromechanical devices were developed to control spatial aspects of sound (primarily positioning sound sources in 3-D space). Typical examples are Stockhausen's rotational table (developed in the 1950s) and Manfred Krause's sound mill (1960). In this presentation, the evolutionary steps in the design of spatial sound controllers will be outlined—beginning with early, purely mechanical devices up to recent approaches including the author's participation in the development of a gestural controllable sound system based on virtual microphone control (ViMiC).

9:30

5aMU4. Deriving individualized control over music synthesis via inversion of psychophysical scaling results. William L. Martens (Schulich School of Music, McGill Univ., Montreal, QC, Canada)

Computer-based interactive music generation systems have an advantage over acoustic instruments with respect to the flexibility of the human interface for their control. Whereas human performers must conform to the relatively invariant constraints of acoustic instruments, a computer interface can be rapidly updated with regard to changes in user preferences and performance requirements.

This paper will describe a software environment that executes miniature psychophysical scaling experiments for a single user of an interactive music generation system in order to derive individualized control over music synthesis via inversion of the obtained psychophysical scaling results. A case study will be presented in which the system has been used to control parametric synthesis of musical timbres using an electronic musical keyboard, providing automatic perceptual mapping of synthesis parameters within their musically useful range. More in-depth exploration of the timbral similarities between a user-selected set of synthesis patches resulted in low-dimensional control structures that could be used to organize musical timbres in preparation for composition or performance.

5aMU5. The method for capturing tilt signal of musical instruments using light sensor. Moonseok Kim (CCRMA, Dept. of Music, Stanford Univ., Stanford, CA 94305-8180)

Players of musical instruments used to express their intuition and emotion not only by playing style but also the motion of the instrument's body. Furthermore, on the ensemble, this gesture plays a role as a language to communicate to each other. Substituting some players for a computer is one part of the information to make interactions between human players and computer. To get them, tilt sensors which catch accelerations are used in general. They are used to generate underdamped signal and have to apply LPF for acquiring stable responses. This method results in delay and may affect temporal difficulties on ensemble. If the light source of the performance room is directional, the light intensity signal that is caught at photoresistors on two or more points of the instrument's surface can be used to calculate the amount of tilting. The photoresistor senses the light intensity which is determined by the distance from the light source, and differences on each value represent relative angle according to the light source direction.

10:30

5aMU6. Time marching spectral analysis of a swept sine melody model. Rama B. Bhat (Concordia Univ., 1455 de Maisonneuve West, QC H3G 1M8, Canada)

A melody is a progression of musical notes in a scale. Since the notes have identified frequencies, a melody rendering involves a quick sweep of frequencies between any two neighboring notes, and a dwell at the notes. A melody rendering is modeled as a dwell at the notes and a sinusoidal sweep in between. A time marching spectral analysis shows that the dwell time and the rate of sweep between notes have significant influence on the melody. Any two notes form the not-so-high harmonics of a periodic process which may or may not necessarily contain the fundamental and some of the lower harmonics. If a three-note combination of a first, a fifth, and an octave higher notes are taken, as the drone in Indian classical music, they have ratios of 1:3/2:2. The combination is a periodic process with half of the first note frequency as the fundamental which is missing, while the second, third, and fourth harmonics are present. A melodic rendering of seven notes or less may be construed as a periodic process with some of the harmonics varying or dancing with time. Results on a melody in pentatonic scale is presented and discussed.

10:45

5aMU7. Ignoring irrelevant dimension variability in frequency discrimination. Blas Espinoza-Varas (Commun. Sci. and Disord., OU Health Sci. Ctr., Oklahoma City, OK 73190), Hyunsook Jang (Hallym Univ., Chuncheon, South Korea), and Praveen Jajoria (OU Health Sci. Ctr., Oklahoma City, OK 73190)

The ability to ignore variability in irrelevant dimensions while attending to pitch plays a significant role in music perception. In frequency-discrimination tasks, this study examined how this ability depends on four factors: the presentation order and time proximity of target and irrelevant dimensions, the dimension conveying irrelevant variability, and training. Each observation interval displayed pairs consisting of a target (T) followed by a nontarget sinusoid (N) or the reverse (N leading T), with 20–250-ms interstimulus intervals (ISI). Frequency discrimination thresholds (FDTs) were measured in the presence or absence of irrelevant variability in the frequency, duration, or level of either T or N. The ability to ignore irrelevant variability depended on all four factors studied. Irrelevant variability in frequency or level of trailing N tones induced large and persistent elevations in the initial FDTs, especially at short ISIs. Irrelevant variability in T or N duration, T level, or leading N-tone frequency yielded only small and transient FDT elevations. With T-N pairs, irrelevant variability was harder to ignore when it was displayed after, rather than simultaneously with, the target increment. Prolonged training in irrelevant-variability conditions nullified all FDT elevations. The results are interpreted in terms of memory, attention, and discrimination-strategy constraints.

11:00

5aMU8. Application of cochlear analysis techniques to finding percussive events in electro-acoustic music. Anderson Mills (The Univ. of Texas, 702 W 32nd St., Austin, TX 78705, nodog@mail.utexas.edu)

Electro-acoustic music is a style of music for which often the pressure signal itself is the only consistent, objective representaiton of the music. A project has been undertaken at The University of Texas to automatically extract audio properties from recordings of electro-acoustic music, and the first property chosen to be extracted is a measure of the ''single damped percussive events'' (SPDEs) found in a piece of music. Because electro-acoustic music often contains sounds which are not considered musical in traditional contexts, the analysis of this type of music must begin by approaching the pressure signal without traditional musical foreknowledge, and therefore this analysis is focused on the extraction of any type of percussive event found in the pressure signal. The explored methods of analysis include bandpass filtering, spectrogram, and Patterson's auditory image model (AIM) as front-ends. The results of these different methods are compared. A human experiment to determine the nature of an SPDE and to generate data to use as a measure for the algorithms is also discussed. Self-similarity at different time scales within the measure of SPDEs during a piece of music provides useful information to a music theorist and therefore is the next step in this analysis research.

11:15

5aMU9. Frequency tracking of ecclesiastical Byzantine music frequency intervals. Kyriakos M. Tsiappoutas (Dept. of Psych., Illinois State Univ., Normal, IL 61790, kmtsiap@ilstu.edu), George E. Ioup, and Juliette W. Ioup (Univ. of New Orleans, New Orleans, LA 70148)

Two Byzantine music (BM) pieces performed by two well-established traditional chanters are quantitatively analyzed using modern frequency tracking methods to estimate the tone frequencies of the diatonic scale, one of the three main scales of BM. The two experimental versions of the diatonic scale are compared with each other and with two of many theoretical diatonic scales proposed by traditional BM theorists. This constitutes a measure of how well theoretical scales model performance. Then a direct comparison between Byzantine and common European music scales is attempted. Statistical techniques are employed to reveal any significant differences among the different scales. The attraction effect (AE) or ''elk-

sis,'' i.e., when a specific secondary tone intentionally takes on different frequency values (micro-sharpened or micro-flattened) depending on its direction in the musical script, is measured. This is part of a continuing attempt to quantify the AE empirically. Both main and secondary tones are independently examined to assess their reliance on the AE, but only secondary tones are found subject to it. A connection to the psychophysics of pitch perception illustrates whether the differences among scales are distinguishable by the human ear.

11:30

5aMU10. Idiomatic guitar synthesis. Leandro L. Costalonga and Eduardo R. Miranda (Interdisciplinary Ctr. for Comput. Music Res., Univ. of Plymouth, PL4 8AA, UK, leandro.costalonga@plymouth.ac.uk)

The aim of this research is to add intelligence to the interface between systems for computer-aided composition and synthesizers. In this paper we introduce a system that is able to play guitar music on a synthesized guitar idiomatically. There are a great number of sound synthesis techniques and computer-aided composition systems available. However, there is a general lack of intelligent interfacing between these two types of systems. For example, when one auditions the different parts of an orchestral piece, the software treats these materials identically; that is, the violin part is not played violinistically or the clarinet part clarinetistically. Musicians tend to blame the synthesizers for such poor performance quality, but if the synthesizer was controlled idiomatically the sound synthesis technique itself would be just one of the design aspects to be considered in such systems, and not the single one. Our idiomatic guitar player system includes knowledge about the biophysical constraints of the performer, the performance characteristics associated with different musical styles, and the performance styles of different individuals. [Research sponsored by CAPES Ministry of Education of Brazil.]

11:45

5aMU11. Synthesis and dynamic behavior of diffracted audio spectra. C. Eswaran and V. Vijayakumar (Faculty of Information Technol., Multimedia Univ., Cyberjaya 63100, Selangor, Malaysia)

It is shown in this paper how the intensity and phase of the harmonics of a spectrum containing a discrete set of input frequecies of unit intensity is modified by diffraction through a circular aperture. The resulting spectrum further shows dynamic behavior which is discussed in terms of a modulation parameter. Examples of synthesized audio spectra which show similarity to known musical instruments are provided as illustration of the synthesis method.

12:00

5aMU12. A system for understanding violin bowing technique through measurement of physical dynamics. Diana Young (MIT, E15-443, 20 Ames St., Cambridge, MA 02142, young@media.mit.edu)

Presented here is a custom-built sensor system for the measurement of violin bowing parameters. An improvement on previous designs, the system includes a set of accelerometers, gyroscopes, and force sensors, installed on a carbon fiber violin bow. In addition, another set of inertial sensors, as well as an electric field position sensor, are mounted on the test violin. When taken together, the data from the violin and bow are combined to achieve estimates (relative to the violin) of the three primary bowing parameters: force, speed, and bow-bridge distance. Because the system is relatively compact and lightweight, it is suitable for operation in realistic performance environments outside the laboratory setting. As such, it is possible to obtain detailed physical gesture data from real performances. The potential of the system is explored in several early studies to investigate the interaction of bowing parameters in common strokes. Distinctions between novices and experts, as well as differences between technique and style among experts, are discussed.

FRIDAY MORNING, 9 JUNE 2006 ROOM 554AB, 8:30 A.M. TO 12:00 NOON

Session 5aSC

Speech Communcation: Perception and Modeling of Speech Processes

Douglas H. Whalen, Chair
Haskins Laboratories, 300 George St., New Haven, CT 06511

Contributed Papers

8:30

5aSC1. The recent origin of human speech. Philip Lieberman (Cognit. and Linguistic Sci., Brown Univ., Providence, RI 02912-1978, philip_lieberman@brown.edu), Robert C. McCarthy (Florida Atlantic Univ., Boca Raton, FL 33431), and David Strait (State Univ. of New York at Albany, Albany, NY)

Studies of human development and swallowing show that a supralaryngeal vocal tract (SVT) capable of producing quantal vowels involves (1) facial restructuring yielding a short oral cavity; (2) a tongue that moves down into the pharynx carrying the larynx down with it; and (3) a long neck. The skeletal features of hominid fossils suggest the absence of fully human speech anatomy until 100 000 years ago. With long faces and short necks, Neanderthals and early anatomically modern humans could not have possessed SVTs capable of swallowing and of producing fully human speech. Probable [i] SVT shapes were computer-modeled from perturbations of vocal-tract area functions obtained from MRIs of adult humans. When normalized to the length of an adult human SVT, $F1/F2$ patterns fall outside of the range of Peterson and Barney's [''Control methods used in a study of the vowels,'' J. Acoust. Soc. Am. **30**, 739–742 (1952)] data used by Lieberman and Crelin, ''On the speech of Neanderthal man,'' Linquistic Inquiry **2**, 203–222 (1971) to assess Neanderthal speech), but at the extreme range for [i] as measured by Hillenbrand *et al.* [''Acoustic characteristics of American-English vowels,'' J. Acoust. Soc. Am. **97**, 3099–3111 (1995)]. In neither case are the high-frequency spectra characteristic of human quantal [i]'s. $F1/F2$ patterns for unnormalized SVTs fall outside the human range for both plots.

8:45

5aSC2. Better model and decoding methods for automatic speech recognition. Douglas D. O'Shaughnessy and T. Nagarajan Li (INRS-EMT, 800 de la Gauchetiere west, Ste. 6900, Montreal PQ, H5A 1K6 Canada)

Different ways to improve the accuracy and performance of automatic speech recognition (ASR) systems are examined. Earlier research in the INRS group concentrated on improvements in adaptation techniques, to try to reduce the mismatch between system training and operating conditions. More recently, a concentration was made on improvements to the

5a FRI. AM

modeling and decoding methodology of the ASR systems. A two-level syllable model-based decoding approach is proposed here. At the first level, a syllable model-based decoding is performed to segment the utterances into syllable segments, and to identify which syllable group this segment belongs to. Then, at the second level, each segment is rescored using the phoneme model, where the possible phoneme sequences are constrained by the syllables in that syllable group. A new heuristic score is proposed to be added in hidden Markov model (HMM) decoding that indicates the degree of competition among different HMM states. Speech features are obtained from the posterior of this HMM approach and these features are used to further improve recognition results. The state evolution tracks are incorporated as features in an HMM-based recognizer. Experiments were carried out on a phoneme classification task (TIMIT) and these methods were found to show improvements compared to a baseline performance. [Work supported by NSERC-Canada and Prompt-Quebec.]

9:00

5aSC3. Development of a binaural speech transmission index. Sander J. van Wijngaarden and Rob Drullman (TNO Human Factors, P.O. Box 23, 3769 ZG Soesterberg, The Netherlands)

Although the speech transmission index (STI) is a well-accepted and standardized method for objective prediction of speech intelligibility in a wide range of environments and applications, it is essentially a monaural model. Advantages of binaural hearing to the intelligibility of speech are disregarded. In specific conditions this leads to considerable mismatches between subjective intelligibility and the STI. A binaural version of the STI was developed, based on interaural cross correlograms, which shows a considerably improved correspondence with subjective intelligibility in dichotic listening conditions. The new binaural STI is designed to be a relatively simple model which adds only few parameters to the original standardized STI, and changes none of the existing model parameters. For monaural conditions, the outcome is identical to the standardized STI. The new model was validated on set of 39 dichotic listening conditions, featuring anechoic, classroom, listening room, and cathedral environments. For these 39 conditions, subjective intelligibility (CVC-wordscore) was measured, as well as the binaural STI. The relation between binaural STI and CVC-wordscores in dichotic listening conditions closely matches the STI reference curve (standardized relation between STI and CVC-wordscore) for monaural listening. The monaural STI performs poorly in these cases.

9:15

5aSC4. New directions for a speech-based speech transmission index. Rob Drullman and Sander J. van Wijngaarden (TNO Human Factors, P.O. Box 23, 3769 ZG Soesterberg, The Netherlands)

The standardized method for determining the speech transmission index (STI) involves the use of a specific intensity-modulated test signal. The STI is obtained from measurements on the transmission channel, usually showing reductions of the modulation depths in the received test signal. Instead of using an artificial signal, various approaches have been suggested in the literature to use speech as a test signal [cf. Payton *et al.*, J. Acoust. Soc. Am. **111**, 2431 (2002)]. Such a speech-based STI has several advantages, e.g., predicting intelligibility differences due to speaking style and enabling the evaluation of vocoders. As we encountered shortcomings and inaccuracies in the existing speech-based STI methods, we propose a new procedure for estimating the speech-based modulation transfer function (MTF) which approaches the accuracy of conventional STI implementations. The new procedure uses the cross spectrum between the transmitted and received speech signals, with special phase weighting to address the relative importance of shifted modulations of the temporal envelope. Evaluation of the algorithm on a vocoder database showed promising results, yielding an average correlation coefficient of 0.93 between the subjective CVC scores and the speech-based STI for male speech. Details of this new speech-based STI algorithm will be discussed.

9:30

5aSC5. Statistical characterization of target-to-interferer ratio of co-channel speech. Brett Smolenski (Res. Assoc. for Defense Conversion, 525 Brooks Rd., Rome, NY 13440)

Recent research in speaker identification technology suggests that it can operate in co-channel environments provided the system can have access to only the less-corrupted segments of speech. In order to identify the uncorrupted speech segments as accurately as possible, it is necessary to fully characterize the statistics of the random processes generating the uncorrupted segments. In a co-channel environment the uncorrupted speech segments are produced when one speaker's voiced speech overlaps with the other speaker's silence or unvoiced speech. Hence, if one has a statistical model of voiced, unvoiced, and silence segments, one can use this information to obtain a model of the uncorrupted speech segments. To accomplish this, statistical models that account for the observed voiced, unvoiced, and silence segment lengths are first developed. Markov models are used to account for dependencies between voiced, unvoiced, and silence segments. In addition, a model of the sampling distribution of the segmental target-to-interferer ratio (TIR) is developed and the short- and long-term correlation present in the segmental TIR signal is also explored.

9:45

5aSC6. Local versus distal speaking-rate normalization effects. Matthew Winn and Rochelle Newman (Univ. of Maryland, College Park, 0100 Lefrak Hall, College Park, MD 20742)

Individuals vary their speaking rate, and listeners typically use the speaking rate of precursor sentences to adjust for these changes (Kidd, 1989). This study examines the temporal window over which these effects occur, by comparing the size of rate normalization effects for local, distal + local, and global rate changes in a precursor phrase. A single talker produced the precursor sentence "Sarah brought a bag so Paul could get the _" at three different speaking rates, followed by a final word containing a duration-based contrast (bin versus pin). Listeners heard trials in which either the whole precursor sentence was spoken at a fast, medium, or slow rate, or (via cross-splicing) only portions of the sentence varied in rate. Subjects rated the target phoneme in the final word as either a "b" or a "p" using a six-step rating scale. Local rate changes (changes in the speaking rate of "get the") yielded significant normalization effects, seen as the shifting of the VOT boundary between p and b. The addition of distal rate changes, however, yielded no significant changes in perception on top of this local effect. This is in contrast to earlier work supporting two separate (local and distal) effects of rate changes.

10:00–10:15 Break

10:15

5aSC7. Speaker identification in hybrid synthesis: Implications for speech perception. Susan R. Hertz (NovaSpeech LLC, 215 N. Cayuga St. #48, Ithaca, NY 14850 and Dept. of Linguist., Cornell Univ., Ithaca, NY 14853) and Isaac C. Spencer (NovaSpeech LLC, Ithaca, NY 14850)

As part of an evaluation of hybrid synthesis [Hertz, Proc. IEEE Workshop on Speech Synthesis (2002)], perceptual experiments were conducted that tested the hypothesis that stressed vowels are the primary cues to speaker identification. Hybrid sentences were constructed for eight voices, including child and adult and male and female, in which stressed vowels were taken from a single human speaker, but other segments were replaced by surrogates from different sources. Some surrogates were natural speech segments; others were formant synthesized. Some matched the age or gender of the stressed vowel speaker; others did not. After being trained on six human target voices, listeners were asked to identify the hybrid stimuli, and also fully synthetic and natural stimuli (for target and nontarget voices), in terms of age, gender, and whether and how much they matched a target voice. For all categories, hybrid stimuli, in contrast to synthetic ones, were identified as accurately as natural speech, both by listeners familiar with a target voice (e.g., family members) and those

unfamiliar. The experiment demonstrated how little attention is paid to consonants and reduced vowels in determining speaker identity, and supported our hybrid approach to modeling voices. [Work supported by NIH Grant 1 R43 DC006761-01.]

10:30

5aSC8. On the relation of apparent naturalness to phonetic perceptual identification of voicing. Robert E. Remez, Claire Landau, and Daria F. Ferro (Dept. of Psych., Barnard College, 3009 Broadway, New York, NY 10027-6598)

Does the qualitative experience of speech sounds influence phonetic perception? Our studies of consonant place perception have revealed a dichotomous relation between phonetic sensitivity and naturalness. Although natural quality and phonetic sensitivity sometimes co-vary, in other conditions phonetic sensitivity is indifferent to huge variation in naturalness. New tests are reported here extending the research to the dimension of voicing, a contrast correlated with qualitatively distinct acoustic constituents in normal production. Two acoustic methods were used to create naturalness variants: (1) variation in the excitation of a synthetic voicing source and (2) variation in the bandwidth of the formant centers. A naturalness tournament was composed of items drawn from the test series, and the sensitivity of perceivers to the voicing contrast was estimated with the cumulative d' across the series in identification tests. Together, the findings show how intelligibility and naturalness can be either orthogonal or contingent aspects of consonant perception for the dimensions of place and voicing. These measures offer a tool to understand the contribution of normative functions in the perception of speech. [Research supported by NIH (DC00308).]

10:45

5aSC9. Garden-path phenomena in spoken word recognition: Gradient sensitivity to continuous acoustic detail facilitates ambiguity resolution. Bob McMurray (Dept. of Psych., E11 SSH, Univ. of Iowa, Iowa City, IA 52242), Michael K. Tanenhaus, and Richard N. Aslin (Univ. of Rochester, Ithaca, NY 14850)

Studies have demonstrated that lexical activation is gradiently sensitive to continuous acoustic detail [McMurray *et al.*, "Gradient effects of within-catagory phonetic variation on lexical access," Cognition **86**, B33–B42 (2002)]. This study investigates the consequences of this for online recognition, hypothesizing that such processes help maintain lexical alternatives and reactivate them if early interpretations are disfavored by subsequent input. Stimuli were pairs like barricade/parakeet, where, if the initial segment was misperceived, disambiguation would occur quite late. The effect of VOT on recognition was assessed for tokens favoring the competitor (barakeet with VOTs between 15 and 0). A categorical system would categorize these as equally [b]; garden path to barricade; and show difficulty reactivating parakeet after /eet/. A gradient system would activate parakeet more for VOTs near the boundary, and recover from the garden path faster. Subjects heard ten 8-step continua of this form and selected the target from screens containing the target (parakeet), competitor (barricade), and unrelated objects, while eye movements were recorded. Fixations revealed a gradient pattern of recovery time to switch from the competitor to the target was linearly related to VOT. Subsequent experiments verified that this was not due to stimulus range, nor to the visual presence of the competitor. Thus, lexical activation is sensitive to continuous detail, and this facilitates ambiguity resolution.

11:00

5aSC10. Not all feedback is created equally: The role of multisensory feedback in the perceptual learning of speech under a novel acoustic transformation. Kevin T. Webster and Lorin Lachs (California State Univ., Fresno, 2576 E. San Ramon, M/S ST11, Fresno, CA 93740, llachs@csufresno.edu)

Previous research has investigated the perceptual learning of speech modified by the frequency-inversion transformation, in which the spectral content of an acoustic pattern is rotated about an arbitrary frequency. The resulting transformed speech is almost completely unintelligible. However, given appropriate training, individuals can learn to perceive the linguistic content of the transformed spoken message. Recent work by Webster and Lachs has indicated that providing multisensory feedback during training appears to enhance the rate at which individuals adapt to the transformation. Furthermore, different types of multisensory feedback give rise to different patterns of learning. For example, learners presented with concurrent visual displays of a talkers lip movements (i.e., articulatory information) demonstrate better learning of training materials than learners presented with concurrent visual displays of text. The goal of the present experiment was to refine the technique for training perceivers in order to exaggerate differences between feedback groups in overall learning. A new control condition was also included to test the hypothesis that nonarticulatory but dynamic visual displays yield qualitatively different patterns of learning that those exhibited by perceivers trained with articulatory displays. The results provided interesting insights into the methodology necessary to test perceptual learning of frequency-inverted speech under multisensory conditions.

11:15

5aSC11. Lexical influences on the progressive facilitation during perception of assimilated speech. Cheyenne Munson, Bob McMurray (Dept. of Psych., Univ. of Iowa, E11 SSH, Iowa City, IA 52242, cheyenne-munson@uiowa.edu), and David Gow (Massachusetts General Hospital, Boston, MA 02114)

Phonological processes such as place assimilation, in which coronal sounds partially adopt the place of a subsequent noncoronal (e.g., green boat becomes green/m boat), may create ambiguity during speech comprehension, but may also paradoxically facilitate word recognition. Gow (2001) demonstrated that partial assimilation facilitates perception of postassimilation context. Two eye-tracking experiments investigated whether this progressive effect is influenced by lexical processes. Assimilated and nonassimilated adjectives (e.g., green) were spliced onto coronal or noncoronal nouns (e.g., boat or dog) to create phonologically plausible and implausible assimilation. In experiment 1, assimilation resulted in nonwords; in experiment 2, words assimilated into other words, cuing lexical competition (e.g., cat box became cat/p box). Subjects viewed a screen showing 4 pictures: a coronal noun, 1 noncoronal, and 2 fillers. Eye movements were monitored as subjects heard instructions to select a picture with a mouse. In both experiments subjects were reliably faster to look at the noncoronal target following the assimilated adjective than the nonassimilated one. This progressive effect occurred approximately 100 ms later when assimilation created competitors (experiment 2). These results support an interactive view of word recognition in which lexical processing interacts in real time with phonological and perceptual grouping and integration processes.

11:30

5aSC12. The effect of tonal information and word frequency on spoken word processing. Yao-ju Lin (Dept. of English, Linguist. Div., Natl. Taiwan Normal Univ., 162, HePing East Rd., Sec. 1, Taipei, Taiwan, 69221021@ntnu.edu.tw) and Janice Fon (Natl. Taiwan Univ., Taiwan)

This paper aims to examine the role of tonal information and word frequency in processing spoken Mandarin lexicon. Experiment 1 uses a lexical decision paradigm in which subjects are to hear high- and low-frequency bisyllabic word pairs whose segmental makeups are similar (e.g., [high frequency] jing4-zheng1 competition vs. [low frequency] jin4-sheng1 promotion). The F0 information of the stimuli are either uncontaminated, transformed for the second syllable, or transformed for both syllables. Experiment 2 uses a shadowing task with the same set of stimuli in which subjects are asked to repeat the words as quickly as possible. Preliminary results showed that tonal information is essential for lexical retrieval, especially for low-frequency words. Based on the TRACE model, it is also expected that subjects are more likely to substitute similar-sounding words of higher frequency for low-frequency words whose F0 information is manipulated.

11:45

5aSC13. Auditory, but perhaps not visual, processing of Lombard speech. Eric Vatikiotis-Bateson, Victor Chung, Kevin Lutz, Nicole Mirante, Jolien Otten, and Johanna Tan (Dept. of Linguist., Univ. of British Columbia, E270-1866 Main Mall, Vancouver, British Columbia V6T 1Z1, Canada)

Perception results for three studies are presented that address the role of Lombard speech in auditory, visual, and auditory-visual speech perception. Predictably, when presented in auditory-only conditions with masking noise, listeners recover speech recorded in noise (Lombard speech) better than speech recorded in quiet and presented with the same level of masking noise. However, there is almost no difference in listener performance when Lombard and quiet speech are presented audiovisually with masking noise. Both conditions are enhanced compared to auditory-alone conditions, but there is no indication that the facial motion correlates, demonstrated previously for quiet speech [H.C. Yehia, *et al.*, Speech Commun. **26**, 23–44 (1998)], play as strong a role in enhancing auditory-visual processing of Lombard speech, even though Lombard speech is accompanied by larger facial motions. Perhaps it is no surprise that, at a cocktail party, one leans in with an ear rather than with the eyes. [Research supported by CFI and NSERC.]

FRIDAY MORNING, 9 JUNE 2006 ROOM 556AB, 7:55 A.M. TO 12:00 NOON

Session 5aSP

Signal Processing in Acoustics, Underwater Acoustics, and Engineering Acoustics: Processing of Acoustic Vector Sensors

Paul Hursky, Cochair
Heat Light and Sound Research, 12730 High Bluff Dr., Suite 130, San Diego, CA 92130

Gerald L. D'Spain, Cochair
Scripps Inst. of Oceanography, Marine Physical Lab., 291 Rosecrans St., San Diego, CA 92106-0701

Chair's Introduction—7:55

Contributed Papers

8:00

5aSP1. Radiated noise measurements with vector sensor arrays. Joseph Clark and Gerald Tarasek (NSWCCD, Code 7340, 9500 MacArthur Blvd., West Bethesda, MD 20817-5000, joseph.a.clark1@navy.mil)

The use of arrays of vector sensors to measure source levels of radiated noise from submarines is currently being studied. Ambient noise limits the accuracy of these measurements. The directional character of the ambient noise field (anisotropy) has been found to affect measurement accuracy differently for alternative kinds of processing. In this talk, two types of vector sensor processing, linear matrix and intensity processing, will be compared theoretically and experimentally. Theoretical comparisons of achievable measurement accuracies will be developed in terms of the fourth moment of the measured signal amplitude (the variance of the sound power). Experimental comparisons will be based on data obtained during recent testing at SEAFAC, the U.S. Navy acoustic signature measurement facility in Behm Canal, Alaska.

8:15

5aSP2. Changes in ocean infrasonic energy density and vector intensity with changes in wind and ocean surface wave conditions as measured by a freely drifting vector sensor. Gerald L. D'Spain and Scott A. Jenkins (Marine Physical Lab., Scripps Inst. of Oceanogr., 291 Rosecrans St., San Diego, CA 92106)

During an experiment in 1.3-km-deep water in the Southern California Bight, the wind speed decreased from about 7 to 1 m/s over a 10-h period, and then increased to 9 m/s over the next 8-h period. Measurements made by a neutrally buoyant, freely drifting vector sensor at 920-m depth show that the corresponding changes in the potential and kinetic energy density levels of the infrasonic sound field have a frequency-dependent delay. The levels in a 0.1-Hz-wide bin at 3 Hz respond to wind-speed changes with approximately a 2-h delay, and the delay in response increases with decreasing frequency at a rate of about 1 h per hertz down to 1 Hz. The corresponding evolution in directionality of the active and reactive acoustic intensity vectors in these same frequency bins and their relationship to the surrounding bathymetry will be presented. The directional spectra of the ocean surface wave field during the experiment were reconstructed using back-refraction modeling with wave data from shore stations and offshore platforms archived by the Coastal Data Information Program to obtain estimates of the temporal variability of the nonlinear wave-wave interactions generating the ocean infrasound. [Work supported by ONR.]

8:30

5aSP3. Optimal detection with vector sensors and vector sensor line arrays. Gerald L. D'Spain (Marine Physical Lab., Scripps Inst. of Oceanogr., 291 Rosecrans St., San Diego, CA 92106), James C. Luby (Univ. of Washington, Seattle, WA 98105), Gary R. Wilson, and Richard A. Gramann (Univ. of Texas, Austin, TX 78113)

The detection performance of single vector sensors and vector sensor line arrays is degraded by nonacoustic self-noise and spatial coherence of the noise between vector sensor components. Results based on optimizing the directivity index for a single vector sensor show that the particle motion channels should always be included in the processing for optimal detection, regardless of self-noise level, assuming these levels are properly taken into account. The vector properties of acoustic intensity can be used to estimate the levels of nonacoustic noise in ocean measurements. Application of conventional, minimum variance distortionless response, and white-noise-constrained adaptive beamforming methods with ocean acoustic data collected by a vector sensor illustrates increase in spatial resolution but corresponding decrease in beamformer output and introduction of bias with increasing beamformer adaptivity. Expressions for the spatial coherence of all pairs of vector sensor components in homogeneous, isotropic noise show that significant coherence exists at half-wavelength spacing between particle motion components. For angular intervals about broadside, an equal spacing of about one wavelength for all components

provides maximum directivity index, whereas each of the component spacings should be different to optimize the directivity index for angular intervals about endfire. [Work supported by ONR.]

8:45

5aSP4. An electronic windscreen for microphones. Gary W. Elko and Jens Meyer (mh acoustics LLC, 26 Blackburn Pl., Summit, NJ 07901)

Wind-noise pickup in microphones can be highly disturbing, especially for directional microphones that attain their directivity by using velocity or spatial derivatives of the acoustic pressure. Since small directional microphones are common in audio communications systems, the problem of wind noise is well known and the typical solution is to use a windscreen. Conventional windscreens that block the wind but do not significantly alter the sound field can be very effective, but need to be relatively large to attain a good reduction in wind-noise pick-up. Small directional microphone arrays are more commonly used in hearing aids since they have been clinically shown to improve hearing in noise for hearing-impaired users. Since hearing aids are required to be compact, an effective conventional windscreen is not practical. This talk describes a novel multi-microphone wind-noise reduction algorithm that we refer to as an ''electronic windscreen.'' This new algorithm and its variants have low computational cost and are therefore applicable to commercial digital hearing aids that use multi-microphone arrays to attain directionality.

9:00

5aSP5. Vector sensor processing results using data from the Makai experiment. Paul Hursky, Michael B. Porter, Martin Siderius (Heat, Light, and Sound Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130), and Bruce M. Abraham (Appl. Physical Sci. Corp., New London, CT 06320)

Interest in small mobile platforms such as AUVs and gliders, and fixed autonomous systems, whose small size and power budget severely limit their ability to deploy larger arrays, has stimulated interest in vector sensors (that sense both pressure and particle velocity). Such combined sensors provide performance that can only be duplicated by larger pressure-only hydrophone arrays. In September 2005, during the Makai experiment, we deployed a four-element vector sensor array in waters off the coast of Kauai in Hawaii. We will present comparisons of processing a towed source and acoustic communications packets recorded on the four-element vector sensor array and a comparable pressure-only sensor array. We will also discuss modifications to propagation models based on Gaussian beams and normal modes to predict particle velocity, showing comparisons between model predictions and our experiment data.

9:15

5aSP6. Imaging marine geological environments with vector acoustics. Dennis A. Lindwall (Marine Geosciences Div., Naval Res. Lab., Stennis Space Ctr., MS, 39529)

Using vector acoustic sensors for marine geoacoustic surveys instead of the usual scalar hydrophones enables one to acquire 3D survey data with instrumentation and logistics similar to current 2D surveys. The addition of a collocated hydrophone allows the signal to be rectified, removing the ghost images. This concept was tested by a scaled experiment in an acoustic water tank that had a well-controlled environment with a few targets. Using vector acoustic data from a single line of sources, the three-dimensional tank environment was imaged by directly locating the source and all reflectors. [Office of Naval Research program element 61153N.]

9:30

5aSP7. Sediment sound speed measurements using buried vector sensors. Anthony P. Lyons (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804-0030, apl2@psu.edu), John C. Osler, David M. F. Chapman, and Paul C. Hines (Defence R&D Canada—Atlantic, Dartmouth, NS, Canada, B2Y 3Z7)

As part of the SAX04 sediment acoustics experiment conducted off the coast of Florida in the Gulf of Mexico, vector sensors containing three-axis accelerometers and pressure sensors were buried in the seabed. These sensors were used as the receivers to measure sediment sound speed dispersion from 300 to 3000 Hz a band in which it has been particularly difficult to make these measurements. The acoustic intensity measured by the vector sensors was combined with the experimental geometry and propagation conditions, to relate the angle of arrival to sediment sound speed as a function of frequency. Lower frequency measurements, 300 to 1200 Hz, used noise radiated from a moored research vessel as the acoustic source. Higher frequency measurements, 800 to 3000 Hz, used transmissions from an acoustic projector in a three-point mooring in the water column that could be adjusted to change the angle of ensonification. Results from the two techniques are compared with each other and previous measurements of dispersion in sandy sediments. [Work performed under ONR Grants N00014-04-1-0013 and N00014-03-1-0883.]

9:45

5aSP8. Development of a triaxial pressure-velocity probe for deep submergence applications. J. A. McConnell, P. D. Lopath, S. C. Jensen (Acoustech Corp., 4900 South Broad St., Philadelphia, PA 19112), D. H. Trivett, V. B. Biesel, J. J. Caspall (Georgia Inst. of Technol., Atlanta, GA 30332), J. F. McEachern, and R. Coughlan (Navmar Applied Science Corp., Warminster, PA 18974)

A triaxial pressure-velocity probe has been developed for the purpose of measuring the ambient acoustic noise field in the ocean at frequencies below 500 Hz. The probe consists of an omnidirectional hydrophone, a compliantly suspended sphere containing a triaxial geophone, and an electronics housing that contains a four-channel preamplifier and a digital compass. All of these components are packaged in a frame which in turn is attached to a deployment cable (i.e., a strength member) and submerged to a prescribed depth. The performance specifications for the transducers include a submergence depth rating of 6 km and a noise floor of 40 dB *re*: 1 mPa^2 per hertz. These two parameters essentially drive the design of the probe and the paper will address these topics from the standpoint of the design evolution that took place in order to meet the specifications. Other aspects of the probe's development include efforts to mitigate flow-induced noise and shielding the compass from the magnetic field emitted by the geophones. Test data obtained on a prototype unit will be presented. [Work supported by C. M. Traweek at the Office of Naval Research Code 321MS.]

10:00–10:15 Break

10:15

5aSP9. Forming first- and second-order cardioids with multimode hydrophones. J. A. McConnell (Acoustech Corp., 4900 South Broad St., Bldg. 6, Ste. LL00, Philadelphia, PA 19112), R. C. Haberman, T. A. McCormick (BBN Technologies, Mystic, CT 06355), and J. Rudzinsky (Appl. Physical Sci. Corp., New London, CT 06320)

Most everyone in sonar signal processing is familiar with forming a first-order cardioid using scalar and vector sensors, which are defined as the reciprocal analog of a monopole and dipole radiator, respectively. The second-order cardioid can be formed using scalar, vector, and dyadic sensors, in which the latter sensor is defined as the reciprocal analog of a quadrupole radiator. Multimode hydrophones configured as piezoelectric cylinders and spheres with segmented electrodes have the ability to form the both types of cardioids. This paper compares and contrasts the use of multimode hydrophones to produce each beam pattern and presents the results of several sensors that were developed. Topics relating to the sen-

sitivity, bandwidth, noise floor, beamwidth, beam steering, and directivity index will be covered. [Work supported by C. M. Traweek at the Office of Naval Research Code 321MS and L. Shumway at the Department of Homeland Security.]

10:30

5aSP10. Development of a miniature uniaxial pressure-acceleration probe for bioacoustic applications. J. A. McConnell and S. C. Jensen (Acoustech Corp., 4900 South Broad St., Bldg. 6, Ste. LL00, Philadelphia, PA 19112)

The bioacoustics community has recently expressed an interest in using collocated measurements of the acoustic pressure and the particle velocity to categorize how certain species of marine life transmit and receive sound. For most applications the frequency range of interest spans from tens of hertz to a few kilohertz. Because the test specimens and the test facilities can be relatively small, a miniature pressure-acceleration ($b-a$) probe was developed. The probe conforms to the geometry of a cube having a principal side length of 31.75 mm (1.25 in.) and contains flexural mode piezoelectric transducers to measure the acoustic pressure and one component of the acoustic particle acceleration vector. The cube also houses a low-noise two-channel preamplifier and is compliantly suspended inside a light frame. This paper highlights the design evolution of a few prototypes and addresses issues associated with the electronic noise floor of the accelerometer, mechanical cross talk between the transducers, damping of the external suspension system and transducers, and the dynamics of the signal cable. [Work supported by Acoustech Corporation IR&D.]

10:45

5aSP11. Position-invariant close-talking microphone array. Jens Meyer and Gary W. Elko (mh acoustics LLC, 26 Blackburn Pl., Summit, NJ 07901)

Close-talking microphones are commonly used for speech pick-up in high-noise environments since they can significantly improve the signal-to-noise ratio (SNR) relative to conventional pressure microphones. Increased SNR is based on the assumption that unwanted noise sources are in the far field. However, close-talking microphones have to be carefully positioned or otherwise they can have reduced SNR improvement. A new close-talking microphone array is proposed that is orientation invariant with respect to the attenuation of far-field noise sources. It is shown that by appropriate processing of the close-talking microphone array signals, one can adaptively compensate for the distance and orientation of the microphone for a near-field source. The proposed close-talking array is based on a spatially orthonormal decomposition of the sound field for a near-field source. It consists of four or more pressure microphones that are mounted in the surface of a small rigid sphere. Finally, it is shown that decomposing the sound field into spatially orthonormal modes leads to a computationally efficient implementation. The orientation compensation is applicable not just to close-taking microphones but to directional microphones in general, e.g., podium microphones or hand-held vocal microphones.

11:00

5aSP12. Intensity processing of vector sensors in the bistatic regime. Nathan K. Naluai, Gerald C. Lauchle, and Thomas B. Gabrielson (Grad. Program in Acoust., The Pennsylvania State Univ., 217 Appl. Sci. Bldg., University Park, PA 16802)

Acoustic intensity processing of signals from directional frequency analysis and recording (DIFAR) acoustic subsystems is used to enhance the detection of submerged bodies in bistatic sonar applications. In some directions, the scattered signals may be completely dominated by the incident blast from the source, depending upon the geometry, making the object undetectable by traditional scalar pressure measurements. Previous theoretical derivations suggest that acoustic vector intensity sensors, and the associated intensity processing, are a potential solution to this problem. Deep-water experiments conducted at Lake Pend Oreille in northern Idaho are described. A large body of revolution is located between a source and a number of SSQ-53D DIFAR sonobuoys positioned from 5 to 30 body lengths away from the scattering body. Scalar pressure measurements change by less than 0.5 dB when the scattering body is inserted in the field. However, the phase of the acoustic intensity component formed between the omnipressure and directional channel orthogonal to the direction of incident wave propagation varies by as much as 75. This metric is shown to be a repeatable and strong indicator of the presence of the scattering body. [Work supported by ONR, code 321MS.]

11:15

5aSP13. Processing of vector fields in underwater waveguides. Brian R. Rapids (Appl. Phys. Lab., Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099, brian.rapids@jhuapl.edu)

The ability to measure the scalar and vector properties of underwater acoustic fields has improved over the past decade with advancements in transducer technology. Investigations regarding the processing of such sensors have principally focused upon the exploitation of a vector sensor as a directional hydrophone and the ability to achieve significant spatial gains in an unusually small form factor (i.e., superdirectivity). These superdirective elements may then be examined in the framework of standard linear array processing techniques. Alternatively the scalar and vector sensors can be combined multiplicatively to generate estimates of the acoustic intensity vector. Several investigations regarding the detection of signals in noise with these multicomponent sensors have found that optimal linear processing produces a superior signal-to-noise ratio at the back end of the processor when compared to the intensity processor. While the intensity-based processing may not provide an optimal detector, it does provide insight into the fundamental nature of the underwater acoustic field by characterizing the energy flux density. This talk will discuss the effects of signal-model mismatch on the linear and multiplicative process by examining cases in which the assumed phase difference between pressure and particle velocity is not zero.

11:30

5aSP14. Comparative beamforming studies employing acoustic vector sensor data. Kevin B. Smith (Dept. of Phys., Naval Postgrad. School, Monterey, CA 93943), Roger T. Richards, and Philip V. Duckett, Jr. (Naval Undersea Warfare Ctr., Newport, RI 02841-1708)

Data obtained from a vector-sensor line array (VSLA), while deployed vertically at Lake Pend Oreille during calibration, are examined in the context of propagation phenomena. Both broadband (FM sweep) and cw signals are analyzed. Only linear plane-wave beamforming is considered, based on well-established array processing techniques for vector sensors [Cray and Nuttall, J. Acoust. Soc. Am. **110**, 324 (2001)]. Normalization is addressed, as is the determination of the vertical plane of propagation for proper steering of the vector components. Results show that the vector sensor array can be properly scaled and steered using a strong, single, cw source. Peak-to-sidelobe improvements of several dB were observed using vector beamforming rather than pressure-only beamforming. Arrival direction resolution using cardioid null is also presented. The vertical configuration allowed testing of predicted multipath interference behavior. As expected, arrival angle determinations with a single vector sensor is possible with the broadband signal. The difficulty of similarly resolving multipath arrival angles with one vector sensor and a single cw tone is shown. An array of vector sensors will resolve these angles. [Work completed with the support of Michael Traweek, Thomas Curtin, and Ellen Livingston, all from the Office of Naval Research, and by Daniel Deitz of NAVSEA-PMS403.]

11:45

5aSP15. Acoustic source separation via particle velocity vector measurement. Kenbu Teramoto and M. D. Tawhidul Kahn (Dept. of Mech. Eng., Saga Univ., Saga, Japan)

A novel blind source separation of a mixture of two or more voice signals has been proposed in the present paper. The separation system has been focused based on the spatio-temporal blind source separation algorithm. The proposed algorithm utilizes the linearity among the signals of sound pressure and the components of three-dimensional (x, y, and z directional) particle velocity, all of which are governed by the equation of motion. Principally, as the mechanism of blind source separation uses no *a priori* information about the parameters of convolution, filtering, as well as mixing of source signals, some simple assumptions such as the statistical independency of the linearly combined (mixed) observed signals containing zero mean as well as unit variance have been implied in the present separation algorithm. Therefore, the proposed method has successfully simplified the convoluted blind source separation problem into an instantaneous blind source separation problem over the spatio-temporal gradient spaces. An acoustic experiment with two female voices has been carried out to compare the simulated data as well. A Micro-Flown system has been adopted to evaluate the voice signals efficiently.

Underwater Acoustics: Acoustic Propagation in Sediments

Nicholas P. Chotiros, Chair

Univ. of Texas, Applied Research Lab., P.O. Box 8029, Austin, TX 78714

8:00

5aUWa1. Acoustic mode at low frequencies in marine sediments: Derivation from first principles using the method of homogenization. Allan D. Pierce, William M. Carey, and Paul E. Barbone (Boston Univ., Boston, MA 02537)

The original low-frequency Biot model factors into three characteristic modes, one being the acoustics mode, having only three significant aggregate parameters: apparent density and bulk modulus, and a numerical coefficient relating attenuation to ω^2. This prediction, although from a heuristic multiparametered model, finds an independent basis in a modification of the derivation by Burridge and Keller ["Poroelasticity equations derived from microstructure," J. Acoust. Soc. Am. **70** 1140–1146 (1981)] of the poroelasticity equations from microstructure, using only the equations of elasticity and of those for a fluid with viscosity, with no exotic mechanisms. The overall mathematical procedure is the method of homogenization. Isolation of the acoustic mode is achieved by introducing a reference velocity scale, c_{ref}, the intrinsic sound speed in the fluid alone, with the macroscopic length scale H taken as c_{ref}/ω. Mass densities of fluid and elastic media are assumed comparable, and the elastic modulus is assumed comparable to bulk modulus of fluid. The nature of sediments suggests that one needs two inner scales, the larger of which is a representative grain dimension, and the smaller of which is associated with the contact areas of adjacent grains caused by gravitational compression.

8:15

5aUWa2. Broadband sound velocity and attenuation in sandy seabottoms in shallow water. Ji-Xun Zhou and Xue-Zhen Zhang (Georgia Inst. of Technol., Atlanta, GA 30332-0405 and Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, China)

A previous paper analyzed and reviewed low-frequency (LF) field measurements conducted at 17 locations in different coastal zones around the world, and indicated that the effective acoustic attenuation curves for sandy seabottoms, derived from different field characteristics at these locations, exhibited similar magnitude and nonlinear frequency dependence in a frequency range of 50–2000 Hz. [Zhou and Zhang, "Nonlinear frequency dependence of the effective seabottom acoustic attenuation from low-frequency field measurements in shallow water," J. Acoust. Soc. Am. **117**, 2494 (2005)]. This paper aims to report the sound velocity in sandy bottoms, derived from the LF field measurements. The resultant LF velocity ratio in the sandy bottom and in the water (at the water/bottom interface) is in a range of 1.04–1.08. Combining the LF field-derived sound velocity and attenuation with the benchmark data of bottom acoustic parameters at mid- to high frequency, obtained from the SAX99 [Williams *et al*, IEEE J. Ocean. Eng. **27**, 413–428 (2002)], offers a reference data set of sound velocity and attenuation in sandy bottoms for a broadband of 50–300 000Hz. The broadband sound velocity data show a significant amount of dispersion. The attenuation data are robust enough to cast doubt on a universal assumption of a linear dependence of attenuation on frequency. [Work supported by ONR and CAS.]

8:30

5aUWa3. Dispersion and attenuation due to scattering from heterogeneities in the frame bulk modulus of sand sediments. Brian T. Hefner and Darrell R. Jackson (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

A model that predicts the sound speed and attenuation of Biot fast compressional waves when there is scattering into the slow compressional wave has been developed. The scattering is due to small scale heterogeneities in the sediment properties such as the porosity or the bulk modulus of the frame that arise due to the random packing of the sediment grains. This model may account for the deviation of measured fast wave attenuation from the predictions of Biot theory that have been observed in both ocean and laboratory sediments. To compare the predictions of this theory with sound speed and attenuation measurements, the spatial statistics of the sediment properties must be known. Despite work in the granular physics community to understand the distribution of the contact forces between the grains, no direct measurements have been made on the spatial variations in the bulk modulus for dry or fluid-saturated sediments. In order to estimate these variations, we have performed molecular dynamics simulations of spherical bead packs which may approximate simple glass bead sediments. The progress of these simulations and the techniques used to estimate the bulk modulus on scales approaching the grain diameter will be presented. [This work is supported by ONR.]

8:45

5aUWa4. Seabed sediment properties from single-channel seismic profiling data. Klaus C. Leurer, Brian O'Connell, and Colin Brown (Dept. of Earth and Ocean Sci., Natl. Univ. of Ireland, Galway, Galway, Ireland, klaus.leurer@nuigalway.ie)

An acoustic model is presented for the calculation of velocity and attenuation of compressional waves in unconsolidated marine sediments. The model uses the concept of a standard sediment structure that assumes spherical grain shapes and a bimodal grain-size distribution in which the

small particles represent the clay fraction. The description of the acoustic response of this bimodal sediment model is based on Biot's poroelastic theory and includes two viscoelastic extensions to the original formulation to enable the resulting combined model to cover a wide range of unconsolidated marine sediments. The first extension, an effective-grain model, is introduced to include the fine-grained spectrum of these sediments and the second, a viscoelastic grain-contact model, to account for their unconsolidated granular nature. The acoustic model provides the basis for a neural-network (NN) inversion scheme to extract sediment physical properties from measured single-channel seismic reflection profiling data. Input parameters for the NN are travel times, attenuation, and reflectivities, which are determined from the seismograms. Preliminary application to real reflection data has provided reasonable results within the framework of our standard sediment model for sediment thickness, density, porosity, sound velocity, and concentration of fine-grained material.

9:00

5aUWa5. Gassy sediment acoustics: Low-frequency sound-speed measurements paired with computed x-ray tomography imaging in reconstituted natural sediments. Preston S. Wilson (Mech. Eng. Dept., Univ. of Texas at Austin, 1 University Station C2200, Austin, TX 78712-0292, pswilson@mail.utexas.edu), Allen H. Reed, Warren T. Wood (Stennis Space Ctr., MS 39529-5004), and Ronald A. Roy (Boston Univ., Boston, MA 02215)

Various models of sound propagation in gas-bearing sediments have appeared in the literature but they are largely unverified by experiment. This is primarily due to the difficulty of assessing the bubble-size distribution and global void fraction in optically opaque sediments. We successfully measured the sound speed in reconstituted natural mud and kaolinite sediments containing varying fractions of biogenic gas bubbles. We used a one-dimensional acoustic resonator technique to determine the low-frequency (100–2000 Hz) sound speed of sediment samples contained within cylindrical acrylic core liners. High-frequency (400 kHz) time-of-flight sound-speed measurements were obtained on a subset of the samples. The sediment samples were contemporaneously imaged with a computed X-ray tomography system that yielded independent estimates of the void fraction and bubble-size distribution. Measured sound speeds ranged from 1520 m/s for gas-free mud to as low as 280 m/s for gassy mud and 110 m/s for gassy kaolinite. CT-derived mud void fractions ranged from 0.001 to 0.002, and the kaolinite void fraction was 0.005. The results of these measurements will be compared to existing theory, but a preliminary analysis shows reasonable agreement between measurement and Wood's suspension model. [Work supported by NRL and the UT College of Engineering.]

9:15

5aUWa6. An experimental laboratory investigation of the low-frequency acoustics of seagrasses. Preston S. Wilson (Mech. Eng. Dept., Univ. of Texas at Austin, 1 Univ. Station C2200, Austin, TX 78712-0292, pswilson@mail.utexas.edu) and Kenneth H. Dunton (Univ. of Texas, Port Aransas, TX 78373-5015)

The acoustics of seagrass beds can impact sonar operation in shallow water and may also be exploited for remotely assessing the health of estuarine and littoral ecosystems. The acoustics are dominated by air channels (aerenchyma) within the plants and air bubbles produced by the plants during photosynthesis. *In situ* studies of seagrass beds have confirmed their unique acoustic properties with respect to side-scan sonar backscatter and propagation effects. The results of these studies suggest a richness of exploitable phenomena, but corresponding forward theoretical models have yet to appear. To address this question, low-frequency acoustic laboratory experiments were conducted on three freshly collected seagrass species, *Thalassia testudinum*, *Syringodium filiforme*, and *Halodule wrightii*. A one-dimensional acoustic resonator technique was used to assess the effective acoustic properties and gas content of individual plants, leaves, and rhizomes. We successfully tracked bubble formation and transport from above- to below-ground tissues and present our results with respect to model predictions based on independent optical gas content estimates obtained via microscopic cross-section imagery. [Work supported by the UT College of Engineering and the Texas Sea Grant College Program Grant R/ES-87.]

9:30

5aUWa7. Ultrasonic velocity measurements for synthetic gas-hydrate samples. Hailan Zhang, Dong Wang, Haibo Zhao, Weijun Lin (Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080 China), and Xiuming Wang (CSIRO Petroleum, Bentley WA 6102, Australia)

Laboratory ultrasonic methods offer a way of studying acoustic velocity of a gas-hydrate bearing formation. By measuring ultrasonic velocities of the gas-hydrate samples in various temperature and pressure conditions, more effective inversion techniques can be developed to quantitatively evaluate gas-hydrate concentration and distributions. Low-temperature laboratory measurements of compressional velocities in compacted samples are conducted. These gas-hydrate samples are synthesized by using various densities at various pressures and temperatures. At $-10°$C, the compressional velocities of the compacted gas-hydrate samples are from 2440 to 3570 m/s with the density range from 475 to 898 kg/m^3. Compressional velocity measurements are made where the temperature and pressure can be controlled. When the pore pressure increases from 10 to 40 MPa, the compressional velocities of the sample increases from 2340 to 2600 m/s at 1.5°C. When the temperature decreases from 10° to $-13°$C, the compressional velocity will increase from 3600 to 3800 m/s at a pore pressure of 6 MPa. Our experimental results are qualitatively in agreement with those of weighted average model and the Biot-Gassmanns model when the gas-hydrate concentration in a sediment bearing sand is about 20%. [Work supported by National Natural Science Fundation of China, No. 10534040.]

5aUWb1. Statistical characterization of sonarlike clutter observed on the STRATAFORM during the 2003 Acoustic Clutter Experiment in the 400–1500-Hz region. John R. Preston (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804)

In 2003 ONR sponsored the Acoustic Clutter Experiment to study shallow-water scattering and clutter in the STRATAFORM area off New Jersey. Sources were bistatically received coherent pulses. The receiver was the five octave research array (used horizontally). The STRATAFORM has benign surface morphology but contains many subsurface features. MIT researchers have shown fish to be a primary source of the observed clutter and reverberation. *K* distributions, with their shape and scale parameters, are used to describe non-Rayleigh behavior. Statistical characterization is presented versus location. The ''bandwidth'' effect is shown where the shape parameter first decreases inversely proportional to bandwidth but then increases back toward the Rayleigh distribution at higher bandwidths. The shape parameter estimates for the 2003 data are well fit by an elongated patch model of Abraham and Lyons. It is shown that shape parameter estimates are about the same for the 2003 and 2001 data taken in the same area. The main differences between the data sets are that the typical scatter sizes/strengths seem to have increased. This is consistent with observations by Nero of NRL and by MIT researchers of higher and more concentrated fish populations observed in 2003. [Work supported by ONR Code 32, Grant N00014-05-1-0156.]

5aUWb2. The effect of multi-path on synthetic aperture sonar image statistics. Shawn F. Johnson, Anthony P. Lyons, Douglas A. Abraham (Appl. Res. Lab., The Penn State Univ., 117 Appl. Sci. Bldg., State College, PA 16804), and Kevin Williams (Univ. of Washington, Seattle, WA 98105)

The K-distribution shape parameter has been shown to be a useful metric of seafloor reverberation statistics. Using this metric, synthetic aperture sonar (SAS) data collected during the Office of Naval Research sponsored SAX04 experiment in the Gulf of Mexico during October 2004 has been processed to examine image statistics as a function of range from the sonar. SAS images are unique in that the resolution cell size does not increase with range as for traditional sonar. Analysis of the SAX04 data has shown that in spite of the fixed resolution cell size, shape parameter estimates were found to increase with range from the sonar. The increase can be attributed to multi-path propagation. At increasing distance from the sonar, scattered returns arising from additional propagation paths arrive in a specified time window, with the result that two or more resolution cells are contributing, which leads to a larger estimate of the shape parameter than would be expected when only the direct path contributes. Model results using the sonar system geometry and seafloor scattering theory will be used to demonstrate this effect. [Work supported by ONR Codes 321 and 333. 5aUWb3. Time evolution of acoustic scattering from a bioturbated seafloor. Anthony L. Gerig, Anthony P. Lyons (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA, 16804, alg14@psu.edu), and Eric Pouliquen (NATO Undersea Res. Ctr., La Spezia, Italy)

Knowledge of the structure, composition, and time evolution of the seabed is essential to modeling acoustic seafloor scattering. The purpose of this work is to quantify the change in a bioturbated seafloor profile with time, and use the results to predict concomitant changes in a backscattered acoustic wave. To accomplish this task, digital stereo photograph pairs of an approximately 0.5-$-m^2$ patch of bioturbated seafloor were taken every 10 min over the course of several days at several different locations off the Florida coast as a part of the Office of Naval Research sponsored SAX04 experiment. Photographs were captured, calibrated, and processed according to standard photogrammetric methods to produce surface height fields of the seafloor. The time sequence of fields was then used to estimate height decorrelation with time. Fields were also used to calculate height spectra for the seafloor, and to estimate spectral decorrelation with time. These estimates were subsequently compared for differences in decorrelation time between frequencies. Finally, quantitative results were used as input for the small perturbation surface scattering model to predict the time evolution of acoustic backscatter. Preliminary results indicate that seafloor decorrelation occurs on the scale of hours. [Work supported by ONR.]

5aUWb4. Statistical and change-detection analyses using quantitative side-scan-sonar data. Jerald W. Caruthers (The Univ. of Southern Mississippi, 1020 Balch Blvd., Stennis Space Ctr., MS 39529)

This paper discusses recent basic, high-frequency, bottom-backscattering research conducted in conjunction with sediment-classification projects and the ONR bottom scattering research projects, KauaiEx and SAX04. This work has a bearing on statistical analyses and bottom change detection relevant to the detection of objects on or near the bottom in shallow water. The research discussed here includes the analyses of data from three surveys made between 2002 and 2004. The primary contributions of this work are based on the use of probability density functions (PDFs) of the backscatter signals to specify the various regimes of bottom sediments and to detect spatial changes in these regimes based on chi-square and other tests applied to these PDFs. A simple, quantitative test for non-Rayleighness of a PDF was also applied. [This work was supported by the ONR.]

5aUWb5. Low-frequency scattering from a mud volcano located offshore Sicily. Anthony L. Gerig and Charles W. Holland (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA, 16804)

Mud volcanoes are objects that form on the seafloor due to the emission of gas and fluidized sediment from the earths interior. They vary widely in size, can be exposed, proud, or buried, and are of interest to the underwater acoustics community as potential sources of active sonar clutter. Coincident seismic reflection data and low-frequency bistatic scattering data were gathered from one such volcano buried in the Straits of Sicily. The bistatic data were generated using a pulsed piston source and a 64-element horizontal array, both towed over the top of the volcano. The purpose of this work was to appropriately model low-frequency scattering from the volcano using the bistatic returns, seismic bathymetry, and knowledge of the general geoacoustic properties of the area's seabed to guide understanding and model development. Ray theory, with some approximations, was used to model acoustic propagation through overlying layers. Due to the volcano's size, scattering was modeled using geometric acoustics and a simple representation of volcano shape. Modeled bistatic data compared relatively well with experimental data, although some features remain unexplained. Results of an inversion for the volcanos reflection coefficient indicate that it is acoustically softer than expected. [Work supported by ONR, NURC.]

5aUWb6. Backscattering by layered elastic seafloors: The equivalent input backscattering strength approach. Laurent Guillon (Ecole Navale, IRENav, BP 600, 29240 Brest Armees, France, guillon@ecole-navale.fr)

In low-frequency experiments, an acoustic signal may penetrate with great depth into the seafloor and interact with submerged structures. Consequently, for many applications, there is need for a model to predict the backscattering strength (BS) of a layered seafloor containing elastic layers. A few models exist; however, two problems exist for their use: first, as most of them are based on specific configurations they are poorly adaptable, and second, very few deal with both layered and elastic seafloors. This paper proposes to extend to the case of elastic layers the equivalent input backscattering strength (EIBS) approach defined for a fluid layered seafloor [L. Guillon and X. Lurton, ''Backscattering from buried sediment layers: The equivalent input backscattering strength model,'' J. Acoust. Soc. Am. **109**, 122–132 (2001)]. The BS is calculated as follows: each layer BS is defined with a specific model, then each local BS is modified to take into account the various effects of stratification, and finally the different modified BS are added to provide the total BS. Two different local models for the individual BS are tested within this general frame. The numerical results obtained show the flexibility of the EIBS approach and its ability to reveal specific effects of layering on the global BS. [Work supported by IFREMER.]
