ACOUSTICAL NEWS—USA

Elaine Moran
Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747–4502

Editor's Note: *Readers of this journal are encouraged to submit news items on awards, appointments, and other activities about themselves or their colleagues. Deadline dates for news items and notices are 2 months prior to publication.*

Reviewers of Manuscripts, 2005

Each year the *Journal* endeavors to publish a list of all the persons who reviewed manuscripts during the preceding year. Such a list is a compendium of names supplied by the Associate Editors. Because our peer review system depends strongly on the continuing anonymity of the reviewers, the *Journal* publishes these names in alphabetical order without identification of the associate editors who provided the names and without identification of the papers they reviewed. The primary reason for the publication of the list is to express the *Journal's* gratitude to its reviewers. Reviewing a paper is often a very time consuming and demanding task, and the anonymity requirement yields no professional recognition to those who generously provide their time to help the Associate Editors decide which papers should be published and to give constructive criticisms to the authors. The *Journal* is justifiably proud of this list, which includes a goodly proportion of all the researchers and eminent authorities in acoustics and related fields. In a compendium of this length, omissions and errors are inevitable. If anyone notices such, please send the corrections and missing names via e-mail or regular mail to either Elaine Moran (asa@aip.org) or Allan Pierce (adp@bu.edu).

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future.

	2006
6–9 June	151st Meeting of the Acoustical Society of America, Providence, RI [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].
17–21 Sept.	INTERSPEECH 2006 (ICSLP 2006), Pittsburgh, PA [www.interspeech2006.org; http://www.interspeech2006.org/].
28 Nov.–2 Dec.	152nd Meeting of the Acoustical Society of America joint with the Acoustical Society of Japan, Honolulu, HI [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747- 4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org]. Deadline for receipt of abstracts: 30 June 2006.
	2007
4–8 June	153rd Meeting of the Acoustical Society of America, Salt Lake City, UT [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].
27 Nov.–2 Dec.	154th Meeting of the Acoustical Society of America, New Orleans, LA (note Tuesday through Saturday) [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747- 4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].
	2008
28 July–1 Aug.	9th International Congress on Noise as a Public Health Problem (Quintennial meeting of ICBEN, the International Commission on Biological Effects of Noise). Foxwoods Resort, Mashantucket, CT [Jerry V. Tobias, ICBEN 9, P. O. Box 1609, Groton, CT 06340-1609; Tel.: 860-572-0680; Web: www.icben.org; E-mail: icben2008@att.net].

Cumulative Indexes to the Journal of the Acoustical Society of America

Ordering information: Orders must be paid by check or money order in U.S. funds drawn on a U.S. bank or by Mastercard, Visa, or American Express credit cards. Send orders to Circulation and Fulfillment Division, American Institute of Physics, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2270. Non-U.S. orders add $11 per index.

Some indexes are out of print as noted below.

Volumes 1–10, 1929–1938: JASA and Contemporary Literature, 1937–1939. Classified by subject and indexed by author. Pp. 131. Price: ASA members $5; Nonmembers $10.

Volumes 11–20, 1939–1948: JASA, Contemporary Literature, and Patents. Classified by subject and indexed by author and inventor. Pp. 395. Out of Print.

Volumes 21–30, 1949–1958: JASA, Contemporary Literature, and Patents. Classified by subject and indexed by author and inventor. Pp. 952. Price: ASA members $20; Nonmembers $75.

Volumes 31–35, 1959–1963: JASA, Contemporary Literature, and Patents. Classified by subject and indexed by author and inventor. Pp. 1140. Price: ASA members $20; Nonmembers $90.

Volumes 36–44, 1964–1968: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 485. Out of Print.

Volumes 36–44, 1964–1968: Contemporary Literature. Classified by subject and indexed by author. Pp. 1060. Out of Print.

Volumes 45–54, 1969–1973: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 540. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).

Volumes 55–64, 1974–1978: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 816. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).

Volumes 65–74, 1979–1983: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 624. Price: ASA members $25 (paperbound); Nonmembers $75 (clothbound).

Volumes 75–84, 1984–1988: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 625. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).

Volumes 85–94, 1989–1993: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 736. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).

Volumes 95–104, 1994–1998: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 632. Price: ASA members $40 (paperbound); Nonmembers $90 (clothbound).

Volumes 105–114, 1999–2003: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 616. Price: ASA members $50; Nonmembers $90 (paperbound).

ACOUSTICAL STANDARDS NEWS

Susan B. Blaeser, Standards Manager
ASA Standards Secretariat, Acoustical Society of America, 35 Pinelawn Rd., Suite 114E, Melville, NY 11747 [Tel.: (631) 390-0215; Fax: (631) 390-0217; e-mail: asastds@aip.org]

George S. K. Wong
Acoustical Standards, Institute for National Measurement Standards, National Research Council, Ottawa, Ontario K1A 0R6, Canada [Tel.: (613) 993-6159; Fax: (613) 990-8765; e-mail: george.wong@nrc.ca]

American National Standards (ANSI Standards) developed by Accredited Standards Committees S1, S2, S3, and S12 in the areas of acoustics, mechanical vibration and shock, bioacoustics, and noise, respectively, are published by the Acoustical Society of America (ASA). In addition to these standards, ASA publishes Catalogs of Acoustical Standards, both National and International. To receive copies of the latest Standards Catalogs, please contact Susan B. Blaeser.

Comments are welcomed on all material in Acoustical Standards News.

This Acoustical Standards News section in JASA, as well as the National and International Catalogs of Acoustical Standards, and other information on the Standards Program of the Acoustical Society of America, are available via the ASA home page: http://asa.aip.org.

Standards Meetings Calendar National

The 151st ASA Meeting, Providence, RI, the Westin Providence Hotel, 5-9 June 2006, the ASA Committee on Standards (ASACOS), ASACOS STEERING Committees, and Accredited Standards Committees S1 Acoustics, S2 Mechanical Vibration and Shock, S3 Bioacoustics, and S12 Noise, and the Standards Plenary Group will meet as follows:

•Monday, 5 June 2006 7:00 P.M.

ASACOS Steering Committee

•Tuesday, 6 June 2006 8.30 A.M.

ASA Committee on Standards (ASACOS). Meeting of the Committee that directs the Standards Program of the Acoustical Society.

•Tuesday, 6 June 2006 10:30 A.M.

Standards Plenary Group. To discuss national and international items relevant to Accredited Standards Committees S1, S2, S3, and S12. This meeting also includes the annual meetings of the U.S. Technical Advisory Groups (TAGs) for ISO/TC 43 Acoustics, ISO/TC 43/SC 1 Noise, IEC/TC 29 Electroacoustics, ISO/TC 108 Mechanical Vibration and Shock, ISO/TC 108/SC 2 Measurement and Evaluation of Mechanical Vibration and Shock as Applied to Machines, Vehicles and Structures; ISO/TC 108/SC3 Use and Calibration of Vibration and Shock Measuring Instruments, ISO/TC 108/SC 4 Human Exposure to Mechanical Vibration and Shock; ISO/TC 108/SC 5 Condition Monitoring and Diagnostics of Machines, and ISO/TC 108/SC 6 Vibration and Shock Generating Systems.

•Tuesday, 6 June 2006 1:45 P.M.

Accredited Standards Committee S1 on Acoustics.

•Tuesday, 6 June 2006 3:30 P.M.

Accredited Standards Committee S12 on Noise.

•Wednesday, 7 June 2006 8:30 A.M.

Accredited Standards Committee S2 on Mechanical Vibration and Shock.

•Wednesday, 7 June 2006 10:30 A.M.

Accredited Standards Committee S3 on Bioacoustics.

American National Standards Call for Comment on Proposals Listed

This section solicits comments on proposed new American National Standards and on proposals to revise, reaffirm, or withdraw existing standards. The dates listed in parentheses are for information only.

ASA (ASC S1) (Acoustical Society of America)

REAFFIRMATIONS

BSR S1.4-1983 (R200x), Specification for Sound Level Meters [reaffirmation of ANSI S1.4-1983 (R 2001)]

This standard specifies minimum requirements for three basic types of sound level meters, types 0, 1, and 2, with performance requirements that become progressively less stringent, proceeding from type 0 to type 2. For each type, the standard requires three frequency weightings, *A*, *B*, and *C*; and two exponential- time-averaging characteristics, slow and fast.

BSR S1.4 A -1985 (R 200x), Amendment to ANSI S1.4-1983 [reaffirmation of ANSI S1.4 A-1985 (R 2001)]

The intent of this amendment is (a) to specify the electrical design goal for the relative response characteristics of the *A*-weighted frequency response up to 100 kHz; and (b) to specify type 0 and type 1 tolerance limits on relative electrical response for frequencies between 16 kHz and 100 kHz.

BSR S1.6-1984 (R 200x), Preferred Frequencies, Frequency Levels, and Band Numbers for Acoustical Measurements [reaffirmation of ANSI S1.6-1984 (R 2001)]

This standard defines the preferred frequencies, or nominal band-center frequencies to be used for acoustical measurements. Frequency levels or band numbers are associated with these sets of frequencies, and the preferred frequencies are rounded values obtained from those for which the corresponding frequency levels or band numbers are integers.

BSR S1.8-1989 (R 200x), Reference Quantities for Acoustical Levels [reaffirmation of ANSI S1.8-1989 (R 2001)]

This standard includes reference quantities for commonly used levels in acoustics, electroacoustics, and mechanical vibration. Acoustical levels of various kinds are commonly used to describe acoustical measurements in gases, liquids, and solids. A reference quantity, preferably independent of the medium, is needed for each kind of level. The preferred unit for an acoustical level is the decibel.

BSR S1.9-1996 (R200x), Instruments for the Measurement of Sound Intensity [reaffirmation of ANSI S1.9-1996 (R 2001)]

Specifies the requirements for instruments to measure sound intensity employing the two-microphone technique and methods for performance verification to meet the requirements. Its primary application is to instruments used for the determination of sound power of sources, in accordance with the requirements of ANSI S12.12-1992. The requirements and methods of performance verification are specified for the complete instrument system and separately for the probes and processors forming the complete system.

BSR S1.15, Part 1-1997 (R200x), Measurement Microphones—Part 1: Specifications for Laboratory Standard Microphones [reaffirmation of ANSI S1.15, Part 1-1997 (R 2001)]

This Standard specifies mechanical dimensions and certain electroacoustical characteristics for capacitor (condenser) microphones used as laboratory standards for sound pressure measurements of the highest attainable accuracy. The specifications are intended to ensure that primary calibration by

 0001-4966/2006/119(5)/2549/4/$22.50

the reciprocity method can be readily carried out. This Standard establishes a system to classify laboratory standard microphones into a number of types according to their dimensions and properties.

BSR S1.42-2001 (R200x), Design Response of Weighting Networks for Acoustical Measurements (reaffirmation of ANSI S1.42-2001)

This Standard provides the design criteria for both the frequency-domain response (amplitude and phase) and time-domain of the *A*- and *C*-weighting networks used in acoustically related measurements. The poles and zeros for each weighting network are given, along with equations for computing the amplitude and phase responses as functions of frequency and impulse and step responses as functions of time. Other known weighting networks that had been standardized, such as the *B*-, *D*-, and *E*-weightings, or weightings that were published in the past, are listed in the Annexes for reference.

ASA (ASC S2) (Acoustical Society of America)

REAFFIRMATIONS

BSR S2.2-1959 (R200x), Methods for the Calibration of Shock and Vibration Pickups [reaffirmation of ANSI S2.2-1959 (R 2001)]

This standard is designed to acquaint the user with the general principles of calibration of shock and vibration pickups and to describe concisely several standard methods that have proven to give reliable and reproducible results. Further details concerning these methods are given in the Appendix. Also, other methods that have not as yet reached the stage of development of the standard methods are described briefly in the Appendix. (20 March 2006)

BSR S2.8-1972 (R200x), Guide for Describing the Characteristics of Resilient Mountings [reaffirmation of ANSI S2.8-1972 (R 2001)]

This standard sets forth suggestions as to subject matter and format for describing resilient mountings, so that there will be a clear understanding by both the user and the manufacturer. It is beyond the scope of this standard to present characteristics of resilient mountings.

BSR S2.9-1976 (R200x), Nomenclature for Specifying Damping Properties of Materials [reaffirmation of ANSI S2.9-1976 (R 2001)]

This standard presents the preferred nomenclature (parameters, symbols, and definitions) for specifying the damping properties of uniform materials and uniform specimens, where "uniform" implies homogeneity on a macroscopic scale.

BSR S2.20-1983 (R200x), Estimating Air Blast Characteristics for Single Point Explosions in Air, with a Guide to Evaluation of Atmospheric Propagation and Effects [reaffirmation of ANSI S2.20-1983 (R 2001)]

Provides qualitative definitions of explosion characteristics for a single-point explosion in air, along with methodologies for scaling these characteristics for a wide range of yield and ambient air conditions. Factors for use with common solid explosives are also included. Methods are provided for predictions of long-range propagation under atmospheric refractive influences. Target damage estimation procedures are provided for use in explosion operation planning and evaluation.

BSR S2.24-2001 (R200x), Graphical Presentation of the Complex Modulus of Viscoelastic Materials [reaffirmation of ANSI S2.24-2001]

This Standard specifies the procedure for generating a graphical presentation of the frequency and temperature dependence of the complex modulus of viscoelastic materials (13 March 2006).

BSR S2.71-1983 (R200x), Guide to the Evaluation of Human Exposure to Vibration in Buildings [reaffirmation and redesignation of ANSI S3.29-1983 (R 2001)]

Assesses reactions of humans to vibrations of 1 to 80 Hz inside buildings by use of degrees of perception and associated vibration levels and durations. Accelerations or velocities inside buildings may be measured to assess perceptibility and possible adverse reactions from those inside. (20 March 2006)

WITHDRAWALS

ANSI S2.13-Part 1-1996 (R2001), Mechanical Vibration of Non-Reciprocating Machines—Measurements on Rotating Shafts and Evaluation—Part 1: General Guidelines [withdrawal of ANSI S2.13-Part 1-1996 (R 2001)]

This Standard provides the test procedure for the measurement and evaluation of the mechanical vibration of nonreciprocating machines, as measured on rotating shafts. The standard also provides guidelines for adapting evaluation criteria for different types of machines.

ANSI S2.41-1985 (R2001), Mechanical Vibration of Large Rotating Machines with Speed Range from 10 to 200 rev/s—Measurement and Evaluation of Vibration Severity in situ [withdrawal of ANSI S2.41-1985 (R 2001)]

Focuses on the measurement and evaluation of vibration severity of large rotating machinery in situ. It is not applicable to reciprocating machinery. The values recommended as limits in this standard are intended to serve as standard values for machines of similar type, when measured in accordance with the procedures describes herein. The recommended vibration limits may be used for acceptance standards or for monitoring the performance of the machine during service operations.

ASA (ASC S12) (Acoustical Society of America)

REVISIONS

BSR S12.65-200x, Rating Noise with Respect to Speech Interference [revision and redesignation of ANSI S3.14-1977 (R 1997)]

This standard defines a simple numerical method for rating the expected speech-interfering aspects of noise using acoustical measurements of the noise.

ASABE (American Society of Agricultural and Biological Engineers)

NEW NATIONAL ADOPTIONS

BSR/ASABE/ISO 5007-200x, Agricultural wheeled tractors—Operator's seat—Laboratory measurement of transmitted vibration (identical national adoption)

Specifies a laboratory method for measuring and evaluating the effectiveness of the suspension of operator seats on agricultural wheeled tractors. (13 March 2006)

BSR/ASABE/ISO 5008-2002 W/Cor. 1-200x Agricultural wheeled tractors and field machinery—Measurement of whole-body vibration of the operator (identical national adoption).

Specifies methods for measuring and reporting the whole body vibration to which the operator of an agricultural wheeled tractor or other field machine is exposed when operating on a standard test track.

ATIS (Alliance for Telecommunications Industry Solutions)

NEW STANDARDS

BSR ATIS 0600005-200x, Acoustic Measurement

This standard identifies sound power as the preferred method of measuring the emission of acoustic noise from telecommunications equipment. The main focus is to use sound power to gain repeatability and accuracy over sound pressure methods. This standard will also provide the emission limits for the temperature-controlled environment (i.e., central office, data centers) for the North American environment. (Comment Deadline: April 10, 2006)

ARI (Air-Conditioning and Refrigeration Institute)

NEW STANDARDS

BSR/ARI 530-200x, Rating of Sound and Vibration for Refrigerant Compressors

This standard applies to external-drive, hermetic and semihermetic refrigerant compressors. In the case of external-drive refrigerant compressors, the driving mechanism shall be excluded from the sound and vibration mea-

surements. However, for semihermetic refrigerant compressors, where the driving mechanism is an integral part of the compressor assembly, it shall be included in the measurements. (25 April 2006)

IEEE (ASC C63) (Institute of Electrical and Electronics Engineers)

REVISIONS

BSR C63.19-200x, Methods of Measurement of Compatibility between Wireless Communications Devices and Hearing Aids (revision of ANSI C63.19-2001)

This standard sets forth uniform methods of measurement and parametric requirements for the electromagnetic and operational compatibility and accessibility of hearing aids used with wireless communications devices operating in the range of 800 MHz to 3 GHz. However, this version is focused on existing services, which are in common use.

Project Initiation Notification System (PINS)

ANSI Procedures require notification of ANSI by ANSI-accredited standards developers (ASD) of the initiation and scope of activities expected to result in new or revised American National Standards (ANS). Early notification of activity intended to reaffirm or withdraw an ANS and in some instances a PINS related to a national adoption is optional. The mechanism by which such notification is given is referred to as the PINS process. For additional information, see clause 2.4 of the ANSI Essential Requirements: Due Process Requirements for American National Standards. Following is a list of proposed actions and new ANS that have been received recently from ASDs.

ASA (ASC S3) (Acoustical Society of America)

BSR S3.20-200x, Bioacoustical Terminology (revision of ANSI S3.20-1995 (R 2003))

This standard provides definitions for a wide variety of terms used in human bioacoustics, including hearing, speech, psychoacoustics, and physiological acoustics. It is intended to supplement ANSI S1.1, American National Standard for Acoustical Terminology, in which more-generally-used terms in acoustics are defined, including a number of terms from physiological and psychological acoustics and music.

ARI (Air-Conditioning and Refrigeration Institute)

BSR/ARI 370-200x, Sound Rating of Large Outdoor Refrigerating and Air-Conditioning Equipment (new standard)

This standard applies to the outdoor portions of factory-made commercial and industrial Large Outdoor Refrigerating and Air-Conditioning Equipment, including heat pumps, used for refrigerating or air-conditioning of spaces.

BSR/ARI 530-200x, Rating of Sound and Vibration for Refrigerant Compressors (new standard)

This standard applies to External-drive, Hermetic and Semi-Hermetic Refrigerant Compressors. In the case of External-drive Refrigerant Compressors, the driving mechanism shall be excluded from the sound and vibration measurements. However, for Semi-Hermetic Refrigerant Compressors, where the driving mechanism is an integral part of the compressor assembly, it shall be included in the measurements.

SMACNA (Sheet Metal and Air-Conditioning Contractors' National Association)

BSR/SMACNA 007-200x, Residential Comfort System Installation Standards Manual (new standard)

The document will provide installation standards for residential heating, ventilating and, air conditioning (HVAC) systems. It will include the most current mechanical and control technology so contractors and designers can design, construct, and install all HVAC systems, from the simplest to the state-of-the-art. Forced-air heating, heat pumps, automatic controls and thermostats, flues, vents, sound and vibration, air cleaning, and other subjects and technologies appropriate for this new century will be included.

IEEE (Institute of Electrical and Electronics Engineers)

BSR/IEEE C57.151-200x, Sound Level Measurement Guide for Liquid Filled and Dry Type

Transformers and Reactors (new standard)

This user guide provides supporting information to help both manufacturers and purchasers apply the measurement techniques described in IEEE C57.12.90 and IEEE C57.12.91. The sources and characteristics of transformer and reactor sound are described. Practical guidance on making measurements is given, and factors that may influence the accuracy of the methods are discussed.

Final actions on American National Standards

The standards actions listed below have been approved by the ANSI Board of Standards Review (BSR) or by an ANSI-Audited Designator, as applicable.

ASA (ASC S12) (Acoustical Society of America)

REAFFIRMATIONS

Model-Based Signal Processing

James V. Candy

Wiley-IEEE Press, New York, 2006, 677 pp. $125.00 hardcover. ISBN 0471236322

The use of models in signal processing already plays a major role in the area of inverse problems, in which the goal is to extract information concerning the medium or certain of its contents. In such problems, the model plays the role of the structure in which the unknown parameters lie. Seismics is a good example of this. However, using models to improve the detection or estimation performance of a processor is a fairly new idea. In the acoustics world, its origins go back to people like Parvelescu, Clay, Hinich, and Bucker, whose ideas led to what is now called matched-field processing. Their ideas made clear that the inclusion of physical models in a processing scheme can be an effective means of introducing *a priori* information and thereby improving performance.

As this concept was developed, it soon became clear that there was a down side. Unless the models (or their parameters) were sufficiently well known, the method would perform poorly or, indeed, fail completely. In the underwater acoustics world, this became known as the "mismatch problem." Methods of dealing with this usually entailed either desensitizing the processor or trying to include some of the troublesome parameters themselves as jointly estimated "nuisance" parameters. In the theory developed in this book, the mismatch problem is seen to be simply a consequence of poor processor design, and, in the case where the model itself is insufficient for the task, it is obvious to the designer.

At some point in the development of any useful discipline, someone usually comes along and organizes things into a coherent and self-consistent structure. This is precisely what James Candy has done for the field of model-based processing. The book is organized in a hierarchical structure. After some necessary introductory material, a thorough review of estimation theory is given. This is followed by the development of parametric signal processing methods, such as time-series analysis and its generalizations. Next is the development of state-space processors, which naturally focuses on the Kalman filter, and it is shown how the parametric processors fit into this scheme. After developing the linear Kalman filter, the nonlinear and adaptive cases are studied. Although, strictly speaking, parametric processors are model based, the models do not necessarily represent the physics in a transparent sense. Thus, the book treats physics-based models as a distinct class of problems.

The Kalman filter is a state-space formulation of a multidimensional Gauss-Markov process and thereby forms a natural basis in which physics-based models can be included. This follows from the fact that the state-space-based equations of the Kalman filter form a natural basis for including the differential equations of the relevant physics. The result is a formulation that can be recursive in either space or time, is adaptive, and can be "augmented" by including the nuisance parameters that were the bane of matched-field processors. This means that such processors provide the basis for self-correcting models. This capability is due, in no small measure, to the fact that the Kalman filter provides a direct measure of the "goodness of fit" of a model via the innovation sequence, one of the natural outputs of the processor.

After this development, the author takes us through a broad spectrum of applications. These include reentry vehicle tracking, laser ultrasonics, towed-array processing, internal waves, acoustic source localization, oceanic inversion, and nondestructive evaluation. The author's experience in these fields lends a great deal to the value of this text. Such a comprehensive emphasis on the reduction to practice of the theory is a critical factor found lacking in many signal processing works.

Besides providing a formal basis for model-based processing, the book serves another purpose. The Kalman filter, in my opinion, is not being used to its full potential in the signal processing world. This is partly due to the fact that it is often viewed simply as a control theory tool and, consequently, many signal processing professionals are not terribly conversant with it, and therefore are not aware of its power beyond the control theory world. To put it succinctly, it is a generalized, multi-channel, recursive, minimum-variance estimator into which the user can insert essentially any model he desires. The modern signal-processing professional ignores it at his own loss.

It should be mentioned that the Kalman filter is strictly optimal only in the linear Gaussian case. The nonlinear case, which usually entails non-Gaussian statistics, is dealt with by the so-called extended Kalman filter (EKF) in which the nonlinearities are treated by a Taylor series approximation. Although the EKF works well and is widely applied with great success, new research in this area has been focusing on the *unscented* Kalman filter, which avoids the linearization approach used by the EKF, and the author gives an introduction to this field.

The book is aimed at the graduate student, and therefore it will help if the reader is already somewhat conversant in modern digital signal processing, estimation theory, time-series analysis, and spectral estimation. For those who do not quite fulfill these requirements, the book is still accessible, since it contains a comprehensive set of problems for each chapter, and appendices on probability and statistics and the algorithmic mechanics of sequential model-based processing. In my judgment, it belongs in the library of every practicing signal processor.

OBITUARY

Peter Nielsen Ladefoged ● 1925–2006

Peter Nielsen Ladefoged, a Fellow of this Society and Society Silver Medal recipient, passed away unexpectedly in London on January 24, 2006 due to a stroke. Professor Ladefoged was returning from a fieldwork trip to India where he was studying Toda, an endangered language with few remaining speakers. This was the last of many fieldwork trips Ladefoged conducted with an array of colleagues, including stays in Nigeria, Botswana, Ghana, Uganda, Tanzania, Sierra Leone, Senegal, India, Yemen, Papua New Guinea, Nepal, Kenya, Korea, South Africa, Brazil, Mexico, Australia, and China. At the time of his death, Ladefoged was Distinguished Professor of Phonetics Emeritus and Research Linguist at University of California, Los Angeles, as well as Leverhulme Professor at University of Edinburgh (2005) and Adjunct Professor at the University of Southern California.

Professor Ladefoged is considered the father of the field of linguistic phonetics, which integrates phonetic sciences with linguistic theory. His seminal textbook used throughout the field, *A Course in Phonetics*, is now in its 5th edition (1st edition, Harcourt Brace 1982; 5th edition, Thomson Wadsworth 2006). Professor Ladefoged emphasized the importance of considering the full diversity of human speech sounds—their articulatory, acoustic, and perceptual properties—in seeking a linguistic characterization of the sounds of language. In particular, he melded field and experimental data collection with pioneering analytical techniques. The volume *The Sounds of the World's Languages*, coauthored with Ian Maddieson (Blackwell 1996), stands as a comprehensive account of their research in this area. At the time of his death he was engaged in developing a web archive of diverse speech sounds gathered from scores of languages in over 50 years of research (archive.phonetics.ucla.edu/ and phonetics.ucla.edu/).

In addition to Ladefoged's contributions investigating and documenting the sounds of the world's languages, his important research on vowel acoustics, perception, and classification began with his Ph.D. thesis and continued throughout his career in collaboration with Donald Broadbent, Walter Lawrence, Richard Harshman, Louis Goldstein, Keith Johnson, and Mona Lindau [Lingua **5.2**, 113–128 (1956); Nature **178**, 815–816 (1956); J. Acoust. Soc. Am. **29**, 98–104 (1957); J. Acoust. Soc. Am. **62**, 693–707 (1977); J. Acoust. Soc. Am. **94**, 701–714 (1993)]. He demonstrated that vowels can be well classified by their auditory properties and advocated that auditory properties, in addition to articulatory ones, are relevant in the categorization of speech sounds.

Ladefoged valued instrumental techniques in the field and in the laboratory, and developed a long-standing interest in seeing that they were appropriately applied outside these arenas as well. He was particularly concerned that spectrographic analysis was being abused in the field of forensic "voiceprinting," and was concerned about factors affecting the reliability of earwitness testimony [Language and Speech **21**, 373–374 (1978); Echoes **14**, 2, 14–15 (2004)]. His scholarly efforts and public advocacy in these areas introduced a measure of healthy skepticism regarding expert and naïve trial testimony.

Ladefoged's seminal contributions led to numerous prestigious awards. During his career, Professor Ladefoged was elected Fellow of the Acoustical Society of America, of the American Speech and Hearing Association, and of the American Academy of Arts and Sciences. He served as President of the Linguistic Society of America (1978) and of the International Phonetic Association (1985), receiving the Gold Medal from the International Congress of Phonetic Sciences in 1991 and the Silver Medal from the Acoustical Society of America in 1994 "for advancing the theory of acoustic phonetics and phonology using acoustic field data from many of the world's languages" [J. Acoust. Soc. Am. **96**(5), 2 (1994)]. He received honorary doctoral degrees from the University of Edinburgh (D.Litt., 1993) and Queen Margaret University (D.Sc., 2002).

Professor Ladefoged was born in Sutton, England in 1925. After his war service from 1944-1947, he received his Ph.D. from University of Edinburgh in 1959, where he studied with David Abercrombie. He continued research on vowel perception with Donald Broadbent and on respiration with David Whitteridge. In 1953, Ladefoged married Jenny Ladefoged (née MacDonald), who became his partner and collaborator throughout his life. Ladefoged joined the faculty of the University of California, Los Angeles in 1962 and founded the UCLA Phonetics Laboratory shortly thereafter. Among his more than 20 Ph.D. students were Victoria Fromkin, John Ohala, Ian Maddieson, Louis Goldstein, and Catherine Browman. He retired in 1991 but remained active in both teaching and research until his death at the age of 80. More details regarding Professor Ladefoged's impact as a teacher and a phonetician can be found at www.linguistics.ucla.edu/people/ladefoge/remember/index.htm. A recognition by the field of his recent 80th birthday, celebrated with a special session at the 150th Meeting of the Acoustical Society [J. Acoust. Soc. Am. **118**(3), 2 (2005)], can be found at sail.usc.edu/peterladefoged80.html. In addition to his wife Jenny, Peter Ladefoged is survived by his three children and his grandchildren.

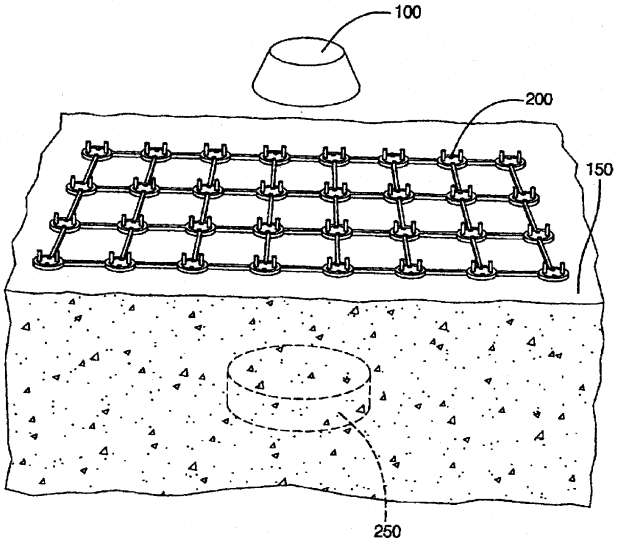
43.20.Gp METHOD AND APPARATUS FOR ACOUSTIC DETECTION OF BURIED OBJECTS

Robert Hickling, Huntington Woods, Michigan
1 March 2005 (Class 367/88); filed 9 September 2003

Detection of buried land mines is accomplished using an array of ''acoustic vector probes'' **200** placed near the surface of the ground **150**. Each probe consists of a tetrahedral arrangement of four microphones allowing for the measurement of sound velocity vector and sound pressure.



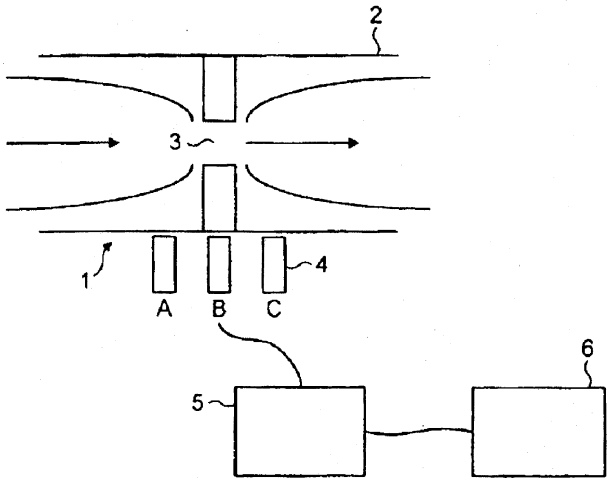
An impulse acoustic source **100** above the array broadcasts 0.05–0.2-ms sound pulses. The detection is based on multichannel processing of the signals echoed from the mine **250**, computing a sound-intensity vector at each probe in the array.—DMD

6,945,094

43.20.Ye VISCOSITY MEASUREMENT

Svein Eggen *et al.*, assignors to Borealis Technology Oy
20 September 2005 (Class 73/54.41); filed in the United Kingdom 22 December 2000

The rheological characterization of a polymer when it leaves the polymerization reactor is accomplished by analysis of the acoustic emissions of the melt when it flows through apparatus **1** consisting of conduit **2** and



constriction **3**. The accelerometers **4** detect the acoustic emissions. Signals from **4** are sent to amplifier/preprocessor **5** and analysis is carried out by computer **6**.—NAS

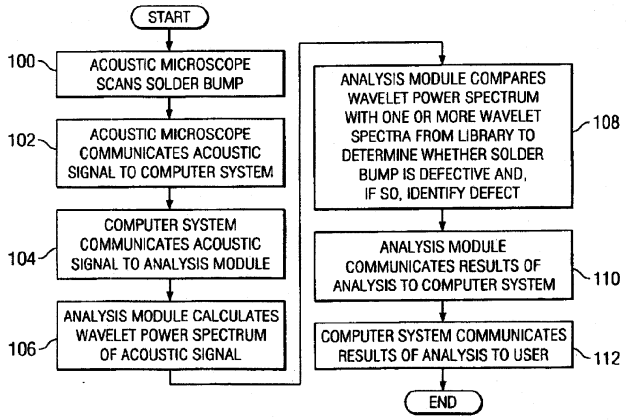
 0001-4966/2006/119(5)/2557/15/$22.50

6,950,761

43.20.Ye WAVELET ANALYSIS OF ONE OR MORE ACOUSTIC SIGNALS TO IDENTIFY ONE OR MORE ANOMALIES IN AN OBJECT

Kartik Ramanujachar, assignor to Texas Instruments Incorporated
27 September 2005 (Class 702/48); filed 31 December 2003

The wavelet analysis of a signal or signals from an acoustic scan of an object is compared to a reference library to determine if the object is known or unknown. The reference library contains both good and bad scans. In the



instant case, this technique is applied specifically to solder bumps in integrated circuits.—NAS

6,954,175

43.30.Xm ACCURATE POSITIONING OF DEVICES SUSPENDED UNDERWATER FROM A FLOATING BODY

Wayne H. Cox, assignor to Input/Output, Incorporated
11 October 2005 (Class 342/357.07); filed 2 November 2004

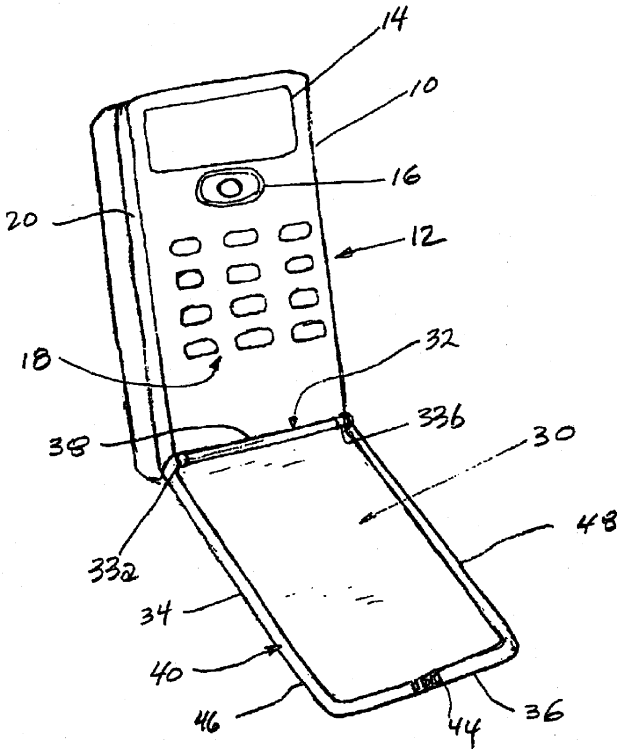
A system is described for accurately determining the position of a sonar device attached to the bottom of a floating buoy. The sonar device is mounted to the buoy collinearly with a pair of GPS antennas, or other antennas, on the top side of the buoy. The position of the sonar device can be computed from knowledge of the range of the two antennas relative to the source of the EM wave that excites them, the known distance between these two antennas, and the known distance between one of the antennas and the sonar device.—WT

6,965,790

43.38.Ar ACOUSTIC PIPE FOR FLIP STYLE CELLULAR TELEPHONE

Gregory S. Mendolia, assignor to Ericsson Incorporated
15 November 2005 (Class 455/575.3); filed 23 June 1997

In conventional cell phone design there is a small electret microphone located in the fold-down ''flap'' portion of the hand-held device. This requires electrical wiring from the electret element back to the main chassis of the system. The patent proposes an ''acoustical pipe'' for this purpose. The



microphone element is located in the main assembly and the acoustical path works its way through the hinge down to the bottom of the flap. The path length is probably no more than 4 or 5 in. and, with reasonable care, should cause no degradation of the voice signal. Manufacturing advantages are obvious.—JME

6,967,430

43.38.Dv FLAT RESONATING ELECTROMECHANICAL DRIVE UNIT

Stefan Johansson, assignor to Piezomotor Uppsala AB
22 November 2005 (Class 310/328); filed 1 October 2003

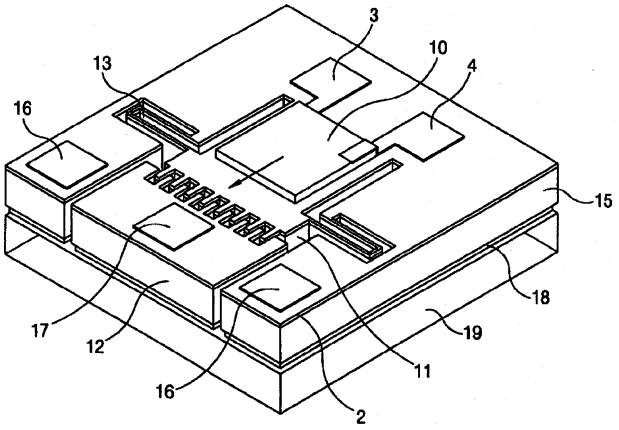
This patent describes an actuator suited to the control of short-throw, high-precision positioning devices for which incremental, not absolute, positioning is adequate. The mode of operation is that of intermittent scrubbing contact between the driver and the driven stage. The drawings are descriptive, but the means by which the requisite hinges could be fabricated without incurring excessive play and losses is not described. There are no dimensions given, although it is suggested that they are all something like a few cm. It is not very well explained in terms of design formulas and considerations, and no performance measurements are given. The patent is not recommended for insights into actuator design.—JAH

6,965,274

43.38.Ew THIN FILM BULK ACOUSTIC RESONATOR FOR CONTROLLING RESONANCE FREQUENCY AND VOLTAGE CONTROLLED OSCILLATOR USING THE SAME

Heon Min Lee and Young Joo Yee, assignors to LG Electronics Incorporated
15 November 2005 (Class 331/107 A); filed 23 June 2003

The present invention concerns a bulk mechanical resonator with spring **13** and mass **12** having an electrically controlled and modifiable spring constant via a comb-shaped gap connected to electrodes **16** and **17**. Utilizing the distance-dependent attraction between the combs when a voltage is applied to them, the mechanical spring constant of the suspension



spring **13** is altered by the existence of a parallel electrical spring. The electronic control is used to create a voltage-tunable oscillator having the capability of feedback control of phase noise. The whole device is conveniently made using surface micromachining techniques.—JAH

6,956,792

43.38.Fx OPENWORK SHELL PROJECTOR

Jason W. Osborn *et al.*, assignors to BAE Systems Information and Electronic Systems Integration Incorporated
18 October 2005 (Class 367/174); filed 28 February 2002

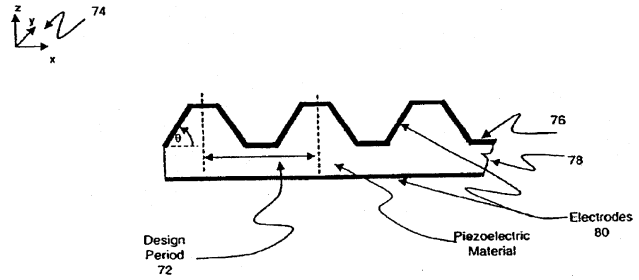
The solid shell of either a flextensional transducer or a slotted-shell cylindrical transducer is replaced by a honeycomb shell. The honeycomb shell provides high specific stiffness with much less weight than a solid shell, thus increasing the transducer's bandwidth, because the honeycomb shell can be thicker, resulting in a greater radiating surface while also reducing total weight and cost.—WT

6,965,189

43.38.Fx BENDING ACTUATORS AND SENSORS CONSTRUCTED FROM SHAPED ACTIVE MATERIALS AND METHODS FOR MAKING THE SAME

Christoph P. Menzel, assignor to Monodrive Incorporated
15 November 2005 (Class 310/330); filed 20 September 2002

This patent describes several different unimorph-style actuators made by nonuniform electroding of piezoelectric materials. The general principle is embodied in the figure, which depicts a slab of piezoelectric material with a corrugated surface. Upon application of a voltage to the top and bottom surfaces, the material will bend due to the nonuniform electric field applied.



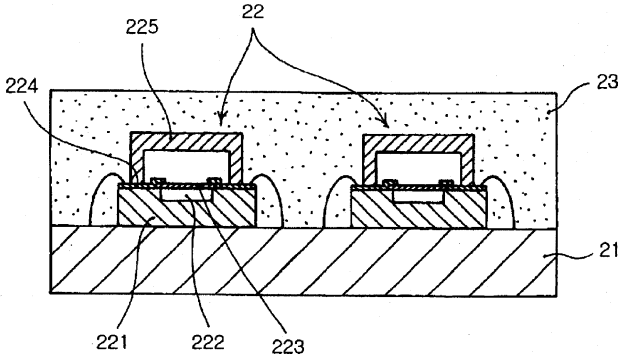
There are several other geometries presented for consideration, but no discussion of the coupling constants or poling details of these configurations is given. Simple electromechanical considerations would suggest that these designs are not as efficient as those created from traditional unimorphs.—JAH

6,965,281

43.38.Fx FBAR, FBAR BASED DUPLEXER DEVICE AND MANUFACTURING METHOD THEREOF

Kook Hyun Sunwoo and Jong Oh Kwon, assignors to Samsung Electro-Mechanics Company, Ltd.
15 November 2005 (Class 333/133); filed in the Republic of Korea 24 September 2003

This patent describes a process for making film bulk acoustic resonators (FBARs) on ordinary PC board or low-temperature cofired ceramic substrates as illustrated by the pair **22**. The objective is to reduce the cost of



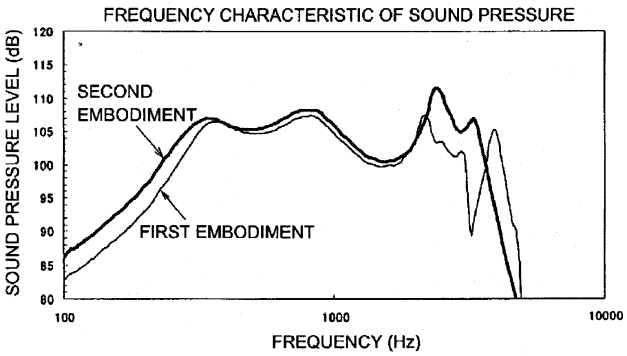
the devices by easing fabrication. However, the performance of such devices is not stated or even hinted at. There is little to be learned from the details.—JAH

6,965,680

43.38.Fx PIEZOELECTRIC ELECTRO-ACOUSTIC TRANSDUCER

Masakazu Yamauchi *et al.*, assignors to Murata Manufacturing Company, Limited
15 November 2005 (Class 381/190); filed in Japan 26 April 2002

The patent first describes the earlier development of a small, multilayer piezoelectric transducer capable of producing high sound levels over a relatively wide frequency range. An improved version is then disclosed which is self-contained and requires no special mounting provisions. Piezoelectric ceramic layers are bonded to the front and back of a resin film.



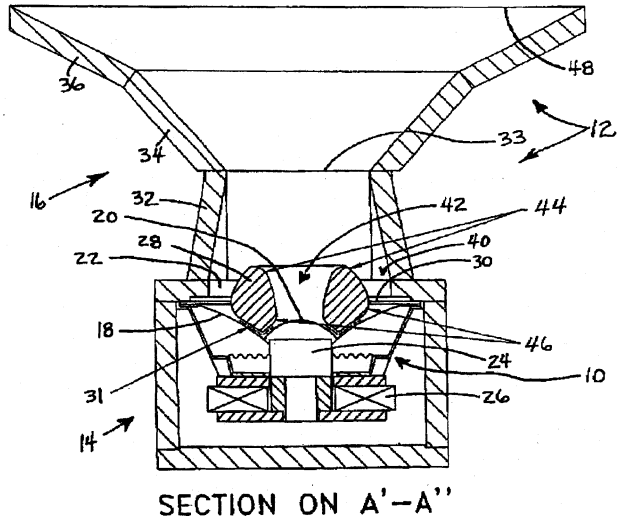
The area of the ceramic vibration elements is 40% to 70% of the area of the film, which is sealed to, and supported by, a rectangular case. The fundamental resonance of the assembly is relatively low, facilitating natural voice reproduction.—GLA

6,950,530

43.38.Ja DIRECTIONAL LOUDSPEAKER UNIT

Jason Baird and William T. Webb, assignors to Martin Audio Limited
27 September 2005 (Class 381/343); filed in the United Kingdom 31 January 2002

This is a mid-frequency, horn-loaded loudspeaker assembly with what is described as a phase-coherent radiating wavefront. Among the items described are a phasing plug **28** of a toroidal (or part-spherical or part-elliptical) shape, a central aperture **42** in the plug **28** which serves princi-



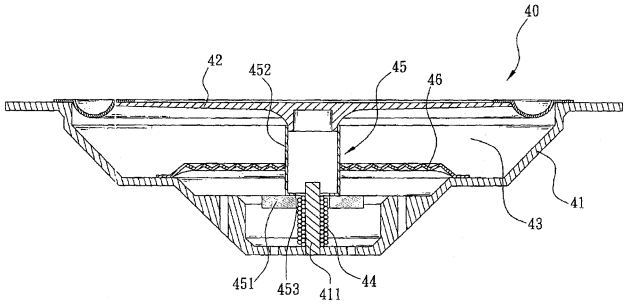
pally as a high-frequency sound path, a second annular path **40** around the plug which is the predominate path for low-frequency sound, and a single driving means for all sounds in the passband.—NAS

6,968,071

43.38.Ja SPEAKER HAVING MAGNETIC MEMBER INSTALLED ON DIAPHRAGM

Chao-Lang Wang, Taipei, Taiwan, Province of China
22 November 2005 (Class 381/423); filed 15 January 2003

The inventor has already patented a moving-magnet loudspeaker in which vaguely defined lines of flux interact with a fixed voice coil (United States Patent 6,415,037 [reviewed in J. Acoust. Soc. Am. **113**(2), 683 (2003)]). This subsequent patent describes the operation of an improved variant in terms that are impossible to decipher: "The primary objective of the present invention is to provide a speaker having a diaphragm disposed around the periphery of a frame on one lateral side of the speaker, such that the diaphragm and the frame enclose a resonant space, and a magnetic



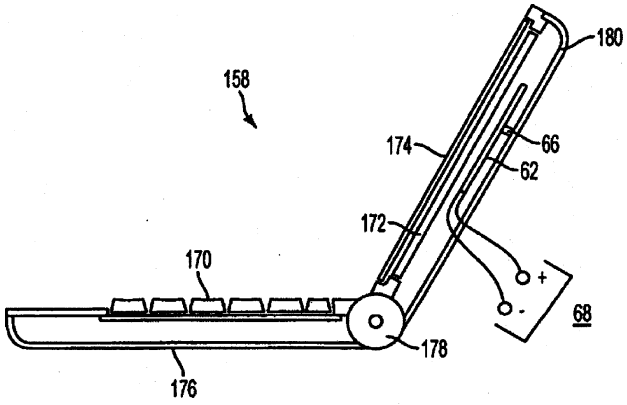
member disposed at the center of the diaphragm and along the direction of the resonant space, thereby when a winding in the middle of the inner side of the frame is excited, the resonant space generates varying magnetic lines, so that an attraction-repulsion effect is generated in the middle of the winding or the reserved space at the position of the periphery to vertically slide the magnetic member and cause the diaphragm to vibrate and generate sound."—GLA

6,965,678

43.38.Ja ELECTRONIC ARTICLE COMPRISING LOUDSPEAKER AND TOUCH PAD

Graham Bank *et al.*, assignors to New Transducers Limited
15 November 2005 (Class 381/152); filed in the United Kingdom 20 July 2001

This patent is concerned with small electronic devices that incorporate touch pads. Although the presence of a touch pad is a requirement of the patent claims, it has no necessary connection with the invention itself. Instead, the patent gives us a detailed analysis of several ways in which mul-



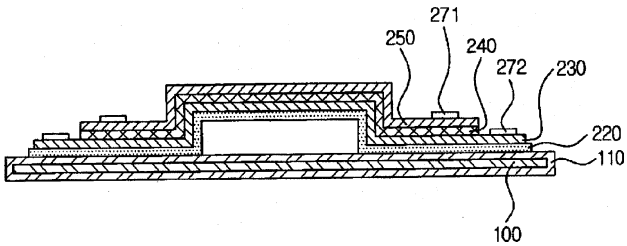
tiresonant, distributed-mode, and/or balanced-mode transduction can be achieved using the outer case of a device as a sound-emitting element. There is a great deal of interesting and valuable information here.—GLA

6,967,362

43.38.Kb FLEXIBLE MEMS TRANSDUCER AND MANUFACTURING METHOD THEREOF, AND FLEXIBLE MEMS WIRELESS MICROPHONE

Yun-woo Nam and Suk-han Lee, assignors to Samsung Electronics Company, Limited
22 November 2005 (Class 257/254); filed in the Republic of Korea 26 September 2002

This patent describes the fabrication of a micromachined microphone said to be flexible and wireless, the motivation for it being to make a wearable information input device. The sensing layer **220** is any of PVDF, Tr-Ef, polyimide, nylon, etc., and is configured as a diaphragm here or, in other implementations, as a cantilever. It all seems miraculous that any such arrangements should create functional microphones without regards to cavity



volume, leaks, materials used for construction, poling direction, and the like. It is probable that none of these devices have been actually made, for there are but one or two dimensions given in the text and no performance measurements. The reader ought to look elsewhere for information on construction of polymer-film microphones.—JAH

6,960,137

43.38.Md SOUND CONTROL METHOD AND DEVICE FOR EXPRESSING GAME PRESENCE

Manabu Nishizawa *et al.*, assignors to Sony Computer Entertainment Incorporated
1 November 2005 (Class 463/35); filed in Japan 19 January 2001

Now Sony is patenting the trivial: In a computer game, divide the sounds into headset and loudspeaker catagories. Now, during playback, you can listen to the headset sounds in one ear and the loudspeaker sounds in the other.—MK

6,965,546

43.38.Md SOUND CRITICAL POINTS RETRIEVING APPARATUS AND METHOD, SOUND REPRODUCING APPARATUS AND SOUND SIGNAL EDITING APPARATUS USING SOUND CRITICAL POINTS RETRIEVING METHOD

Junichi Tagawa and Hiroaki Yamane, assignors to Matsushita Electric Industrial Company, Limited
15 November 2005 (Class 369/30.19); filed in Japan 13 December 2001

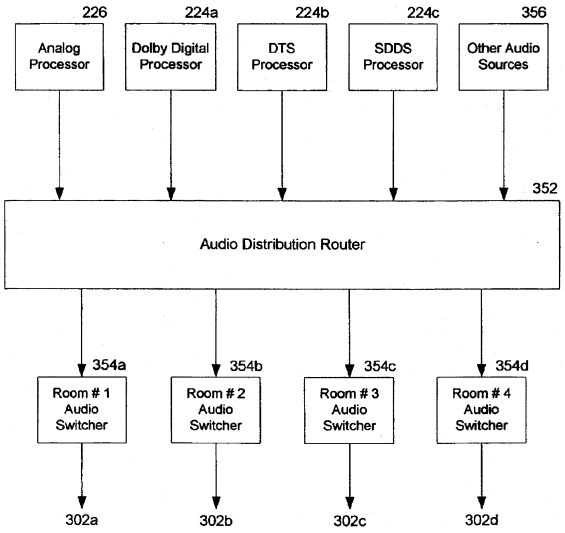
Essentially, the inventor proposes automatically finding "sound critical points" in audio material without listening to the data. These critical points can be used to segment the sound for preview as well as other editing tasks. The features proposed are not given good psychoacoustic justification unless you count, "these properties are determined by the human auditory system and cerebrum." These properties include rms, beat noisiness, and attack ratio.—MK

6,972,829

43.38.Md FILM SOUNDTRACK REVIEWING SYSTEM

Tom McCormick *et al.*, assignors to NT Audio Visual Supply, Incorporated
6 December 2005 (Class 352/40); filed 17 November 2003

This Hollywood-specific invention illustrates how a 35-mm film with multiple audio tracks (e.g., with different spatial encoding methods) can be



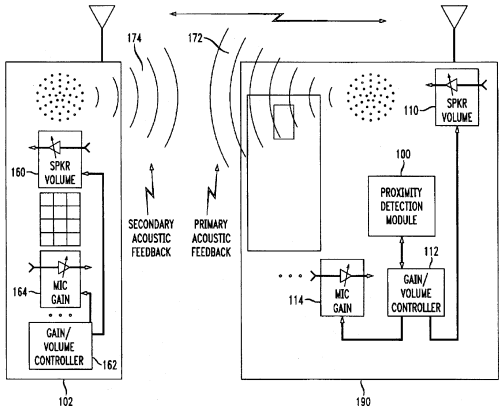
previewed in multiple viewing rooms. As presented, it's reasonable engineering but borders on the obvious.—MK

6,952,471

43.38.Si HANDSET PROXIMITY MUTING

Joseph M. Cannon *et al.*, assignors to Agere Systems Incorporated
4 October 2005 (Class 379/390.01); filed 9 June 2000

The figure "shows a cordless telephone including a proximity detection module in a base unit, and gain/volume controllers in both the base and the handset, for muting or attenuating a microphone and/or speaker path when a simultaneously (sic) hand set and base unit come within close prox-



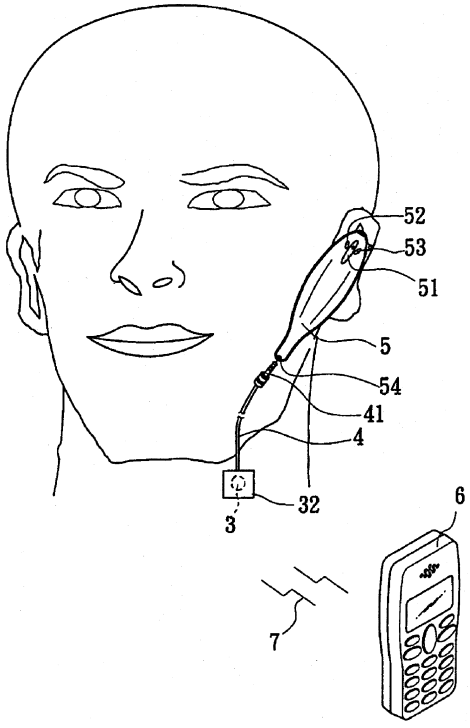
imity to one another." This is done using a receive-strength indicator, a proximity-detection module, and even GPS satellites, among other methods, both explicitly described and implied.—NAS

6,968,066

43.38.Si WIRELESS HANDS-FREE APPARATUS WITH SOUND-ABSORBING FUNCTION

Wen Hsiang Yueh, assignor to Partner Tech Corporation
22 November 2005 (Class 381/151); filed 1 December 2003

This invention is defined throughout the patent as "A wireless and hands-free earphone with a sound-absorbing function." However, it is really a throat-contact microphone held in place by an adhesive patch that also provides an airtight seal. The inventor is confident that this arrangement cuts



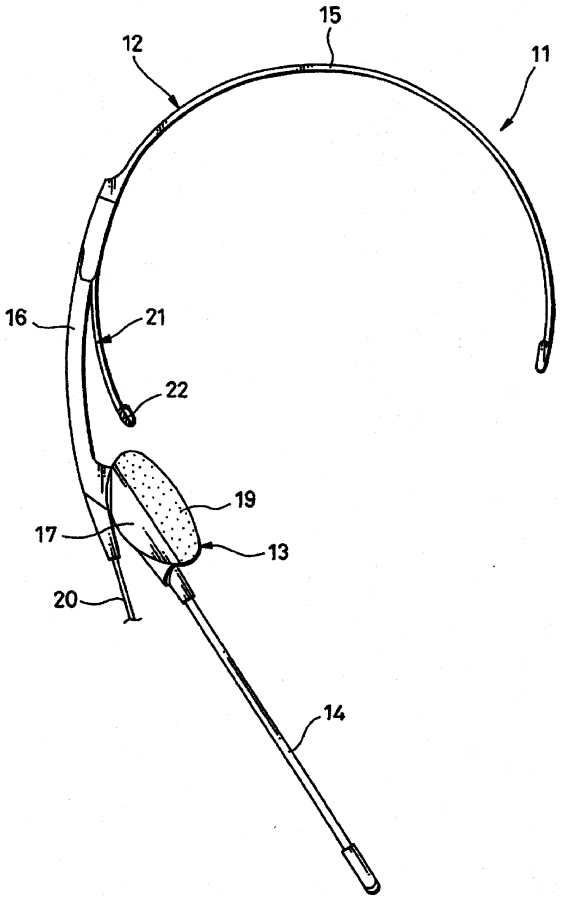
out ambient sound and also resolves the drawbacks of too much bass and lack of high frequencies. Not surprisingly, there is no indication that a working model has actually been tried.—GLA

6,970,572

43.38.Si HEADPHONE DEVICE

Katsunori Murozaki and Koji Nageno, assignors to Sony Corporation
29 November 2005 (Class 381/381); filed in Japan 31 August 2000

This is the latest Sony nonslip headset. It includes a headphone **17** that



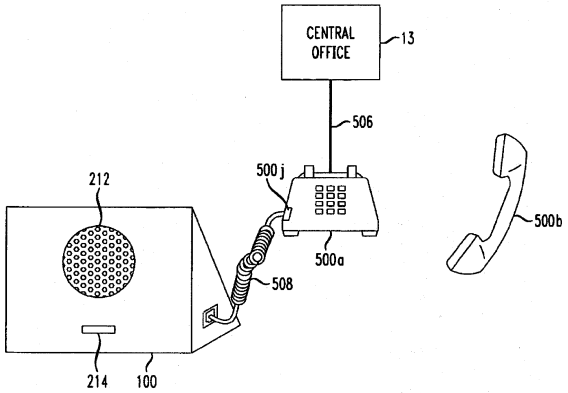
is tilted to match the inclination of the user's ear, and a little clip **22** to keep the assembly from creeping down.—GLA

6,973,179

43.38.Si POCKET SPEAKERPHONE

Steven B. Kaufman and John P. Veschi, assignors to Agere Systems Incorporated
6 December 2005 (Class 379/388.02); filed 11 September 1998

According to this patent, ''There is no conventional technique or apparatus to allow use of the common telephone as a speakerphone. ... There is thus a need for a convenient technique and apparatus for temporarily adapting a conventional common telephone as a speakerphone on an as needed



basis.'' What is proposed is a little box containing a microphone, loudspeaker, and associated electronics that plugs into the telephone's handset jack. This rather modest concept has been expanded into 23 patent claims, none of which require it to be pocket-size.—GLA

6,947,569

43.38.Vk AUDIO SIGNAL PROCESSING DEVICE, INTERFACE CIRCUIT DEVICE FOR ANGULAR VELOCITY SENSOR AND SIGNAL PROCESSING DEVICE

Yuji Yamada and Hirofumi Kurisu, assignors to Sony Corporation
20 September 2005 (Class 381/310); filed 24 July 2001

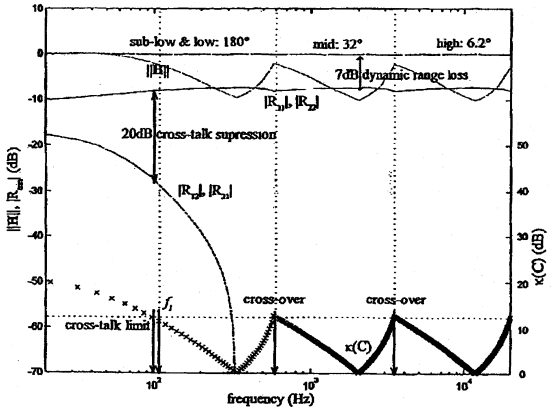
Although giving few references to related devices, this patent acknowledges various prior versions of essentially the same invention. The argument here seems to be for more accurate measurement of the user's head motions as a basis for improved HRTF computations. In various embodiments, alternate sensors, including a vibration gyroscope, a geomagnetic rate sensor, or multiple instances of such sensors, are specified. Details of the actual HRTF computations are not discussed.—DLR

6,950,524

43.38.Vk OPTIMAL SOURCE DISTRIBUTION

Philip Arthur Nelson and Takashi Takeuchi, assignors to Adaptive Audio Limited
27 September 2005 (Class 381/17); filed in the United Kingdom 24 June 2000

This intense (in the best patentese) patent, with 30 figures, describes a solution for multichannel reproduction, which is said to correct a litany of problems with prior art, including loss of dynamic range. There is a detailed



discussion and illustration of some of the patent's various implementations.—NAS

6,973,192

43.38.Vk DYNAMIC ACOUSTIC RENDERING

Alan Gerrard and Nam Do, assignors to Creative Technology, Limited
6 December 2005 (Class 381/17); filed 4 May 1999

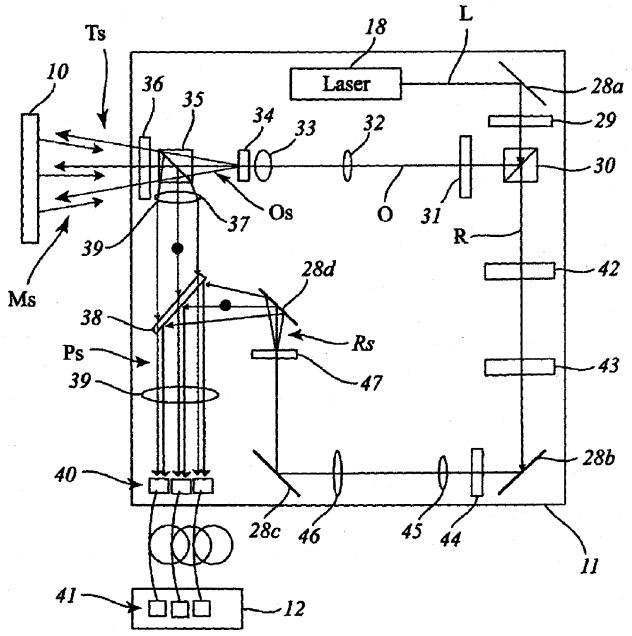
This patent relates to enhanced stereo/binaural audio to accompany on-screen action in video games. Using some of the techniques previously developed for auralization in spaces yet unbuilt, rapid on-screen action can be backed up by a parallel audio scenario in which acoustical effects, bouncing off walls, coming around corners, or simply being reverberated, can be realistically rendered over stereo loudspeakers or via binaural headphones—all in synchronism with what is taking place on-screen.—JME

6,972,846

43.40.Le MULTI-BEAM HETERODYNE LASER DOPPLER VIBROMETER

Amit K. Lal *et al.*, assignors to MetroLaser, Incorporated
6 December 2005 (Class 356/486); filed 31 March 2003

As this patent explains, laser interferometry is a well-established technique for nondestructive measurement and analysis of the vibration of an object. In many applications it is used in conjunction with acoustical elements. For example, to search for buried land mines, an acoustical signal from a loudspeaker can induce vibrations in the ground. The transient vibrations at the surface of the soil can then be detected and mapped to detect the object. Although sequential scanning can be used to gather data from a



relatively large area, an ideal system would measure multiple locations simultaneously. The patent discloses such a simultaneous multibeam system based on heterodyne detection and describes numerous variants. In view of the substantial body of prior art in this field, it is a little surprising that only two previous patents (one cited by the examiner) are referenced, plus one other publication.—GLA

6,971,491

43.40.Tm MAGNETO-RHEOLOGICAL FLUID ENCASED IN FLEXIBLE MATERIALS FOR VIBRATION CONTROL

Faramarz Gordaninejad *et al.*, assignors to The Board of Regents of the University and Community College System of Nevada, on behalf of the University of Nevada, Reno
6 December 2005 (Class 188/267.2); filed 26 December 2002

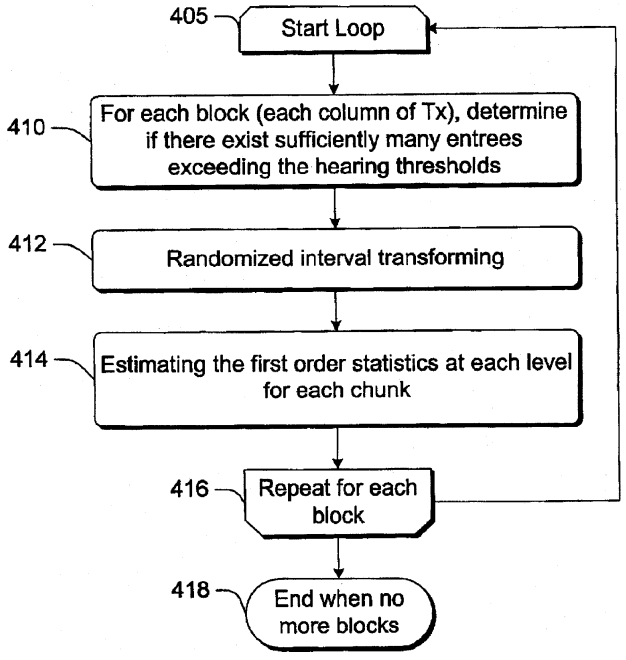
A magneto-rheological fluid is one whose effective viscosity can be varied by applying a magnetic field. In most devices that have used such fluids, the fluid has been contained in pipes or other rigid-walled structures. In devices according to the present patent the magneto-rheological fluid fills the space in a containment element that is flexible and resilient, and ideally also tough and durable. The containment elements may be in the shape of pillows or hoses, for example, and may contain several fluid-filled interior spaces. Illustrative data presented in the patent indicate that application of a magnetic field to such a device results in significant increases in the effective storage and loss moduli in certain frequency ranges, but in reductions of the loss factor (the ratio of the loss modulus to the storage modulus).—EEU

6,973,574

43.60.Cg RECOGNIZER OF AUDIO-CONTENT IN DIGITAL SIGNALS

M. Kivanc Mihcak and Ramarathnam Venkatesan, assignors to Microsoft Corporation
6 December 2005 (Class 713/180); filed 24 April 2001

"Hashing" is a well-known search technique—the hash function is a map from a large domain to a much smaller and fixed range. This audio hash function is computed by (1) transforming a windowed signal into the frequency domain via a lapped transform, (2) estimating the signal statistics



from the frequency-domain blocks, (3) applying an adaptive quantizer, and, lastly, (4) using an error correcting code (in this case Reed-Muller). The text is well written and is a useful introduction to audio content hashing.—MK

6,965,676

43.60.Mn VOLUME-RESPONSIVE LOUDNESS COMPENSATION CIRCUITS, SYSTEMS, AND METHODS

Rustin W. Allred, assignor to Texas Instruments Incorporated
15 November 2005 (Class 381/104); filed 27 June 2000

This patent describes a more complex incarnation of the notorious ''loudness circuit'' found on many audio amplifiers, which is intended to provide a bass boost at low overall listening volumes to compensate for the hearing curve's elimination of apparent bass at low average sound-pressure level. The method here is difficult to follow and seems to refer to previous patents for exposition; the loudness compensation is a gain-dependent variable function that uses the base 2 log of the overall volume, multiplied by a slope function whose details are left to the implementer.—SAF

6,968,063

43.60.Mn DYNAMIC VOLUME ADJUSTMENT IN A SLOT MACHINE

Scott Boyd, assignor to Acres Gaming Incorporated
22 November 2005 (Class 381/57); filed 11 March 2003

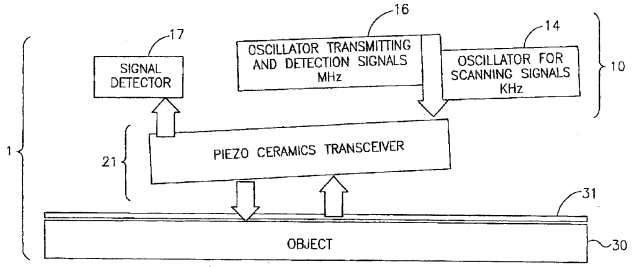
A simple component of a gaming machine is described which adjusts the volume of the machine's sounds in accord with a measurement of ambient noise level.—SAF

6,964,640

43.60.Vx SYSTEM AND METHOD FOR DETECTION OF MOTION

Jona Zumeris *et al.*, assignors to P M G Medica L I D
15 November 2005 (Class 600/459); filed 22 January 2003

The Doppler effect forms the basis for this motion-detection device that consists of two electronic oscillators, one to produce a scanning signal and the other to produce a Doppler signal. A vibrating element vibrates in response to the scanning and Doppler signals and a vibration transducer receives signals reflected from a structure inside the motion detector, converting the reflected signals into electrical signals. The velocity of the structure from which the vibrations are reflected can then be estimated by comparing the frequencies of the transmitted and reflected vibrations. The transducers may be made of piezo-ceramic materials.—DRR

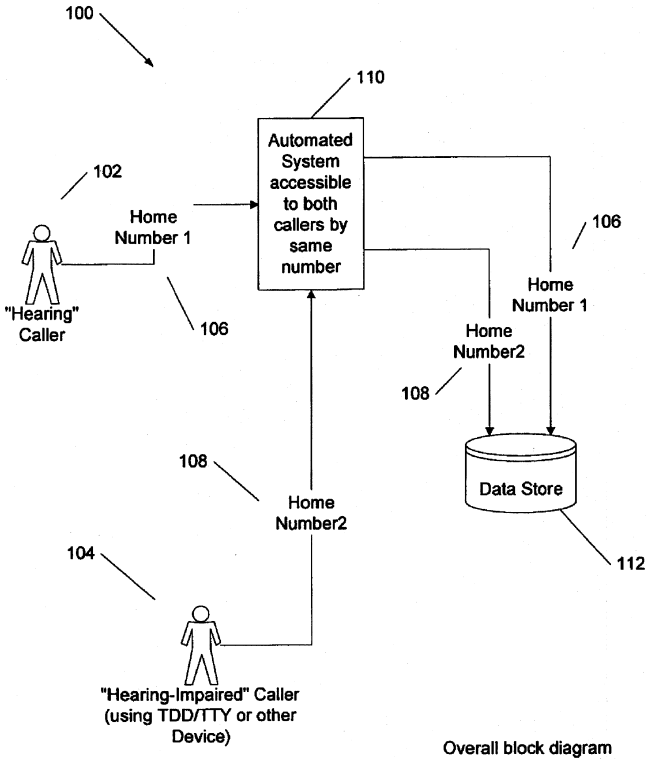


6,965,664

43.66.Ts SYSTEM, METHOD, AND COMPUTER-READABLE MEDIUM FOR ENABLING BOTH HEARING AND HEARING-IMPAIRED CALLERS TO ACCESS A RESOURCE

Jonathan P. McIntosh *et al.*, assignors to West Corporation
15 November 2005 (Class 379/52); filed 25 June 2003

This is a system that enables either a hearing or a nonhearing caller to make a call to either a hearing or nonhearing party through an automated system. The call will be routed to the appropriate platform for a hearing call recipient or for a hearing-impaired recipient who depends on a TDD/TTY or another device to receive messages.—DRR



Overall block diagram

6,968,238

43.66.Ts METHOD FOR INSERTING COCHLEAR ELECTRODE AND INSERTION TOOL FOR USE THEREWITH

Janusz A. Kuzma, Parker, Colorado
22 November 2005 (Class 607/137); filed 5 August 2003

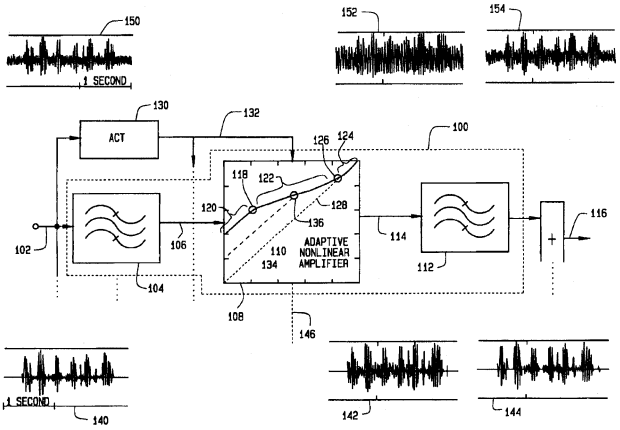
To ensure that an electrode array better conforms to the modiolus during implantation, a stylet wire is inserted into a lumen projection while the array is held within a sheath. Subsequently, the sheath and stylet wire are removed while the array is pushed into the cochlea.—DAP

6,970,570

43.66.Ts HEARING AIDS BASED ON MODELS OF COCHLEAR COMPRESSION USING ADAPTIVE COMPRESSION THRESHOLDS

Julius L. Goldstein, assignor to Hearing Emulations, LLC
29 November 2005 (Class 381/321); filed 23 August 2001

Traditional hearing aid multichannel-compression circuitry is augmented by making the compression threshold (CT) in each channel variable in response to input signal changes. The CT increases or decreases, respectively, if the peak value of the input signal increases or decreases repeatedly



or stays the same if the peak value of the input signal has only minor fluctuations. Increases in CT are instantaneous, whereas decreases in CT are performed slowly.—DAP

6,965,681

43.66.Vt ARRANGEMENT IN ACOUSTIC HEADSETS

Christer Almqvist, assignor to Peltor AB
15 November 2005 (Class 381/371); filed in Sweden 15 August 1997

A radio receiver has been added to a muff-type hearing protector with buttons on the earcup to control the electronics.—JE

6,970,571

43.66.Vt LOW COST HEARING PROTECTION DEVICE

Jon P. Knorr and Benjamin P. Knapp, assignors to Jackson Products, Incorporated
29 November 2005 (Class 381/370); filed 3 February 2003

This ''low-cost'' hearing protector incorporates circuitry to permit gain control of the sound at the speakers inside the earmuff-type headset and to allow configuration changes. Of course, the degree of protection is limited by the earmuffs themselves. One wonders if the cost of the two batteries required to power the unit, let alone the circuits shown in six accompanying figures, are as ''low cost'' as a pair of foam earplugs.—JE

6,959,276

43.72.Dv INCLUDING THE CATEGORY OF ENVIRONMENTAL NOISE WHEN PROCESSING SPEECH SIGNALS

James G. Droppo *et al.*, assignors to Microsoft Corporation
25 October 2005 (Class 704/226); filed 27 September 2001

A problem is identified with conventional adaptive-noise-canceling methods in speech processing systems, namely that their effectiveness is often hampered by unwelcome switching between noise-correction vectors resulting from imperfect matches between training noise and operation noise. The solution proposed here is to incorporate a separate noise-category classifier (e.g., vehicle, airplane) whose decision then governs the action of a conventional noise-canceling system, thereby forcing a possibly locally suboptimal match between training and operational noise, but resulting in a globally improved performance thanks to the elimination of rapid switching between correction vectors.—SAF

6,959,277

43.72.Dv VOICE FEATURE EXTRACTION DEVICE

Shingo Kiuchi *et al.*, assignors to Alpine Electronics, Incorporated
25 October 2005 (Class 704/233); filed in Japan 12 July 2000

This patent proposes to augment a basic Fourier spectral-feature extraction scheme [and suggests numerous times to employ a Humming (sic) window] with a ''noise reduction system.'' The main innovation over conventional adaptive-filtering NR methods is the apparently novel insight that one need only apply the noise-reduction filter (obtained by established adaptive-noise-canceling routines) in the frequency domain to half the Fourier-transform points, the other half being first discarded as the redundant frequency spectrum.—SAF

6,965,860

43.72.Dv SPEECH PROCESSING APPARATUS AND METHOD MEASURING SIGNAL TO NOISE RATIO AND SCALING SPEECH AND NOISE

David Llewellyn Rees and Robert Alexander Keiller, assignors to Canon Kabushiki Kaisha
15 November 2005 (Class 704/227); filed in the United Kingdom 23 April 1999

A method is described for compensating speech processing frame by frame in the presence of noise. The signal-to-noise ratio is estimated from the signal prior to the onset of speech, so it presumably works well only with fairly stationary noise. Working with cepstral feature vectors for the average noise and the current frame, the noise vector is subtracted from the frame vector when the SNR is low and performs no correction when the SNR is high.—SAF

6,959,082

43.72.Ew METHOD AND SYSTEM FOR AUTOMATIC GAIN CONTROL WITH ADAPTIVE TABLE LOOKUP

Lee F. Holeva, assignor to 3Com Corporation
25 October 2005 (Class 379/388.03); filed 10 July 2001

A simple method is outlined for automatic gain control in a speech communication device, which involves the generation and use of a ''lookup table'' storing a fixed set of gain values which can be selected by a standard sort of adaptive signal-power estimation scheme. The goal is presumably to reduce the computational complexity of deciding on the gain at each step, although an additional element of the proposal involves the capability to recalculate the gain values in the table by means of an adaptive error signal.—SAF

6,959,275

43.72.Ew SYSTEM AND METHOD FOR ENHANCING THE INTELLIGIBILITY OF RECEIVED SPEECH IN A NOISE ENVIRONMENT

Adoram Erell, assignor to D.S.P.C. Technologies Limited
25 October 2005 (Class 704/225); filed 30 May 2001

Systems which enhance speech received under noisy conditions often involve automatic gain control and dynamic range compression components which operate adaptively. This patent proposes to improve the adaptive performance of this type of method by invoking a long-term peak-amplitude value calculated for each frame containing a speech signal. The intuition is that speech is an inherently dynamic and fluctuating signal which can easily trick a simplistic adaptive system that relies entirely on the short-term signal characteristics.—SAF

6,961,702

43.72.Fx METHOD AND DEVICE FOR GENERATING AN ADAPTED REFERENCE FOR AUTOMATIC SPEECH RECOGNITION

Stefan Dobler *et al.*, assignors to Telefonaktiebolaget LM Ericsson (publ)
1 November 2005 (Class 704/244); filed in the European Patent Office 7 November 2000

Speech recognition of an utterance normally involves comparison against a reference model. The proposal here is to take account of each different speaker or environment by adapting the reference model and trying again. If this iteration gets somewhere, the adapted reference may be kept and used for future recognition.—SAF

6,961,703

43.72.Fx METHOD FOR SPEECH PROCESSING INVOLVING WHOLE-UTTERANCE MODELING

Alan Lawrence Higgins and Lawrence George Bahler, assignors to ITT Manufacturing Enterprises, Incorporated
1 November 2005 (Class 704/249); filed 13 September 2000

The basic task at hand is speaker verification from a single utterance, and it is suggested that instead of using traditional frame-by-frame speech recognition sorts of algorithms, for this purpose it will be better to model and recognize one huge vector of features for the entire utterance at once. The normal computational obstacle with this idea arises from the extreme dimensionality of such a vector, preventing computation of linear discriminant analysis. This problem is said to be solved here by a new eigenvector approach in which a subspace is first selected upon which the observed between-speaker variations lie—the intuition being that it will not be worth keeping account of a large fraction of the feature differences.—SAF

6,961,696

43.72.Gy CLASS QUANTIZATION FOR DISTRIBUTED SPEECH RECOGNITION

Tenkasi V. Ramabadran and Alexander Sorin, assignors to Motorola, Incorporated
1 November 2005 (Class 704/207); filed 7 February 2003

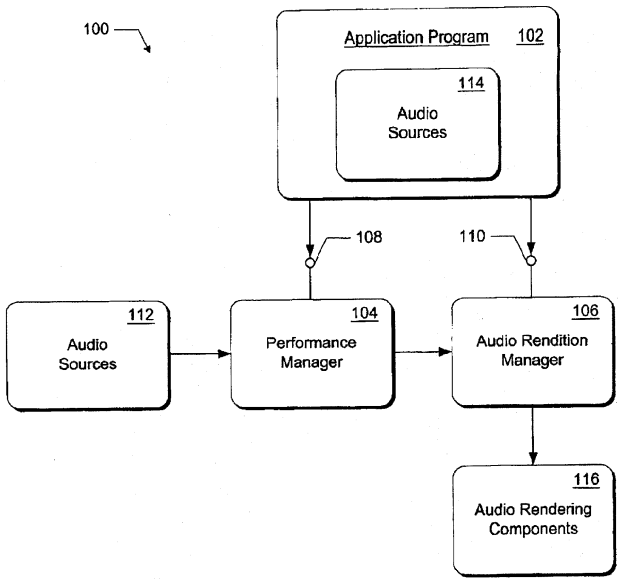
This patent presents a new bit-coding scheme which incorporates pitch class and other sound class information into code words that ultimately involve a one-bit savings over more well-known coding schemes. This small compression amounts to large network bandwidth gains for wireless communications sending coded audio back to servers for distributed speech recognition from cell phones and such.—SAF

6,970,822

43.72.Gy ACCESSING AUDIO PROCESSING COMPONENTS IN AN AUDIO GENERATION SYSTEM

Todor J. Fay and Brian L. Schmidt, assignors to Microsoft Corporation
29 November 2005 (Class 704/270); filed 7 March 2001

To provide a multimedia application program direct access to the audio data-processing components, a performance manager (audio source manager) and an audio rendition manager are provided by the application. The performance manager instantiates audio data processing components for



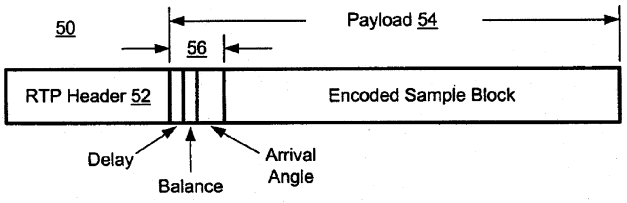
each audio source. The audio rendition manager includes a synthesizer component that generates audio-waveform data from the received audio instructions and buffers the processed data.—DAP

6,973,184

43.72.Gy SYSTEM AND METHOD FOR STEREO CONFERENCING OVER LOW-BANDWIDTH LINKS

Shmuel Shaffer and Michael E. Knappe, assignors to Cisco Technology, Incorporated
6 December 2005 (Class 379/420.01); filed 11 July 2000

A pseudo-stereo conferencing encode/decode scheme is implemented in about the same bandwidth as a monaural signal by sampling the sound field at two locations. The relative delay between the two sound-field signals is recorded and transmitted over a packet network with a single audio pay-



load formed by combining the separate sound signals. At the decoder, the relative delay is used to form two spatially separated playback signals, so the listener receives source location information for multiple participants.—DAP

6,947,731

43.72.Ja METHOD FOR CONVERTING STATUS MESSAGES OUTPUT IN SPOKEN FORM

Erich Kamperschroer, assignor to Siemens Aktiengesellschaft
20 September 2005 (Class 455/419); filed in Germany 30 September 1999

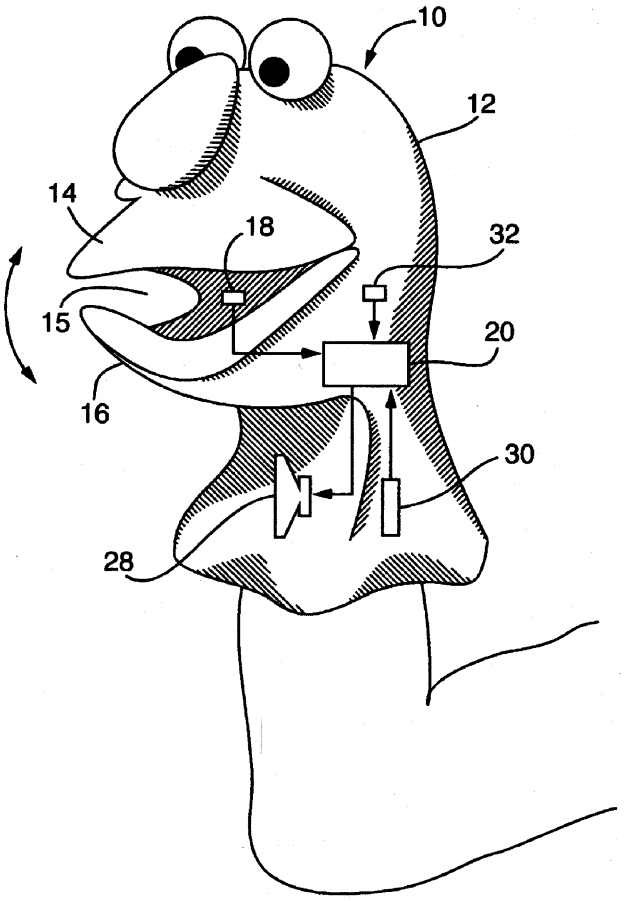
Well into the realm of the completely obvious, this patent deals with the use of speech synthesis to notify a user of the status of a device which was not equipped for speech output. However, it is also assumed that the device in question does have some means of data signalling and that a speech-synthesis device is available. The only remaining task is then the translation of various device signals into the appropriate spoken phrases. And for this, we maintain a Patent Office?—DLR

6,971,943

43.72.Ja INTERACTIVE SOUND PRODUCING TOY

Arne Schulze, Santa Monica, California
6 December 2005 (Class 446/327); filed 9 August 2004

A hand-operated puppet **10** has a switch in the mouth **18** that controls the voice synthesizer **20** (element **32** is a program select switch). The idea is to synchronize an on-chip recording with the hand movements. The switch



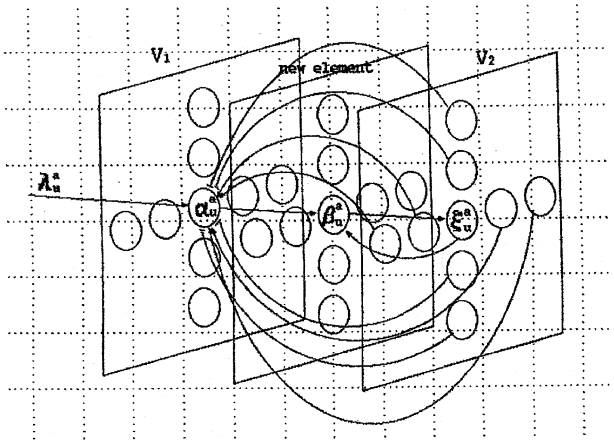
18 provides a very coarse quantization of mouth position, but child amusement is assured.—MK

6,947,890

43.72.Ne ACOUSTIC SPEECH RECOGNITION METHOD AND SYSTEM USING STEREO VISION NEURAL NETWORKS WITH COMPETITION AND COOPERATION

Tetsuro Kitazoe, Miyazaki, Japan *et al.*
20 September 2005 (Class 704/232); filed in Japan 28 May 1999

This speech-recognition architecture begins with a typical (Mel cepstrum) analysis of each acoustic frame. This is followed by a neural network analyzer which incorporates both time and vocabulary contexts to recognize the input speech. Written in the language of neural net math, the patent



includes an extensive discussion of the frame-comparison processes used. Some evaluations are presented in support of the assertion that the method is superior to the more traditional HMM recognizer architecture.—DLR

6,957,183

43.72.Ne METHOD FOR ROBUST VOICE RECOGNITION BY ANALYZING REDUNDANT FEATURES OF SOURCE SIGNAL

Narendranath Malayath and Harinath Garudadri, assignors to Qualcomm Incorporated
18 October 2005 (Class 704/246); filed 20 March 2002

The typical speech recognition front end involves the generation of a feature vector for each analysis frame, for example, by spectral or cepstral analysis. Such feature vectors are preferred when their components are decorrelated. This patent lays claim to a general method whereby, in addition to the primary feature vector, some sort of secondary feature vector is also obtained for each analysis frame, and this secondary vector is assumed to be somehow correlated with the primary. The intention is to improve recognition performance by somehow combining the two correlated feature vectors—nearly all conceivable ways of generating and combining the vectors are covered in the patent claims, although no specific embodiment is proven to accomplish the desired improvement.—SAF

6,959,278

43.72.Lc SYSTEMS AND METHODS FOR IMPLEMENTING SEGMENTATION IN SPEECH RECOGNITION SYSTEMS

Chang-Qing Shu and Han Shu, assignors to Verizon Corporate Services Group Incorporated
25 October 2005 (Class 704/243); filed 5 April 2001

The proposed method attacks the problem of segmenting speech into phones for further processing by examining tracks of cepstral peaks. The intuition is that where cepstral peaks change dramatically from one frame to the next, one is likely to find a transition between speech segments.—SAF

6,961,701

43.72.Ne VOICE RECOGNITION APPARATUS AND METHOD, AND RECORDING MEDIUM

Hiroaki Ogawa *et al.*, assignors to Sony Corporation
1 November 2005 (Class 704/236); filed in Japan 2 March 2000

The rather unbelievable suggestion here is that one can get around all of the usual out-of-vocabulary problems with speech recognition by somehow involving a huge dictionary of over a million forms. The general approach is to search this massive dictionary (don't the authors realize that no

dictionary could ever be sufficient?) using restricted or partial matching criteria which might help the computational complexity.—SAF

6,963,837

43.72.Ne ATTRIBUTE-BASED WORD MODELING

Michael Finke *et al.*, assignors to Multimodal Technologies, Incorporated
8 November 2005 (Class 704/256); filed 6 October 2000

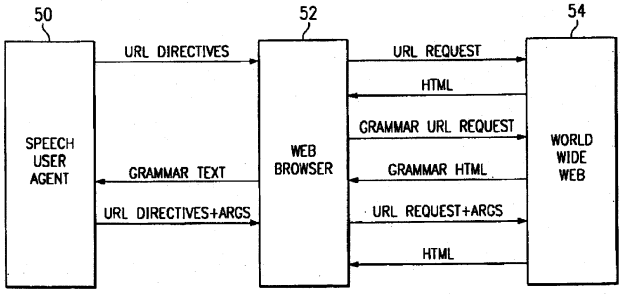
This patent describes an apparently novel approach to speech recognition that moves beyond the usual phone-based segmental methodology. The general idea involves creating a new kind of acoustic model for recognition that uses phonetic ''attributes'' together with suprasegmental attributes. ''A word is transcribed as a sequence of instances ... which are bundles of instantiated attributes (i.e., attribute-value pairs).'' The attributes may involve traditional phonetic features, but also dialect, gender, word or syllable position, word class, etc. This new approach addresses the fundamental problems with the prior art involving multiple possible pronunciations for each word in the dictionary, which can paradoxically lead to decreased recognition performance.—SAF

6,965,864

43.72.Ne VOICE ACTIVATED HYPERMEDIA SYSTEMS USING GRAMMATICAL METADATA

Philip R. Thrift and Charles T. Hemphill, assignors to Texas Instruments Incorporated
15 November 2005 (Class 704/275); filed 10 April 1995

A flexible-vocabulary speech interface to the Web is proposed for accessing information via voice-activated control information embedded in HTML pages. The system utilizes phonetic models for speaker-independent



voice recognition without any training required. Grammars are dynamically modified for particular applications.—DAP

6,968,310

43.72.Ne METHOD, SYSTEM, AND APPARATUS FOR SPEECH RECOGNITION

Kazuo Nemoto, assignor to International Business Machines Corporation
22 November 2005 (Class 704/231); filed in Japan 2 May 2000

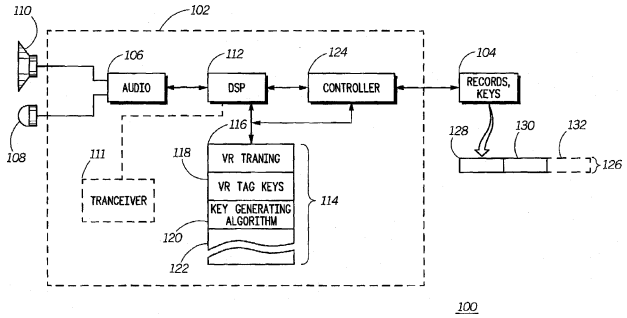
Here is another speech-recognition tweak which suggests matching whole words against stored pronunciations found to match the current-session speaker in favor of other stored models, when recognition accuracy would thereby improve. The objective is to reduce the number of possible online templates in the grammar in response to the actual pronunciations employed by the speaker. The context is digit recognition in Japanese.—SAF

6,970,817

43.72.Ne METHOD OF ASSOCIATING VOICE RECOGNITION TAGS IN AN ELECTRONIC DEVICE WITH RECORDS IN A REMOVABLE MEDIA FOR USE WITH THE ELECTRONIC DEVICE

Douglas Eugene Ross *et al.*, assignors to Motorola, Incorporated
29 November 2005 (Class 704/201); filed 31 October 2001

Voice-recognition training data stored in a remote device, such as a cellphone or PDA, is associated with corresponding records in removable



media by generating a key when a new voice-recognition tag is trained. The keys are stored in the remote device and/or the removable media.—DAP

6,970,818

43.72.Ne METHODOLOGY FOR IMPLEMENTING A VOCABULARY SET FOR USE IN A SPEECH RECOGNITION SYSTEM

Xavier Menedez-Pidal and Lex S. Olorenshaw, assignors to Sony Corporation
29 November 2005 (Class 704/236); filed 14 March 2002

This is yet another patent describing a method for employing an n-best list which ranks speech-recognition hypotheses in decreasing order of likelihood. How many variations on this idea can be patented?—SAF

6,973,427

43.72.Ne METHOD FOR ADDING PHONETIC DESCRIPTIONS TO A SPEECH RECOGNITION LEXICON

Mei-Yuh Hwang *et al.*, assignors to Microsoft Corporation
6 December 2005 (Class 704/249); filed 26 December 2000

A speech-recognition methodology is outlined which augments the standard art by attempting to recognize a spoken word phonetically when the usual vocabulary-based recognition fails, though a phone-based approach is not employed since these are known to be poor performers. Instead, a scheme based on ''syllable-like units'' is put forth, which has several variants including an n-gram language-model implementation for these empirical approximations to syllables. In this way, unknown utterances such as personal names can at least be represented ''syllabically'' rather than treated as garbage, as is commonly done.—SAF

6,973,426

43.72.Pf METHOD AND APPARATUS FOR PERFORMING SPEAKER VERIFICATION BASED ON SPEAKER INDEPENDENT RECOGNITION OF COMMANDS

John E. Schier and Patrick E. Jackson, assignors to Cisco Technology, Incorporated
6 December 2005 (Class 704/246); filed 29 December 2000

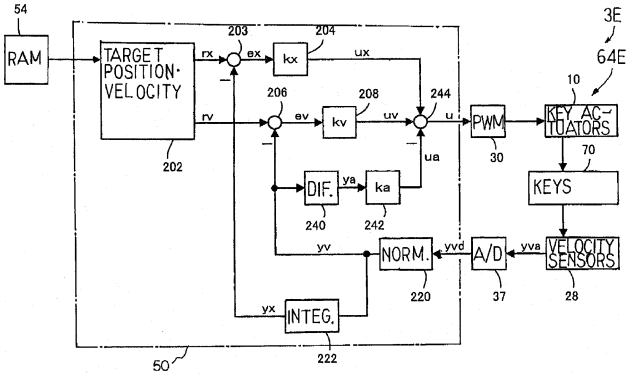
The patent describes a system that combines speaker-independent recognition of simple commands with speaker-verification computations on the same spoken utterance. Each speaker's verification template is updated with their subsequent utterances of the command. The recognition and verification procedures themselves are black boxes here.—SAF

6,969,791

43.75.Mn AUTOMATIC PLAYER KEYBOARD MUSICAL INSTRUMENT EQUIPPED WITH KEY SENSORS SHARED BETWEEN AUTOMATIC PLAYING SYSTEM AND RECORDING SYSTEM

Yuji Fujiwara, assignor to Yamaha Corporation
29 November 2005 (Class 84/13); filed 8 March 2004

This patent follows in the long line of Synclavier patents previously reviewed. The inventor proposes changing the actuator/sensor open-loop control with closed-loop control to eliminate errors and improve performance. Multiple implementation schemes are illustrated and discussed. —MK



6,972,362

43.75.Wx METHOD AND DEVICE FOR GENERATING ELECTRONIC SOUNDS AND PORTABLE APPARATUS UTILIZING SUCH DEVICE AND METHOD

Yutaka Nakamura, assignor to Rohm Company, Limited
6 December 2005 (Class 84/603); filed in Japan 9 January 2002

This patent attacks the so-called "parameter update problem" where a realtime DSP must update synthesis parameters and process samples in a fixed sample period. The inventor makes several assumptions: (a) complex timbres demand more processor cycles, (b) missed samples are acceptable if the stale sample data is held, and (c) everything will be acceptable if the mean deviation of the processing time is zero. None of these are absolutely true. Complex timbres depend on the algorithm, not just cycles. Missed samples can be audible depending on the program material and, finally, updates come in large batches, ruining the short-term mean.—MK

6,968,224

43.80.Qf METHOD OF DETECTING ORGAN MATTER SHIFT IN A PATIENT

Paul Kessman *et al.*, assignors to Surgical Navigation Technologies, Incorporated
22 November 2005 (Class 600/407); filed 19 September 2003

This surgical instrument tracking method uses a navigation system incorporating an ultrasound machine with an attached computer. The computer generates an icon representing the tip of a surgical instrument and the instrument's trajectory. The icon is overlayed on a real-time ultrasound image in an image plane, so that when the instrument traverses the image plane, the trajectory display is altered to represent the instrument's travel. The system also contains a localizer coupled to the ultrasound machine and a display which shows the generated icon superimposed on the real-time image.—DRR

43.75.St SONG-MATCHING SYSTEM AND METHOD

Daniel Ozick, assignor to iRobot Corporation
22 November 2005 (Class 84/616); filed 24 June 2003

This inventor argues that previous art has not included automatic accompaniment in synchrony with a song-matching system. It's a pity he didn't read (or cite) Dannenberg's 1988 patent (United States Patent 4,745,836, filed in 1985). This well-known work used dynamic time warping to do the score match and provide an accompaniment to a solo player.—MK

43.80.Qf SYSTEM AND METHOD FOR ELECTRODE LOCALIZATION USING ULTRASOUND

N. Parker Willis *et al.*, assignors to SciMed Life Systems, Incorporated
29 November 2005 (Class 600/424); filed 21 October 2002

This localization system uses one or more ultrasound reference catheters to establish a fixed three-dimensional coordinate system within a patient's heart using the principles of triangulation. The coordinate system is represented graphically in three dimensions on a video monitor and helps the clinician guide other medical devices equipped with ultrasound transducers through the body to locations at which they are needed to perform clinical procedures. For example, the system can be used in the heart to help a physician guide mapping catheters for measuring electrical activity and ablation catheters for ablating selected regions of cardiac tissue at specific locations.—DRR

43.80.Sh APPARATUS AND METHOD FOR TRANSCERVICAL STERILIZATION BY APPLICATION OF ULTRASOUND

Thomas P. Ryan and John S. Crombie, assignors to Gynecare a division of Ethicon, Incorporated
6 December 2005 (Class 606/50); filed 28 June 2002

This is an ultrasound device for sterilizing a female patient in a transcervical procedure. The device consists of an elongated catheter featuring a piezoelectric ultrasound transducer at its distal end. The catheter is inserted transcervically into the uterus and directed to the intramural region of a fallopian tube, to be in direct contact with the surrounding tissue. The transducer produces a radially dispersing acoustical wave front, heating the adjacent tissue and forming a thermal lesion therein. A fibrous tissue forms during the healing process, thereby sealing off the fallopian tube. One embodiment of the device includes a movable thermal sensor for monitoring the tissue temperature at multiple locations along the lesion.—DRR

43.80.Vj ADAPTABLE INTRAOPERATIVE OR ENDOCAVITY ULTRASOUND PROBE

Vaughn R. Marian, assignor to Acuson Corporation
29 November 2005 (Class 600/459); filed 25 September 2001

This probe has an adjustable section between the handle and the transducer. This section allows the transducer to be rotated relative to the handle prior to insertion within a patient. The shape of the section is maintained while the probe is in use and need not be further adjusted.—RCW

6,971,991

43.80.Vj APPARATUS FOR MULTIMODAL PLANE WAVE ULTRASOUND IMAGING

Robert S. Lasser *et al.*, assignors to Imperium, Incorporated
6 December 2005 (Class 600/437); filed 7 March 2003

This apparatus contains an ultrasonic imaging unit and an x-ray imaging unit as well as a capability to hold in compression the object to be imaged. The x-ray source and the ultrasonic source can each be moved from an active imaging position to an inactive or nonimaging position. Both x-ray images and ultrasonic images are made in the transmission mode and the images are registered to assist user correlation of images. Speckle contained in the ultrasonic image is reduced to improve contrast resolution.—RCW

6,971,992

43.80.Vj ULTRASONIC IMAGING METHOD AND APPARATUS

Marino Cerofolini, assignor to Esaote, S.p.A.
6 December 2005 (Class 600/447); filed in Italy 13 August 2002

Transducers in this system are excited with delays to produce a rela-

tively homogeneous acoustic field over a large region of interest. Two subgroups are used, one transmitting a waveform and the other transmitting an inverted version of the waveform. Because the transmitted waveform produces a relatively homogeneous distribution of energy over the whole region of interest, received signals can be processed with different delays to cover the entire region with receive beams that are focused along scan lines to permit a higher frame rate than would be possible with a narrow transmit beam.—RCW

FORUM

Forum is intended for communications that raise acoustical concerns, express acoustical viewpoints, or stimulate acoustical research and applications without necessarily including new findings. Publication will occur on a selective basis when such communications have particular relevance, importance, or interest to the acoustical community or the Society. Submit such items to an appropriate associate editor or to the Editor-in-Chief, labeled FORUM. Condensation or other editorial changes may be requested of the author.

Poincaré's criterion in room acoustics

James Bernard Lee[a)]
6016 S.E. Mitchell Street, Portland, Oregon, 97206

(Received 13 January 2006; revised 28 February 2006; accepted 6 March 2006)
[DOI: 10.1121/1.2190188]

Three papers by W. B. Joyce, published in this Journal, are crucial in applying statistical methods to the physics of sound in rooms.[1–3] They are well known and occasionally cited, but rarely applied to justify statistical approximations to the acoustics of large rooms, either in presentations at meetings of this Society or in articles published in this Journal.

They are difficult papers, presuming readers understand abstract terms like "mixing" and "ergodicity," as well as knowing recondite theorems and methods of mathematical analysis; perhaps this is why their conclusions most often are honored in the breach. Following is a précis of an analogous problem to help authors, editors, and reviewers readily to apply Joyce's findings to submissions in room acoustics:

"…let us imagine for a moment a gas whose molecules cannot collide mutually, but can be deviated by the sides of the vessel in which the gas is enclosed. If the form of the vessel is sufficiently complicated, it will not be long before the distribution of the molecules and that of their velocities become uniform. This will not happen if the vessel is spherical, or if it has the form of a rectangular parallelepiped. And why not? Because in the former case the distance of any particular trajectory from the center remains constant, and in the latter case we have the absolute value of the angle of each trajectory with the sides of the parallelepiped."[4]

Thus Henri Poincaré in his essay, "Chance." This system is formally identical to Joyce's concept of sound as a "phonon gas," the "particles" of which do not affect each other and rebound only from the surfaces of a room. Joyce does not cite Poincaré, but in the final paragraphs of his last paper does remark that "spheres" and "rectangular parallelepipeds" are not mixing if their surfaces are not complicated. Clearly the two authors are in accord.

Following is a contrary assertion, and the original basis for statistical methods in room acoustics:

"The above results, then, all point to the evident, but perhaps not appreciated, fact that the dispersion of sound between all parts of a hall is very rapid in comparison with the total time required for its complete absorption, and that in a very short time after the source has ceased the intensity of the residual sound, except for the phenomenon of interference to be considered later, is very nearly the same everywhere in the room."[5]

Thus Wallace Clement Sabine expressly acknowledges that admitting the wave nature of sound concomitantly admits the existence of nonuniform fields of sound in rooms, but asserts that absent physical acoustics sound in rooms is effectively uniform for purposes of calculation.

So could Poincaré be wrong and Joyce's effort to reconcile these assertions pointless? This must be resolved.

The kinetic theory of gases, new in Poincaré's time, is a well tested and widely applied theory of physics. But the system Poincaré analyzes in the passage quoted is unusual, applying only to tenuous gases in small containers, with the mean free path much larger than the linear dimensions of the container. In such systems the particles do not interact with each other, do not exchange momentum and energy, and so do not converge to equilibrium of themselves. Such particles become distributed uniformly only if the shape of their container "…is sufficiently complicated." This is termed "mixing," and requires a finite time, called the "mixing time," to eventuate.

Clearly Sabine does not understand this need of suitable geometry for mixing, although he does acknowledge the requirement of a definite time, assumed to be negligible, for its completion. Sabine, contemporary with Poincaré and using the kinetic theory of gases as an analogy to sound, does not know that concepts such as uniform density and mean free path come freighted with pertinent restrictions.

Joyce successfully quantifies both these criteria vital to Sabine's model of sound in rooms, and following Joyce we may assume that practical auditoriums are "sufficiently complicated" to fulfill Poincaré's requirement. But mixing time is another matter. Sabine asserts, without proof, that uniform energy density should obtain in a time much shorter than what we call "reverberation time." He says nothing about growth of sound.

This cannot be correct, for the decay of sound, characterized by reverberation time, is mediated by the logarithmic scale with which it is measured; on the same scale the time for the growth of sound is much shorter, reaching only 2 dB below its asymptotic level in one time constant, about 1/14th of the reverberation time. The time constant therefore is the realistic datum for temporal events in room acoustics, as Allan Pierce and others understand.[6]

Close study of Joyce's papers reveals a change of emphasis, as he gradually comes to grasp the central fact of room acoustics: it is absorption that primarily determines uniformity of sound in most practical rooms; "Poincaré geometry" and mixing time are not important if much absorption is present. For example, in concert halls and opera houses about 1/3 of the surface area is occupied by the audience, which is strongly absorbent; uniform fields of sound, even as the severe abstraction of a "phonon gas," cannot exist in such rooms. Some rooms, notably reverberation chambers, are designed for very small absorption, and in these complexity and mixing time are relevant.[7]

I propose that articles and presentations in room acoustics presuming a statistical basis, as submitted to the Acoustical Society of America, be vetted *a priori* by the following criteria:

(1) Is the room "sufficiently complicated" to ensure mixing in Poincaré's sense?

(2) Is the mixing time much shorter than one time constant?

(3) Is the absorption small enough for uniform fields of sound to be generated?

These are basic, reasonable, and answerable questions. Well conducted relevant research reported in well written papers should supply convincing answers to them.

LETTERS TO THE EDITOR

This Letters section is for publishing (a) brief acoustical research or applied acoustical reports, (b) comments on articles or letters previously published in this Journal, and (c) a reply by the article author to criticism by the Letter author in (b). Extensive reports should be submitted as articles, not in a letter series. Letters are peer-reviewed on the same basis as articles, but usually require less review time before acceptance. Letters cannot exceed four printed pages (approximately 3000–4000 words) including figures, tables, references, and a required abstract of about 100 words.

Pseudo-3D modeling of a surface-bonded Lamb wave source (L)

Emmanuel Moulin,[a] Sébastien Grondel, Mustapha Baouahi, and Jamal Assaad
IEMN, UMR CNRS 8520, OAE Department, Université de Valenciennes et du Hainaut Cambrésis, Le Mont Houy, 59313 Valenciennes Cedex 9, France

(Received 21 July 2005; revised 1 March 2006; accepted 1 March 2006)

In this paper, a simple technique allowing the prediction of the Lamb wave field excited in an isotropic plate by a transducer of finite dimensions is presented. The basic idea is to separate the problem into two uncoupled parts. First, the Lamb wave excitation problem, in the plane defined by the thickness and width directions of the transducer, is treated. Then the source diffraction effects in the plane of the plate can be quantitatively estimated. The subsequent formulation thus offers a simple way of developing three-dimensional (3D) solutions from a two-dimensional (2D) modeling. Compared to a heavy full-3D numerical modeling, this technique appears to be a very satisfying alternative. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2189447]

I. INTRODUCTION

For several years, Lamb wave testing has been seen as a promising technique for health monitoring of civil or aerospace structures. In order to make such monitoring faster, less expensive, and effortless, the integration of piezoelectric patches to the material has been considered.[1,2] The behavior of such an integrated transducer and the type of waves emitted depend strongly on the nature of the host material and the insertion conditions. Then a proper modeling tool, allowing to take into account the whole complexity of the problem, is required.

In this context, previous works have focused on the development of a 2D hybrid technique for the modeling of plates containing integrated sources.[3–5] The imposed plane-strain condition implied the infiniteness along one dimension, which is only a rough approximation of a bar-shaped transducer. In order to account for the finite length of an actual transducer, a 3D modeling is required. However, instead of developing unpractical full 3D numerical models, the idea suggested here is to uncouple the divergence effects in the plane of the plate from the mode characteristics with respect to the plate thickness.

This concept has already been presented in a previous paper[6] and applied to multi-element sources for Lamb wave beam-steering.[7] However, the simplistic approach used then only provided qualitative results. This paper aims at extending these works so that quantitative results are accessible, allowing direct comparison to experimental or 3D numerical results.

Up to now, only a very small number of works have dealt with 3D modeling of Lamb wave excitation by finite sources. Among them, a recent paper by Rose *et al.*[8] is particularly noticeable. Based on Mindlin plate theory, the authors derived analytical solutions for point forces and bending moments and then deduced solutions for circular-or rectangular-shaped surface-mounted sources by spatial integration. However, the formulation is relatively delicate to handle and since Mindlin theory is an approximate plate model, a number of physical aspects are not correctly described (symmetric modes, higher order antisymmetric modes,…).

The modeling method proposed here is based on line- and point-source solutions derived from the works by Viktorov and Ditri, respectively.[9,10] A remarkable synthesis and useful applications of these works have been presented by Wilcox.[11] Though not fundamentally different in nature, the formulation introduced in the present paper is more suited to the objective. As will be seen indeed, the link established with the normal mode expansion method[12] results in a very versatile and lightweight pseudo-3D modeling technique.

II. MODELING PRINCIPLE

A. Finite length excitation

Let us consider an isotropic plate with thickness d, excited by a given harmonic stress applied to a localized area of its upper surface (Fig. 1). The excitation area S is supposed to be rectangular shaped, with length L and width W. The applied stress profile is described by a function $\sigma_0(x,y)$ defined over S and representing the action of a transducer. In order to simplify the notations, all the derivations presented

[a]Electronic mail: emmanuel.moulin@univ-valenciennes.fr

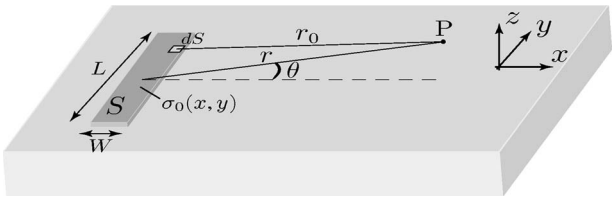

FIG. 1. Description of the problem geometry.

below will consider the normal component of the displacement on the plate surface only. If required, expressions for the transverse displacement or the displacement inside the plate thickness could be derived exactly the same way.

Assuming that a single Lamb wave is generated in the plate (this assumption can be released afterwards), the normal displacement du excited at a given point P of the plate upper surface by a small part dS with coordinates (x,y) of the actuation area can be deduced from the axisymmetric solution proposed by Ditri *et al.*[10] This can be written in a compact form as

$$du = \frac{j\sigma_0(x,y)}{4\mu}\frac{\Gamma k}{\Delta'}H_0^{(1)}(kr_0)e^{-j\omega t}dS, \tag{1}$$

where r_0 is the distance from the excitation point, k is the wave number of the considered Lamb wave, and Γ and Δ are functions depending on k and the material properties. They are representative of eigenmode-related features. Their complete expressions can be found in the literature[10] whenever needed and thus will not be reminded here. The prime $'$ denotes derivation with respect to k. $H_0^{(1)}$ represents the zeroth-order Hankel function of the first kind. For conciseness, the term $e^{-j\omega t}$ will be omitted in the next equations.

Let us now consider the case of an excitation represented by separable variable functions:

$$\sigma_0(x,y) = \sigma_{0x}(x)\sigma_{0y}(y). \tag{2}$$

Here σ_{0x} will be supposed to depend on W only and σ_{0y} on L only. In the case of an actual transducer, such an assumption is acceptable provided L and W are different enough to allow the length and width vibration modes to be uncoupled.[6]

Considering a location far enough from the source so that $r \gg L, W$ yields

$$r_0 \simeq r - x\cos\theta - y\sin\theta. \tag{3}$$

Then, by integrating Eq. (1) over the excitation area S and using the far-field asymptotical approximation of the Hankel function along with Eq. (3), the total normal displacement at a point P with polar coordinates (r,θ) can be expressed as

$$u(r,\theta) = \frac{j(1-j)\Gamma}{4\mu\sqrt{\pi}\Delta'}\sqrt{\frac{k}{r}}e^{jkr}\int_{-L/2}^{L/2}\sigma_{0y}(y)e^{-jky\sin\theta}dy \times \int_{-W/2}^{W/2}\sigma_{0x}(x)e^{-jkx\cos\theta}dx. \tag{4}$$

B. Infinite length excitation

Let us now consider the same plate, subject to an excitation defined by the same width W and the same applied stress function σ_{0x} as in the previous section. This case, however, will significantly differ from the previous one in that the length L will be considered infinite. In that case, a two-dimensional, plane-strain formulation is valid. Then the displacement at a given point, located at a distance r from the source, can be obtained by integration of a line-source solution. Such a solution can be derived from the work by Viktorov on wedge transducer excitation,[9] which had also been applied by Wilcox.[11] This yields an expression of the form

$$u_{2D}(r) = \frac{j\Gamma}{2\mu\Delta'}e^{jkr}\int_{-W/2}^{W/2}\sigma_{0x}(x)e^{-jkx}dx, \tag{5}$$

where Γ and Δ are the same as in Eqs. (1) and (4).

By introducing the modal amplitude A_m for the given Lamb mode, derived from the 2D normal mode formalism,[3,12] this displacement can also be written as

$$u_{2D}(r) = A_m u_m e^{jkr}, \tag{6}$$

where u_m is the modal displacement field (eigen vector) for the considered mode.

C. Connection of the 2D and 3D problems

Equations (4) and (5) are independently established from two geometrically different excitation cases. However, since the propagation medium (the solid plate) is supposed to be the same in both cases, it is no surprise that some eigenmode terms remain identical in both equations. This is indeed the case with Γ and Δ, as written above. Besides, the integrals over x are the same in Eqs. (4) and (5) if either the source width W is small compared to the wavelength or θ is small, or a combination of both.

In those conditions, comparison of these two equations and substitution of the above-mentioned identical terms yield the following relation between the finite-length and the 2D infinite-length solutions:

$$u(r,\theta) = \frac{(1-j)}{2\sqrt{\pi}}\sqrt{\frac{k}{r}}u_{2D}(r)\int_{-L/2}^{L/2}\sigma_{0y}(y)e^{-jky\sin\theta}dy \tag{7}$$

Then, by invoking Eq. (6), the finite-length displacement can finally be expressed as

$$u(r,\theta) = \frac{(1-j)}{2\sqrt{\pi}}\sqrt{\frac{k}{r}}A_m u_m e^{jkr}\int_{-L/2}^{L/2}\sigma_{0y}(y)e^{-jky\sin\theta}dy \tag{8}$$

In the case of an actual rectangular shaped surface-mounted transducer, it has been shown in a previous work[6] that the excitation $\sigma_{0y}(y)$ could be considered uniform over the transducer length L, provided the condition $W/L \leqslant 0.4$ is ensured. In that case, Eq. (8) can be simplified as

$$u(r,\theta) = \frac{(1-j)}{\sqrt{\pi}}\sqrt{\frac{k}{r}}A_m u_m \frac{\sin(k(L/2)\sin\theta)}{k\sin\theta}e^{jkr}. \tag{9}$$

This equation is similar to the general formulation given in Ref. 6. In this previous work, however, the directivity

relation was obtained by merely using a basic scalar diffraction model, which constituted quite a rough approximation. This resulted in rather satisfying qualitative directivity predictions but an undetermined, frequency- and mode-dependent amplitude term remained. This made direct comparison to 3D numerical modeling or experimental results impossible. On the contrary, Eq. (9) of the present paper allows the displacement waveforms to be correctly predicted, even in the multi-mode case.

The first step of the pseudo-3D modeling scheme is the treatment of the 2D plane-strain problem (assuming L infinite). This provides the modal amplitudes A_m for the considered transducer width W. It should be noted that the actual transducer thickness and piezoelectric characteristics can also be taken into account if required. A complete description of the procedure can be found in previous works.[3–5] Therefore, it will not be repeated here. Then, the third dimension is introduced by using Eq. (9). Hence, wave radiation in the (x,y) plane can be quantitatively characterized for each propagating mode. Finally, if required, summation of all mode contributions can be performed in order to obtain the total 3D displacement field in the plate.

III. APPLICATION TO A KNOWN EXCITATION

A. Problem description

In order to verify its pertinence and predicting ability, the modeling procedure will be applied to a simple case. We will consider a 3-mm-thick aluminum plate subject to a uniform pressure p_0 over the excitation area S as described in Fig. 1.

In such a simple situation, solution to the related 2D problem can be processed analytically. Details of the derivation can be found in Refs. 3 and 5. This yields

$$A_m = \frac{j\omega p_0 u_{mz}^*}{2kP_{mm}} \sin\left(\frac{kW}{2}\right) \tag{10}$$

with

$$P_{mm} = \frac{\omega}{2} \mathrm{Im}\left[\int_{-d/2}^{d/2} (u_{mx}^* \sigma_{mxx} + u_{mz}^* \sigma_{mxz}) dz\right], \tag{11}$$

where Im and * denote the imaginary part and the complex conjugate, respectively. u_m and σ_m are the modal displacement and stress tensors for the considered Lamb mode.

Though Eq. (9) has a meaning in a harmonic case only, transient excitations can be very classically dealt with using Fourier inversion.[5,13]

B. Results and comments

The first example corresponds to a two-cycle rectangular-windowed sinusoid at 150 kHz. At this frequency-thickness product and considering an out-of-plane excitation, the first antisymmetric mode A_0 is practically the only excited mode. The excitation area is defined by $W=8$ mm and $L=20$ mm. The resulting normal displacement at a distance $r=45$ mm is presented in Fig. 2(a). The dashed line represents the 2D solution, derived from the normal mode formalism. Application of Eq. (9), corresponding to the pseudo-3D solution, is represented by the solid line.

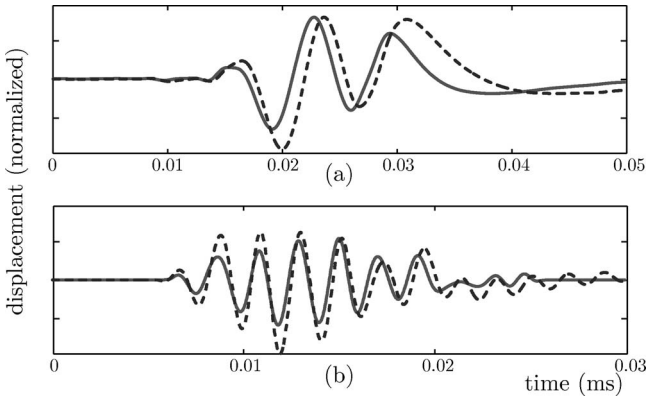

FIG. 2. Influence of 3D effects on the waveform shape (2D solution in dashed line, 3D solution in solid line). (a) Transducer size 8×20 mm, central frequency 150 kHz, $r=45$ mm, $\theta=0°$. (b) Transducer size 6×20 mm, central frequency 475 kHz, $r=28$ mm, $\theta=0°$.

A second demonstrative example is presented in Fig. 2(b). It corresponds to a multi-modal case. The excitation is a five-cycle sine-windowed sinusoid at 475 kHz and the source dimensions are $W=6$ mm and $L=20$ mm. The considered propagation distance is $r=28$ mm. All three modes: A_0, S_0 and A_1 are excited, though with different modal amplitudes. Here again, the solid and dashed lines represent the 3D and 2D results, respectively.

As shown here, taking into account the 3D behavior can lead to significant changes in the received waveforms. This can be easily interpreted from the form of Eq. (9). In addition to a mere amplitude decay proportional to $1/\sqrt{r}$ and related to the beam divergence in the (x,y) plane, the $\sqrt{k}$ factor disturbs the dispersive effects in the wave propagation. Indeed, components with low frequencies tend to be attenuated whereas higher frequency components tend to be amplified. Therefore the frequential reconstruction of the signal naturally yields modified waveforms. Besides, since S_0 and A_1 have smaller wave numbers than A_0, they appear more attenuated in the 3D case than in the 2D one. This results logically in a visible modification of the global waveform.

C. Comparison to numerical predictions

For quantitative validation purpose, both examples will be compared to results from a 3D finite element modeling (FEM). The excitation is modelized by applying normal point forces to the surface nodes in the corresponding area. The finite element mesh definition is guided by two, rather contradictory, criteria. First, the lateral dimensions of the plate have to be large enough so that no reflection pollutes the incident wave packets. Then, the elements should be numerous enough so that their sizes are smaller than a quarter of the shorter wavelength.[14] This ordinarily results in a rather cumbersome 3D mesh and, subsequently, in a huge memory and time consumption. Therefore, only a limited number of test cases can be reasonably treated in this way.

The obtained results are shown in Figs. 3(a) and 3(b).

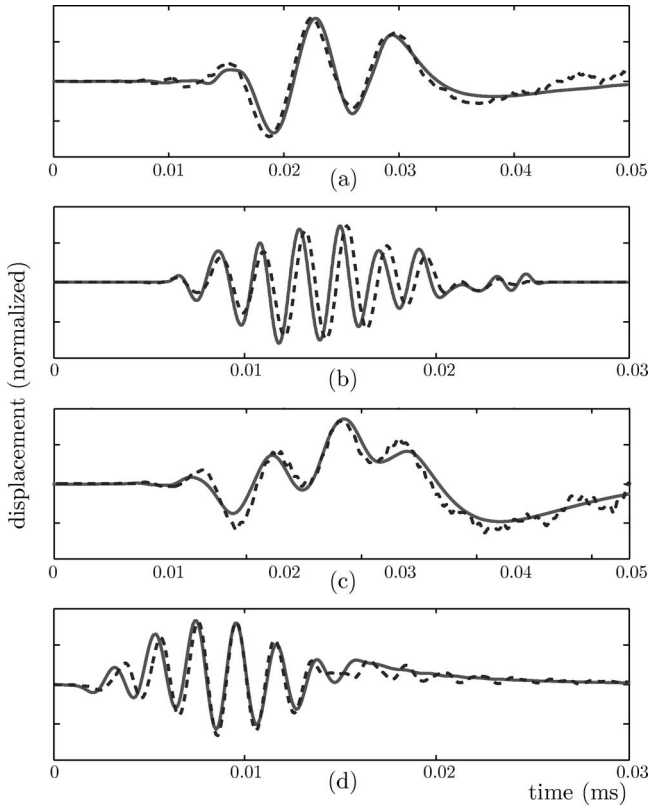

FIG. 3. Comparison of pseudo-3D solutions (solid) to 3D-FEM results (dashed). (a) Transducer size 8×20 mm, central frequency 150 kHz, $r=45$ mm, $\theta=0°$. (b) Transducer size 6×20 mm, central frequency 475 kHz, $r=28$ mm, $\theta=0°$. (c) Transducer size 8×20 mm, central frequency 150 kHz, $r=45$ mm, $\theta=50°$. (d) Transducer size 6×20 mm, central frequency 475 kHz, $r=12$ mm, $\theta=35°$.

The dashed lines correspond to the FEM results whereas the solid lines represent the same pseudo-3D results as in the previous section.

As can be seen, there is a very good agreement between the two sets of curves. Both the waveform shapes as well as the relative mode amplitudes are correctly predicted. Additionally, in order to provide validation for off-axis predictions, some results for $\theta\neq0$ are presented in Figs. 3(c) and 3(d). These results correspond to the same excitation cases as in Figs. 3(a) and 3(b), respectively. The first curve [Fig. 3(c)] is obtained at $r=45$ mm, $\theta=50°$. The second one [Fig. 3(c)] corresponds to $r=12$ mm, $\theta=35°$. These comparisons clearly demonstrate the ability of the hybrid pseudo-3D technique to provide quantitative results with a satisfying accuracy.

IV. CONCLUSION

This work was concerned with the problem of plate wave generation by a surface-mounted transducer with finite dimensions. In many practical cases, the 3D source effects cannot be neglected without leading to significantly erroneous results. As it has been verified indeed, both the waveform shapes and the mode amplitudes can be strongly affected by the finite length of the emitter.

Relying on existing works, it has been shown how the 3D characterization could be achieved by merely applying a corrective term to a 2D result. The formulation introduced allows the use of the normal mode expansion technique for solving the 2D problem, which results in a very convenient, polyvalent, and easy-to-use model. Comparison with results provided by a full-3D finite element computation have demonstrated the quantitative validity of the technique.

Besides, in previous works, a 2D hybrid FEM-normal mode technique has been successfully applied and has already been subject to adaptations to physical effects of growing complexity (anisotropy, attenuation,…). Then, the introduction of such effects into the pseudo-3D modeling could be considered without starting from the basis again.

Stochastic inversion is a well known technique for the solution of inverse problems in tomography. It employs the idea that the propagation medium may be represented as random with a known spatial covariance function. In this paper, a generalization of the stochastic inverse for acoustic travel-time tomography of the atmosphere is developed. The atmospheric inhomogeneities are considered to be random, not only in space but also in time. This allows one to incorporate tomographic data (travel times) obtained at different times to estimate the state of the propagation medium at any given time, by using spatial-temporal covariance functions of atmospheric turbulence. This increases the amount of data without increasing the number of sources and/or receivers. A numerical simulation for two-dimensional travel-time acoustic tomography of the atmosphere is performed in which travel times between sources to receivers are calculated, given the temperature and wind velocity fields. These travel times are used as data for reconstructing the original fields using both the ordinary stochastic inversion and the proposed time-dependent stochastic inversion algorithms. The time-dependent stochastic inversion produces a good match to the specified temperature and wind velocity fields, with average errors about half those of the ordinary stochastic inverse. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2180535]

I. INTRODUCTION

Acoustic tomography is widely used in physics, technology, and medicine for the remote sensing of inhomogeneous media. When applied to the atmosphere, acoustic tomography allows one to estimate (reconstruct) temperature and wind velocity within a tomographic volume or area.[1–4] The practical realization of acoustic tomography in an atmospheric boundary layer was reported in Refs. 5–10. In these tomography experiments, the sources and receivers of sound were located on masts several meters above the ground along the perimeter of a tomographic area that was a square or rectangular with side lengths of several hundred meters. The sound travel times between all pairs of sources and receivers were measured and used as input data for inverse algorithms to estimate temperature and wind velocity fields within a horizontal slice. This kind of tomography is called travel-time tomography. The inverse algorithms used were the stochastic inversion (SI) approach[5] and the simultaneous iterative reconstruction technique.[6–10] In the present paper, a generalization of the SI approach in travel-time acoustic tomography of the atmosphere is developed that allows one to effectively increase the number of data without increasing the number of sources and receivers.

The idea of travel-time acoustic tomography of the atmosphere is based on the fact that the time required for sound to propagate through a certain volume depends on the adiabatic sound speed (and hence on temperature) and wind velocity within that volume. More specifically, the travel time t_i^{tr} of the sound impulse propagation along the ith ray can be expressed as the following integral along the path L_i of this ray (e.g., Ref. 11):

$$t_i^{\mathrm{tr}} = \int_{L_i} \frac{dl}{u_g(\mathbf{R})}. \tag{1}$$

Here, $u_g(\mathbf{R})$ is the group velocity of a sound impulse, $\mathbf{R}$ is the position vector in three dimensions, and $i=1,2,\ldots,I$, where I is the number of ray paths of sound impulses simultaneously propagating through this volume from sources to receivers. It can be shown[11] that, in the presence of wind, the u_g can be expressed as $u_g=[c_{\mathrm{L}}^2(\mathbf{R})+V^2(\mathbf{R})+2c_{\mathrm{L}}(\mathbf{R})\mathbf{n}_i(\mathbf{R})\cdot\mathbf{V}(\mathbf{R})]^{1/2}$. Here $\mathbf{n}_i$ is the unit vector normal to

the wave front of a sound wave, $\mathbf{V}$ is the vector of wind velocity, and c_L is the Laplace adiabatic sound speed that relates to the acoustic virtual temperature T_{av} by

$$c_L^2 = \gamma R_a T_{av}, \tag{2}$$

where $\gamma \approx 1.41$ is the ratio of the specific heats and R_a is the universal gas constant for dry air. It is necessary to take into account the specific humidity of the air q to obtain the values of the actual thermodynamic temperature T_{th} from the acoustic virtual temperature by using the following relationship:[11] $T_{av} \cong T_{th}(1+0.511q)$. Note that the acoustic virtual temperature differs from the virtual temperature used by atmospheric scientists. When deriving Eq. (1), it is assumed that u_g does not depend on time during the propagation of sound impulses. Since in the atmosphere $c_L \gg |\mathbf{V}|$, this assumption is valid for tomographic arrays of order of several hundred meters considered in Refs. 5–10 and in Sec. IV. The goal of acoustic travel-time tomography is to estimate the fields $T_{av}(\mathbf{R})$ and $\mathbf{V}(\mathbf{R})$ within a tomographic volume, given the travel times t_i^{tr} and the locations of sources and receivers.

There are different techniques available to solve this problem. Many of them pursue the goal of finding a solution that, after substitution back into Eq. (1), yields travel times as close to the measured ones as possible. These methods are quite reliable and accurate if there are more data points (e.g., travel times) than unknown model values (e.g., total number of points at which the fields are to be reconstructed). However, this condition does not hold for atmospheric tomography unless the reconstruction is performed with low resolution.[2,6–10,12,13] In the opposite case, when the number of unknowns is greater than the number of available data points, such techniques cannot provide a unique solution, and some additional restrictions must be imposed on the sought fields. Since it is unknown in advance whether the actual fields being estimated obey such restrictions, these techniques may yield a spurious solution that perfectly matches the data but has little to do with the real fields.

In contrast, the SI approach is based on the idea that, using the available data, one seeks fields that have the minimum average deviation from the real ones. This approach also requires additional information about the sought fields, namely, the sought fields are treated as random ones with known spatial covariance functions.[1,3,5,14] Although the actual covariance functions in the turbulent atmosphere are not exactly known, they can be approximated by those corresponding to the von Kármán or Gaussian spectra of turbulence.[11,15,16] Note that other techniques that partition the fields into constant-valued grid cells implicitly assume step-like covariance functions, such that the field values are perfectly correlated within a grid cell and completely uncorrelated outside. Such functions are much less plausible than those used in the SI approach. The applicability and advantages of the SI approach in travel-time tomography of the atmosphere with high resolution are demonstrated in Refs. 3 and 5. A disadvantage of SI is that it does not use the fact that the sought fields are correlated not only in space but also in time.

In this paper, a generalization of the SI approach for acoustic travel-time tomography of the atmosphere is developed that allows one to use the data obtained at different times to reconstruct the temperature and wind velocity fields within a tomographic volume at any particular time, by using spatial-temporal covariance functions of these fields. This generalization is called time-dependent stochastic inversion (TDSI).

The general idea of using spatial-temporal covariance functions in SI is known in the literature. For example, it has been successfully used in satellite altimetry of the ocean surface, e.g., Refs. 17 and 18. In altimetry, the deviations of the ocean surface height from its average level are known at certain times and spatial points (along the satellite tracks). The problem is to estimate these deviations at other points (in space and time). Thus, this problem can be formulated as the space-time interpolation problem. There are many different techniques to interpolate the data. However, SI interpolates them in such a way that the covariance of the resulting fields holds true. The application of SI for these purposes was proposed in Ref. 19.

In contrast to satellite altimetry, travel-time tomography cannot be formulated as an interpolation problem, since the fields that are subject to estimation are unknown everywhere. Therefore, the mathematical formalism of TDSI in acoustic travel-time tomography of the atmosphere differs from that in altimetry. In the present paper, this mathematical formalism is developed. To verify that the TDSI approach improves the quality of the reconstruction, a numerical experiment was carried out for two-dimensional (2-D) travel-time acoustic tomography of a horizontal atmospheric layer.

The paper is organized as follows. In Sec. II, a general theory of 2-D TDSI is developed and a formula for the optimal stochastic inversion matrix is derived. Calculations of the covariance matrices that appear in the inversion matrix are presented in Sec. III. In Sec. IV, the numerical experiment of 2-D travel-time acoustic tomography of the atmosphere is described. Some aspects of the SI and TDSI algorithms are discussed in Sec. V. The conclusions are presented in Sec. VI.

II. THEORY

In this section, the theory of 2-D TDSI is developed. There are three steps that precede this development. First, it is taken into account that T_{av} and $\mathbf{V}$ depend not only on the spatial coordinates but also on time t. Therefore, t_i^{tr} depends on time t as well. Second, Eq. (1) is linearized due to specific conditions in the atmosphere, and, with the same degree of accuracy, the travel paths L_i are approximated by straight lines. Third, it is shown how to reconstruct the spatial mean values of the temperature and wind velocity fields within a tomographic area with the help of the conventional least square estimation. Finally, the problem for the TDSI approach in the reconstruction of temperature and wind velocity fluctuations is stated and a general solution of this problem is obtained.

A. Linearization

Let $\tilde{u}(\mathbf{r},t)$ and $\tilde{v}(\mathbf{r},t)$ be x and y components of the two-dimensional vector of wind velocity $\mathbf{V}$:

$$\mathbf{V}(\mathbf{r},t) = \tilde{u}(\mathbf{r},t)\mathbf{e}_x + \tilde{v}(\mathbf{r},t)\mathbf{e}_y. \tag{3}$$

Here t is time, a 2-D vector $\mathbf{r}$ specifies a spatial point within a tomographic area with the Cartesian coordinates (x,y), and $\mathbf{e}_x$ and $\mathbf{e}_y$ are the unit vectors along the x and y axes, respectively. The adiabatic sound speed c_L, temperature T_av, and wind velocity fields within a tomographic area at time t can be represented as sums of their spatial average values $c_0(t)$, $T_0(t)$, $u_0(t)$, and $v_0(t)$ and their fluctuations $c(\mathbf{r},t)$, $T(\mathbf{r},t)$, $u(\mathbf{r},t)$, and $v(\mathbf{r},t)$:

$$\begin{aligned} &c_\mathrm{L}(\mathbf{r},t) = c_0(t) + c(\mathbf{r},t), \quad T_\mathrm{av}(\mathbf{r},t) = T_0(t) + T(\mathbf{r},t), \\ &\tilde{u}(\mathbf{r},t) = u_0(t) + u(\mathbf{r},t), \quad \tilde{v}(\mathbf{r},t) = v_0(t) + v(\mathbf{r},t). \end{aligned} \tag{4}$$

Since in the atmosphere the absolute values of the adiabatic sound speed fluctuations and the wind components are much smaller than the spatial average value of c_0, Eq. (1) can be linearized to the first order of these fluctuations[2] and the travel paths of sound can be approximated by straight lines:[5,11]

$$\begin{aligned} t_i^\mathrm{tr}(t) = \varepsilon_i(t) + \frac{L_i}{c_0(t)}\left(1 - \frac{u_0(t)\cos\varphi_i + v_0(t)\sin\varphi_i}{c_0(t)}\right) \\ - \frac{1}{c_0^2(t)}\int_{L_i} dl\left(\frac{c_0(t)}{2T_0(t)}T(\mathbf{r},t) + u(\mathbf{r},t)\cos\varphi_i \right. \\ \left. + v(\mathbf{r},t)\sin\varphi_i\right), \end{aligned} \tag{5}$$

where $i=1,2,\ldots,I$ denotes the ray's path number, I is the total number of travel paths, L_i is the length of the ith ray path, $\mathbf{r}\in L_i$, and φ_i is the angle of the ith ray relative to the positive direction of the x axis. Note that the noise ε_i in the ith measured travel time was added to the right-hand side of Eq. (5). Furthermore, when deriving this equation the following relationship between the fluctuations of temperature and adiabatic sound speed was used: $c(\mathbf{r},t) = [c_0(t)/2T_0(t)]T(\mathbf{r},t)$. This relationship follows from Eqs. (4) and (2), with accuracy up to the first order of these fluctuations. The inverse problem, which is studied in this paper, is to reconstruct c_0, T_0, T, u, and v, given t_i^tr, L_i, and φ_i.

B. Reconstruction of mean fields

The mean values T_0, u_0, and v_0 within a tomographic area at any time can be reconstructed with the help of the least square estimation by using the travel times obtained at the same moment of time. For this purpose one should set the fluctuating parts of these fields to zero, so that the integral in Eq. (5) vanishes. Then Eq. (5) can be rewritten in matrix notation:

$$\mathbf{G}\mathbf{f} = \mathbf{b}, \tag{6}$$

where the elements of the column vector $\mathbf{b}$ are known and given by $b_i = t_i^\mathrm{tr}(t)/L_i$, the unknown column vector $\mathbf{f}$ has three elements, $f_1 = 1/c_0(t)$, $f_2 = u_0(t)/c_0^2(t)$, $f_3 = v_0(t)/c_0^2(t)$, and the matrix $\mathbf{G}$ is given by

$$\mathbf{G} = \begin{bmatrix} 1 & -\cos\varphi_1 & -\sin\varphi_1 \\ \vdots & \ddots & \vdots \\ 1 & -\cos\varphi_I & -\sin\varphi_I \end{bmatrix}. \tag{7}$$

Then, using the I elements of the vector $\mathbf{b}$ (I is assumed to be greater than 3), one should solve the overdetermined problem for the three unknowns (the elements of the vector $\mathbf{f}$) using the least square estimation:

$$\mathbf{f} = (\mathbf{G}^T\mathbf{G})^{-1}\mathbf{G}^T\mathbf{b}, \tag{8}$$

extract from them the values of c_0, u_0, and v_0, and calculate T_0 using Eq. (2).

C. Time-dependent stochastic inversion

Once the spatial mean values of temperature, adiabatic sound speed, and wind velocity fields within a tomographic area are known, it is worthwhile to introduce the column vector of data $\boldsymbol{d}(t)$ obtained at time t with elements

$$d_i(t) = L_i[c_0(t) - u_0(t)\cos\varphi_i - v_0(t)\sin\varphi_i] - c_0^2(t)t_i^\mathrm{tr}(t) + \xi_i(t), \tag{9}$$

where noise $\xi_i(t)$ includes the errors of travel time measurements $\varepsilon_i(t)$ and errors in the estimation of T_0, c_0, u_0, and v_0. Using Eq. (5), this data vector can be expressed as $\boldsymbol{d}(t) = \boldsymbol{d}_0(t) + \boldsymbol{\xi}(t)$, where the elements of the noise-free data column vector $\boldsymbol{d}_0(t)$ are given by

$$d_{0i}(t) = \int_{L_i} dl\left(\frac{c_0(t)}{2T_0(t)}T(\mathbf{r},t) + u(\mathbf{r},t)\cos\varphi_i + v(\mathbf{r},t)\sin\varphi_i\right). \tag{10}$$

The problem now is to reconstruct the fields of fluctuations $T(\mathbf{r},t_0)$, $u(\mathbf{r},t_0)$, and $v(\mathbf{r},t_0)$ at any chosen time t_0. Thus, the column vector of models at this time moment t_0 is given by

$$\begin{aligned} \mathbf{m}(t_0) = [&T(\mathbf{r}_1,t_0);\ldots;T(\mathbf{r}_J,t_0); \\ &u(\mathbf{r}_1,t_0);\ldots;u(\mathbf{r}_J,t_0);v(\mathbf{r}_1,t_0);\ldots;v(\mathbf{r}_J,t_0)], \end{aligned} \tag{11}$$

where J is the number of spatial points within the tomographic area at which the fields are being reconstructed; here and in what follows, the semicolon between elements denotes that these elements are arranged in a column.

Let us assume that one can collect data $(N+1)$ times during the time $N\tau$ by performing sound scans of the tomographic area and forming the vector $\boldsymbol{d}$ at each scan. Suppose that the last scan was performed at the time t, which can be earlier, equal to, or later than the time t_0 at which one tries to reconstruct the models. In this paper it is assumed that these scans are performed at equal time intervals τ, although such an assumption is not necessary. The temperature and wind velocity fields in this tomographic area are changing with time, which yields different data vectors at each scan. In this case, at the time t there will be data available from $(N+1)$ scans. That is, at the moment t one can form the vector $\mathbf{d}$ of all available data:

$$\mathbf{d} = [\boldsymbol{d}(t - N\tau); \boldsymbol{d}(t - N\tau + \tau); \ldots; \boldsymbol{d}(t)]. \tag{12}$$

Here $\mathbf{d}$ is a column vector containing the $(N+1)$ column-vectors $\boldsymbol{d}(t-n\tau)$, each of length I, where $n=0,1,\ldots,N$. Therefore, the total length of the data vector $\mathbf{d}$ is $(N+1)I$.

1. Problem statement

Using the data vector $\mathbf{d}$ given by Eq. (12), it is necessary to find a linear estimation $\hat{\mathbf{m}}(t_0)$ of unknown models $\mathbf{m}(t_0)$ at time t_0. The case $t_0 > t$ corresponds to advanced estimation; the case $t_0 < t$ corresponds to posterior estimation; and $t_0 = t$ corresponds to a real time reconstruction. In all these cases, one can use available data obtained from all scans to estimate the unknown fields. If one uses only the data obtained at moment t_0 to estimate the models $\mathbf{m}(t_0)$ at the same moment, that would correspond to standard SI in atmospheric travel-time tomography.[5]

In TDSI, the estimation of the unknown fields is sought in the same form as in standard SI:

$$\hat{\mathbf{m}}(t_0) = \mathbf{A}\mathbf{d}, \tag{13}$$

where unknown elements a_{jk} of matrix $\mathbf{A}$ must be determined. Here $j=1,2,\ldots,3J$, where $3J$ is the length of models, and $k=1,2,\ldots,(N+1)I$. We now introduce the column vector of discrepancy $\boldsymbol{\epsilon}$ between the true and reconstructed fields at time t_0:

$$\boldsymbol{\epsilon}_j = \hat{m}_j(t_0) - m_j(t_0). \tag{14}$$

To find the elements a_{jk}, let us require that they give the minimum of the elements of the mean square errors vector $\langle \boldsymbol{\epsilon}^2 \rangle$:

$$\langle \epsilon_j^2 \rangle \mapsto \min_{\{a_{jk}\}} \langle \boldsymbol{\epsilon}_j^2 \rangle, \tag{15}$$

where parentheses $\langle \cdot \rangle$ denote the mathematical expectation. These mean square errors are the diagonal elements of the error covariance matrix $\mathbf{R}_{\boldsymbol{\epsilon}\boldsymbol{\epsilon}}$:

$$\mathbf{R}_{\boldsymbol{\epsilon}\boldsymbol{\epsilon}} \equiv \langle \boldsymbol{\epsilon}\boldsymbol{\epsilon}^T \rangle, \tag{16}$$

where $\boldsymbol{\epsilon}$ is the column vector of discrepancy given by (14).

2. Solution

The matrix $\mathbf{A}$ that solves the problem stated above is given by the same formula as for ordinary SI, since the derivation of this formula does not depend on a particular structure of the models $\mathbf{m}$ and data $\mathbf{d}$ (see Appendix A):

$$\mathbf{A} = \mathbf{R}_{\mathbf{md}} \mathbf{R}_{\mathbf{dd}}^{-1}, \tag{17}$$

where $\mathbf{R}_{\mathbf{md}} \equiv \langle \mathbf{m}\mathbf{d}^T \rangle$ and $\mathbf{R}_{\mathbf{dd}} \equiv \langle \mathbf{d}\mathbf{d}^T \rangle$ are model-data and data covariance matrices.

Since the data and models have been chosen, as shown in Eqs. (12) and (11), these matrices have the following block structure:

$$\mathbf{R}_{\mathbf{md}} = [\mathbf{B}_{\boldsymbol{md}}(t_0, t - N\tau), \mathbf{B}_{\boldsymbol{md}}(t_0, t - N\tau + \tau), \ldots, \mathbf{B}_{\boldsymbol{md}}(t_0, t)], \tag{18}$$

$$\mathbf{R}_{\mathbf{dd}} = \begin{bmatrix} \mathbf{B}_{\boldsymbol{dd}}(t - N\tau, t - N\tau) & \mathbf{B}_{\boldsymbol{dd}}(t - N\tau, t - N\tau + \tau) & \cdots & \mathbf{B}_{\boldsymbol{dd}}(t - N\tau, t) \\ \mathbf{B}_{\boldsymbol{dd}}(t - N\tau + \tau, t - N\tau) & \mathbf{B}_{\boldsymbol{dd}}(t - N\tau + \tau, t - N\tau + \tau) & \cdots & \mathbf{B}_{\boldsymbol{dd}}(t - N\tau + \tau, t) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{B}_{\boldsymbol{dd}}(t, t - N\tau) & \mathbf{B}_{\boldsymbol{dd}}(t, t - N\tau + \tau) & \cdots & \mathbf{B}_{\boldsymbol{dd}}(t, t) \end{bmatrix}. \tag{19}$$

Here $\mathbf{B}_{\boldsymbol{md}}(t_1, t_2) \equiv \langle \mathbf{m}(t_1)\boldsymbol{d}^T(t_2) \rangle$ is the covariance matrix of size $[3J, I]$ between the models at time moment t_1 and data at moment t_2, $\mathbf{B}_{\boldsymbol{dd}}(t_1, t_2) \equiv \langle \boldsymbol{d}(t_1)\boldsymbol{d}^T(t_2) \rangle$ is the covariance matrix of size $[I, I]$ between data at moment t_1 and data at moment t_2, and the comma between the elements of the $\mathbf{R}_{\mathbf{md}}$ matrix denotes that the $\mathbf{B}_{\boldsymbol{md}}$ matrices are arranged in a row. Thus, the dimensions of the $\mathbf{R}_{\mathbf{md}}$ and $\mathbf{R}_{\mathbf{dd}}$ matrices are $[3J, (N+1)I]$ and $[(N+1)I, (N+1)I]$, correspondingly. Note that the $\mathbf{R}_{\mathbf{dd}}$ matrix is symmetric.

It is assumed that noise in the data $\boldsymbol{\xi}(t)$ is independent of the sought fields and the noise-free data vectors, is not correlated with itself for different time moments and for different paths, and can be described by the normal distribution $N(0, \sigma_\xi)$. Therefore, in the presence of noise,

$$\mathbf{R}_{\mathbf{md}} = \mathbf{R}_{\mathbf{md}_0}, \tag{20}$$

$$\mathbf{R}_{\mathbf{dd}} = \mathbf{R}_{\mathbf{d}_0\mathbf{d}_0} + \sigma_\xi^2 \mathbf{I}, \tag{21}$$

where $\mathbf{I}$ is the identity matrix. Since noise in the data can easily be taken into account by these formulas, further considerations will be focused on the noise-free data $\mathbf{d}_0$.

It can be shown (see Appendix B) that the error covariance matrix $\mathbf{R}_{\boldsymbol{\epsilon}\boldsymbol{\epsilon}}$ that corresponds to such an estimation of models [see Eq. (13)] with the optimal matrix $\mathbf{A}$ given by Eq. (17) is

$$\mathbf{R}_{\boldsymbol{\epsilon}\boldsymbol{\epsilon}} = \mathbf{R}_{\mathbf{mm}} - \mathbf{R}_{\mathbf{md}} \mathbf{R}_{\mathbf{dd}}^{-1} \mathbf{R}_{\mathbf{md}}^T, \tag{22}$$

where $\mathbf{R}_{\mathbf{mm}} \equiv \langle \mathbf{m}(t_0)\mathbf{m}^T(t_0) \rangle$ is the models covariance matrix at time t_0. The elements of the main diagonal of the $\mathbf{R}_{\boldsymbol{\epsilon}\boldsymbol{\epsilon}}$ matrix are equal to expected mean square errors of the reconstruction at each point. They can be calculated without knowledge of the original fields. These averaged errors can differ from the errors of the reconstruction of a particular realization of the original fields.

Note that the developed mathematical formalism of TDSI is valid for statistically nonstationary and inhomogeneous random fields.

III. COVARIANCE MATRICES

Since the optimal stochastic inverse operator **A** given by Eq. (17) is determined in terms of the $\mathbf{R_{md}}$ and $\mathbf{R_{dd}}$ matrices, it is worthwhile to consider some important particular cases when these matrices can be calculated explicitly. These considerations will be carried out taking 2-D travel-time tomography of the atmosphere as an example.

A. 2-D travel-time tomography

In the case of travel-time tomography, one can use the linear relationship between $\boldsymbol{d}_0$ and the sought fields given by Eq. (10) to obtain an expression for the covariance matrix $\mathbf{B}_{\mathbf{m}\boldsymbol{d}_0}(t_1,t_2)$ between the models at time t_1 and the noise-free data at time t_2:

$$
\begin{aligned}
[\mathbf{B}_{\mathbf{m}\boldsymbol{d}_0}(t_1,t_2)]_{ji} &= \langle m_j(t_1) d_{0i}(t_2)\rangle \\
&= \int_{L_i} dl \left(\frac{c_0(t_2)}{2T_0(t_2)} \langle m_j(t_1) T(\mathbf{r},t_2)\rangle + \langle m_j(t_1) u(\mathbf{r},t_2)\rangle \cos\varphi_i + \langle m_j(t_1) v(\mathbf{r},t_2)\rangle \sin\varphi_i \right) \\
&= \begin{cases}
\displaystyle\int_{L_i} dl \left(\frac{c_0(t_2)}{2T_0(t_2)} B_{TT}(\mathbf{r}_j,t_1;\mathbf{r},t_2) \right), & \text{if } 1 \leqslant j \leqslant J, \\
\displaystyle\int_{L_i} dl (B_{uu}(\mathbf{r}_j,t_1;\mathbf{r},t_2)\cos\varphi_i + B_{uv}(\mathbf{r}_j,t_1;\mathbf{r},t_2)\sin\varphi_i), & \text{if } J+1 \leqslant j \leqslant 2J, \\
\displaystyle\int_{L_i} dl (B_{vu}(\mathbf{r}_j,t_1;\mathbf{r},t_2)\cos\varphi_i + B_{vv}(\mathbf{r}_j,t_1;\mathbf{r},t_2)\sin\varphi_i), & \text{if } 2J+1 \leqslant j \leqslant 3J,
\end{cases}
\end{aligned}
\tag{23}
$$

where $i=1,2,\ldots,I$, $j=1,2,\ldots,3J$, $\mathbf{r}\in L_i$, B_{TT}, B_{uu}, B_{vv}, B_{uv}, and B_{vu} are the spatial-temporal covariance functions of the corresponding fields marked as the subscripts, and the $\mathbf{r}_j$ are the chosen spatial points within the tomographic area at which the sought fields are reconstructed; these points stay fixed during the integration.

Similarly, an expression for the covariance matrix $\mathbf{B}_{\boldsymbol{d}_0\boldsymbol{d}_0}(t_1,t_2)$ between the noise-free data at time t_1 and time t_2 is given by

$$
\begin{aligned}
[\mathbf{B}_{\boldsymbol{d}_0\boldsymbol{d}_0}(t_1,t_2)]_{ip} = \langle d_{0i}(t_1) d_{0p}(t_2)\rangle = \int_{L_i} dl \int_{L_p} dl' \Bigg\{ & \frac{c_0(t_1)c_0(t_2)}{4T_0(t_1)T_0(t_2)} B_{TT}(\mathbf{r},t_1;\mathbf{r}',t_2) + B_{uu}(\mathbf{r},t_1;\mathbf{r}',t_2)\cos\varphi_i\cos\varphi_p \\
& + B_{vv}(\mathbf{r},t_1;\mathbf{r}',t_2)\sin\varphi_i\sin\varphi_p + B_{uv}(\mathbf{r},t_1;\mathbf{r}',t_2)\cos\varphi_i\sin\varphi_p + B_{vu}(\mathbf{r},t_1;\mathbf{r}',t_2)\cos\varphi_p\sin\varphi_i \Bigg\},
\end{aligned}
\tag{24}
$$

where $i,p=1,2,\ldots,I$, $\mathbf{r}\in L_i$, $\mathbf{r}'\in L_p$. Note that $B_{vu}(\mathbf{r},t_1;\mathbf{r}',t_2)=B_{uv}(\mathbf{r}',t_2;\mathbf{r},t_1)$. When deriving Eqs. (23) and (24), it is assumed that $B_{Tu}=B_{Tv}\equiv 0$.

Once the matrices $\mathbf{B}_{\mathbf{m}\boldsymbol{d}_0}(t_1,t_2)$ and $\mathbf{B}_{\boldsymbol{d}_0\boldsymbol{d}_0}(t_1,t_2)$ are calculated, one should use Eqs. (18) and (19) to form the $\mathbf{R}_{\mathbf{md}_0}$ and $\mathbf{R}_{\mathbf{d}_0\mathbf{d}_0}$ matrices and, then, Eq. (21) to take noise into account.

B. Stationary fields

If the temperature and wind velocity fields are statistically stationary, their covariance functions depend only on the difference of their temporal arguments:

$$
B(\mathbf{r},t_1;\mathbf{r}',t_2) = B(\mathbf{r},\mathbf{r}',\Delta t), \quad \Delta t \equiv t_2 - t_1. \tag{25}
$$

The notation B without subscripts stands for the covariance function of any two fields considered above. In this case, Eqs. (18) and (19) are modified as follows:

$$
\begin{aligned}
\mathbf{R_{md}} = [&\mathbf{B}_{\mathbf{m}\boldsymbol{d}}(t - N\tau - t_0), \mathbf{B}_{\mathbf{m}\boldsymbol{d}}(t - N\tau + \tau - t_0), \ldots, \\
&\mathbf{B}_{\mathbf{m}\boldsymbol{d}}(t - t_0)],
\end{aligned}
\tag{26}
$$

$$
\mathbf{R_{dd}} = \begin{bmatrix}
\mathbf{B}_{dd}(0) & \mathbf{B}_{dd}(\tau) & \cdots & \mathbf{B}_{dd}(N\tau) \\
\mathbf{B}_{dd}(-\tau) & \mathbf{B}_{dd}(0) & \cdots & \mathbf{B}_{dd}(N\tau - \tau) \\
\vdots & \vdots & \ddots & \vdots \\
\mathbf{B}_{dd}(-N\tau) & \mathbf{B}_{dd}(-N\tau + \tau) & \cdots & \mathbf{B}_{dd}(0)
\end{bmatrix}. \tag{27}
$$

Note that, for any Δt,

$$
\mathbf{B}_{dd}(\Delta t) = \mathbf{B}_{dd}^T(-\Delta t). \tag{28}
$$

It is sufficient to know only the first cell row of the matrix $\mathbf{R_{dd}}$ since it has the same matrices along each diagonal (a block Toeplitz-like structure). Also note that the $\mathbf{R_{dd}}$ matrix is independent of time t_0, i.e., for the given set of data it is

necessary to calculate this matrix only once to reconstruct fields at any time. Another interesting fact is that the matrices $\mathbf{B}_{dd}(0)$ on its main diagonal are equal to the covariance matrix $\mathbf{R}_{\mathbf{dd}}$ of ordinary SI.

C. Frozen turbulence

If turbulence may be considered frozen, each spatial point of the temperature and wind velocity fields is moving with a constant speed $\mathbf{U}$. In this case, the temperature field at time t_2 can be expressed in terms of the field at time t_1 by the following relationship:[20]

$$T(\mathbf{r},t_2) = T(\mathbf{r} - \mathbf{U}\,\Delta t, t_1). \tag{29}$$

The same relationship is valid for the turbulent wind velocity fields. This allows one to obtain the spatial-temporal covariance matrices, which are unknown in general, in terms of the spatial covariance matrices. The latter can be modeled by the covariance functions corresponding, for example, to the von Kármán or Gaussian spatial spectra of turbulence. For example, for the temperature field, we have

$$B_{TT}(\mathbf{r},t_1;\mathbf{r}',t_2) \equiv \langle T(\mathbf{r},t_1)T(\mathbf{r}',t_2)\rangle = \langle T(\mathbf{r},t_1)T(\mathbf{r}' - \mathbf{U}\,\Delta t, t_1)\rangle = B^s_{TT}(\mathbf{r},\mathbf{r}' - \mathbf{U}\,\Delta t), \tag{30}$$

where B^s_{TT} is the spatial covariance matrix of the temperature field. The last equality is true for statistically stationary fields. Similar equations can be derived for the spatial-temporal covariance functions of the other fields. Since frozen turbulence is a particular case of stationary fields, Eqs. (26)–(28), stay valid for this case as well. Thus, for frozen turbulence the spatial-temporal covariance matrices $\mathbf{R}_{\mathbf{md}}$ and $\mathbf{R}_{\mathbf{dd}}$ can be expressed in terms of known or inferred spatial covariance matrices.

The frozen turbulence hypothesis is widely used in meteorology and the study of wave propagation in random media, e.g., Refs. 20 and 21. This hypothesis is valid with a good accuracy for eddies in the inertial range of turbulence. However, the applicability of this hypothesis to eddies in the energy range is questionable.[22] Note that in the present paper, the frozen turbulence hypothesis is used to concretize the spatial-temporal covariance functions. TDSI can still be used if this hypothesis is invalid.

IV. NUMERICAL EXPERIMENT

In this section, a numerical experiment that demonstrates the significant improvement in the quality of temperature and wind velocity field reconstructions possible with TDSI is described. A snapshot of the temperature and wind velocity fields was created by large eddy simulation (LES),[23] which is widely used in meteorology (e.g., Refs. 24 and 25). LES numerically solves the Navier-Stokes equations for eddies large enough to be resolved by the spatial grid. The effect of smaller eddies on the resolved flow is parametrized. LES produces realistic wind velocity and temperature fields for flow processes that are well resolved by the grid.

Using the single snapshot of the LES temperature and wind velocity fields, the perfectly frozen turbulent fields with

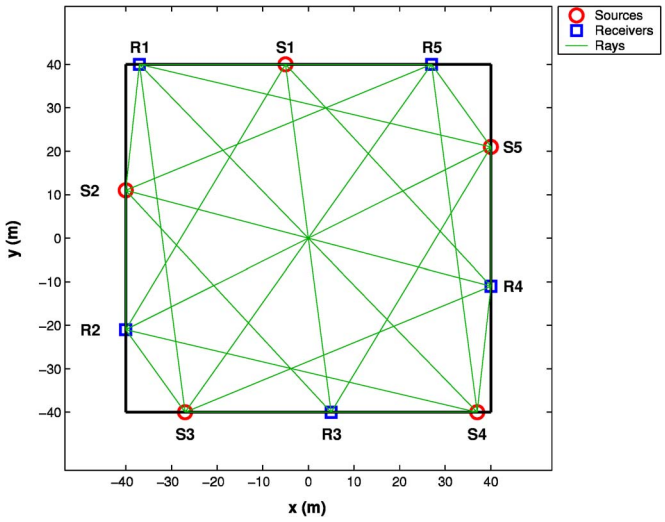

FIG. 1. (Color online) The layout of sources and receivers in the numerical experiment.

the velocity components U_x=4 m/s and U_y=0 m/s were created. The travel times were calculated each second (τ =1 s) using Eq. (5). Two-dimensional linear interpolation was employed to obtain the value of the integrand in Eq. (5) along the travel paths; then the integral was calculated numerically. These travel times were disturbed by white noise with standard deviation σ_ε=5 μs, which corresponds to relative errors of order 1% to 42% in the data $\boldsymbol{d}_0(t)$. The total number of such numerical scans was 18, and the problem was to estimate the temperature and wind velocity fields $T_{\text{av}}(\mathbf{r},t_0)$, $\tilde{u}(\mathbf{r},t_0)$, and $\tilde{v}(\mathbf{r},t_0)$ at time t_0=9 s. The time origin coincided with the first scan. The number of sources as well as receivers was 5, so that the number of rays I at each scan was 25. The tomographic area was a square of 80 by 80 meters. The layout of acoustic sources and receivers and the corresponding ray paths are shown in Fig. 1.

The reconstruction consisted of two stages. In the first stage the spatial mean values of the temperature and wind velocity fields $T_0(t_0)$, $u_0(t_0)$, and $v_0(t_0)$ within the tomographic area were reconstructed using the approach described in Sec. II B. The true and estimated spatial mean values of temperature and wind fields are presented in Table I.

One can see from Table I that the reconstruction of spatial mean fields was very accurate, the differences between true and estimated mean values was 0.14 K for the temperature field, 0.03 m/s for the x component of the wind velocity vector, and 0.01 m/s for its y component.

In the second stage, the fluctuations of the temperature and wind fields $T(\mathbf{r},t_0)$, $u(\mathbf{r},t_0)$, and $v(\mathbf{r},t_0)$ from their spatial mean values were reconstructed using either standard SI (only data at time t_0 were used, the total number of data

points was equal to the number of rays $I=25$) or TDSI (data obtained at 18 different times were used, which resulted in 450 data points). To describe the spatial covariance of the temperature and wind velocity fields within the tomographic area, the following Gaussian covariance functions were used:[11]

$$B^s_{TT}(\mathbf{r},\mathbf{r}') = \sigma_T^2 \exp\left(-\frac{(\mathbf{r}-\mathbf{r}')^2}{l_T^2}\right), \tag{31}$$

$$B^s_{uu}(\mathbf{r},\mathbf{r}') = \sigma_u^2 \exp\left(-\frac{(\mathbf{r}-\mathbf{r}')^2}{l^2}\right)\left(1-\frac{(y-y')^2}{l^2}\right), \tag{32}$$

$$B^s_{vv}(\mathbf{r},\mathbf{r}') = \sigma_v^2 \exp\left(-\frac{(\mathbf{r}-\mathbf{r}')^2}{l^2}\right)\left(1-\frac{(x-x')^2}{l^2}\right), \tag{33}$$

$$B^s_{uv}(\mathbf{r},\mathbf{r}') = \sigma_u\sigma_v \exp\left(-\frac{(\mathbf{r}-\mathbf{r}')^2}{l^2}\right)\frac{(x-x')(y-y')}{l^2}, \tag{34}$$

where $\sigma_T, \sigma_u, \sigma_v$ are the standard deviations of the corresponding fields, l_T and l are their correlation lengths, $\mathbf{r}=(x,y)$, and $\mathbf{r}'=(x',y')$. Then, the relations similar to that given by Eq. (30) were used to obtain the spatial-temporal covariance functions of the sought fields. The noise-free matrices $\mathbf{R}_{\mathbf{md}_0}$ and $\mathbf{R}_{\mathbf{d}_0\mathbf{d}_0}$ were formed with the help of Eqs. (26) and (27), where the $\mathbf{B}_{\mathbf{m}d_0}$ and $\mathbf{B}_{d_0d_0}$ matrices were calculated using Eqs. (23) and (24); noise was taken into account by Eq. (21).

In the described numerical experiment, there were five parameters in the SI and TDSI algorithms that must be chosen: σ_T, σ_u, σ_v, l_T, and l. These parameters were estimated from the original LES fields: $\sigma_T=0.14$ K, $\sigma_u=0.72$ m/s, $\sigma_v=0.42$ m/s, and $l_T=l=15$ m.

The original and reconstructed fields were described by matrices of size 21 by 21. After all calculations were done, the fields were interpolated (2-D linear interpolation) for illustrative purposes. The fluctuating parts of the original fields are presented in Figs. 2(a)–2(c). Figures 2(d)–2(f) show the reconstructed fields using the SI approach. The reconstruction results of TDSI are given in Figs. 2(g)–2(i). As one can see, standard SI matched the contours of the sought u field fairly well, but the v and T fields were reconstructed poorly. In contrast, the time-dependent stochastic approach allowed the much more detailed and accurate reconstruction of all fields. To characterize the expected improvement of the reconstruction it is worthwhile to consider the expected errors of the reconstruction given by Eq. (22). It is convenient to normalize these mean square errors by the corresponding field variances so that their values lie in $[0, 1]$. If these normalized mean-squared errors (NMSE) are of order unity, the errors of reconstruction are of the order of variance of the original field, i.e., one has a poor reconstruction. Conversely, if NMSE are zeros, it is expected that the reconstructed and actual fields are identical. NMSE can be recalculated into root mean-square errors (RMSE). NMSE for SI are presented in Figs. 3(a)–3(c) while Figs. 3(d)–3(f) show NMSE for TDSI. To characterize the overall quality of the reconstruction, NMSE at each spatial point and corresponding RMSE were averaged over the tomographic area. These averaged values of NMSE and RMSE are presented in Table II.

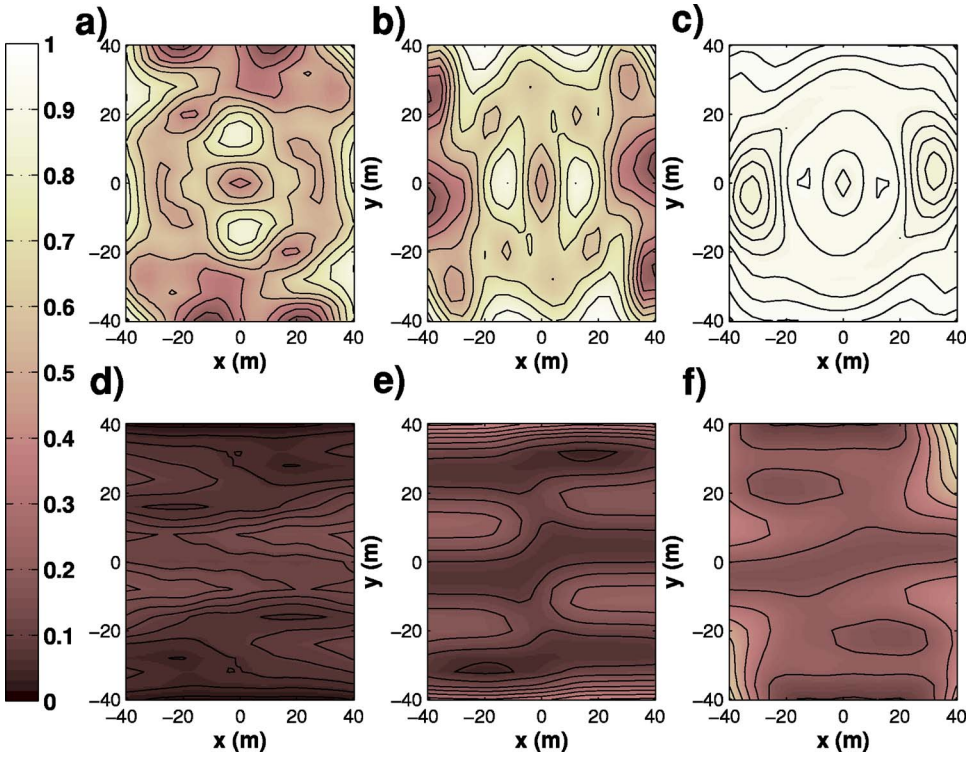

FIG. 3. (Color online) The expected normalized mean square errors. (a) The u field reconstructed by SI. (b) The v field reconstructed by SI. (c) The T field reconstructed by SI. (d) The u field reconstructed by TDSI. (e) The v field reconstructed by TDSI. (f) The T field reconstructed by TDSI.

It follows from Fig. 3 and Table II that, for TDSI, the average NMSE is about four times less for the T and v fields and seven times less for the u field than the corresponding NMSE for ordinary SI. This corresponds to a 46% reduction of the RMSE for the T field, a 52% reduction for the v fields, and a 62% reduction for the u field.

V. DISCUSSION

The idea of the stochastic approach is based on the assumption that covariance matrices of the sought fields are known. That means that in the case of the Gaussian covariance functions all five parameters (variances and correlation lengths of the sought fields) should be known in advance. In the practical implementation of travel-time tomography, however, these parameters are unknown. One can estimate these parameters by measuring the temperature and wind velocity fluctuations with the use of conventional meteorological sensors or using a turbulence similarity theory.

Furthermore, the covariance of the isotropic turbulence in the atmosphere is better described by the von Kármán spectrum rather than by the Gaussian spectrum. The latter was used in the numerical experiment because it was then possible to calculate the $\mathbf{R_{md}}$ matrix analytically and use only a single numeric integration to get the $\mathbf{R_{dd}}$ matrix. This significantly improved the accuracy and speed of the calculations. Since the actual fields were not described by the Gaussian covariance functions, the reconstruction quality improvement seems rather unexpected. However, there is a relatively simple explanation of this fact. In a certain spatial scale range, the covariance functions of atmospheric turbulence can be approximated by the Gaussian covariance functions with appropriate variances and correlation lengths.[27] Therefore, the Gaussian covariance functions can be used for SI and TDSI as approximations of the actual ones. It is expected that the use of the covariance function corresponding to the von Kármán spectrum of turbulence will improve the reconstruction.

TABLE II. Average expected errors of the reconstruction of temperature and wind velocity fields by SI and TDSI.

Fields	T		u		v	
Errors	NMSE	RMSE (K)	NMSE	RMSE (m/s)	NMSE	RMSE (m/s)
SI	0.96	0.13	0.56	0.53	0.63	0.33
TDSI	0.24	0.07	0.08	0.20	0.15	0.16

One of the advantages of the stochastic approach is that noise in the data plays, in a certain sense, a positive role by regularizing the $\mathbf{R_{dd}}$ matrix [see Eq. (21)]. Indeed, the presence of noise just adds an additional term to the main diagonal of the $\mathbf{R_{dd}}$ matrix, which improves its condition (keeps it invertible), although it does smooth the solution somewhat. This regularization is especially important for TDSI, where the condition of the matrix $\mathbf{R_{dd}}$ may be very poor and may lead to spurious solutions.

Figures 2(a)–2(i) show that the reconstruction of the temperature fluctuation field was not as good as that for the velocity fluctuations. The probable reason for this is a small effect of the temperature fluctuations on the travel times in comparison to the wind-velocity fluctuations. Indeed, the LES temperature fluctuations were in the range $[-0.15, 0.35]$ K while, for many meteorological problems, the acceptable error of temperature measurements is ± 0.3 K.[7,8] Note that to improve the reconstruction of temperature fluctuations in acoustic tomography, one can use reciprocal transmission of sound waves.[8,26]

The proposed TDSI algorithm also allows one to estimate the temporal mean values of the temperature and wind velocity fluctuations at any given spatial point. This might be important when the temporal changes of these fluctuations are negligible during the time interval $N\tau$. For this purpose, it is necessary to set all temporal arguments in the matrices $\mathbf{R_{md}}$ and $\mathbf{R_{dd}}$ equal to zero. Note that in this case the noise variance σ_ξ^2 should be enlarged, because the noise includes not only the measurement uncertainty but also the neglected variation of the original fields during the observed time interval.

VI. CONCLUSION

In this paper, a generalization of the stochastic inversion approach for tomographic problems in the atmosphere was developed. The key idea of this generalization is that, by using spatial-temporal covariance functions of temperature and wind velocity fields, one can use data obtained at different times to reconstruct these fields at any particular time. This allows one to significantly enlarge the effective amount of tomographic data, while keeping the total number of sources and/or receivers fixed. The efficiency of the developed method was demonstrated in a numerical experiment that simulated the acoustic 2-D travel-time tomography problem of the atmosphere. This numerical experiment showed a remarkable improvement of the reconstruction when one used TDSI instead of standard SI.

ACKNOWLEDGMENTS

Patton and P. P. Sullivan of the National Center for Atmospheric Research for providing the LES data. The LES was supported in part by the DoD High-Performance Computing Modernization Program. Finally, we would like to thank anonymous reviewers, whose comments allowed us to improve this paper.

APPENDIX A: OPTIMAL STOCHASTIC OPERATOR DERIVATION

Let $\mathbf{m}$ and $\mathbf{d}$ be two arbitrary random column-vectors of lengths M and D, correspondingly, with a known matrix of the second statistical moment $\mathbf{R_{md}} \equiv \langle \mathbf{m}\mathbf{d}^T \rangle$. Furthermore, let the matrix $\mathbf{R_{dd}} \equiv \langle \mathbf{d}\mathbf{d}^T \rangle$ also be known. Note that, in the case when $\langle \mathbf{m} \rangle = \mathbf{0}$, $\langle \mathbf{d} \rangle = \mathbf{0}$, the $\mathbf{R_{md}}$ and $\mathbf{R_{dd}}$ are the covariance matrices. The problem is to estimate the unknown vector $\mathbf{m}$ if a particular realization of the random vector $\mathbf{d}$ is given. To do this, one can seek for the estimation $\hat{\mathbf{m}}$ of the unknown vector $\mathbf{m}$ in the form

$$\hat{\mathbf{m}} = \mathbf{A}\mathbf{d}. \tag{A1}$$

Introduce the column vector of discrepancy $\boldsymbol{\epsilon}$ between the true and reconstructed vectors:

$$\epsilon_j = \hat{m}_j - m_j, \tag{A2}$$

where $j = 1, 2, \ldots, M$.

To find the elements a_{jk} of matrix $\mathbf{A}$, let us require that they give the minimum of each element of the mean square errors vector $\langle \boldsymbol{\epsilon}^2 \rangle$:

$$\langle \epsilon_j^2 \rangle \mapsto \min_{\{a_{jk}\}} \langle \epsilon_j^2 \rangle, \tag{A3}$$

where $k = 1, 2, \ldots, D$.

To satisfy the requirement (A3), one should take the partial derivative along the current element a_{ip} of the matrix $\mathbf{A}$ and make it equal to 0:

$$\begin{aligned} \frac{\partial}{\partial a_{ip}} \langle (a_{jk} d_k - m_j)^2 \rangle &= 2 \langle (a_{ik} d_k - m_i) d_p \rangle \\ &= 2 (a_{ik} \langle d_k d_p \rangle - \langle m_i d_p \rangle) \\ &= 2 (a_{ik} [\mathbf{R_{dd}}]_{kp} - [\mathbf{R_{md}}]_{ip}) = 0, \end{aligned} \tag{A4}$$

where the equality $\partial a_{jk} / \partial a_{ip} \equiv \delta_{ij} \delta_{pk}$ was taken into account, and the δ's are Kronecker's delta symbols. The last equation, after canceling the factor 2, can be written in matrix notation:

$$\mathbf{A}\mathbf{R_{dd}} - \mathbf{R_{md}} = \mathbf{0}. \tag{A5}$$

Therefore, under assumption that the inverse matrix $\mathbf{R_{dd}^{-1}}$ exists, the optimal matrix $\mathbf{A}$ is given by

$$\mathbf{A} = \mathbf{R_{md}} \mathbf{R_{dd}^{-1}}. \tag{A6}$$

APPENDIX B: ERROR COVARIANCE MATRIX DERIVATION

If a random column vector $\boldsymbol{\eta}$ relates to another random column vector $\boldsymbol{\xi}$ by a known nonrandom matrix $\mathbf{C}$ as $\boldsymbol{\eta} = \mathbf{C}\boldsymbol{\xi}$, then its covariance matrix $\mathbf{R}_{\eta\eta} \equiv \langle \boldsymbol{\eta}\boldsymbol{\eta}^T \rangle$ is expressed in terms of the covariance matrix $\mathbf{R}_{\xi\xi} \equiv \langle \boldsymbol{\xi}\boldsymbol{\xi}^T \rangle$ as

$$\mathbf{R}_{\eta\eta} = \mathbf{C}\mathbf{R}_{\xi\xi}\mathbf{C}^T. \tag{B1}$$

In the case of travel-time tomography, the column vector of discrepancy is given by $\boldsymbol{\epsilon} \equiv \hat{\mathbf{m}} - \mathbf{m}$, where $\hat{\mathbf{m}} = \mathbf{A}\mathbf{d}$. Therefore, the discrepancy can be expressed in terms of the matrix multiplication using block matrix notation:

$$\boldsymbol{\epsilon} = [\mathbf{A} - \mathbf{I}] \begin{bmatrix} \mathbf{d} \\ \mathbf{m} \end{bmatrix}, \tag{B2}$$

where $\mathbf{I}$ is the identical matrix. Using the formula (B1), one can get the expression for covariance matrix $\mathbf{R}_{\epsilon\epsilon}$:

$$\begin{aligned} \mathbf{R}_{\epsilon\epsilon} &= [\mathbf{A} - \mathbf{I}] \left\langle \begin{bmatrix} \mathbf{d} \\ \mathbf{m} \end{bmatrix} [\mathbf{d}^T \mathbf{m}^T] \right\rangle \begin{bmatrix} \mathbf{A}^T \\ -\mathbf{I} \end{bmatrix} \\ &= [\mathbf{A} - \mathbf{I}] \begin{bmatrix} \langle \mathbf{d}\mathbf{d}^T \rangle & \langle \mathbf{d}\mathbf{m}^T \rangle \\ \langle \mathbf{m}\mathbf{d}^T \rangle & \langle \mathbf{m}\mathbf{m}^T \rangle \end{bmatrix} \begin{bmatrix} \mathbf{A}^T \\ -\mathbf{I} \end{bmatrix} \\ &= \mathbf{A}\mathbf{R_{dd}}\mathbf{A}^T - \mathbf{A}\mathbf{R_{md}^T} - \mathbf{R_{md}}\mathbf{A}^T + \mathbf{R_{mm}}. \end{aligned} \tag{B3}$$

Note that this formula for the covariance matrix of the discrepancy vector is valid for any matrix $\mathbf{A}$. Since the optimal matrix $\mathbf{A}$ of the stochastic inversion and time-dependent stochastic inversion is given by $\mathbf{A} = \mathbf{R_{md}}\mathbf{R_{dd}^{-1}}$, the $\mathbf{R}_{\epsilon\epsilon}$ matrix takes the form

$$\mathbf{R}_{\epsilon\epsilon} = \mathbf{R}_{\mathbf{mm}} - \mathbf{R}_{\mathbf{md}}\mathbf{R}_{\mathbf{dd}}^{-1}\mathbf{R}_{\mathbf{md}}^{T}. \quad \text{(B4)}$$

Note that the diagonal elements of the error covariance matrix $\mathbf{R}_{\epsilon\epsilon}$ represent the mean square errors of the estimation $\hat{\mathbf{m}}$.

Recently, development of a numerical calculation of the head-related transfer function (HRTF) has been conducted using a computer model of a human head and the boundary element method. The reciprocity theorem is incorporated into the computational process in order to shorten the computational time, which is otherwise very long. On the other hand, another fast HRTF calculation method for any source position, which is realized by calculating factors independent of the source position in advance, has been suggested by the authors. Using this algorithm, the HRTF for any source position can be obtained in a few seconds with a common PC. The resulting HRTFs are more precise and are calculated faster than those by using the reciprocity theorem. However, speeding the process up even further is required in order to respond to a head movement and rotation or to moving sources during binaural sound reproduction. In this paper, a faster calculation method by incorporating a time domain operation into the authors' previous algorithm is proposed. Additionally, the new formulation, which eliminates the extra computational time in the preprocess, is proposed. This method is shown to be faster than the previous ones, but there are some discrepancies at higher frequencies.

I. INTRODUCTION

In order to reproduce sound accurately for binaural detection, the head-related transfer function (HRTF) is necessary to synthesize sound signals at each ear. HRTF databases, which are usually measured in an anechoic chamber, are published[1,2] and are widely used. These HRTF databases, however, only provide HRTFs for measured source positions. Thus, much work has been done to interpolate the existing HRTFs[3] in order to generate HRTFs that are not available in the database. In addition, HRTF calculation has been studied using analyses treating the head as a sphere or spheroid.[4] Recently, a large-scale numerical simulation has been shown to be a practical means of simulating acoustical phenomena around the human head. Such research has used a computer model of a human head and the boundary element method (BEM). Katz measured the geometry of the human head by using a 3D laser scanner in order to analyze an accurate model of the head by the BEM.[5] Subsequently, he measured the acoustic impedances of human skin and hair[6] to incorporate these results into the HRTF simulation.[7] Kahana *et al.* developed a computer model of the KEMAR dummy head and calculated the HRTF based on this model.[8] Finally, by constructing a computer model of the head including ear canals and eardrums, Walsh *et al.* confirmed numerically that a sound pressure is accurately reproduced on an eardrum if the sound pressure is modeled correctly at the entrance to the ear canal.[9]

The main problem with BEM-based calculation of the HRTF is its computational cost, especially with respect to computational time. In this method, element length needs to be less than $\frac{1}{4}-\frac{1}{6}$ of the wavelength of the sound that is modeled. Therefore, an accurate head model with a very finely discretized boundary is required to obtain accurate results. It has been shown that calculated HRTFs agree well with measured HRTFs if the geometry of the head and external ears is accurately reproduced in a computer model and its boundary elements satisfy the condition mentioned above.[7,8,10] However, for high frequencies which are within the audible range of humans, very long computational time is required because of the large number of elements. A goal of the work described in this paper is to speed up BEM-based HRTF calculation and, consequently, to develop a useful tool for calculating the HRTF for any source position more quickly than conventional methods, while maintaining the accuracy of the calculation.

The performance and resources of computers are constantly improving. However, computing costs required for BEM-based HRTF calculation are still large. In the HRTF calculation, the number of sound sources is one and that of receivers is two, that is, each ear. However, a sound source configuration is infinitely variable whereas the two receiver positions are constant. In order to save computational time

[a)]Electronic mail: otani@ae-gatel.archi.kyoto-u.ac.jp

involved in repetitive calculation for many source configurations, two solutions have been proposed. The first is a frequently used method that defines multiple source positions before the calculation and obtains results for each source position simultaneously. This method is realized by applying the lower-upper (LU) decomposition to a coefficient matrix and by solving simultaneous equations sequentially with changing factors dependent on the source position, i.e., the right-hand side of the linear system. One disadvantage to this method is that the LU decomposed matrices must be preserved in order to restart the back substitution process for source configurations, which were not initially defined. In the second method, the reciprocity theorem is invoked, which interchanges source and receiver positions.[5,8,10] In this method, changing a source position can be interpreted as changing a receiver position. Therefore, results for multiple source configurations can be obtained simultaneously. In addition, by reusing surface pressures obtained in the process of calculation, it becomes possible to calculate results for any source position, even those that are not defined before the calculation. However, it is necessary to be careful about possible errors introduced by the reciprocity theorem. That is, applying the theorem to the BEM could give rise to different results from those obtained with the normal BEM. Kahana *et al.* defined the boundary elements of the external ears to be finer than other elements in order to improve the performance of the method using the reciprocity theorem.[8] This method is referred to as the "reciprocity-theorem method" in this paper.

As described above, previous solutions have had some disadvantages. Therefore, another solution has been suggested by the authors.[11] In order to calculate the HRTF quickly for any source position without the reciprocity theorem, it may be preferable to divide the computational processes of the BEM into two steps, one independent of source position and the other dependent upon it. In this paper, these parts are referred to as the "preprocess" and "postprocess," respectively. The preprocess is calculated as the inverse of the coefficient matrix, which is independent of source position. For the postprocess, the HRTF can be calculated very quickly between any source position and each ear by using the results of the preprocess with maintaining the accuracy of the calculation. Unless the boundary conditions of the head model change, the preprocess, which takes a much longer time to calculate than the postprocess, does not need to be performed again. The postprocess of the authors' previous method calculates the HRTF more quickly for any source position compared to the postprocess of the reciprocity-theorem method, which involves more computational processes. Additionally, although the reciprocity-theorem method and the conventional method are, in theory, identical, the reciprocity-theorem method has the possibility of numerical errors. However, the results of the authors' previous method and those of the conventional BEM are virtually identical both in theory and in numerical analysis.[11] This method is referred to as the "source-independent method" in this paper.

In previous work, as mentioned above, to execute all the processes independently of the source position in the preprocess enables rapid calculation of the HRTF for any source position in the postprocess. Although this method is faster than the reciprocity-theorem method, it does take more than a few seconds. Because this computational time turns out to be mainly due to the frequency-domain operation involved in the postprocess, the current paper describes an enhancement of postprocess speed by executing it in the time domain instead of the frequency domain. Additionally, an improved formulation, which reduces the preprocess computational time, is described. The main disadvantage of the source-independent method is that the preprocess requires a lot more time than the reciprocity-theorem method. However, this new formulation enables the preprocess to be executed as fast as the conventional BEM and the reciprocity-theorem method. In this paper, an algorithm, which implements these improvements, is proposed and its computational time and precision are examined.

II. A FAST HRTF CALCULATION BASED ON THE BEM

In this section, an outline of the source-independent method previously proposed by the authors[11] is described. The most time-consuming process in the BEM is the calculation of surface pressures by solving simultaneous equations written as

$$\left(\tfrac{1}{2}\mathbf{I}_M + \mathbf{G}_n + j\omega\rho\mathbf{G}\mathbf{Y}\right)\hat{\mathbf{P}} = g\mathbf{A}, \tag{1}$$

where

$$\mathbf{I}_M = \mathrm{diag}(1,1,1,\ldots,1) \in \mathbf{C}^{M\times M},$$

$$\mathbf{G} = \left[\int\int_{S_j} G(\mathbf{r}|\mathbf{r}_j)\,dS\right] \in \mathbf{C}^{M\times M},$$

$$\mathbf{G}_n = \left[\int\int_{S_j} \frac{\partial G(\mathbf{r}|\mathbf{r}_j)}{\partial n}\,dS\right] \in \mathbf{C}^{M\times M},$$

$$g = [G(\mathbf{r}'_k|\mathbf{r}_j)] \in \mathbf{C}^{M\times N},$$

$$\mathbf{A} = [q_1, q_2, q_3, \ldots, q_N]^T \in \mathbf{C}^N,$$

$$\mathbf{Y} = \mathrm{diag}(y_n(\mathbf{r}_1), y_n(\mathbf{r}_2), y_n(\mathbf{r}_3), \ldots, y_n(\mathbf{r}_M)) \in \mathbf{C}^{M\times M},$$

M is the number of boundary elements or nodes, N is the number of sources, S_j is the jth surface element ($j=1,\ldots,M$), $\mathbf{r}'_k$ is the kth source position ($k=1,\ldots,N$), $\mathbf{r}_j$ is the center of S_j, $G(\mathbf{s}|\mathbf{r})$ is the Green function between $\mathbf{s}$ and $\mathbf{r}$, q_k is the volume velocity of the kth source, ω is the angular frequency, ρ is the air density, n is the normal vector, y_n is the acoustic admittance in the normal direction, and all the boundary elements are given acoustic admittances $\mathbf{Y}$.

Furthermore, since $g\mathbf{A}$ depends on the source position, the back substitution process of Eq. (1) must be restarted whenever the source position changes. Thus, the total time necessary for calculation is very long. However, if the calculation is specialized to the HRTF, boundary conditions and receiver positions near entrances to the ear canals are constant, enabling an enhancement of calculation speed. In the

conventional BEM, the sound pressure at a point $\mathbf{s}$ can be calculated by solving the simultaneous equations as written in Eq. (1) and given as

$$P(\mathbf{s},\omega) = g_s(\omega) - (\mathbf{G}_{ns} + j\omega\rho\mathbf{G}_s\mathbf{Y})\hat{\mathbf{P}},$$

where

$$g_s = [G(\mathbf{r}'_k|\mathbf{s})] \in \mathbf{C}^N,$$

$$\mathbf{G}_s = \left[\int \int_{\mathbf{S}j} G(\mathbf{r}_j|\mathbf{s})\, ds \right] \in \mathbf{C}^M,$$

$$\mathbf{G}_{ns} = \left[\int \int_{\mathbf{S}_j} \frac{\partial G(\mathbf{r}_j|\mathbf{s})}{\partial n}\, ds \right] \in \mathbf{C}^M,$$

and, since the calculation is specialized to the HRTF, $\mathbf{A}=1$ because the sound source number is one and its strength is unity. On the other hand, in the source-independent method, $\mathbf{Q}$, which is derived from the inverse of the coefficient matrix and is independent of source position, can be obtained by

$$\mathbf{Q} = (\mathbf{G}_{ns} + j\omega\rho\mathbf{G}_s\mathbf{Y})\left(\tfrac{1}{2}\mathbf{I}_M + \mathbf{G}_n + j\omega\rho\mathbf{G}\mathbf{Y}\right)^{-1}. \quad (2)$$

Calculating $\mathbf{Q}$ by Eq. (2) requires more time than solving Eq. (1), since the computation of an inverse of the coefficient matrix includes M back substitution processes, which is an $O(M^2)$ process, whereas solving the simultaneous equations includes N back substitution processes. Note that $N=1$ when the calculation is specialized for the HRTF and that $N=2$ when the reciprocity theorem is applied.

By substituting $\mathbf{Q}, P(\mathbf{s},\omega)$ can be obtained by

$$P(\mathbf{s},\omega) = g_s(\omega) - \mathbf{Q}_g(\omega). \quad (3)$$

Here, $\mathbf{Q}(\in C^{1\times M})$ depends on a frequency. In Eq. (3), $g_s(\omega)$ represents a direct sound from the sound source and $\mathbf{Q}_g(\omega)$ describes indirect sounds from each element. Then, $\mathbf{Q}(\in C^{1\times M})$ can be interpreted as the coefficient of $g(\omega)$ that represents the transfer function between each element and the source position.

In the conventional BEM, changing the source configuration requires a recalculation of $\hat{\mathbf{P}}$ and a back substitution process in Eq. (1), which is an $O(M^2)$ process. However, once $\mathbf{Q}$ is calculated in this method, $\mathbf{Q}$ does not need to be recalculated, which allows the total time necessary for the HRTF calculation to be greatly reduced since assessing $P(\mathbf{s},\omega)$ in Eq. (3) is only an $O(M)$ process.

Here, the process in which $\mathbf{Q}$ is calculated for each frequency is termed the preprocess, whereas the process that computes $P(\mathbf{s},\omega)$ at any receiver position from $\mathbf{Q}$ using Eq. (3) is referred to as the postprocess. The postprocess includes the inverse Fourier transform of the frequency response at $\mathbf{s}$ in order to obtain an impulse response.

As for the method using the LU decomposition, sound pressures for multiple source configurations can be obtained easily by changing the right-hand side of Eq. (1), which includes factors dependent upon source position, and by calculating each of these equations sequentially. In this method, it is necessary to preserve the coefficient matrices in order to define a source position after the calculation and calculate a sound pressure for such source configuration. Such calculations require an excessively large amount of hard-drive space, however, making them impractical for actual use. For example, computation for 10 000 boundary elements with double-precision arithmetic would require about 1.6 GB of hard-drive storage space for each frequency calculated. If the HRTF is calculated up to 12 kHz at 43-Hz increments, total hard drive space wouid be approximately 450 GB.

If the reciprocity theorem is used and positions of the source and receiver position are swapped, the source position adjacent to the entrance to the ear canal remains constant and $\hat{\mathbf{P}}$ in Eq. (2) can be reused even if the receiver position changes. Therefore, the HRTF for any source position can be obtained after the calculation if the surface pressures $\hat{\mathbf{P}}$ are preserved. Unlike in the case of the LU decomposition, only the vector needs to be preserved. Thus, it is easy to calculate a sound pressure for a source position defined after the calculation, which is equivalent to calculating the sound pressure at the receiver position when the reciprocity theorem is invoked.

Compared to the computational time required for the reciprocity-theorem method, the preprocess in the source-independent method requires more time to execute since computing the inverse of the coefficient matrix requires more back substitution processes than solving the simultaneous equations in Eq. (1). However, the postprocess in the source-independent method is significantly faster than for the reciprocity-theorem method. This is because the postprocess of the reciprocity-theorem method uses integrals that are not included in the postprocess of the source-independent method.

III. SPEEDING UP THE PREPROCESS

As described in the preceding section, the main disadvantage of the source-independent method is the computational time required for the preprocess, since the inverse of the coefficient matrix in Eq. (2) takes much longer to compute. However, there is an alternative way to obtain $\mathbf{Q}$ as follows. Equation (2) can be transformed into

$$\mathbf{Q}^T = \left(\left(\tfrac{1}{2}\mathbf{I}_M + \mathbf{G}_n + j\omega\rho\mathbf{G}\mathbf{Y}\right)^{-1}\right)^T (\mathbf{G}_{ns} + j\omega\rho\mathbf{G}_s\mathbf{Y})^T,$$

where T denotes the transposition of a matrix, and, subsequently,

$$\mathbf{Q}^T = \left(\left(\tfrac{1}{2}\mathbf{I}_M + \mathbf{G}_n + j\omega\rho\mathbf{G}\mathbf{Y}\right)^T\right)^{-1} (\mathbf{G}_{ns} + j\omega\rho\mathbf{G}_s\mathbf{Y})^T.$$

Therefore, $\mathbf{Q}$ can also be obtained by solving simultaneous equations written as

$$\left(\tfrac{1}{2}\mathbf{I}_M + \mathbf{G}_n + j\omega\rho\mathbf{G}\mathbf{Y}\right)^T \mathbf{Q}^T = (\mathbf{G}_{ns} + j\omega\rho\mathbf{G}_s\mathbf{Y})^T. \quad (4)$$

$\mathbf{Q}$ can be computed as fast as assessing $\hat{\mathbf{P}}$ in Eq. (1) by using Eq. (4) instead of Eq. (2). Thus, it is possible to eliminate the main disadvantage of the source-independent method, that is, a long computational time in the preprocess.

IV. SPEEDING UP THE POSTPROCESS

As described in Sec. II, it is possible to obtain the HRTF quickly for an arbitrary source position based on the BEM.

However, the time required for calculation is still more than a few seconds. Therefore, the authors developed an improved method, which enables the enhancement of postprocessing speed. The first step is to compute the inverse Fourier transform of $\mathbf{Q}(\mathcal{F}(\mathbf{Q})^{-1})$ for each frequency prior to the postprocess, so that it can be executed in the time domain. The second step is to replace the convolution of $\mathcal{F}(\mathbf{Q})^{-1}$ and $\mathcal{F}(g)^{-1}$ with adjustments for the delay and amplitude.

A. Computation in the time domain

$\mathbf{Q}$ in terms of the angular frequency ω can be represented as

$$\mathbf{Q} = [Q_1(\omega)Q_2(\omega)\cdots Q_M(\omega)],$$

where $Q_j(\omega)(j=1,\ldots,M)$ are sound pressures at receiver positions attributed to the sound waves radiating from the jth boundary element. By computing the inverse Fourier transform of $Q_j(\omega)$, an impulse response can be written as

$$\mathbf{q}_j(t) = \mathcal{F}(Q_j(\omega))^{-1}, \tag{5}$$

where t denotes a continuous time.

By adding a new process, which computes and preserves the time domain signals $\mathbf{q}_j(t)$, to the preprocess, the impulse response $\mathbf{p}(t)$ at a receiver position $\mathbf{s}$ can be obtained by the postprocess as

$$\mathbf{p}(t) = \mathbf{g}_s(t) - \sum_{j=1}^{M} \mathbf{q}_j(t) * \mathbf{g}_j(t), \tag{6}$$

where * denotes convolution, and where $\mathbf{g}_s(t)$ and $\mathbf{g}_j(t)$ are time-domain signals obtained by computing the inverse Fourier transform of transfer functions for direct sounds from a sound source to a receiver position, and indirect sounds from a sound source to the jth boundary element, respectively. If $\mathbf{r}'$ is defined as a source position and $\mathbf{r}_j$ as a center of jth boundary element, $\mathbf{g}_s(t)$ and $\mathbf{g}_j(t)$ can be derived from the Green function as

$$g_s(\omega) = \frac{e^{-jk|\mathbf{r}'-\mathbf{s}|}}{4\pi|\mathbf{r}'-\mathbf{s}|}$$

and

$$g_j(\omega) = \frac{e^{-jk|\mathbf{r}'-\mathbf{r}_j|}}{4\pi|\mathbf{r}'-\mathbf{r}_j|},$$

where k is the wave number.

B. High-speed operation

As described in Sec. IV A, the postprocess can be computed in the time domain. However, the calculation of Eq. (6) includes a convolution in the time domain and, therefore, takes longer than the source-independent method. However, $\mathbf{g}_j(t)$ in Eq. (6) corresponds to a delta function with a delay and a decay and can be given as

$$\mathbf{g}_j(t) = \frac{1}{4\pi|\mathbf{r}'-\mathbf{r}_j|}\delta\left(t - \frac{|\mathbf{r}'-\mathbf{r}_j|}{c}\right), \tag{7}$$

where c is the sound velocity and $\delta(t)$ is a delta function. Therefore, the convolution appearing on the right-hand side of Eq. (6) can be replaced with an operation that multiplies the amplitude of $\mathbf{q}_j(t)$ by $1/(4\pi|\mathbf{r}'-\mathbf{r}_j|)$ and gives $|\mathbf{r}'-\mathbf{r}_j|/c$ seconds delay to $\mathbf{q}_j(t)$, expressed as

$$\mathbf{p}(t) = \mathbf{g}_s(t) - \sum_{j=1}^{M} \frac{1}{4\pi|\mathbf{r}'-\mathbf{r}_j|}\mathbf{q}_j\left(t - \frac{|\mathbf{r}'-\mathbf{r}_j|}{c}\right). \tag{8}$$

As a result, the postprocessing speed is increased. Figure 1 shows a flowchart comparing the source-independent method and the proposed method.

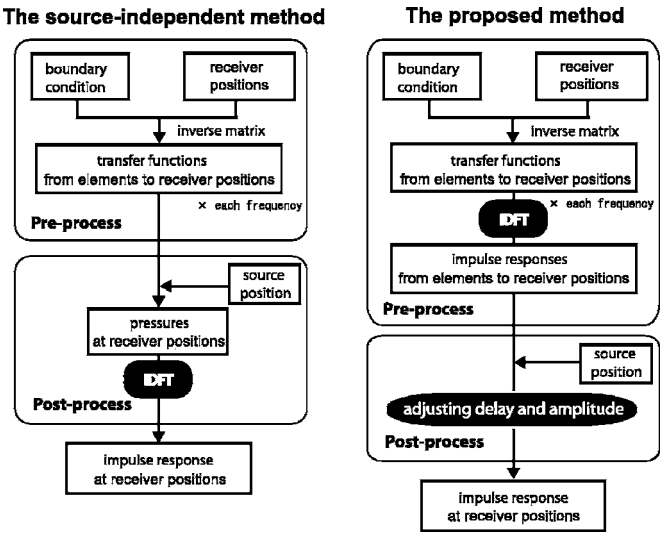

FIG. 1. Flow chart comparing the source-independent method and the newly proposed method. An inverse Fourier transformation is included in the preprocess of the proposed method.

When Eq. (8) is applied to a discrete time system in a practical calculation, Eq. (8) is replaced with the following equation:

$$\mathbf{p}[n] = \mathbf{g}_s[n] - \sum_{j=1}^{M} \frac{1}{4\pi|\mathbf{r}-\mathbf{r}_j|}\mathbf{q}_j\left[n - \mathrm{round}\left(\frac{|\mathbf{r}-\mathbf{r}_j|}{c}S\right)\right], \tag{9}$$

where $S(=\Delta f L)$ is the sampling frequency (Δf is a frequency interval, L is the length of $\mathbf{p}[n]$) and round (x) denotes an integer near x. Thus, the $O(L^2)$ process required by the convolution is reduced to an $O(L)$ process.

The $|\mathbf{r}'-\mathbf{r}_j|/c$ seconds delay in Eq. (8) is approximated by the delay of round $(|\mathbf{r}'-\mathbf{r}_j|S/c)$ samples in Eq. (9). Therefore, using Eq. (9) introduces computational errors not elicited with the source-independent method, because delay can only be expressed as an integral multiple of one sample ($1/S$ seconds). To reduce these computational errors, an oversampling is applied to $\mathbf{q}_j[n]$ in the preprocess. If sampling frequency becomes T times larger, it is possible to represent a delay as integral multiples of $1/(TS)$ seconds, thus limiting the potential computational errors.

V. COMPUTER MODEL

In this section, a procedure for developing a computer model of a dummy head is described. First, the geometry of the head and torso simulator B&K4128C was measured at about 500 000 points using a 3D laser scanner (Cyberware

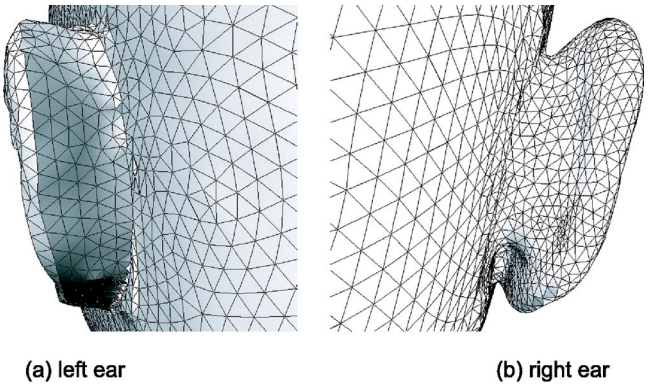

FIG. 2. (a) Backside of the left external ear scanned by a laser scanner. The area behind the ear is filled. (b) Backside of the right external ear scanned by a micro-CT scanner. Compared with the left ear scanned by a laser scanner, the right ear is modeled more precisely than the left ear.

3030RGB/I). Then, the data relating to the head were extracted and triangular elements were generated from these data. Surfaces that were blocked by others, such as the backside of the external ear, could not be measured by the laser scanner. Such surfaces were thus modeled using data obtained with a micro-CT (computerized tomography) scanner. The right ear of the model head obtained by the laser scanner was replaced by the one measured using the micro-CT scanner, but the left ear was not, permitting comparison between the two different ear models. Figures 2(a) and 2(b) show the left and right ears, respectively. Whereas no information is available about the backside of the left ear, which is simply filled in continuously, the right ear is modeled more accurately due to the incorporation of the micro-CT data.

The resulting computer model has too many surface elements to be applied to the BEM computation. Therefore, the model's surface is remeshed by a 3D mesh generator[12] in order to construct a tractable model for the BEM. Figure 3 shows the head model of B&K 4128C, including 28 000 triangular elements and 14 000 nodes. The maximum element

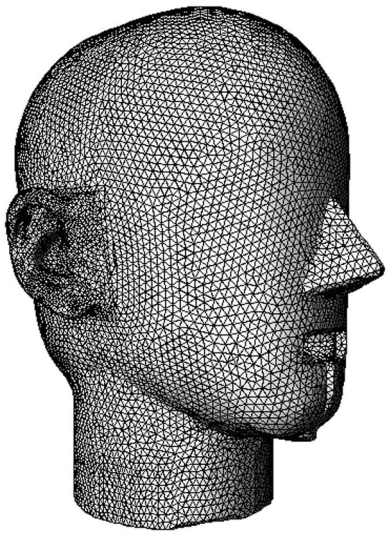

FIG. 3. Computer model of a head of B&K 4128C. This model consists of 28 000 elements and 14 000 nodes, and a maximum boundary-element length of 5.64 mm, corresponding to a frequency limitation of 10 kHz for six elements per wavelength and 15 kHz for four elements.

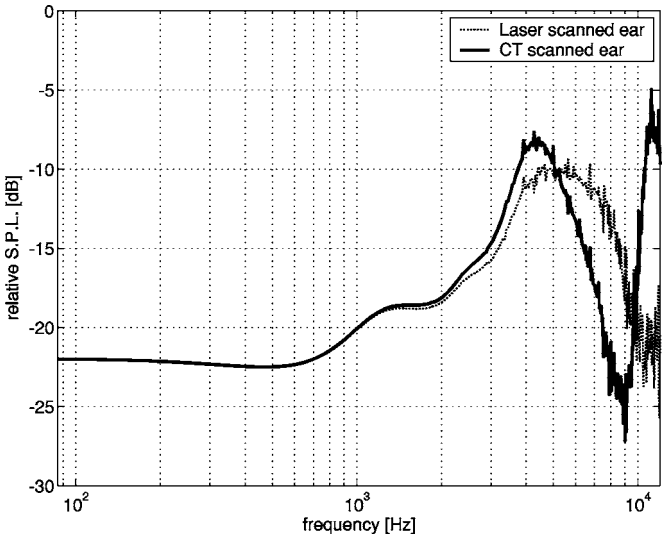

FIG. 4. Comparison between micro-CT scanned ear model and laser scanned ear model. A sound source is located 1 m in front of the head.

length is 5.64 mm. Allowing five elements per wavelength, this model is valid up to 12 000 Hz. In this model, the ear canals are blocked at their entrances. Thus, the receiver points are located near the blocked entrances, not on the eardrums. Hammershøi *et al.* showed, and Walsh *et al.* confirmed numerically, that HRTFs even at blocked ear canals contain complete spatial information.[9,13]

The HRTFs demonstrated in this paper are those calculated at the right ear, which was scanned by a micro-CT scanner. HRTFs calculated with the same micro-CT scanned ear model agree well with actual measurements below 10 kHz.[10] When comparing the HRTFs obtained for the right (micro-CT scanned) and the left (laser scanned) ear in response to a point source in front of the head, it was found that the results are consistent below 4 kHz. However, significant discrepancies are observed at higher frequencies as shown in Fig. 4, especially at frequencies where the notches appear. The first notch appears at 9 kHz for the right ear, but the first notch appears above 10 kHz for the left ear. The location of this dip provides important spectral cues for localizing a sound source on a median plane.[14] Thus, the HRTFs calculated at the left ear, i.e., a laser-scanned ear, may not provide precise spectral cues, especially for localizing sound sources on a median plane. These discrepancies are caused by inaccurate modeling of the left ear using a laser scanner. These results indicate that accurate modeling of the ear is crucial for the HRTF calculation.

VI. CALCULATION TIME AND ACCURACY

Table I shows the calculation time required using the conventional BEM, the reciprocity-theorem method, the source-independent method, and the currently proposed method with no oversampling and twofold, fourfold, eightfold, and 16-fold oversampling. The frequency range of calculation is 43–12 015 Hz at intervals of 43 Hz. All boundary elements were assumed to be rigid. Sampling frequency was 44.1 kHz and the length of $\mathbf{p}[n]$ and $\mathbf{q}_j[n]$ were both 1024. An Itanium2 1-GHz machine was used for the preprocess

TABLE I. Calculation time, required for the HRTF calculation for single receiver position and single source position using the conventional BEM, the reciprocity-theorem method, the source-independent method, and the proposed method with and without oversampling. Except for the conventional BEM, the computational processes are divided into the preprocess and postprocess.

	Preprocess (h)	Postprocess/source position (s)
Conventional BEM	420	—
Reciprocity-theorem method	420	239.94
Source-independent method	814	4.44
Proposed method without oversampling	420	0.08
Proposed method with "×2" oversampling	420	0.13
Proposed method with "×4" oversampling	420	0.20
Proposed method with "×8" oversampling	420	0.36
Proposed method with "×16" oversampling	420	0.61

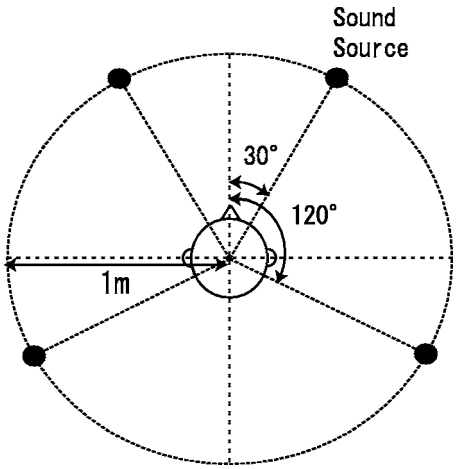

FIG. 5. The HRTF at the right ear is calculated. A sound source is located at 1-m distance from the midpoint of both ears with 30, 120, 240, and 330 deg azimuth.

and a Xeon 2.8-GHz machine was used for the postprocess. All computations were executed in double-precision arithmetic. The conventional BEM takes about 420 h to calculate the HRTF for a single source position. Applying the LU decomposition to the coefficient matrix allows the surface pressures of previously defined source configurations to be simultaneously solved. However, the LU decomposed matrices must be preserved when the source configurations are not previously defined, which requires an enormous amount of hard drive storage, making them impractical for actual use, as described in Sec. II. Katz, Kahana *et al.*, and Kakuhari *et al.* incorporated the reciprocity theorem into the BEM.[5,8,10] A calculation for multiple source configurations is thus converted into one for multiple receiver positions by replacing a receiver position with a source position. As a result, the surface pressures remain constant even when a source position changes. In addition, if surface pressures are preserved, it is possible to calculate quickly the HRTFs for any source position as the source-independent method does. Using the reciprocity-theorem method, the calculation required about 420 h for the preprocess and 239.94 s for the postprocess. On the other hand, using the source-independent method the postprocess took 4.44 s, but the preprocess took 814 h, which is significantly longer than the time required for either the conventional BEM or the reciprocity-theorem method. As stated in Sec. II, the difference in computational time required by the postprocess between these methods arises mainly from the use of integrals of the Green function and its normal derivative, which are included in the postprocess of the reciprocity-theorem method. Finally, the preprocess of the proposed method requires 420 h due to an improved formulation, which is stated in Sec. III, and the postprocess of proposed method requires 0.08 s without oversampling, 0.36 s with eightfold oversampling, and 0.61 s with 16-fold oversampling.

Next, the accuracy of the proposed method was assessed. The results of the source-independent method, which are identical to those of the conventional BEM,[11] are the benchmark for assessing the accuracy of the currently proposed method. The HRTF at the right ear, which was modeled using data from a micro-CT scanner, of the head with 28 000 triangular elements from 43 to 12 015 Hz in 43-Hz intervals was used. A sound source was located 1 m away from the midpoint of both ears at 30, 120, 240, and 330 deg azimuth. Figure 5 demonstrates the locations of sound sources and a head. Figures 6(a)–6(d) show the frequency responses obtained using the source-independent method and the newly proposed method for 30-, 120-, 240-, and 330-deg-azimuth sounds, respectively. At higher frequencies, there are numerous discrepancies between the two methods. The frequency responses obtained using the proposed method include many steep peaks and dips that appear locally and, consequently, the spectral slopes, the major peaks, and notches are incorrectly reproduced. There are fewer steep peaks and dips at frequencies below 4 kHz, but the curves of the proposed method deviate from those of the source-independent method. Thus, the proposed method without oversampling does not provide correct HRTFs.

Figures 7(a)–7(d) show the corresponding results obtained with an eightfold oversampling. Note that the ranges of the vertical axes in Fig. 7 are smaller than those in Fig. 6. Although the steep peaks and dips at higher frequencies cause many discrepancies in the results obtained by the proposed method with eightfold oversampling, there are fewer peaks and dips and their respective heights and depths are much smaller at lower frequencies. Deviations from the curves by the source-independent method at lower frequencies, as demonstrated in Fig. 6, cannot be seen in these figures. Hence, the results are better with respect to the non-oversampled method. Figures 8(a)–8(d) show the corresponding results with 16-fold oversampling, which compared to eightfold oversampling suppresses the discrepancies at higher frequencies. Thus, it is concluded that the proposed method provides more accurate results.

The root mean square (rms) errors of the newly proposed method were also calculated in the frequency and time domains and compared with the results to those from the source-independent method. The rms errors in both domains are expressed as

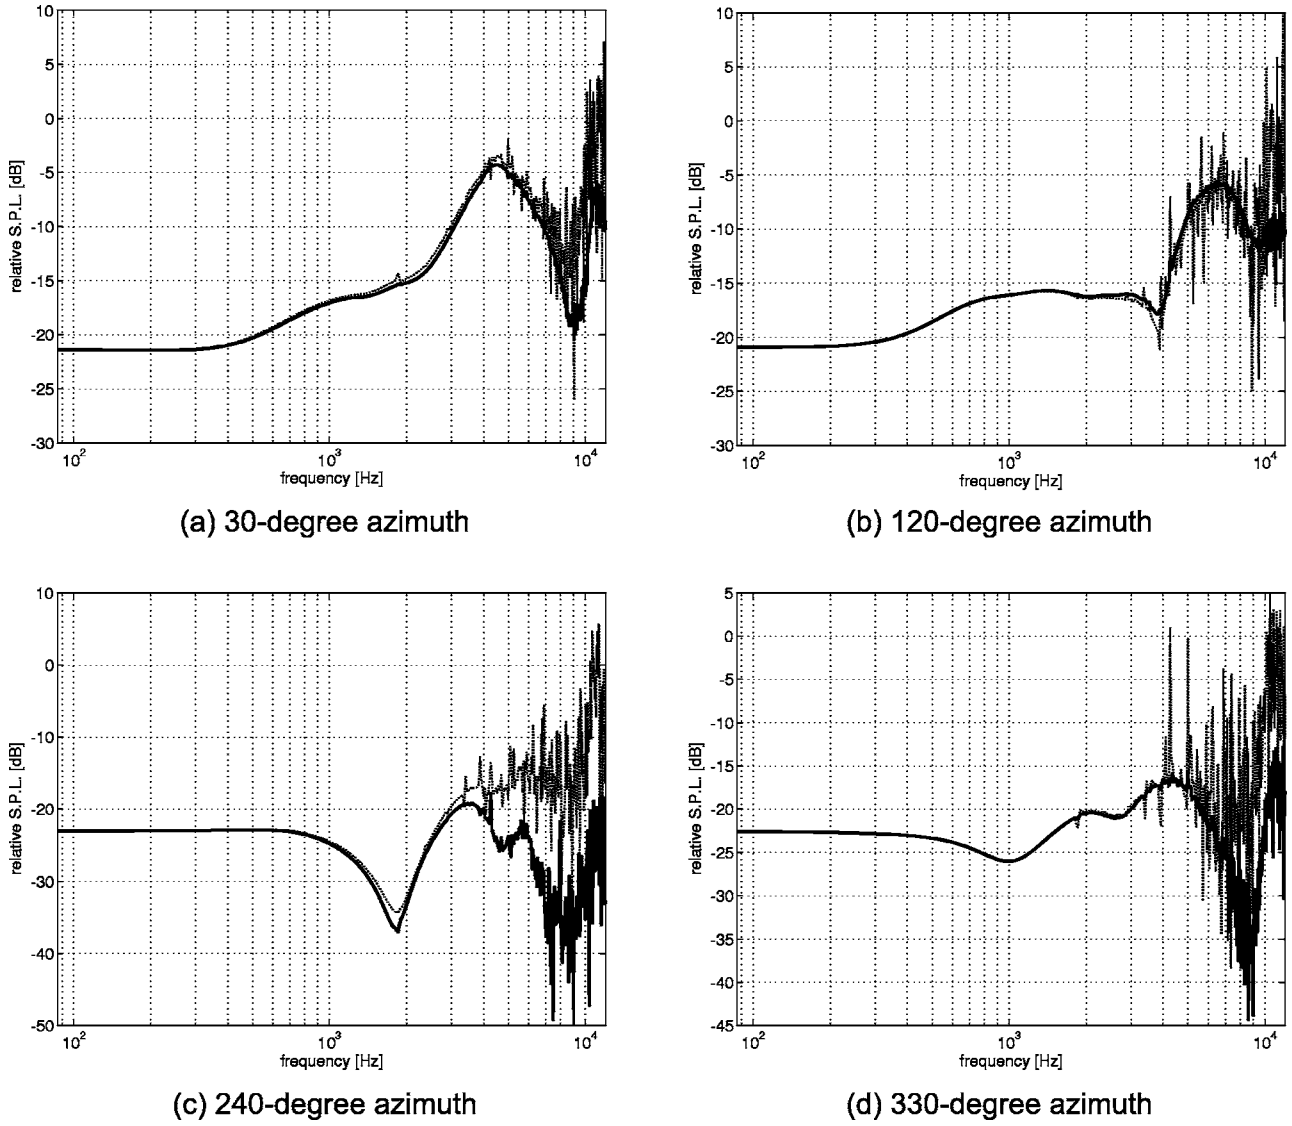

FIG. 6. Comparison in the frequency domain between the source-independent method and the newly proposed method without oversampling at (a) 30 deg azimuth, (b) 120 deg azimuth, (c) 240 deg azimuth, and (d) 330 deg azimuth. The solid line and the dotted line show the results obtained by the source-independent method and the newly proposed method, respectively.

$$\mathrm{rms}_{\mathrm{freq}} = \sqrt{\frac{1}{K}\sum_{h=1}^{K} (|P(\mathbf{s},\omega_h)| - |\hat{P}(\mathbf{s},\omega_h)|)^2}$$

and

$$\mathrm{rms}_{\mathrm{time}} = \sqrt{\frac{1}{L}\sum_{n=1}^{L} (\mathbf{p}[n] - \hat{\mathbf{p}}[n])^2},$$

respectively, where K is the number of frequencies calculated in the postprocess. $\omega_h(=\Delta f \times 2\pi h)$ is the angular frequency. $P(\mathbf{s},\omega_h)$ and $\hat{P}(\mathbf{s},\omega_h)$ are the frequency responses obtained using the source-independent method and the method proposed in this paper, respectively. $\mathbf{p}[n]$ and $\hat{\mathbf{p}}[n]$ are impulse responses obtained by these two methods. Figures 9(a) and 9(b) show the rms errors in the frequency and time domains, respectively, "×1," "×2," "×4," "×8," and "×16" in the figure denote the fold of oversampling. "×1" indicates that oversampling is not applied. As shown in Figs. 9(a) and 9(b), the value of rms error becomes smaller in each source direction for both domains with the more degrees of oversampling. Therefore, it is concluded that the accuracy of the proposed method increases with more degrees of oversampling. The rms error values are nearly the same for the four source positions, especially with eight and 16-fold oversampling, indicating that the total absolute error does not significantly vary with a source position. However, as seen in Figs. 7 and 8, the results at the 240- and 330-deg azimuths differ more from the source-independentmethod than those at other source positions. Since the source is located at the opposite side of the listening ear, the overall power of the HRTF is smaller at the 240 and 330-deg azimuths than at the 30- and 120-deg azimuths. Therefore, the relative errors are larger at the 240- and 330-deg azimuths than at other source positions.

As shown in Figs. 6–8, some of the steep peaks and dips obtained by the proposed method appear at frequencies that also have steep peaks and dips in the source-independent

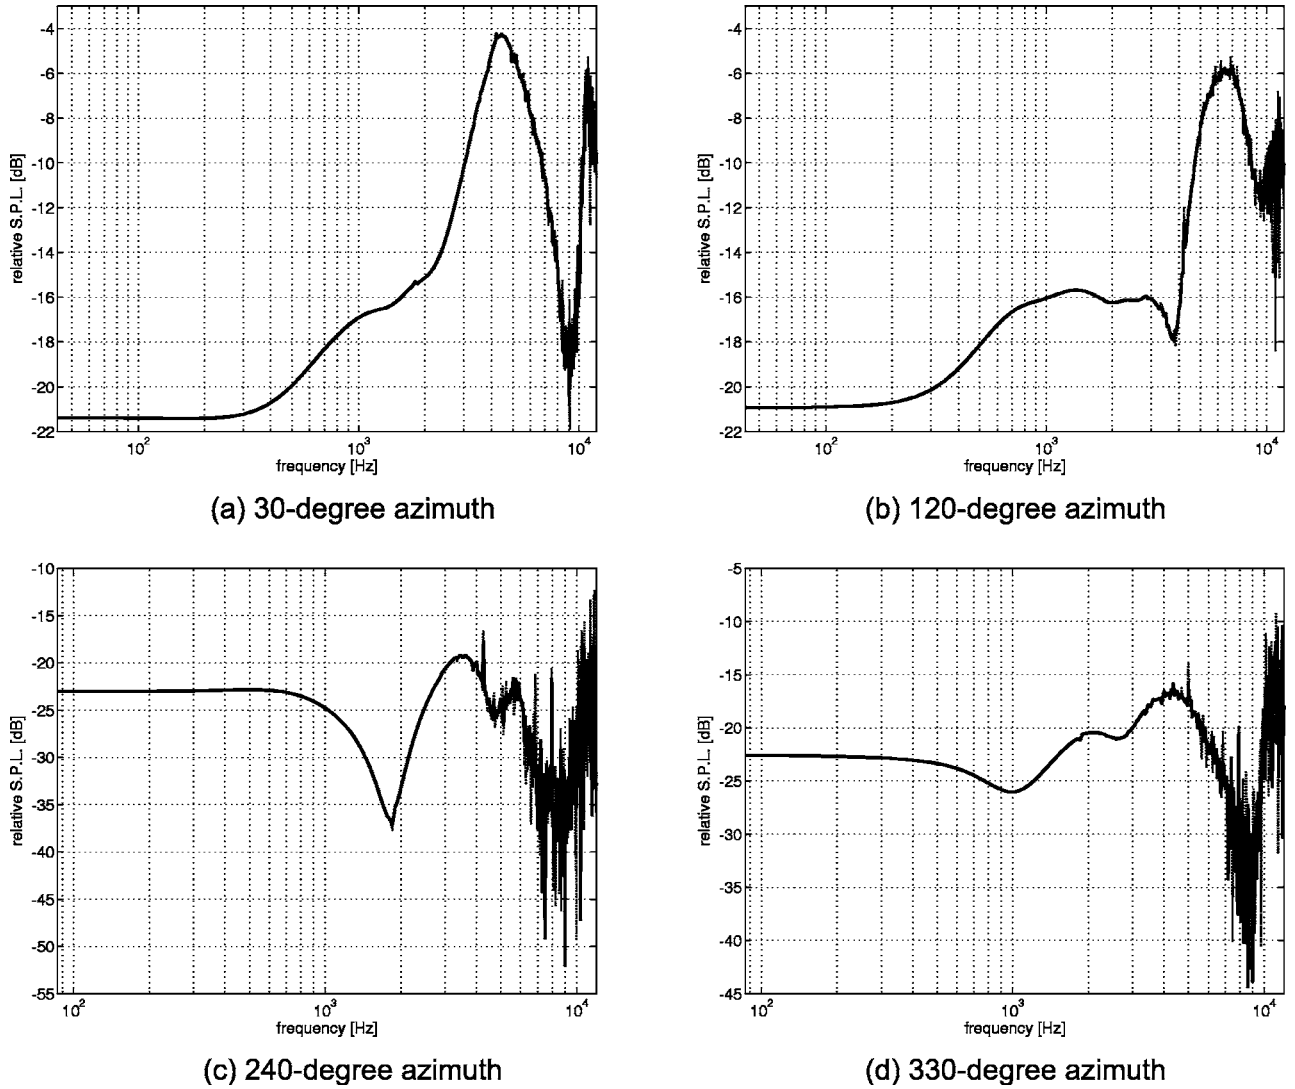

FIG. 7. Comparison in the frequency domain between the source-independent method and the newly proposed method with eightfold oversampling at (a) 30 deg azimuth, (b) 120 deg azimuth, (c) 240 deg azimuth, and (d) 330 deg azimuth. The solid line and the dotted line show the results obtained by the source-independent method and the newly proposed method with eightfold oversampling, respectively.

method. The approximations used in the proposed method may amplify these peaks and dips. As the azimuth increases, the results obtained using the source-independent method include more peaks and dips at higher frequencies. Consequently, increasing the azimuth in the proposed method increases the number of unwanted steep peaks and dips, i.e., the differences from the source-independent method increases.

As stated above, the main features of a frequency response of the HRTF such as spectral slopes, major peaks, and notches, which may be crucial for localizing sound sources,[14] are reproduced below 12 kHz by the proposed method with eightfold oversampling, which enables faster calculations than using the source-independent method. Furthermore, 16-fold oversampling enables the proposed method to give more accurate results with fewer peaks and dips at higher frequencies. However, if more accuracy of the overall source direction and/or higher frequencies are needed, then a higher degree of oversampling should be applied, which will increase the computational time of the proposed method.

VII. CONCLUSION

This paper provides two improvements upon the source-independent method previously proposed by the authors,[11] which is used to calculate the HRTF based on the BEM. A new formulation makes the preprocess faster, which may eliminate the main disadvantage of the source-independent method. Subsequently, the speed of the postprocess has been enhanced by performing a major operation in the time domain rather than in the frequency domain. The HRTFs are calculated based on a computer model of the head with 28 000 elements generated by a 3D laser scanner and a micro-CT scanner. Comparing the calculated HRTFs based on a micro-CT scanned ear and laser-scanned ear, which has an inaccurate shape, reveals the differences in the locations of peaks and notches and shows that accurate modeling of the external ears is significant for numerical simulation of the HRTFs.

Compared to previous methods, the postprocess of the proposed method with 16-fold oversampling is faster than

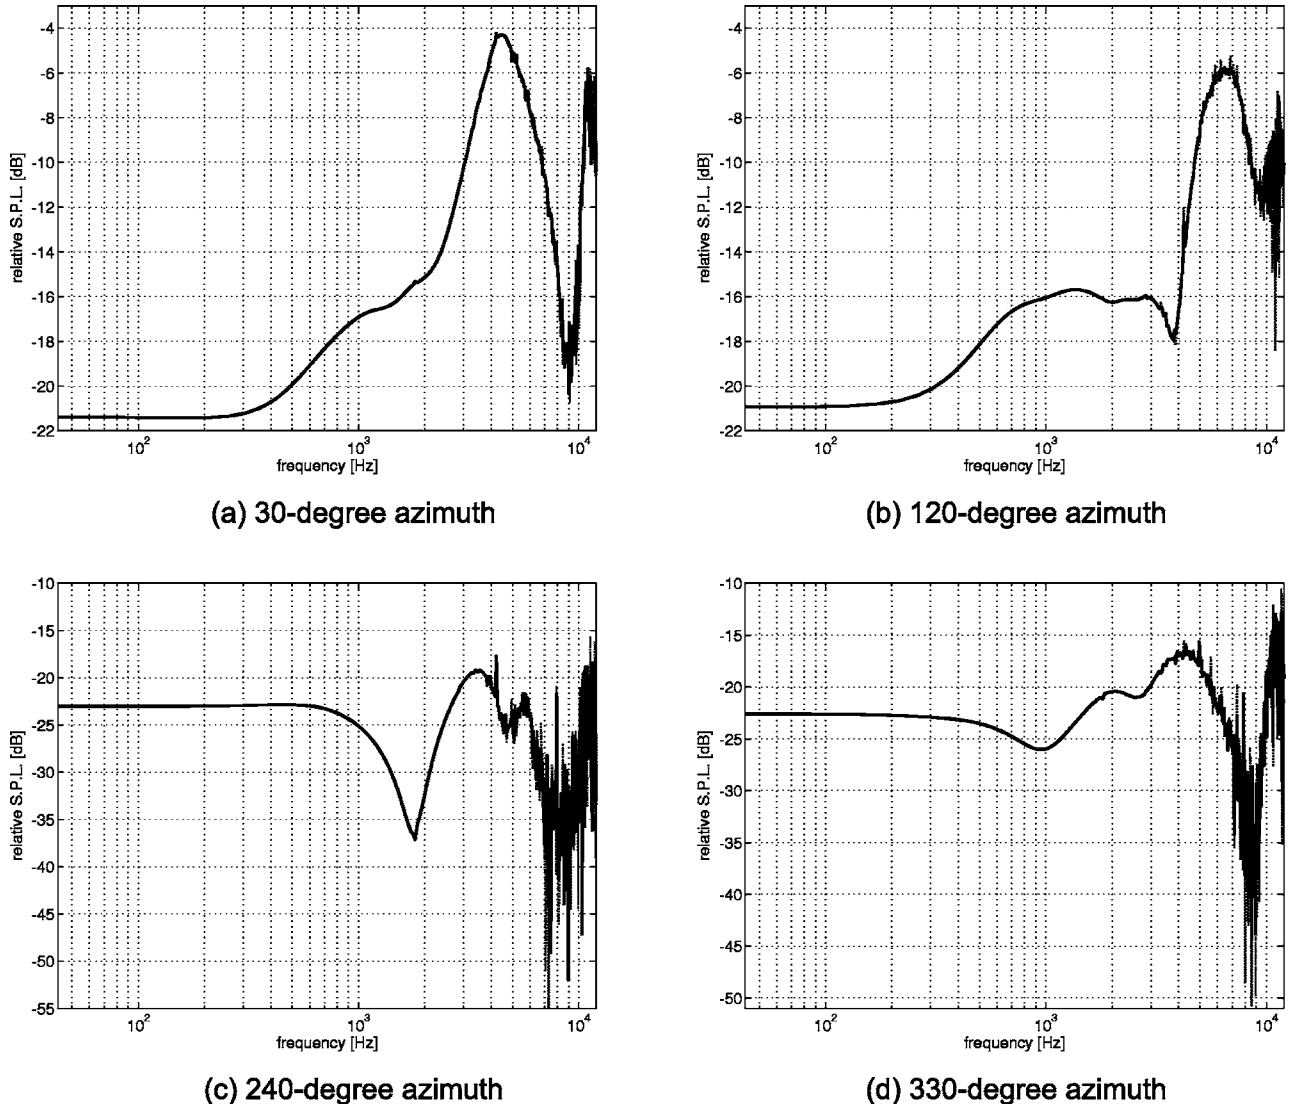

FIG. 8. Comparison in the frequency domain between the source-independent method and the newly proposed method with 16-fold oversampling at (a) 30 deg azimuth, (b) 120 deg azimuth, (c) 240 deg azimuth, and (d) 330 deg azimuth. The solid line and the dotted line show the results obtained by the source-independent method and the newly proposed method with 16-fold oversampling, respectively.

that of the source-independent method. The proposed method, which was compared to the source-independent method since the source-independent method is identical to the conventional BEM method, is faster and has improved accuracy when the preprocess is oversampled and can reproduce the main features of the HRTFs, such as spectral slopes, major peaks, and notches, with eightfold oversampling. Furthermore, the proposed method with 16-fold oversampling suppresses more discrepancies at higher frequencies and gives more accurate results. However, there are still steep peaks and dips at higher frequencies. Thus, if a higher precision is required, then a higher degree of oversampling should be applied.

The calculation method described in this paper is a simple but effective way to speed up boundary-element simulation of the HRTFs. In addition to an improved preprocess in speed, the postprocess is optimized to calculate the HRTF for source configurations defined *a posteriori*. The HRTFs generated using this algorithm can thus be applied to various virtual auditory displays, in order to present accu-

rately localized stimuli directly to a listener's ears. At present, the calculation time may still be too long to allow its use in systems that require HRTFs for many source positions to be calculated in real time. However, compared to the traditional BEM, the proposed method can reduce the overall computational time necessary to generate a HRTF database based on a BEM simulation. Additionally, the major limitation of the current HRTF databases is the limited number of HRTFs for predetermined source configurations. Therefore, when the HRTFs for source configurations not included in the database are needed, the HRTFs for these source configurations must be interpolated. Since the proposed method is faster, it can be used to generate the HRTF quickly for required source configuration without interpolation using HRTFs from the database.

ACKNOWLEDGMENTS

Iterative simulation of elastic wave scattering in arbitrary dispersions of spherical particles[a)]

Timothy E. Doyle
Department of Physics, Utah State University, Logan, Utah 84322-4415

(Received 15 September 2005; revised 6 February 2006; accepted 15 February 2006)

A numerical modeling approach was developed to simulate the propagation of shear and longitudinal waves in arbitrary, dense dispersions of spherical particles. The scattering interactions were modeled with vector multipole functions and boundary condition solutions for each particle. Multiple scattering was simulated by translating the scattered wave fields from one particle to another with the use of translational addition theorems, summing the multiple-scattering contributions, and recalculating the scattering using an iterative method. The approach can simulate 3D dispersions with a variety of particle sizes, compositions, and volume fractions. To test the model, spectra and wave field images were generated from ordered and disordered microstructures containing up to several thousand particles. The model predicted wave propagation phenomena such as refractive focusing and mode conversion. The iterations converged for many particle configurations, but did not converge or only partially converged for certain conditions, specifically large particle dispersions (>100 particles) at short wavelengths ($\lambda \sim$ particle diameter). Incorporating viscoelastic damping into the matrix properties reduced these numerical instabilities. The model is currently constrained by these convergence limitations and by the computation of sufficiently high multipole order for large numbers of particles. The theory and initial results for the model are presented. [DOI: 10.1121/1.2184989]

I. INTRODUCTION

The propagation of elastic waves through particles dispersed in an elastic or viscoelastic solid is relevant to many applications, including the nondestructive evaluation of particulate composites, the design of advanced acoustic materials, the ultrasonic characterization of biological tissues, and the remote sensing of geologic media. Predicting elastic wave behavior in such systems with statistical approaches is difficult, however, due to multiple scattering between particles, mode conversion at particle surfaces, lack of periodicity in the dispersion, and heterogeneity of particle sizes and compositions.[1–3] Nonempirical, physics-based models are therefore desired to simulate elastic wave propagation in dense, random dispersions of particles and predict the resultant macroscopic wave propagation properties.

This paper presents the theory and results of a numerical model developed to address these goals. The model uses vector multipole functions, boundary condition solutions, translational addition theorems, and direct iteration to solve the multiple-scattering problem for an arbitrary 3D distribution of spheres in an elastic or viscoelastic matrix. The model computes the spatial distributions and frequency spectra of elastic wave fields for a simulated particle configuration. From these results macroscopic properties such as attenuation and velocity can be predicted for a wide variety of particulate systems.

Elastic wave propagation in heterogeneous materials, particularly those with polycrystalline structures, has been theoretically addressed by perturbation methods,[4–8] radiative transfer theory,[9,10] and the Dyson equation.[11–14] For dispersions with spherical, spheroidal, or cylindrical particles, however, multipole expansions provide a means for directly simulating elastic wave scattering and computing macroscopic properties. Several multipole techniques have been developed for acoustic scattering in particulate systems, notably by Peterson and Ström,[15] Koc and Chew,[16] and most recently Gumerov and Duraiswami.[17,18] These models have focused on the transfer matrix (T-matrix) and fast multipole methods, but have been limited to longitudinal wave propagation and have not addressed the more complex problem of shear wave propagation and mode conversion. Elastic wave propagation in particulate systems has been addressed with multipole methods by Liu *et al.*,[19] however, who modeled elastic wave scattering in ordered lattices of particles by using a formulism based on periodic scatterers in a planar layer.

The T-matrix method has been favored for scattering models since it imposes an algebraic structure on the multiple scattering interactions that is accessible to many numeric methods.[15] Both fast multipole and periodic lattice models generally incorporate the T-matrix approach to solve the multiple-scattering problem.[16,18–20] Although T-matrix approaches have been formulated for elastic wave scattering,[21–24] very little work has been reported on simulating full elastic wave propagation in random particulate systems (i.e., with longitudinal and shear waves in both particles

[a)]Portions of this work were presented in "Iterative Simulation of Elastic Wave Scattering in Particle-Filled Materials," in *Review of Progress in Quantitative Nondestructive Evaluation*, Vol. 24, edited by D. O. Thompson and D. E. Chimenti (American Institute of Physics, Melville, New York, 2005), pp. 1121–1128.

and matrix). This is in contrast to electromagnetic scattering, where random particulate media have been extensively modeled with use of the T-matrix method.[20]

The direct iterative method is an alternative to the T-matrix method and simulates wave scattering in particle systems by iteratively recomputing the multiple-scattering contributions at each particle until convergence of the wave fields. It has been applied to electromagnetic scattering in small collections of spherical particles, where it is also known as the order-of-scattering method.[25–30] The direct iterative method has remained relatively unexplored for simulating elastic wave propagation, however, or for modeling fully random 3-D particle systems with large numbers of particles (>100 particles), high particle concentrations (>20%), and mixed particle sizes and properties.

The direct iterative method may offer advantages over a T-matrix formulism for modeling elastic waves in particulate systems. Specifically, the direct iterative method is computationally simpler than the T-matrix approach and avoids the problems of numerically solving large systems of linear equations for large numbers of particles. Although these linear systems are themselves often solved using iterative methods, the direct iterative approach circumvents the need to explicitly formulate and solve the multiple scattering in a matrix formulism. Scattering interactions that include shear waves and mode conversion can therefore be more readily modeled since they do not have to be incorporated into a T matrix.

An additional feature of the direct iterative method stems from the step-by-step computation of each successive scattering order (for example, zeroth order single scattering from the pre-iteration computations, first-order multiple scattering from the first iteration, and so forth). This ability provides greater access in the model to different levels of the scattering process, and allows the effects of multiple scattering to be quantified with respect to single scattering. It also provides a useful diagnostic of the model's performance and accuracy and allows certain interactions to be individually monitored and manipulated for computational efficiency (e.g., different convergence rates for different wave modes). Such access is difficult in the T-matrix approach, where all orders of multiple scattering are solved simultaneously with solution of the linear system.

The present research extends the work of Gumerov and Duraiswami,[17,18] Liu *et al.*,[19] and other investigators by modeling full elastic waves in arbitrary dispersions of spherical particles. The objectives were to develop the theory, demonstrate the feasibility, and explore the potential of a direct iterative approach for elastic wave propagation in particulate systems. An iterative multipole model was developed that computes the propagation of waves by using single-particle scattering solutions, addition theorems to translate the scattered fields from one particle to another, and iteration to arrive at a convergent solution for the multiply scattered fields. Simulations were performed on a personal computer for particulate systems of up to several thousand particles and particle volume fractions up to 50%. Initial results are presented for example simulations, and the capabilities and deficiencies of the current model are summarized.

II. THEORY

A. Vector multipole functions

Elastic waves in solids derive from the Navier equation for linear, homogeneous materials:

$$\rho \frac{\partial^2 \mathbf{u}}{\partial t^2} = (\lambda + 2\mu)\,\nabla\,(\nabla \cdot \mathbf{u}) - \mu\,\nabla \times (\nabla \times \mathbf{u}), \tag{1}$$

where λ and μ are Lamé's constants, ρ is the density, and $\mathbf{u}$ is the displacement vector. Equation (1) can be recast as two separate vector Helmholtz equations by splitting $\mathbf{u}$ into longitudinal ($\mathbf{u}_L$) and transverse ($\mathbf{u}_S$) parts and imposing a harmonic time dependency of the form $e^{-i\omega t}$:

$$(\nabla^2 + k_L^2)\mathbf{u}_L = 0, \tag{2}$$

$$(\nabla^2 + k_S^2)\mathbf{u}_S = 0, \tag{3}$$

where k_L and k_S denote the longitudinal and shear wave vectors, respectively.

Solutions to Eqs. (2) and (3) in spherical coordinates are the vector multipole functions, also referred to as vector spherical wave functions. Since they are solutions to the Helmholtz equation, the vector multipole functions can be generated from a scalar potential Φ and vector potential $\boldsymbol{\Psi}$ defined as

$$\Phi = \sum_{n=0}^{\infty} \sum_{m=-n}^{+n} z_n(kr) Y_{nm}(\theta, \varphi), \tag{4}$$

$$\boldsymbol{\Psi} = \sum_{n=0}^{\infty} \sum_{m=-n}^{+n} z_n(kr) \mathbf{Y}_{nm}^{n}(\theta, \varphi). \tag{5}$$

The radial function $z_n(kr)$ represents either a spherical Bessel function $[j_n(kr)]$ or a spherical Hankel function of the first or second kind $[h_n^{(1)}(kr)$ or $h_n^{(2)}(kr)]$. The vector spherical harmonic $\mathbf{Y}_{nm}^{l}(\theta, \varphi)$ is a pure-orbital vector spherical harmonic and is defined with Clebsch-Gordan coefficients, scalar spherical harmonics, and helicity basis vectors as follows:[31–33]

$$\mathbf{Y}_{nm}^{l}(\theta, \varphi) = C_{l,m+1,1,-1}^{n,m} Y_{l,m+1} \mathbf{e}_{-1} + C_{l,m,1,0}^{n,m} Y_{l,m} \mathbf{e}_0 + C_{l,m-1,1,1}^{n,m} Y_{l,m-1} \mathbf{e}_{+1}. \tag{6}$$

The notation used is from Ref. 33. The vector multipole functions are derived by taking the gradient of the scalar potential, the curl of the vector potential, and the double curl of the vector potential in the following manner:

$$\mathbf{U} = \frac{1}{k}\,\nabla\,\Phi, \tag{7}$$

$$\mathbf{V} = \frac{1}{k}\,\nabla \times \boldsymbol{\Psi}, \tag{8}$$

$$\mathbf{W} = \frac{1}{k^2}\,\nabla \times (\nabla \times \boldsymbol{\Psi}). \tag{9}$$

The resulting functions are complete and orthogonal multipole expansions for $n=0$ to ∞ and $m=-n$ to $+n$:

$$\mathbf{U} = \sum_{n=0}^{\infty} \sum_{m=-n}^{+n} \left(\sqrt{\frac{n}{2n+1}} z_{n-1}(kr) \mathbf{Y}_{nm}^{n-1}(\theta,\varphi) + \sqrt{\frac{n+1}{2n+1}} z_{n+1}(kr) \mathbf{Y}_{nm}^{n+1}(\theta,\varphi) \right), \tag{10}$$

$$\mathbf{V} = \sum_{n=0}^{\infty} \sum_{m=-n}^{+n} \left(i \sqrt{\frac{n+1}{2n+1}} z_{n-1}(kr) \mathbf{Y}_{nm}^{n-1}(\theta,\varphi) - i \sqrt{\frac{n}{2n+1}} z_{n+1}(kr) \mathbf{Y}_{nm}^{n+1}(\theta,\varphi) \right), \tag{11}$$

$$\mathbf{W} = \sum_{n=0}^{\infty} \sum_{m=-n}^{+n} z_n(kr) \mathbf{Y}_{nm}^{n}(\theta,\varphi). \tag{12}$$

The **U**, **V**, and **W** vector multipoles are similar to the vector spherical wave functions of Stratton;[34] the vector multipoles of Rose,[35] Edmonds,[36] and Greiner and Maruhn;[31] and the vector spherical harmonic of Jackson.[37] **U** represents the longitudinal displacement field. **V** and **W** are transverse fields that can represent either elastic shear waves or electromagnetic waves. The shear fields are designated by their electromagnetic counterparts since the horizontal and vertical conventions normally used to differentiate the two types of shear fields are ambiguous in a spherical coordinate system. **V** and **W** therefore correspond to the shear-electric and shear-magnetic displacement fields, respectively.

The initial waves incident on the particles are modeled as plane waves. The spherical expansion for the longitudinal plane wave is derived from the gradient of the partial wave expansion for scalar fields:

$$\begin{aligned} \mathbf{e}_z e^{ikz} &= \frac{1}{ik} \nabla e^{ikz} \\ &= \frac{1}{ik} \nabla \left[\sum_{n=0}^{\infty} i^n \sqrt{4\pi(2n+1)} j_n(kr) Y_{n,0}(\theta,\varphi) \right] \\ &= \sum_{n=0}^{\infty} i^{n-1} \sqrt{4\pi(2n+1)} \mathbf{U}_{n,0}. \end{aligned} \tag{13}$$

At least three different partial wave expansions have been presented in the literature for transverse vector planes waves, including those by Stratton,[34] Jackson,[37] and Greiner and Maruhn.[31] Grandy further derived expansions for plane-polarized waves from Jackson's circularly polarized waves.[38] Mathematical analysis and numerical testing, however, showed that only the expansions of Greiner and Maruhn were correct and converged properly. Adapting their expressions, the partial wave expansions for shear waves propagating in the z direction and polarized in the x and y directions are the following:

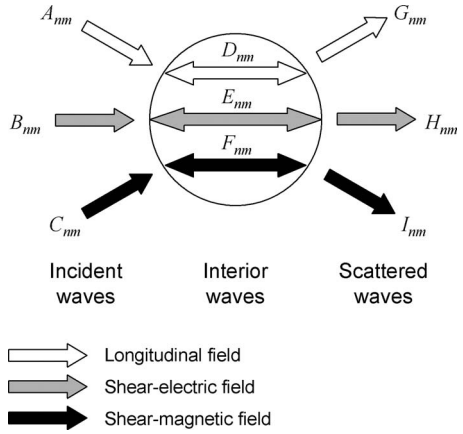

FIG. 1. Diagram of incident, interior, and scattered elastic waves for single-particle scattering, with associated amplitude coefficients for the (n,m) multipole moment.

$$\mathbf{e}_x e^{ikz} = \sum_n i^n \sqrt{\pi(2n+1)} [\mathbf{W}_{n,+1} + \mathbf{V}_{n,+1} + \mathbf{W}_{n,-1} - \mathbf{V}_{n,-1}], \tag{14}$$

$$\mathbf{e}_y e^{ikz} = (-i) \sum_n i^n \sqrt{\pi(2n+1)} [\mathbf{W}_{n,+1} + \mathbf{V}_{n,+1} - \mathbf{W}_{n,-1} + \mathbf{V}_{n,-1}]. \tag{15}$$

B. Boundary condition solutions

Simulation of multiple scattering in a dispersion of spherical particles first requires scattering solutions for the individual spheres. For scattering from a single solid sphere in a solid matrix, there will be an incoming incident field, a refracted interior field, and an outgoing scattered field for each of the **U**, **V**, and **W** wave fields. Each wave field component will also have an associated amplitude coefficient. Figure 1 shows the relationship between each of the field components and the coefficients.

Single-sphere scattering has been solved numerous times in the literature, but often not in the most general form. These solutions model the incident fields as plane waves with only a longitudinal or shear component.[39–44] Although these conditions are often sufficient for dilute suspensions, the incident fields for each particle in multiple-scattering computations will not in general be plane waves, but a combination of the initial plane waves and the scattered waves from other particles. Also, the incident fields will be a combination of both longitudinal and shear waves. Single-sphere scattering solutions were therefore required for arbitrary incident fields comprised of both longitudinal and shear waves.

Given an arbitrary incident field, the amplitude coefficients of the interior and scattered fields are found by solving the boundary conditions on the surface of the sphere. The boundary conditions provide a set of six linear equations for the six unknown coefficients. Three of these equations are obtained from continuity of the displacements:

$$\mathbf{u}^{\text{incident}} + \mathbf{u}^{\text{scattered}} = \mathbf{u}^{\text{interior}}. \tag{16}$$

Orthogonality conditions for the vector spherical harmonics are used to eliminate the angular dependence from the boundary conditions:

$$\int_0^{2\pi} d\varphi \int_0^{\pi} d(\cos\theta) \mathbf{Y}_{NM}^{L} {}^{*}(\theta,\varphi) \mathbf{Y}_{nm}^{l}(\theta,\varphi) = \delta_{Ll}\delta_{Nn}\delta_{Mm}. \tag{17}$$

The multipole fields [Eqs. (10)–(12)] and associated amplitude coefficients are first substituted into Eq. (16). The resulting equation is then multiplied with $\mathbf{Y}_{NM}^{N-1}{}^{*}(\theta,\varphi)$, $\mathbf{Y}_{NM}^{N}{}^{*}(\theta,\varphi)$, and $\mathbf{Y}_{NM}^{N+1}{}^{*}(\theta,\varphi)$ to obtain three separate equations. Finally, the equations are integrated over θ and φ to obtain the first three coefficient equations.

The other three equations are derived from continuity of the stresses, where σ is the stress tensor:

$$\sigma^{\text{incident}} + \sigma^{\text{scattered}} = \sigma^{\text{interior}}. \tag{18}$$

Equations for continuity of the radial stresses σ_{rr} and tangential stresses $\sigma_{r\theta}$ and $\sigma_{r\varphi}$ are solved separately. The stresses are related to the displacements by the following:

$$\sigma_{rr} = \lambda(\nabla \cdot \mathbf{u}) + 2\mu \frac{\partial u_r}{\partial r}, \tag{19}$$

$$\sigma_{r\theta} = \mu \cdot \left(\frac{1}{r}\frac{\partial u_r}{\partial \theta} + \frac{\partial u_\theta}{\partial r} - \frac{u_\theta}{r} \right), \tag{20}$$

$$\sigma_{r\varphi} = \mu \cdot \left(\frac{1}{r\sin\theta}\frac{\partial u_r}{\partial \varphi} - \frac{u_\varphi}{r} + \frac{\partial u_\varphi}{\partial r} \right). \tag{21}$$

Since Eqs. (19)–(21) contain only scalar components of the displacement, the angular dependence is removed using orthogonality of the scalar spherical harmonics:

$$\int_0^{2\pi} d\varphi \int_0^{\pi} d(\cos\theta) Y_{NM}{}^{*}(\theta,\varphi) Y_{nm}(\theta,\varphi) = \delta_{Nn}\delta_{Mm}. \tag{22}$$

To solve the σ_{rr}, $\sigma_{r\theta}$, and $\sigma_{r\varphi}$ boundary conditions, Eqs. (19)–(21) are substituted into Eq. (18) with the appropriate scalar components and amplitude coefficients for the multipole fields. This yields three equations that are then multiplied with $Y_{NM}{}^{*}(\theta,\varphi)$ and integrated over θ and φ to obtain the last three coefficient equations.

The resulting six equations have the following matrix form that relates the six unknown coefficients to the three known coefficients:

$$\begin{pmatrix} \eta_{1j} & -\eta_{1h} & \eta_{2j} & -\eta_{2h} & 0 & 0 \\ \eta_{6j} & -\eta_{6h} & \eta_{7j} & -\eta_{7h} & 0 & 0 \\ \eta_{4j} & -\eta_{4h} & \eta_{5j} & -\eta_{5h} & 0 & 0 \\ \eta_{9j} & -\eta_{9h} & \eta_{10j} & -\eta_{10h} & 0 & 0 \\ 0 & 0 & 0 & 0 & \eta_{3j} & -\eta_{3h} \\ 0 & 0 & 0 & 0 & \eta_{8j} & -\eta_{8h} \end{pmatrix} \begin{pmatrix} D_{NM} \\ G_{NM} \\ E_{NM} \\ H_{NM} \\ F_{NM} \\ I_{NM} \end{pmatrix} = \begin{pmatrix} A_{NM}\eta_{1g} + B_{NM}\eta_{2g} \\ A_{NM}\eta_{6g} + B_{NM}\eta_{7g} \\ A_{NM}\eta_{4g} + B_{NM}\eta_{5g} \\ A_{NM}\eta_{9g} + B_{NM}\eta_{10g} \\ C_{NM}\eta_{3g} \\ C_{NM}\eta_{8g} \end{pmatrix}. \tag{23}$$

Lines 1, 3, and 5 in Eq. (23) derive from the displacement boundary conditions [Eq. (16)]. Line 2 derives from the radial stress boundary condition (σ_{rr}), and lines 4 and 6 derive from the tangential stress boundary conditions ($\sigma_{r\varphi}$ and $\sigma_{r\theta}$). The η matrix elements are functions of the spherical radial functions [denoted by the subscript $j = j_N(ka)$, $h = h_N^{(1)}(ka)$, or $g = h_N^{(2)}(ka)$], multipole order N, longitudinal wave vector k_L, shear wave vector k_S, and sphere radius a.[45] The η matrix elements are given in the Appendix. Since the coefficient matrix separates into a 4×4 matrix and 2×2 matrix, the shear-magnetic fields are decoupled from the longitudinal and shear-electric fields and do not participate in mode conversion. In the scattering model the scattering amplitudes are obtained for each particle from algebraic solutions for the 2×2 and 4×4 matrices using Cramer's rule.

For monopole ($N=0$) terms, many of the η matrix elements in Eq. (23) vanish, resulting in a singular matrix that cannot be solved using Cramer's rule. This is due to the fact that the lowest moment possible for shear waves is the dipole ($N=1$) term. Therefore, a different matrix equation is solved for the longitudinal monopole fields. For monopole scattering, a system of only two equations is required for solution of the two unknown coefficients (the interior and scattered longitudinal field coefficients). In matrix form they are

$$\begin{pmatrix} \eta_{1j} & -\eta_{1h} \\ \eta_{6j} & -\eta_{6h} \end{pmatrix} \begin{pmatrix} D_{00} \\ G_{00} \end{pmatrix} = \begin{pmatrix} A_{00}\eta_{1g} \\ A_{00}\eta_{6g} \end{pmatrix}. \tag{24}$$

The first line is from the displacement boundary condition [Eq. (16)], and the second line is from the radial stress boundary condition (σ_{rr}). There are no tangential stresses for the monopole moment. Similar modifications to Eq. (23) are required for scattering from a fluid-filled sphere in a solid matrix and from a solid sphere in a fluid matrix. The 4×4 submatrix in Eq. (23) reduces to a 3×3 matrix for these cases.

C. Translation of scattered fields

In multiple scattering of elastic waves, the scattered waves from each particle impinge on the other particles and modify their incident wave fields. Since the multipole functions are specific to each particle's coordinate system, the

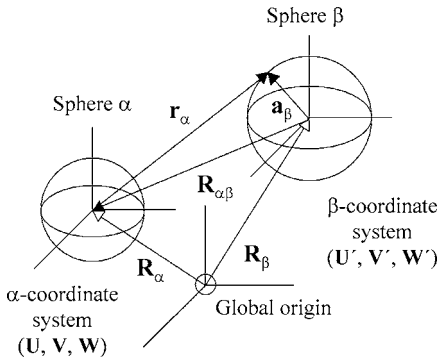

FIG. 2. Position ($\mathbf{R}_\alpha$ and $\mathbf{R}_\beta$) and translation ($\mathbf{r}_\alpha$) vectors for addition theorems with respect to local and global coordinates for spheres α and β.

vector multipole functions for each particle must be transformed into the coordinate systems of the other particles in order to update the incident fields. These transformations are the following:

$$\mathbf{U}'_{\nu\mu} = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} Q_{\nu\mu}^{nm} \mathbf{U}_{nm}, \tag{25}$$

$$\mathbf{V}'_{\nu\mu} = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} (S_{\nu\mu}^{nm} \mathbf{V}_{nm} + T_{\nu\mu}^{nm} \mathbf{W}_{nm}), \tag{26}$$

$$\mathbf{W}'_{\nu\mu} = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} (S_{\nu\mu}^{nm} \mathbf{W}_{nm} + T_{\nu\mu}^{nm} \mathbf{V}_{nm}), \tag{27}$$

where $\mathbf{U}_{nm}$, $\mathbf{V}_{nm}$, and $\mathbf{W}_{nm}$ are wave fields scattered from the originating sphere (α) and are therefore in sphere α's coordinate system (r_α, θ_α, and φ_α). $\mathbf{U}'_{\nu\mu}$, $\mathbf{V}'_{\nu\mu}$, and $\mathbf{W}'_{\nu\mu}$ are the same wave fields incident on a second sphere (β) and are therefore in sphere β's coordinate system (r_β, θ_β, and φ_β). Equations (25)–(27) transform the wave fields with expansions containing the original multipole functions and translation coefficients ($Q_{\nu\mu}^{nm}$, $S_{\nu\mu}^{nm}$, and $T_{\nu\mu}^{nm}$) derived from the translational addition theorems.

Figure 2 shows the geometric relationship for the field translations between the two spheres. The position of sphere α with respect to sphere β is $\mathbf{R}_{\alpha\beta}=\mathbf{R}_\alpha-\mathbf{R}_\beta$, where $\mathbf{R}_\alpha$ and $\mathbf{R}_\beta$ are the global position vectors for the two spheres. The translation coefficients are only valid on the surface of sphere $\beta(r_\beta=a_\beta)$, and the center of sphere α must lie outside of sphere β. Although addition theorems can also be derived for spheres embedded within larger spheres ($a_\beta>R_{\alpha\beta}$), this work only considered spheres external to each other and nonoverlapping ($a_\beta<R_{\alpha\beta}$).

The scalar addition theorem is sufficient for translating the longitudinal field since the longitudinal vector multipole function arises from a scalar potential [Eq. (7)]. The scalar addition theorem has been published extensively[33,46–49] and provides the $Q_{\nu\mu}^{nm}$ translation coefficients:

$$Q_{\nu,\mu}^{n,m} = \sqrt{4\pi} \sum_{p=0}^{\infty} \left\{ i^{\nu-p-n} h_p^{(1)}(kR_{\alpha\beta}) Y_{p,m-\mu}(\Theta_{\alpha\beta}, \Phi_{\alpha\beta}) \times C_{\nu,0,p,0}^{n,0} C_{\nu,\mu,p,m-\mu}^{n,m} \sqrt{\frac{(2\nu+1)(2p+1)}{(2n+1)}} \right\}. \tag{28}$$

Vector addition theorems are required to translate the shear fields since the transverse vector multipoles arise from a vector potential [Eqs. (8) and (9)]. Cruzan was one of the earliest to derive expressions for the $S_{\nu\mu}^{nm}$ and $T_{\nu\mu}^{nm}$ translation coefficients by directly transforming the coordinates in the vector multipole functions and applying various identities and relationships to arrive at an analytical solution.[50] Another approach is to expand the vector multipoles in the α coordinate system as a series comprised of expansion coefficients and vector spherical harmonics in the β coordinate system. The expression can then be integrated in a manner similar to a Fourier series to determine the translation coefficients.[45] The results produce a set of solutions for the translation coefficients $S_{\nu\mu}^{nm}$ and $T_{\nu\mu}^{nm}$, the most direct of which are the following:

$$S_{\nu\mu}^{nm} = Z_{\nu,\nu,\mu}^{n,n,m}, \tag{29}$$

$$T_{\nu\mu}^{nm} = -i\sqrt{\frac{2\nu+1}{\nu+1}} Z_{\nu-1,\nu,\mu}^{n,n,m} = i\sqrt{\frac{2\nu+1}{\nu}} Z_{\nu+1,\nu,\mu}^{n,n,m} = i\sqrt{\frac{2n+1}{n+1}} Z_{\nu,\nu,\mu}^{n-1,n,m} = -i\sqrt{\frac{2n+1}{n}} Z_{\nu,\nu,\mu}^{n+1,n,m}, \tag{30}$$

where

$$Z_{\lambda,\nu,\mu}^{l,n,m}(\mathbf{R}_{\alpha\beta}) = \sum_{p=|l-\lambda|}^{l+\lambda} \left\{ i^{\lambda-l-p} h_p^{(1)}(kR_{\alpha\beta}) Y_{p,m-\mu}(\Theta_{\alpha\beta}, \Phi_{\alpha\beta}) \times C_{\lambda,0,p,0}^{l,0} \sqrt{\frac{4\pi(2\lambda+1)(2p+1)}{2l+1}} \times \sum_{\tau=-1}^{1} C_{l,m-\tau,1,\tau}^{n,m} C_{\lambda,\mu-\tau,1,\tau}^{\nu,\mu} C_{\lambda,\mu-\tau,p,m-\mu}^{l,m-\tau} \right\}. \tag{31}$$

Numerical testing of Eqs. (29)–(31) showed they were numerically equivalent to those of Cruzan.[50] Recurrence formulas have additionally been derived for both the scalar and vector addition theorems, and significantly reduce the number of operations for computing the translation coefficients.[51–53] These formulas were expanded for elastic wave scattering and implemented in the iterative multipole model.

D. Multiple-scattering computations

The iterative multipole model first calculates the scattered wave fields for each particle in the system due to an initial plane wave. The scattered wave fields are then translated between all particle pairs and summed at each particle. The new incident wave field (initial plane wave+scattered wave fields) is then used to compute revised scattered wave fields from each particle. This process is repeated iteratively

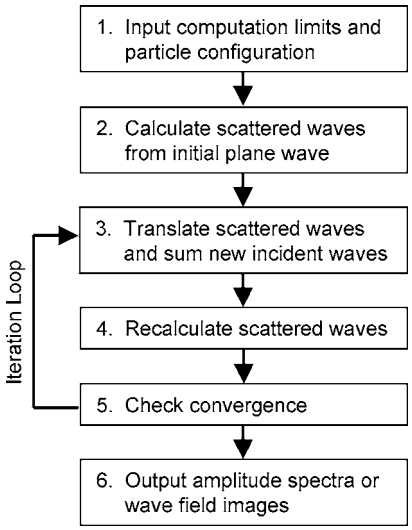

FIG. 3. Flow diagram of computation steps performed in the elastic wave scattering model.

until the scattered wave fields converge (i.e., no change in wave field amplitudes between consecutive iterations). Each iteration represents a successive order of scattering (first iteration=first-order multiple scattering, second iteration =second-order multiple scattering, etc.). Figure 3 illustrates the computation process.

Computation limits include the maximum multipole expansion order to compute ($n_{\max}$) and the convergence criteria (precision limit) for stopping the iterations. Computer algorithms for the model were written, debugged, and compiled in FORTRAN 90. Simulations were performed on personal desktop computers with up to 2.0 GB RAM and either a 1.7- or 3.2-GHz processor. Computation times varied from a few minutes to 36 h.

The model can be configured to provide wave field images, amplitude spectra, or elastic wave velocity. Wave velocity was computed using a Fourier transform method that modified the spectral input of the initial plane wave with appropriate wavelet functions [Fig. 4(a)], calculated the interactions of the modified wave in the simulated particle pack, and applied an inverse Fourier transform to the resultant spectra to simulate a wave pulse in the time domain. The time delay between this pulse and one with the simulated particle pack absent [Fig. 4(b)] provided the effective wave velocity. This procedure can also provide pulse attenuation and is equivalent to simulating the frequency characteristics of a transmitting ultrasonic transducer. Complex wave vectors were also implemented in the algorithm to model dispersions with viscoelastic or intrinsic attenuation properties.

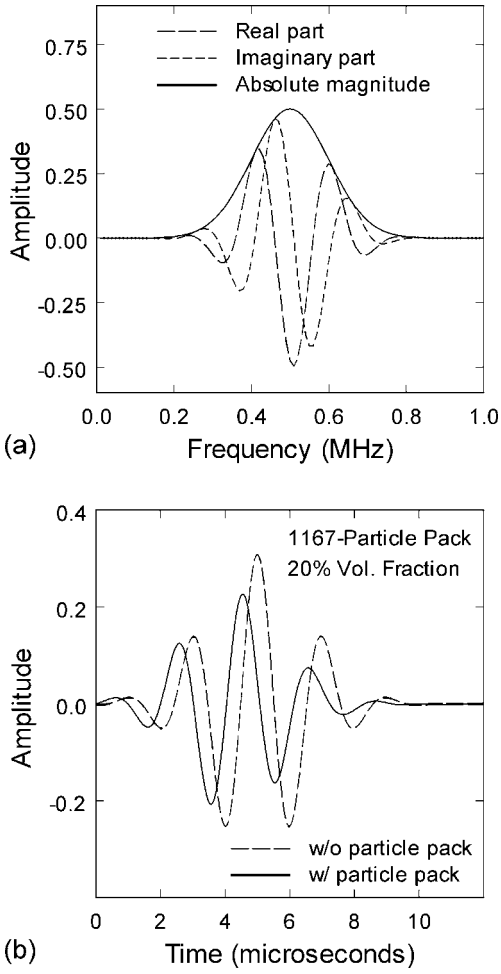

FIG. 4. Modulation of the initial plane wave spectrum using wavelet functions (a) and a time-delay comparison of resultant pulses for an 1167-particle dispersion (b).

III. RESULTS

A. Simulations of 2 to 16 particles

The scattering interactions between 2 and 16 particles were simulated to test the ability of the model to reproduce wave propagation phenomena. The particles were modeled as quartz spheres in a matrix of water ice since the elastic properties of quartz and ice are sufficiently different to clearly show scattering phenomena such as reflection, but not too different to preclude other types of wave propagation such as refraction through particles.

Figure 5 shows images of the scattered wave fields resulting from a longitudinal wave incident on two spheres aligned along the direction of wave propagation (from left to right in the images in the $+z$ direction). The incident wave is not superimposed on the scattered wave fields in order to emphasize the scattering mechanisms, and the gray scale is proportional to the scattered wave field amplitude. The images display both refractive focusing (forward scattering) of the longitudinal wave, Fig. 5(a), and mode conversion of the longitudinal wave to shear waves, Fig. 5(b).

Since most of the scattered wave behavior in Fig. 5 arises from single-sphere scattering, single-scattering computations were compared to the multiple-scattering computations to ascertain differences between the two solutions and determine the effects of multiple scattering. The single-scattering computations superimpose the single-scattering solutions from each of the spheres to calculate the effective field. Figure 6(a) shows the z component of the total displacement field (initial plane wave+multiple-scattered waves) for the two particles. Figure 6(b) is the difference image between the multiply scattered waves shown in Fig.

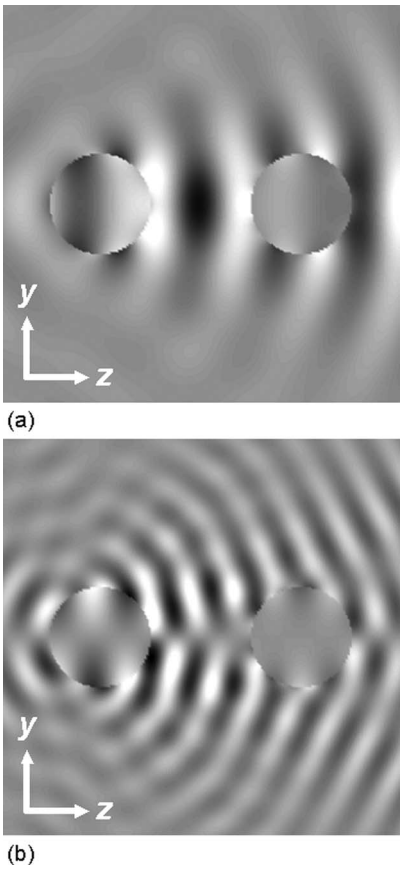

FIG. 5. Wave field images for a 5-MHz longitudinal wave incident on a pair of 1.0-mm-diam quartz spheres in ice: (a) scattered longitudinal wave (z component) displaying focusing and (b) scattered shear wave (y component) displaying mode conversion from longitudinal wave. Wave propagation in these and subsequent images is in the $+z$ direction.

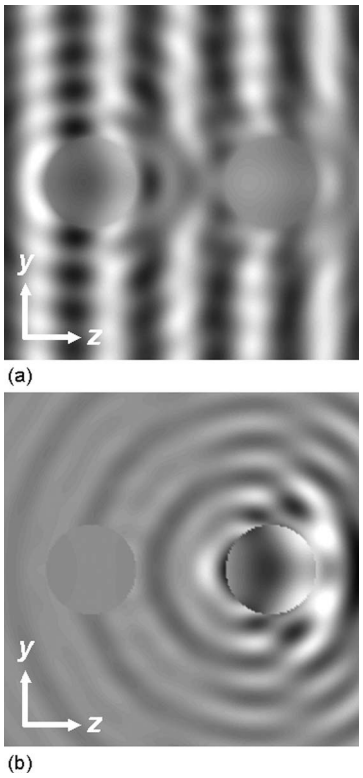

FIG. 6. Wave field images for a 5-MHz longitudinal wave incident on a pair of 1.0-mm-diam quartz spheres in ice: (a) total displacement field (z component) and (b) displacement differences (z component) between multiple-scattering and single-scattering computations.

6(a) and the wave fields generated by the single-scattering solutions. The difference plot highlights the spatial regions where multiple scattering has the largest contribution to the wave fields, and clearly shows the primary effect of multiple scattering in the two-sphere configuration is the shielding of the second (right) sphere by the first (left) sphere.

Figure 7 displays the propagation of a 1.0-MHz [Fig. 7(a)] and 2.0-MHz [Fig. 7(b)] shear plane wave through a random configuration of 16 quartz particles lying in a plane. Here the images show the x component of the total shear wave field (incident+scattered wave fields). The greater attenuation exhibited for the 2.0-MHz waves can be attributed to the fact that Mie scattering is inversely proportional to the wavelength. Figure 7 additionally shows distortion of the wave front from the initial plane-wave geometry for the 2.0-MHz image. The distortion arises from disorder in both particle size and position.

The results from simulations of small particle configurations demonstrated the model's ability to reproduce basic wave propagation behavior such as refraction, mode conversion, shielding, and wave-front distortion at a qualitative level. All of the above simulations were calculated to a maximum multipole order of $n_{\max}=12$.

B. Simulations of dispersions with 10^2–10^3 particles

Wave field images, amplitude spectra, and ultrasonic velocities were computed for larger 3-D particle packs (100–

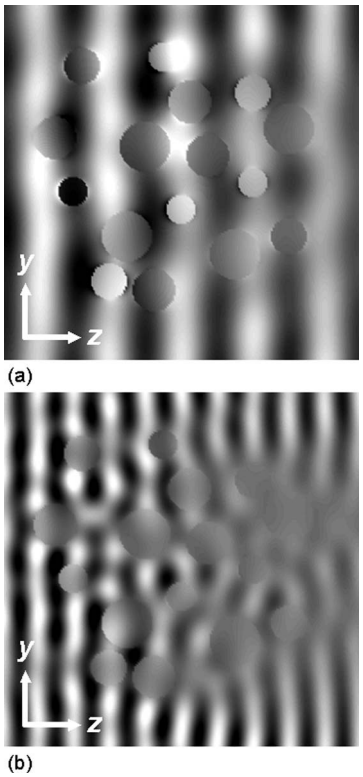

FIG. 7. Total (scattered+incident) shear wave x component for an incident shear wave at 1.0 MHz (a) and 2.0 MHz (b) for a disordered configuration of quartz particles in ice (diameter=0.8–1.4 mm).

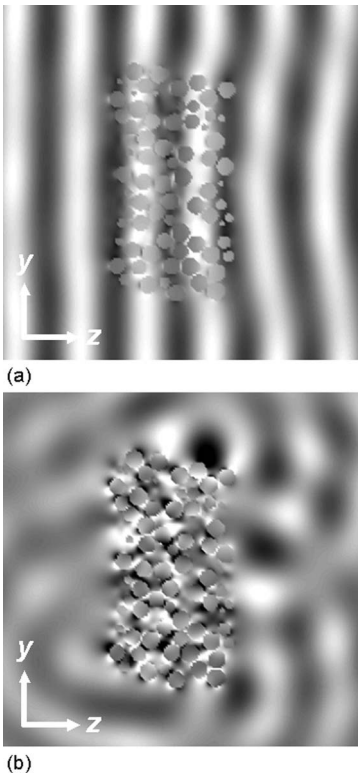

FIG. 8. Wave field images of the z component (a) and y component (b) of displacement resulting from an incident 2.0-MHz longitudinal wave in a cylindrical packing of 200-μm-diameter NaCl particles in rubber. Images are of a random packing of 736 particles at 50% volume fraction.

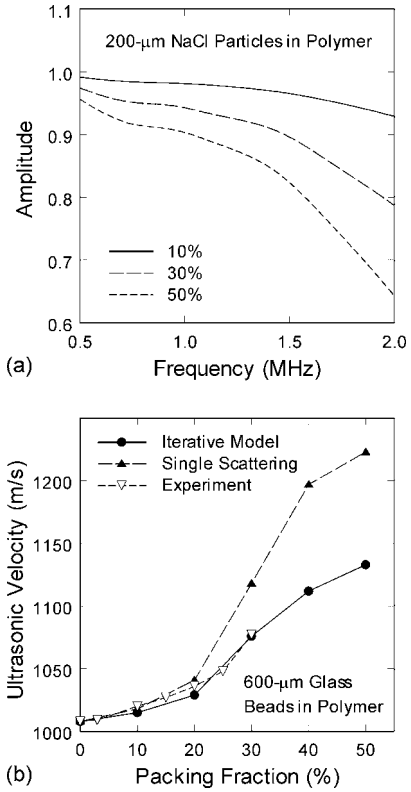

FIG. 9. Amplitude spectra and velocity results for large particle dispersions in a viscoelastic polymer matrix: (a) longitudinal wave spectra for 200-μm NaCl particles; and (b) comparison of longitudinal wave velocity at 500-kHz center frequency for multiple-scattering computations, single-scattering computations, and experimental measurements for 600-μm glass beads.

3000 particles at 10%–50% volume fraction) to test the model's ability to simulate material microstructures. The particle dispersions were configured into a cylindrical disk with the initial plane wave incident on one of the cylinder's end faces. For the simulation of spectra and velocities, the wave fields were evaluated on a planar array of points with a circular shape. This array simulated the face of an ultrasonic transducer by averaging the wave field amplitudes over a defined area. This averaging eliminated local interference effects that arose when the fields were evaluated at a single point. The simulations were computed to a maximum multipole order of $n_{\max}=6$ to make the computations tractable for a desktop computer. An effective interaction distance was also used that excluded less significant interactions between widely separated particles.

Wave field images were generated for both periodic and random arrangements of 200-μm diameter NaCl particles in a viscoelastic polymer matrix (rubber). Figure 8 displays wave field images for a random packing of 736 particles at 50% volume fraction. The image plane in Fig. 8 slices through the center of the cylinder along the cylinder's axis, and the incident wave is included in order to show the refraction of the elastic wave field by the random particle dispersion [Fig. 8(a)]. Since the incident longitudinal field is wholly in the z direction, it does not show up in the y-component image [Fig. 8(b)]. However, both single and multiple scattering redirect a portion of the wave field energy into the y-direction (i.e., refraction), thus producing y-component waves.

Figure 9 displays amplitude spectra and velocity results for large particle dispersions in a viscoelastic polymer matrix. Amplitude spectra for 200-μm NaCl particles [Fig. 9(a)] showed increases in attenuation (decreases in amplitude) with particle volume fraction and frequency, a result qualitatively consistent with experimental observations. Longitudinal wave velocities were additionally calculated for random dispersions of 600-μm glass beads and compared to velocities from both single-scattering computations and ultrasonic measurements of laboratory specimens [Fig. 9(b)]. The results from the iterative model show an increase in effective velocity with increasing packing density and are consistent with the experimental data up to 30%. In comparison, the single-scattering model agrees with the experimental data up to only 20% volume fraction. Although the experimental data only goes to 30% volume fraction, the iterative model appears to deviate from the trend of the experimental velocities above 30%, indicating the computations may not be accurate for dense packings. This deficiency can be attributed to a lack of iterative and addition theorem convergence (an $n_{\max}=6$ value was used for the simulations) resulting in increasingly larger errors for the multiple scattering. The particle packs in the velocity simulations varied from 148 particles (10% volume fraction) to 736 particles (50% volume fraction).

C. Convergence

The convergence of the iterative multipole model has three components: Addition theorem convergence, single-

scattering convergence, and iterative convergence. Although convergence of all three components is necessary for computational fidelity, they are not strongly coupled to one another, and convergence of any one component is not directly dependent on the convergence of the other two. Therefore, the properties of each must be considered separately.

1. Addition theorem convergence

The convergence of the addition theorems was numerically tested by translating a quadrupole moment ($n=2$, $m=1$) for all three elastic fields from one sphere (α) to a point on another sphere (β) and comparing the translated fields to the untranslated fields at that point (see Fig. 2). Convergence was evaluated as a function of $n_{\max}$, frequency, sphere size, sphere separation, orientation of the two spheres, and orientation of the evaluation point on sphere β.[45] The size and distance scale for sphere β was in the millimeter range, and the frequencies were in the 0.10–10.0-MHz range. Since the addition theorems couple the $\mathbf{V}$ and $\mathbf{W}$ fields [Eqs. (26) and (27)], the sum of the two transverse fields have to be compared instead of the two fields individually (i.e., $\mathbf{V}+\mathbf{W}$ is compared to $\mathbf{V}'+\mathbf{W}'$, rather than $\mathbf{V}$ to $\mathbf{V}'$ and $\mathbf{W}$ to $\mathbf{W}'$).

Following the coordinate conventions in Fig. 2, Fig. 10 displays convergence plots for sphere β positioned at $\Theta_{\alpha\beta}=34°$, $\Phi_{\alpha\beta}=295°$, and with four separation distances ($R_{\alpha\beta}=1.0$, 2.0, 3.0, and 4.0 mm). The evaluation point on sphere β was positioned at $\theta_\beta=163°$, $\varphi_\beta=320°$, and $a_\beta=0.5$ mm. Results are displayed for 0.10 MHz [Fig. 10(a)] and 5.0 MHz [Fig. 10(b)]. At low frequencies [Fig. 10(a)], the field translations converge more rapidly with $n_{\max}$ for greater sphere separations. However, as the frequency increases the convergence curves shift and eventually overlap at 5.0 MHz [Fig. 10(b)]. The curves continue to shift to higher $n_{\max}$ as frequency increases, indicating slower convergence of the addition theorem expansions.

The convergence curves in Fig. 10 indicate the degree of error present in the field translations for a specified $n_{\max}$, frequency, and particle separation. For example, the convergence curve for $R_{\alpha\beta}=2$ in Fig. 10(b) would correspond to the two-sphere simulations in Figs. 5 and 6. For this case, computations at $n_{\max}=6$ would result in field translation errors on the order of 10%, whereas computations at $n_{\max}=12$ would produce errors on the order of only 1%.

2. Single-scattering convergence

In multipole-based optical scattering models for single scatterers, the convergence of the scattered wave amplitudes as a function of frequency is dependent on the particle diameter d and $n_{\max}$. Simulation results verify the relationship between $n_{\max}$, d, and convergence frequency $\nu_{\max}$ (the highest frequency at which the wave fields converge) is proportional for elastic wave scattering as well. This relationship has been found to be approximately

$$\nu_{\max} \cong \frac{9}{10}\frac{c}{\pi d} n_{\max}. \tag{32}$$

where c is the longitudinal or shear wave velocity in the matrix. As an example, for longitudinal wave scattering from

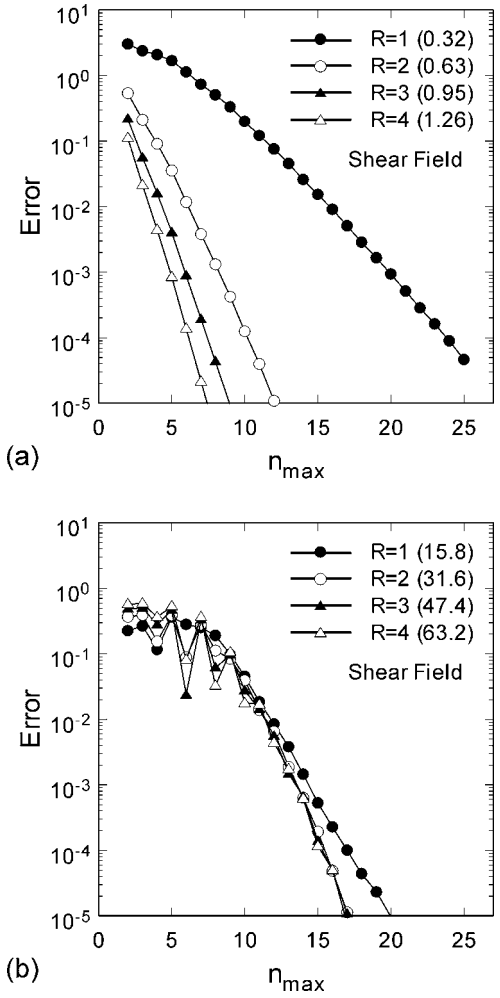

FIG. 10. Addition theorem convergence for translation of 0.10-MHz (a) and 5.0-MHz (b) shear fields between two 1.0-mm-diam quartz spheres in ice. $R=R_{\alpha\beta}$=center-to-center distance between spheres in mm. Numbers in parentheses are $kR_{\alpha\beta}$ values.

1-mm-diam quartz particles in ice ($c_L=3.98\times10^5$ cm/s) and for $n_{\max}=4$, the maximum frequency at which the spectrum converges is $\nu_{\max}\approx4.6$ MHz. Therefore the elastic wave spectra will be convergent for frequencies from 0 to 4.6 MHz, but higher $n_{\max}$ values will be required for convergence at higher frequencies. Lack of single-scattering convergence has been found to contribute significant error to multiple-scattering results in simulations of ordered and disordered clusters of eight particles.[45]

3. Iterative convergence

Iterative convergence assures that the back-and-forth scattering interactions modeled with each iteration step converge to stable wave field amplitudes. This is physically required since each successive multiple scattering should produce a diminishing contribution to the total field, eventually resulting in the final field configuration. Simulations of small particle packings (2–16 particles) have shown that all three elastic fields converge to within computational limits (10^{-16} for double precision) for arbitrary structures and a wide range of frequencies.

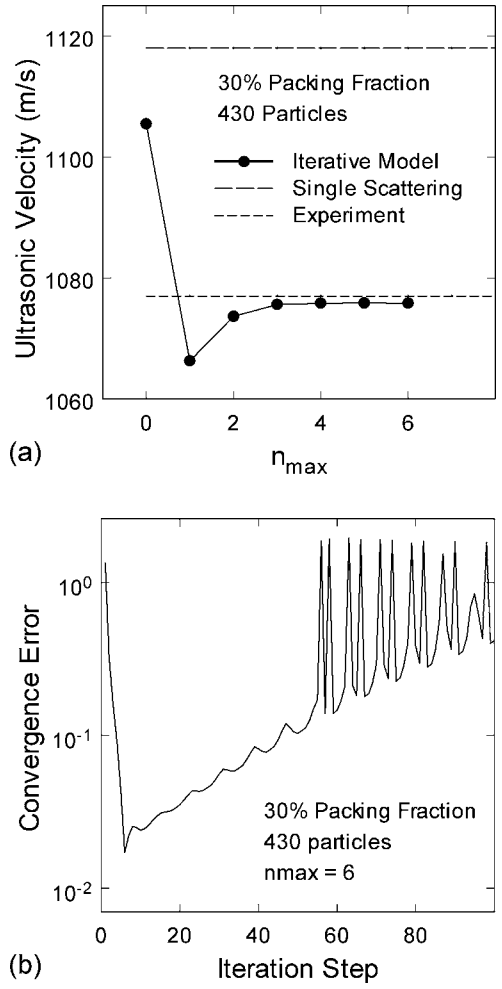

FIG. 11. Convergence behavior for 600-μm glass beads in polymer, 30% volume fraction: (a) predicted ultrasonic velocity as a function of n_{max} and (b) convergence error as a function of iteration step for the longitudinal field at 600 kHz.

Simulations of large particle packings (>100 particles) have revealed, however, that the elastic wave computations are numerically unstable and do not converge or only partially converge for short wavelengths ($\lambda \sim$ particle diameter). The shear waves contribute most significantly to the instability due to their shorter wavelengths in materials as compared to longitudinal waves. Damping the interactions with attenuation factors of a magnitude common in viscoelastic polymers has been found to reduce the instability. At short wavelengths the iterative model therefore appears better suited for particles embedded in viscoelastic materials (for example, Figs. 8 and 9) than in highly elastic materials. Another approach to resolving the nonconvergence is to relax the convergence criteria since the iterations for large particle packings often partially converge to errors less than 10^{-1} before instability causes the iterations to diverge. Iterative convergence has also been found to be strongly dependent on particle volume fraction, but only weakly dependent on n_{max}.

Figure 11 displays the convergence behavior of the velocity simulation results shown in Fig. 9(b) (the 600-μm glass bead/polymer system) for 30% volume fraction. The convergence of the predicted ultrasonic velocity as a function of n_{max}, Fig. 11(a), demonstrates the computed values converge rapidly by $n_{max}=6$ and closely approach the experimental value. Also, the $n_{max}=0$ simulation (monopole-only scattering) is closer in agreement with the single-scattering model than the higher n_{max} simulations, thereby showing the importance of the dipole, quadrupole, and octupole terms in multiple scattering.

Figure 11(b) presents the convergence error as a function of iteration step for the 30% volume fraction simulation. The convergence error is the fractional difference in the average computed wave field amplitude between iteration steps and is shown in Fig. 11(b) for the longitudinal field at 600 kHz and $n_{max}=6$. Extensive testing revealed that the velocity simulations for this system were only marginally stable, converging for the first five to ten iteration steps but then diverging as in Fig. 11(b). Additionally, the lowest error in the iterations varied with frequency from 10^{-1} to 10^{-6}. In this situation, defining the convergence criterion as the point at which the iterations reach a fixed error value such as 10^{-6} does not work, and the model fails to converge. Rather, limiting the number of iterations to a fixed value (for example, five iterations) allows results to be obtained from the model when the minimum convergence error varies across the frequency range. Although this produces a variable convergence error for the computed fields, it permits a maximum of frequency steps to be computed with an overall minimum error. (A more sophisticated approach would be to program the model to detect when such a minimum has passed and to use the results from the minimum error iteration step.)

The results from Fig. 11 illustrate the instability of the iterative model for particle packs greater than a few hundred particles, but also show how the instabilities do not preclude the acquisition of multiple scattering results. If the convergence error as a function of iteration step has a minimum with an error less the 10^{-1} as in Fig. 11(b), then simulation results can be obtained as in Fig. 11(a) that display reasonable convergence properties with respect to n_{max} and experimental data.

IV. DISCUSSION

The results to date indicate the iterative multipole model reproduces realistic wave propagation behavior at a qualitative level. Phenomena such as mode conversion, refraction, wave front distortion, and scattering-induced attenuation have been observed in both wave field images and spectra. The model can also simulate large numbers of particles (10^2–10^3) and random structures directly for viscoelastic materials. Random particle packings of up to 3000 particles and 50% particle volume fraction have also been tested. The iterations are numerically stable and converge for small particle configurations, but become unstable for large particle configurations. Simulations at long wavelengths or with strong attenuation of shear waves can improve the stability of the numerical process.

A common approach to validating numerical-based multiple-scattering models is to compare the results for a small cluster of spheres to other numerical approaches such as the boundary element method.[17] This approach is feasible for clusters of two or three spheres, but becomes computa-

tionally intractable for large particle packings with more than a few dozen particles. Alternatively, model results can be compared to experimental data. This approach has been used extensively for evaluating classical formulations where multiple scattering is treated statistically.[1,2] Analogous experimental validation of the iterative multipole method was therefore implemented as a test for the model. Comparisons between multiple-scattering and single-scattering computations were additionally used to quantify the magnitude of multiple scattering in a particulate system and to establish the limits of validity for the computations.

The results indicate that both addition theorem and iterative convergence are the current limiting factors for the iterative multipole approach implemented on a personal computer. Due to the virtual memory requirements involved with the addition theorems, the maximum computed multipole order has so far been limited to $n_{\max}=6$ for large dispersions (10^2-10^3 particles). Convergence studies of the addition theorems (Fig. 10) and model comparisons with experimental data [Figs. 9(b) and 11(a)] indicate low $n_{\max}$ values ($n_{\max}\leqslant 6$) are sufficient for particle dispersions up to 30% particle volume fraction but not for denser packings. Consequently, simulations performed to date with high particle densities have exhibited significant error due to inadequate convergence of both the field translations and iterations.

The results also indicate dilute dispersions ($\leqslant 20\%$) are not sufficient to validate numerical models for multiple scattering since single scattering will dominate over multiple scattering in such systems. In such cases the models may produce accurate results for a dilute particle dispersion although the multiple scattering may be insufficiently or incorrectly calculated. As shown in Fig. 9(b), a single-scattering model shows good agreement with experimental results for volume fractions up to 20%. Validation with dense particle systems is therefore necessary for accurately evaluating a model's performance. Since iterative convergence, addition theorem convergence, and single-scattering convergence are not strongly coupled, care must also be taken in interpreting the accuracy of a multiple-scattering model with regards to any single convergence component.

The iterative or order-of-scattering method appears to be a direct and accessible approach for modeling elastic wave scattering in arbitrary dispersions of spherical particles. Computational modeling of multiple scattering at moderate volume fractions (30%) and particle numbers (~400 particles) has been demonstrated and verified against experimental data. It is a simple and highly generalized approach that can be applied to dispersions of spherical scatterers of almost any configuration and composition. Although the model currently has significant computational and convergence limitations, it is likely methods can be found or developed to resolve these issues. Such methods include implementation of the model on larger computer systems and development of more advanced scattering algorithms to resolve the efficiency and stability constraints.

V. CONCLUSIONS

An iterative multipole method has been developed to model arbitrary configurations of spherical, elastic particles in either an elastic or viscoelastic matrix and has been implemented on a personal computer to test its functioning and performance. Initial results for systems of two to several hundred particles show that the model predicts many aspects of elastic wave behavior at the qualitative level. The model is also quantitatively accurate for simulating multiple scattering in dispersions with moderate particle densities ($\leqslant 30\%$). At higher particle densities, the model predictions deviate due to limitations in computing sufficiently high multipole orders ($n_{\max}=7-16$) for convergence of the addition theorems. The current model is also numerically unstable for large particle configurations in elastic materials at short wavelengths ($\lambda\sim$ particle diameter), but is partially to fully stable for either elastic materials at long wavelengths or viscoelastic materials.

APPENDIX

The η matrix elements from the elastic wave boundary condition matrix, Eq. (23), are presented below. The matrix elements are functions of the multipole order N, longitudinal wave vector k_L, shear wave vector k_S, and the sphere radius a. The spherical radial functions are denoted by $z_n(kr)$ and vary according to the radial function designated by the subscripts in Eq. (23) as $j=j_n(kr)$, $h=h_n^{(1)}(kr)$, or $g=h_n^{(2)}(kr)$:

$$\eta_{1z}=N\frac{z_N(k_La)}{k_La}-z_{N+1}(k_La), \tag{A1}$$

$$\eta_{2z}=i\sqrt{(N)(N+1)}\frac{z_N(k_Sa)}{k_Sa}, \tag{A2}$$

$$\eta_{3z}=z_N(k_Sa), \tag{A3}$$

$$\eta_{4z}=\frac{z_N(k_La)}{k_La}, \tag{A4}$$

$$\eta_{5z}=\frac{i}{\sqrt{(N)(N+1)}}\left[(N+1)\frac{z_N(k_Sa)}{k_Sa}-z_{N+1}(k_Sa)\right], \tag{A5}$$

$$\eta_{6z}=-\lambda k_Lz_N(k_La)+2\mu k_L\left\{\left[\frac{(N-1)(N)}{(k_La)^2}-1\right]z_N(k_La)+2\frac{z_{N+1}(k_La)}{k_La}\right\}, \tag{A6}$$

$$\eta_{7z}=2i\mu k_S\sqrt{(N)(N+1)}\left[(N-1)\frac{z_N(k_Sa)}{(k_Sa)^2}-\frac{z_{N+1}(k_Sa)}{k_Sa}\right], \tag{A7}$$

$$\eta_{8z} = \mu k_S \left[(N-1)\frac{z_N(k_S a)}{k_S a} - z_{N+1}(k_S a) \right], \tag{A8}$$

$$\eta_{9z} = 2\mu k_L \left[(N-1)\frac{z_N(k_L a)}{(k_L a)^2} - \frac{z_{N+1}(k_L a)}{k_L a} \right], \tag{A9}$$

$$\eta_{10z} = \frac{i\mu k_S}{\sqrt{(N)(N+1)}} \left[\left[\frac{2(N^2-1)}{(k_S a)^2} - 1 \right] z_N(k_S a) + 2\frac{z_{N+1}(k_S a)}{k_S a} \right]. \tag{A10}$$

Paranasal sinus ventilation by humming

(Received 21 June 2005; revised 16 February 2006; accepted 17 February 2006)

The gas nitric oxide (NO) is generated in the human paranasal sinuses and can be measured in nasally exhaled air. During humming, a marked increase in exhaled NO content has been observed. The acoustic phenomenon responsible for this evacuation of NO gas from the sinuses was analyzed. A tube model was constructed with a syringe containing NO gas attached radially. This tube was excited with an air stream modulated by a sine wave. Increased evacuation was observed whenever the syringe was not located at a pressure node of the exciting sine wave. A computer model of the system showed a good matching of observed pressure versus frequency data in the syringe resonator. The results thus suggest that the alternating pressure in the nasal cavity forces the air plug in the ostium of the paranasal sinus resonators to vibrate, thus expelling from the cavity NO gas, which is transported to free air by the exhalatory air stream. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188887]

I. INTRODUCTION

The maxillary sinuses, located in the skull bone just below the eyes (Fig. 1), contain an enzyme that produces large amounts of nitric oxide (NO) gas. NO is thought to play an important role in the airway immune defense system (Lundberg *et al.*, 1995).

The volume of the sinus cavities is on the order of a few cubic centimeters and they are connected to the nasal cavity via narrow bony passages, the sinus ostia (Knops *et al.*, 1993; Aust and Drettner, 1974). Hence, acoustically they can be regarded as Helmholtz resonators.

Recent investigations have shown that sinus NO is efficiently evacuated during the production of nasal murmur or humming (Weitzberg and Lundberg, 2002); great increases of the NO content in the air exhaled have been measured during humming, as illustrated in Fig. 2.

It can be hypothesized that the sound field present in the nasal tract during humming is responsible for the evacuation of the sinus NO gas. The aim of the present experiments was to test this hypothesis.

II. METHOD

Nasal murmur is associated with a compound nasal air stream containing a static and an alternating component. An air stream from a pressure tank was conducted through a tube. An alternating pressure component was added to this air stream. The alternating component was obtained from a loudspeaker enclosed in a 2 l box, attached to the tube by means of a T-joint. Three experiments were carried out with this compound airflow.

In Experiment A, the alternating pressure component consisted of a 20 s sine sweep from 800 down to 50 Hz. This compound airflow was fed to one nostril through an olive-shaped mouthpiece while the subjects held their breath and kept the velopharyngeal port closed. A rapid-response chemiluminescence system (Aerocrine AB, Stockholm, Sweden) was used to monitor the NO gas content in the air stream through the other nostril. This system was attached to another olive-shaped mouthpiece that completely sealed off the subject's nostril. The signal output from this device was connected to a computer-based system (Aerocrine NO system; Aerocrine AB), which yielded an instant on-screen display of flow, pressure, NO concentration, and NO output. The data were also recorded to computer files.

In Experiment B the air stream was passed through a tube, $L=700$ mm, inner diameter 20 mm, modeling the nasal tract, see Fig. 3. The compound airflow was fed to one end of the 700-mm-long tube (location marked "A" in the figure). The size of the T-joint was a few cm from the end of the tube. A syringe, modeling a maxillary sinus, ID 28.7 mm and with volume variable between 2.7 and 60 ml, was inserted radially into the tube. The diameter of the syringe tip, representing the ostium, was 1.7 mm and its length 9 mm. The Helmholtz resonance frequency of the syringe was varied by choosing volumes ranging between 40 and 2.7 ml. To estimate the resulting Helmholtz frequency the transfer function of the system, including the tube and the syringe, was recorded with the microphone at the free end of the tube. The frequency of the zero thus observed was accepted as the Helmholtz frequency of the syringe. These frequencies are listed in Table I.

The syringe was filled with NO gas 10 ppm (parts per million, AGA AB, Stockholm, Sweden). This low concentration does not affect the speed of sound appreciably. The NO content of the output gas was measured downstream of the syringe by means of the same chemiluminescence system, attached to a thin catheter that was inserted into the tube.

FIG. 1. Coronal section of a male showing the location of the maxillary sinuses in the skull bone.

Sound was recorded by an electret microphone, diameter 7 mm, length 16 mm (AV-JEFE TCM 110) attached to the microphone input of the computer.

In Experiment C a computer model was developed in order to examine the acoustic flow in the syringe neck, see Fig. 4. This model was compared with a tube model similar to that used in Experiment B, although without flow meter, without the connection to the pressure tank (marked "A" in Fig. 3), and without the constriction corresponding to the gas meter. The computer model included a loudspeaker model, two cavities (C_{v1} and C_{v2}), a lumped-element model of the tube, a radiation impedance (M_{al} and R_{al}), and a Helmholtz resonator. The Helmholtz resonator was modeled as a series resonator (C_{ah}, R_{ah}, M_{ah}). The tube was modeled by a number of sections (typically 26) each consisting of an acoustic mass, a compliance and two resistances ($M_{at}, C_{at}, R_{atp}, R_{ats}$). However, the model did not include the static flow T-joint.

III. RESULTS

It seemed reasonable to assume that the NO evacuation resulted from a driving of the airplug in the ostia of the

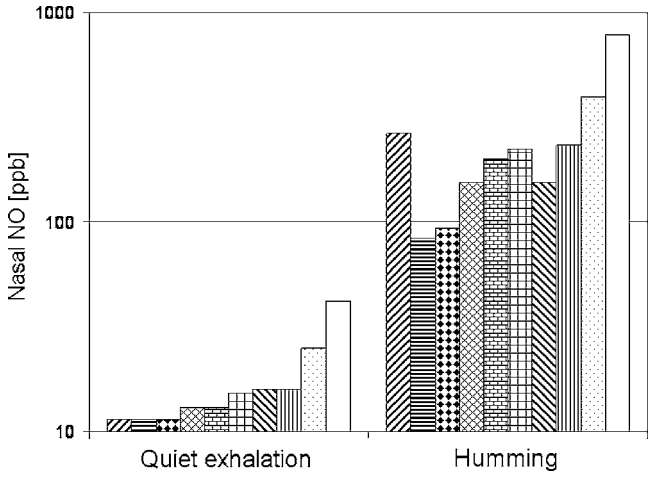

FIG. 2. NO content in parts per billion (ppb) in the air exhaled during silent exhalation and during humming (left and right columns). Column colors refer to subjects. Data from Weizberg and Lundberg, 2002.

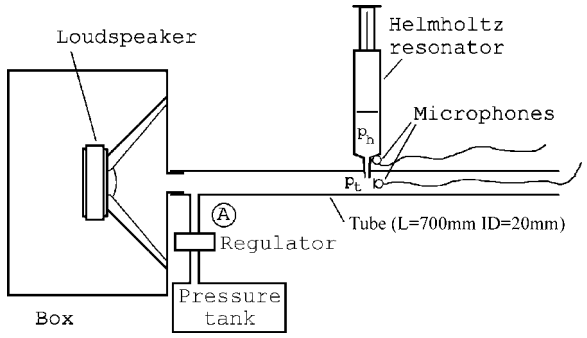

FIG. 3. Tube model of the nasal system, including the excitation system, used in Experiment B. One of the maxillary sinuses is represented by a syringe forming a Helmholtz resonator. The sound pressures in the Helmholtz resonator p_h and in the tube p_t were recorded by the microphones.

maxillary sinuses into and out of the resonator. It could further be assumed that this driving was caused by the sound wave in the nasal tract. If this assumption is correct, one might expect that for a constant excitation pressure the evacuation would reach a maximum at the Helmholtz resonance frequency, so the effect should vary with the frequency of the alternating component of the airflow. Also, the excitation of the airplug in the neck of the syringe should be influenced by the pressure amplitude at the neck location in the tube, which depends both on the standing wave pattern and the Helmholtz resonator's loading of the tube. If the neck is located in a pressure node, no evacuation should occur.

Experiment A, where the compound airflow was fed to a nostril, was carried out with two males and two females. As can be seen in Fig. 5 the NO content varied substantially during the sweep and peaked at different frequencies in these two subjects.

The lowest resonance frequencies of the entire tube system used in Experiment B with the compound airflow were measured by sine sweep in the absence of the syringe resonator. They were found to be about 250, 530, and 750 Hz, so the second resonance had a pressure node near $\frac{1}{2}$ of the wavelength, i.e., near $\frac{1}{2} \cdot c/530 = 0.33$ m from the tube end, and an antinode near $\frac{1}{4}$ of the wavelength, i.e., near $\frac{1}{4} \cdot c/530 = 0.16$ m from the tube end. A Helmholtz resonator located at a pressure node will not affect the corresponding tube resonance frequency, but in other locations the pressure distribution along the tube will be altered.

Figure 6 illustrates the relevance of the location of the resonator relative to the standing wave pattern of the tube. In the left graph the resonator was placed at the node of the second resonance, and in the right it was placed off this

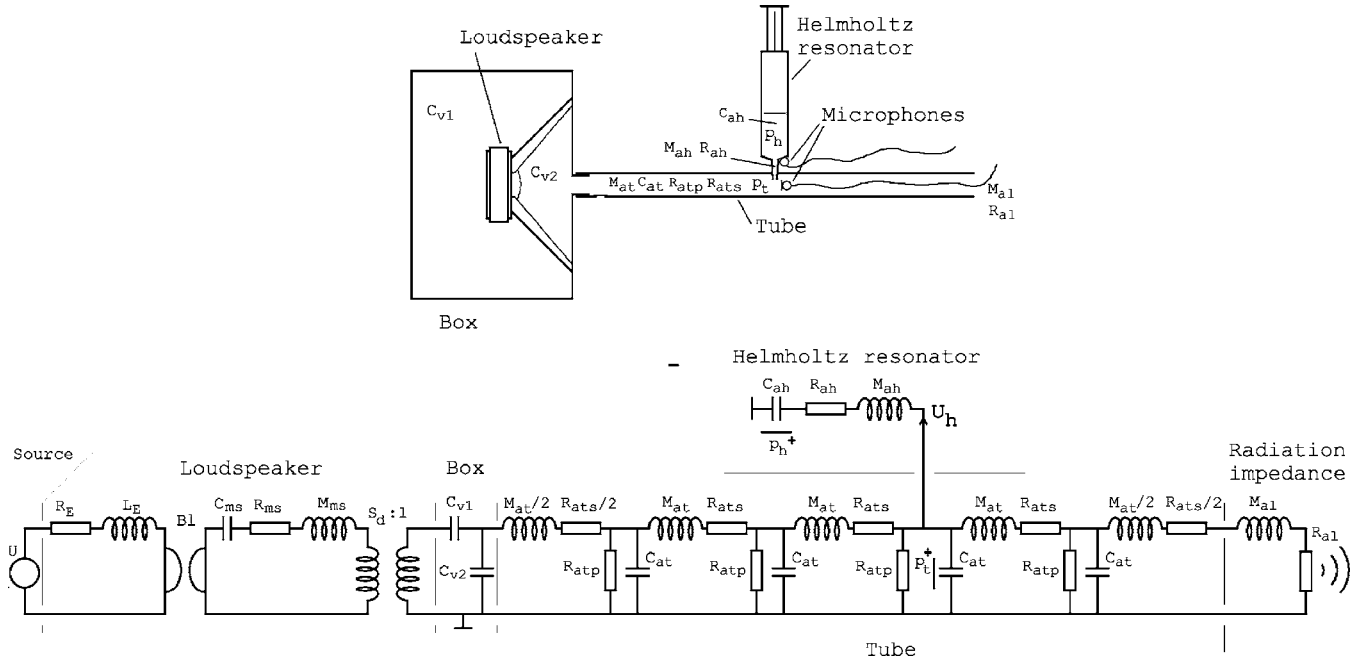

FIG. 4. Tube model and its electrical analog (upper and lower figures). The tube model included a classic loudspeaker model, two cavities (C_{v1} and C_{v2}), a lumped-element model of the tube, a radiation impedance (M_{al} and R_{al}), and a number of sections, each consisting of an acoustic mass, a compliance and two resistances ($M_{at}, C_{at}, R_{atp}, R_{ats}$). The Helmholtz resonator was modeled as a series resonator (C_{ah}, R_{ah}, M_{ah}). In the electrical analog only four tube sections are shown. The flow U_h is of prime interest for the ventilation of NO gas from the Helmholtz cavity.

node, approximately at $L/4$, i.e., about 0.17 m from the free end of the tube. In both cases the excitation frequency was manually varied according to the sequence F2, F1, F1, F2, remaining at each frequency for about 5 s and with an interval of at least 1 s between excitations. The volume of the resonator was chosen such that the resonance appeared at 183 Hz. The occurrence of NO gas did not exceed the background level when the resonator was located at the F2 node and approximately 10 ppb (parts per billion) in the other case. The evacuation was quite efficient at 249 Hz.

The relevance of the Helmholtz resonance is illustrated in Fig. 7 showing the evacuation of the NO gas at 249 and 530 Hz, i.e., at the first and second tube resonance. The evacuation was more efficient when the Helmholtz frequency was 250 Hz than when it was tuned to 305 Hz.

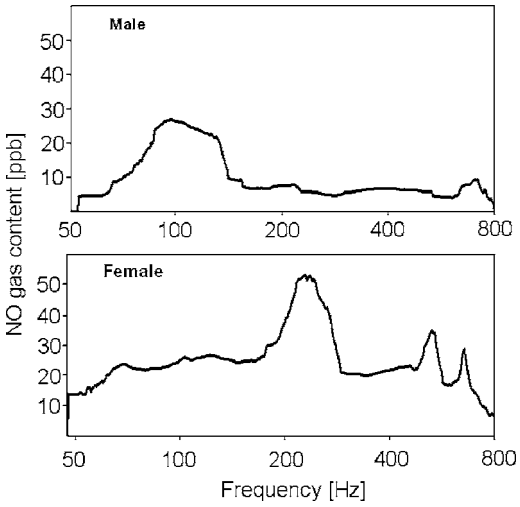

FIG. 5. NO-gas content in ppb obtained from one nostril of a male and a female subject, when a sine sweep from 800 down to 50 Hz plus a dc airflow was fed to the other nostril while the subjects held their breath and kept their velopharyngeal port closed.

These observations illustrate the complex acoustic conditions of the system. To gain a better understanding of this system, co-author S.G. developed the computer model, described earlier (see Fig. 4). This model was tested in Experiment C.

The inclusion in the model of the loudspeaker and the cavities of the box were essential for a good fit with the data observed in the tube model. The loudspeaker and the box were simulated as lumped elements (see, e.g., Small, 1972) using parameters from the manufacturer's datasheet, except for the voice coil inductance, which was considered lossy according to Leach (2002). The values of the lossy inductance were obtained by matching the model against the electrical impedance curve supplied by the manufacturer.

The compliances C_{v1} and C_{v2} were calculated as

$$C_{v1} = \frac{V_1}{\rho_0 c^2}, \tag{1}$$

$$C_{v2} = \frac{V_2}{\rho_0 c^2}, \tag{2}$$

where V_1 and V_2 are the volumes of the cavities, ρ_0 is the density of air (1.2 kg/m^3), and c is the sound velocity in air (345 m/s). The lumped elements of the tube were calculated as

$$M_{at} = \frac{L}{n\rho_0 S_t}, \tag{3}$$

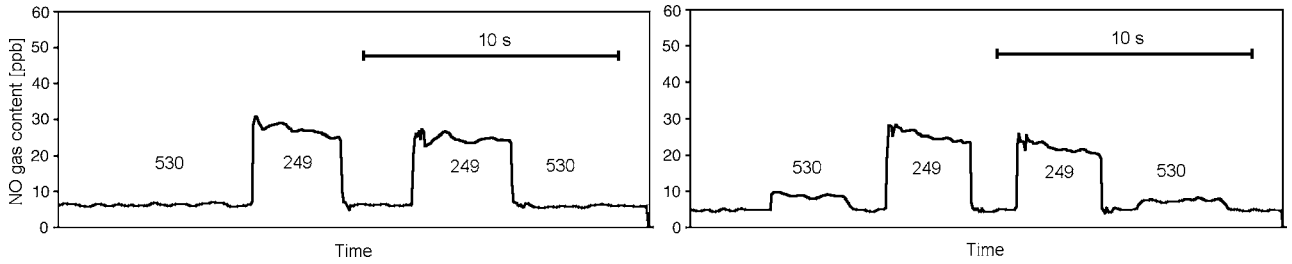

FIG. 6. NO-gas content in ppb observed in the tube model when it was excited with sinewaves at 530, 249, 249, and 530 Hz corresponding to the two lowest resonances in the tube in the absence of the Helmholtz resonator. In the left graph the resonator, tuned to 183 Hz with a 40 ml volume, was placed at the node of the second resonance (530 Hz), and in the right it was placed off this node.

$$C_{at} = \frac{S_t L}{n\rho_0 c^2}, \tag{4}$$

$$R_{atp} = \sqrt{\frac{M_{at}}{C_{at}}} \cdot Q_{\text{tubep}} \cdot n, \tag{5}$$

$$R_{ats} = \frac{\sqrt{M_{at}/C_{at}}}{n \cdot Q_{\text{tubes}}}, \tag{6}$$

where S_t is the cross-sectional area of the tube, L is the total length of the tube, Q_{tubes} and Q_{tubep} are values describing the losses, and n is the number of tube sections.

The Helmholtz resonator was modeled by entering the volume of the syringe cavity V_h, the Helmholtz frequency f_h, and a Q value Q_h. The software also optionally provided a possibility to lock the value of M_{ah} and recalculate f_h when V_h was changed [Eq. (10)],

$$C_{ah} = \frac{V_h}{\rho_0 c^2}, \tag{7}$$

$$M_{ah} = \frac{1}{C_{ah}(2\pi f_h)^2}, \tag{8}$$

$$R_{ah} = \frac{\sqrt{M_{ah}/C_{ah}}}{Q_h}, \tag{9}$$

$$f_h = \frac{1}{2\pi\sqrt{M_{ah}C_{ah}}}. \tag{10}$$

The radiation impedance was modeled as the low-frequency behavior of a baffled piston:

$$R_{al} = \frac{\rho_0}{2\pi c}\omega^2, \tag{11}$$

$$M_{at} = \frac{8\rho_0}{3\pi r_t}, \tag{12}$$

where ω is the angular frequency and r_t is the radius of the tube. The use of the baffled piston impedance is an approximation; the real tube end was not baffled. However, the error caused by this approximation can be assumed to be small, since the radiation impedance of both a baffled piston and an unbaffled tube is small as compared to the impedance of the tube (Beranek, 1954).

The results obtained from this computer model were compared to those obtained from a simplified tube model, without the static flow T-joint and the gas meter. Moreover, for practical reasons a different syringe was used from that used in Experiment B.

Figure 8 shows the agreement between the two models with respect to the pressure driving the resonator, and the pressure inside the resonator cavity. The testing was performed for resonator volumes V_h of 5, 10, 20, 40, and 60 ml. The associated Helmholtz resonance frequencies are listed in Table II. The results show that the computer model was capable of predicting the behavior of the physical model up to about 2 kHz. Some of the parameters had to be manually adjusted in order to make the curves fit. This was particularly true for the resistive losses, which are hard to estimate from the geometry of the model. However, once a good match was achieved, all parameters were kept constant, except for the V_h parameter which was set to the values above-listed.

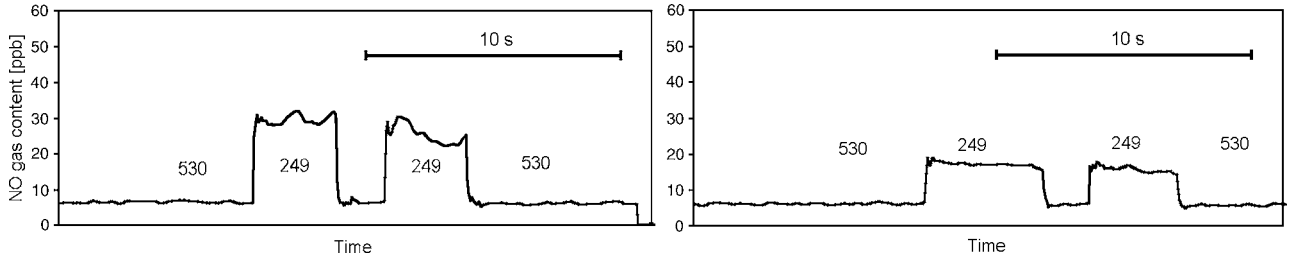

FIG. 7. NO-gas content in ppb observed in the tube model when it was excited with sinewaves at 530, 249, 249, and 530 Hz corresponding to the two lowest resonances in the tube in the absence of the Helmholtz resonator. The Helmholtz resonator was placed at the F2 node, near $L/2$. The resonator volumes were 20 and 10 ml, resulting in Helmholtz frequences at 255 Hz and to 305 Hz (left and right graphs, respectively).

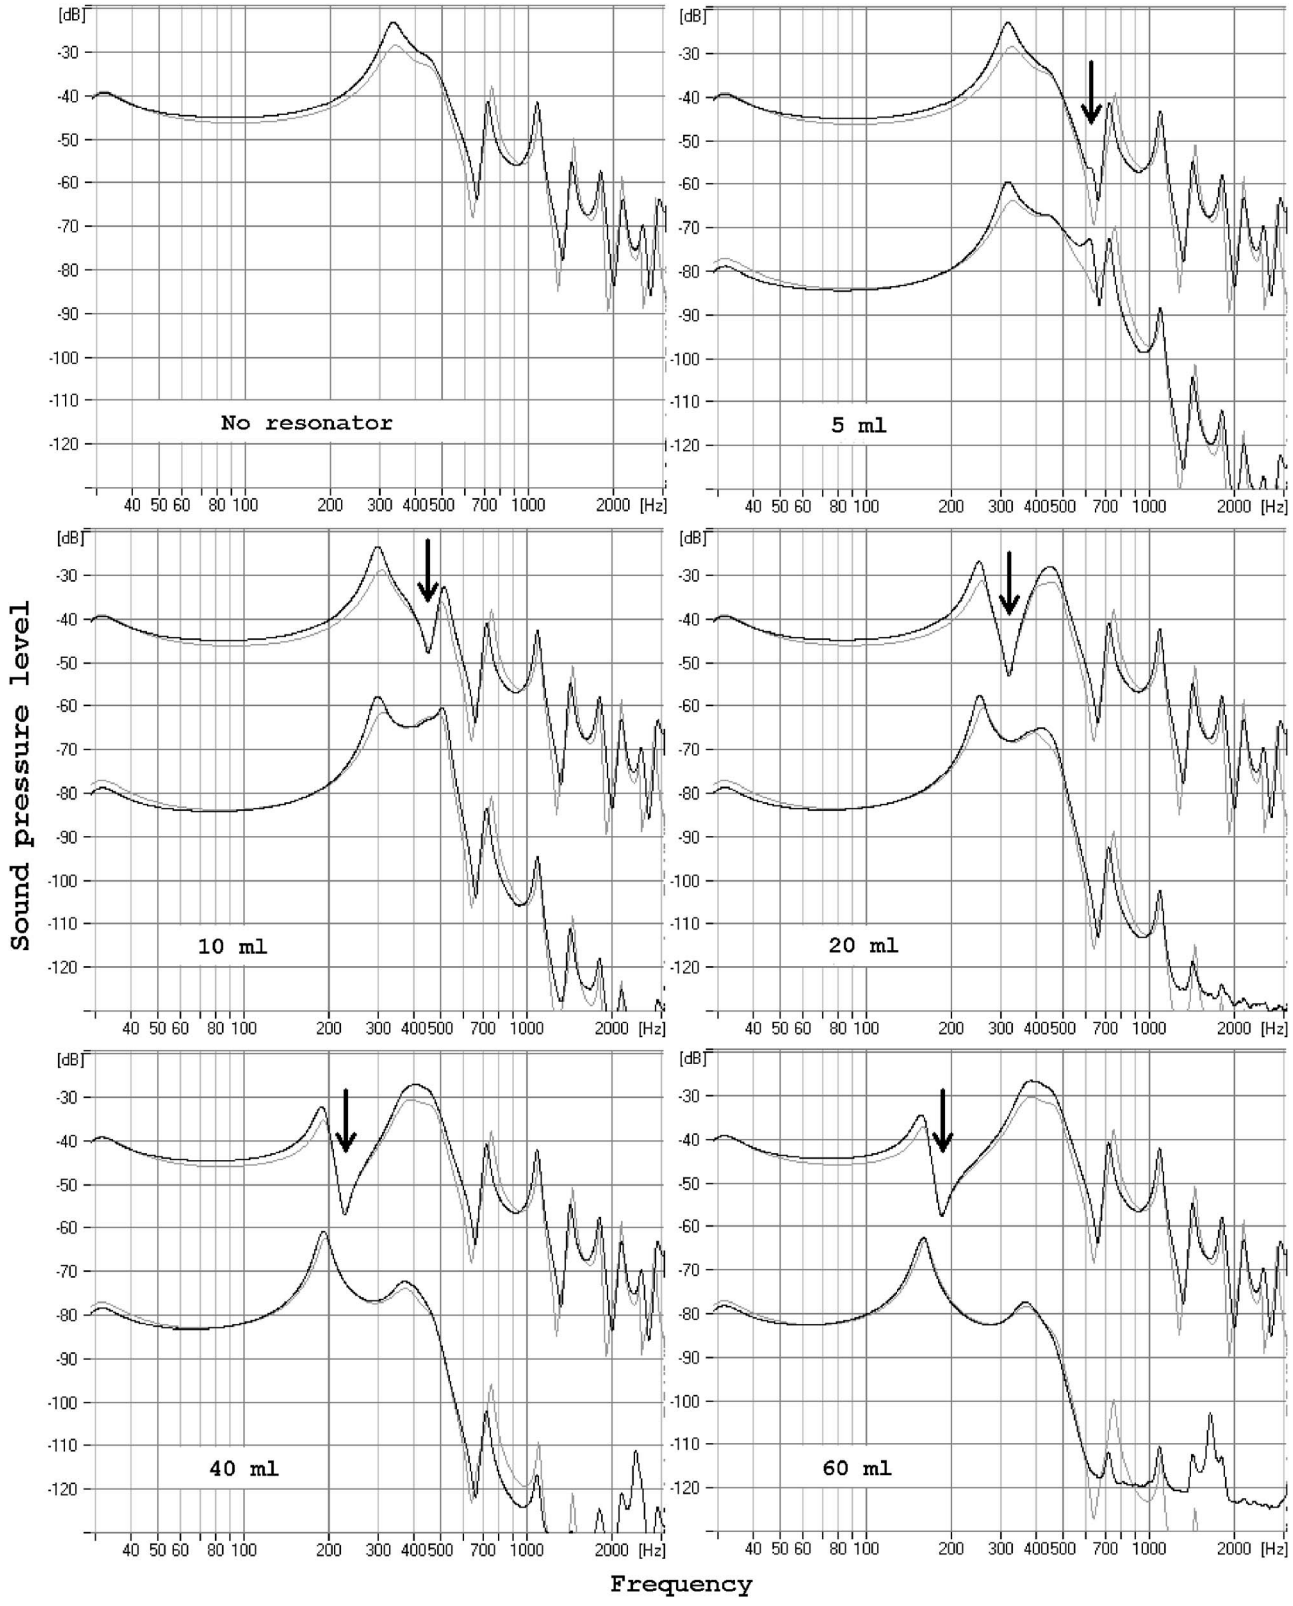

FIG. 8. Simulated and measured data. The top left panel represents the p_t pressure, when the Helmholtz resonator was removed and the hole was plugged. The other five panels represent five different resonator volumes (5, 10, 20, 40, and 60 ml, respectively). In each graph the upper curves represent the driving pressure p_t, and the lower the pressure inside the Helmholtz resonator cavity p_h. The black curves were measured on the physical model and the gray curves were derived from the computer model. The arrows indicate the Helmholtz frequency. The reference for the sound pressure level was arbitrary.

After the iterative manual adjustments, the following parameter values were used: $Q_{\text{tubes}}=30$, $Q_{\text{tubep}}=6$, $Q_h=13$, number of sections: 26. The volumes of the two cavities were: $V_1=2.2$ l, $V_2=0.19$ l. These volumes were also manually adjusted, since the actual volumes were hard to measure exactly due to the space occupied by the loudspeaker driver, and also the isothermal effects of the damping material in compartment V_1.

TABLE II. Volumes and calculated Helmholtz frequencies of the syringe used in Experiment C.

Volume (ml)	Frequency (Hz)
60	185
40	224
20	317
10	448
5	634

The loudspeaker parameters, taken from the data sheet and the impedance curve, were: $V_{as}=10.69$ l, Bl=6.11 N/A, $f_s=54.94$ Hz, $R_e=6.28\ \Omega$, $Q_{ts}=0.35$, lossy Le parameters (Leach, 2002) $K=3.18\times10^{-7}$, $n=0.78$, $S_d=84$ cm^2. The tube length was $L=465$ mm, tube diameter $d=20$ mm.

M_{ah} was determined for one of the syringe volumes by adjusting it such that the dip at F_h in the model's pressure curve coincided with the measured data. This M_{ah} value was then kept when using Eq. (10) for calculating the pressure curves for other syringe volumes.

The displacement of air in the resonator neck is proportional to the pressure inside the cavity. Furthermore, the maximum displacement amplitude in the neck does *not* occur at the Helmholtz resonance frequency f_h. The reason can be seen in the curve representing the driving pressure, which shows a minimum at f_h. Such a driving pressure minimum obviously will counteract an efficient excitation of the Helmholtz resonator. This indicates that the frequency for maximum exchange of NO gas in the paranasal sinuses probably cannot be predicted from dimensions of the sinuses and the channel to the nasal cavities alone. Also the rest of the nasal cavity would have to be taken into account.

IV. DISCUSSION

Our results appear to explain why the NO gas is evacuated from the paranasal sinuses during humming (Weitzberg and Lundberg, 2002); the oscillatory movement of the alternating pressure in the nasal tract at the ostium forces the airplug in the ostium to oscillate, thus increasing the NO gas evacuation. If this explanation is correct, the magnitude of the gas evacuation should be frequency dependent, and such a frequency dependence was also observed in Experiment A. The phenomenon was further examined by means of the physical model used in Experiment B. A syringe modeling a maxillary sinus was filled with NO gas and a dc flow was inserted near the loudspeaker end of the tube, at "A" in Fig. 3. It was shown that the rate of evacuation of NO gas varied depending on the frequency induced by the loudspeaker.

In Experiment C, we focused on the displacement of air in the resonator neck. It can be assumed that this air displacement is closely related to the ventilation of NO gas. As mentioned before, the displacement and flow in the physical model can be indirectly measured in terms of the pressure inside the resonator cavity. Since this pressure appears as a result of the flow through the neck into the cavity, the displacement is proportional to the pressure and the flow to its derivative.

It could be assumed that the flow U_h could be affected by several factors. One would be the relation between the Helmholtz frequency and the exciting frequency. A maximum flow could be expected if these frequencies are identical and if the exciting pressure is constant. On the other hand, the exciting pressure varies due to resonances in the tube. If the Helmholtz resonator neck is placed in a pressure antinode of such a resonance, a maximum could be expected to occur since the exciting pressure would then be maximized. However, the acoustic load from the resonator affects the resonances in the tube. So, if the Helmholtz resonator is placed at position where a pressure node would be expected in the unloaded tube, the node pressure drops. The simulations and measurements in this study indicate that the net effect of this is that two U_h flow maxima occur, one at each side of the original resonance/node frequency.

The manual matching of the computer model to the measured data was highly enlightening. It turned out to be fairly easy to achieve a good agreement in the low-frequency range ($<$500 Hz). However, in order to achieve a good match at higher frequencies, up to 2–3 kHz, the accuracy of the microphone placement and of the dimensions of the box, tube, and resonator turned out to be important. Another experience with the tube model was that it was fairly easy to overload the microphones, since the sound pressure inside the tube and resonator can easily reach very high levels.

Our results support the assumption that the evacuation of the NO gas from the paranasal sinuses is caused by sound pressure produced in the nasal tract during humming. The basic mechanism seems to be that the sound pressure causes the airplug in the ostium to move in and out of the sinus, thereby driving exhalation air into the cavity which then reacts by expelling a portion of the gas it contains.

The magnitude of the effect depends on the frequency. No gas evacuation occurs if the ostium is located at a pressure node. The risk for this case to occur in reality is small, however, since voice F0 is typically in the range 100–200 Hz, i.e., a quarter wavelength of 0.85–0.43 m. The frequency that would fail to ventilate the sinus would be much higher than F0, i.e., an overtone, but the lower spectrum partials would contribute to the ventilation.

Another factor that could be assumed to affect the ventilation is the size of the sinus. On the other hand, a doubling of the Helmholtz volume would cause a resonance frequency shift of no more than 1.4, other factors kept constant. Thus, the size of the sinus would have a modest influence on the ventilation effect. The dimensions of the ostium, on the other hand, would be influential. For example, an obstructed ostium, such as during sinusitis, will obviously prevent all NO-gas ventilation. Indeed, in patients with chronic sinusitis and completely blocked sinus ostia, the humming-induced nasal NO increase is completely absent (Lundberg *et al.*, 2003). The physiological and pathophysiological aspects of humming, nasal NO, and sinus ventilation have been recently discussed in more detail (Weitzberg and Lundberg, 2002; Maniscalco *et al.*, 2003; Lundberg *et al.*, 1995).

Singers often regard the nasal tract as an important part of their resonator system. Evidence of a more or less open velopharyngeal port was recently found for the vowel [a] as

sung by professional opera singers (Birch *et al.*, 2002). Thus in many singers a constant nasal air stream could be measured when the singers sang this vowel. It would be interesting and easy to use the current experimental setup for checking the relevance of the paranasal sinuses to such singers. NO gas in the nasal airflow should be a reliable indicator of excitation of the sinuses.

V. SUMMARY AND CONCLUSIONS

In this study we analyzed the acoustic background of the NO gas evacuation from the paranasal sinuses that has previously been observed to occur during humming. Experiment A revealed that this evacuation varied with frequency and Experiment B elucidated the acoustics underlying this frequency dependence by means of gas evacuation measurements in a tube provided with a radially mounted Helmholtz resonator containing this gas. Experiment C showed that the phenomenon can be explained in terms of a computer model and accurately replicated the complex transfer functions measured in a system similar to that used in experiment B. The computer model could easily be adjusted so as to reflect geometrical data obtained from human subjects. However, it is clear already from the present rather coarse modeling of the nasal resonator system that the increased NO ventilation during nasal murmur can be explained by the acoustic flow into and out of the paranasal sinuses. These sinuses act as Helmholtz resonators with the necks corresponding to the ostia. The sinusoidally alternating acoustic pressure forces the airplug in the Helmholtz resonator neck to vibrate, thus expelling NO from the cavity. This gas is transported to free air by the exhalatory air stream.

Active control of buzz-saw tones: Experimental results from a laboratory-scale, no-flow rig

M. J. Wilkinson and P. F. Joseph[a)]
Institute of Sound and Vibration Research, University of Southampton, Southampton, SO17 1BJ, United Kingdom

(Received 15 March 2005; revised 20 February 2006; accepted 28 February 2006)

This paper details the results of an experiment on a small scale no-flow rig to control a spinning mode with similar characteristics to the modes generated by buzz-saw noise. The spinning mode ($m=-3$, $n=1$) is generated by a mode synthesizer ring which has similar characteristics to that of a low frequency buzz-saw mode. A control system using seven microphones and seven control actuators is used to minimize the sum of the squared pressures at the duct wall using a filtered reference least mean squares (FXLMS) algorithm. It is shown that at certain frequencies the sound power transmitted to the duct termination is reduced by 14.5 dB. The control mechanisms at different frequency ranges are identified and discussed with reference to computer simulations. It is shown that cut-off modes excited by the secondary actuator array have a significant effect on control performance at frequencies close to the cut-on frequency of the ($m=-4$, $n=1$) mode. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188817]

I. INTRODUCTION

Buzz-saw noise is the noise radiated forward of aircraft engines on take-off when the tip speed of the fan becomes supersonic. Currently, passive liner sections are used to attenuate this subjectively annoying tonal sound field. However, the liners do not have sufficiently good performance to efficiently attenuate the low frequency components of the buzz-saw noise field. It is therefore proposed that active noise control (ANC) techniques be employed either after, or embedded into, the linear to attenuate these low frequency tones. This paper describes a laboratory experiment aimed at assessing the performance of an active control system in controlling a low-order spinning mode in a duct, typical of that found in a low frequency buzz-saw tone.

Characteristics of buzz-saw noise. Buzz-saw tones occur at multiples (engine orders, EO) of the shaft rotational frequency of the fan. The sound field at each EO in the duct comprises a single propagating spinning modes of order $m=m_B=\mathrm{EO}$. The pressure due to buzz-saw modes can therefore be expressed as the sum of the modal contributions summed over all multiples of the shaft rotational frequencies $\omega_l=l\Omega$,

$$p(x,r,\theta,t)=\sum_{l=1}^{\infty}\sum_{m=-\infty}^{\infty}\sum_{n=1}^{\infty}A_{m,n,l}\psi_{m,n}(r,\theta)\times\exp\left(ik_l\left(\frac{\alpha_{mnl}-M_x}{(1-M_x^2)}\right)x\right)e^{-i\omega_l t} \quad (1)$$

where

$$\alpha_{mnl}=\sqrt{1-\frac{k_{r_{m,n}}^2}{k_l^2}(1-M_x^2)}. \quad (2)$$

In the above equation, k_l is the acoustic wave number ω_l/c.

Each of the spinning modes comprises a number of radial modes (of order n). At typical take-off fan tip speeds only the first order radial mode $n=1$ is usually cut-on and hence can radiate efficiently to the far-field. This simple modal structure, and the low frequencies at which it occurs, suggests that active control may be potentially very effective in reducing the buzz-saw sound field.

Previous active control studies on aircraft engines (Fruteau *et al.* 2000; Joseph *et al.* 1999a, 1999b; Kousen and Verdon, 1994; Kraft and Kontos, 1993; Maier *et al.*, 2001; Risi *et al.*, 1996; Smith and Burdisso, 1999; Thomas *et al.*, 1993; Walker, 2001) have focused on the control of rotor-stator interaction tones, which are radiated at subsonic tip-speeds and at the blade passing frequencies of the fan, i.e., EO=B, where B is the number of blades. At these higher frequencies, the sound field is more spatially complex since there is a potentially much larger number of modes which can propagate, whose spinning mode order m is given by the well-known Tyler and Sofrin condition (Tyler and Sofrin, 1962). Each of these spinning modes comprises multiple radial modes. Moreover, at these higher frequencies, there is also a greater possibility for the control actuators to excite large numbers of additional modes. This effect is known as modal spillover. The active control of buzz-saw tones should therefore be much more effective, and simpler to implement, than rotor-stator interaction tones.

The investigation by Walker (Walker, 2001) on the control of rotor-stator interaction tones discusses the degradation of control performance due to cut-off modes excited by the actuator array. This effect is also relevant in the control of buzz-saw modes. However, most of the spillover modes excited by the actuator array on our experimental rig are evanescent. Their effect on control performance is discussed in the final section of this paper.

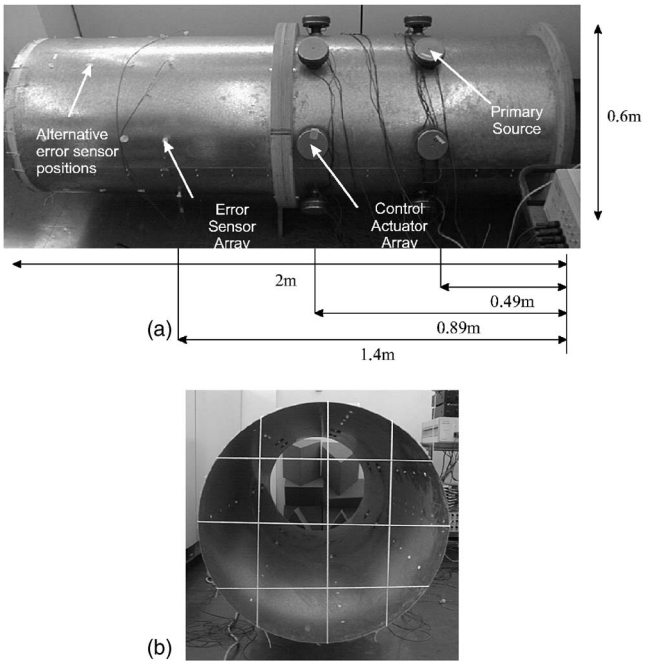

FIG. 1. (a) The duct section and active control system, (b) the measurement grid at the duct "inlet."

This paper describes the results from a laboratory experiment aimed at investigating the performance of a simple active control system in attenuating a single low-order spinning mode at frequencies above and below its cut-off frequency. This spinning mode was excited by a mode synthesizer ring in order to simulate the modal characteristics of a buzz-saw mode at EO=3. The control system consisted of a single ring of seven error microphones and a single ring of seven control actuators, situated in a circular duct made from steel plate of length 2 m and radius 0.3 m. Note that this number of sources and sensors is greater than the minimum criteria suggested by Walker (2001). The duct and the positions of the sources and sensors are shown in Fig. 1(a).

II. THE EXPERIMENTAL RIG

A. Mode synthesizer ring

Each of seven loudspeakers used in the primary source actuator ring shown to the far right of the duct in Fig. 1(a) was driven by a single frequency signal such that adjacent loudspeakers were delayed in time corresponding to a phase shift of $6\pi/7$. This phase variation is designed to excite the $m=-3$ spinning mode, independent of the excitation frequency. The amplitude and phase response of the loudspeakers were measured to be within 3 dB and 20° of each other and hence some degree of spillover into extraneous modes will occur, as occurs in a real engine duct.

In order to assess the performance of the mode synthesizer array in exciting this mode, a spinning mode decomposition was performed on the measured complex pressure amplitudes $p(\theta_l,\omega)$ made at $l=1-7$ error microphones. The procedure for determining these complex amplitudes from the measured time series is described in Wilkinson (2004). This was performed using the Fourier series decomposition,

$$\hat{a}_m(\omega)=\frac{1}{L}\sum_{l=1}^{L}p(\theta_l,\omega)e^{-im\theta_l}\left(\frac{-(L-1)}{2}\leqslant m\leqslant\frac{(L-1)}{2}\right). \tag{3}$$

Thus it is assumed that contributions to the pressure from cut-off modes $|m|\geqslant 4$ can be neglected. We will show in Sec. V that this is not the case after control and that the inability to discriminate the $m=\pm 4$ cut-off modes from propagating modes of lower order degrades control performance.

Control was implemented separately at 14 discrete frequencies between 740 and 950 Hz. This frequency range corresponds to cut-off ratios of $\zeta=0.97$ to 1.24 for the $(-3,1)$ mode. Note that by assuming $M_x=0$ the modal cut-off ratio ζ may be related to that produced by a rotor with blade tip Mach number M_t by

$$\zeta=\frac{mM_t}{k_{r_{m,n}}a}, \tag{4}$$

where $k_{r_{m,n}}$ is the radial component of the acoustic wave number and a is the duct radius. Equation (4) shows that the above-given range of ζ corresponds to a range of M_t of 1.36–1.74, which is significantly higher than the take off fan speed of full-scale rotors. This mode is therefore usually cut-off in a real engine duct. Nevertheless, many of the control principles established here also apply at higher engine orders.

Figure 2 shows the result of the spinning mode decomposition at each frequency.

The spinning mode amplitude of the $(-3,1)$ mode is observed to be approximately 10–20 dB greater than those of the extraneous modes, excited due to loudspeaker mismatch. Note that in this measurement, it is assumed that the contribution from the cut-off $m=\pm 4$ modes can be neglected due to the large separation distance between primary ring and error sensor ring.

B. The FXLMS controller

The filtered-x least mean squares (LMS) algorithm adopted here is a modification of the LMS algorithm and has been successfully used in earlier active control system applications in aircraft engines (Maier *et al.*, 2001; Thomas *et al.*, 1993). The approach followed in the experiment is a modified version of the multichannel control approach used by Elliott *et al.* (1987). In the experiment the excitation frequency is known. A reference signal is generated by the controller and not from a reference microphone in the duct. At each sample time, with the modified FXLMS algorithm the following operations are performed.

(1) The reference signal for the nth sample is generated using

$$x(n)=\cos(\omega nT).$$

(2) The matrix of filtered reference signals $\mathbf{R}(n)$ is constructed using the amplitude and phase of the single frequency transfer function matrix $\mathbf{Z}$, with elements of the form

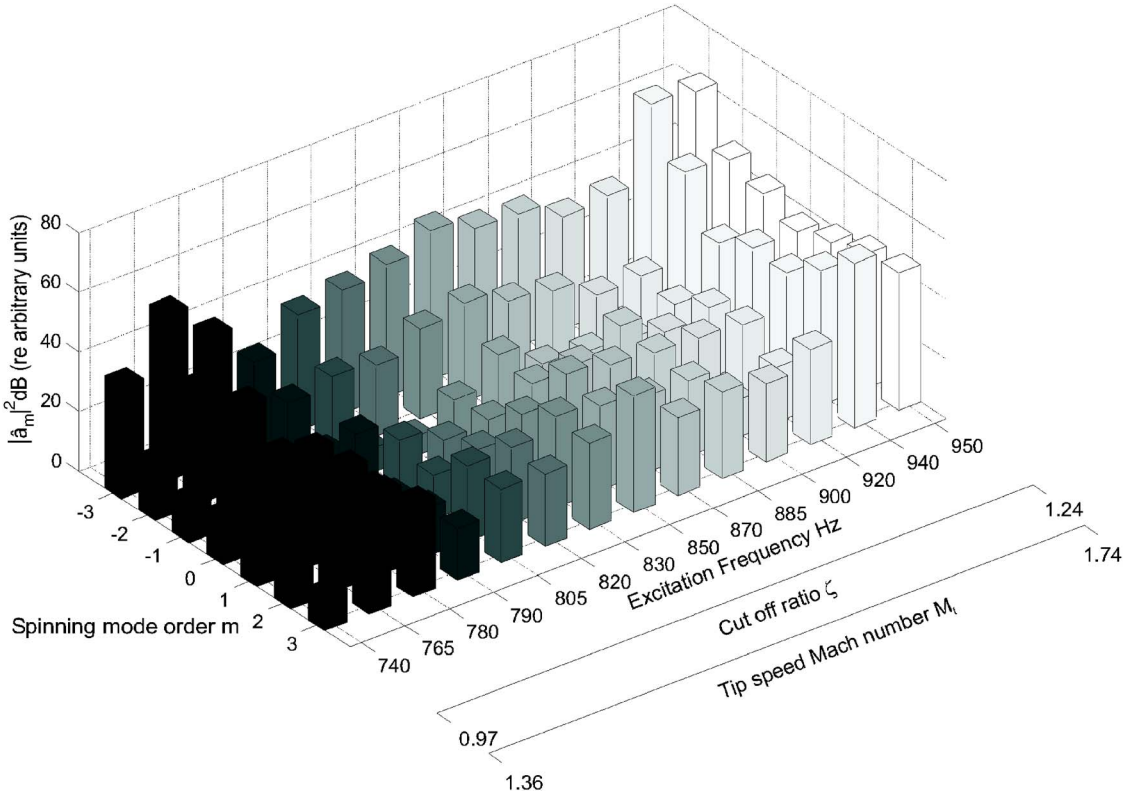

FIG. 2. Measured spinning mode decomposition at the wall at each excitation frequency.

$Z_{ml}=A_{ml}e^{i\phi_{ml}}$. The transfer functions are measured offline, prior to control. The internally generated reference signals are of the form,

$$\hat{r}_{ml}(n) = A_{ml}\cos(\omega nT + \phi_{ml}).$$

(3) The actuator u_m signals are generated by filtering the reference signal $\mathbf{x}=[x(n)x(n-1)]^T$ using the current values of the filter coefficients $\mathbf{w}(n)$,

$$u_m(n) = \mathbf{w}^T\mathbf{x}.$$

(4) Finally, the error signal $e(n)$ is obtained from the voltage signal measured at the microphone array. This is acquired for the nth sample and used together with the filtered reference signals to update the filter coefficients, according to

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \alpha\mathbf{R}^T e(n)$$

where $\mathbf{R} = [\mathbf{R}(n)|\mathbf{R}(n-1)]$.

III. COMPUTER MODEL

The measured control performance from this experiment will be compared against the performance predicted by the computer model detailed in Wilkinson (2004). The model includes the following assumptions:

(1) The engine inlet is a finite-length, axisymmetric circular duct with rigid walls containing an axial, uniform mean flow.
(2) The modal amplitudes of the primary field in the absence of reflections in the duct (the sound field generated by the buzz-saw noise) are known at the fan plane x_f.
(3) The secondary sources are mounted flush with the duct wall and behave as point monopoles.
(4) At tip speeds close to $M_t=1$, the buzz-saw tone associated with each engine order EO generates a single propagating primary mode $m=m_B=$EO (McAlpine and Fisher, 2001), which propagates linearly along the duct.
(5) Blockage of the sound field by the rotor and stator can be neglected.

IV. EXPERIMENTAL RESULTS

The active control system was used to minimize the sum of the squared pressures at the error sensors at 14 excitation frequencies in the frequency range $f_{-3,1}<f<f_{-4,1}$ where $f_{-3,1}$ and $f_{-4,1}$ are the cut-off frequencies of the $(-3,1)$ and $(-4,1)$ modes, respectively. Control was implemented at one frequency at a time. The reduction in the sum of the squared pressures determined using the signals recorded at the microphone array, before and after control, is plotted in Fig. 3. In this first experiment the error sensors are positioned closest to the secondary source array at a separation distance of 0.51 m. The effect on control performance of increasing the separation distance will be investigated in later sections.

The pressure reduction at the error sensors is shown to vary from 14 dB in the worst case at 900 Hz to 39 dB at

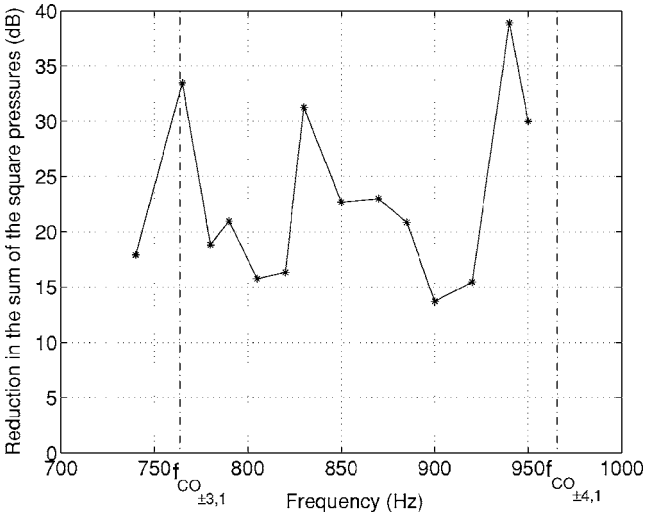

FIG. 3. Sound pressure level reduction with varying excitation frequency.

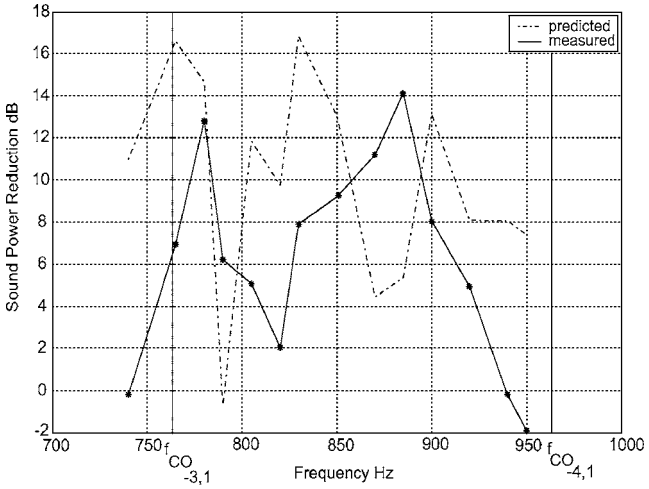

FIG. 4. Sound power level reduction with varying excitation frequency.

940 Hz. This variation in sound pressure reduction is likely to be due to inaccuracies, at each excitation frequency, in the transfer function measurements.

The corresponding reduction in the sound power level transmitted downstream of the error sensors after control is plotted in Fig. 4 (solid curve).

The sound power reduction is determined by integrating the axial intensity component over the duct termination using an intensity probe before and after control. This procedure was achieved by dividing the duct face into 16 sections, as shown in Fig. 1(b). The area-averaged intensity $\langle \bar{I}_n \rangle_i$ flowing normally across each section i was then measured and summed to give the total sound power.

The sound power reduction is observed to be highly frequency dependent, but unrelated to the variation in sound pressure reductions plotted in Fig. 3. The levels of sound power reduction are shown to be typically 10–20 dB less than the sound pressure reduction, suggesting that the sound power reduction cannot be directly inferred by the sound pressure reduction at the error sensors. The control mechanism, and hence the relationship between sound pressure and sound power, will be discussed in Sec. V.

Also plotted in Fig. 4 (dashed curve) is the sound power reduction predicted by the computer model. The level of agreement is generally poor. At most excitation frequencies the model predictions a sound power reduction within 5–10 dB of the measured value. The discrepancy between measured and predicted control performance is mainly due to the assumption in the model that the pressure is driven perfectly to zero. In the experiment, however, the pressure level is only reduced by between 20 and 40 dB. The precise phase relationship between modes after control, predicted by the computer model, is therefore not realized in practice, leading to the large discrepancies observed in Fig. 4. Nevertheless, we shall see in Fig. 6 that predictions obtained from the model of the detailed variation in induct pressure are, in general, in excellent qualitative agreement with measurement. Despite the poor agreement between predicted and measured sound power reduction, therefore, the theoretical model will be shown to provide useful insight into the con-

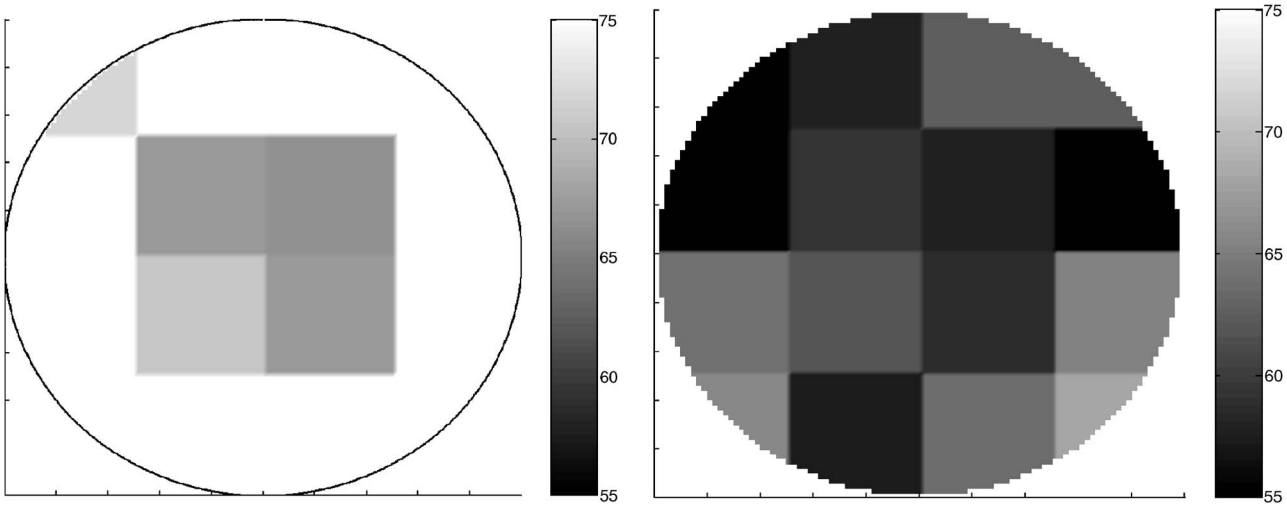

FIG. 5. Measured sound intensity distribution before control (a) and after control (b) at 885 Hz.

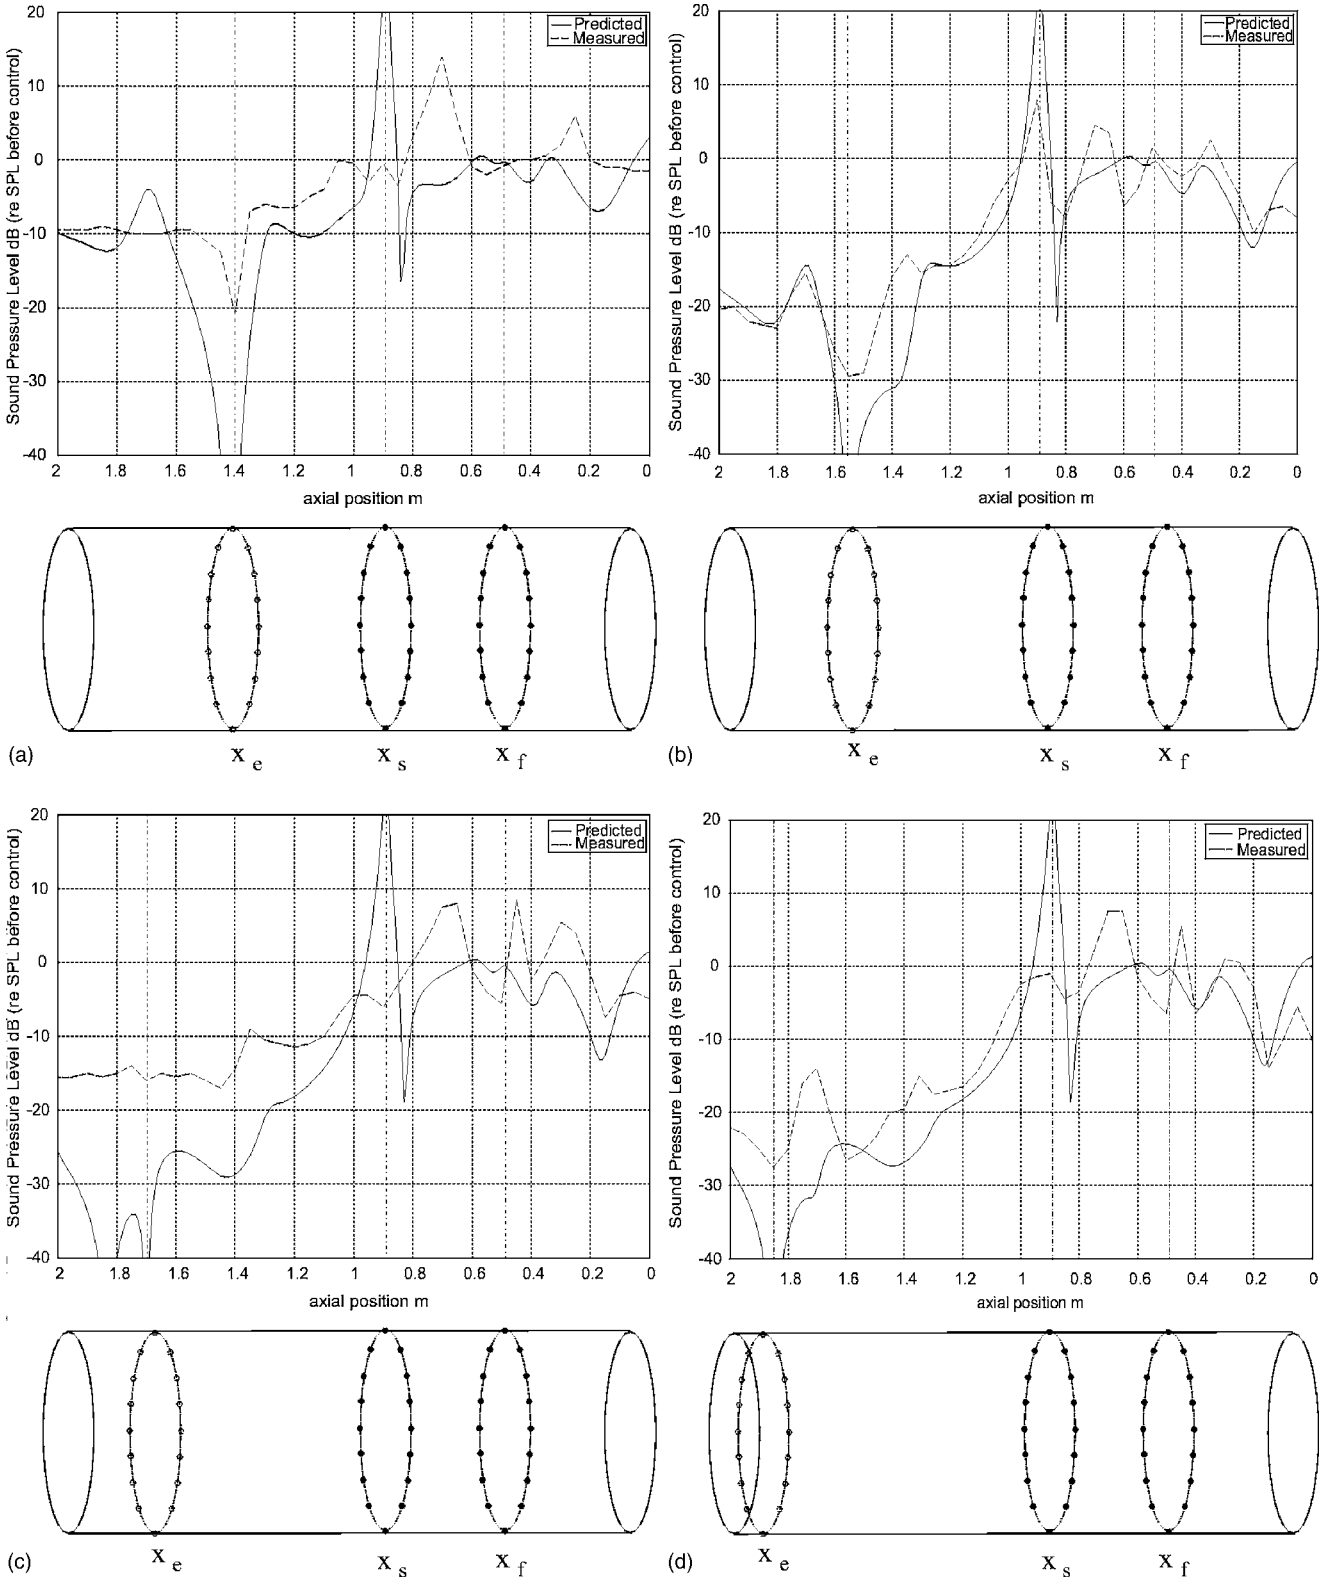

FIG. 6. Comparison of measured and predicted sound pressure reduction with varying axial position 885 Hz: $x_e = 1.4m$ (a), $1.55m$ (b), $1.7m$ (c), and 1.85 (d).

trol mechanism. A further reason for the discrepancy observed in Fig. 4 is that the hard-walled assumption made in the model may not be valid in the case of a steel plate duct. Vibration of the duct wall causes some sound to be reradiated into the duct or sound to "breakout" through the duct walls.

The acoustic intensity distribution across the duct "inlet" at a representative excitation frequency of 885 Hz, before and after control, is plotted in Figs. 5(a) and 5(b). Before control, the acoustic energy is concentrated close to the duct walls. This provides some evidence for the dominance in the sound field of the first radial mode order $n=1$. Figure 5(b) confirms that after control the intensity at the duct wall has reduced by approximately 15 dB, commensurate with the overall power reduction of 14 dB at this frequency seen in Fig. 4. Furthermore, the radial variation of sound intensity is

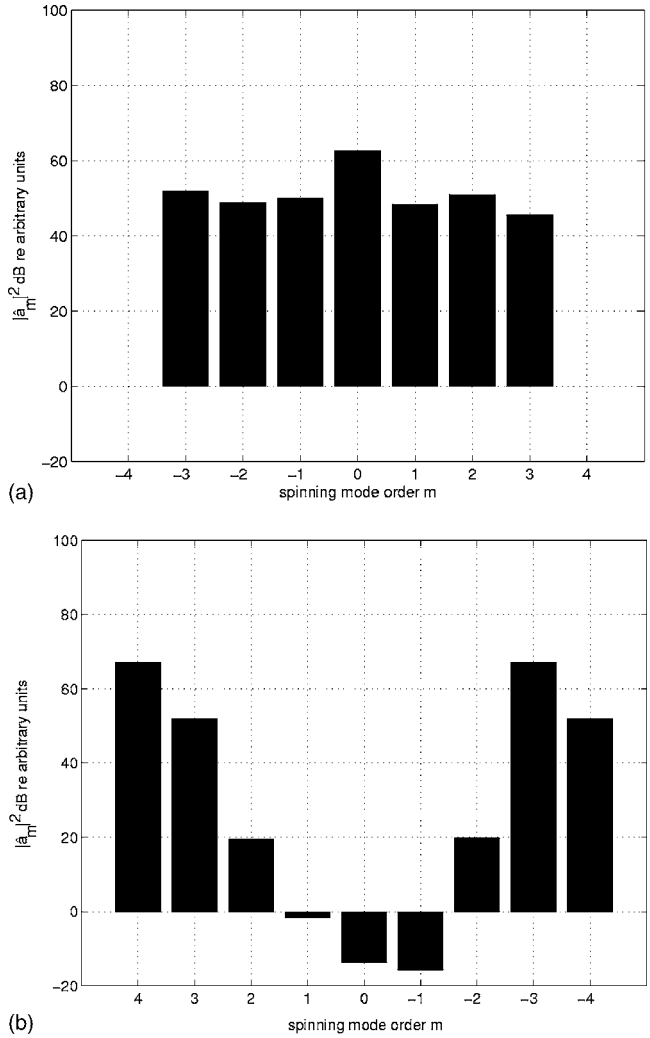

FIG. 7. (a) Measured and (b) predicted spinning mode amplitudes at the error sensors after control at 885 Hz.

now significantly smaller compared with that before control, suggesting that the single radial mode no longer dominates the sound field in the duct after control.

Further insight into the control process is obtained from measurements of the sound pressure level reduction versus axial distance along the duct at the duct wall. Figures 6(a)–6(d) show the sound pressure reduction at 885 Hz measured in 5 cm increments along the duct for the error sensor positions of $x_e = 1.4m$, $1.55m$, $1.7m$ and $1.85m$, respectively (solid curves). Also plotted are the predicted sound pressure reductions calculated using the theoretical model (dashed curves).

Good qualitative agreement is generally observed between the measured and predicted axial variation in sound pressure level reduction. An interesting feature of these figures is that the pressure drops to a minimum at the error sensor array and then rises to a finite level at the duct termination, before being radiated to the far-field. The control mechanism, from a modal point of view, therefore, does not simply involve driving the mode amplitudes to zero, which would give constant sound pressure level reductions downstream of the error sensor plane. This behavior indicates the existence of destructive interference between different modes. This control mechanism is explored in greater detail in the following section.

V. GENERAL CONTROL MECHANISM

The control system seeks to drive the pressure at L error sensors to zero. The pressure at the lth error sensor can be expressed in terms of the spinning mode amplitudes $\hat{a}_m$ at the duct wall in the form,

$$p(\theta_l, \omega) = \sum_{m=-\infty}^{\infty} \hat{a}_m(\omega) e^{im\theta_l}, \tag{5}$$

where $\hat{a}_m$ comprises a number of radial modes,

$$\hat{a}_m(\omega) = \sum_{n=1}^{\infty} a_{m,n} \Psi_{m,n}(a), \tag{6}$$

where $a_{m,n}$ is the amplitude of the mode (m,n), and $\Psi_{m,n}(a)$ is the radial mode shape function evaluated at the duct wall.

Provided there is a sufficient number of sensors, the spinning mode amplitudes $\hat{a}_m$ can be determined by performing a discrete spatial Fourier transform of the pressure signals at the error sensors using Eq. (3). Thus if the pressure is driven to zero at all seven error sensors, i.e.,

$$p(\theta_l, \omega) = 0 \quad (l = 1, \ldots, 7) \tag{7}$$

Eq. (3) suggests that the spinning mode amplitudes are independently driven to zero at the error sensor array, i.e.,

$$\hat{a}_m(\omega) = 0 \quad (-3 \leqslant m \leqslant 3). \tag{8}$$

Equation (8) assumes that the contribution from cut-off $m = \pm 4$ modes can be neglected. Subject to this assumption being valid, Eqs. (7) and (8) indicate that driving the pressure at the error sensors to zero, and driving the spinning mode amplitudes to zero, are identical control strategies.

The computer model was also used to predict the reduction in mode amplitudes following control, and hence the sound power reduction. The input to the model was the mode amplitude spectrum for $-3 \leqslant m \leqslant 3$ measured at the error sensors before control, as plotted in Fig. 2. For simplicity the amplitude of the two axi-symmetric $m = 0$ modes are assumed equal. A comparison of the measured and predicted spinning mode amplitudes after control is shown in Figs. 7(a) and 7(b), respectively.

Agreement between measurement and prediction is poor. Contrary to Eq. (8), Figs. 7(a) and 7(b) show that neither the predicted nor measured mode amplitudes are driven to zero. The main discrepancy between them arises for the $m = \pm 4$ modes. In the measurement it is assumed that these can be neglected in order for the modal decomposition of Eq. (3) to be valid. However, the amplitude of the $m = +4$ mode is predicted to be exactly equal to the $m = -3$ mode, and the amplitude of the $m = -4$ mode equal to that of $m = +3$ mode. The source of the discrepancy for the $m = 0$ and $m = \pm 1$ modes in Fig. 7 arises from imperfect cancellation between the two radial mode amplitudes $a_{m,1}$ and $a_{m,2}$. We shall show in the next section that the modal amplitudes $\hat{a}_0$ and $\hat{a}_{\pm 1}$ are driven to zero by exciting their component radial mode amplitudes

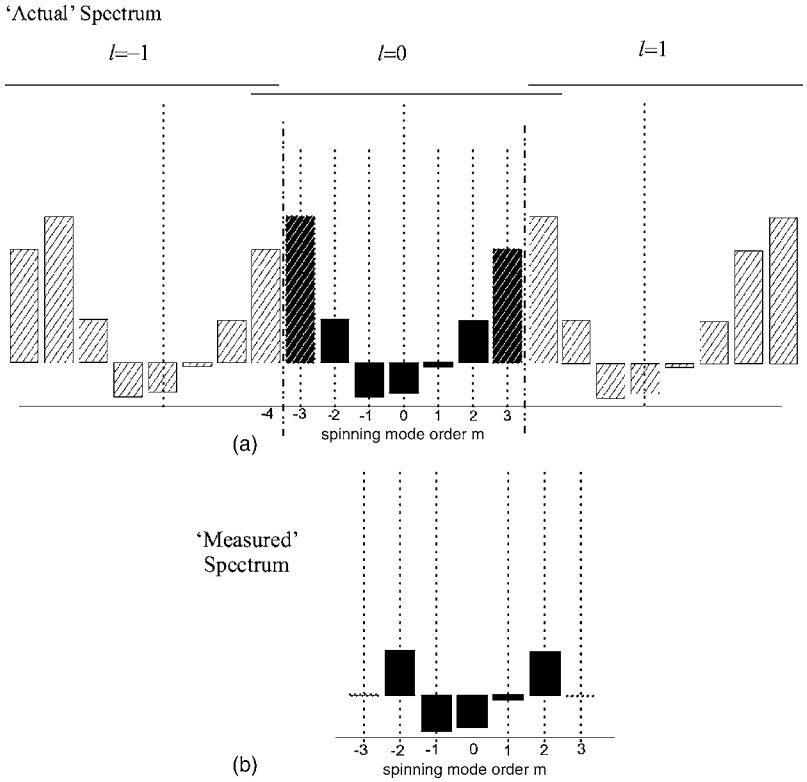

FIG. 8. The "measured," aliased spectrum of spinning mode amplitudes after control at 885 Hz.

to perfectly cancel. Since the single source and sensor ring cannot control and detect individual radial modes, they are excited to high amplitude and become the dominant modes (see Figs. 10 and 12). Imperfect cancellation of these modes due to imperfect pressure cancellation at the error sensors leads to large spinning mode amplitudes, as observed in the measurements of Fig. 7(a).

Aliasing of higher order evanescent modes. Due to the close proximity of the secondary sources to the error sensor in the duct rig, evanescent modes, which are close to cutting on at the frequencies of interest here, will make a significant contribution to the pressure at the error sensor array. The seven sources and sensors used in the control system were chosen to satisfy the Nyquist criterion for the maximum propagating mode order $m=\pm 3$. Pressure contributions from the $m=\pm 4$ cut-off modes will therefore be aliased and hence will contribute to the modal amplitudes observed by the control system in the range $-3 \leqslant m \leqslant 3$.

The use of seven error microphones in the control system for mode detection assumes periodicity in the spinning mode spectrum such that

$$\hat{a}_m = \hat{a}_{m+7l} \quad (l = -\infty, \ldots, 0, \ldots, \infty). \tag{9}$$

If the actual mode spectrum after control is of the form shown in Fig. 7(b) comprising modes in the range $-4 \leqslant m \leqslant 4$, then the mode spectrum that appears to the control system over the range $-3 \leqslant m \leqslant 3$ will be of the form shown in Fig. 8(a).

The periodicity property indicated in Fig. 8(a) shows that the spinning mode amplitudes $\hat{a}_{\pm 3}$ appearing at the error sensor array actually include an $m=\pm 4$ cut-off mode. From Eq. (9) the measured $m=+3$ and $m=-3$ modes comprise the following:

$$\begin{aligned} \underbrace{\hat{a}_3}_{measured} &= \underbrace{\hat{a}_3 + \hat{a}_{-4}}_{actual} \quad (l=-1), \\ \underbrace{\hat{a}_{-3}}_{measured} &= \underbrace{\hat{a}_{-3} + \hat{a}_4}_{actual} \quad (l=-1), \end{aligned} \tag{10}$$

Equation (10) suggests that the "measured" spinning mode amplitudes, of order $m=\pm 3$, have been driven to zero by arranging for them to cancel with a corresponding $m = \mp 4$ cut-off mode i.e.,

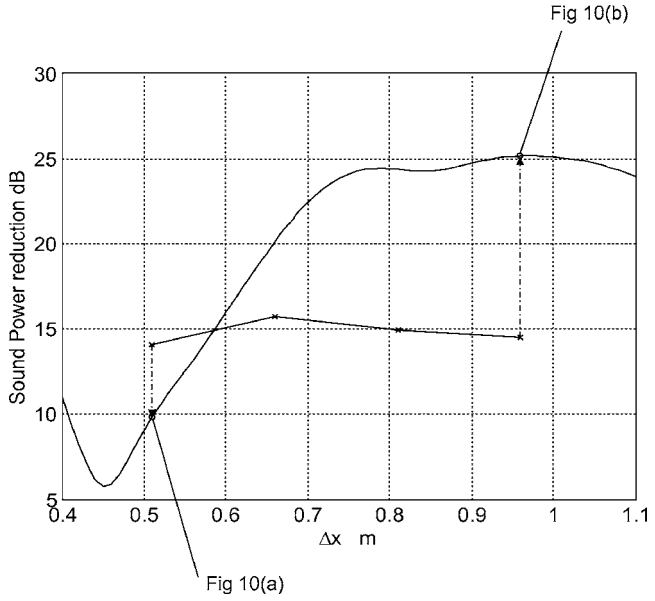

FIG. 9. Comparison between measured and predicted variation of sound power reduction with source/sensor separation distance at 885 Hz. Predicted mode amplitudes at $\Delta x=0.51$ and $0.96m$ are plotted in Fig. 10.

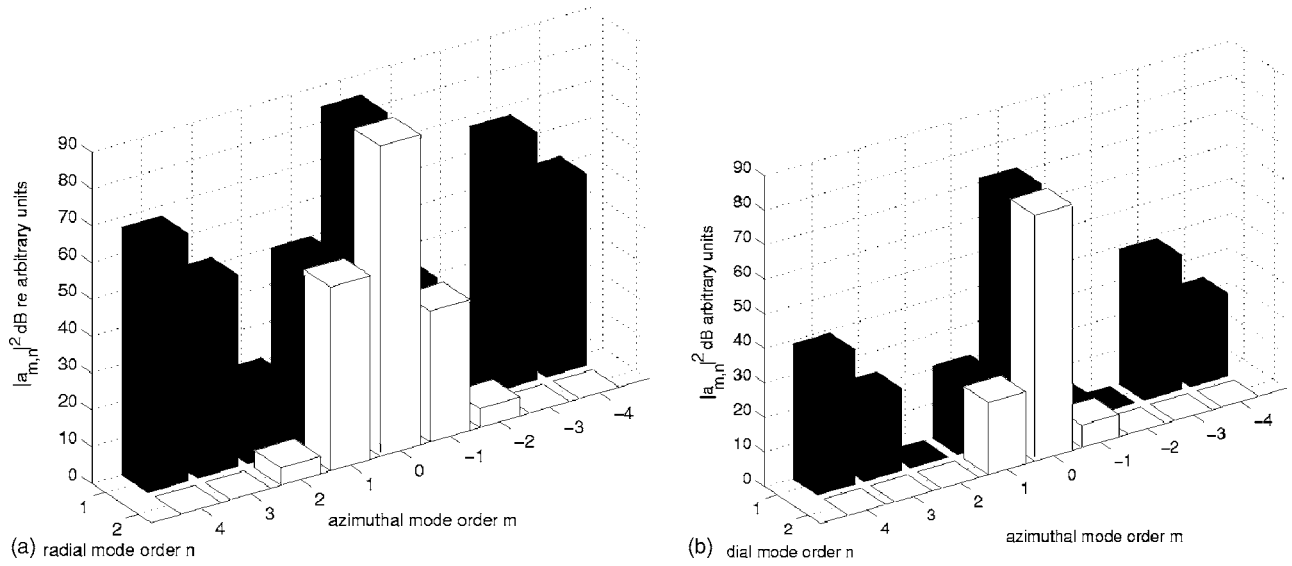

FIG. 10. Mode amplitudes after control at the error sensor array at 885 Hz, (a) $\Delta x = 0.56m$ and (b) $0.91m$.

$$\hat{a}_3 + \hat{a}_{-4} = 0, \qquad \hat{a}_{-3} + \hat{a}_4 = 0. \tag{11}$$

Precisely this behavior is observed in Figs. 7(a) and 7(b), where the amplitudes of $\hat{a}_3$ and $\hat{a}_{-4}$ are exactly equal.

The modal interpretation of the control mechanism involved in the cancellation of the pressure to zero at the error sensors in the experimental duct has been shown to be surprisingly subtle. It may be summarized as follows:

(1) The pressure is driven to zero by arranging for $\hat{a}_{\pm 4} = -\hat{a}_{\mp 3}$ at the error sensor plane. This is because the $m = \pm 4$ modes cannot be controlled independently by the seven sources and sensors of the control system.
(2) The amplitudes of the axi-symmetric $m = 0$ radial modes and the $m = \pm 1$ and $m = \pm 2$ are arranged to cancel, $\hat{a}_{0,1} = -\hat{a}_{0,2}$, since the two radial modes associated with $m = 0$ cannot be independently controlled by the single ring of sources and sensors, even though $\hat{a}_{\pm 1,2}$ are cut-off.

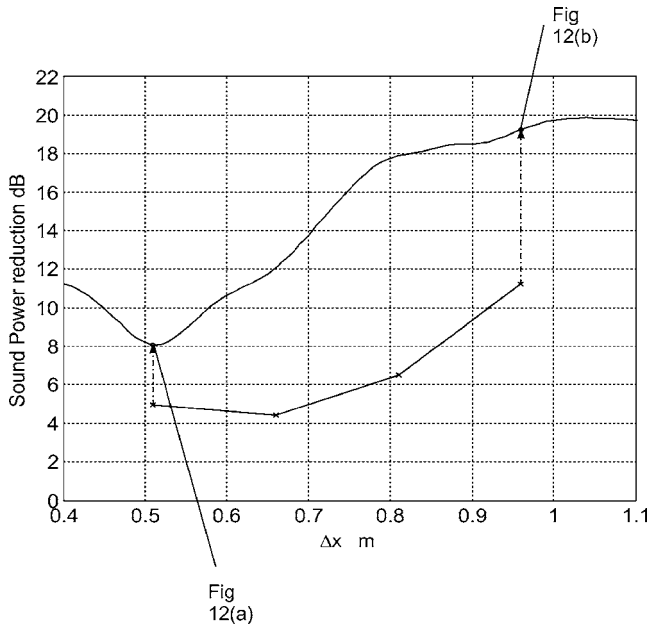

FIG. 11. Variation of sound power reduction with source/sensor separation distance at 920 Hz.

We now consider in detail the control mechanism versus source-sensor separation distance at 885 Hz and at frequencies greater than 900 Hz, since the control mechanism is substantially different in these two cases.

VI. CONTROL PERFORMANCE VERSUS SOURCE-SENSOR SEPARATION DISTANCE

One of the few parameters that may be varied in the experimental rig is the axial separation distance Δx between the sources and sensors. We now investigate control performance for different Δx at two different frequencies. At the lower frequency of 885 Hz, the excitation frequency is sufficiently low for the control system not to be affected by the presence of higher order cut-off modes. At 920 Hz, the cut-off $m = \pm 4$ modes make a significant pressure contribution at the error sensors and therefore begin to degrade control performance. The decay in SPL between sources and sensors of the (4, 1) evanescent mode can be determined from

$$\Delta \mathrm{SPL} = -8.7 \frac{2\pi}{c} \Delta x \sqrt{f_{4,1}^2 - f^2} \quad (f < f_{4,1}). \tag{12}$$

At 920 Hz, with a separation distance of $\Delta x = 0.51m$ the $m = \pm 4$ mode will decay by 24 dB before reaching the error sensor array, increasing to 32 dB at the lower frequency of 885 Hz.

A. Results at 885 Hz

The measured sound power reduction for the four separation distances Δx is plotted in Fig. 9 (asterisks). Also shown are the sound power reductions predicted using the theoretical model (continuous line).

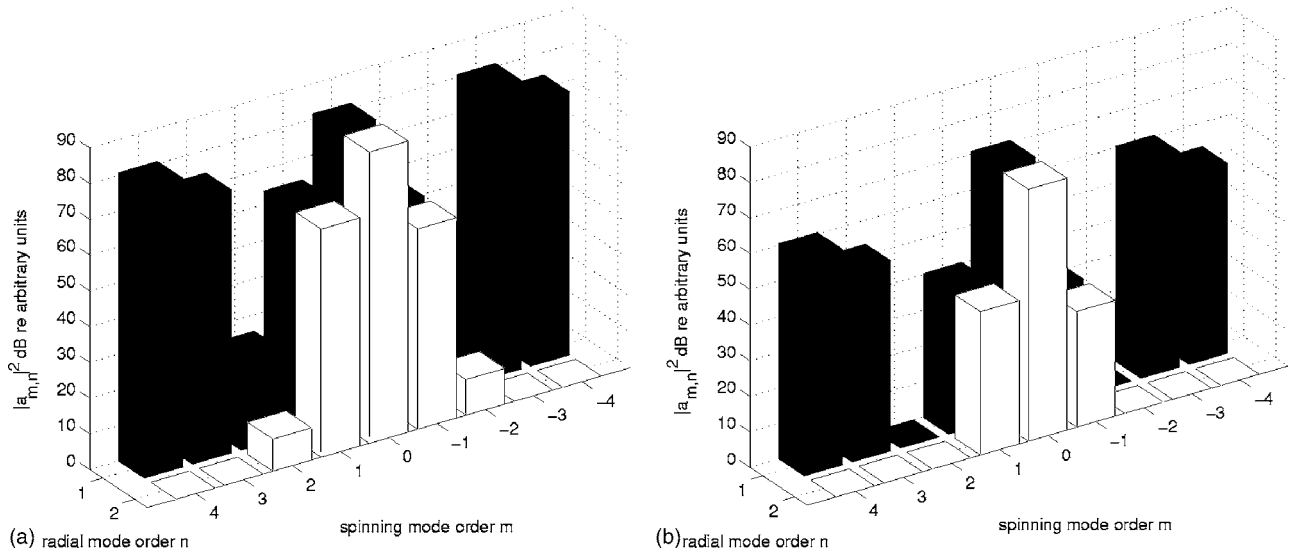

FIG. 12. Predicted mode amplitudes after control at the error sensor array at 920 Hz: $\Delta x=0.56m$ (a) and $0.91m$ (b).

Once again, agreement between the measured and predicted sound power reductions is generally poor. This can be explained by Figs. 7(a) and 7(b) showing the measured and predicted spinning mode amplitudes after control. Predicted individual mode amplitudes after control for $\Delta x=0.51m$ and $0.96m$ are plotted in Fig. 10. The theoretical prediction in Fig. 10(a) shows that the axi-symmetric $m=0$ radial modes are excited in anti-phase, to give $\hat{a}_m=0$. However, the measured pressure reduction at the error sensors is only 30 dB. Cancellation between the radial modes is therefore imperfect.

Figures 10(a) and 10(b) show that with the error sensors positioned furthest from the source array, $\Delta x=0.96m$, the axi-symmetric modes $m=0$ modes are excited to a lower level than at the smaller separation distance and hence the sound power reduction is predicted to be greater. A simple analytic model predicting this behavior is presented by the first author in Wilkinson (2004).

B. Results at $f \geqslant 900$ Hz

In this section we investigate the mechanism of control at frequencies greater than 900 Hz. The important difference here compared with the results presented in Sec. VI A is that the $m=\pm 4$ modes are significantly less cut-off, and hence now make a significant contribution to the pressure at the error sensors.

Figure 11 shows the measured and predicted variation in sound power reduction with varying Δx at 920 Hz.

Once again the measured sound power reduction is overestimated by about 10 dB. The overall trend in both measurement and prediction, however, is similar. Both indicate a sound power reduction that increases with increasing separation distance. This behavior confirms that the $m=\pm 4$ cut-off modes dominate the control mechanism at this higher frequency. This is verified in a prediction of the mode amplitudes at the error sensors at separation distances Δx of $0.51m$ and $0.96m$, as shown in Figs. 12(a) and 12(b).

With the source-sensor separation distance equal to $\Delta x=0.51m$, Fig. 12(a) shows that the amplitudes of the $m=\pm 4$ modes are slightly greater than that of the two $m=0$ radial modes. As explained in Sec. V, the $m=\pm 3$ modes will therefore be excited in order to cancel with this cut-off mode, and will therefore dominate the sound power after control. Global control performance is therefore diminished by the presence of the $m=\pm 4$ modes. As Δx is increased, the level of the cut-off modes reduces. With the error sensors positioned furthest from the source array, $\Delta x=0.91m$, the cut-off mode has decayed to a level that is lower than that of the axi-symmetric modes. The situation in this case is therefore similar to that described in Sec. VI A.

VII. CONCLUSIONS

The design and implementation of an active control system to control a low order spinning mode in a no-flow duct has been described. An $m=-3$ mode was generated using a mode synthesizer ring and this spinning mode was controlled using seven sources and seven error sensors. Sound power reductions of up to 14.5 dB were measured at the duct face when minimizing the sum of the squared pressures at the error sensors using a single frequency FXLMS algorithm. The control mechanism was examined using a theoretical model developed in previous work by the authors. It was seen that the level of the axi-symmetric $m=0$ modes dominate the sound power after control, and hence sound power reduction was found to be significantly less than the pressure reduction at the error sensors. At higher frequencies it was shown that aliasing of the $m=\pm 4$ cut-off modes also degrades control performance at the frequencies at which these cut-off modes contribute significantly to the pressure at the error sensors.

Broadband sound reflection by plates covering side-branch cavities in a duct

Lixi Huang[a)]
Department of Mechanical Engineering, The Hong Kong Polytechnic University, Kowloon, Hong Kong

(Received 9 December 2005; revised 3 February 2006; accepted 18 February 2006)

When a segment of a rigid duct is replaced by a plate backed by a hard-walled cavity, grazing incident sound waves induce plate bending, hence sound reflection. The mechanism is similar to the drumlike silencer with tensioned membranes [L. Huang, J. Acoust. Soc. Am. **112**, 2014–2025 (2002)]. However, the logarithmic bandwidth over which the reflection occurs is much wider than that of a drumlike silencer of the same cavity geometry, the typical difference being nearly one octave band. The difference in the silencing performance is explained in terms of the intermodal acoustic interference between the odd and even *in vacuo* vibration modes. For a given cavity volume, the widest stopband for noise in air is obtained by using long plates with two free lateral edges parallel with the duct axis. The optimal material should be stiff and light, and the critical parameter is found to be the ratio of the Young's modulus over the cube of density. Typically, this ratio is 250 times higher than those of common metallic materials like aluminum alloys, but it is within the reach of existing ultralight foam materials or composite beams with a light core. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2186431]

I. INTRODUCTION

Duct noise control finds many applications such as ventilation systems in built-up environments. Medium and high-frequency noise is easily tackled by duct lining using porous materials, for which the technology is rather mature. Low-frequency noise remains a technical challenge. Active control could, in principle, deal with such problem with ease, but the actual applications of the technology have been few due to cost, reliability, and other practical concerns. The present author has been developing an alternative for the low-frequency duct noise control through the use of flexible walls (Huang, 1999) leading to a prototype device of drumlike silencer (Huang, 2002) in which a segment of tensioned membrane lines part of the duct wall, and each membrane is backed by a hard-walled cavity. Incident sound waves from upstream induce the membrane to vibrate and the vibration radiates sound in both directions of the duct. The upstream radiation forms the wave reflection while the downstream radiation combines with the incident wave and destructive acoustic interference ensues. In fact, the acoustics of such device is very similar to a successful scheme of active duct noise control using a single side-branch loudspeaker except that the secondary source in this case is the tensioned membrane, and there is absolutely no chance that the destructive acoustic interference in the downstream region could turn out to be constructive. This is so because the incident wave is the only energy source and the acoustic energy conservation guarantees that there is transmission loss of noise across such flexible segments. When compared with duct lining and splitter-type silencers, the drumlike silencer carries the extra merit of creating zero back pressure and using no porous material. The prototype device has been tested successfully for the conditions of without (Choy and Huang, 2002) and with flow (Choy and Huang, 2005).

It has been shown that the drumlike silencer achieves its best silencing performance under an optimal tensile force (Huang, 2004). When the membrane is too loose, reflection waves from different parts of the membrane simply cancel themselves out. When the membrane is too tight, it approaches the condition of a hard wall. The mechanism of the superior sound reflection capability achieved for the optimal configuration lies in the delicate acoustic interference between different parts of the tensioned membranes. If the membrane vibration is decomposed into *in vacuo* modes of velocity $\sin(j\pi x/L)$, where the membrane occupies $x \propto [0,L]$, the broadband performance is found to derive mainly from the first two modes, $j=1,2$. The first mode is very effective in reflecting low-frequency sound but is hard to excite due to the cavity air stiffness. The second mode is relatively ineffective in reflecting low-frequency sound but is rather easy to excite. The two modes are found to supplement each other in achieving a broadband silencing performance.

In this study, the tensioned membrane is replaced by a plate with its natural bending moment as the sole structural restoring force. The parametric relationship between the first two *in vacuo* modes is changed, and a corresponding change in the intermodal acoustic interference is also expected to take place. For example, the second membrane (string) mode has its eigenfrequency twice as much as that of the first mode. But, this is changed to four times when it comes to the plate. It is shown in later sections that the change in the intermodal relationship is beneficial for sound reflection provided that the parameters of the plate are optimized.

The use of a plate and, for this matter, the tensioned membrane in noise abatement may not be new, but its use as

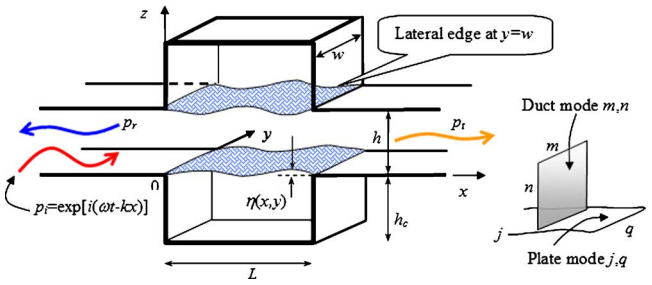

FIG. 1. (Color online) Theoretical model of sound wave reflection by two cavity-backed plates forming part of the otherwise rigid duct walls.

a side-branch wave reflector is. For example, a plate has been used as a means to adjust certain acoustic resonance. Panel absorbers are used in broadcasting studios and other architectural practices (Brown, 1964; Ford and McCormick, 1969; Horoshenkov and Sakagami, 2001), membrane absorbers are used as splitter silencers in the form of arrays of Helmholtz resonators (Frommhold *et al.*, 1994). However, in all these applications the panel, or the membrane, is a component of a resonator which works for a narrow frequency band. The structural mass is often a desirable property to achieve a low resonance frequency. Here, it is shown that the most desirable properties of a plate as a side-branch wave reflector are the high stiffness and low density.

In what follows, theoretical outlines are given in Sec. II, and the relationship between plate/cavity resonance and wave reflection is examined for the three-dimensional acoustic model and two-dimensional plate model. In Sec. III, the model is changed to two-dimensional duct and one-dimensional beam, leading to the optimal wave reflection performance. The effects of plate and cavity damping are also studied. Section IV examines the effect of plate mass and the issue of material selection.

II. THEORETICAL MODEL AND PLATE RESONANCE

A. Three-dimensional theoretical model

As shown in Fig. 1, a segment of a rigid duct of height h and width w is lined by two plates of length L and width w. Each plate is supported by a cavity of depth h_c. The four edges of the plate may have different structural boundaries. The leading and trailing edges located at $x=0,L$ are simply supported. This condition is preferred over the clamped condition for a uniform plate since it allows the plate to respond to incident waves with a higher vibration magnitude. The two lateral edges, defined as those located at $y=0,w$, can be either simply supported, as is the case in the analysis of this section, or free, which is the case for the later sections. A plane incident wave comes from the left to the right with a unit amplitude,

$$p_i = e^{i(\omega t - kx)}, \tag{1}$$

and it induces the plate to vibrate with a transverse displacement of complex amplitude $\eta(x,y)$ and velocity $V(x,y)$ with the same time dependence, $\exp(i\omega t)$, which is henceforth omitted. The plate motion radiates sound in both directions of the duct axis, $\pm x$, and it induces a fluid loading of

$$\Delta p = (\,p|_{z=0+} - \,p|_{z=0-})^{(\eta)}. \tag{2}$$

Note that Δp is defined as that induced by the plate vibration (hence the superscript η) excluding the loading by the incident wave. The plate vibration is governed by the following equation:

$$m_s \frac{\partial^2 \eta}{\partial t^2} + B\nabla^4 \eta + p_i + \Delta p = 0, \tag{3}$$

where $B=Es^3/[12(1-\nu^2)]$ is the bending stiffness, m_s, E, ν, s are, respectively, the plate mass per unit surface area, the Young's modulus, Poisson's ratio, and the plate thickness. The effect of damping is investigated in the next section where relevant formulation is given. In order to solve Eq. (3) both the plate vibration and the fluid loading on the plate are expanded into the *in vacuo* modes of the simply supported plate denoted by $\varphi_{jq}(x,y)$,

$$\varphi_{jq}(x,y) = \sin(j\pi x/L)\sin(q\pi y/w),$$

$$V(x,y) = \sum_{j=1}^{\infty}\sum_{q=1}^{\infty} V_{jq}\varphi_{jq}(x,y),$$

$$V_{jq} = \frac{4}{Lw}\int_0^w dy \int_0^L V(x,y)\varphi_{jq}dx,$$

$$\Delta p^{(\eta)} = \sum_{j,q} V_{jq} \sum_{j',q'} Z_{jqj'q'}\varphi_{j'q'}, \tag{4}$$

$$Z_{jqj'q'} = \frac{4}{Lw}\int_0^w dy \int_0^L \Delta p^{(\varphi_{jq})}\varphi_{j'q'}dx,$$

where $\Delta p^{(\varphi_{jq})}$ denotes the fluid loading induced by the modal vibration of indices (j,q) with a unit amplitude, and $Z_{jqj'q'}$ is the modal impedance defined as the fluid loading of mode (j',q') arising from the plate vibration of mode (j,q) with a unit velocity amplitude. The formulations for $Z_{jqj'q'}$ and the convergence of the solution for the truncated set of equations are documented in Huang (2002) and Huang and Choy (2005) for tensioned membranes. Since $Z_{jqj'q'}$ is the acoustic property of the duct and the cavity, it is independent of the structural mechanics. In other words, $Z_{jqj'q'}$ found for the membrane problem can also be used here. Briefly, the modal impedance problem becomes a standard radiation problem and the solution can be expanded into the duct acoustics modes (Doak, 1973) of indices m in the y direction and n in the z direction, illustrated in the right-hand part of Fig. 1. Using the standard Galerkin procedure, the following set of linear equations are obtained:

$$\mathcal{L}_{jq}V_{jq} + \sum_{j',q'} Z_{j'q'jq}V_{j'q'} + I_{jq} = 0, \quad j,q = 1,2,3,\cdots, \tag{5}$$

where $\mathcal{L}_{jq}$ is the structural mechanics operator,

$$\mathcal{L}_{jq} = m_s i\omega + \frac{B}{i\omega}\left[\left(\frac{j\pi}{L}\right)^4 + 2\left(\frac{j\pi}{L}\right)^2\left(\frac{q\pi}{w}\right)^2 + \left(\frac{q\pi}{w}\right)^4\right], \tag{6}$$

and I_{jq} is the modal excitation of the given incident wave p_i,

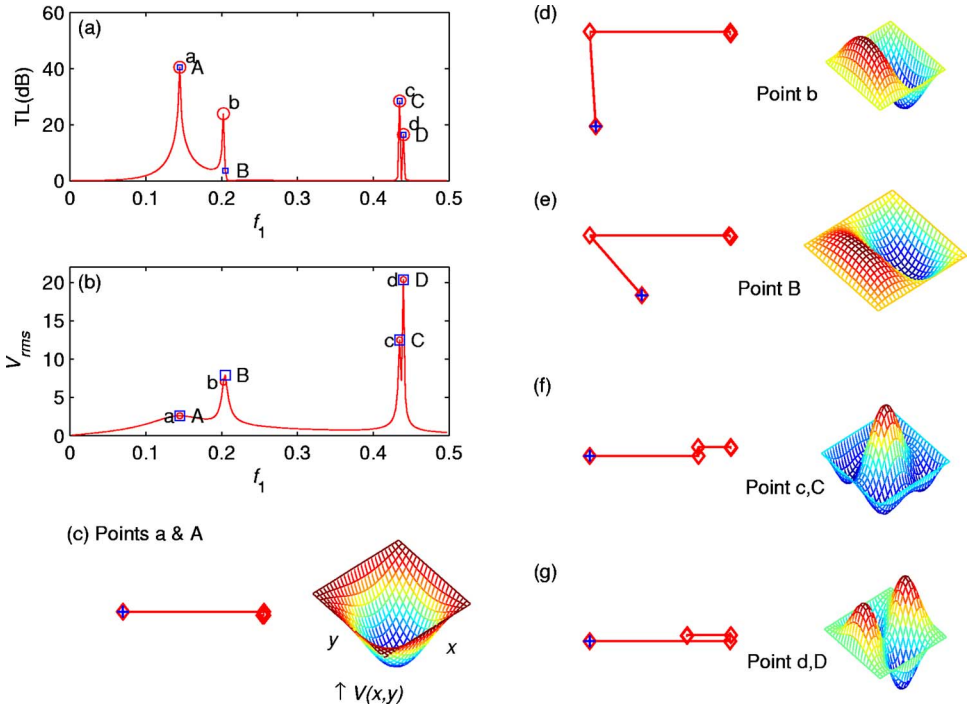

FIG. 2. (Color online) Resonance of the cavity-backed, side-branch plate with $L=h$, $h_c=h$, $B_1=0.001$. (a) System TL. (b) Plate vibration velocity (V_{rms}, relative scale). (c) Modal decomposition of the reflected sound and the instantaneous plate vibration velocity distribution for the first resonance frequency, point A, where TL also peaks. (d) Second TL peak point b. (e) Second resonance frequency point B. (f) Third and (g) fourth TL peak and resonance frequency points.

$$I_{jq} = \frac{4}{Lw}\int_0^w \left(\int_0^L p_i(x)\varphi_{jq}(x,y)dx\right)dy$$
$$= 4\frac{1-\cos(q\pi)}{q\pi} \times j\pi e^{ikL/2}\left[\frac{1-e^{i(-kL+j\pi)}}{(j\pi)^2-(kL)^2}\right]. \quad (7)$$

The set of linear equations (5) is truncated to a finite number of modes in all three dimensions: axial plate mode j, lateral plate mode q, and duct acoustics modes, m,n. Numerical tests show that the modal convergence properties for the plate problem are similar to the membrane problem, and details are not given here. In the numerical examples given below, the plate modes are truncated to 20 in both length and width directions while 50 modes are used for the duct acoustics. Once the complex modal velocity V_{jq} is obtained, the far-field sound radiation to the upstream represents the reflection wave calculated by

$$p_r = \sum_{j,q} p_{rjq} = \sum_{j=1}^{\infty} p_{rj}, \quad p_{rj} = \sum_{q=1}^{\infty} p_{rjq},$$

$$p_{rjq} = \frac{\rho_0 c_0}{2hw^2} V_{jq} \int_0^w \left(\int_0^L \varphi_{jq}(x,y)e^{-ikx}dx\right)dy, \quad (8)$$

where ρ_0, c_0 are the fluid density and speed of sound, respectively, and the contribution from each axial mode, j, is calculated by a summation over the lateral mode of index q. The radiation to the downstream combines with the incident wave to become the transmitted wave, which is written below together with the definition of the transmission loss TL,

$$p_t = p_i + \frac{\rho_0 c_0}{2hw^2}\sum_{j,q} V_{jq}\int_0^w \left(\int_0^L \varphi_{jq}(x,y)e^{+ikx}dx\right)dy, \quad (9)$$

$$\text{TL} = 20\log_{10}\frac{|p_i|}{|p_t|}.$$

When the two lateral edges at $y=0,w$ are set free, the problem is degenerated into two dimensions for the duct acoustics and one dimension for the plate (or beam). The above equations can be easily adapted by eliminating the modes in the y direction with indices q and m. The formulations for the 2D problem are similar to Huang (2002) and are not listed separately here for the sake of brevity.

In all numerical examples, parameters are normalized. Three basic normalization quantities are chosen, fluid density ρ_0, speed of sound c_0, and duct height h. Time and pressure quantities are normalized by c_0/h and $\rho_0 c_0^2$, respectively. By doing so, three most important parameters emerge,

$$f_1 = \frac{\omega h}{2\pi c_0}, \quad m_1 = \frac{m_s}{\rho_0 h}, \quad B_1 = \frac{B}{\rho_0 c_0^2 h^3}, \quad (10)$$

which are, respectively, the dimensionless frequency, the plate-to-fluid mass ratio, and the dimensionless bending stiffness. Here, a dimensionless variable is identified by a subscript of "1" added to its dimensional variable of the same symbol, while dimensional variables are used as much as possible. For the sake of comparative study, tensioned membranes are also investigated, and the relevant dimensionless tension is defined as $T_1=T/(\rho_0 c_0^2 h^2)$, where T is the dimensional tensile force applied.

B. Compact plate resonance

In order to best appreciate the fluid-plate interaction, an example of compact plate resonance is given with the following parameters:

$$m_1 = 1, \quad L = w = h_c = h, \quad B_1 = 0.001.$$

The results are shown in Fig. 2 with seven subfigures. Figure 2(a) shows the transmission loss (TL) spectrum and Fig. 2(b) the root-mean-square value of the plate vibration velocity integrated over the whole plate denoted by V_{rms}. Peaks in the TL spectrum are indicated by open circles and marked by lower-case letters, while the V_{rms} peaks are marked by open squares and upper-case letters. The two sets of peaks are shown in both subfigures. Figures 2(d)–2(g) are details of the vibration velocity distribution and the sound reflection for individual frequencies marked in Figs. 2(a) and 2(b).

As shown in Figs. 2(a) and 2(b), the first TL peak, "*a*," is over 40 dB and the same frequency position happens to be a rather flat peak of V_{rms}, denoted by "*A*." This common peak features mainly the fundamental mode vibration, $j=q=1$, shown in Fig. 2(c). In the left-hand side of Fig. 2(c), the sound reflection is decomposed into contributions from various axial modes of index j; cf. Eq. (8). The contribution of each axial mode is represented by a vector bounded by open diamonds based on the complex amplitude of the sound reflection. The vectorial summation indicates how the modal contributions interfere with each other. In this particular frequency of $f_1=0.145$ for points *a* and *A*, there is hardly any contribution from modes of $j>1$. The reason why V_{rms} is so low is as follows. At this frequency, most sounds are reflected by the plate. The plate becomes a pressure release surface, and the actual sound pressure is an antinode ($p \approx 0$) there. In other words, part of the excitation force is canceled out by the plate response. As shown in Figs 2(a) and 2(b), TL decreases when $f_1>0.145$ before it increases again, while V_{rms} decreases only slightly before it approaches its next peak. The TL peak deviates from the V_{rms} peak although they are not too far apart. At the point where the plate vibration is the highest, point "*B*," TL is actually very low. This is the best illustration of the fact that the plate resonance is not necessarily good for sound reflection. Modal decomposition of the sound reflection and the instantaneous plate vibration velocity are shown in Fig. 2(d) for point "*b*" and in Fig. 2(e) for point *B*. Figure 2(d) shows that good silencing performance is achieved when the reflections by the first two axial modes of $j=1,2$ are essentially out of phase (the vectors being perpendicular to each other). As shown in Fig. 2(e), a slight adjustment of frequency to point *B* shifts such phase relation, and the two modes interfere destructively. When the dimensionless frequency is further increased towards 0.44, two more sets of peaks are identified in Figs. 2(a) and 2(b). This time, the TL peaks also coincide with the V_{rms} peaks like the first point at $f_1=0.145$, but they can actually be separated by using a finer frequency resolution. Details of the vibration are shown in Fig. 2(f) for points "*c*" and "*C*," and Fig. 2(g) for points "*d*" and "*D*." Two observations are made here. First, the main contributions of sound reflection derive from the first and third modes, $j=1,3$. Second, the plate vibrations are very different for the two sets of peaks, although the frequencies are not too far apart.

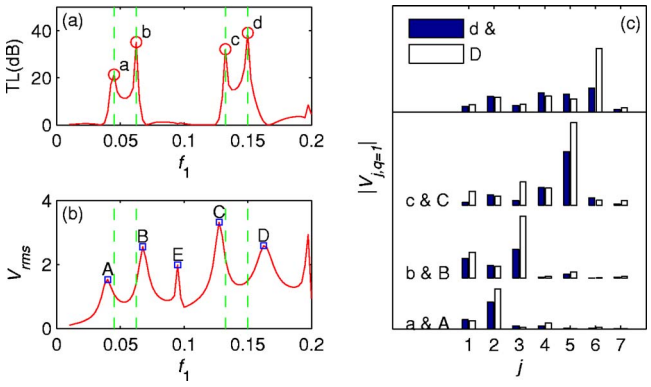

FIG. 3. (Color online) Response of a long plate with $L=5h$, $h_c=h$, $B_1=0.003$. (a) Transmission loss. (b) Root-mean-square plate vibration velocity V_{rms}. (c) Comparison of modal responses at the TL peaks (filled bars) and a nearby resonance (open bars) with frequency locations labeled in the other two subfigures.

C. Noncompact plate

The results of the short plate studies shown in Fig. 2 indicate that good silencing performance occurs near the plate resonance. This implies that, in order to obtain good low-frequency performance, the plate has to be long. The results for the following configuration:

$$m_1 = 1, \quad L = 5h, \quad w = h_c = h, \quad B_1 = 0.003,$$

are shown in Fig. 3 with frequencies zoomed in to $f_1=0$ to 0.2. For such a long plate, the first mode has very high radiation resistance and is very difficult to excite at low frequencies. Comparing the results in Figs. 3(a) and 3(b) with those of Figs. 2(a) and 2(b), there are much larger and clearer separations between the TL peaks, which are marked a,b,c,d in Fig. 3(a), and the V_{rms} peaks, which are marked by A,B,C,D in Fig. 3(b), for the long plate than for the shorter ones studied above. The resonance frequency labeled as "*E*" does not have a corresponding TL peak and is left out of the discussion. The modal amplitudes for the first peaks, *a* and *A*, are shown in the bottom row of Fig. 3(c). It is found that there is a strong second mode vibration, $j=2$, instead of the first, $j=1$, since the latter is too difficult to excite at low frequencies due to the cavity fluid stiffness. Nevertheless, the first mode still makes the dominant contribution to the sound reflection (not shown) at the first TL peak point *a*. The modal amplitudes for the second group of peak points, *b* and *B*, are shown in the second row from the bottom of Fig. 3(c). Here, the first mode response is enhanced but the third mode dominates. Point *c* and *C* feature the fifth mode, while *d* and *D* the sixth mode. It may be concluded that, for low structural bending stiffness, resonances featuring dominant axial modes occur at increasing frequencies, but not all resonance can produce a TL peak at its nearby frequencies. There is a clear frequency deviation between TL peaks and the resonance frequencies; the former generally consists of a mixture of different modes interacting constructively.

III. CAVITY AND PLATE OPTIMIZATIONS

In the previous studies for the drumlike silencer (Huang and Choy, 2005), it is found that high tension is necessary to obtain better silencing performance since a strong structure promotes low-order modes which are more effective in reflecting sound than high-order modes. However, the lateral structural constraints prohibit the overall response, and are generally unhelpful for responses at nonresonance frequencies. This is also found to be the case for plate silencer. Details are not given for such similar conclusions. In this section, a comparative study is conducted for the drumlike silencer and the plate silencer, both limited to the two-dimensional configuration in which the two lateral edges, $y=0,w$, are free to move. Since the frequency of interest is limited to that below the cut-on frequency of the duct, $f_1=0.5$, plane incident wave does not excite the lateral modes. The plate therefore behaves as a one-dimensional beam, and the duct acoustics is limited to two dimensions. The proof of such 1D structural response is given in Huang and Choy (2005) for the drumlike silencer, and is not repeated here. For simplicity, the configuration with two free lateral edges is referred to as the 2D model in the following discussions. To materialize such a 2D configuration, a small gap has to be allowed between the lateral plate edges and the duct walls. Too big a gap would cause serious leaking of sound, but a previous study for the 2D membrane configuration (Choy and Huang, 2002) showed that common design techniques used in minimizing the leakage flow between stationary and moving parts in a rotary machine would work. In the said experimental study using a duct of 5 by 5 cm cross section, a slit of 2 mm in depth was created in each lateral duct wall allowing the membrane to be inserted into the recess with an all-round clearance of no more than 0.5 mm. The experimental results demonstrated that the acoustic leakage was prevented satisfactorily. It is believed that, when the dimension of the duct cross section is increased, such gap would prevent acoustic leaking even more effectively.

In this section, the cavity shape is optimized for a given volume. The optimal shape is then fixed for the parametric study of other variables such as the plate and cavity damping. Comparative study is conducted between the plate silencer and the drumlike silencer to understand the commonality and the differences in terms of the intermodal interference.

A. Cavity shape optimization

The procedure described in Huang (2004) is followed here. For a given cavity volume, Lh_c, the aspect ratio, L/h_c, can be varied by changing the length and cavity depth simultaneously. For a given structure-to-air mass ratio, m_1, the dimensionless bending stiffness, B_1, can be varied by changing the material elasticity. The objective function is the frequency ratio, f_b/f_a, where the transmission loss, TL, is above a criterion value, $\mathrm{TL}_{\mathrm{cr}}$, over the whole frequency band $f\propto[f_a,f_b]$, or $f_1\propto[f_{1a},f_{1b}]$ in dimensionless form, where $f_{1a}=f_ah/c_0, f_{1b}=f_bh/c_0$. The choice of $f_b/f_a=f_{1b}/f_{1a}$ as the objective value instead of f_{1b}-f_{1a} is based on the consideration that the low-frequency noise control is a true technical challenge. The criterion value $\mathrm{TL}_{\mathrm{cr}}$ is somewhat arbitrary but a procedure described in Huang (2004) recommends that the value be chosen as the peak transmission loss for an expansion chamber whose cavity volume is three times the actual cavity volume in the silencer. For the example of volume $Lh_c=5h^2$, the criterion value thus derived is rounded up to 10 dB. This configuration and the $\mathrm{TL}_{\mathrm{cr}}$ value are adopted here. The results of the optimization are shown in Fig. 4 for the following given parameters: $m_1=1, Lh_c=5h^2$. The procedure is described as follows. With some parameters fixed as above, two variables remain: dimensionless cavity length $L_1=L/h$ and plate bending stiffness B_1. The optimization begins by fixing the value of L_1 and searching for the optimal B_1 so that f_b/f_a is the highest. This set of optimal results may be called a local optimum. The highest value of f_b/f_a for all lengths is identified as the global optimum. The local optimal parameters, f_{1a}, f_{1b}, and $B_{1\mathrm{opt}}$, are functions of the cavity length L_1, and are presented in Figs. 4(a)–4(c). Figure 4(a) shows the peak logarithmic bandwidth as a function of L_1. It is found that the global optimum is achieved right at $L_1=5$, $h_c/h=1$, since the result for $L_1=5.1$ is worse than that of $L_1=5$. Figure 4(b) shows that the dimensionless lower frequency limit, $f_{1a}=f_ah/c_0$, as a function of L_1 and the lowest f_{1a} is achieved for $L_1=5$. Figure 4(c) shows that the optimal bending stiffness, $B_{1\mathrm{opt}}$, increases with L_1 and there is no peaky appearance around $L_1=5$. The following set of optimal results is found:

$$L_{\mathrm{opt}}=5h,\quad B_{1\mathrm{opt}}=0.129,\quad f_{1a}=0.0353,$$

$$f_{1b}=4.25f_{1a}=0.149.$$

The right-hand column of Fig. 4 shows some spectral comparisons with frequency points where $\mathrm{TL}=\mathrm{TL}_{\mathrm{cr}}$ marked by

open circles for easy identification of stopbands. Figure 4(d) compares the overall optimum for $L=5h$ (solid curve) with the typical results for a three-dimensional model in which the plate is simply supported along all four edges (dashed curve) with $L=4h$, $h_c=1.25h$. The latter is not optimized under the strict criterion of $\text{TL}\geqslant\text{TL}_{\text{cr}}$ since TL=10 dB is hard to achieve for such 3D configuration described in the last section. The comparison shows that the major improvement of the 2D model from the 3D model is the low-frequency performance. The reason why the 2D configuration performs better is common with that of the drumlike silencer (Huang and Choy, 2005) and detailed analysis is not given here.

Figure 4(e) shows a very interesting 2D configuration of $L=5.25h$ for which the TL is almost flat over much of the stopband. Similar spectrum also appears for $L=5h$ when B_1 exceeds the optimal value of $B_{1\text{opt}}=0.129$, and the second and third spectral peaks merge. For the case of $L=5.25h$ shown in Fig. 4(e), the logarithmic bandwidth f_b/f_a is deemed to be lower than that of $L=5h$ due to the slight deterioration of TL near f_{1b}. Note also that there are only two spectral peaks within the band. Figure 4(f) shows that, when L_1 is further increased to 6, the bandwidth is severely narrowed due to the rather uniform drop of TL between the first two peaks in the spectrum. If the strict rule of $\text{TL}\geqslant\text{TL}_{\text{cr}}$ is somehow relaxed, it may be said that the silencer works for an ultralow frequency for a given geometry. If the dimensional frequency of interest is given, it means that the plate dimension may be reduced. For this reason, it might well be that this configuration is practically more preferable.

B. Comparison with the drumlike silencer

Coincidentally, the optimal cavity shape for the drumlike silencer for the specific volume of $Lh_c=5h^2$ is $L_{\text{opt}}=5.7h$ (Huang, 2004), not too far from $5.0h$ found for the plate silencer here. For simplicity, the performance of the drumlike silencer with $L=5h$, $h_c=h$ and the dimensionless optimal tension $T_1=0.475$ is chosen for comparative study in Fig. 5. The results for the plate silencer are shown in solid lines and those of the drumlike silencer in dashed lines. The spectral comparison is shown in Fig. 5(a) together with the performance of the expansion chamber of the same cavity geometry (dotted line). Evidently, the superiority of the plate silencer lies in the low-frequency region. Figure 5(b) compares the decomposition of the sound reflection, cf. Eq. (8) into the summation over odd *in vacuo* modes, $j=1,3,5,\ldots$ and that over the even *in vacuo* modes, $j=2,4,6,\ldots$. Focusing on the stopband below the dimensionless frequency of around 0.15, it is found that the odd-mode contribution for the two types of silencers is almost identical. For the even modes, however, the plate-type silencer outperforms the drumlike silencer with its first peak at a much lower frequency. In fact, this peak of the even-mode reflection is related to the second-mode resonance determined by the structural restoring forces (Huang, 2002), tension or bending moment, and the total mass of the coupled system. The virtual mass imposed by the cavity air is found to be much more than the structural mass for this example, and the acoustic impedance analysis for the drumlike silencer remains unchanged. The difference between the two silencers is this. For the plate silencer, a bending stiffness of $B_{1\text{opt}}=0.129$ is chosen in such a way that the second mode resonance occurs at a frequency lower than that of the drumlike silencer under $T_{1\text{opt}}=0.475$. Of course, it is also possible to choose a lower value of tension so that the second mode resonance for the drumlike silencer also occurs at a lower frequency. But, then the TL in the low-frequency regime cannot be maintained at a level above TL_{cr} due to the adverse cross-modal interference, which is shown in Fig. 5(c) as the part of the dashed curve near the label "Drum" with negative values. If the phase angle between the reflected wave from the odd modes and those of the even modes is denoted by θ, the interference index is given by $\cos\theta$, which varies from the lowest extreme of complete cancellation to complete addition. For frequency $f_1=0.03$ to 0.05, the plate silencer

works since its odd-even interference is neutral, $\cos\theta \approx 0$, while the drumlike silencer fails as its odd-even interference is rather destructive. Note that the structural responses at the three spectral peaks are rather similar to those of Huang, (2002), namely, the first peak is from the combined effect of the first and second *in vacuo* modes, the second peak is from the first mode, and the third peak is from the second mode.

C. Effects of plate and cavity damping

The effect of damping is investigated by two approaches. One is to consider various levels of structural damping on the plate, and the other is to add sound absorption materials in the cavity. For plate damping, the model adopted is written as

$$m_s(1 - i\sigma_m)\frac{\partial^2 \eta}{\partial t^2} + B\nabla^4 \eta(1 + i\sigma_s) + p_i + \Delta p = 0 \tag{11}$$

for harmonic oscillations, $\eta \propto e^{i\omega t}$, where σ_m and σ_s are, respectively, the mass and stiffness damping coefficients in the Rayleigh damping model. The mass damping coefficients acts mainly on the high-frequency oscillation while the stiffness damping on low frequencies. The exact damping mechanisms are hard to model. For the purpose of qualitative illustration, it may suffice to assume a balanced damping mechanism as

$$\sigma = \sigma_m = \sigma_s, \tag{12}$$

and focus on the overall effect of σ on the silencing performance. For the second method of adding sound absorption material into the cavity, the fluid inside the cavity is modeled as one in which the density and the speed of sound are modeled as complex quantities. Following Mechel and Vér (1992), the mass and momentum conservation laws are combined in a familiar manner to form the wave equation in the porous media,

$$\frac{1}{\rho_c c_c^2}\frac{\partial p}{\partial t} + \nabla \cdot \mathbf{v} = 0, \quad \rho_c \frac{\partial \mathbf{v}}{\partial t} + \nabla p = 0 \rightarrow \nabla^2 p - \frac{1}{c_c^2}\frac{\partial^2 p}{\partial t^2} = 0, \tag{13}$$

where $\rho_c, \mathbf{v}, c_c$ are, respectively, the complex density, particle velocity and wave speed. Note that the particle velocity is defined in such a way that $\rho_0 \mathbf{v}$ represents the true oscillating mass flow of the fluid through the porous material per unit cross section instead of $\rho_c \mathbf{v}$. Similar to sound wave propagation in lossless fluid, a velocity potential can be introduced and is related to sound pressure and velocity perturbations as follows:

$$\mathbf{v} = \nabla\phi, \quad p = -\rho_c \frac{\partial \phi}{\partial t}, \quad \left(\nabla^2 - \frac{1}{c_c^2}\frac{\partial^2}{\partial t^2}\right)\phi = 0. \tag{14}$$

The boundary condition on a solid wall with its unit normal vector $\mathbf{n}$ and the plate surface at $z=0$ are given as follows:

$$\left.\frac{\partial \phi}{\partial n}\right|_{\text{hard wall}} = 0, \qquad \left.\frac{\partial \phi}{\partial z}\right|_{\text{plate}} = \frac{\partial \eta}{\partial t}. \tag{15}$$

The sound pressure on the lower surface of the plate is obtained as $p|_{z=0-} = -\rho_c \partial\phi/\partial t$ and is used in calculating the fluid loading, $\Delta p = p|_{z=0+} - p|_{z=0-}$, used in Eq. (3). The complex wave number and impedance are given by empirical formulas (Mechel and Vér, 1992) using the data of glass fiber in the low frequency range,

$$Z_c = \rho_c c_c, \quad Z_0 = \rho_0 c_0, \quad k_0 = \omega/c_0, \quad R = -U^{-1} dp/dx,$$

$$k_c/k_0 = c_0/c_c = 0.396E^{-0.458} + i(1 + 0.135E^{-0.646}),$$

$$Z_{1c} = Z_c/Z_0 = (1 + 0.0668E^{-0.707}) - i \times 0.196E^{-0.549},$$

$$E = \rho_0 f/R \leqslant 0.025. \tag{16}$$

Note that R is the dimensional flow resistance, and a dimensionless version is defined below in the current study,

$$R_1 = \frac{Rh}{\rho_0 c_0}. \tag{17}$$

The parameters of σ and R_1 are collectively called damping factors for simplicity.

The effects of plate damping and sound absorption material filled in the cavity are investigated separately. For each type of damping mechanism and the level of damping factor chosen, the plate bending stiffness B_1 is varied to seek the widest logarithmic stopband f_b/f_a, while the geometry of $L = 5h$, $h_c = h$, and the dimensionless plate mass of $m_1 = 1$ are fixed in this optimization exercise. Again, the global optimum is identified for the highest bandwidth. The results are shown in Fig. 6. Figure 6(a) shows the optimal stopband as a function of the damping factor for the two damping mechanisms, with the global optimal point marked by a filled circle (with cavity damping) and a diamond (plate damping). For plate damping (solid line) the overall optimum is found at $\sigma_{\text{opt}} = 0.1$, $f_b/f_a = 4.54$, which is only slightly better than the bandwidth of $f_b/f_a = 4.27$ without damping. When σ exceeds around 0.12, the bandwidth suffers a sudden drop. For cavity damping (dashed line), a maximum bandwidth of $f_b/f_a = 4.84$ is achieved at $R_{1\text{opt}} = 0.07$. There is no sudden drop in bandwidth as R_1 increases further but excessive damping reduces the bandwidth. Figure 6(b) shows the optimal bending stiffness, $B_{1\text{opt}}$, as a function of the damping factors with the global optimal points shown in the same filled symbols as in Fig. 6(a). Spectral comparisons between the plate damping factors of $\sigma = 0$, σ_{opt}, 0.2 are given in Fig. 6(c). It is found that sharp peaks predicted for $\sigma = 0$ are smoothed out when there is plate damping, and excessive damping causes the TL to drop between the second and third peaks; hence, the sudden drop of f_b/f_a shown as the solid line in Fig. 6(a). The results for the cavity damping of $R_1 = 0$, $R_{1\text{opt}}$, 0.2 are shown in Fig. 6(d). It is found that the cavity damping brings a rather uniform TL across the whole frequency band, and excessive damping suppresses the responses near the lower limit of the stopband.

The contributions of the damping mechanisms towards the overall silencing effect are shown in Fig. 7 when the plate bending stiffness is fixed at its optimal value found in Fig. 6. For a plate with damping, the optimal value of $B_{1\text{opt}} = 0.132$ is given and the results are shown in Fig. 7(a). With the optimal damping factor of $\sigma_{\text{opt}} = 0.1$ (thick solid line), the average contribution of sound absorption by the damped

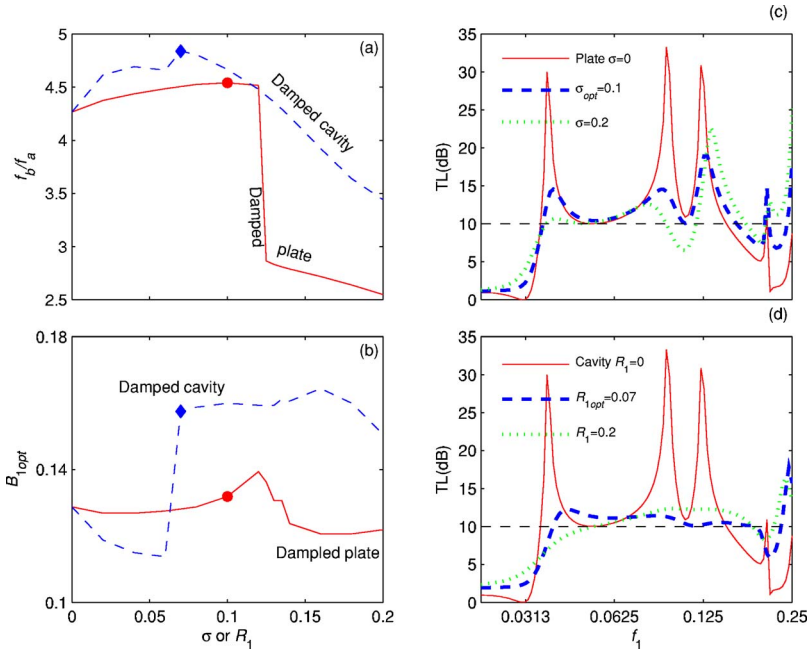

FIG. 6. (Color online) Effect of plate damping and porous material filled cavity for $L=5h$, $h_c=h$. (a) Logarithmic bandwidth. (b) Optimal bending stiffness. (c) Spectral comparison for plates with various damping factors. (d) Spectral comparison for cavity filled with sound absorption materials of various flow resistance.

plate is around 9% in the stopband marked by the two thin vertical lines. When the damping factor is increased to 0.2, the sound absorption is indeed increased to an average of 16%, but the overall TL is reduced, as shown in Fig. 6(c), due to the reduced sound reflection. For a plate without damping but the cavity filled with sound absorption material, the optimal bending stiffness is $B_{1\text{opt}}=0.158$ and the results are shown in Fig. 7(b). The contribution of sound absorption in this case is much more prominent than that of plate damping. Within the stopband marked by the two thin vertical lines, the average contribution by the cavity damping is 46% when $R_{1\text{opt}}=0.07$ is used, and is 63% when a higher value of $R_1=0.2$ is used. Again, excessive use of sound absorption mechanism stifles the plate response and reduces the overall transmission loss.

IV. EFFECT OF PLATE MASS AND CHOICE OF MATERIAL

A. Effect of plate mass

The effect of plate mass is investigated by varying the plate-to-air mass ratio m_1 while the geometry is fixed as $L=5h$, $h_c=h$. For each mass ratio given, bending stiffness is varied to find the optimal bandwidth f_b/f_a. The results are shown in Fig. 8. Figure 8(a) shows the optimal bandwidth as a function of m_1. All calculated points are marked by crosses. The overall optimum is shown by a filled triangle, while the result for $m_1=1$ is shown by a filled square. The horizontal scale is logarithmic except the special point of $m_1=0$, which is shown as an open circle. For the range of $m_1=0.05$ to 0.5, the bandwidth hovers around $f_b/f_a\approx 6.0$ with the overall optimum located at $m_1=0.25$. Figure 8(b) gives $B_{1\text{opt}}$ as a function of m_1 which shows a monotonous trend of increase. Figures 8(c) and 8(d) compare the optimal spectra for different values of m_1. Figure 8(c) explains why the bandwidth of $m_1=0$ suffers from a sudden drop of f_b/f_a from $m_1=0.05$ to 0.01 in Fig. 8(a). The reason is found as the mild decrease of TL between the first and second spectral peaks. For practical purposes, such drop can be ignored and a general conclusion can be drawn that a lighter plate provides wider stopband. Figure 8(c) also shows that, when the plate mass is increased, the stopband shrinks from both low and moderately high frequencies. Figure 8(d) shows the overall optimum (thick solid line) of $m_1=0.25$, and a rather heavy plate of $m_1=10$ (dashed line). The latter has nearly one octave stopband ranging from $f_1=0.029$ to 0.055. The bandwidth may be low, but the location in the very low frequency region could prove to be a practical advantage for the noise control at very low frequencies. In addition, a higher mass ratio also makes it easier for such a plate to be realized with a low-cost material and structure.

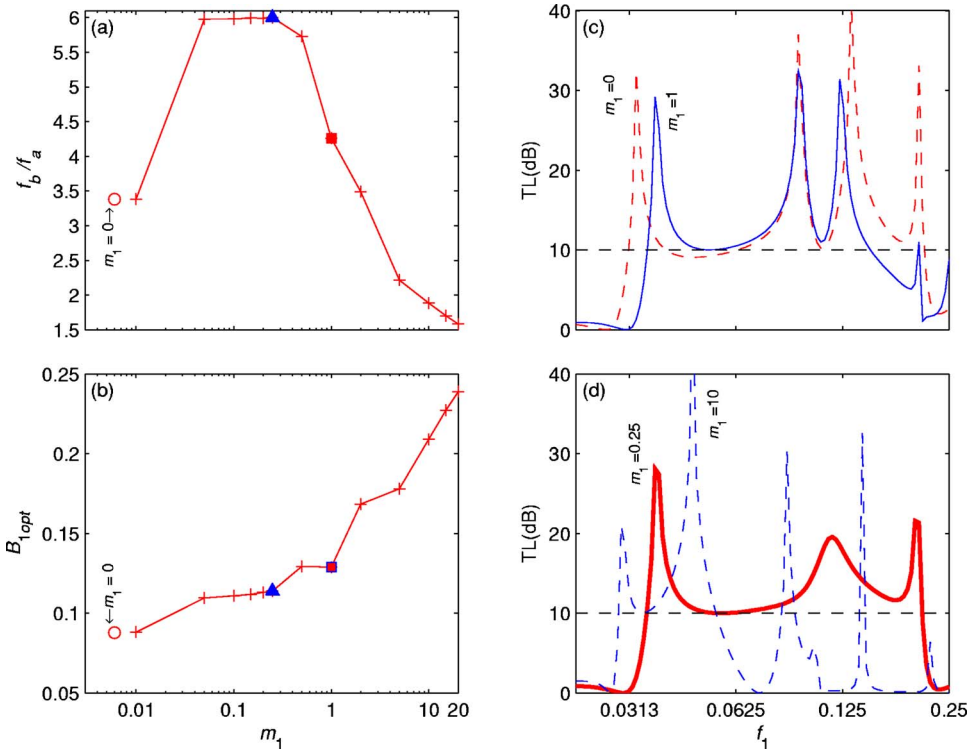

FIG. 8. (Color online) Effect of mass on (a) logarithmic bandwidth f_b/f_a, and (b) dimensionless optimal bending stiffness $B_{1\text{opt}}$, with spectral comparisons for (c) light, and (d) heavy plates. The cavity geometry is $L=5h$, $h_c=h$.

B. Choice of plate material and structure

As is shown below, it is generally difficult to satisfy the condition of a high bending stiffness with a low mass ratio. Stiffness-enhancing structures may have to be used. Denote the overall thickness of the plate as s and the volume density of the plate as ρ_s, which may be much lower than the density of the core material. The dimensionless bending stiffness, mass ratio, and the dimensional moment of inertia I are expressed below,

$$B_1 = \frac{EI}{\rho_0 c_0^2 w h^3}, \quad m_1 = \frac{\rho_s s}{\rho_0 h}, \quad I = \int_A y^2 dA = Cwh^3, \quad (18)$$

where the constant C is 1/12 for a homogeneous plate of rectangular cross section and the ratio of the actual value of C to the normal value of 1/12 can be called stiffness efficiency for a sandwich beam construction. Substituting the thickness s by $m_1 h\rho_0/\rho_s$, the dimensionless bending stiffness can be rewritten as follows:

$$B_1 = Cm_1^3 \frac{E}{\rho_0 c_0^2}\left(\frac{\rho_0}{\rho_s}\right)^3. \quad (19)$$

For a given material and sandwich beam construction, the most influential parameter is the dimensionless mass ratio m_1. When the mass ratio is increased by increasing the plate thickness, the required optimal bending stiffness also increases, cf. Fig. 8(b), and the bandwidth reduces, cf. Fig. 8(a). For $m_1=0.5,1,5$, the required values of the optimal bending stiffness are $B_1=0.114$, 0.1289, and 0.1780. The increase of $B_{1\text{opt}}$ with respect to m_1 is mild, roughly proportional to $m_1^{0.15}$ in this region of mass ratio. In other words, the requirement for $B_{1\text{opt}}$ is much easier to satisfy if the allowed mass ratio is increased with the price of having a much smaller stopband. For $m_1=5$, the logarithmic bandwidth is $f_b/f_a=2.2$. If this performance is accepted as the lower limit of a design, the mass ratio as high as 5 is considered to be relevant, and is included in the following analysis alongside the moderate mass ratio of unity.

Equation (19) also shows that, for a given set of m_1, B_1 to be satisfied, the most crucial material property is E/ρ_s^3, which is typical in the selection of weight-saving materials in aerospace applications. According to Chart 1 given in Ashby (1999), and Ashby and Johnson (2002), the best material for this purpose would be balsa, a type of wood, polyvinychloride (PVC), a type of polymer, or carbon fiber-reinforced polymer. Two materials are examined here using the normal rectangular cross section for the plate, for which $C=1/12$. The first material is the aluminum alloy with $\rho_s=2700$ kg/m^3, and $E=75$ GPa. Taking the air properties as $\rho_0=1.225$ kg/m^3, $c_0=340$ m/s, the dimensionless bending stiffness calculated by Eq. (19) is $B_1=4.12\times10^{-6}$, 5.15×10^{-4} for the mass ratios of 1 and 5, respectively, far below the required values of 0.1289 and 0.1780. It is concluded that a simple aluminum plate is about 250 times too elastic for a plate silencer even with a mass ratio of 5. The second material chosen is the PVC foam with $\rho_s=40$ kg/m^3, and $E=200$ MPa, a set of moderate values taken from Chart 1 of Ashby and Johnson (2002). The relative bending stiffness is found as $B_1=0.0034, 0.4226$ for the mass ratios of 1 and 5, respectively. In fact, this material would satisfy the optimal bending stiffness condition shown in Fig. 8(b) when the mass ratio is around 3.5.

A composite beam with a light core material like PVC foam bonded together with aluminum facings can be employed to achieve the effect of having an overall stiffness determined mainly by the elastic modulus of aluminum while the total mass is reduced drastically by the light core. Sandwich beams with honeycomb, I-beam, or corrugated

cores may also be considered to achieve the same purpose. Among the above structures, the I-beam made of a homogeneous material is perhaps most suitable for the purpose of illustrating how such structures can help satisfy the parametric requirement predicted by the current study. An I-beam cross section is mainly characterized by its depth, here denoted as s, and its flange width, w. Take the standard I-beam designated as S380×74 as an example. It has a depth of $s=381$ mm and width $w=143$ mm, the latter being roughly twice the second designation number, cf. Gere (2004). The discussion here is limited to the shape instead of the actual dimension of w and s. As listed in the tables of Gere (2004), the moment of inertia is $I=201\times10^6$ mm^4 and the cross section is 9500 mm^2. To achieve the same moment of inertia I, a plate of rectangular cross section must have a different depth s calculated by $I=\frac{1}{12}ws^3$, $s=\sqrt[3]{12I/w}\approx256$ mm. The cross section of such rectangular plate is $256\times143=36\,608$ mm^2, which is $36\,608/9500=3.85$ times that of the I-beam of the same moment of inertia. In other words, the weight-saving efficiency for such a typical I-beam is 3.85. Since the PVC foam described above can satisfy the parametric requirement of the plate silencer when the structure-to-air mass ratio is about 3.5, the weight-saving efficiency of 3.85 means that an I-beam made purely by PVC foam can satisfy the parametric requirement with a mass ratio of less than 1.0. The use of a thin rigid facing material would further enhance the structural rigidity for any given thickness s. As a result, the requirement of very light core material can be further relaxed. It is expected that a more common material like balsa may be adopted in a sandwich structure.

When using such smart structures, however, care must be taken to check whether the composite structure vibrates as one piece as assumed by the theoretical model, and whether the structural damping coefficient is low enough to allow vigorous plate response to achieve a high degree of sound reflection. More practical work needs to be done in this aspect, but it is argued that the optimal parameters predicted in this study are entirely within the reach of existing known light materials possibly with the help of composite beam construction.

V. CONCLUSIONS

This theoretical study reveals that, in a duct, a plate covering a side-branch rigid cavity can function effectively as a low-frequency wave reflector over a very broad frequency band, about one octave band broader than a drumlike silencer of the same cavity geometry. Effects of various boundary conditions and parameters are investigated. The following specific conclusions are made:

(1) When all edges of the plate are restrained to the duct walls, the response of the plate under grazing incident waves shows various axial and lateral vibration modes which consist of a combination of *in vacuo* modes in both directions depending on the excitation frequency and plate stiffness. Although the transmission loss depends very much on the magnitudes of the induced plate vibration, the spectral peaks in the plate vibration velocity, e.g., resonances, do not necessarily correspond to the peaks in the spectrum of the transmission loss. The latter depends more crucially on the acoustic interference between the wave reflections from various vibration modes. When the plate is simply supported at the leading and trailing edges and is free at the two lateral edges, the performance of the plate silencer is much better than when all edges are fixed.

(2) The first *in vacuo* plate vibration mode is effective in reflecting sound but is difficult to excite due to cavity stiffness. The second *in vacuo* mode is easy to excite but its capability to cause sound reflection is significant only when there is significant phase difference of sound over the length of the plate. The acoustic interference between the odd and even *in vacuo* modes is crucial to achieving a broad stopband. The mechanics of the plate bending differs from that of a tensioned membrane, leading to a different pattern of acoustic interference in favor of the plate silencer towards the ultralow frequencies like $f_1=0.03$.

(3) The effect of plate mass is generally counterproductive, but zero mass is not quite the optimal configuration, which differs somewhat from the drumlike silencer. The effect of the plate damping is marginally beneficial for the bandwidth, so is the use of sound absorption material in the covered cavity. However, the contribution of sound absorption in the overall noise abatement is higher in the latter case. This result can be easily understood since a highly damped plate generally responds less to the incoming sound. In other words, the effect of damping on the reduction of sound reflection is more serious when the damping is embedded in the plate motion than if it is distributed in the cavity.

(4) The optimal parameters predicted for sound reflection in air require a plate material which is very light and yet extremely stiff. When aluminum is considered, it is found that the Young's modulus E is at least 250 times too low. The critical parameter is E/ρ_s^3, for which nonmetallic materials like PVC foam can easily satisfy the requirement. In addition, composite beam structure can be used to reduce the crucial structural mass while achieving a fairly high structural stiffness.

(Received 11 October 2005; revised 3 March 2006; accepted 3 March 2006)

The acoustic nonlinear parameter, B/A, is an important piece of data whenever high intensity pressure fields are under consideration. In this work, an alternative method is proposed to measure this parameter. First, the method involves measuring the sound velocity and nonlinear waveform distortion of a finite amplitude plane wave propagating through a medium, Butanediol, whose density and attenuation law have been preliminarily determined. Measurements were performed in the nearfield of a piston where plane wave propagation regime exists. Impulse response of the hydrophone was determined and pressure waveforms were obtained by a convolution process. Then, the method involves modeling, in time domain and under experimental conditions, the theoretical nonlinear waveform distortion and fitting it to the experimental results by adjusting the B/A parameter. Comparative measurements were performed using the technique of parametric interaction. The respective results for the two methods ($B/A=11.0\pm10\%$ and $10.9\pm5\%$) are in a good agreement despite a smaller degree of accuracy for the proposed method. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2190161]

I. INTRODUCTION

The acoustic nonlinear parameter, called B/A, is a commonly used term in the field of nonlinear acoustics. It is derived from the Taylor series expansion of the variations of the pressure in a medium in terms of variations of the density or alternatively of the variations of the sound velocity in terms of variations of the pressure. So, whenever high amplitude regime and/or highly nonlinear medium are involved, it is of major interest to know this parameter. This is especially true for medical applications. For example, when thermally ablating tissues using high intensity focused ultrasound, the nonlinear waveform distortion produces harmonics frequencies in tissues near the focus of the transducer. Consequently, the total attenuation of the wave increases and leads to enhanced local heating.[1–4] Similarly, in harmonic imaging, Verma *et al.* (Ref. 5) recently showed that a high degree of nonlinear distortion may occur during propagation through biological fluids and produce significant temperature rises in the application of three-dimensional (3D) ultrasound imaging in obstetrics. In the field of lithotripsy, knowledge of the nonlinear parameter of a medium or media through which the wave passes is indispensable for predicting the pressure waveform at the focus.[6] These nonexhaustive examples illustrate that nonlinear parameter must be known for accurate modeling and understanding of modern US medical applications. Obviously, the interest for the acoustic nonlinear parameter is not limited to biological tissues. For example, in other fields and applications such as nondestructive evaluation in industrial applications[7] or search for hydrocarbon reservoirs,[8] the nonlinear characteristics of materials were investigated.

Beyer[9] listed different methods described in the literature to determine B/A. He insisted on the fact that method accuracy was rarely better than 5%. The most common method is the thermodynamic method where the sound velocity is measured as a function of the pressure and the density. The finite amplitude method consists in measuring the amplitude of the second harmonic of a distorted plane monochromatic wave.[10] In the phase comparison method,[11] B/A is determined from the time shift of tone bursts due to adiabatic variation of the hydrostatic pressure. Sarvazyan[12] developed a specific method for aqueous solutions and Everbach[13] another one for immiscible mixtures. More recently, Barrière and Royer[14] presented a new method based on the parametric interaction of a high frequency acoustic wave with a low-frequency acoustic pulse. High-frequency acoustic wave gets modulated in phase when interacting with a lower frequency acoustic pulse and B/A is determined by detecting the phase modulation.

The goal of this study was to develop an alternative method for determining the nonlinear parameter B/A of a medium. First, the method involves measuring the sound velocity and the nonlinear waveform distortion of the pressure for a finite amplitude acoustic wave propagating through a medium whose density and attenuation law have been preliminarily determined. Then, the method involves modeling, in time domain and under experimental conditions, the theoretical nonlinear waveform distortion and fitting it to the

experimental result by adjusting the B/A parameter. Attenuation, nonlinearity, and diffraction must be taken into account for simulating the waveform distortion of a finite amplitude wave. As taking into account diffraction effects increases dramatically time of calculation, it was proposed to limit the model to finite amplitude plane waves. So, measurements were performed in the nearfield of a circular piston where plane wave propagation regime exists.

II. PRINCIPLE

Let us consider an acoustic plane wave propagating in the z direction and traveling in thermoviscous medium. Nonlinear distortion of the pressure waveform can be described by the Burgers equation,

$$\frac{\partial P(z,\tau)}{\partial z} = \frac{\beta}{\rho_0 c_0^3} P(z,\tau)\frac{\partial P(z,\tau)}{\partial \tau} + \frac{\delta}{2c_0^3}\frac{\partial^2 P(z,\tau)}{\partial \tau^2}, \tag{1}$$

where $P(z,\tau)$ is the sound pressure, $\beta=1+B/2A$ is the coefficient of nonlinearity, ρ_0 is the ambient density, c_0 is the sound speed, $\tau=t-z/c_0$ is the retarded time and δ is the dissipative coefficient of the medium. In many media such as biological tissues, this equation can be written in another form:[15]

$$\frac{\partial P(z,\tau)}{\partial z} = \frac{\beta}{\rho_0 c_0^3} P(z,\tau)\frac{\partial P(z,\tau)}{\partial \tau} + \int_{-\infty}^{\tau} g(z,\tau-\tau') \,.\, P(z,\tau')d\tau', \tag{2}$$

where the kernel, $g(z,\tau)$, can be evaluated from the frequency dependence of the attenuation $\alpha(\omega)$.[16]

Thus, the nonlinear propagation of a finite amplitude plane wave through a medium is determined by four intrinsic parameters: The density, ρ_0, the sound velocity, c_0, the frequency-dependent attenuation coefficient, $\alpha(\omega)$, and the acoustic nonlinear parameter, B/A. If ρ_0, c_0, and $\alpha(\omega)$ are known or measured elsewhere, B/A parameter can be obtained through matching experimental data to theoretical results.

Based on this observation, the principle of measuring the nonlinear parameter involves:

(1) Determining the parameters ρ_0 and $\alpha(\omega)$ of the medium being studied;
(2) measuring the distortion of a finite amplitude plane wave through a sample of medium with a calibrated hydrophone. Waveforms will be collected at the input and output of the sample;
(3) converting these electrical signals into pressure signals;
(4) determining, from these measurements, the parameter c_0 of the medium and of the water in experimental conditions;
(5) developing a numerical model to solve Eq. (2) and injecting the input pressure waveform and the parameters ρ_0, c_0, and $\alpha(\omega)$ into this model;
(6) varying the parameter B/A numerically until theoretical and experimental output pressure waveforms coincide as closely as possible.

III. NUMERICAL MODEL

The model implemented is a time-domain algorithm based on the principle of the fractional steps method, widely developed by Lee,[17] Tavakkoli,[18] and Khokhlova.[19] In summary, Eq. (2) is separated into two equations, Eqs. (3) and (4), and these equations are solved independently over each incremental step Δz.

$$\left.\frac{\partial P(z,\tau)}{\partial z}\right|_{NL} = \frac{\beta}{\rho_0 c_0^3} P(z,\tau)\frac{\partial P(z,\tau)}{\partial \tau}, \tag{3}$$

$$\left.\frac{\partial P(z,\tau)}{\partial z}\right|_{Att} = \int_{-\infty}^{\tau} g(z,\tau-\tau') \,.\, P(z,\tau')d\tau'. \tag{4}$$

Because Eq. (4) is a convolution sum, $P(z,\tau)$ at step z (index k) is sampled by a uniform time interval $\Delta\tau$ and labeled P_i^k at time $\tau_i=i\Delta\tau (i=0,\ldots,N-1)$.

Nonlinearity: The evolution equation for a plane wave in a nonlinear medium, Eq. (3), has an analytical solution, called the Poisson's solution, Eq. (5). To avoid multivalued waveform solutions, Δz must satisfy the condition given by Eq. (6)

$$P(z+\Delta z,\tau) = P(z,\tau+\Delta\tau_{NL}) \text{ with } \Delta\tau_{NL} = \frac{\beta\Delta z}{\rho_0 c_0^3} P(z,\tau), \tag{5}$$

$$\Delta z < \frac{\rho_0 c_0^3}{\beta \max(\partial P/\partial\tau)}. \tag{6}$$

Numerically, using the waveform samples P_i^k, an adapted Δz is first calculated according to Eq. (6). Then, for each time index, i, $\Delta\tau_{NL}$ is calculated and P_i^{k+1} is determined using 2nd degree polynomial interpolations.

Attenuation: In biological tissues, the attenuation effect, Eq. (4), is frequency-dependent and can be written in the general form:

$$G(\Delta z,\omega) = \exp\{-\alpha(\omega) \,.\, \Delta z + i\omega[c(\omega)^{-1} - c_0^{-1}] \,.\, \Delta z\}, \tag{7}$$

where $c(\omega)$ and $\alpha(\omega)$ are, respectively, the frequency-dependent sound velocity and attenuation coefficient of the medium. If the $\alpha(\omega)$ law is known, the Kramers-Kronig relationship between attenuation and phase velocity (i.e. dispersion) makes it possible to calculate $G(\Delta z,\omega)$ as a minimum-phase digital filter.[18,20] In the time domain, Eq. (4) is numerically implemented as a convolution sum, Eq. (8), where the impulse response g is the inverse Fourier transform of $G(\Delta z,\omega)$.

$$P_i^{k+1} = \sum_{j=0}^{+\infty} P_j^k . g_{i-j}^k \,.\, \Delta\tau. \tag{8}$$

Propagation: For precise synchronization of theoretical results with measurements, the absolute time $t_i^k=t_0^k+i\Delta t$ with $\Delta t=\Delta\tau$ must be determined for each sample P_i^k. Let us consider that $\Delta z_{\text{water}}^k$ and $\Delta z_{\text{medium}}^k$ are, at step z, the total distances of propagation through water and medium, the absolute time t_0^k is written,

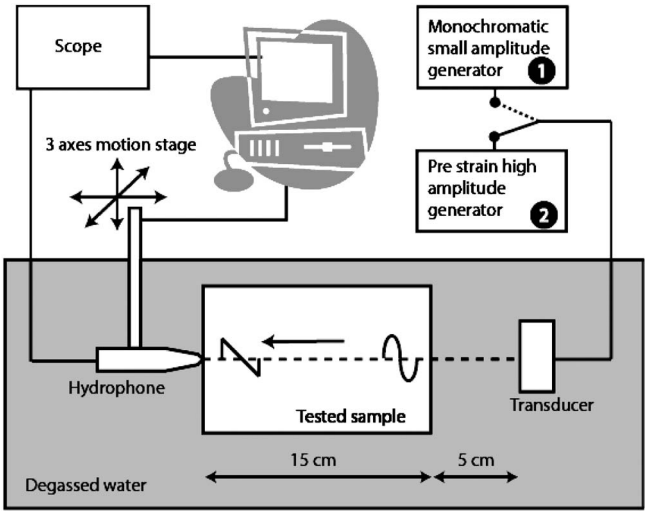

FIG. 1. Experimental setup. To find the acoustic axis, the transducer was excited monochromatically (position 1). To collect signals S1–S5, the transducer was excited with pulses (position 2).

$$t_0^k = t_0^0 + \frac{\Delta z^k_{\text{water}}}{c_{0\ \text{water}}} + \frac{\Delta z^k_{\text{medium}}}{c_{0\ \text{medium}}}. \tag{9}$$

Interface transmission: Finally, because the plane wave passes experimentally through several media in succession (sample of medium immersed in water), reflections at the interfaces should be taken into account in the model. If Z_w is the impedance of water and Z_m the impedance of the medium, the amplitudes of the pressure transmitted at the water-medium and medium-water interfaces can be written, respectively,

$$P_m = \frac{2Z_m}{Z_m + Z_w} P_w \quad \text{and} \quad P_w = \frac{2Z_w}{Z_m + Z_w} P_m. \tag{10}$$

IV. MATERIALS AND METHODS

A. Experimental setup

High-pressure pulses were generated at the surface of a piezo-composite transducer using electrical pre-strain. This method and the electronic driving system which enables more pressure to be generated from a piezo-composite transducer, have been described in detail elsewhere.[21]

The experiments were performed with a 50 mm diameter and 720 kHz central frequency piezo-composite planar transducer (Imasonic, Besançon, France). The transducer was air-backed and had a quarter wavelength matching layer. It was positioned in a tank filled with degassed water at ambient temperature (Fig. 1). The material being studied was conditioned in a sample-holder. A stand joined to the transducer enabled the sample-holder to be centered on the acoustic axis and its front to be positioned 50 mm away from the transducer. At this distance, the wave propagating through the front face of the sample is plane over a long temporal window. Furthermore, no electro-acoustical coupling prevents measuring pressure. The sample-holder was a 150 mm long cylinder, 90 mm in diameter. A polyethylene membrane was stretched over both ends of the cylinder. This extremely fine membrane (25 μm) was nevertheless sufficiently stiff to ensure that the faces of the sample were parallel to the transducer. A preliminary experiment was performed with a view to testing this membrane's transparency to ultrasound. The transducer was excited with a high-intensity pulse (nonlinear regime) and the hydrophone was placed at 280 mm from the transducer. Two signals were recorded when the sample-holder, filled with degassed water, was placed on its stand and then when it was withdrawn from it. The estimated frequency-dependent transmission loss increases from less then 0.04 dB at 1 MHz to 0.4 dB at 10 MHz and 1.5 dB at 20 MHz. These results show that transmission losses are low on this frequency band. A "Golden lipstick 0.2 mm" hydrophone (Onda, Sunnyvale, CA) was moved by a computer-controlled three-axis drive unit (Newport Corporation, Irvine, CA). The output signal from the hydrophones was collected using a Waverunner LT264 oscilloscope (Lecroy, Chesnut Ridge, NY).

Measurements were made on the acoustic axis, where the time window corresponding to the plane wave (preceding the arrival of the "edge wave") is maximal. According to the length and the position of the sample and according to the diameter of the transducer, the usable time window covered the first arch of the signal ($\approx$1 μs). It should be noted that the excitation system generates waveforms which present maximal nonlinear distortion in the first arch (where amplitude and slope were maximal). Moreover, the sensitivity of measurements increases with the propagation distance through the medium. So, this configuration is the good trade off to maximize the sensitivity of measurements (see Sec. IV).

B. Methodology of measurements

During setup, a special phase of the control program was used to accurately determine the acoustic axis by means of a series of measurements made with low amplitude monochromatic signals.

In order to determine the velocities of sound in experimental conditions, the transducer was switched to the pulse generator, whose discharge voltage was set to 117 Volts. The maximum pressure amplitude at the surface of the transducer was then 0.04 MPa (linear regime). With no sample, signals S1 and S2 were recorded when the hydrophone was placed at 50 and 201 mm from the transducer, respectively. With sample, signal S3 was recorded when the hydrophone was placed at 201 mm from the transducer. Measurements S1, S2, and S3 were the result of an average over 5 pulses.

To measure nonlinear distortion, the discharge voltage of the generator was then set to 3850 Volts. In these conditions the maximum pressure amplitude at the surface of the transducer was around 2 MPa (nonlinear regime). With the sample still in place, signal S4 was recorded when the hydrophone was placed at 201 mm from the transducer. Without sample, signal S5 was recorded when the hydrophone was placed at 50 mm from the transducer. At this level of excitation, the measurements were very reproducible. Averaging was, therefore, dispensed in order to protect the hydrophone. The choice of this sequence makes it possible to con-

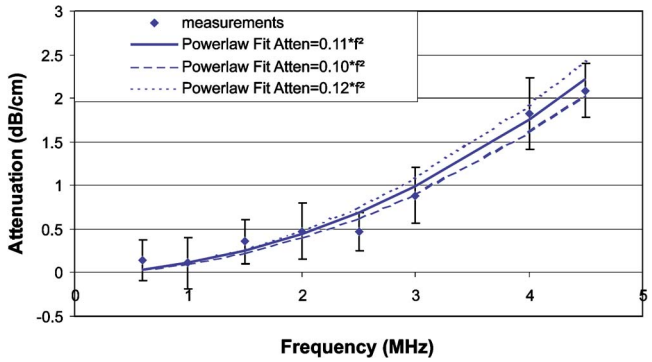

FIG. 2. Attenuation of 1.3 Butanediol over the band 0.5–4.5 MHz. Estimation of the attenuation law.

serve the alignment by keeping sample manipulations to a minimum and keeping the same excitation levels for the measurements in water and in the sample.

Finally, to be compatible with the numerical model, the electrical signals, S4 and S5, must be converted into pressure signals, P4 and P5. Given the spectrum of nonlinear signals, convolution sum was necessary, as $P(t)=S(t)*h(t)$ where $P(t)$ is the investigated pressure signal and $h(t)$ the pulse response from the hydrophone. To ensure that this conversion operation is carried out accurately, the pulse response from the hydrophone was measured using the "thick transducer" method.[22,23] The principle behind this method is to excite a transducer (50 mm in diameter and 20 mm thick) whose physical parameters are accurately known by a step of voltage (rise time=12 ns). As the transducer is sufficiently wide and thick, it is possible to separate the time taken by the response coming from the front of the transducer from those coming from its rear and its edges. In this way, by placing the sensor at 6 mm from the transducer, we can get its frequency response (amplitude and phase) and then, by inverse Fourier transform, its impulse response (4 μs). It should be noted that the characteristics of our calibration bench limit measurement to the frequency range situated between 0.25 and 20 MHz.

V. RESULTS

The material studied was 1.3—Butanediol (99%, Sigma-Aldrich Chimie, Saint-Quentin Fallavier, France) proposed as a tissue phantom for shockwave propagation.[24] Its density, 1005 kg/m^3, was found in manufacturer's data sheets. Water density, 1000 kg/m^3, and attenuation law, 0.0022 dB/cm/MHz^2, were available from the literature. Using a specific bench, the attenuation law of Butanediol was estimated from the series of attenuation measurements made in transmission mode on the frequency band 0.5–4.5 MHz (Fig. 2). Given the equipment used, the maximum error on these measurements was calculated as ±16%. The powerlaw $\alpha(f)=\alpha_0 f^2$ with $\alpha_0=0.11$ dB/cm/MHz^2 was found to be the best fit for experimental results. Considering the error bars on the measurements, α_0 ranges between 0.10 and 0.12 dB/cm/MHz^2 resulting in a ±10% accuracy. These results are in a good agreement with Andreev's data[25] measured in a 3–25 MHz frequency range.

Before the experiment, the Butanediol was degassed and the sample-holder immersed in the tank until the temperatures stabilized ($T=25$ °C). According to the described methodology, the electrical signals S1 to S5 were collected at the output of the hydrophone (Fig. 3) and recorded (time and amplitude).

From signals in linear regime, velocities, $c_{0\text{water}}=1496.93$ m.s^{-1} and $c_{0\text{but}}=1530.21$ m.s^{-1}, were, respectively, measured from the time shift (T_s) of the first arch of signals S1 and S2 ($T_s=100.873$ μs through 151 mm of water) and S1 and S3 ($T_s=98.694$ μs through 150 mm of Butanediol plus 1 mm of water).

Electrical signals S4 and S5 were converted into pressure signals P4 and P5. Then, signal P5 was injected into the model (time step=1 ns, $\alpha_{\text{but}}=0.11$ dB/cm/MHz^2, propagation distance=150 mm through Butanediol+1 mm through water). In order to approach the B/A value, simulations were made for B/A varying between 5.0 and 13.0 with increment $\Delta B/A=1.0$. The measured pressure, P4, and the simulated pressures $\{P4_S:\Delta B/A=1.0\}$ are shown in Fig. 4(a). The set of simulated pressures show that, for a given input signal, the

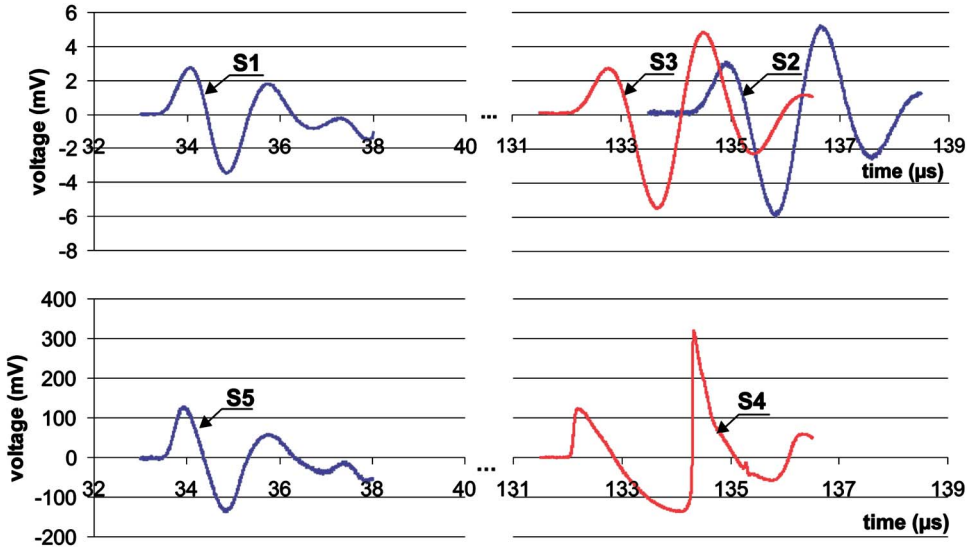

FIG. 3. Signals S1, S2, and S3 measured under linear regime and S4 and S5 measured under nonlinear regime. Time resolution = 1 ns.

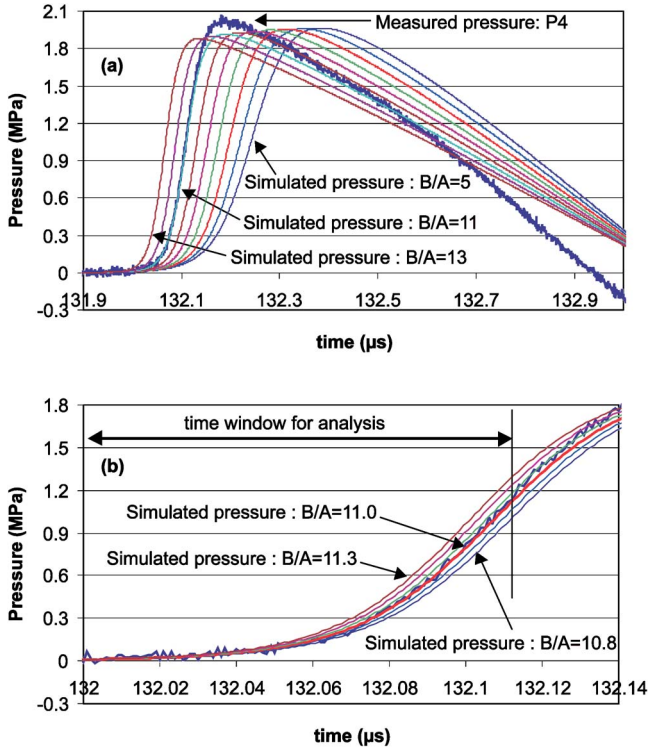

FIG. 4. Experimental response, P4, and theoretical responses: (a) For B/A varying between 5 and 13 with an increment of 1.0, (b) for B/A varying between 10.8 and 11.3 with an increment of 0.1. Time step = 1 ns, $\alpha(f) = 0.11\,f^2$, propagation distance = 150 mm through Butanediol +1 mm through water.

amplitude, the slope and the position of the first leading edge depend of the B/A parameter. The accuracy of the calibration of hydrophone, the uncertainty of the attenuation law and/or the nonuniformity of pressure distribution (amplitude and phase) on the edges of the transducer may be the cause of the discrepancy on amplitude between measured and simulated results. Furthermore, the slope of the first leading edge also varies with the α_0 value. Finally, for a given input signal, the position of the first leading edge appears as the most significant factor. Indeed, it principally depends of the velocity (accurately determined from linear signals) and of the B/A parameter. Moreover, the position of the first edge is much more sensitive to B/A than amplitude and slope. According to these observations, the time window for analysis was focused to a smaller area corresponding to the first part of the leading edge and more discriminating simulations were made for B/A varying between 10.8 and 11.3 with increment $\Delta B/A = 0.1$. The measured pressure, P4, and the simulated pressures $\{P4_S : \Delta B/A = 0.1\}$ are shown in Fig. 4(b). The best correlation coefficient (99.7958%) was obtained for the value $B/A = 11.0$.

VI. DISCUSSION

The nonlinearity parameter measured in the butanediol, $B/A = 11.0$, is different from the value given by Granz ($B/A = 7.3$, estimated according to Ballou's rule). In order to validate our measurement method, a sample of Butanediol was sent to the *Laboratoire Ondes et Acoustique (Paris, France)* where the nonlinearity parameter was measured using the nonlinear interaction of two waves with a high-frequency ratio and generated by planar transducers. The measurement principle and the experimental setup are described in detail by Barrière[14] and Jacob.[7] Briefly, the nonlinear collinear interaction of a 10 MHz tone burst with a 1 MHz central frequency pulse leads to a phase modulation of the highest frequency wave. The nonlinearity parameter is deduced from the phase modulation measurement and from the calibration of the low-frequency transducer with an optical interferometer. Several measurements were taken at 25 °C, for three interaction distances (10, 15, and 20 mm) and three different central frequencies of the lower frequency pulse (0.25, 0.5, and 1 MHz). The average value deduced from these experiments is $B/A = 10.9 \pm 0.6$. This means that the two methods concur.

Obviously, the theoretical model used in this work is valid for determining the nonlinear parameter B/A of liquids and biological tissues that satisfy both equations $B/A = 2(\beta - 1)$ and $\alpha(f) = \alpha_0 f^p (1 \leqslant p \leqslant 2)$. However, the proposed method remains suitable for determining β of many solids.

The sensitivity of the proposed method can be discussed. First, the results (Fig. 4) show that, for a finite amplitude plane wave propagating through a medium, the B/A parameter is directly linked to the position of the first leading edge. Consequently, the fit process can be focused on this part of the measured signal in order to increase the sensitivity. Additionally, simulations carried out with different propagation distances, show that the sensitivity increases with the length of the sample. For example, if the input pressure amplitude is 2 MPa and if the sample length is 80 mm, the simulations for B/A varying between 10.8 and 11.3 with an increment of 0.1 are nearly superposed. In these conditions, the determination of B/A with a decimal accuracy requires increasing the pressure at the surface of the transducer. Maximizing the sample length is preferable for protecting the hydrophone. Finally, the sensitivity of the method depends of several factors such as the dynamic range of the excitation system, the transducer diameter and/or the sample dimensions.

Concerning measurements, it should be noted that the accuracy of the proposed method is dependent upon the accuracy of the pressure measurements (amplitude and time) and the estimation of the attenuation law. First, the method turns out to be very sensitive as far as pressure injected into the model is concerned. A variation of ±2% in the pressure injected leads to a variation of ±3% in evaluating parameter B/A. In these conditions, a perfectly calibrated hydrophone must be used. Generally, hydrophone calibration procedures provide, in terms of frequency, a limited range of sensitivities (between 0.25 and 20 MHz for our calibration procedure). To ensure the accuracy of pressure measurements, the transducer was chosen with a low central frequency (720 kHz) and the excitation level was adapted so that the maximal frequency of the first leading edge remains below 20 MHz. Thus, the accuracy of pressure measurements can be estimated at ±5% (accuracy of our hydrophone calibration procedure). Concerning time measurements, it should be noted that the time shift of the synchronization signal (±5 ns) could lead to a variation of ±3% in evaluating parameter B/A.

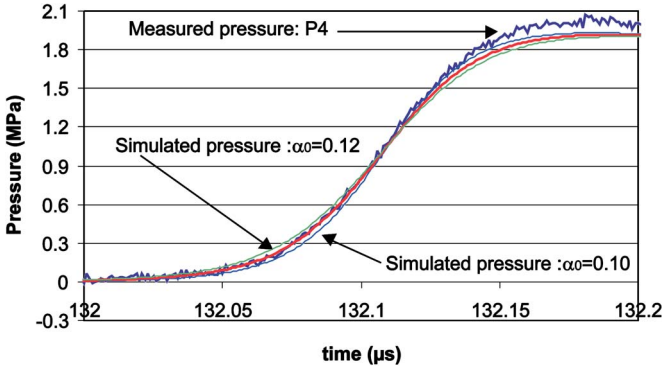

FIG. 5. Experimental response and theoretical responses for α_0 varying between 0.10 and 0.12 dB/cm/MHz^2 by increments of 0.01 dB/cm/MHz^2. Time step = 1 ns, $\alpha(f) = \alpha_0 f^2$, propagation distance = 150 mm through Butanediol + 1 mm through water, $B/A = 11.0$.

Another source of uncertainty is related to estimating the attenuation law for the material being studied. For Butanediol, a quadratic law was measured in agreement with data of Andreev.[15] However, with our bench, the dispersion of measurements in transmission on a restricted frequency range (Fig. 2) does not allow us to estimate α_0 with any great accuracy (±10%). Figure 5 shows simulations made for different attenuation laws, $\alpha(f) = \alpha_0 f^2$, when α_0 varies between 0.10 and 0.12 dB/cm/MHz^2 by increments of 0.01 dB/cm/MHz^2 (time step = 1 ns, propagation distance = 150 mm through Butanediol + 1 mm through water, $B/A = 11.0$). These results confirm that the amplitude and the slope of the first leading edge depend of α_0. So, by fitting the slopes, it seems possible to approach α_0 more accurately. Here, it clearly appears that simulation with $\alpha_0 = 0.11$ dB/cm/MHz^2 provides the best fit of measured pressure. Finally, in this work, the poor accuracy of the method used to measure the attenuation law does not really affect the accuracy of B/A measurement. Unfortunately, this conclusion is valid if the exponent of the powerlaw of the attenuation is known with accuracy. Indeed, if α_0 and p are unknown, different couples of values (α_0, p) may provide a good fit of measured pressure and consequently the accuracy of B/A measurement decreases. So, the necessity to accurately know the attenuation law $\alpha(f) = \alpha_0 f^p$ over a broad frequency range remains a constraint of the proposed method in comparison with other methods that require only few values of attenuation at specific frequencies.

In conclusion, the proposed method turns out to be relatively simple to use, from both the theoretical and experimental standpoints. It makes it possible to obtain reasonable results with a degree of accuracy (of ±10% in our experimental conditions) which is, to a great extent, correlated with the accuracy of the measurement of the pressure (amplitude and time) and of the medium's attenuation law.

Acoustical origin of rainbands in an ideal tropical hurricane

S. A. Elder[a)]
Physics Department, United States Naval Academy, Annapolis, Maryland 21402

(Received 29 November 2004; revised 29 August 2005; accepted 13 January 2006)

An acoustical model of hurricane rainband formation is proposed. Self-excited acoustic resonance inside the spinning eye produces strong azimuthal and radial standing waves. These modes can cause large temperature fluctuations about the dew point which are believed to be responsible for observed dry/wet bands in the outer storm disk. Distortion of standing wavefronts into spirals occurs in the transition layer region between approximately geostrophic flow inside the eyewall and irrotational flow outside. Tonal emissions from hurricane eyes should be detectable at great distances and are likely to be in a range below 0.01 Hz. © *2006 Acoustical Society of America.*

I. INTRODUCTION

An ideal tropical cyclone is characterized by a clear/unclouded and elegantly rounded eye cavity, from which issue alternating spirals of rainy and dry bands. In this treatment we consider only counter-clockwise (CCW) rotating storms, the type found in the northern hemisphere. In order to seek a physical understanding of possible acoustical involvement of this natural phenomenon, it is helpful to visualize the underlying steady flow, upon which the acoustical field is superposed, in terms of a simple model. Emanuel[1,2] has derived an approximate formula for the maximum theoretical azimuthal velocity of a tropical hurricane, based on thermodynamic quantities such as the amount of enthalpy available from the warm moist air close to the ocean surface. At the eyewall, which occurs at a slightly smaller radius than that defined by this limiting speed, the steady flow is approximately geostrophic. Thus the eye is in essentially rigid-body rotation, important for understanding the acoustics of the problem. The reasoning for this assumption is that both viscous and inertial forces in the Navier-Stokes equation are likely to be small compared to the Coriolis force in the eye.

That is, in the eye, the steady-state Navier-Stokes equation reduces to

$$\frac{1}{\rho}\nabla p \cong -2\boldsymbol{\Omega}\times\mathbf{u} \tag{1}$$

where p is the pressure, ρ is the density of the air, $\boldsymbol{\Omega}$ is the angular speed of rotation of the earth, and $\mathbf{u}$ is the velocity of the fluid inside the eye cylinder.

Dropping the inertial term near the center is justified by the fact that this term varies as the square of the azimuthal velocity and must therefore be negligible near $r=0$, where r is measured from the center of the slowly translating storm. Furthermore, any friction between the nearly circular rotating layers of fluid within the eye should tend to make all layers rotate at the same angular speed, removing the differential effects of viscosity. Therefore, within the eyewall, the Coriolis and pressure gradient forces dominate, with low Rossby and Ekman numbers[3] almost out to the radius of maximum winds. Beyond the eye uniform angular rotation can no longer be maintained, and the wind begins to slow down. In the extreme far field, on the other hand, conservation of angular momentum requires that the velocity profile must approach irrotational flow, since nearly all the vorticity is confined to the region in and immediately around the eye. This also simplifies acoustical considerations. We may think of the region between these two extremes as a sort of transition layer over which the necessary adjustments are made by both the steady and acoustical motions. It is the presence of this layer that distinguishes real hurricanes from ideal free vortex motion.

II. PRESSURE PROFILE IN THE EYE OF AN IDEAL HURRICANE

Geostrophic flow leads to a barometric pressure in the eye cavity which rises parabolically from a minimum at the center out to the eyewall as shown in Fig. 1. This gives a pressure gradient proportional to the Coriolis acceleration, which is itself in proportion to the radius. Beyond the eyewall, pressure should rise more slowly, since it is assumed to approach some ambient atmospheric pressure in the far field. Outside the concentrated vorticity within the eye cavity, the velocity field beyond becomes increasingly irrotational, eventually allowing the azimuthal velocity to fall off approximately as the distance from the center in the far field. Figure 1 gives a plausible barometric pressure profile for the entire lowered pressure region based on the above understanding. It is assumed that the eyewall cloud begins at the radius for which the effect of the inertial and viscous terms begin to be felt, ending the conditions for geostrophic flow.

III. IDEAL FREE VORTEX VELOCITY, VORTICITY, AND CIRCULATION PROFILES

Ideal free vortex profiles of azimuthal velocity, vorticity, and circulation are shown in Fig. 2 for comparison.[4] Since, within the eye of the free vortex, the fluid is assumed to be in solid-body rotation, a linear azimuthal velocity profile prevails out to the beginning of the eyewall. The ideal free vortex has uniform vorticity within the eye and zero outside.

[a)]Retired.

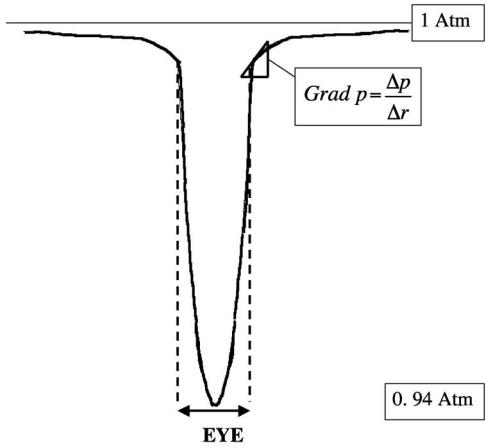

FIG. 1. Barometric pressure profile, $p(r)$, for ideal hurricane, showing radial gradient of barometric pressure at a particular radius. Dashed lines indicate diameter of the eyewall.

Circulation grows in proportion to the square of the radius, from zero at the center to a maximum at the eyewall. With all vorticity contained within the eye, the circulation must remain constant thereafter, providing pure irrotational motion.

IV. CUTAWAY VIEW OF HURRICANE OVER OCEAN

In Fig. 3(b) we see a closeup of the eye cavity region taken from the schematic hurricane cross section shown in Fig. 3(a). The CCW geostrophic motion inside the eye cavity

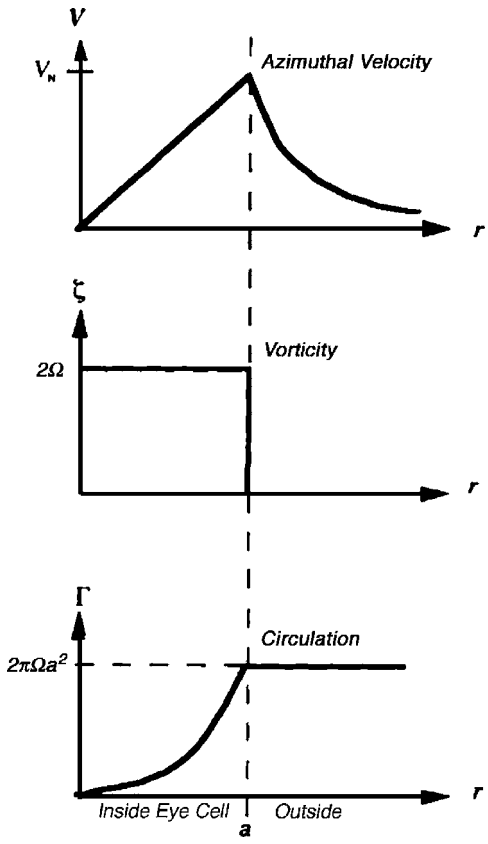

FIG. 2. Free vortex profiles are shown for comparison. Ideal velocity, vorticity, and circulation are plotted as a function of radius from the center. Adapted from Ref. 4.

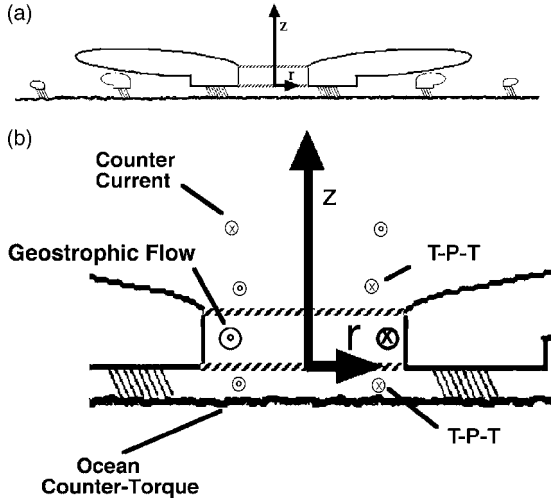

FIG. 3. Geostrophic flow in eye cavity. (a) Idealized hurricane cross section, showing a cylindrical acoustical resonator at the center, surrounded by the eyewall and outer rainbands. (b) Closeup of the eye cylinder, showing directions of steady currents. Approximate geostrophic flow extends above and below as well as in the cavity, illustrating the consequences of the Taylor-Proudman theorem (T-P-T).

is indicated by dot and "x" symbols. Since the Rossby number is small but not zero, some CCW flow occurs above and below the eye cylinder as well. Thus results the CCW twisting of warm moist air up from the ocean surface into the eye cylinder leading, in the steady state, to approximately geostrophic conditions within the eye cavity. That is, the regions of the cylindrical column immediately above and below the cloud layer also partake of this motion, consistent with the Taylor-Proudman theorem.[5] A diminishing azimuthal speed, accompanied by a counter torque, must occur in a boundary layer at the air-sea interface of the ocean, however, due to the inertia of the heavier fluid.

At the top of the eye cylinder, CCW rotation of the fluid weakens in the horn-shaped region defined by the outward sloping wall clouds above the hurricane. In order to balance lost angular momentum, a clockwise counter flow is generated above the top of the eye cavity by this effect. Along the vertical axis the active acoustical cavity is most effective from the point where the wall clouds begin to appear above the ocean and continues up to the point at which the slope of the pressure gradient changes abruptly.

V. CLOSE-UP OF PRESSURE PROFILE AT THE EYEWALL BOUNDARY

Figure 4 is a close-up that shows what a plausible pressure profile might look like at the radius where it begins to depart from the geostrophic conditions inside the eye. That is, the edge of the eyewall is the beginning of the transition regime between geostrophic flow and the outer region leading to irrotational flow. Beyond this radius the relative strength of inertial and drag forces are both greater than the Coriolis force. It is here that the rotating mass has to be able to settle down into a stable configuration consistent with a gentler pressure gradient, a process that tends to challenge the *de facto* fixed cylinder of the eye cavity. In the process of adjustment, spontaneous fluctuations—indicated by the

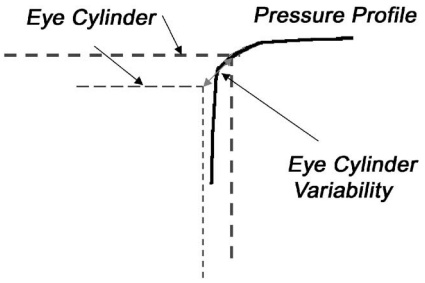

FIG. 4. Close-up of pressure profile $p(r)$ near the eyewall.

arrow—doubtless occur about the set point along the pressure profile on account of instability due to the high Reynolds number of the hurricane field. These cause the radius and height of the acoustically active eye cavity to vary slightly.

It is therefore reasonable to examine whether acoustic modes of the eye cylinder could be excited by instability of the set point at the eyewall. In the steady state, small deviations from the mean radius of the eyewall tend to be offset by the restoring forces associated with the balance between the effects of inertia and drag on the neutral radius.

Any fluctuation of the radius, however, would result in an acoustic pulse traveling from the eyewall both outward and inward, introducing a new phase lag into the oscillation. Reflections will cause the sound pulse to return to the eyewall, producing a second inward pulse. In a short time the circular boundaries will result in standing radial waves on account of the need to avoid a singularity at the center. If the wall has sufficient acoustic impedance mismatch, inward acoustic pulses will continue to be generated. Though the original pulse could either advance or retard the strength of the acoustic field inside the cavity, depending on the time elapsed in transit, there exist some special timings that reinforce sound energy density. Sooner or later the acoustic excitation will find these resonant modes and the oscillation frequency inside the cavity will stabilize, since timings that do not favor reinforcement will tend not to be repeated. Such fluctuations can be amplified by the extraction of energy from modulations of the steady wind corkscrewing up through the eye. Initially there is little to stop this positive feedback mechanism. On account of the very low linear damping at the expected infrasonic frequencies, the acoustic energy within the cavity will therefore tend to build up until it reaches an intensity limited by some nonlinear loss process. This behavior is typical of self-excited oscillators, which tend to lock in on a resonant frequency of the system when the gain exceeds some amount and the phase of the feedback is just right. Witness the screaming of sound amplification systems in a closed room when the gain is turned up too much!

The circular symmetry of the eye, together with the fact that rain clouds can have as much as 10% lower impedance[6] than dry air, makes it possible for some sound energy to be reflected at the wall and remain trapped in the cavity. In addition, known higher temperatures inside the eye[7] provide additional impedance mismatch at the boundaries, which should enhance the acoustic reflectivity of the cavity wall. Besides radial acoustic modes, azimuthal and vertical standing wave modes can be expected to couple in. Thus amplification of the acoustically resonant eye chamber by the pumping action of the disturbed winds in the eye will cause the internal sound level to rise until limited by nonlinear damping. Even though the Q of the cavity is probably small, very intense resonances can build up inside because nonlinear losses, being amplitude dependent, must maintain a strong internal sound level.

Since rain may occur at the altitude where clouds form, a likely way for the trapped sound energy to be dissipated could be through the formation of sound-induced rain clouds around the eye. At a height above the ocean where the ambient temperature is close to the dew point, sufficiently intense infrasonic field could induce evaporation and condensation by causing fluctuations of the local temperature. Such processes must take place outside the eye, since the higher temperature inside, previously noted, inhibits clouds from forming there.

Later we will show that the boundary with the eyewall cloud is where the typical rainband spirals that show up in the skirts of hurricanes begin to be formed, in conjunction with intense acoustic resonances in the eye. Such acoustical resonances may even be a source of stability for the hurricane, since a damped acoustic mode, associated with the set point, limits the variability of the operating point of the dynamical system.

VI. RESONANT MODES

Without going through a detailed calculation of the internal modal frequencies to be expected from a cylinder bordered by rain clouds, we can get an upper limit on expected frequencies associated with horizontal sound modes by analogy. For a hollow finite rigid cylinder the acoustic modal frequencies are given by[8]

$$f_{lmn} = \frac{c}{2\pi}\sqrt{k_l^2 + k_{mn}^2}, \tag{2}$$

where l, m, and n are the indices of the z, θ, and r modes, respectively, k_l is the wave number for modes along the vertical axis, and k_{mn} is the wave number for radial Bessel function and azimuthal modes in the horizontal plane. If $k_l=0$, the modes are determined by k_{mn} alone. Thus, for an eyewall of radius, a, one may take

$$f \approx f_{mn} = \frac{c(k_{mn}a)}{2\pi a} \tag{3}$$

for the modal frequencies of the $l=0$ modes.

The boundary conditions that cause downward reflection at the top of the cylinder are likely associated with the same conditions that cause cloud layers to have a top. The fact that there is a cloud ceiling shows that conditions that favor cloud formation at lower altitude must encounter an abrupt change at some height. Such a sudden change in medium must necessarily produce a corresponding change in acoustical impedance, so the problem is calculable for any location for which vertical properties of the atmosphere are known. One may reasonably conjecture that the cloud ceiling represents

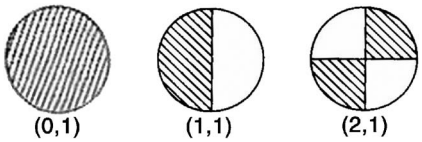

FIG. 5. The three lowest acoustic pressure modes and frequencies for a lightly mass-loaded cylindrical resonator, where c=speed of wave.

something more akin to a pressure-release condition than a rigid one. Likewise, the bottom of the cloud-layer probably also represents an approximate pressure release, though one cannot ignore the possibility of enough sound passing on to the ocean surface to produce interesting resonance conditions between sea and sky. For the purposes of this study we will ignore z-axis modes, except to say that they will have some affect on the resonant frequencies of the radiated sound for the case $l>0$. Regardless of the presence of vertical modes, horizontal modes can be compared with the case of a vibrating circular membrane. The three lowest resonant modes of membrane displacement with a rigid circular boundary[9] are shown in Fig. 5. By analogy, this may also be used for the acoustic case if we replace membrane displacement by acoustic pressure, since approximate pressure-release at the wall cloud is equivalent to approximate zero displacement at the nearly rigid boundary of a membrane.

Turning to the modal patterns again, let us assume that the shaded regions of a pattern are where the acoustic pressure, p, and therefore the local temperature variation, ΔT, are negative. Allan Pierce, in his excellent textbook[10] on acoustics, shows that sound pressure is a good surrogate for temperature fluctuation in the disturbed medium and supplies the following formula relating these variables:

$$\Delta \boldsymbol{T} = \left(\frac{\beta \boldsymbol{T}}{\rho \boldsymbol{c}_p} \right) p(\boldsymbol{r},\boldsymbol{t}), \tag{4}$$

where the constants β and c_p are, respectively, the thermal expansion coefficient and specific heat at constant pressure. This formula is accurate to first order in the variables $p(r,t)$ and ΔT.

A possible scenario is as follows: as a hurricane begins to form, a cloud begins to develop around the eyewall, providing the reflecting surface that allows the lowest frequency acoustic mode (0,1) to appear. This has motion in the r direction, but lacks motion in the θ direction. However, remembering that the eye is filled with vorticity, strange things can happen. If the radius of a vortex is increased, rotational motion is momentarily slowed down, which could excite the (1,1) mode. Furthermore, if axial modes are involved, there are more possibilities. If one stretches a vortex, its diameter shrinks and its rotation speeds up. If one compresses it, the diameter grows and the rotation slows down. This means that exciting even a pure axial sound wave produces r and θ fluctuations because they are all interrelated by the conservation of angular momentum. It may be that transverse inertia-gravity waves between temperature layers in the atmosphere, which some have associated with spiral rainbands,[11] provide just such a mechanism for pumping the axial mode. So once a rain cloud is formed, some internal modes will doubtless be excited. For the purpose of illustration, let us consider the (1,1) mode.

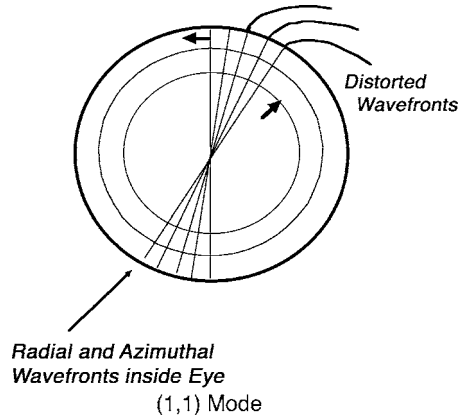

FIG. 6. Protrusion of the azimuthal standing sound waves into the transition layer region at the eyewall causes the standing wave-fronts to be distorted into spirals. Over one period, T, of the eye rotation, the starting point progresses a distance, $S=a\omega T=2\pi a$, along the circumference of the eyewall as the eye is rotated at angular speed ω. Multiple startup wavefronts are created as the modal structure, oscillating at a frequency $f=1/T_{\text{sound}}$, revolves about the center of the eye, with a separation of startups along the wall governed by the magnitudes of the relative periods of oscillation and revolution.

VII. OUTGOING WAVE-FRONTS FORMED IN THE EYEWALL

Consistent with the concept that the eyewall cloud is the beginning of a region where transition takes place between solid-body rotation inside and irrotational motion outside, it is likely that this is where the formation of rainbands begins to take place. Acoustically, the standing waves inside have azimuthal wave-fronts which are like spokes of a wheel that is slowly rotating, superposed on radial waves, as shown in Fig. 6. Outside the transition region wave-fronts are dominated by radial wave modes, as they approach the Hankel function shape of the outgoing far-field wave. The effect of decreasing angular speed at the eyewall causes distortion of the standing wave pattern into a spiral pattern within the transition layer, made visible by the formation of rain clouds.[12] These cloud bands formed in standing waves quickly become vestigial, being preserved in the irrotational flow as the invisible sound waves move on. Thus at the infrasonic wavefront formed just outside the active eye cylinder, there is momentarily produced a matching rain cloud structure which does not propagate with the outgoing sound. This must take place within the eyewall layer just outside the active eye cylinder.

Due to the continuing falloff of wind velocity with distance in the irrotational field outside the wall cloud, the outward sound rays will be refracted as they proceed away from the eyewall. The spiral formed near the eye will continue to be transported by the medium as it rotates. Any continuing rain in the spiral clouds away from the eye is probably of local origin from other causes, such as inertial gravity waves

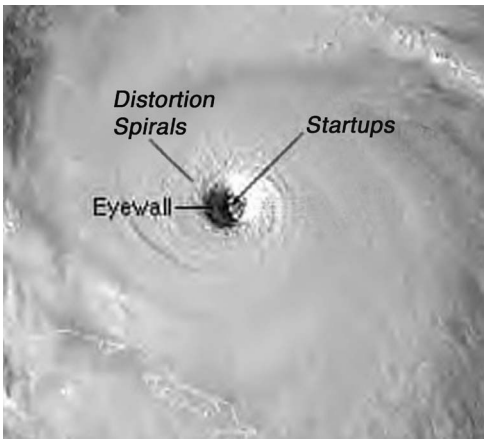

FIG. 7. Satellite view of startups along the eyewall of an actual hurricane, photographed and posted on the web by NOAA. Count of startups for a hurricane of given radius and azimuthal speed at the eyewall gives an estimate of the resonant mode frequency in the eye.

suggested by Abdullah[11] and others,[13] though some continuing sonic excitation might be possible from outgoing waves if the source is sufficiently intense.

VIII. PATTERN OF WAVE STARTUPS AROUND THE CYLINDER

The evidence of startup spirals may be observed in Fig. 7, which is an actual satellite photograph of an unknown hurricane in the open ocean, probably posted on the web by NOAA sometime in 2004. Notice the regular array of distortion spirals visible along the top of the storm cylinder, and the ribbonlike startup "wave-fronts" below them. Not all the hurricane pictures posted on the web are as suitable for observing these effects, since the eye is not always this clear. Recent hurricanes like Katrina, for example, were photographed crossing over islands in the Caribbean where the clarity of the eye was somewhat disturbed by local conditions. Nevertheless, in one of these pictures—Katrina NOAA-15—three or four startups may be seen evenly spaced along the eyewall on the right side.

Since typically the frequencies of the acoustic modes are an order of magnitude or more greater than the frequency of rotation of the eye, there will be a discrete sequence of many tilted wave-fronts formed in the transition layer for each complete rotation of the eye. It should be pointed out that, because of the solid-body rotation of the central region, the acoustic modal pattern itself must revolve at the angular speed of the eye. By measuring the spacing along the eyewall of these startups and knowing the diameter of the eye, one can estimate the number of wave startups, N_{mn}, in one revolution for a particular mode, f_{mn}. For the case pictured, incidentally, there are about 28 startups. The startup number can be equated to the ratio of acoustic-mode frequency to rotation frequency, giving the handy formula

$$N_{mn} = \frac{(\boldsymbol{k}_{mn}a/2\pi a)\boldsymbol{c}}{(V_H/2\pi a)} = \left(\frac{\boldsymbol{k}_{mn}a}{V_H}\right)c, \tag{5}$$

where $(k_{mn}a)$ determines the wave number for the (m,n) mode for the ideal pressure release boundary, a=radius of the eye, c=speed of sound, and V_H is the maximum hurricane speed at the eyewall. From this one may deduce that the frequency of the (m,n) mode in the cavity is given by

$$f_{mn} = \frac{(k_{mn}a)}{2\pi a}c = \frac{N_{mn}V_H}{2\pi a}. \tag{6}$$

So, from Eq. (5), one may find the value of $(k_{mn}a)$, guessing the values of m and n, and then use that to find the frequency of the acoustic resonance in the eye chamber with Eq. (6). The radius and speed of the hurricane pictured here are unknown. However, historical data on famous hurricanes are posted on the web by the National Hurricane Center (NHC). An example is Hurricane Luis in 1995. For that storm NHC reported a maximum speed of 138 mph and an eye radius of 23 miles. (For more precise comparison it would be helpful to ascertain the height at which the wind was measured.) If we assume a (1,1) mode for which the pressure release model gives $(k_{11}a)$=3.82, and taking c=777 mph, we find that

$$f_{11} = 0.95N_{11}\ \text{cycles/hour} = 0.000264\text{N}_{11}\ \text{Hz}. \tag{7}$$

N_{11} for this case has the value 21.5 [from Eq. (5)] corresponding to a frequency of about 0.006 Hz. The theoretical frequency, taking the end correction for radiation from a cylinder into account, would have been somewhat lower than this.

As one can see, the ideal model is still in a primitive stage, and more data from real hurricanes is needed to check out some of the assumptions. However, it suggests that very-low-frequency infrasound is probably present in hurricanes with well-formed eyes. A microphone with a response nearly down to dc would be required to detect such emissions. Actually a recording manometer would suffice at these frequencies. Since at low frequencies the absorption of sound is approximately proportional to the square of the frequency,[14] it is clear that infrasonic hurricane tones should be transmitted to great distances away from the source and therefore available to anyone, with the right equipment, who wishes to look for them.

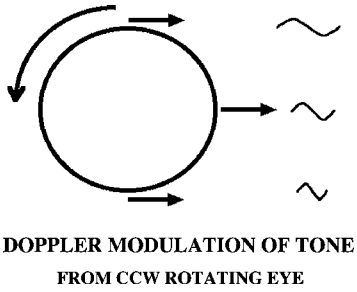

FIG. 8. Doppler effect on radiated sound produces a warble-tone about the modal frequency detected in the far field.

IX. DOPPLER COMPLICATIONS FROM THE ROTATING SOURCE

Figure 8 shows the effect of Doppler shifts on the moving sources. Where the sources are retreating from a distant observer, the wavelength is stretched, sending a lower-frequency tone, while for the approaching sources the fre-

quency will be raised. The sound coming from the nearest point of the cylinder should have a frequency midway between the two extremes and therefore represents the actual resonant value inside the cavity. Thus the sound received at a distance from the hurricane will be a sort of warble tone with pitches continually going up and down about the actual modal frequency inside.

Making use of high-resolution satellite photos such as those from the NOAA website it should be possible to compare the frequencies received via microphone with modal frequencies calculated from the spacing of the multiple sources around the eyewall.

ACKNOWLEDGMENT

The author is deeply indebted to Professor Wesley L. Nyborg, who first taught him the beauty of nonlinear acoustics and who has been very helpful in discussing the present paper.

[1]K. Emanuel, "Tropical Cyclones," Annu. Rev. Earth Planet Sci. **31**, 75–104 (2003). See p. 84, Eq. (8).

[2]Emanuel[1] on p. 81, states that some "air is slowly subsiding in the eyes, usually at velocities of $5-10\ \mathrm{cm\,s^{-1}}$." This important z axis feedback effect occurs at such small velocities compared to the azimuthal velocities in the hurricane that it may be neglected in considering the overall steady flow in the eye for acoustical purposes.

[3]For the benefit of nonspecialists, Rossby and Ekman numbers are nondimensional ratios of the inertial force and viscous force, respectively, to the coriolis force.

The radiation of atmospheric microbaroms by ocean waves

Roger Waxler[a] and Kenneth E. Gilbert
National Center for Physical Acoustics, University of Mississippi, University, Mississippi 38677

(Received 24 August 2005; revised 6 March 2006; accepted 7 March 2006)

A two-fluid model, air over seawater, is used to investigate the radiation of infrasound by ocean waves. The acoustic radiation which results from the motion of the air/water interface is known to be a nonlinear effect. The second-order nonlinear contribution to the acoustic radiation is computed and the statistical properties of the received microbarom signals are related to the statistical properties of the ocean wave system. The physical mechanisms and source strengths for radiation into the atmosphere and ocean are compared. The observed ratio of atmospheric to oceanic microbarom peak pressure levels (approximately 1 to 1000) is explained. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2191607]

I. INTRODUCTION

Energetic systems of ocean waves, such as those produced by storms at sea, radiate detectable levels of infrasound into both the atmosphere and the ocean and, through the ocean, generate seismic waves at the sea floor which radiate into the earth.[1–6] The radiation is in a frequency band approximately 0.1 Hz wide centered at about 0.2 Hz. This radiation is referred to as microbaroms in the atmospheric case and as microseisms in the seismic case. Although the oceanic signals are sometimes referred to as microseisms, in this paper the terminology oceanic microbaroms will be used.

The microbarom and microseism peak is a permanent feature of the oceanic and seismic noise floors, respectively.[1,7,8] Spectra measured on the floor of the Pacific Ocean show peak levels up to 100 Pa/$\sqrt{\text{Hz}}$.[7,8] Atmospheric microbaroms are detected at large distances (up to thousands of kilometers) from the waves which produced them. Their propagation is highly dependent on the direction of the atmospheric winds.[9–12] Atmospheric microbarom spectra measured downwind from the wave system have typical peak levels of about 0.1 Pa/$\sqrt{\text{Hz}}$.[13] Note that oceanic microbarom signals are a thousand times greater than atmospheric signals.

In this paper a detailed calculation of the microbarom source strength is presented. It is shown that the physical mechanism for the radiation of microbaroms into the atmosphere is different from that for the radiation of microbaroms into the ocean. The predicted radiation into the atmosphere is three orders of magnitude less than the radiation into the ocean, in agreement with observation. Further, in order to relate sea states to observed microbarom levels, a direct connection is obtained between the stochastic models used to describe ocean waves[14,15] and the statistical properties of the received microbarom signal.

The problem of the generation of oceanic microbaroms was solved by Longuet-Higgens.[2] He showed that microbaroms and, through their interaction with the ocean floor, microseisms are produced through a second-order non-linear effect by the interaction of gravity waves of nearly equal frequency and nearly opposite propagation direction. He found that to obtain the source strength for the radiation of oceanic microbaroms it is sufficient to assume that the ocean is incompressible and that the atmosphere is a vacuum. In particular, once the ocean surface is in motion, the atmosphere's effect on the radiation of microbaroms into the ocean is negligible. Hasselmann[3] extended Longuet-Higgens' result to general sea states and made a direct connection between the stochastic models used to describe ocean waves[14,15] and the statistics of the observed microseism signals.

It was pointed out by Brekhovskikh *et al.* in Ref. 5 that the ocean's effect on the radiation of atmospheric microbaroms is significant. A large part of the atmospheric microbarom signal is due to sound radiated into the atmosphere from pressure fluctuations produced in the water by the motion of the ocean surface. It will be seen in this paper that the rest of the signal is due to the compression of the air by the motion of the ocean surface.

It follows that the study of atmospheric microbaroms requires a two-fluid model, consisting of a rare fluid, the atmosphere, over a dense fluid, the ocean. The interface between atmosphere and ocean must be allowed to deviate from its equilibrium position, assumed in this paper to be at $z=0$. For simplicity, in this paper the ocean will be assumed to be infinitely deep.

Of interest is the case in which there is a region of the ocean surface in which the sea state contains energetic counter-propagating waves. The acoustic signal radiated from this region to a distant sensor is considered. The mechanism through which the sea surface has been excited (presumably through strong winds produced by storms[14,15]) is not considered here. As in Refs. 3 and 5, the statistical properties of the microbarom signal are related to those of the sea state.

The paper is organized as follows. In Sec. II the notion of a source region, the region of the ocean surface from which the infrasound is radiated, is defined. The equations of fluid mechanics are then solved in the source region to sec-

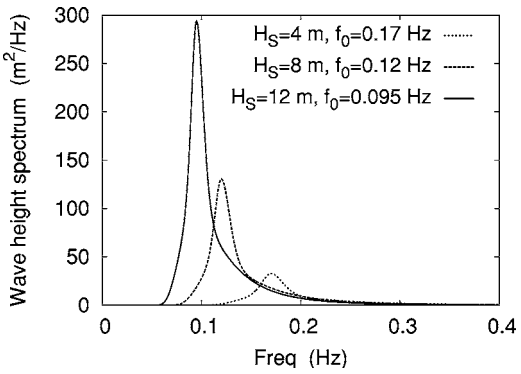

FIG. 2. The JONSWAP model for the frequency spectrum $\bar{F}(f) = \int_0^{2\pi} F(f,\theta)\, d\theta$ for significant wave heights H_S equal to 4, 8, and 12 m and peak frequencies f_0 equal to 0.17, 0.12, and 0.095 Hz, respectively.

ond order in the ratio of wave height to acoustic wavelength. In Sec. III the statistical properties of the received microbarom signal are related to those of the sea state. The source strength spectra for both atmospheric and oceanic microbaroms are obtained and compared. An explanation for the nearly three order of magnitude difference between the atmospheric and the oceanic signal strength is given. In Sec. IV an example is presented: a simple model is considered for the atmospheric microbarom signal received from storms over the deep ocean far from land masses. Section V contains our conclusions.

II. THE SOURCE REGION

Let S be a region of the ocean surface in which the sea is extremely active. Let z represent altitude relative to the undisturbed air/water interface at $z=0$. Assume that the surface of the water has been disturbed in such a way that the actual air/water interface is at $z=\xi(\mathbf{x}_H,t)$. Here, and throughout, $\mathbf{x}_H$ denotes the two-dimensional horizontal coordinate vector with components x and y. The function $\xi(\mathbf{x}_H,t)$ will be said to specify the sea state. A two-dimensional cross section of a portion of S is depicted in Fig. 1.

A. The sea state

Sea states are usually treated statistically[14,15] in the sense that $\xi(\mathbf{x}_H,t)$ is taken to be a stochastic process, commonly assumed to be Gaussian with mean zero. Let ξ_S be this Gaussian process and let $\langle\cdot\rangle_S$ be the expectation value of functions of ξ_S. If one writes

$$\xi_S(\mathbf{x}_H,t) = \mathrm{Re}\int \hat{\xi}_S(\mathbf{k}) e^{i(\mathbf{k}\cdot\mathbf{x}_H-\omega(\mathbf{k})t)}\, d^2k, \tag{1}$$

then, since it is Gaussian, the expectation value $\langle\cdot\rangle_S$ is completely specified by

$$\langle\hat{\xi}_S(\mathbf{k})\hat{\xi}_S(\mathbf{q})\rangle_S = \langle\hat{\xi}_S(\mathbf{k})^*\hat{\xi}_S(\mathbf{q})^*\rangle_S = 0$$

and

$$\langle\hat{\xi}_S(\mathbf{k})\hat{\xi}_S(\mathbf{q})^*\rangle_S = \mathcal{F}(\mathbf{k})\,\delta(\mathbf{k}-\mathbf{q}). \tag{2}$$

Here $\mathbf{k}$ in (1) is the two dimensional wave vector and $\mathcal{F}(\mathbf{k})$ is the wave number spectral density function;[14,15] $\mathcal{F}(\mathbf{k})$ is real valued. The physical picture is that, under the action of a fairly steady wind over long times and large areas of the sea surface, an approximate equilibrium is reached between the energy being deposited in the sea by the wind and the various linear and nonlinear loss mechanisms. The resulting steady state may be described as a superposition of linear waves, (1), whose statistics are specified by (2).[14,15]

Given a sea state dispersion relation $2\pi f=\omega(\mathbf{k})$, one can relate the wave vector density function $\mathcal{F}(\mathbf{k})$ to the directional spectral density function $F(f,\theta)$ by[14,15]

$$\mathcal{F}(\mathbf{k})d^2k = F(f,\theta)df d\theta. \tag{3}$$

Here f is frequency in Hz and θ indicates direction of propagation relative to some fixed direction. As a function of θ, $F(f,\theta)$ is generally strongly peaked at angles near those of the direction of the prevailing winds. The integrated spectrum,

$$\bar{F}(f) = \int_0^{2\pi} F(f,\theta)\, d\theta, \tag{4}$$

is known as the frequency spectrum. The "significant wave height"

$$H_S = 4\sqrt{\int \mathcal{F}(\mathbf{k})\, d^2k} = 4\sqrt{\int_0^\infty \bar{F}(f)\, df} \tag{5}$$

is commonly used as a measure of how excited the sea state is.

Ocean wave spectra generally have sharp low-frequency cutoffs and high-frequency tails. These features are due to nonlinear effects which cause energy to cascade from longer to shorter wavelengths. For energetic seas the frequency spectrum generally saturates at some limiting form strongly peaked in a narrow frequency band centered at around 0.1 Hz.[14,15] A quasi-empirical form for the frequency spectrum is given by the two-parameter JONSWAP[15,16] model for highly excited seas. JONSWAP spectra are shown in Fig. 2 for several significant wave heights and peak frequencies. Note that while observed microbarom spectra are peaked at about 0.2 Hz, the spectra of the ocean waves that produced them are peaked at about 0.1 Hz. The frequency doubling observed in the microbarom spectra is a consequence of the nonlinearity of the radiation mechanism.[2]

Assuming that the source region is over deep water one has[17] $\omega(\mathbf{k})=\sqrt{g|\mathbf{k}|}$, where g is the acceleration due to gravity at the earth's surface, $g=9.8\ \mathrm{m/s^2}$. At the peak frequency, 0.1 Hz, one has an ocean surface wavelength of $2\pi/|\mathbf{k}| \approx 156$ m. At the microbarom peak frequency of 0.2 Hz the acoustic wavelengths are about 1700 m in the air and about 7500 m in the water. Thus, in the frequency band in which microbarom radiation is significant, the ocean surface wavelengths are much shorter than the acoustic wavelengths. It follows that, if c_a and c_w are the speeds of sound in the atmosphere and ocean, respectively, the values of $\mathbf{k}$ for which $\mathcal{F}(\mathbf{k})$ is significant satisfy

$$\frac{\omega}{c_w} < \frac{\omega}{c_a} \ll |\mathbf{k}|. \tag{6}$$

Note as well that the effect of gravity is small in the sense that

$$\frac{g}{\omega c_w} < \frac{g}{\omega c_a} \ll 1. \tag{7}$$

The pointlike correlation between sea state wave vector components indicated by the δ function in (2) is equivalent to the translation invariance of the stochastic process. In reality the statistical properties of the sea state are neither temporally nor translationally invariant. However, these changes are negligible over times of several ocean periods (tens of seconds) and distances of several ocean wavelengths (hundreds of meters). It will be assumed that (2) remains valid if $\mathcal{F}$ is allowed to vary slowly with both time and horizontal position.

B. The equations of motion in the source region

The highly active region S of the ocean surface and a shallow layer of the ocean and atmosphere surrounding S will be referred to as the source region. The vertical extent of the source region, above and below the ocean surface, is greater than the significant ocean wavelengths; however, the height to which it extends in the atmosphere is much less than the acoustic wavelength in air and the depth to which it extends in the water is much less than the acoustic wavelength in water. In this region the effects of viscosity, thermal conduction and molecular relaxation can be ignored. Thus, in the source region the air and the water obey the equations of lossless fluid mechanics.[18] One has the equation of continuity

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{8}$$

the Euler equation

$$\rho\left(\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\cdot\nabla)\mathbf{v}\right) + \nabla P = -\rho g \hat{\mathbf{z}}, \tag{9}$$

where g is the acceleration due to gravity, and the thermodynamic equation of state,

$$\rho = f_\sigma(P) \tag{10}$$

where f_σ, for $\sigma=a,w$, are the adiabatic equations of state for air, a, and water, w, respectively. Note that this notation will be used throughout for quantities which are discontinuous across the air/water interface: the subscript σ will be assumed to be a for air and w for water.

The pressure and normal components of the velocity field must be continuous at the air/water interface. Thus one has

$$P(\mathbf{x}_H, \xi + 0^+, t) = P(\mathbf{x}_H, \xi - 0^+, t), \tag{11}$$

and

$$\mathbf{n}(\mathbf{x}_H, t)\cdot(\mathbf{v}(\mathbf{x}_H, \xi + 0^+, t) - \mathbf{v}(\mathbf{x}_H, \xi - 0^+, t)) = 0 \tag{12}$$

where $\mathbf{n}$ is an upwardly pointing normal vector to the interface (see Fig. 1) chosen here to be

$$\mathbf{n}(\mathbf{x}_H, t) = \begin{pmatrix} -\nabla_H \xi \\ 1 \end{pmatrix}$$

with

$$\nabla_H = \begin{pmatrix} \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} \end{pmatrix}.$$

Further, the vertical component of the acceleration of the interface must equal that of the adjoining fluid elements,

$$v_z(\mathbf{x}_H, \xi \pm 0^+, t) = \frac{\partial \xi}{\partial t} + \mathbf{v}(\mathbf{x}_H, \xi \pm 0^+, t)\cdot\nabla\xi. \tag{13}$$

C. The ambient state

A solution to (11)–(13) with $\xi=0$ will be called an ambient state. The corresponding pressure, density, and velocity will be denoted P_0, ρ_0, and $\mathbf{v}_0$, respectively. We will assume that P_0, ρ_0, and $\mathbf{v}_0$ depend only on height/depth z and that $\hat{\mathbf{z}}\cdot\mathbf{v}_0=0$. With these assumptions the equations of fluid mechanics reduce to

$$\frac{dP_0}{dz} = -\rho_0 g \tag{14}$$

for which the general solution is given implicitly by

$$\int_{P_0(0)}^{P_0(z)} \frac{1}{f(P_0)}\, dP_0 = -gz.$$

Letting

$$\rho_\sigma = f_\sigma(P_0(0))$$

and introducing the small-signal sound speeds at the interface

$$c_\sigma = \sqrt{\frac{1}{f'_\sigma(P_0(0))}}$$

one has, for small z,

$$P_0(z) = P_0(0) - \rho_\sigma g z + \frac{\rho_\sigma g^2}{2c_\sigma^2} z^2 + \ldots. \tag{15}$$

It will be assumed here that

$$\mathbf{v}_0 = 0. \tag{16}$$

Note that the ambient density and sound speed profiles, $\rho_0 = f_\sigma(P_0(z))$ and $c_0(z) = 1/\sqrt{f'_\sigma(P_0(z))}$, are discontinuous at the air/water interface. By (7) and (15) both are approximately piecewise constant,

$$\rho_0 \approx \begin{cases} \rho_a & \text{if } z > 0, \\ \rho_w & \text{if } z < 0, \end{cases}$$

and

$$c_0 \approx \begin{cases} c_a & \text{if } z > 0, \\ c_w & \text{if } z < 0, \end{cases}$$

in the source region. For later reference note that $f''_\sigma(P_0)$ is related to the "B/A" parameter of nonlinearity[19] through

$$\frac{B}{A} = -\rho_0 c_0^4 f''_\sigma(P_0) \approx -\rho_\sigma c_\sigma^4 f''_\sigma(P_0(0)). \tag{17}$$

The parameter B/A has been tabulated for many gases and fluids.[19,20] For air one has $B/A \approx 0.4$ and for sea water $B/A \approx 5.25$.

D. The order expansion

Solving (11) and (13) in the case in which $\xi \neq 0$ requires some approximation method. It was pointed out in Ref. 2 that the nonlinearity of the equations can be treated using regular perturbation theory to second order.[20,21] The procedure is to perform an expansion about the ambient state,

$$P = P_0 + P_1 + P_2 + \cdots,$$

$$\mathbf{v} = \mathbf{v}_1 + \mathbf{v}_2 + \cdots,$$

$$\rho = \rho_0 + \rho_1 + \rho_2 + \cdots,$$

and

$$\xi = \xi_1 + \xi_2 + \cdots,$$

where the subscript 1 indicates solutions of the linear approximation and the subscript 2 indicates terms quadratic in the linear solutions. In the expansion of the sea state ξ it will be assumed[3,5] that the linear approximation ξ_1 is given by the Gaussian process ξ_S specified by (1) and (2). One then substitutes the order expansions into the equations of fluid mechanics and interface conditions and expands. The solution is obtained order by order, beginning with the ambient state at zeroth order.

In expanding the interface conditions some care is required since the interface is in motion. The interface conditions for the full problem are imposed at $z = \xi(\mathbf{x}_H, t)$, however, for the ambient state they are imposed at $z = 0$. Thus the order expansion for the interface conditions involves both expanding in powers of ξ about $\xi = 0$ as well as in the order expanded variables.

The order parameter, or Mach number, for such a perturbation expansion is the ratio of a typical fluid velocity to the small-signal sound speed.[20] For this problem the order parameter can be taken to be $\omega_0 H_S/c_0$ where $\omega_0 = 2\pi f_0$ and f_0 is the peak frequency of the sea state, about 0.1 Hz. Note that this order parameter is in fact the Mach number at the interface times 2π and that the Mach numbers for air and water are different. The subscript n in the perturbation expansion indicates a term whose magnitude is proportional to $(\omega_0 H_S/c_0)^n$. In addition to Mach number one may exploit the small parameters $\omega_0/c_\sigma k_0$ and $g/\omega_0 c_\sigma$; here k_0 is equal to $|\mathbf{k}|$ evaluated at the peak frequency f_0. The second-order solutions are required, but only to lowest nonzeroth order in these small parameters.

E. The linear response

In this section the linear approximation will be obtained[17] and put into a suitable form. It has been emphasized[2,4–6] that in the linear approximation the sea does not radiate. Indeed, the first-order acoustic fields are vertically evanescent and are negligible outside of the source region itself.

Substituting the order expansions into the equations of fluid mechanics at first order one has the familiar equations of lossless acoustics. The equation of state, (10), becomes

$$\rho_1 = \frac{1}{c_\sigma^2} P_1,$$

the equation of continuity, (8), becomes

$$\frac{\partial P_1}{\partial t} + \rho_\sigma c_\sigma^2 \nabla \cdot \mathbf{v}_1 = 0,$$

and the Euler equation (9) becomes

$$\nabla P_1 + \rho_\sigma \frac{\partial \mathbf{v}_1}{\partial t} + g\rho_1 \hat{\mathbf{z}} = 0.$$

The interface conditions must be expanded about $\xi = 0$ to first order in ξ_1 as well as in the first-order variables. The first-order part of the pressure interface condition (11) is

$$P_1|_{z=-0^+}^{0^+} + \xi_1 \left.\frac{\partial P_0}{\partial z}\right|_{z=-0^+}^{0^+} = 0,$$

which, with (14) gives

$$(P_1 - \rho_\sigma g \xi_1)|_{z=-0^+}^{0^+} = 0. \tag{18}$$

The velocity interface condition, (12), together with the assumption, (16), of no mean flow, gives

$$v_{1z}|_{z=-0^+}^{0^+} = 0 \tag{19}$$

and (13) gives

$$\frac{\partial \xi_1}{\partial t} = v_{1z}(\mathbf{x}_H, 0^+, t) = v_{1z}(\mathbf{x}_H, -0^+, t). \tag{20}$$

Introduce a velocity potential ϕ_1 with $\mathbf{v}_1 = \nabla\phi_1 + \mathbf{w}_1$, with $\nabla \cdot \mathbf{w}_1 = 0$ and with

$$P_1(\mathbf{x}_H, z, t) = -\rho_\sigma \frac{\partial \phi_1}{\partial t}. \tag{21}$$

Choosing

$$\rho_\sigma \frac{\partial \mathbf{w}_1}{\partial t} = -\frac{g}{c_\sigma^2} P_1 \hat{\mathbf{z}} \tag{22}$$

the first-order Euler equation is solved. Substituting into the first-order equation of continuity one obtains the wave equation for the velocity potential,

$$\left(\nabla^2 - \frac{1}{c_\sigma^2}\frac{\partial^2}{\partial t^2}\right)\phi_1 = 0. \tag{23}$$

The system is driven by the interface motion through (18). As in (1) one has the horizontal wave vector expansion

$$\xi_1(\mathbf{x}_H, t) = \mathrm{Re}\int \hat{\xi}_1(\mathbf{k}) e^{i(\mathbf{k}\cdot\mathbf{x}_H - \omega(\mathbf{k})t)}\, d^2k \tag{24}$$

for the interface. The solutions to the first-order equations can be expanded similarly. Substituting in (23) one obtains

$$\phi_1(\mathbf{x}, t) = \mathrm{Re}\int \hat{\phi}_1^{(\sigma)}(\mathbf{k}) e^{i(\mathbf{k}\cdot\mathbf{x}_H - \omega(\mathbf{k})t) - \sqrt{|\mathbf{k}|^2 - \omega^2/c_\sigma^2}|z|}\, d^2k. \tag{25}$$

It follows from (22) that $w_{1z} \sim (g/\omega_0 c_\sigma)(1/\rho_\sigma c_\sigma)P_1$. Substituting (25) into (21) one finds that $\partial\phi_1/\partial z \sim (k_0 c_\sigma/\omega_0)(1/\rho_\sigma c_\sigma)P_1$. It follows that $w_{1z} \sim (g/\omega_0 c_\sigma) \times (\omega_0/k_0 c_\sigma)(\partial\phi_1/\partial z)$ so that, by (6) and (7), $\mathbf{w}_1$ is negligible as compared to $\nabla\phi_1$. It follows that one may write $\mathbf{v}_1 = \nabla\phi_1$.

Expanding with respect to the horizontal wave vector one has

$$P_1(\mathbf{x}, t) = \mathrm{Re}\int \hat{P}_1^{(\sigma)}(\mathbf{k}) e^{i(\mathbf{k}\cdot\mathbf{x}_H - \omega(\mathbf{k})t) - \sqrt{|\mathbf{k}|^2 - \omega^2/c_\sigma^2}|z|}\, d^2k \tag{26}$$

and

$$\mathbf{v}_1(\mathbf{x}, t) = \mathrm{Re}\int \hat{\mathbf{v}}_1^{(\sigma)}(\mathbf{k}) e^{i(\mathbf{k}\cdot\mathbf{x}_H - \omega(\mathbf{k})t) - \sqrt{|\mathbf{k}|^2 - \omega^2/c_\sigma^2}|z|}\, d^2k. \tag{27}$$

Substituting into (18)–(20) and letting $(-1)^\sigma$ be 1 in the air, $\sigma = a$, and -1 in the water, $\sigma = w$, one obtains

$$\hat{\phi}_1^{(\sigma)}(\mathbf{k}) = (-1)^\sigma \frac{i\omega}{\sqrt{|\mathbf{k}|^2 - \omega^2/c_\sigma^2}} \hat{\xi}_1(\mathbf{k}), \tag{28}$$

$$\hat{P}_1^{(\sigma)}(\mathbf{k}) = -(-1)^\sigma \frac{\rho_\sigma \omega^2}{\sqrt{|\mathbf{k}|^2 - \omega^2/c_\sigma^2}} \hat{\xi}_1(\mathbf{k}), \tag{29}$$

and

$$\hat{\mathbf{v}}_1^{(\sigma)}(\mathbf{k}) = \omega\left(-(-1)^\sigma \frac{\mathbf{k}}{\sqrt{|\mathbf{k}|^2 - \omega^2/c_\sigma^2}} - i\hat{\mathbf{z}}\right)\hat{\xi}_1(\mathbf{k}). \tag{30}$$

By (6) the first-order solutions decrease exponentially with either altitude or depth. At distances large compared to $1/|\mathbf{k}|$ from the interface they become negligible. In particular, the linear solutions do not radiate. The continuity of pressure (18) gives the surf dispersion relation

$$0 = (\rho_w - \rho_a)g + \frac{\omega^2}{|\mathbf{k}|}\left(\frac{\rho_w}{\sqrt{1 - \dfrac{\omega^2}{|\mathbf{k}|^2 c_w^2}}} + \frac{\rho_a}{\sqrt{1 - \dfrac{\omega^2}{|\mathbf{k}|^2 c_a^2}}}\right)$$

which gives

$$|\mathbf{k}| \approx \frac{\omega^2}{g}$$

so that

$$\omega(\mathbf{k}) \approx \sqrt{g|\mathbf{k}|}. \tag{31}$$

Note that with this dispersion relation the two order parameters $\omega_0/k_0 c_\sigma$ and $g/\omega_0 c_\sigma$ are identical.

Checking the orders of the first-order solutions one finds that

$$\mathbf{v}_1 \sim c_\sigma \frac{\omega_0 H_S}{c_\sigma}$$

while

$$P_1 \sim \rho_\sigma c_\sigma^2 \frac{\omega_0}{k_0 c_\sigma}\frac{\omega_0 H_S}{c_\sigma}.$$

Both are first order in Mach number as expected, however, the pressure P_1 is also first order in the small parameter $\omega_0/k_0 c_\sigma$.

The first-order solutions given by Eqs. (28) and (30) are well approximated by setting $\omega/|\mathbf{k}|c_\sigma = 0$. In the linear approximation this is equivalent to assuming both air and water to be incompressible. In this approximation the acoustic pressure fields, $\hat{P}_1^{(\sigma)}$, are zero and the velocity fields, $\hat{\mathbf{v}}_1^{(\sigma)}$, differ in the water and in the air only by phase: the vertical components are equal while the horizontal components have equal magnitudes but opposite signs. In Ref. 2 it was shown that to obtain the oceanic microbaroms it is sufficient to replace the first-order solutions with their incompressible approximations. It will be seen below that to obtain the atmospheric microbaroms the incompressible approximation to the first-order solutions is not sufficient.

F. The second-order acoustics

It is known[2,5] that in the second-order approximation the sea does radiate. In this section the leading-order corrections to the linear approximation, the terms of second order in Mach number, are obtained. The solution is simplified somewhat by obtaining only the leading-order terms in the small parameter $\omega_0/k_0 c_\sigma$. The general form of the second-order solution is quite complicated, even to leading order in $\omega_0/k_0 c_\sigma$, and will not be given here. Rather, in this section the solution will be presented as a superposition of pairs of plane waves. The explicit determination of the solution is postponed to Sec. III where it is shown that, to determine the statistical properties of the microbarom signal, only the terms corresponding to counter-propagating ocean waves of equal frequency are required.[3]

Continuing the order expansion, at second order one finds[21] that the equation of state, (10), can be written

$$\rho_2 - \frac{1}{c_\sigma^2}P_2 = \frac{1}{2}f''(P_0)P_1^2,$$

the equation of continuity, (8), can be written

$$\frac{\partial P_2}{\partial t}+\rho_\sigma c_\sigma^2\nabla\cdot\mathbf{v}_2=\frac{(1-\rho_\sigma c_\sigma^4 f''(P_0))}{\rho_\sigma c_\sigma^2}P_1\frac{\partial P_1}{\partial t}-\mathbf{v}_1\cdot\nabla P_1$$

and the Euler equation, (9), can be written

$$\nabla P_2+\rho_\sigma\frac{\partial\mathbf{v}_2}{\partial t}+g\rho_2\hat{\mathbf{z}}=-\frac{1}{c_\sigma^2}P_1\frac{\partial\mathbf{v}_1}{\partial t}-\frac{1}{2}\rho_\sigma\nabla(\mathbf{v}_1\cdot\mathbf{v}_1).$$

Consider the orders of the various terms in the second-order equations of state and continuity. Note that, recalling (17),

$$\frac{1}{2}f''(P_0)P_1^2\sim\frac{B}{A}\rho_\sigma\left(\frac{\omega_0}{k_0c_\sigma}\right)^2\left(\frac{\omega_0H_S}{c_\sigma}\right)^2$$

and

$$\frac{(1-\rho_\sigma c_\sigma^4 f''(P_0))}{\rho_\sigma c_\sigma^2}P_1\frac{\partial P_1}{\partial t}\sim\left(1+\frac{B}{A}\right)\rho_\sigma c_\sigma^2\omega_0\left(\frac{\omega_0}{k_0c_\sigma}\right)^2\left(\frac{\omega_0H_S}{c_\sigma}\right)^2.$$

while

$$\mathbf{v}_1\cdot\nabla P_1\sim\rho_\sigma c_\sigma^2\omega_0\left(\frac{\omega_0H_S}{c_\sigma}\right)^2.$$

All of these terms are second order in Mach number ω_0H_S/c_σ. However, the two terms involving the second derivative $f''(P_0)$ are second-order in the small parameter ω_0/k_0c_σ as well and thus can be dropped. Similarly, on the right side of the second-order Euler equation one has the terms

$$\frac{1}{c_\sigma^2}P_1\frac{\partial\mathbf{v}_1}{\partial t}\sim\rho_\sigma c_\sigma\omega_0\frac{\omega_0}{k_0c_\sigma}\left(\frac{\omega_0H_S}{c_\sigma}\right)^2$$

and

$$\frac{1}{2}\rho_\sigma\nabla(\mathbf{v}_1\cdot\mathbf{v}_1)\sim\rho_\sigma c_\sigma^2k_0\left(\frac{\omega_0H_S}{c_\sigma}\right)^2.$$

The first of these terms is again smaller by two orders of the small parameter ω_0/k_0c_σ than the second and can be dropped. One thus obtains the simpler set of equations

$$\rho_2-\frac{1}{c_\sigma^2}P_2=0,\tag{32}$$

$$\frac{\partial P_2}{\partial t}+\rho_\sigma c_\sigma^2\nabla\cdot\mathbf{v}_2=-\mathbf{v}_1\cdot\nabla P_1\tag{33}$$

and

$$\nabla P_2+\rho_\sigma\frac{\partial\mathbf{v}_2}{\partial t}+g\rho_2\hat{\mathbf{z}}=-\frac{1}{2}\rho_\sigma\nabla(\mathbf{v}_1\cdot\mathbf{v}_1).\tag{34}$$

The second-order part of the pressure interface condition (11) is

$$\left(P_2+\xi_2\frac{\partial P_0}{\partial z}+\xi_1\frac{\partial P_1}{\partial z}+\frac{1}{2}\xi_1^2\frac{\partial^2P_0}{\partial z^2}\right)\Bigg|_{z=-0^+}^{0^+}=0.$$

Using the first-order Euler equation one finds

$$\xi_1\frac{\partial P_1}{\partial z}=-\rho_\sigma\xi_1\frac{\partial v_{1z}}{\partial t}\sim\rho_\sigma c_\sigma^2\left(\frac{\omega_0H_S}{c_\sigma}\right)^2$$

and using (15) one finds

$$\frac{1}{2}\xi_1^2\frac{\partial^2P_0}{\partial z^2}=\frac{1}{2}\frac{\rho_\sigma g^2}{c_\sigma^2}\xi_1^2\sim\rho_\sigma c_\sigma^2\left(\frac{g}{\omega_0c_\sigma}\right)^2\left(\frac{\omega_0H_S}{c_\sigma}\right)^2.$$

The last term is second order in g/ω_0c_σ and can be dropped. Using (15), the second-order part of the pressure interface condition can be written

$$(P_2-\rho_\sigma g\xi_2)|_{z=-0^+}^{0^+}=\rho_\sigma\xi_1\frac{\partial v_{1z}}{\partial t}\Bigg|_{z=-0^+}^{0^+}.\tag{35}$$

The second order part of the velocity interface condition (12) is

$$v_{2z}|_{z=-0^+}^{0^+}=\left(-\xi_1\frac{\partial v_{1z}}{\partial z}+\mathbf{v}_1\cdot\nabla_H\xi_1\right)\Bigg|_{z=-0^+}^{0^+}\tag{36}$$

and the second-order part of (13) is

$$\frac{\partial\xi_2}{\partial t}=\left(v_{2z}+\xi_1\frac{\partial v_{1z}}{\partial z}-\mathbf{v}_1\cdot\nabla_H\xi_1\right)\Bigg|_{z=\pm0^+}.\tag{37}$$

The procedure is to substitute the linear solutions (25)–(30) into the second-order wave equations (32)–(34) and find the outgoing solution which satisfies the interface conditions (35)–(37). The solutions are simplified somewhat by using the inequality (6) to conclude that compressibility is insignificant in the linear approximation so that $\sqrt{|\mathbf{k}|^2-\omega(\mathbf{k})^2/c_\sigma^2}\approx|\mathbf{k}|$. This approximation is valid as long as it gives a nonzero result.

The source terms in (36) and (37), however, can be written

$$-\xi_1\frac{\partial v_{1z}}{\partial z}+\mathbf{v}_1\cdot\nabla_H\xi_1=-\xi_1\nabla\cdot\mathbf{v}_1+\nabla_H(\xi_1\mathbf{v}_1).\tag{38}$$

The term $\nabla\cdot\mathbf{v}_1$ is zero in the incompressible approximation. In the product $\xi_1\mathbf{v}_1$ the terms which are responsible for the microbarom radiation, those with wave numbers of equal magnitude (and thus equal frequency) but opposite direction,[2,3] are constant so that for these components the term $\nabla_H\cdot(\xi_1\mathbf{v}_1)$ is zero as well. Thus, while the right side of (36) appears to be large, of order $(\omega_0/k_0c_\sigma)^{-1}(\omega_0H_S/c_\sigma)^2$, in fact its contribution to the microbarom radiation will be seen to be small. For this reason some care must be taken in evaluating the inhomogeneous part of the velocity interface condition (36). In particular, the incompressible approximation cannot be used.

To solve the second-order Euler equation (34) one can write $\mathbf{v}_2=\nabla\phi_2+\mathbf{w}_2$ where $\nabla\cdot\mathbf{w}_2=0$,

$$\rho_\sigma\frac{\partial\mathbf{w}_2}{\partial t}+\frac{g}{c_\sigma^2}P_2\hat{\mathbf{z}}=0,$$

and ϕ_2 is given by

$$P_2 + \rho_\sigma \frac{\partial \phi_2}{\partial t} = -\frac{1}{2}\rho_\sigma \mathbf{v}_1 \cdot \mathbf{v}_1. \tag{39}$$

With these definitions (34) is satisfied. As in Sec. II E, $\mathbf{w}_2$ can be shown to be smaller than $\nabla\phi_2$, in this case by a single power of $g/\omega_0 c_\sigma$. Consequently, it can be ignored so that one has $\mathbf{v}_2 = \nabla\phi_2$.

Substituting (39) into the second-order equation of continuity (33) and using the first-order Euler equation to simplify, one obtains the second-order wave equation

$$\left(\nabla^2 - \frac{1}{c_\sigma^2}\frac{\partial^2}{\partial t^2}\right)\phi_2 = \frac{1}{c_\sigma^2}\frac{\partial}{\partial t}\mathbf{v}_1 \cdot \mathbf{v}_1. \tag{40}$$

Note that, since the linear solutions decrease rapidly with distance from the interface, the source term on the right side of (40) does so as well.

The second-order wave equation contains the effects of nonlinearities in the air and the water themselves. The second-order interface conditions contain the nonlinear effects due the fact that the motions of the fluids affect the motion of the interface. To separate the effects of the fluid media from those of the undulating interface one may write the solution of (40) as

$$\phi_2(\mathbf{x}_H, z, t) = \phi_p(\mathbf{x}_H, z, t) + \phi_h(\mathbf{x}_H, z, t), \tag{41}$$

where ϕ_p is a particular solution and ϕ_h is the solution of the homogeneous wave equation required so that the interface conditions (35)–(37) are satisfied.

To determine ϕ_p substitute (27) and (30), into (40). In evaluating the source term the incompressible approximation $\sqrt{|\mathbf{k}|^2 - \omega(\mathbf{k})^2/c_\sigma^2} \approx |\mathbf{k}|$ may be used here since it gives a nonzero result. The source term on the right of (40) becomes

$$\begin{aligned}
&\frac{1}{c_\sigma^2}\frac{\partial}{\partial t}\mathbf{v}_1 \cdot \mathbf{v}_1 \\
&\quad = \int\int [\mathcal{R}_\sigma^{(+)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q}) e^{i((\mathbf{k}+\mathbf{q})\cdot\mathbf{x}_H - (\omega(\mathbf{k})+\omega(\mathbf{q}))t)} \\
&\qquad + \mathcal{R}_\sigma^{(-)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q})^* e^{i((\mathbf{k}-\mathbf{q})\cdot\mathbf{x}_H - (\omega(\mathbf{k})-\omega(\mathbf{q}))t)}] \\
&\qquad \times e^{-(|\mathbf{k}|+|\mathbf{q}|)|z|}\, d^2k\, d^2q + \text{complex conjugate}
\end{aligned} \tag{42}$$

with

$$\mathcal{R}_\sigma^{(\pm)}(\mathbf{k},\mathbf{q}) = -\frac{i}{c_\sigma^2}\omega(\mathbf{k})\omega(\mathbf{q})(\omega(\mathbf{k}) \pm \omega(\mathbf{q}))\left(\frac{\mathbf{k}\cdot\mathbf{q}}{|\mathbf{k}||\mathbf{q}|} \mp 1\right).$$

Using (42) the particular solution ϕ_p can be chosen to be

$$\begin{aligned}
&\phi_p(\mathbf{x}_H, z, t) \\
&\quad = \int\int [\mathcal{Q}_\sigma^{(+)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q}) \\
&\qquad \times e^{i((\mathbf{k}+\mathbf{q})\cdot\mathbf{x}_H - (\omega(\mathbf{k})+\omega(\mathbf{q}))t) - (|\mathbf{k}|+|\mathbf{q}|)|z|} \\
&\qquad + \mathcal{Q}_\sigma^{(-)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q})^* \\
&\qquad \times e^{i((\mathbf{k}-\mathbf{q})\cdot\mathbf{x}_H - (\omega(\mathbf{k})-\omega(\mathbf{q}))t) - (|\mathbf{k}|+|\mathbf{q}|)|z|}]\, d^2k\, d^2q \\
&\qquad + \text{complex conjugate}
\end{aligned} \tag{43}$$

with

$$\mathcal{Q}_\sigma^{(\pm)}(\mathbf{k},\mathbf{q}) = \frac{\mathcal{R}_\sigma^{(\pm)}(\mathbf{k},\mathbf{q})}{[(\omega(\mathbf{k}) \pm \omega(\mathbf{q}))^2/c_\sigma^2] + 2(|\mathbf{k}||\mathbf{q}| \mp \mathbf{k}\cdot\mathbf{q})}.$$

The homogeneous solution ϕ_h is then of the form

$$\begin{aligned}
&\phi_h(\mathbf{x}_H, z, t) \\
&\quad = \int\int [C_\sigma^{(+)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q}) \\
&\qquad \times e^{i((\mathbf{k}+\mathbf{q})\cdot\mathbf{x}_H + \Omega_+(\mathbf{k},\mathbf{q})|z| - (\omega(\mathbf{k})+\omega(\mathbf{q}))t)} \\
&\qquad + C_\sigma^{(-)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q})^* \\
&\qquad \times e^{i((\mathbf{k}-\mathbf{q})\cdot\mathbf{x}_H + \Omega_-(\mathbf{k},\mathbf{q})|z| - (\omega(\mathbf{k})-\omega(\mathbf{q}))t)}]\, d^2k\, d^2q \\
&\qquad + \text{complex conjugate}
\end{aligned} \tag{44}$$

with

$$\Omega_\pm(\mathbf{k},\mathbf{q}) = \sqrt{\frac{(\omega(\mathbf{k}) \pm \omega(\mathbf{q}))^2}{c_\sigma^2} - (\mathbf{k} \pm \mathbf{q})^2}$$

and the second-order contribution to the sea state is given by

$$\begin{aligned}
\xi_2(x_H, t) = \int\int [&\hat{\xi}^{(+)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q}) \\
&\times e^{i((\mathbf{k}+\mathbf{q})\cdot\mathbf{x}_H - (\omega(\mathbf{k})+\omega(\mathbf{q}))t)} + \hat{\xi}^{(-)}(\mathbf{k},\mathbf{q})\hat{\xi}_1(\mathbf{k})\hat{\xi}_1(\mathbf{q})^* \\
&\times e^{i((\mathbf{k}-\mathbf{q})\cdot\mathbf{x}_H - (\omega(\mathbf{k})-\omega(\mathbf{q}))t)}]\, d^2k\, d^2q \\
&+ \text{complex conjugate}.
\end{aligned} \tag{45}$$

The coefficients $C_\sigma^{(\pm)}(\mathbf{k},\mathbf{q})$ and $\hat{\xi}^{(\pm)}(\mathbf{k},\mathbf{q})$ are determined by the condition that the interface conditions (35)–(37) must be satisfied. The explicit determination of $C_\sigma^{(\pm)}(\mathbf{k},\mathbf{q})$ and $\hat{\xi}^{(\pm)}(\mathbf{k},\mathbf{q})$ will be postponed until the next section where it is shown that, to determine the statistical properties of the microbarom signal, only the coefficients $C_\sigma^{(+)}(\mathbf{k},-\mathbf{k})$ and $\hat{\xi}^{(+)}(\mathbf{k},-\mathbf{k})$ are required. Note that these particular coefficients correspond to the interaction of ocean waves of equal frequency and opposite propagation direction.

The decomposition (41) with the choice (43) for the particular solution separates the second-order velocity potential into a term, the particular solution, which is negligible outside of the source region and a term, the homogeneous solution, which contains the part of the field which radiates into the atmosphere and into the ocean. The particular solution contains the nonlinear effects produced in the air or water in the bulk rather than at the interface. These volume contributions do not directly produce acoustic radiation. The radiation is produced by the requirement that the interface conditions be satisfied. Note that the homogeneous solution must both account for nonlinear contributions to as well as correct for the deviations of the particular solution from the interface conditions. Specifically, the air and the water must accommodate both the nonlinear contributions to the interface motion as well as the nonlinear contributions to the flow in the bulk.

III. THE RECEIVED MICROBAROM SIGNAL

Let $P_\sigma(\mathbf{x}_H,z,t)$ be the acoustic pressure at large distances from the source region, either in the atmosphere, $\sigma=a$ and $z\geqslant 0$, or in the ocean, $\sigma=w$ and $z\leqslant 0$. To determine P_σ one must find the outward-propagating solution to the equations for acoustic propagation in the atmosphere/ocean which reduces in the source region to the solution produced in Sec. II F. One may write

$$P_\sigma = P_{\sigma p} + P_{\sigma h},$$

where

(*i*) in the source region $P_{\sigma p}$ and $P_{\sigma h}$ reduce to the solutions produced in Sec. II F,

$$P_{\sigma p} = -\rho_\sigma \frac{\partial \phi_p}{\partial t} - \frac{1}{2}\rho_\sigma \mathbf{v}_1 \cdot \mathbf{v}_1$$

and

$$P_{\sigma h} = -\rho_\sigma \frac{\partial \phi_h}{\partial t},$$

where ϕ_p and ϕ_h are given by (43) and (44);

(*ii*) away from the source region $P_{\sigma p}$ is negligible, so that $P_\sigma = P_{\sigma h}$, and $P_{\sigma h}$ is taken to satisfy the rigid ground boundary condition at the atmospheric side of the air/water interface and the pressure release boundary condition at the oceanic side

$$0 = \left.\frac{\partial P_{\sigma h}(\mathbf{x}_H,z,t)}{\partial z}\right|_{z=0^+} = P_{\sigma h}(\mathbf{x}_H,z,t)|_{z=-0^+}$$

Let $G_a(\mathbf{x}_H,z,\mathbf{x}'_H,z',t)$ be the Green's function describing the propagation of sound in the atmosphere over a rigid surface and let $G_w(\mathbf{x}_H,z,\mathbf{x}'_H,z',t)$ be the Green's function describing the propagation of sound in the ocean under a pressure release surface. Let S be the part of the $z=0$ plane which is in the source region. Then the Helmholtz-Kirchoff integral theorem gives

$$P_{\sigma h}(\mathbf{x}_H,z,t) = -\rho_\sigma \int_{-\infty}^{\infty}\int_S G_\sigma(\mathbf{x}_H,z,\mathbf{y}_H,0,t-\tau) \times \frac{\partial v_\sigma(\mathbf{y}_H,\tau)}{\partial \tau}\, d^2\mathbf{y}_H\, d\tau, \tag{46}$$

where

$$v_\sigma(\mathbf{x}_H,t) = \left.\frac{\partial \phi_h(\mathbf{x}_H,z,t)}{\partial z}\right|_{(-1)^\sigma z=0^+} \tag{47}$$

is the normal component of the homogeneous part of the fluid velocity at the interface.

A. The statistics of the microbarom signal and the sea state

Let $\langle\cdot\rangle_T$ represent both the sea state ensemble average, $\langle\cdot\rangle_S$, given in (2) as well as, if required, an average, $\langle\cdot\rangle_P$, over fluctuations in the propagation medium. Of interest is the correlation

$$\langle P_\sigma(\mathbf{x}_H,z,0)P_\sigma(\mathbf{x}'_H,z',\tau)^*\rangle_T = \lim_{T\to\infty}\frac{1}{T}\int_0^T P_\sigma(\mathbf{x}_H,z,t)P_\sigma(\mathbf{x}'_H,z',t+\tau)^*\, dt \tag{48}$$

between the signals received at (possibly) spatially separated points (see Fig. 3). The Fourier transform of (48) with respect to τ is known as the cross spectral density; for $\mathbf{x}'_H=\mathbf{x}_H$ it is the power spectrum.[22] Substituting (46) and (47), into (48) one has

$$\begin{aligned}\langle P_\sigma(\mathbf{x}_H,z,0)P_\sigma(\mathbf{x}'_H,z',\tau)^*\rangle_T &= \rho_\sigma^2\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_S\int_S \langle G_\sigma(\mathbf{x}_H,z,\mathbf{y}_H,0,-\tau_1) \\ &\times G_\sigma(\mathbf{x}'_H,z',\mathbf{y}'_H,0,\tau-\tau_2)^*\rangle_P \\ &\times \left\langle \frac{\partial v_\sigma(\mathbf{y}_H,\tau_1)}{\partial\tau_1}\frac{\partial v_\sigma(\mathbf{y}'_H,\tau_2)^*}{\partial\tau_2}\right\rangle_S d^2y_H\, d^2y'_H\, d\tau_1\, d\tau_2.\end{aligned} \tag{49}$$

To compute v_σ in (47) one may substitute from (44) for the velocity potential ϕ_h. Note that v_σ is a binomial in the linear sea state amplitudes $\hat{\xi}_1$. As discussed in Sec. II D, to compute the average over the sea state in (49) we assume that $\hat{\xi}_1$ is the Gaussian process $\hat{\xi}_S$ given by (2). Since $\langle\cdot\rangle_S$ is Gaussian[23]

$$\begin{aligned}&\langle\hat{\xi}_1(\mathbf{k}_1)\hat{\xi}_1(\mathbf{q}_1)\hat{\xi}_1(\mathbf{k}_2)^*\hat{\xi}_1(\mathbf{q}_2)^*\rangle_S \\ &=\langle\hat{\xi}_1(\mathbf{k}_1)\hat{\xi}_1(\mathbf{k}_2)^*\rangle_S\langle\hat{\xi}_1(\mathbf{q}_1)\hat{\xi}_1(\mathbf{q}_2)^*\rangle_S \\ &\quad+\langle\hat{\xi}_1(\mathbf{k}_1)\hat{\xi}_1(\mathbf{q}_2)^*\rangle_S\langle\hat{\xi}_1(\mathbf{q}_1)\hat{\xi}_1(\mathbf{k}_2)^*\rangle_S \\ &=\mathcal{F}(\mathbf{k}_1)\mathcal{F}(\mathbf{q}_1)(\delta(\mathbf{k}_1-\mathbf{k}_2)\delta(\mathbf{q}_1-\mathbf{q}_2)+\delta(\mathbf{k}_1-\mathbf{q}_2) \\ &\quad\times\delta(\mathbf{q}_1-\mathbf{k}_2))\end{aligned}$$

so that one has

$$\begin{aligned}\langle v_\sigma(\mathbf{y}_H,\tau_1)v_\sigma(\mathbf{y}'_H,\tau_2)^*\rangle_S &= 2\int\int \mathcal{F}(\mathbf{k})\mathcal{F}(\mathbf{q}) \\ &\times|C_\sigma^{(+)}(\mathbf{k},\mathbf{q})|^2|\Omega_+(\mathbf{k},\mathbf{q})|^2 \\ &\times e^{i((\mathbf{k}+\mathbf{q})\cdot(\mathbf{y}_H-\mathbf{y}'_H)-(\omega(\mathbf{k})+\omega(\mathbf{q}))(\tau_1-\tau_2))}\, d^2k\, d^2q \\ &+\text{complex conjugate}+\text{time-independent terms}\end{aligned} \tag{50}$$

for the correlation between the normal velocity field v_σ at different positions and times.

Substitute (50) into (49). The integrals over τ_1 and τ_2 are Fourier transforms in time of the G_σ. Let $\hat{G}_\sigma(\mathbf{x}_H,z,\mathbf{x}'_H,z',\nu)$ be these Fourier transforms at angular frequency ν. Since the Green's functions for the acoustic propagation are approximately constant over distances which are small compared to acoustic wavelengths and since the significant sea state wave vectors $\mathbf{K}$ satisfy (6), one has,[24] to leading order in ω_0/k_0c_σ,

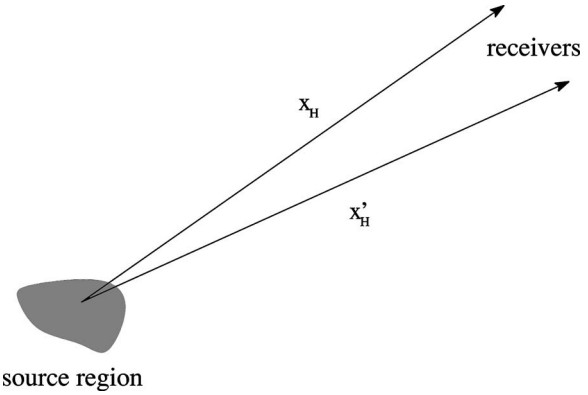

FIG. 3. The geometry. Microbaroms radiated from the source region are detected by distant sensors.

$$\int_S \int_S \hat{G}_\sigma(\mathbf{x}_H, z, \mathbf{y}_H, 0, \nu)\hat{G}_\sigma(\mathbf{x}'_H, z', \mathbf{y}'_H, 0, \nu)^* \times e^{i\mathbf{k}\cdot(\mathbf{y}_H - \mathbf{y}'_H)}\, d^2\mathbf{y}_H\, d^2\mathbf{y}'_H \approx (2\pi)^2 \delta(\mathbf{k}) \int_S \hat{G}_\sigma(\mathbf{x}_H, z, \mathbf{y}_H, 0, \nu) \times \hat{G}_\sigma(\mathbf{x}'_H, z', \mathbf{y}_H, 0, \nu)^*\, d^2\mathbf{y}_H.$$

It follows that

$$\langle P_\sigma(\mathbf{x}_H, z, 0) P_\sigma(\mathbf{x}'_H, z', \tau)^* \rangle_T = \frac{32\rho_\sigma^2 \pi^2}{c_\sigma^2} \int \left(\int_S \langle \hat{G}_\sigma(\mathbf{x}_H, z, \mathbf{y}_H, 0, 2\omega(\mathbf{k})) \times \hat{G}_\sigma(\mathbf{x}'_H, z', \mathbf{y}_H, 0, 2\omega(\mathbf{k}))^* \rangle_P\, d^2\mathbf{y}_H \right) \times \mathcal{F}(\mathbf{k})\mathcal{F}(-\mathbf{k}) |C_\sigma^{(+)}(\mathbf{k}, -\mathbf{k})|^2 \omega(\mathbf{k})^4 e^{-i2\omega(\mathbf{k})\tau}\, d^2k. \quad (51)$$

Equation (51) was first obtained by Hasselmann for the oceanic microbarom signal. It gives a direct relation between the spectral density function of the sea state and the statistical properties of the received microbarom signals.

The sharp low-frequency cutoff in the wave spectrum means that there is a smallest $|\mathbf{k}|$ and ω, corresponding to a longest wavelength and period in the ocean wave spectrum. At separations, $|\mathbf{y}_H - \mathbf{y}'_H|$, much longer than this longest wavelength or at time delays much greater than this longest period the motions of the sea surface become uncorrelated.[14] Thus, the normal velocity (50) becomes uncorrelated at separations large compared to the longest wavelength and at time delays long compared to the longest period. However, by (6) these separations are small compared to acoustic wavelengths. The physical picture which emerges from the stochastic sea state model is one of intermittent radiation, persisting for times long compared with the longest ocean wave period, from patches of the ocean surface randomly distributed across S, whose diameters are larger than the longest ocean wave wavelengths but smaller than acoustic wavelengths. This picture is consistent with the observations of individual microbarom wave trains reported in Ref. 25. Recall that radiation produced by patches which are small compared to acoustic wavelengths can be represented at large distances as a acoustic monopole fields. Thus the microbarom signal can be thought of as an incoherent superposition of fields produced by monopole sources at the sea surface (see also Ref. 5), precisely as presented by (51).

B. Solving the reduced problem

Taking the dispersion relation $\omega(\mathbf{k})$ to be given by the deep water dispersion relation, (31), all that remains is a determination of the coefficients $C_\sigma^{(\pm)}(\mathbf{k}, \mathbf{q})$ in (44). The task is greatly simplified by the fact that we need only $C_\sigma^{(+)}(\mathbf{k}, -\mathbf{k})$. Hence, only the sum frequency components for sea state wave vectors of equal magnitude and opposite direction are required. Referring to Eqs. (44) and (45), one sees that the restriction to interface waves of equal and opposite wave vectors reduces the acoustic problem to one of plane waves propagating normal to the air/water interface. The determination of the reduced set of coefficients is thus equivalent to the one-dimensional problem of finding the outward propagating velocity potential

$$\phi = C_\sigma^{(+)}(\mathbf{k}, -\mathbf{k}) e^{i[2\omega(\mathbf{k})/c_\sigma]|z| - i2\omega(\mathbf{k})t} \quad (52)$$

and uniformly vibrating surface displacement

$$\xi = \hat{\xi}^{(+)}(\mathbf{k}, -\mathbf{k}) e^{-i2\omega(\mathbf{k})t}, \quad (53)$$

which satisfy the interface conditions.

The interface conditions simplify as well. Substituting (39) and (41) into the pressure condition (35) one obtains

$$\left(\rho_\sigma \frac{\partial \phi_h}{\partial t} + \rho_\sigma g \xi_2 \right) \Bigg|_{z=-0^+}^{0^+} = \left(-\rho_\sigma \frac{\partial \phi_p}{\partial t} - \frac{1}{2}\rho_\sigma \mathbf{v}_1 \cdot \mathbf{v}_1 - \rho_\sigma \xi_1 \frac{\partial v_{1z}}{\partial t} \right) \Bigg|_{z=-0^+}^{0^+}.$$

Referring to (43), the relevant component of ϕ_p, to leading order in $\omega_0/k_0 c_\sigma$, is

$$i \frac{\omega(\mathbf{k})^3}{|\mathbf{k}|^2 c_\sigma^2} e^{-2|\mathbf{k}||z| - i2\omega(\mathbf{k})t}.$$

Substituting the linear form (27) in $\frac{1}{2}\rho_\sigma \mathbf{v}_1 \cdot \mathbf{v}_1 + \rho_\sigma \xi_1 \partial v_{1z}/\partial t$, one finds the relevant component to be

$$2\rho_\sigma \omega(\mathbf{k})^2 e^{i[2\omega(\mathbf{k})/c_\sigma]|z| - i2\omega(\mathbf{k})t}.$$

Thus, recalling that the density of water is much greater than that of air and noting that the contribution from ϕ_p is higher order in $\omega_0/k_0 c_\sigma$, the reduced velocity potential (52) and surface displacement (53) satisfy

$$\left(\rho_\sigma \frac{\partial \phi}{\partial t} + \rho_\sigma g \xi \right) \Bigg|_{z=-0^+}^{0^+} = 2\rho_w \omega(\mathbf{k})^2 e^{-i2\omega(\mathbf{k})t}. \quad (54)$$

Similarly, substituting (41) into the velocity condition (36) one obtains

$$\left.\frac{\partial \phi_h}{\partial z}\right|_{z=-0^+}^{0^+} = \left.\left(-\frac{\partial \phi_p}{\partial z} - \xi_1 \frac{\partial v_{1z}}{\partial z} + \mathbf{v}_1 \cdot \nabla_H \xi_1\right)\right|_{z=-0^+}^{0^+}$$

Using (38) one needs only the relevant component of $-\xi_1 \nabla \cdot \mathbf{v}_1 = (1/\rho_\sigma c_\sigma^2)(\partial P_1/\partial t)$. Referring to (29) one finds this component to be

$$(-1)^\sigma i \frac{\omega(\mathbf{k})^3}{|\mathbf{k}| c_\sigma} e^{i[2\omega(\mathbf{k})/c_\sigma]|z| - i2\omega(\mathbf{k})t}.$$

Adding the contribution from ϕ_p and dropping $1/c_w^2$ relative to $1/c_a^2$ one obtains

$$\left.\frac{\partial \phi}{\partial z}\right|_{z=-0^+}^{0^+} = 3i \frac{\omega(\mathbf{k})^3}{|\mathbf{k}| c_a^2} e^{-i2\omega(\mathbf{k})t} \tag{55}$$

and

$$\frac{\partial \xi}{\partial t} = \left.\left(\frac{\partial \phi}{\partial z} - 3i \frac{\omega(\mathbf{k})^3}{|\mathbf{k}| c_\sigma} e^{-i2\omega(\mathbf{k})t}\right)\right|_{z=\pm 0^+}. \tag{56}$$

Substitute (52) and (53), into (54)–(56) to obtain

$$\rho_a[-2i\omega(\mathbf{k}) C_a^{(+)}(\mathbf{k},-\mathbf{k}) + g\hat{\xi}^{(+)}(\mathbf{k},-\mathbf{k})] + \rho_w[2i\omega(\mathbf{k}) C_w^{(+)}(\mathbf{k},-\mathbf{k}) - g\hat{\xi}^{(+)}(\mathbf{k},-\mathbf{k})] = 2\rho_w \omega(\mathbf{k})^2,$$

$$\frac{2}{c_a} C_a^{(+)}(\mathbf{k},-\mathbf{k}) + \frac{2}{c_w} C_w^{(+)}(\mathbf{k},-\mathbf{k}) = 3\frac{\omega(\mathbf{k})^2}{|\mathbf{k}| c_a^2}$$

$$\hat{\xi}^{(+)}(\mathbf{k},-\mathbf{k}) = -\frac{1}{c_w} C_w^{(+)}(\mathbf{k},-\mathbf{k}) + \frac{3\omega(\mathbf{k})^2}{2|\mathbf{k}| c_w^2}.$$

Solving, one finds to leading order

$$C_a^{(+)}(\mathbf{k},-\mathbf{k}) = i\omega(\mathbf{k})\left(\frac{c_a}{c_w} - \frac{3}{2} i \frac{\omega(\mathbf{k})}{|\mathbf{k}| c_a}\right) \tag{57}$$

$$C_w^{(+)}(\mathbf{k},-\mathbf{k}) = -i\omega(\mathbf{k}), \tag{58}$$

and

$$\hat{\xi}(\mathbf{k},-\mathbf{k}) = i\frac{\omega(\mathbf{k})}{c_w}.$$

The atmospheric and oceanic velocity potential amplitudes (57) and (58) are of rather different forms. The oceanic microbarom velocity potential amplitude (58) is equivalent to that obtained by Longuet-Higgens[2] (it is also equivalent to that obtained, incorrectly, by Arendt and Fritts[6] for the atmospheric microbarom amplitude). The imaginary part of the atmospheric microbarom velocity potential amplitude (57) is equivalent to the form predicted by Brekhovskikh *et al.* in Ref. 5 for the normally propagating component of the atmospheric radiation.

The ratio of the velocity potential amplitudes (57) and (58), is given by the term $c_a/c_w - \frac{3}{2} i\omega(\mathbf{k})/|\mathbf{k}| c_a$. This term is plotted in Fig. 4 assuming the deep water dispersion relation (31). Note that for frequencies near 0.1 Hz the velocity potential amplitude in the atmosphere is smaller than in the ocean by about a factor of four. The real and imaginary parts, c_a/c_w and $-\frac{3}{2}\omega(\mathbf{k})/|\mathbf{k}| c_a$, respectively, of the ratio of (57) and (58), are of comparable magnitude. The real part c_a/c_w is the larger of the two, by about a factor of 3, and represents the contribution from sound radiated from the ocean into the atmosphere; that such a term is significant was pointed out in Ref. 5. The imaginary part $-\frac{3}{2}\omega(\mathbf{k})/|\mathbf{k}| c_a$ represents the compression of the air by the ocean waves.

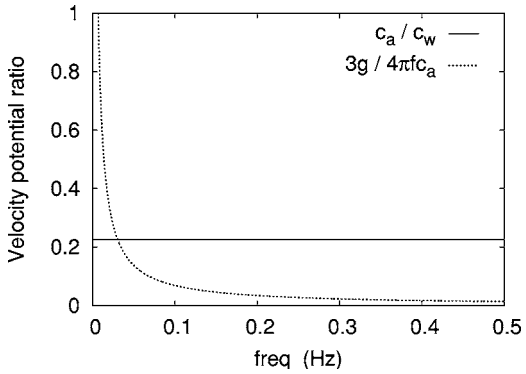

FIG. 4. The real and imaginary parts of the complex conjugate (so that both parts are positive) of the ratio, $c_a/c_w - \frac{3}{2} ig/2\pi f c_a$, of velocity potential amplitude in the atmosphere to that in the ocean for an infinitely deep ocean plotted as a function of frequency f.

Generally speaking, because of the enormous impedance contrast between air and water, the acoustic pressure radiated into the air by sound in the water is reduced by a factor of $\rho_a c_a/\rho_w c_w$. In this case, however, the effective interface pressure source given by the right side of (35) is proportional to the density of the water, ρ_w. This is the origin of the factor c_a/c_w in (57) and illustrates the basic physics of the problem. Once the interface is in motion the air and water in the source region must have roughly the same velocity fields [up to phase, see (30)]. However, the changes in pressure required to support changes in velocity are proportional to density. Thus the sound pressure fluctuations in the water associated with the motion of the interface are greater than those in the air by a factor of $\rho_w/\rho_a \approx 1000$.

The compressibility of the air arises in (57) because, as discussed above, the horizontally constant part of the effective interface velocity source given by the right side of (36) is proportional to $\nabla \cdot \mathbf{v}_1$, which is zero in the incompressible approximation. Indeed, to have a horizontally constant velocity source requires the fluid to be compressible.

C. The source spectra

Substituting (57) and (58), in (51), using the deep water dispersion relation (31) to relate the wave vector spectral density to the frequency direction spectral density through $\mathbf{k} = (4\pi^2/g) f^2(\cos\theta, \sin\theta)$ and

$$\mathcal{F}(\mathbf{k}) = \frac{g^2}{32\pi^4 f^3} F(f,\theta),$$

and choosing as integration variable the frequency of the received acoustic signal one finds

$$\langle P_\sigma(\mathbf{x}_H,z,0)P_\sigma(\mathbf{x}'_H,z',\tau)^*\rangle_T = \int_S \int_0^\infty \mathcal{Q}_\sigma(\mathbf{x}_H,\mathbf{x}'_H,z,z',\mathbf{y}_H,f)\mathcal{D}_\sigma(f)e^{-i2\pi f\tau}\,df\,d^2\mathbf{y}_H, \quad (59)$$

where $\mathcal{Q}_\sigma$ is the cross spectral density,[22]

$$\mathcal{Q}_\sigma(\mathbf{x}_H,\mathbf{x}'_H,z,z',\mathbf{y}_H,f) = \langle \hat{G}_\sigma(\mathbf{x}_H,z,\mathbf{y}_H,0,2\pi f)\hat{G}_\sigma(\mathbf{x}'_H,z',\mathbf{y}_H,0,2\pi f)^*\rangle_P, \quad (60)$$

for propagation from a point source at $\mathbf{y}_H \in S$ to receivers at $(\mathbf{x}_H,z)$ and $(\mathbf{x}'_H,z')$, and $\mathcal{D}_\sigma$ is the source strength spectrum squared

$$\mathcal{D}_\sigma(f) = \int_0^{2\pi} F\left(\frac{f}{2},\theta\right)F\left(\frac{f}{2},\theta+\pi\right)d\theta \cdot \begin{cases} \dfrac{4\rho_a^2 g^2\pi^4 f^3}{c_a^2}\left(\dfrac{9g^2}{4\pi^2 c_a^2 f^2}+\dfrac{c_a^2}{c_w^2}\right) \text{ in the atmosphere,} & \sigma = a \\ \dfrac{4\rho_w^2 g^2\pi^4 f^3}{c_w^2} \text{ in the ocean,} & \sigma = w. \end{cases} \quad (61)$$

A similar form for the source strength spectrum $\mathcal{D}_w$ for radiation into the ocean was first obtained by Hasselmann in Ref. 3. If $\hat{P}_\sigma$ is the Fourier transform in time of the received acoustic pressure P_σ, then[22] the cross spectral density of the received microbarom signals is given by

$$\langle \hat{P}_\sigma(\mathbf{x}_H,z,2\pi f)\hat{P}_\sigma(\mathbf{x}'_H,z',2\pi f)^*\rangle_T = \int_S \mathcal{Q}_\sigma(\mathbf{x}_H,\mathbf{x}'_H,z,z',\mathbf{y}_H,f)\mathcal{D}_\sigma(f)\,d^2\mathbf{y}_H. \quad (62)$$

The integral over S in (62) is required because, in general, as discussed above, $\mathcal{D}_\sigma$ is not constant over the source region, but varies slowly enough to be considered constant over distances of many ocean wavelengths.

Consider the ratio of the atmospheric to oceanic source strength spectra. Note that this ratio is independent of the sea state. One has

$$\sqrt{\frac{\mathcal{D}_a(f)}{\mathcal{D}_w(f)}} = \frac{\rho_a c_w}{\rho_w c_a}\sqrt{\frac{9g^2}{4\pi^2 c_a^2 f^2}+\frac{c_a^2}{c_w^2}}. \quad (63)$$

The source strength spectra ratio (63) is plotted in Fig. 5. For higher frequencies the ratio is asymptotic to the incompressible value $\rho_a/\rho_w \approx 10^{-3}$. In the frequency range of interest, 0.1 to 0.3 Hz, the ratio is always less than 2×10^{-3}. This explains the observation, pointed out in the Introduction, that atmospheric microbarom levels are generally three orders of magnitude lower than oceanic levels.

The integral,

$$\int_0^{2\pi} F\left(\frac{f}{2},\theta\right)F\left(\frac{f}{2},\theta+\pi\right)d\theta, \quad (64)$$

first obtained by Hasselmann,[3] is the only term in (61) which is not explicit. It is a factor common to both atmospheric and oceanic radiation and is a measure of the density of counter propagating waves at frequency f. Its determination is problematic. The largest component of a wave field consists of traveling waves propagating in the direction of the prevailing wind. Evaluating (64) requires knowing the tails of the angular part of the wave vector distribution. The determination of (64) thus depends on quantities which are difficult to determine, either experimentally or numerically.[7,15,26,27] It is possible that observed atmospheric and oceanic microbarom levels will ultimately be used to constrain ocean wave models.

IV. A SIMPLE MODEL FOR THE ATMOSPHERIC MICROBAROM SIGNAL FROM STORMS OVER THE OPEN OCEAN

In this section an example calculation is presented to illustrate an application of (61) and (62) to the atmospheric microbarom signal. A simple model is considered for the signal received from a distant isolated storm over the deep ocean far from any land masses. It is assumed that the source region is roughly centered at the origin $\mathbf{y}_H=\mathbf{0}$, that the horizontal extent of the source region is small compared with the distance $|\mathbf{x}_H|$ to the receiver, and that the source spectrum is constant over the source region.

To compute the power spectrum,

$$\langle|\hat{P}_\sigma(\mathbf{x}_H,z,2\pi f)|^2\rangle_T = \int_S \mathcal{Q}_\sigma(\mathbf{x}_H,\mathbf{x}_H,z,z,\mathbf{y}_H,f)\mathcal{D}_\sigma(f)\,d^2\mathbf{y}_H,$$

of the received signal both the power spectral density, $\mathcal{Q}_\sigma(\mathbf{x}_H,\mathbf{x}_H,z,z,\mathbf{y}_H,f)$, for acoustic propagation from $(\mathbf{y}_H,0)$ to $(\mathbf{x}_H,z)$ as well as the source spectrum, $\mathcal{D}_\sigma(f)$, are required. Let $|S|$ be the area of the source region interface S. As a consequence of the assumption that the source spectrum is constant one has

$$\langle|\hat{P}_\sigma(\mathbf{x}_H,z,2\pi f)|^2\rangle_T = |S|\mathcal{Q}_\sigma(\mathbf{x}_H,\mathbf{x}_H,z,z,\mathbf{0},f)\mathcal{D}_\sigma(f).$$

The term $\sqrt{\mathcal{Q}_a(\mathbf{x}_H,\mathbf{x}_H,0,0,\mathbf{y}_H,f)}$ will be referred to here as the propagation factor so that to obtain the received microbarom power spectral density one simply takes the product of source strength squared, propagation factor squared, and area $|S|$. Note that −20 times the logarithm of the propagation factor is generally called the transmission loss.[28]

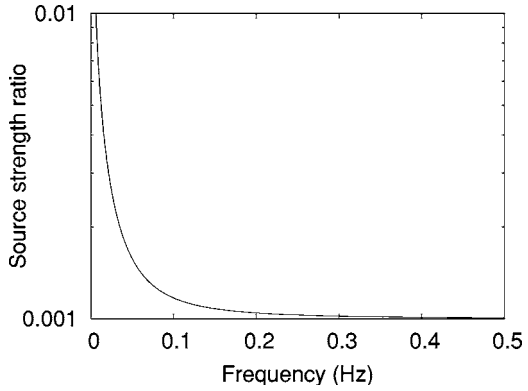

FIG. 5. The ratio of the microbarom source strength spectra for radiation into the atmosphere versus radiation into the ocean.

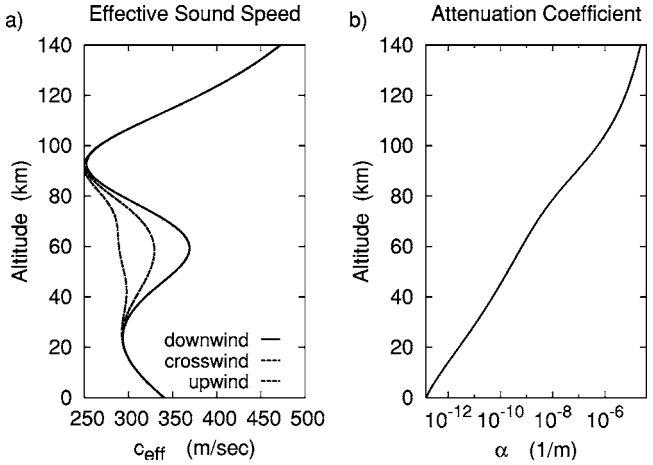

FIG. 6. (a) The model effective sound speed for downwind, crosswind, and upwind propagation. (b) The classical attenuation coefficient, as a function of altitude.

A. Propagation model

To model the propagation a stratified model will be used.[29] In this model the mean thermodynamic properties of the atmosphere, mean temperature, mean pressure, mean density ρ_a, and mean entropy, are assumed to depend only on altitude. It is assumed that the mean winds $\mathbf{v}_0$ have no vertical component and that the horizontal components again depend only on altitude.[30,31] The frequencies of interest here are much larger than the Brunt-Väisälä frequency in the atmosphere so that the effects of buoyancy can be ignored. Thus one may set $g=0$ in the equation for the Green's function. To simplify the model further the effective sound speed approximation, in which the wind velocity in the direction of horizontal propagation,

$$\hat{\mathbf{k}} = \frac{\mathbf{x}_H - \mathbf{y}_H}{|\mathbf{x}_H - \mathbf{y}_H|},$$

is added to the adiabatic sound speed, is used. The effective sound speed approximation is valid for low angle propagation.

Atmospheric attenuation is included by adding an imaginary part, an attenuation coefficient $\alpha(z)$,[32] to the wave number. Here only the classical attenuation coefficient, that due to thermo-viscous effects alone, will be used.

The resulting equation for the Green's function for atmospheric propagation, $\hat{G}_a$, is[30,31,33]

$$\left(\nabla_H^2 + \rho_a \frac{\partial}{\partial z}\frac{1}{\rho_a}\frac{\partial}{\partial z} + \left(\frac{\omega}{c_{\text{eff}}} + i\alpha(z)\right)^2\right)$$

$$\times \hat{G}_a(\mathbf{x}_H, z, \mathbf{y}_H, z', \omega) = \delta(\mathbf{x}_H - \mathbf{y}_H)\delta(z - z')$$

for $z>0$ with

$$c_{\text{eff}}(z) = c_a(z) + \hat{\mathbf{k}} \cdot \mathbf{v}_0(z)$$

and with rigid ground boundary conditions

$$\left.\frac{\partial P_a(\mathbf{x}_H, z, \omega)}{\partial z}\right|_{z=0} = 0$$

taken at $z=0$. For the purposes of this example the sound speed c_a is taken to be given by the polynomial fit to the "Standard Atmosphere"[34] given in Ref. 35. To simulate downwind versus upwind propagation a simple model for wind speed is used: $\hat{\mathbf{k}} \cdot \mathbf{v}_0(z)$ is assumed to have a Gaussian profile centered at the stratopause (an altitude of 60 km in the model used here) and 17.5 km wide. Explicitly,

$$\hat{\mathbf{k}} \cdot \mathbf{v}_0(z) = \pm 40 \cdot \exp\left[-\left(\frac{z - 6.0 \times 10^4}{1.75 \times 10^4}\right)^2\right] \text{m/s}.$$

The effective sound speeds that result for downwind, upwind, and crosswind propagation, as well as the classical attenuation coefficient, are plotted in Fig. 6.

To solve for $\hat{G}_a$ one may expand in vertical normal modes.[28,36] At long ranges from the source ($\mathbf{x}_H$ and $\mathbf{y}_H$ widely separated) one has

$$\hat{G}_a(\mathbf{x}_H, z, \mathbf{y}_H, z', \omega) = \frac{1}{\rho_a(z')}\sqrt{\frac{i}{8\pi|\mathbf{x}_H - \mathbf{y}_H|}}\sum_j \frac{e^{ik_j|\mathbf{x}_H - \mathbf{y}_H|}}{\sqrt{k_j}}\psi_j(z)\psi_j(z') \tag{65}$$

with

$$\left(\rho_a \frac{\partial}{\partial z}\frac{1}{\rho_a}\frac{\partial}{\partial z} + \left(\frac{\omega}{c_{\text{eff}}} + i\alpha(z)\right)^2 - k_j^2\right)\psi_j(z) = 0$$

and $\psi_j'(0)=0$. The modes satisfy the bi-orthogonality (no complex conjugation) condition

$$\int_0^\infty \psi_j(z)\psi_n(z)\frac{1}{\rho_a(z)}\,dz = \delta_{jn}.$$

The condition that this integral converges for $j=n$ uniquely determines the mode numbers.

Rather than the Green's function, the cross spectral density $\mathcal{Q}$ from (60) is required. For a stationary atmosphere the cross spectral density is the product of two Green's functions. In this case the propagation factor is simply the magnitude $|G_a(\mathbf{x}_H, 0, \mathbf{y}_H, 0, 2\pi f)|$ of the Green's function. For a fluctuating atmosphere a simple model for the average over the propagation medium $\langle\cdot\rangle_P$ is obtained by assuming that the different modes have statistically independent, uniformly distributed phases. Under such assumptions the square of the propagation factor for surface to surface propagation is given by the "incoherent modal sum"[28]

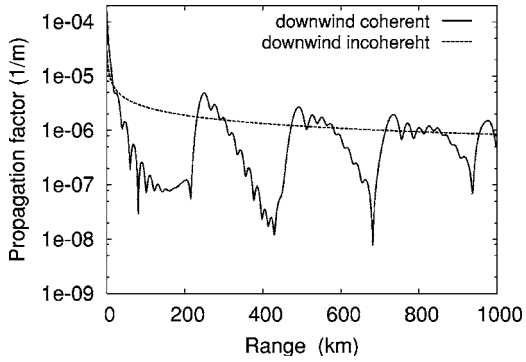

FIG. 7. The propagation factor for downwind propagation. Both the coherent modal sums, representing propagation in a stationary atmosphere, and the incoherent modal sum, representing the mean for propagation in a fluctuating atmosphere, are shown.

$$\mathcal{Q}_a(\mathbf{x}_H,\mathbf{x}_H,0,0,\mathbf{0},f)=\frac{1}{8\pi\rho_a(0)^2|\mathbf{x}_H|}\cdot\sum_j\frac{e^{-2\ \mathrm{Im}\ k_j|\mathbf{x}_H|}}{|k_j|}|\psi_j(0)^4|. \tag{66}$$

The mode functions ψ_j and wave numbers k_j have been determined using the finite difference methods described in Ref. (28). The modal attenuation coefficients, $\mathrm{Im}\,k_j$, are determined perturbatively: the modes are determined for the lossless case $\alpha=0$ and then first-order perturbation theory[36] is used to approximate the imaginary parts of the modal wave numbers. Both upwind and crosswind the surface-to-surface propagation paths must pass through the thermosphere (the region above 120 km). In these cases there is a severe reduction in predicted levels as a consequence of the increased attenuation in the thermosphere. While this is consistent with observations[1,9,11,12,37] the numerical values for the propagation as predicted by such linear models should not be taken literally since, in the thermosphere, the density ρ_a decreases dramatically so that the accuracy of the linear approximation to the atmospheric response is doubtful.[38] For downwind propagation, however, the sound gets trapped in the duct formed by the stratosphere (below 60 km) so that received levels are not greatly influenced by the thermosphere. Thus, for downwind propagation a linear propagation model is reasonable. In Fig. 7 the propagation factor for the downwind model is plotted as a function of range $|\mathbf{x}_H|$ at frequency $f=0.2$ Hz.

B. Sea state model

Now consider the sea state angular integral (64). It is common to write $F(f,\theta)$ as[15]

$$F(f,\theta)=\bar{F}(f)a(f,\theta)$$

where $\bar{F}(f)$ is the frequency spectrum given by (4). For purposes of illustration it will be assumed here that the frequency spectrum $\bar{F}(f)$ can be taken to be given by the JONSWAP[15,16] model of highly excited seas, that both $\bar{F}(f)$ and $a(f,\theta)$ are independent of position in the source region, and that $a(f,\theta)=a(\theta)$ is independent of frequency. Then one has

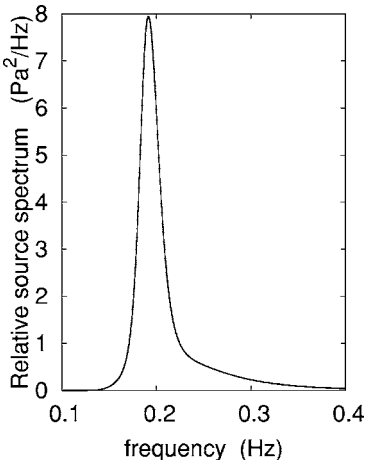

FIG. 8. The relative source spectrum for atmospheric microbaroms, $\mathcal{D}_a(f)/b$.

$$\int_0^{2\pi}F\left(\frac{f}{2},\theta\right)F\left(\frac{f}{2},\theta+\pi\right)d\theta=\bar{F}\left(\frac{f}{2}\right)^2\int_0^{2\pi}a(\theta)a(\theta+\pi)\,d\theta.$$

If $\int_0^{2\pi}a(\theta)a(\theta+\pi)d\theta=b$, then

$$\mathcal{D}_a(f)=4b\bar{F}\left(\frac{f}{2}\right)^2\frac{\rho_a^2g^2\pi^4f^3}{c_a^2}\left(\frac{9g^2}{4\pi^2c_a^2f^2}+\frac{c_a^2}{c_w^2}\right).$$

In Fig. 8 the atmospheric microbarom source strength squared divided by b, $\mathcal{D}_a(f)/b$, is plotted for a significant wave height of 10 m and peak frequency of 0.95 Hz. Referring to Figs. 8 and 7, one finds that to produce a microbarom signal with amplitude of 0.1 $\mathrm{Pa}/\sqrt{\mathrm{Hz}}$ at the peak frequency 1000 km from the source region would require

$$\left(10^{-12}\frac{1}{\mathrm{m}^2}\right)\left(8\frac{\mathrm{Pa}^2}{\mathrm{Hz}}\right)b|S|=0.01\frac{\mathrm{Pa}^2}{\mathrm{Hz}}.$$

This gives $b|S|\approx10^9$ m^2. Assuming the source region to be a disk of radius 200 km gives $b\approx0.01$. For comparison, note that assuming the sea to be isotropic gives $b=2\pi$. It should be emphasized, however, that the value for b obtained here is illustrative only. The forms used for both the propagation factor and the source strength are based on simplifying assumptions: for the propagation factor these are the use of the standard model for the atmospheric temperature and the exponential profile for the atmospheric wind; for the source strength these are the use of the JONSWAP model for the frequency spectrum and the assumption that the sea state statistics are constant over the source region.

V. DISCUSSION OF THE RESULTS

A complete solution of the problem of the radiation of infrasound by ocean waves, the so-called microbarom radiation, has been presented. A direct connection is made between the statistical properties of the microbarom signal and the stochastic models commonly used to describe ocean wave systems. Since the acoustic wavelengths are so much longer than the correlation lengths for the ocean waves the received microbarom signal can be described as an incoherent superposition of fields produced by monopole sources at

the sea surface. The problem of finding the source strength of the radiation has been reduced to oceanography: the determination of the density of counter-propagating waves of equal frequency (standing waves) on the ocean surface, as given by the integral (64), is required.

The source strength spectral density function for the radiation of atmospheric microbaroms has been derived and compared to that for oceanic microbaroms. The primary radiation is into the ocean; the source strength for radiation into the atmosphere is three orders of magnitude smaller than that for radiation into the ocean. This is in accord with observations: typical peak atmospheric microbarom levels are measured in the tenths of Pascals while typical peak oceanic microbarom levels can reach 100 Pascals. The reason for this difference lies in the fact that sea water is three orders of magnitude denser than air. The velocity of the air/water interface is fixed by the ocean waves. Consequently, the air and water have similar velocity fields near the interface. However, the variations in pressure required to maintain variations in velocity are proportional to the density of the fluid. Thus the pressure fluctuations in the ocean are three orders of magnitude larger than those in the air. Indeed, the ratio of the atmospheric to the oceanic microbarom source strengths is shown to be approximately equal to the ratio of the atmospheric to the oceanic densities.

The full atmospheric microbarom signal is shown to be the sum of two terms. The first term, responsible for about 80% of the radiation, represents sound radiated from pressure fluctuations produced in the ocean by the motion of the interface plus a term, responsible for the remaining 20% of the radiation, due to the compression of the air by the ocean waves. The single unknown factor, the standing wave density (64), is common to both the atmospheric and oceanic source strength spectra.

(Received 21 September 2005; revised 8 March 2006; accepted 9 March 2006)

The time-domain impedance boundary conditions of Tam and Auriault are extended for impedance boundaries with subsonic mean flows. This extension requires an effective impedance. A model for the effective impedance is proposed, which guarantees the continuity of particle displacement over an infinitely thin shear layer connecting the fluid to the impedance boundary as described by Myers. Together with the effective impedance model, the time domain impedance boundary condition renders the requirement of measuring the effective impedance under flow conditions unnecessary. To demonstrate the feasibility of the extended boundary conditions, a numerical validation using the NASA Grazing Incidence Tube measurements of Jones *et al.* is carried out. The assumed velocity on the infinitely thin shear layer connecting the flow over the surface to the locally reacting wall is shown to have a strong influence on the performance of the liner. Another important parameter identified is the shape of the mean flow profile, which not only causes convective effects but also may excite possible flow instabilities. It is demonstrated that satisfactory results can be obtained using the extended time domain impedance boundary condition based on the correct effective impedances and mean flow profiles. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Acoustic lining is a key technology in the reduction of sound radiation from flow ducts. It is found in simple air conditioning systems as well as in commercial aeroengines. Consequently, the development of tools suitable for the prediction of sound propagation in lined flow ducts has been a very important subject in acoustics for some time. The liner impedance arising from a simple mechanical or acoustic model for the locally reacting wall is defined in the frequency domain and normally used for frequency-domain analysis. According to Hamilton and Astley[1] as well as Li *et al.*,[2] for a large number of aeroacoustics problems, e.g., large 3D, broadband, nonlinear, and transient problems, it is preferable to use time-domain methods.

Time-domain impedance boundary conditions (TDIBCs) appear separately in electromagnetism and acoustics. So far, several different TDIBCs have been proposed for computational aeroacoustics (CAA). Tam and Auriault[3] proposed both a single-frequency and a broadband TDIBC and have proved the well-posedness for cases without flow on porous surfaces. Özyörük and Long[4] proposed the implementation of a convective-modified impedance in the time domain via z-transformation. Fung and Ju[5,6] constructed stable TDIBCs using a reflection coefficient instead of the impedance. The detailed history and theoretical and numerical issues of TDIBCs have been recently reviewed by Fung and Ju.[7]

All three kinds of TDIBCs have been validated using the NASA Grazing Incidence Tube (GIT) data.[8] Özyörük and Long[4] and Fung and Ju[5,6] validated their TDIBC using several flow conditions showing good agreement.[9–11] Very good agreement compared to the cases measured in the NASA GIT with zero mean flow on the impedance surface[12] and for multi-dimensional problems[13] has been demonstrated by Zheng and Zhuang using TDIBCs of Tam and Auriault.[3] However, for some cases Özyörüz *et al.*[9] as well as Ju and Fung[11] reported that impedance jumping between the hard and soft walls could result in amplified numerical instabilities. This type of instability was first found by Tester,[14] who showed the convective impedance boundary condition could lead to an unstable solution in the study of a lined duct with mean flow. Tam and Auriault[3] proved that the existence of a Kelvin-Helmholtz-type instability renders the initial value problem ill-posed for the time-domain solution by the direct implementation of the convective impedance boundary condition. To overcome this difficulty, they suggested a direct iteration model by measuring the effective impedance in the presence of mean flow. However, possibly due to the problems in measuring the effective impedance described below, no comprehensive proof was provided in their paper. Özyörük and Long[10] found that the numerical instabilities can be removed using a convective impedance with a shear

[c)]Electronic mail: frank.thiele@cfd.tu-berlin.de

layer assumption. Ju and Fung[11] proposed and validated that the use of an effective plane-wave impedance in their time-domain method was unconditionally stable even for a slip flow. However, the drawbacks of the use of effective plane-wave impedance[11] are that the incident angle of sound waves must be assumed as known before the calculation and the curvature effects cannot be accounted for. In fact, the use of an effective impedance is a very useful idea which can be traced back to even earlier works by Ingard,[15] Goldstein and Rice,[16] and Nayfeh *et al.*[17] The present work is motivated by several works referring to the effective impedance[3,11,15–17] and the widely used impedance boundary condition by Myers based on the continuity of particle displacement.[18]

The main objective of this paper is to extend Tam and Auriault's TDIBCs[3] for arbitrary subsonic mean flow profiles using the effective impedance and to provide a method to calculate the effective impedance Z' from the flow field and the flow impedance Z. To overcome the requirement of measuring the effective impedance, the impedance boundary condition by Myers[18] based on the continuity particle displacement is resorted. The next section will give the mathematical formulation of the extended TDIBCs and provide a stability analysis on their well-posedness. In Sec. III the mathematical model and numerical algorithm for the NASA GIT using the extended TDIBCs are presented. The corresponding numerical results are presented in Sec. IV and compared against the latest GIT measurement results by Jones *et al.*[19] The concluding remarks are finally given in Sec. V.

II. TDIBCS FOR SURFACES WITH SUBSONIC MEAN FLOWS

Throughout this paper a $e^{-i\omega t}$ convention applies and the surface normal vector $\mathbf{n}$ is defined positive when pointing into the surface. The effective impedance for arbitrary subsonic mean flow profiles is used to provide a TDIBC based on the idea of Tam and Auriault,[3] which is shown to be stable for subsonic mean flows. A detailed analysis of the stability is given in Appendix A. Both the single-frequency TDIBC and the broadband time domain impedance boundary condition are used in this way, extending the applicability of the original TDIBC, while the well-posedness remains guaranteed.

A. Single-frequency TDIBC for surfaces with subsonic mean flows

Using the effective impedance within the definition of the single-frequency one-dimensional TDIBCs by Tam and Auriault[3] to allow subsonic mean flow profiles leads to

$$\frac{\partial p}{\partial t} = R' \frac{\partial v_n}{\partial t} - X' \omega v_n, \quad X' < 0, \tag{1}$$

$$p = R' v_n + \frac{X'}{\omega} \frac{\partial v_n}{\partial t}, \quad X' \geqslant 0. \tag{2}$$

Equations (1) and (2) are equivalent to the frequency-domain effective impedance boundary condition $Z' = p/v_n$, with $(Z' = R' - iX')$ for a sound field of the single frequency ω. Contrary to the zero mean flow assumption required on the impedance wall used by Tam and Auriault, the effective impedance Z' is defined under subsonic mean flow conditions. Thus it is necessary to measure the effective impedance in the presence of mean flow, or preferably to try to represent it by a model with mean flow effects accounted for. In general Z' can be written as a function of the flow impedance Z, angular frequency ω, effective mean flow Mach number $\mathbf{M_e}$, and the intensity of sound: $Z' = Z'(Z, \omega, \mathbf{M_e}, \mathrm{SPL})$, where the flow impedance only depends on the magnitude of the effective flow Mach number on the surface. For zero mean flow on the impedance surface, Eqs. (1) and (2) reduce to the original single-frequency TDIBCs by Tam and Auriault and the well-posedness has already been proved[3] in their investigation. The analysis on the well-posedness of Eqs. (1) and (2) is addressed in Appendix A.

Considering only an effective axial mean flow Mach number $\mathbf{M_e}$, the nondimensionalized linearized Euler equations (LEEs) on the surface of the liner can be written as

$$\frac{\partial v}{\partial t} + \mathbf{M_e} \frac{\partial \mathbf{v}}{\partial x} = -\nabla p \tag{3}$$

$$\frac{\partial p}{\partial t} + \mathbf{M_e} \frac{\partial p}{\partial x} + \frac{\partial \mathbf{v}}{\partial x} = 0. \tag{4}$$

The extended single-frequency TDIBC of Eqs. (1) and (2) can also be formulated in the following form for numerical implementation through the combination of Eq. (3) with Eq. (1), and Eq. (4) with Eq. (2):

$$\nabla_n p = \frac{1}{R'} \left(\frac{\partial \mathbf{v}}{\partial x} - X' \omega v_n \right) + \frac{\mathbf{M_e}}{R'} \frac{\partial p}{\partial x} - \mathbf{M_e} \frac{\partial v_n}{\partial x}, \quad X' < 0, \tag{5}$$

$$\nabla_n p = \frac{\omega}{X'} (R' v_n - p) - \mathbf{M_e} \frac{\partial v_n}{\partial x}, \quad X' \geqslant 0. \tag{6}$$

Given $\mathbf{M_e} = \mathbf{0}$ on the impedance wall, Eqs. (5) and (6) will be reduced to the original implementation form of Tam and Auriault[3] as

$$\nabla_n p = \frac{1}{R} \left(\frac{\partial \mathbf{v}}{\partial x} - X \omega v_n \right), \quad X < 0, \tag{7}$$

$$\nabla_n p = \frac{\omega}{X} (R v_n - p), \quad X \geqslant 0. \tag{8}$$

B. Broadband TDIBC for surfaces with subsonic mean flows

The three-parameter broadband TDIBC by Tam and Auriault[3] can be applied for subsonic mean flows and written as

$$\frac{\partial p}{\partial t} = R'_0 \frac{\partial v_n}{\partial t} - X'_{-1} v_n + X'_1 \frac{\partial^2 v_n}{\partial t^2}. \tag{9}$$

This is equivalent to a frequency-domain impedance boundary condition with the effective impedance Z' defined by

$$Z' = R'_0 - i[X'_{-1}/\omega + X'_1\omega], \tag{10}$$

where the valid range of the three parameters is given by $R'_0 > 0$, $X'_{-1} < 0$ and $X'_1 > 0$ from the transfer of the causal impedance and reactance conditions by Tam and Auriault[3] to the effective impedance.

In the same way as for the extended single-frequency TDIBC [Eqs. (1) and (2) and Eqs. (5) and (6)], the effective impedance can be defined as $Z' = Z'(Z, \omega, \mathbf{M_e}, \mathrm{SPL})$. For $\mathbf{M_e} = \mathbf{0}$, the extended broadband TDIBC will be reduced to the form given by Tam and Auriault.[3] It can also be proved that the proposed effective impedance in the broadband TDIBC Eq. (9) would lead to well-posed problems with the detailed stability analysis given in Appendix B. In the following, two different numerical implementation forms are presented, where the first is used for the computations of this paper and the second is chosen to show the link to the original form used by Tam and Auriault.[3]

Divided by $-i\omega$, then transformed back to the time domain using the auxiliary variable q, $\partial q/\partial t = v_n$, the broadband TDIBC Eq. (9) can be formulated into the implementation form used in this paper:

$$\frac{\partial v_n}{\partial t} = \frac{1}{X'_1}[p - R'_0 v_n + X'_{-1} q]. \tag{11}$$

The condition for the time derivative of v_n is used to calculate the pressure derivative normal to the wall by inserting Eq. (11) into the LEE multiplied by the impedance wall normal vector,

$$\boldsymbol{\nabla}_n p = -\left(\mathbf{M_e} \cdot \boldsymbol{\nabla}_n \mathbf{v} + \frac{\partial v_n}{\partial t}\right). \tag{12}$$

The original method by Tam and Auriault used $Q = \partial v_n/\partial t$, and to consider the LEE of Eqs. (3) and (4), in which case the extended broadband TDIBC can also be written as

$$\frac{\partial}{\partial t}\begin{bmatrix} v_n \\ Q \end{bmatrix} = \begin{bmatrix} Q \\ \dfrac{1}{X'_1}(-\mathbf{M_e} \cdot \boldsymbol{\nabla} p - \boldsymbol{\nabla} \cdot \mathbf{v} - R'_0 Q + X'_{-1} v_n) \end{bmatrix}. \tag{13}$$

Again Eq. (12) will be used to calculate the pressure derivative with a given Q. Assuming a zero effective mean flow on the impedance wall, Eqs. (12) and (13) can be simplified to the original forms by Tam and Auriault[3] as

$$\frac{\partial}{\partial t}\begin{bmatrix} v_n \\ Q \end{bmatrix} = \begin{bmatrix} Q \\ \dfrac{1}{X_1}(-\boldsymbol{\nabla} \cdot \mathbf{v} - R_0 Q + X_{-1} v_n) \end{bmatrix}, \tag{14}$$

$$\boldsymbol{\nabla}_n p = -Q. \tag{15}$$

C. An effective impedance model based on the Myers boundary condition

It is shown that the extended single-frequency TDIBC of Eqs. (1) and (2) or Eqs. (5) and (6) and the extended broadband TDIBC of Eq. (9) or Eqs. (12) and (13) can admit subsonic mean flows without losing the well-posedness. However, the problem has only been shifted to the determination of the effective impedance considering the mean flow effects. The Myers boundary condition[18] is designed to describe the mean flow effects if only the thickness of the mean flow and the acoustic boundary layers are small compared to the acoustic wavelength, which can be written into the following dimensionless form:

$$\hat{v}_n = \hat{p}/Z + (i\omega)^{-1}\mathbf{M} \cdot \boldsymbol{\nabla}(\hat{p}/Z) - (i\omega Z)^{-1}\mathbf{n} \cdot (\mathbf{n} \cdot \boldsymbol{\nabla}\mathbf{M})\hat{p}, \tag{16}$$

where $\hat{v}_n$ denotes the normal velocity (which is, by the definition of $\mathbf{n}$, positive when pointing into the impedance wall), $\mathbf{M}$ is the grazing mean flow Mach number, $\hat{p}$ is the pressure fluctuation, and Z denotes the flow impedance. Equation (16) can be rewritten into the following form:

$$Z = \frac{\hat{p}}{\hat{v}_n} + \frac{Z}{i\omega\hat{p}}\frac{\hat{p}}{\hat{v}_n}\mathbf{M} \cdot \nabla\frac{\hat{p}}{Z} - \frac{\mathbf{n} \cdot (\mathbf{n} \cdot \boldsymbol{\nabla}\mathbf{M})}{i\omega}\frac{\hat{p}}{\hat{v}_n}. \tag{17}$$

Defining the effective impedance as $Z' = \hat{p}/\hat{v}_n$ in the presence of the mean flows, Eq. (17) can be written as

$$Z' = \frac{\hat{p}}{\hat{v}_n} = Z \Bigg/ \left[1 + \frac{Z}{i\omega\hat{p}}\mathbf{M} \cdot \boldsymbol{\nabla}\frac{\hat{p}}{Z} - \frac{\mathbf{n} \cdot (\mathbf{n} \cdot \boldsymbol{\nabla}\mathbf{M})}{i\omega}\right], \tag{18}$$

where Z' is the effective acoustic impedance and equals $R' - iX'$, where R' and X' represent the effective acoustic resistance and reactance, respectively. Z is the flow impedance according to Myers.[18] To account for the refraction effects from mean flows, an effective mean Mach number $\mathbf{M_e}$ is introduced. Using $\mathbf{M_e}$ Eq. (18) is formulated into

$$Z' = \frac{\hat{p}}{\hat{v}_n} = Z \Bigg/ \left[1 + \frac{Z}{i\omega\hat{p}}\mathbf{M_e} \cdot \boldsymbol{\nabla}\frac{\hat{p}}{Z} - \frac{\mathbf{n} \cdot (\mathbf{n} \cdot \boldsymbol{\nabla}\mathbf{M_e})}{i\omega}\right]. \tag{19}$$

In many cases a slip condition is employed in the acoustic calculations with the frequency domain boundary condition, which leads to a so-called plug flow with $\mathbf{M_e} = \mathbf{M}$ at the liner surface. For a two-dimensional plane impedance wall with curvature effects neglected, Eq. (19) can be simplified as

$$Z' = Z \Bigg/ \left[1 + \frac{Z}{i\omega\hat{p}}\mathbf{M_e} \cdot \boldsymbol{\nabla}(\hat{p}/Z)\right], \tag{20}$$

which can also be derived directly from the Ingard boundary condition.[15] Equations (19) and (20) constitute the basis for the calculation of effective impedances in this paper.

If assuming a plane harmonic wave in a plug flow in the x direction with unity amplitude ($e^{[i(k_x x - \omega t)]}$), Eq. (20) can be further simplified into the following form verified by Ju and Fung,[11]

$$\hat{v}_n = \hat{p}/Z', \tag{21}$$

where $Z' = Z/(1 - \mathrm{M}_x \cos\theta)$ denotes the effective plane-wave impedance with the effective incident wave angle $\theta = \cos^{-1}[k_x/\omega]$ depending on ω and M through k_x. The main advantage of using Eqs. (19) and (20) over Eq. (21) is that the incident angle of a sound wave has been trans-

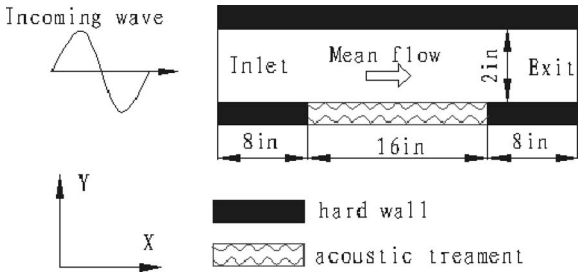

FIG. 1. Configuration of NASA Langley 2D grazing flow impedance tube.

ferred to an impact angle as part of the solution of the effective impedance.

D. Implementation of the extended TDIBC

Both the extended single-frequency and broadband TDIBCs can be validated. Here we only focus on the implementation of the broadband TDIBC. The key element of the implementation is on the calculation of the effective impedance by Eq. (19) in the time domain. Assuming that the impedance Z under flow conditions is known, only the denominator of Eq. (19) has to be calculated. Considering there are no curvature effects involved in the validation configuration of the NASA GIT as shown in Fig. 1, this paper will focus on the convective term in Eq. (19). However, the extension of the presented method to the curvature term is straightforward. The effective impedance is initially defined in the frequency domain; the key idea is to do the transfer to the time domain after calculating the complex amplitude ratio within the convective term. As the spectra are very simple for a single frequency, it is possible to calculate the complex amplitude ratio within the convective term by a ratio of amplitudes obtained in the time domain. The complex pressure amplitude is present in both numerator and denominator. As the time and length scales are coupled in acoustic waves, the ratio is real if the wave number vector is real. Unfortunately the wave number vector along the impedance wall is complex, describing the decay along the liner. Therefore the ratio may contain a phase shift. If no cutoff or close to cutoff modes are present, the phase shift is small and may be neglected. The convective term includes $(i\omega\hat{p})^{-1}\nabla\hat{p}$, which is interpreted as the gradient of the time integral of $\hat{p}$ over $\hat{p}$. The convective term in Eq. (20) can be written in the following form:

$$\frac{Z}{i\omega\hat{p}}\mathbf{M_e}\cdot\nabla(\hat{p}/Z)=\frac{1}{\hat{p}}\mathbf{M_e}\cdot\nabla(\hat{P}), \tag{22}$$

where $\hat{p}/i\omega$ has been replaced by the auxiliary variable $\hat{P}$, which is calculated in the time domain by an integration:

$$\frac{\partial\hat{P}}{\partial t}=-\hat{p}. \tag{23}$$

Among the many possibilities, this is numerically the easiest to use, as the broadband TDIBC without flow would also require the integral. In general integral quantities add stability to the computation, as they arise from filtered field variables, which contain no short waves. For the presented results, the gradient operator is applied after the integration and requires the overhead of calculating $\hat{P}$ in the whole computational domain. If the gradient is applied first and the time integration afterwards, the computational effort could be significantly reduced especially for large node numbers.

As discussed above, for a single frequency it is possible to replace the complex amplitude ratio of Eq. (22) by the amplitudes of numerator and denominator. Assuming the phase angle of the convective term is neglectable, the root mean squares (rms) may be used. This yields the following replacement for the convective term:

$$\frac{1}{\hat{p}}\mathbf{M_e}\cdot\nabla(\hat{P})=\left|\mathbf{M}\cdot\frac{\mathbf{k}}{\omega}\right|=\frac{[\mathbf{M}\cdot\nabla\hat{P}]_{\mathrm{rms}}}{\hat{p}_{\mathrm{rms}}}. \tag{24}$$

As the rms operation allows only arcs between 0 and π, the scalar product has to be multiplied by -1 or 1 for downstream and upstream propagating waves, respectively. The root mean square values of both parts are calculated with the time simulation. As the simulation starts from $t=0$ with the undisturbed average flow field, the calculation of the rms values also starts with zero. The rms value for the new time level $n+1$ is obtained by the value at the old time level n for both parts, e.g.,

$$\hat{p}_{\mathrm{rms}}^{n+1}=\sqrt{(n[\hat{p}_{\mathrm{rms}}^{n}]^2+[\hat{p}^n]^2)/(n+1)}. \tag{25}$$

Only the two root mean square values have to be stored; the whole time history is included. Inserting the discussed denominator into Eq. (20) one obtains

$$Z'=Z\Bigg/\left(1+\frac{[\mathbf{M}\cdot\nabla\hat{P}]_{\mathrm{rms}}}{\hat{p}_{\mathrm{rms}}}\right), \tag{26}$$

which is used in connection with Eqs. (25) and (23) to calculate the effective impedance in the time domain. At the present time, the presented extension is theoretically limited to single frequency and mode of wave propagation only.

Together with Eq. (11) the effective impedance is used to calculate $\partial v_n/\partial t$. Inserted into the momentum equation, this provides a condition to the pressure gradient:

$$-\mathbf{n}\cdot\nabla p+\mathbf{n}\cdot\nabla p\Big|_{p_{\mathrm{ghost}}=0}=\frac{1}{X_1'}[p-R_0'v_n+X_{-1}'q]-\left.\frac{\partial v_n}{\partial t}\right|_{p_{\mathrm{ghost}}=0}. \tag{27}$$

The gradient is used in connection to the definition of the finite difference scheme at the wall to obtain $p_{\mathrm{ghost}}=0$:

$$\frac{1}{X_1'}[p-R_0'v_n+X_{-1}'q]-\left.\frac{\partial v_n}{\partial t}\right|_{p_{\mathrm{ghost}}=0}=-a_7^{51}p_{\mathrm{ghost}}. \tag{28}$$

In the special case of plane waves it is simple to prove the method. In this special case, the free field wave number k is dependent on the effective flow Mach number M_e and linearly dependent on $i\omega$. The convective term discussed above represents the cosine of the impact angle of the acoustic wave with respect to the mean flow direction in the frequency domain. The liner can change this propagation direc-

tion and **k** is a vector in general. The dot product must be obtained with the calculation of the acoustic field.

III. NUMERICAL ALGORITHM

A. Configuration of the NASA grazing incidence tube

The test section of the NASA Langley GIT[8] is selected to validate Eqs. (5) and (6) and (11)–(13). Since the shortest acoustic wavelength considered is much larger than the span of the test sections, the three-dimensional flow-impedance tube can be simplified into a two-dimensional configuration as shown in Fig. 1. The GIT consists of hard-walled inflow and outflow sections with the impedance wall section between. Due to this setup, the impedance jumps from the inlet to the liner and from the liner to the outlet section. In the simulation this jump is not considered in terms of derivatives within the formulation of the effective impedance. The effects due to the mismatch of hard-walled modes and soft-walled modes at these two interfaces are considered by a block interface in the computation.

The inflow and outflow regions are assumed anechoic. The sound source impedance is not known from the experiment, therefore a sponge layer in combination with the sound source is used as an anechoic termination. The outflow impedance was measured and it is shown that the outflow is only approximately anechoic under flow conditions.[19] Jones *et al.* state a strong influence of the assumed termination impedance on the educed impedance.[19] However, the conditions of the impedance eduction would approximately be reproduced by a anechoic termination. This avoids errors due to interactions of the imperfectly anechoic sponge layer at the inflow and the termination impedance. Therefore, at the outflow, a nonreflective perfectly matched layer[20] boundary condition is used.

B. Governing equations

The two-dimensional linearized Euler equations for nonuniform flow are utilized as the governing equations which can be written in the following form,

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{A_x}\frac{\partial \mathbf{U}}{\partial \mathbf{x}} + \mathbf{A_y}\frac{\partial \mathbf{U}}{\partial \mathbf{y}} + (\mathbf{B_x} + \mathbf{B_y})\mathbf{U} = \mathbf{S}, \tag{29}$$

where

$$\mathbf{U} = \begin{bmatrix} \rho \\ u \\ v \\ p \end{bmatrix}, \quad \mathbf{S} = \begin{bmatrix} 0 \\ -\frac{\rho}{\bar{\rho}}\left(\bar{u}\frac{\partial \bar{u}}{\partial x} + \bar{v}\frac{\partial \bar{u}}{\partial y}\right) \\ -\frac{\rho}{\bar{\rho}}\left(\bar{u}\frac{\partial \bar{v}}{\partial x} + \bar{v}\frac{\partial \bar{v}}{\partial y}\right) \\ 0 \end{bmatrix},$$

$$\mathbf{A_x} = \begin{bmatrix} \bar{u} & \bar{\rho} & 0 & 0 \\ 0 & \bar{u} & 0 & \frac{1}{\bar{\rho}} \\ 0 & 0 & \bar{u} & 0 \\ 0 & \gamma\bar{p} & 0 & \bar{u} \end{bmatrix}, \quad \mathbf{A_y} = \begin{bmatrix} \bar{v} & 0 & \bar{\rho} & 0 \\ 0 & \bar{v} & 0 & 0 \\ 0 & 0 & \bar{v} & \frac{1}{\bar{\rho}} \\ 0 & 0 & \gamma\bar{p} & \bar{v} \end{bmatrix},$$

$$\mathbf{B_x} = \frac{\partial}{\partial \mathbf{x}}\begin{bmatrix} \bar{u} & \bar{\rho} & 0 & 0 \\ 0 & \bar{u} & 0 & 0 \\ 0 & \bar{v} & 0 & 0 \\ 0 & \bar{p} & 0 & \gamma\bar{u} \end{bmatrix}, \quad \mathbf{B_y} = \frac{\partial}{\partial \mathbf{y}}\begin{bmatrix} \bar{v} & 0 & \bar{\rho} & 0 \\ 0 & 0 & \bar{u} & 0 \\ 0 & 0 & \bar{v} & 0 \\ 0 & 0 & \bar{p} & \gamma\bar{v} \end{bmatrix},$$

and $\bar{u}, \bar{v}$ and u, v denote the velocity components of mean flow and fluctuations, respectively. $\bar{\rho}$ and ρ represent the mean flow and fluctuation densities, respectively. γ is the specific heat ratio. In this paper, all the variables are nondimensionalized by the following scales: length L, velocity c_∞, time L/c_∞, density ρ_∞, pressure $\rho_\infty c_\infty^2$, and impedance $\rho_\infty c_\infty$.

C. Discretization schemes

For solving the 2D LEE of Eq. (29), a computational aeroacoustics (CAA) approach is adopted and extended based on our previous works on the azimuthal sound mode propagation in hard-walled axisymmetric flow ducts[21] and the generation of supersonic jet screech tones.[22] The dispersion-relation-preserving (DRP) scheme[23] is employed for spatial discretization. The optimized coefficients of the centralized stencil are obtained for wave numbers up to the effective wave number $\eta = 1.1$. The required spatial resolution for the scheme is given by the optimized range to be approximately 5.7 points per wavelength (PPW). However, 10 PPW is usually required for the application to practical problems with high demands of accuracy. The alternating 5/6 step low-dissipation and low-dispersion Runge-Kutta (LDDRK) scheme of Hu *et al.*[24] in the 2*N* storage form[25] is used for time integration. Since the centralized DRP scheme has no inherent dissipation, a set of explicit standard filters with a stencil of up to 11 points is used in the numerical computations to eliminate the spurious waves and grid odd-even oscillations.

D. Boundary conditions

The implementation of the extension of the time-domain impedance boundary condition for subsonic flow on the surface as the main contribution of this paper were discussed in Sec. II D. Only the special case of hard wall boundary conditions is discussed here. Computational boundary conditions are used for the sound source with inflow and the anechoic outflow of the GIT, which are also briefly described below.

1. Hard wall boundary condition

The hard wall regions of the duct are treated as a special case of the impedance wall with $Z'(i\omega) = (\infty, i\infty)$. The single-frequency TDIBC Eqs. (5) and (6) or the broadband TDIBC Eqs. (11)–(13) can then be used as the hard wall boundary conditions. If the three-parameter model is applied for the impedance of the hard wall as well as the lined parts, the hard wall is obtained setting $1/X_+ = 0$. This will return the impedance boundary condition given by Eq. (11) back to the hard wall condition:

$$\frac{\partial v_n}{\partial t} = 0. \tag{30}$$

2. Inflow boundary condition

In the inflow region, a nonreflecting boundary condition permits the upstream propagating acoustic waves to leave the domain without reflection and generates an incoming plane waves simultaneously. Assuming a uniform mean flow in the x direction, the upstream $[\rho_{us}, u_{us}, v_{us}, p_{us}]^T$ and downstream $[\rho_{ds}, u_{ds}, v_{ds}, p_{ds}]^T$ propagating acoustic waves can be expressed in the following form,[26]

$$\begin{bmatrix} \rho_{us} \\ u_{us} \\ v_{us} \\ p_{us} \end{bmatrix} = \begin{bmatrix} 1 \\ -1 \\ -1 \\ 1 \end{bmatrix} F\left(\frac{x}{1-M} + t \right), \tag{31}$$

$$\begin{bmatrix} \rho_{ds} \\ u_{ds} \\ v_{ds} \\ p_{ds} \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 0 \\ 1 \end{bmatrix} G\left(\frac{x}{1+M} - t \right). \tag{32}$$

By differentiation and eliminating the unknown functions F and G, the acoustic disturbances would satisfy the following radiation boundary equations,

$$\left[\frac{\partial}{\partial t} - (1-M)\frac{\partial}{\partial x} \right] \begin{bmatrix} \rho \\ u \\ v \\ p \end{bmatrix} = -2\frac{\partial}{\partial x} \begin{bmatrix} \rho_{ds} \\ u_{ds} \\ v_{ds} \\ p_{ds} \end{bmatrix}, \tag{33}$$

where the downstream propagating wave at the inflow region $[\rho_{ds}, u_{ds}, v_{ds}, p_{ds}]^T$ will be excited as the sound source.

3. Perfectly matched layer outflow boundary condition

At the exit region of the duct, reflection waves may arise due to their termination not being fully anechoic in real situations. The complex impedance measured by Jones *et al.*[19] for the termination at the outflow may be used as a boundary condition. However, they represent only one value in a one-dimensional model and to reproduce a measured standing wave pattern the impedance of the inlet was also required. Therefore a nonreflecting boundary condition is prescribed at the outflow region.

This means there is no reflection of acoustic waves from the outflow boundary. At the same time hydrodynamic (vorticity and entropy) modes are allowed to leave the computational domain without sound generation. In order to allow acoustic, entropy and vorticity mode waves to leave the computational domain, a complex stretching of the spatial variable towards the outflow is applied. This stretching factor controls the imaginary part of the spatial variable and produces decreasing amplitudes without any change to the dispersion relation. In a limited zone the stretching factor for the axial direction of the flow duct (σ_x) is increased exponentially with decreasing distance to the outflow. All waves fade away before they reach the boundary of the computational domain. For the boundary point a zero-perturbation boundary condition is applied.

TABLE I. Impedance values for the three parameter model.

	$M_{avg}=0.255$			$M_{avg}=0.335$		
f (Hz)	R_0	$1/X_1$	X_{-1}	R_0	$1/X_1$	X_{-1}
500	0.57	20.8	−14.5	0.61	31.9	−8.1
1000	0.27	12.9	−24.6	0.675	13.1	−23.5
1500	1.26	12.9	−24.6	1.18	13.1	−23.5
2000	5.32[a]	123[a,b]	−34.4[a,b]	4.4	36.1[b]	−98.5[b]
2500	1.02	16.3	−198	0.93	17.8	−186
3000	0.73	16.3	−198	0.73	17.8	−186

[a]Original value from Ref. 19, but data table communicated by Jones to the authors shows the given value.
[b]Negative slope; no fit possible for $X_1 > 0$ and $X_{-1} \leqslant 0$. 2000 and 3000 Hz are used for the nonlinear curve fit to get X_1 and X_{-1}.

As the dispersion relation is perfectly matched between the boundary zone and the inner domain, this technique is called perfectly matched layer (PML) boundary condition[20] and can be expressed as

$$\frac{\partial \mathbf{U}}{\partial t} = \underbrace{-\mathbf{A}_x \cdot \frac{\partial \mathbf{U}}{\partial x} - \mathbf{A}_y \cdot \frac{\partial \mathbf{U}}{\partial y} - [\mathbf{B}_x + \mathbf{B}_y] \cdot \mathbf{U}}_{\text{Euler-equation}} - \underbrace{\sigma_x \mathbf{U}}_{\text{sponge layer}}$$
$$\underbrace{-\sigma_x \mathbf{A}_y \cdot \frac{\partial \mathbf{U}_1}{\partial y}}_{\text{perfect match}} - \underbrace{\frac{M_x}{1-M_x^2}\sigma_x \mathbf{A}_x \cdot \mathbf{U}}_{\text{Prandtl-Glauert-transform}}. \tag{34}$$

In this equation $\mathbf{U_1}$ denotes the auxiliary vector $\partial \mathbf{U_1}/\partial t = \mathbf{U}$, which makes it possible to allow a wave propagation along the nonreflective boundary, whereas the friction in the sponge layer removes any wave traveling into the boundary. The last term was obtained by Hu[20] in order to ensure the PML remains well-posed under homogeneous mean flow conditions.

IV. NUMERICAL RESULTS FOR THE NASA GIT

The extended TDIBCs are validated by the latest experimental results of Jones *et al.*[19] measured at the NASA GIT. A single-frequency 130-dB sound source excites plane waves at frequencies in the range of 0.5–3.0 kHz with 0.5-kHz increments, which fits the experiments published by Jones *et al.*[19]

The educed flow impedance of the ceramic tubular liner used by Jones *et al.*[19] changes under flow conditions. The liner is not a so-called linear liner, at least in the 2D model assumed here. Therefore the impedance educed with the particular mean flow of two selected mean flow Mach numbers is used to validate the new TDIBCs. The impedances used for the calculations are shown in Table I for the selected cases.[19] The corresponding dimensionless angular frequency ω is defined with the length unit $L=1$ m as $\omega = 2\pi L f_e / c_\infty$.

Then the incoming sound waves at the inflow boundary condition Eq. (33) can be written as

$$\begin{bmatrix} \rho_{ds} \\ u_{ds} \\ v_{ds} \\ p_{ds} \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 0 \\ 1 \end{bmatrix} A \sin\left[\omega\left(\frac{x}{1+M} - t\right) + \phi\right], \tag{35}$$

where A denotes the amplitude of the incoming acoustic waves.

The computational domain is $x \in [-0.197, 1.000]$ and $y \in [0, 0.0508]$ with unit length $L=1$ m. Since the estimated shortest wavelength is approximately 0.1147 m in the x direction given by the highest frequency without mean flow ($f_e=3.0$ kHz at $M=0.0$) and the DRP scheme has an accuracy limit of about 10 PPW, the grid size in the x direction could be chosen at about 11.3 mm. This would mean only five points in the height direction of the duct are to be used ending up with a quasi-one-dimensional computation.

To reduce possible errors due to an irregular aspect ratio in the grid, a uniform Cartesian mesh is used in all computations with $\Delta x \approx \Delta y \approx 4$ mm. The CFL number is taken to be 0.5 for all cases. The computational domain is split into three multi-blocks for the application of hard wall and impedance boundary condition in the inlet, outlet, and duct sections, respectively. The total number of grid points including two exchange blocks of 6-points overlap is 322×15. This yields a grid resolution higher than 28 PPW for all cases. The overall computation time for 20 000 iterations with a time step size of $\Delta t \approx 4 \times 10^{-6}$ s (the results do not change essentially after 10 000 iterations) is about 10.5 min on a Pentium 4 with 3.06 GHz.

A. Effects of the mean flow

1. Influence of the mean flow velocity on the liner surface

First of all, numerical tests are carried out to find a good approximation of the mean flow velocity on the liner surface. The experimental data of Jones *et al.*[19] also includes mean flow profiles for the investigated Mach numbers at some positions.

As the model of Myers[18] considers an infinitely thin shear layer between the oscillating surface of the liner and the grazing flow, we need an velocity on the flow side of this shear layer. However, the experimental data does not provide this information, as the pitot probe method used by Jones *et al.*[19] does not allow us to measure velocities in the extreme vicinity to the wall.

The missing data can be reconstructed from the flow profile using the same assumption as Özyörük and Long[10] and Ju and Fung.[11] A fully developed laminar channel flow is assumed to evaluate the refraction effects as

$$\mathrm{M}(y) = (\mathrm{M}_{\max} - \mathrm{M}_e)(y/h)(1 - y/h) + \mathrm{M}_e \tag{36}$$

where h denotes the height of the duct and M_e is introduced for the missing velocity on the surface of the ceramic tubular liner, in order to study the influence of an assumed mean flow velocity on the decay observed in the simulation of the liner. This is done in the first step for the frequency of $f=2500$ Hz.

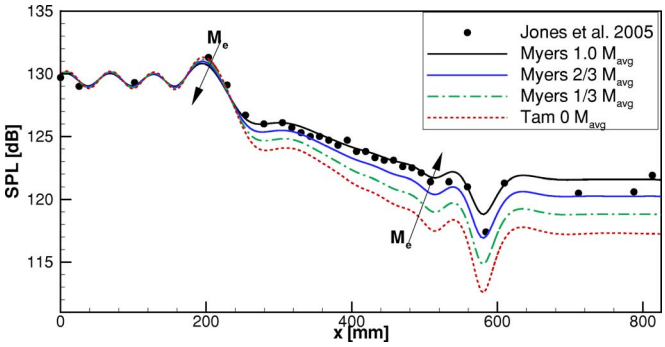

FIG. 2. (Color online) Parametric study for the effective Mach number on the liner surface for $f=2.5$ kHz in a constant mean flow with average Mach number $\mathrm{M}_{avg}=0.335$. The arrows denote the change with increasing M_e.

The result of this test is shown in Fig. 2. The Mach number is varied in the range of 0 to M_{avg} in the increment of $\frac{1}{3}\mathrm{M}_{avg}$. The mean flow profile for this test is a plug flow at the average Mach number $\mathrm{M}_{avg}=0.335$, only the convection correcture of Eq. (19) is varied. The results of the numerical experiment in Fig. 2 show a strong influence of the Mach number used for the convection correction on the decay rate.

As the waves propagate downstream with the mean flow, the effective impedances decrease with the assumed effective Mach number, which finally leads to the increase of sound pressure levels. The convective effect of the mean flow remains constant for the constant plug flow, only the Myers boundary condition is changed from no shear layer ($\mathrm{M}_e = \mathrm{M}_{avg}$) to a full shear layer assumption ($\mathrm{M}_e=0$).[3] The results suggest not to use the full average flow velocity, as the decay rate is too small. A good compromise is found with about $\frac{2}{3}$ of the peak Mach number, which is $0.796\mathrm{M}_{avg}$.

2. Influence of the mean flow profile

The measurement of the mean flow provided by Jones *et al.*[19] allows a more precise input of the real flow profile. The average measured flow profile is parabolic as it is typical for a laminar duct flow (see Fig. 3). As stated before, the information on the flow velocity on the perforated surface is missing in these data. Averaged over the liner there will be a

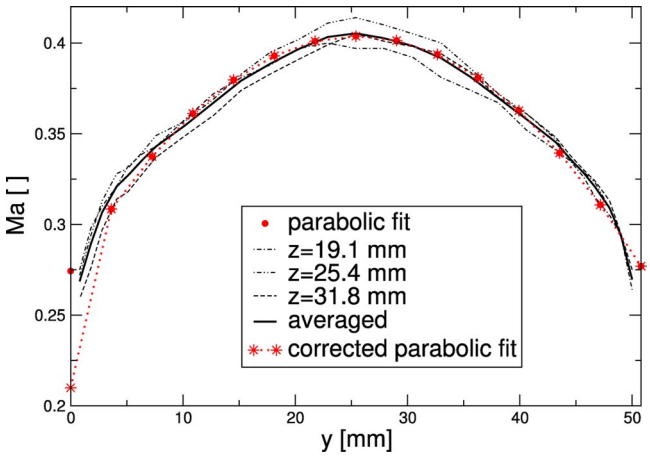

FIG. 3. (Color online) Parabolic fit of the averaged measured mean flow profiles at the average Mach number $\mathrm{M}_{avg}=0.335$. The corrected parabolic-fitted 15 data points are used in the following validation (measured profile).

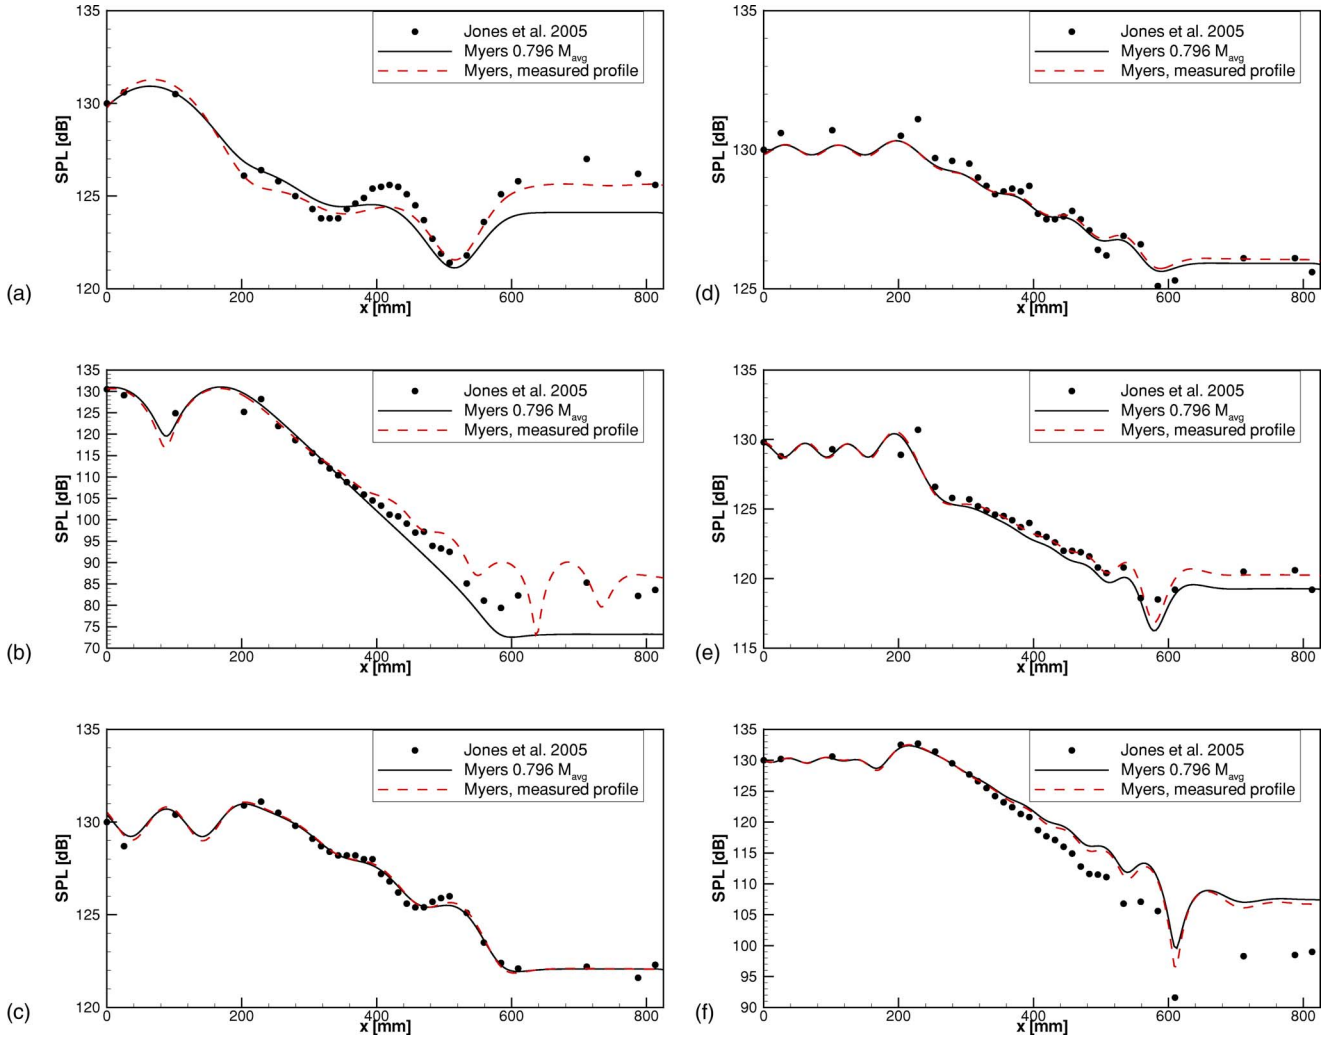

FIG. 4. (Color online) Sound pressure level along the opposite wall with flow (M_{avg}=0.255). The experimental data (bullets) are compared to the CAA results based on a plug flow (M_e=0.796M_{avg}; solid line) and the measured profile of Jones *et al.*[19] (M_e=0.6M_{avg}, dashed line). (a) f=500 Hz, (b) f=1000 Hz, (c) f=1500 Hz, (d) f=2000 Hz, (e) f=2500 Hz, and (f) f=3000 Hz.

velocity, as the orifices of the perforated liner allow grazing flow, while a no-slip condition should apply on the clean solid surface.

The velocity on the liner has to be based on some assumption, as it is not available from the measured data. Hot wire measurements could provide this data, however they must be averaged over orifices and solid clean parts depending on the perforated ratio of the liner. In the case shown in Fig. 3 the value at the surface of the liner has been fixed to M_e=0.21, which is around 60% of the average flow velocity. This value is obtained by a linear extrapolation of the velocity towards the liner starting from the last two measured values in the profile. For the effective impedance boundary condition this value acts as the effective velocity on the fluid side of the infinitely thin shear layer. Different from the plug flow investigated before, the convection is also described by the same value at the surface.

B. Validation with the NASA GIT experimental data

1. General comparison

Numerical results are presented against the experimental data as shown in Figs. 4 and 5, in which the solid and dashed lines represent the assumed plug flow with an effective Mach number of 79.6% of the average flow Mach number and the measured parabolic flow profile with an effective Mach number of 60% of the average flow Mach number, respectively. The first value assumed for the plug flow is obtained taking $\frac{2}{3}$ of the maximum Mach number of the laminar flow profile which is the extrapolated [see Eq. (36)] flow velocity arising at the 57% perforated surface of the liner. The second value is obtained by a linear extrapolation of the measured velocity values close to the liner.

The numerical results agree very well with the experimental data. Especially the measured flow profile leads to a very small difference of the SPL predicted and measured in the outlet duct except for the two cases at 3.0 kHz. In this case the first higher duct mode is very close to cut-on in the hard-walled outlet duct as well as in the lined section, which could possibly violate the assumption of the effective impedance calculation or even the eduction procedure by Jones *et al.*[19]

The numerical results obtained by the TDIBC using the plug flow assumption agree very well for the test frequencies around 2.0 kHz. However, for the low frequencies 500 Hz,

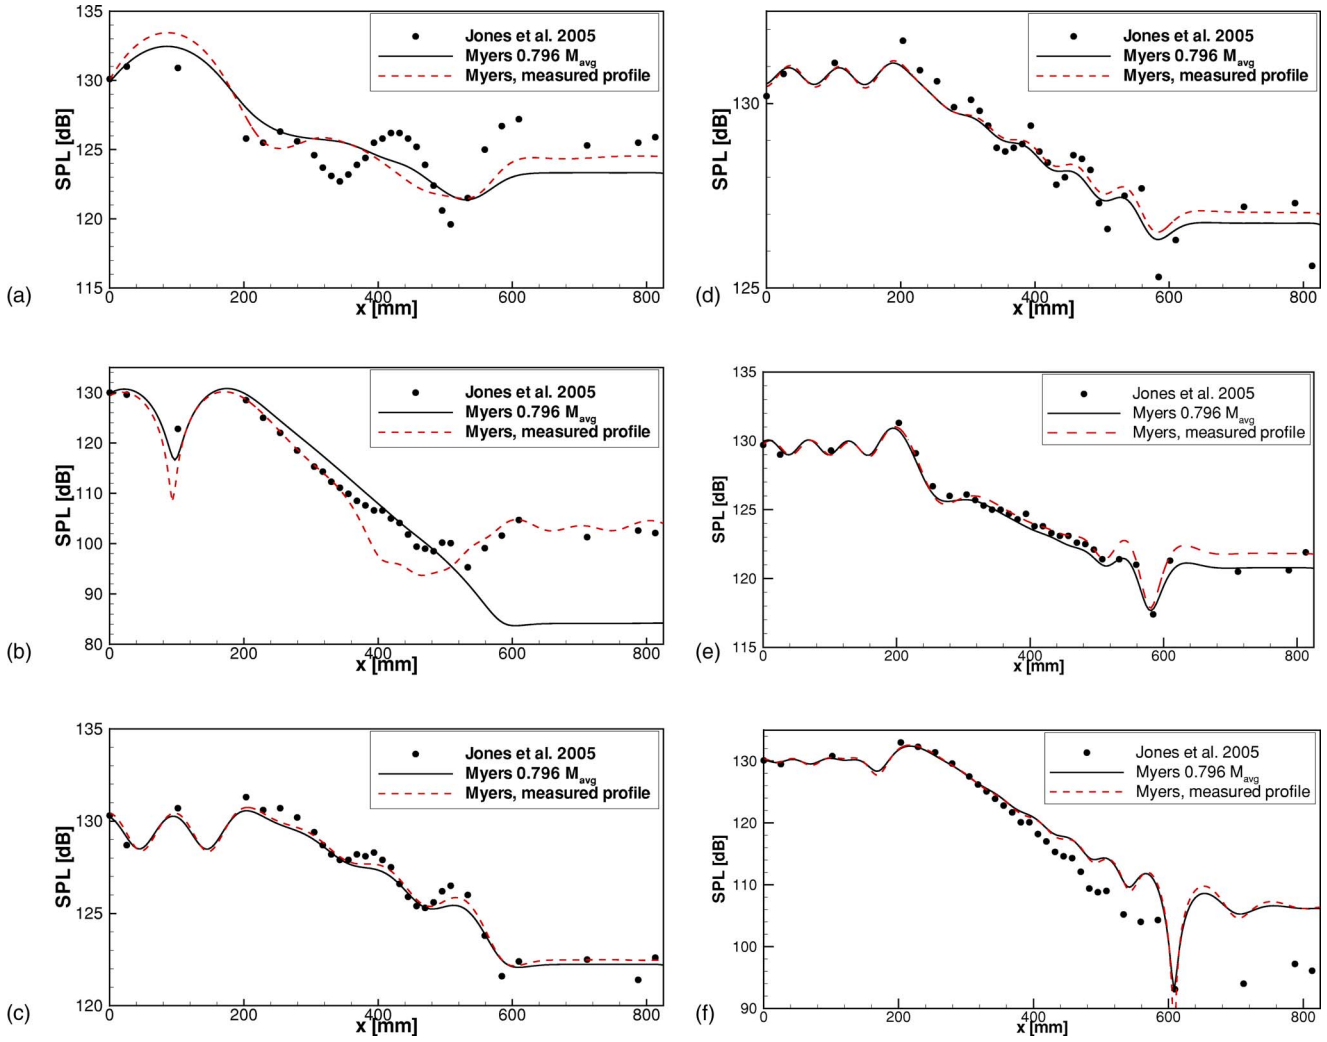

FIG. 5. (Color online) Sound pressure level along the opposite wall with flow (M_{avg}=0.335); The experimental data (bullets) is compared with the CAA results based on a plug flow (M_e=0.796M_{avg}; solid line) and the measured profile of Jones *et al.*[19] (M_e=0.6M_{avg}, dashed line). (a) f=500 Hz, (b) f=1000 Hz, (c) f=1500 Hz, (d) f=2000 Hz, (e) f=2500 Hz, and (f) f=3000 Hz.

1.0 kHz, and again the 3.0-kHz cases, the sound pressure levels in the outlet duct are mispredicted. This different behavior compared to the realistic flow assumption is discussed in detail in the next section.

2. Detailed investigation of the flow instability

The numerical results based on the plug flow assumption consistently underpredict the sound pressure levels for the frequencies f_e=0.5 and 1.0 kHz for the two test Mach numbers. The measured flow profile leads to a remarkably better prediction for these frequencies. The look at the instantaneous pressure contours in Fig. 6 can display the difference. A spatially growing hydrodynamic instability is excited at the trailing edge of the hard-walled section and, due to flow profile in the lined section, the amplitude increases linearly in space, but does not increase in time.

Hydrodynamic instabilities are inherent to the linearized Euler equations. In this case it is excited from the shear layer of the mean flow at the wall supported by the resonant frequency of the liner. The liner allows a vorticity wave to pass in the vicinity of the liner surface through the sheared flow, which allows a self-excited oscillation transferring energy from the shear layer to the growing hydrodynamic surface wave. It is also observed with the standard TDIBC of Tam and Auriault under sheared mean flow conditions and depends only on the flow profile. There is no instability observed with a plug flow. Once the instability wave hits the trailing edge of the wall downstream of the liner, it leads to increased near-field pressures on the upper wall as shown in Fig. 6. In real applications the growth of the instabilities is

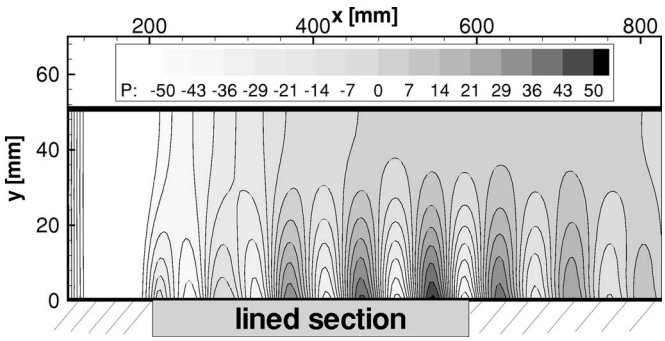

FIG. 6. Instantaneous pressure contours of the instability wave excited by the real flow profile at f_e=1000 kHz.

usually limited by nonlinear and viscous effects. If an instability is physically possible, it should also be observed in the experimental data. And, in fact, the decay along the opposite wall of the liner stops significantly earlier at 1.0 kHz than for all other frequencies. This observation could be connected to the acoustic field produced by the instability interacting with the trailing edge of the liner. As the impedance is modeled the impedance wall is similar to a compliant wall, which may attenuate or amplify boundary layer instabilities. The flow of the NASA GIT is laminar, therefore we assume the hydrodynamic instability is a Tollmien-Schlichting instability. For the interpolated flow profile shown in Fig. 3, the frequency of the Tollmien-Schlichting instability can be estimated. With the following connection of the perpendicular wave length λ in the shear layer and the momentum loss gage δ_1 obtained from $u_{\text{eff}}=0.335c$, $u_{\max}=0.4c$ and the channel height $h=0.051\ m$,

$$\lambda = 21\delta_1 = \frac{21}{2}\left(h - \sqrt{h^2\frac{u_{\text{eff}}}{u_{\max}}}\right) = 45.437\ \text{mm},$$

the typical frequency for this kind of flow instability is given by

$$f = \frac{u_c}{\lambda} = \frac{0.4u_{\text{eff}}}{\lambda} = 1002.71\ \text{Hz}.$$

As the Reynolds number of the average flow obtained with the boundary layer thickness is about 20 000, the flow can be unstable in general. This means that the flow instability observed in the computation at 1000 Hz is physically explainable as Tollmien-Schlichting instability that is amplified due to the resonance of the ceramic tubular liner described by the wall impedance. However, the missing exact flow profile at the wall leads to a overprediction of the amplitudes by the proposed effective impedance model.

With the assumption of parabolic mean flow, the numerical results improved significantly for most of these test cases. This shows that the refraction effects due to sheared mean flows become stronger at higher Mach numbers, which must be considered appropriately.

V. CONCLUSION

The single-frequency and broadband time-domain impedance boundary condition by Tam and Auriault have been shown to be suitable to include the mean flow convection effects without the requirement of a zero mean flow assumption on the impedance wall. The extended boundary conditions have been proved to be well-posed via a stability analysis. Furthermore, the traditional Myers boundary condition is connected to the extended time-domain impedance boundary conditions, which provides the effective acoustic impedance under flow conditions. This coupling releases the effective impedance from the requirement to be measured under given special acoustic conditions. The latest measurement data from the NASA greasing incidence tube is used for numerical validations. It is demonstrated that the extended boundary conditions can be used for slip and parabolic mean flow profiles, and the numerical results agree very well with the measurement data. The numerical validations demonstrate that the extended TDIBCs are suitable for different mean flow profiles. Providing a correct impedance and an appropriate mean flow profile, the sound propagation in lined ducts can be predicted accurately. It should be pointed out that it is not so easy to give the correct impedance in the presence of mean flow for nonplane incident waves. More general impedance models as well as more realistic mean flow profiles are still highly desirable. An instability on the liner surface is observed using the measured flow profile at the excitation frequency of 1000 Hz. This instability is connected to the presence of a Tollmien-Schlichting instability for the flow profile in nearly exact concurrence with the liner resonance. In addition, further numerical validation is required for the presented time-domain impedance boundary conditions with complex geometries and for higher mode propagation.

APPENDIX A: THE WELL-POSEDNESS OF THE SINGLE-FREQUENCY TDIBC FOR SURFACES WITH SUBSONIC MEAN FLOWS

Assuming the impedance surface located in the $x-z$ plane and applying the Fourier-Laplace transform to Eqs. (3) and (4), it can be found that the solution satisfies the outgoing wave condition at $y\to\infty$:

$$\begin{bmatrix}\tilde{u}\\ \tilde{v}\\ \tilde{w}\\ \tilde{p}\end{bmatrix}=A\begin{bmatrix}\alpha/(k\hat{\omega})\\ (\hat{\omega}^2-1)^{1/2}/\hat{\omega}\\ \beta/(k\hat{\omega})\\ 1\end{bmatrix}\exp\left[k(\hat{\omega}^2-1)^{1/2}y\right], \tag{A1}$$

where $\hat{\omega}=(\Omega-M_e\alpha)/k$, $k=(\alpha^2+\beta^2)^{1/2}$. The branch cuts of the function $(\hat{\omega}^2-1)^{1/2}$ are taken to be $0\leqslant\arg(\hat{\omega}^2-1)^{1/2}\leqslant\pi$ as shown in Fig. 7.

The Fourier-Laplace transforms of Eqs. (1) and (2) are

$$\tilde{p}=\left[-R'+\frac{iX'\omega}{\hat{\omega}k+\alpha \mathrm{M}_e}\right]\tilde{v},\quad X'<0, \tag{A2}$$

$$\tilde{p}=\left[-R'+\frac{iX'}{\omega}(\hat{\omega}k+\alpha \mathrm{M}_e)\right]\tilde{v},\quad X'\geqslant 0, \tag{A3}$$

respectively. Substitution of Eq. (A1) into Eqs. (A2) and (A3) leads to the following dispersion relations:

$$(\hat{\omega}k+\alpha \mathrm{M}_e)\left(R'+\frac{\hat{\omega}}{\sqrt{\hat{\omega}^2-1}}\right)=iX'\omega,\quad X'<0, \tag{A4}$$

$$\frac{\hat{\omega}}{(\hat{\omega}^2-1)^{1/2}}-\frac{i(\hat{\omega}k+\alpha \mathrm{M}_e)X'}{\omega}=-R',\quad X'\geqslant 0. \tag{A5}$$

The extended single-frequency TDIBC is well posed if only Eqs. (A4) and (A5) have no solutions in the upper half $\hat{\omega}$ plane. Tam and Auriault[3] have proved the well-posedness for cases without mean flow. For cases with mean flows, let the left-hand side of Eqs. (A4) and (A5) be expressed by $f(\hat{\omega})$ and $g(\hat{\omega})$, respectively:

$$f(\hat{\omega})=(\hat{\omega}k+\alpha \mathrm{M}_e)\left(R'+\frac{\hat{\omega}}{\sqrt{\hat{\omega}^2-1}}\right), \tag{A6}$$

$$g(\hat{\omega})=\frac{\hat{\omega}}{(\hat{\omega}^2-1)^{1/2}}-\frac{i(\hat{\omega}k+\alpha \mathrm{M}_e)X'}{\omega}. \tag{A7}$$

Assuming a subsonic mean flow $(0<\mathrm{M}_e<1)$, the stability problem can be discussed for $\alpha>0$, $\alpha=0$, and $\alpha<0$, respectively. For $\alpha=0$, the single-frequency TDIBCs are also well-posed since Eqs. (A4) and (A5) have the same forms as for cases of zero mean flow. Figures 8 and 9 show the maps of the upper half $\hat{\omega}$ plane in the f and g planes for cases of $\alpha>0$. The shaded regions are the image points of the upper half $\hat{\omega}$ plane. For the case of $X'<0$, there is no value of $\hat{\omega}$ in the upper half $\hat{\omega}$ plane that can satisfy dispersion relation of Eq. (A4) since the right-hand side of Eq. (A4) is imaginary and negative. For the case of $X'\geqslant 0$, the right-hand side of Eq. (A5) is real and negative, and no value of $\hat{\omega}$ in the upper

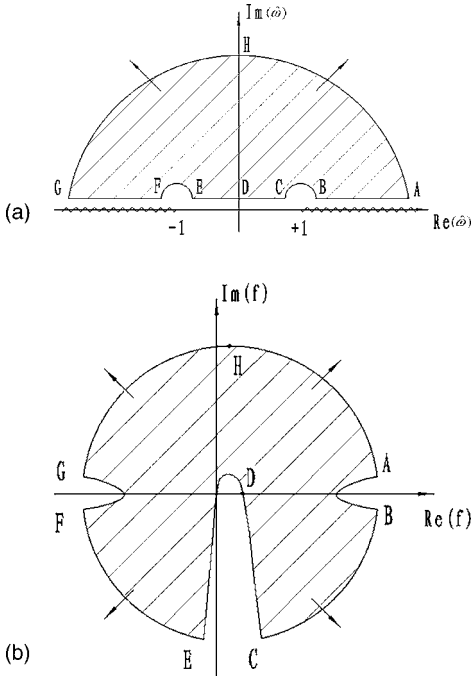

FIG. 8. Map of the upper half $\hat{\omega}$ in the f plane. (a) $\hat{\omega}$ plane. (b) f plane.

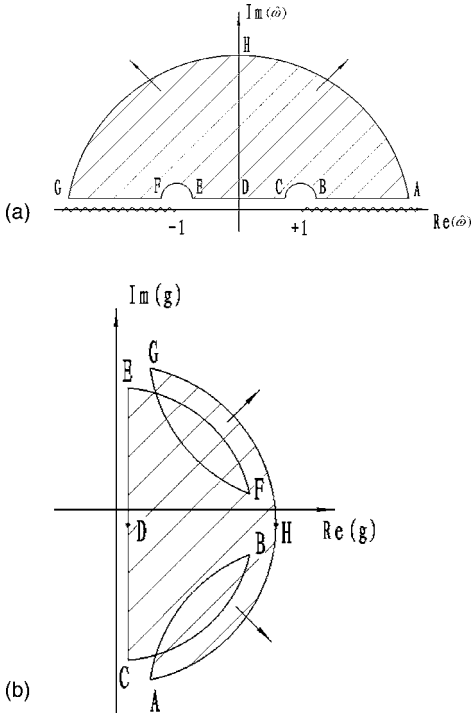

FIG. 9. Map of the upper half $\hat{\omega}$ in the g plane. (a) $\hat{\omega}$ plane. (b) g plane.

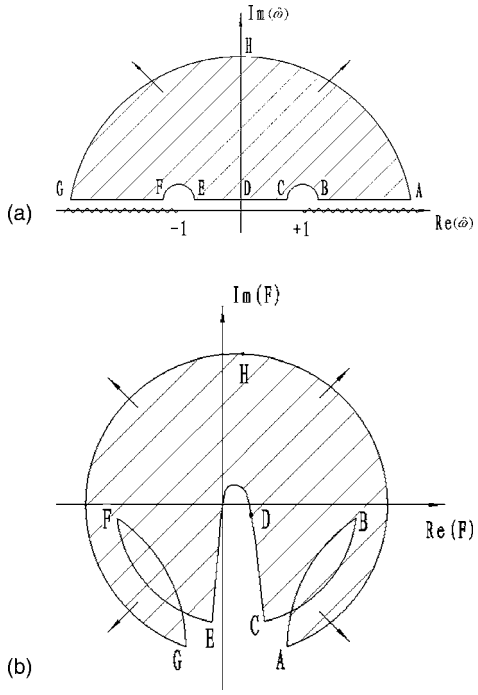

FIG. 10. Map of the upper half $\hat{\omega}$ in the F plane. (a) $\hat{\omega}$ plane. (b) F plane.

half $\hat{\omega}$ plane can satisfy the dispersion relation of Eq. (A5). Similarly, it can also be proved that there is no stability problem for the cases of $\alpha<0$. Detailed discussion is neglected here for conciseness. And it is easy to find that the above discussion is still valid for $-1<M_e<0$ through the sign change of α. Therefore, the extended single-frequency TDIBC of Eqs. (1) and (2) are well-posed.

APPENDIX B: THE WELL-POSEDNESS OF THE BROADBAND TDIBC FOR SURFACES WITH SUBSONIC MEAN FLOWS

The well-posedness of the extended TDIBC Eq. (9) is analyzed by a Fourier-Laplace transform

$$-\omega\tilde{p}=[\omega R_0'-i(X_{-1}'+\omega^2X_1')]\tilde{v}_n. \tag{B1}$$

Substitution of Eq. (A1) into Eq. (B1) yields the following dispersion relation,

$$(\hat{\omega}k+\alpha\mathrm{M}_e)\left[R_0'-iX_1'(\hat{\omega}k+\alpha\mathrm{M}_e)+\frac{\hat{\omega}}{\sqrt{\hat{\omega}^2-1}}\right]=iX_{-1}'. \tag{B2}$$

Figure 10 shows the map of the upper half $\hat{\omega}$ plane in the F plane for $\alpha>0$. Since the right-hand side of Eq. (B2) is imaginary and negative, no value of $\hat{\omega}$ in the upper half plane can satisfy the dispersion relation Eq. (B2). A similar proof can be given for the opposite case of $\alpha<0$. Thus the extended broadband TDIBC for subsonic mean flows leads to well-posed problems.

Measurement and simulation of the channel intensity impulse response for a site in the East China Sea

Jee Woong Choi and Peter H. Dahl
Applied Physics Laboratory, University of Washington, 1013 NE 40th Street, Seattle, Washington 98105-6698

(Received 20 September 2005; revised 16 February 2006; accepted 2 March 2006)

A model for the channel intensity impulse response $I^c(t)$ is presented that is generally applicable for source-receiver ranges less than ten water depths. The separate impulse response functions from each arrival, such as the single surface bounce or surface-to-bottom bounce, are modeled using bistatic scattering concepts and are incoherently summed for the total response function. The expression $I^c(t)$ is equivalent to a time-averaged response and embodies the boundary scattering and reflection physics corresponding to the center frequency at which computations are made. To compare with observations, $I^c(t)$ is convolved with representations of the 8- and 16-kHz continuous wave (CW) pulses, and an 8–16-kHz frequency-modulated (FM) pulse, that were used in the Asian Sea International Acoustics Experiment conducted in the East China Sea (depth 105 m). For the FM case the computation frequency is 12 kHz, the center frequency of the FM pulse. It is found that six primary arrivals dominate the response for ranges less than about 1 km. With modeling of $I^c(t)$ limited to these paths, the basic structure of $I^c(t)$ is set by bottom properties and acquisition geometry with some changes in intrapath time spreading that depend on sea surface conditions.

I. INTRODUCTION

Sound propagation in shallow water is greatly influenced by multiple interactions of the transmitted waveform with the sea surface and seabed boundaries producing time and frequency spread as well as energy loss. Here the channel impulse response is investigated for a shallow water waveguide in which the frequency range, water depth (D), and nominal source-receiver range (R) are 8–16 kHz, 105 m, and 500 m, respectively. In this regime, it makes sense to describe the channel in terms of identifiable eigenrays[1] corresponding to the direct path, sea surface path, bottom path, and surface-bottom path (and so on). In this paper a channel intensity impulse response function (IIRF) $I^c(t)$ is constructed using ray theory to estimate the arrival time and scattering and reflection models (discussed below) that characterize the boundary interaction.

To compare with observations, $I^c(t)$ is convolved with functions representing the continuous wave (CW) and frequency-modulated (FM) pulses that were used in the Asian Seas International Acoustics Experiment (ASIAEX) conducted in the East China Sea.[2] For the CW signals (3-ms duration, center frequencies of 8 and 16 kHz), this function is a simple boxcar function of the same duration. For the frequency-modulated (FM) signal (linear frequency-modulated between 8 and 16 kHz, duration 20 ms), this function is the square of the autocorrelation function of the FM pulse. Both CW and FM cases are compared with measurements; for the FM case, the received signals are matched filtered with the FM pulse replica and, after travel time alignment, the data are intensity averaged over 20 independent realizations. In the context of underwater acoustic communications, this represents (in an averaged sense) the front end of an optimal receiver.[3] Intersymbol interference associated with multipath propagation is an important and limiting feature in underwater acoustic communication,[4,5] motivating study of alternate techniques, e.g., involving time-reversal,[6,7] to overcome this effect. Also note that the IIRF, because of its strong relation to bottom properties, has been used in geoacoustic parameter inversion.[8]

This paper is organized as follows. A description of the field measurements is given in Sec. II. Construction of the model for the IIRF is presented in Sec. III. Results of convolving the model with representations of the CW and FM pulses and comparison with field measurements are presented in Sec. IV. Section V discusses the contribution from individual paths, and their incoherent sum that yields $I^c(t)$. A summary is given in Sec. VI.

II. FIELD MEASUREMENTS

The measurements were part of a set of nominally 0.5-km range propagation measurements designed to study sea surface scattering[9] and bottom reflection.[10] The measurements were made from the R/V *Melville* at a site 350 km east of Shanghai off the Chinese continental margin (29° 39′N, 126° 40′E) in waters 105 m deep (Fig. 1). The acoustic source system was deployed at depths of 25 and 50 m from the stern of the R/V *Melville*, which maintained position by dynamic positioning. (The positioning accuracy of the reference point, in this case *Melville*'s stern and location of source, was within 10 m.) Received signals were recorded with two collocated vertical line arrays, each of length 1 m, with one array at depth 26 m and the other array at depth 52 m, referenced to the array center (see Ref. 9 for discussion of array measurement). The location of the vertical line

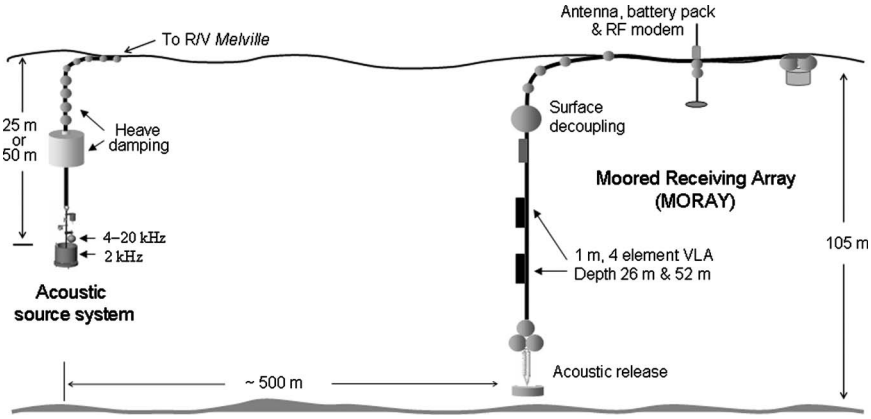

FIG. 1. Experimental layout for measuring the IIRF. The data presented in this paper originate from a single hydrophone on the receiving arrays at 26 and 52 m depth.

array was maintained by a stiff mooring. The three waveforms (two CW, one FM) were transmitted sequentially, separated by 200 ms, with a given waveform transmitted every 100 s and repeated 20 times to form an experimental set. The received signals were sampled at 50 kHz and intensity averaged over 20 pulses.

In terms of bottom properties, measurements of the fine scale sediment roughness[11] and bottom loss,[10] made simultaneously with those reported here, are applied. Specifically, the bottom roughness consists of small features with a root-mean-square (rms) height of about 5 mm and there is a surficial sediment layer of thickness $O(1)$ m within which sound speed increases from 1557 m/s at the water-sediment interface to 1625 m/s.

Figure 2 summarizes one measurement set for range 416 m taken at 13:54 UTC May 31 during which the wind speed was 7 m/s and rms waveheight was ~0.3 m. The right-hand side of Fig. 2(a) shows eigenrays corresponding to the first six arrivals: direct (D), sea surface (S), bottom (B), surface-bottom (S-B), bottom-surface (B-S), and surface-bottom-surface (S-B-S) paths in this order, and are computed using a ray-based propagation code based on the sound speed profile [Fig. 2(a), left]. The received intensity level for the CW pulse [Fig. 2(b)] and the amplitude of the matched filter response for the FM pulse [Fig. 2(c)] are referenced to those of the peak value for the direct path. The FM case is plotted in amplitude space for ready comparison with other results of this kind.[8,12] At this ~0.5-km range, there are essentially six paths that dominate the response, corresponding to the eigenrays in Fig. 2(a); all have no or only one interaction with the bottom (a range of approximately 1.7 km is required for bottom loss to be significantly reduced by precritical angle effects). The standard deviations for both data sets is ~5.6 dB and is consistent with the stan-

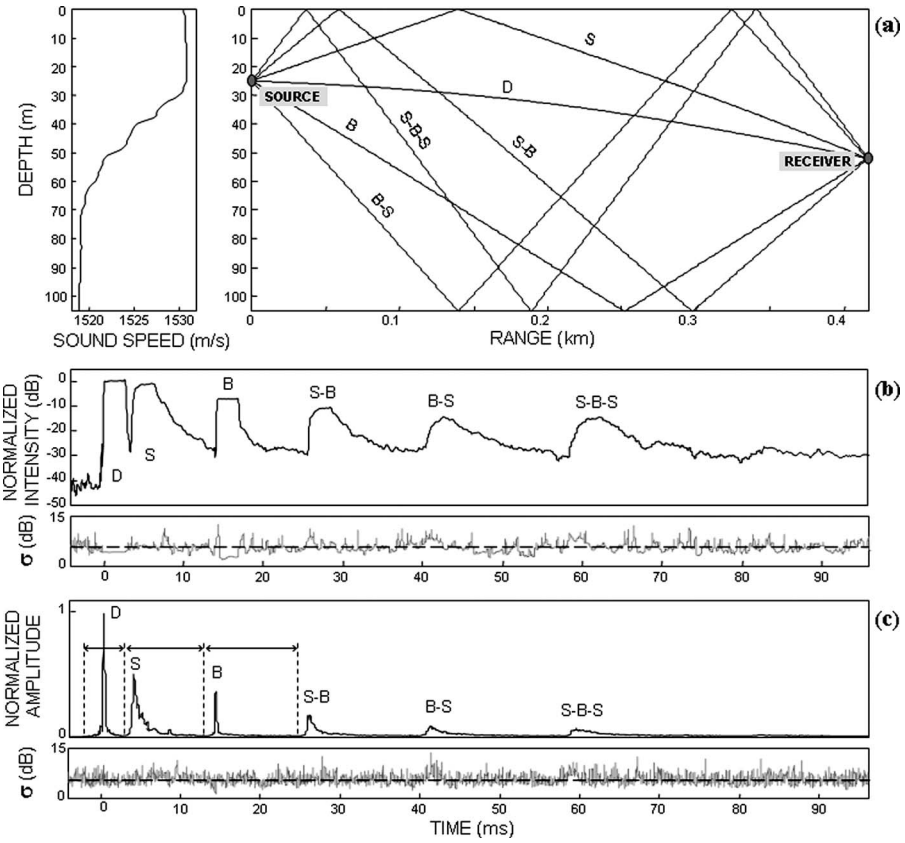

FIG. 2. First six eigenrays (right-hand side) for source depth 25 m, receiver depth 52 m, and range 416 m based on the average sound speed profile (left-hand side) corresponding to time of acoustic measurement. (b) Averaged intensity ($N=20$ realizations) and the standard deviation expressed in decibels for the 16-kHz CW signal. (c) Averaged amplitude ($N=20$ realizations) of the matched filter envelope response for the FM signal (averaging performed in intensity domain and square root taken) and its standard deviation expressed in decibels. The dashed line in the standard deviation plots indicates 5.6 dB. Measurements were taken on 31 May at 13:54 UTC during which the wind speed and rms waveheight were 7 m/s and ~0.3 m, respectively. Labels D, S, and B, etc. denote paths referred to in text as direct, surface, bottom, and their combinations.

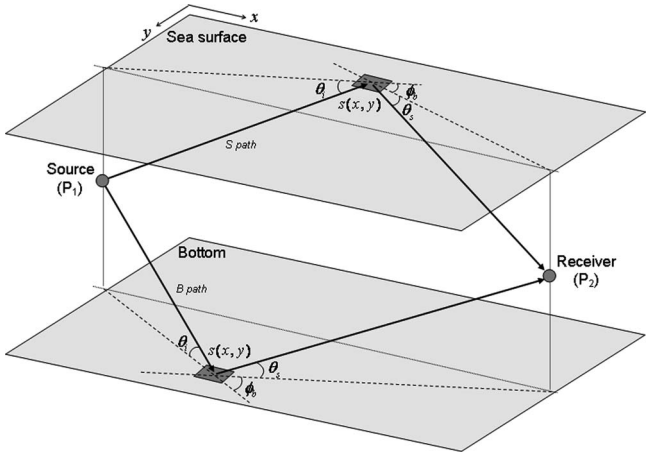

FIG. 3. The scattering geometry for sea surface (S) path and bottom (B) path. The angles θ_i, θ_s, and ϕ_b are the incident grazing angle, scattered angle, and bistatic angle, respectively.

dard deviation for an approximately instantaneous intensity measurement.[13,14] The D and B paths shown in the CW case are an exception; they are not subject to fluctuations of the kind imposed by the sea surface and have standard deviations of 4.1 and 2.5 dB, respectively. The corresponding portions for the FM case are not distinguishable owing to the impulselike shape of the matched filter response.

III. CONSTRUCTION OF CHANNEL INTENSITY IMPULSE RESPONSE WITH MULTIPATH ARRIVALS

The IIRF $I^c(t)$ is constructed using separate response functions, labeled generally as $I^p(t)$, with p designating each path eigenray. For example, the path interacting once with the sea surface is $I^s(t)$. This has been modeled by Dahl[15] utilizing the sea surface incoherent bistatic cross section for the case $\chi \gg 1$, where χ is the Rayleigh parameter; based on the grazing angle for the nominal specular path θ_g, then χ equals $2kH \sin \theta_g$, where k is acoustic wave number and H is rms waveheight. Recently Culver and Bradley[16] relate $I^s(t)$ based on this same modeling approach to signal bandwidth and frequency correlation. The path interacting with the bottom once is $I^b(t)$, which has been modeled by Williams and Jackson.[17] Here, the approaches largely similar to Refs. 15 and 17 are used to estimate $I^s(t)$ and $I^b(t)$ with some modifications discussed subsequently. The expression $I^c(t)$ gives the reflected, plus scattered and time-spread, intensity originating from (quoting from Ref. 17) a "short-duration or 'impulse' pulse." Upon convolving $I^c(t)$ with the squared envelope of the transmitted signal (CW case) or the squared autocorrelation function (FM case), a prediction for mean intensity level is obtained that is comparable to measurements.

The single boundary interaction case (Fig. 3) conveys the basic approach for obtaining an expression for the intensity reflected and scattered from a short-duration pulse transmitted at position P_1 and measured at the receiver position P_2. This interaction is described by the distribution of the bistatic cross section over the boundary surface as a function of position $s=s(x,y)$, with position s_{sp} corresponding to the specular point. (These positions are taken to be on the plane associated with the mean surface height.) Define $I^p(t)$ [applying to either the sea surface $I^s(t)$ or seabed $I^b(t)$ case] as follows:

$$I^p(t) = I_{\text{coh}}(t)\exp(-\chi^2) + I_{\text{scat}}(t). \tag{1}$$

The first term is the coherently reflected intensity where

$$I_{\text{coh}}(t) = \frac{I_0 BxBr|\Re(\theta_g)|^2}{(R_1+R_2)^2} 10^{-\alpha_w(R_1+R_2)/10}\delta(t-t_g), \tag{2}$$

with I_0 being the source intensity at range 1 m from the transducer (source level), Bx and Br are the intensity beam pattern weightings for the transmitter and receiver, respectively, $\Re(\theta_g)$ is the reflection coefficient, and α_w is the sea water attenuation coefficient in dB/m. The time dependence $\delta(t-t_g)$ depends on the path delay associated with the specular point t_g, which is set by the slant ranges $R_1=P_1s_{sp}$ and $R_2=P_2s_{sp}$, and the depth-averaged sound speed in the water column through which the ray propagates. The Rayleigh parameter is an important descriptor for the ASIAEX geometries, environmental conditions, and frequency range. For the sea surface, χ generally exceeds unity and the incoherent intensity dominates; the exception is the lowest frequency (8 kHz) and calmer conditions. For the seabed, χ is $\sim$0.1 and reflection dominates.

The second term is the result of incoherently scattered intensity and is computed as follows:[15] The travel time from the nth scattering patch located at s_n is computed from geometry and grouped within the interval defined by $t_g+k\Delta t$ and $t_g+(k+1)\Delta t$, $k=0,1,2,\ldots$, where $\Delta t=0.02$ ms. The scattered intensity for this path is I_{scat_n} and is given by

$$I_{\text{scat}_n} = I_0 \frac{Bx(s_n)Br(s_n)\sigma(s_n)10^{-\alpha_w[(P_1s_n)+(P_2s_n)]/10}dA}{(P_1s_n)^2(P_2s_n)^2}, \tag{3}$$

whereas the scattering patch area dA is 1 m^2, and σ is the incoherent bistatic scattering cross section per unit area, which is expressed as a function of angles θ_i, θ_s, and ϕ_b (Fig. 3). All scattered intensities whose travel times fall within the same kth interval associated with an equal travel time ellipse are summed, with result identified as I_k, and the scattering component of the intensity impulse response [i.e., in Eq. (1)] is given by

$$I_{\text{scat}}(t) = \sum_k I_k \delta(t-t_k). \tag{4}$$

A. Bistatic scattering cross section for the sea surface

Forward scattering from the sea surface is modeled using the small slope approximation for the incoherent bistatic cross section plus a bubble scattering component to give $\sigma_{sfc}=\alpha_b\sigma_{sr}+\sigma_b$, where σ_{sr} is the bistatic scattering cross section associated with the air-sea interface, α_b accounts for attenuation due to near-surface bubbles, and σ_b is the scattering cross section from near-surface bubbles.[18] Computing σ_{sr} is achieved by way of directional averaging of the sea surface autocorrelation function, since there was no significant improvement in model-data comparisons upon incorpo-

TABLE I. Input parameters for the bottom bistatic scattering model.

	Parameter							
	Density ratio	Sound speed ratio	Loss parameter	Spectral exponent	Spectral strength	Fluctuation ratio	Inhomogeneity exponent	Inhomogeneity strength
Symbol	ρ	ν	δ	γ	ω_2	μ	γ_3	ω_3
Value	2.0	1.025	0.00704	2.99	0.00379	−1	3	0.0001558

rating directional wave properties. The directionally averaged cross section requires evaluation of the integral

$$\sigma_{sr} \sim \int_0^\infty \rho J_0(2\kappa\rho)[e^{-\chi^2[1-C(\rho)]} - e^{-\chi^2}]d\rho, \tag{5}$$

where $C(\rho)$ is the isotropic autocorrelation function of sea surface waveheight variation, which is a function of the radial lag coordinate ρ, and κ is the magnitude of the horizontal component of the incident minus scattered wave vector.[15,18] The second term contributing to the integral can be ignored for $\chi \gg 1$ as a result of higher frequencies; inclusion here is needed for the mid frequencies (8 kHz) and moderate wind speeds that put $e^{-\chi^2}$ equal to ~ 0.1.

B. Bistatic scattering cross section for the seabed

The APL-UW bistatic bottom scattering model[17,19] is, upon incorporating a small modification, used to predict the bottom interaction of the acoustic energy. Note first that this model calculates the total cross section rather than the incoherent scattering cross section, so the first term in Eq. (1) is not used.[19] The modification entails inserting the reflection coefficient model from Ref. 10 into the bistatic scattering model that is based on a two-layered sediment for which the sound speed in the surficial sediment layer is allowed to vary. The sediment sound speed and density estimated from the geoacoustic inversion work from ASIAEX reported in Ref. 10 are also used. The one-dimensional roughness spectrum $W_1(K_x)$ for the bottom can be represented as follows,[19]

$$W_1(K_x) = \frac{w_1}{|K_x|^{\gamma_1}}, \tag{6}$$

where K_x is the spatial wave number of bottom relief features. For the ASIAEX site γ_1 and w_1 were estimated to be 1.99 and 0.0076 $\mathrm{cm}^{3-\gamma_1}$, respectively,[11] and these are converted to their isotropic two-dimensional counterparts. The input parameters for the APL-UW bistatic scattering model used in this work are given in Table I.

C. Multiple boundary interactions

For multiple boundary interactions two cases are addressed: (1) single bottom plus single surface interaction or the S-B and B-S paths for which $I^{sb}(t)$ and $I^{bs}(t)$ are constructed, and (2) single bottom plus double surface interaction or the S-B-S path for which $I^{sbs}(t)$ is constructed. In the first case the ansatz is taken that the impulse response for such a path can be described by a surface scattering process plus a bottom reflection process.[20] This approach (Fig. 4) invokes either an image source or receiver, depending on the path. The data show that time spreading associated with bottom scattering is minimal, which is consistent with $\chi \ll 1$ for the bottom, and it is assumed that any time spreading associated with the bottom will be not observable upon subsequent interaction with the sea surface which dominates the spreading. This point is quantified as follows using an integrated measure of time spread. The results shown in Fig. 2(c) represent a band-limited approximation to the time-averaged intensity impulse response; let us compute an integrated measure (defined in Ref. 15 and called L) of this response for its separate components, D, S and B, as delineated by the markers in Fig. 2(c). The result for the D, S, and B paths are 0.29, 1.16, and 0.34 ms, respectively. Consider the estimate for the D path as the baseline or minimum value given the FM pulse used in the measurements and system bandwidth, and effective time spread is in excess of this value. Thus, the effective time spread for the B path is minimal and that for the S path exceeds it by more than one order of magnitude. Bottom loss, however, remains an important feature, and this is accounted for by multiplying each I_{scat_n} by $|\Re_b(\theta)|^2$, where θ equals θ_i at the air-sea interface for the B-S path, and θ_s at the air-sea interface for the S-B path (see Fig. 4).

For the second case, $I^{sbs}(t)$ is constructed via the convolution of impulse response functions that correspond to each sea surface interaction, $I^{sbs'}(t)$ for the first interaction and $I^{s'bs}(t)$ for the second interaction, where $I^{sbs'}(t)$ is computed as if both the seabed and second sea surface interaction are replaced by reflection processes, and $I^{s'bs}(t)$ is computed in an analogous manner (Fig. 5). Bottom loss is not computed for $I^{sbs'}(t)$ because it is already included in the computation of $I^{s'bs}(t)$, and the intensity impulse response function $I^{sbs}(t)$ results from the following convolution

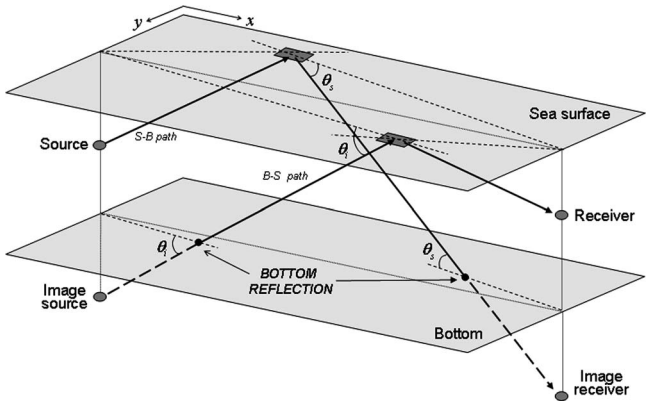

FIG. 4. The scattering geometry for S-B path and B-S path. An image receiver and image source are used for the S-B path and B-S path, respectively.

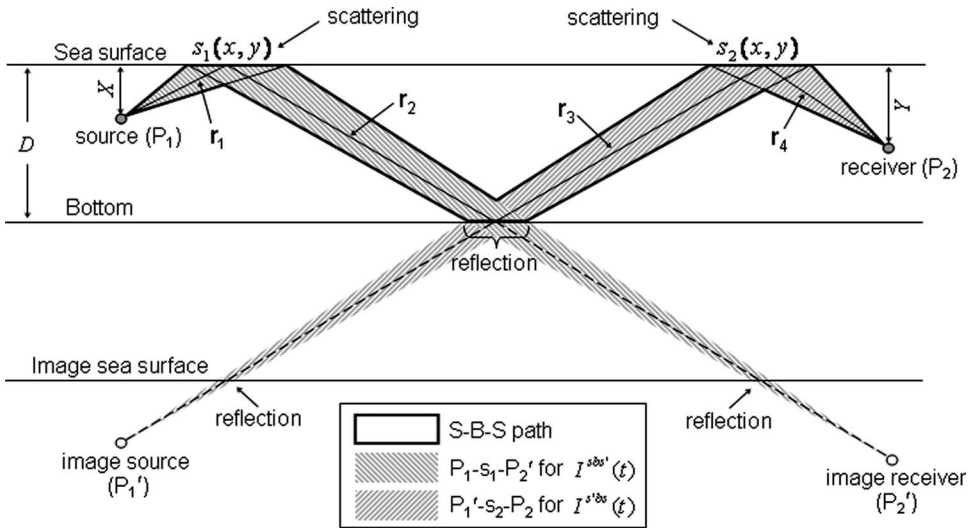

FIG. 5. Illustration of method to model the intensity impulse response for the S-B-S path, $I^{sbs}(t)$, which is constructed by convolving $I^{sbs'}(t)$ and $I^{s'bs}(t)$. These correspond to the paths P_1-s_1-P_2' and P_1'-s_2-P_2, respectively. An image receiver of depth $(2D+Y)$ and an image source of depth $(2D+X)$ are used for $I^{sbs'}(t)$ and $I^{s'bs}(t)$, respectively, where D, X, and Y are the depths shown in the figure. The ranges for specular paths are given by $r_{i=1,4}$.

$$I^{sbs}(t) = I^{sbs'} * I^{s'bs}\left(\sum_{i=1}^{4} r_i\right)^2, \tag{7}$$

where the factor in parentheses is equal to total range for the specular reflected path. This factor is required to compensate for a double counting of spreading loss that results from the convolution operation.

D. Modeling the channel intensity impulse response with multipath arrivals and comparison with CW intensity level and the matched filter envelope response

The intensity impulse response function for a direct path is calculated as $I_0 10^{-TL_d/10}\delta(t-t_d)$, where TL_d and t_d are the transmission loss and travel time, respectively, for a direct path computed using a ray-based propagation code. Combining this with the other five response functions results in an IIRF $I^c(t)$ along a common time base.

Figure 6 shows the modeled (and noise free) $I^c(t)$ that corresponds to the measurement geometry and conditions in Fig. 2, with modeling frequency equal to 8 kHz. Only the D and B paths are impulselike, whereas paths interacting with the sea surface undergo significant time spreading. For reference, the small horizontal mark near the label of each path gives the intensity impulse level when intrapath time spreading associated with scattering is ignored, and only bottom reflection loss is operative. That there is very little difference between this mark and the full-model result for the B path further suggests that reflection and consequent bottom loss dominate bottom interaction.

To compare with the ensemble-average intensity level for CW pulse, the IIRF $I^c(t)$ is convolved with a magnitude-squared representation of the transmit CW pulse. A prediction for the matched filter squared envelope $m(t)$ is derived using $I^c(t)$ computed at 12 kHz, the center frequency of the FM signal. The prediction for the FM signal is given by

$$m(t) = |H[s(t) * s(-t)]|^2 * I^c(t), \tag{8}$$

where $H[\cdot]$ denotes the Hilbert transform and $s(t)$ is the transmitted FM signal.

IV. COMPARISON OF MODEL PREDICTIONS WITH MEASUREMENTS

Figure 7 shows a comparison between the average intensity (over 20 pings) for CW signals (thick gray line), for which the center frequency of the 3-ms pulse is 8 kHz, and a model prediction (black line) also computed at 8 kHz. Surrounding the model-data comparison are maps of the distribution of bistatic cross section per unit area σ for the sea surface and seabed interfaces that were used to compute the intensity impulse response for a given ray path (diagrammed below each distribution), as outlined in the previous section. A total of six paths are modeled, yet in this 8-kHz data set, expressed on a decibel scale, prominent features of the time series are clearly reproduced by the model, with notable ex-

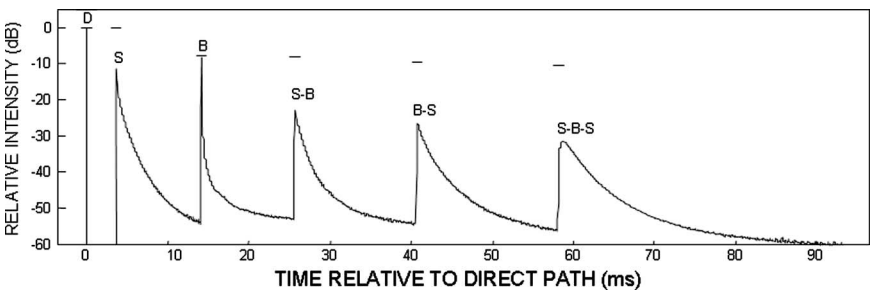

FIG. 6. Predicted (and noise free) IIRF $I^c(t)$ for frequency 8 kHz showing the primary arrivals: D, S, B, S-B, B-S, and S-B-S paths, with level referenced to that of the peak value for the direct path (D). The acquisition geometry and environmental conditions correspond to those described in Fig. 2. The small horizontal mark near each path label denotes the intensity impulse level were intrapath time spreading associated with scattering to be ignored, and only bottom reflection loss is operative.

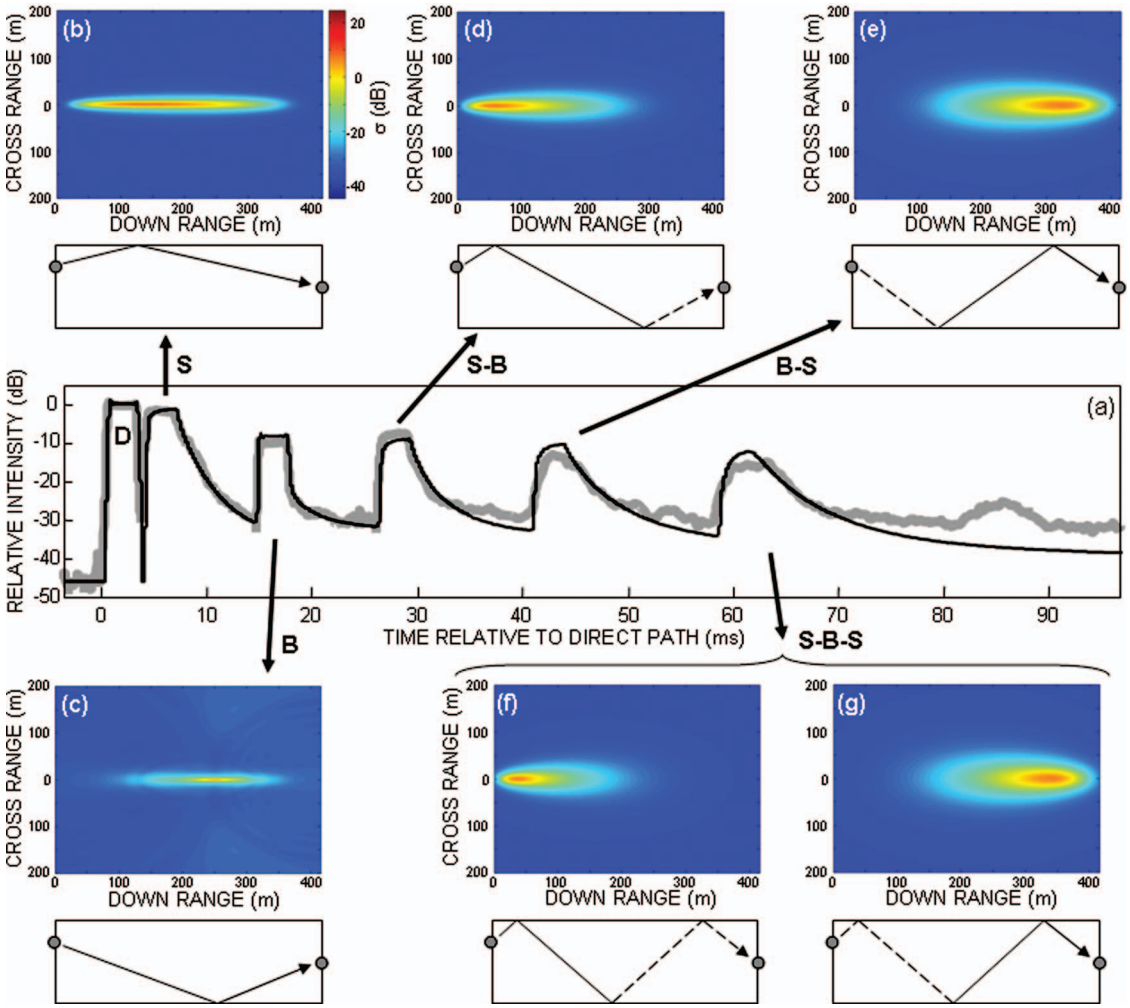

FIG. 7. (a) Comparison between the predicted intensity level (black line) and measured averaged intensity (thick gray line) for the 8-kHz CW signal from the same experimental set described in Fig. 2. The intensity level is referenced to that of the mean peak value for the direct path. Panels (b), (d), and (e) are maps of the sea surface bistatic scattering cross section for the S, S-B, and B-S paths, respectively, and (c) is a map of the bistatic cross section (incoherent +coherent) for the B path. Panels (f) and (g) show maps of the sea surface bistatic scattering cross section for computing $I^{sbs'}(t)$ and $I^{s'bs}(t)$, respectively, which are subsequently convolved to predict the impulse response for the S-B-S path. The ray diagram below each bistatic cross section map shows the corresponding specular ray path, for which a dashed line indicates a specular reflection.

ception of the seventh path that is not modeled. However, note that 99% of the time-integrated intensity is transmitted by the first six paths. Other differences of order 1 to 3 dB, tending to be located at the intensity tails of the S-B, B-S, and S-B-S paths, could result from several causes, as discussed in Sec. V.

A comparison for a 16-kHz CW pulse also shows reasonable agreement with the model prediction (Fig. 8). Recall that in this work bottom loss is computed using a two-layered sediment reflection coefficient model derived from ASIAEX measurements at the same site.[10] This model shows significant oscillations in bottom loss as a function of grazing angle for angles between 14° and 23° at 8 kHz, while beyond this range angular dependence is smoother and bottom loss at 8 and 16 kHz are nearly the same (Fig. 9). For the data set shown in Figs. 7 and 8, the nominal grazing angle for the bottom bounce (B) path is 18°, with this angle being greater than 24° for subsequent paths involving the bottom (S-B, B-S, etc.) The predicted bottom loss for the B path is 8.1 and 6.5 dB for 8 and 16 kHz, respectively, and this is consistent with the difference in intensity level between the D and B paths observed in the data (8.7 dB for 8 kHz and 7.2 dB for 16 kHz).

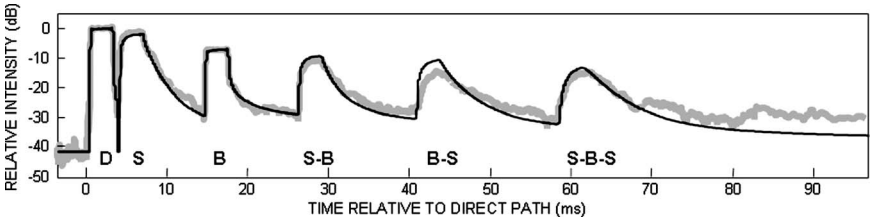

FIG. 8. Comparison between the predicted intensity level (black line) and measured averaged intensity (thick gray line) for the 16-kHz CW signal from the same experimental set described in Fig. 2. The intensity level is referenced to that of the mean peak value for the direct path.

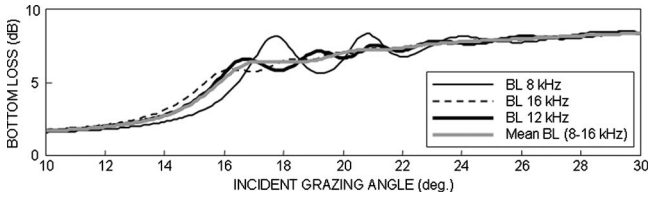

FIG. 9. Bottom loss as a function of grazing angle θ_g, or $-20\log|\Re(\theta_g)|$, based on the two-layered sediment model for the reflection coefficient $\Re$ in Ref. 10 for 8, 12, 16 kHz, and 8–16 kHz average.

An intensity average of bottom loss model curves for frequencies between 8 and 16 kHz is reasonably close to the model curve at 12 kHz (Fig. 9), which supports the approach of using 12 kHz as the modeling frequency for the 8–16-kHz FM signal. Figure 10 shows the averaged envelope (over 20 pings) of the matched filter response for the FM signals from two experimental runs, wind speed 7 m/s with range 416 m, (i.e, the May 31st data from Fig 2), and wind speed 5 m/s with range 456 m, taken at 01:05 UTC June 1. The measurements compare well with their model predictions including fair agreement in the relative amplitudes between the direct and boundary interaction paths, and in the relative amplitudes between the two experimental runs. In terms of the latter, both model and data for the 416-m range measurements (upper figure) display lower amplitudes relative to the direct path compared to the 456-m range measurements (lower figure). It is postulated that this difference arises from a combination of (1) the greater time spreading and subsequently lower peak amplitude in matched filtering seen in the 416-m measurements made at 7 m/s wind speed involving the sea surface (~1 dB effect) and (2) the greater transmission loss (in excess of geometric spreading) in the direct path owing to refraction effects for the 456-m range measurements, to which follow-on paths are not subjected because of their steeper propagation angles (~2 dB effect).

V. DISCUSSION

It is of interest to examine further the relation among each of the arrivals in the modeling process, including the small influence of near-surface bubbles in forward scattering from the sea surface. This is best illustrated with a CW model result (Fig. 11), shown previously in comparison with measurements (Fig. 8), but shown here with and without the influence of bubbles and with individual paths prior to their incoherent superposition. The contribution from near-surface bubbles for the paths associated with sea surface interaction (e.g., S, S-B, B-S, and S-B-S paths) becomes significant approximately 7 ms after the arrival onset (nominal specular arrival), a point at which scattering from bubbles exceeds Bragg scattering from the rough surface. For the S path, bubble scattering extends intrapath time spread significantly beyond that due to rough surface scattering, albeit at intensity levels ~30 dB below peak level. This effect is not clearly evident in observations (Fig. 8) owing to the arrival of the B path; however, in other geometries wherein these paths have greater time separation, the effect is observable.[21]

The intensity level of the B path shows little time spread, consistent with the Rayleigh parameter χ being ~0.2 at 16 kHz, and thus reflection dominates. However, after one pulse duration (3 ms) the time decay is similar to that of bubble scattering but with higher levels. Such decay is due to the contribution from both sustained Bragg scattering and scattering from sediment volume inhomogeneities as described in the APL-UW model,[19] and results here suggest that bottom scattering is a major contributor to the background floor for multipath return.

There exist 1- to 3-dB differences between the model and data curves displayed in Figs. 7 and 8 that show up primarily at the intensity tails of the S-B, B-S, and S-B-S paths. Possible sources for these differences are (1) late-arriving scattered returns from buoys and other experimental equipment (see Fig. 1), (2) multiple scattering (via surface-bottom and bottom-surface paths) not accounted for in the modeling, and (3) scattering from the fine-scale sediment layers, which is the cause of the disagreement between model and bottom scattering and reflection measurements.[22]

In this work model predictions for multipath propagation at ranges of order 0.5 km were limited to the sixth arrival, in view of the fact that subsequent arrivals were severely attenuated owing to bottom loss. However, as the source-receiver range increases, the bottom loss will be lessened, i.e., the bottom grazing angle goes precritical. Still, the limitation to the sixth arrival is a reasonable assumption even out to longer ranges. This is illustrated with a set of measurements of the arrival structure at ranges varying from 485 to 1024 m made with the same FM probe pulse on 6

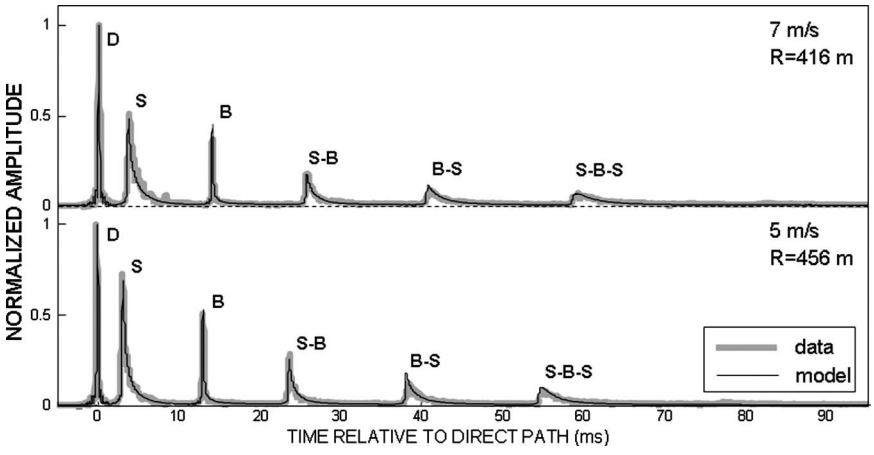

FIG. 10. Averaged envelope for the matched filter response over 20 pulses for measurements made 31 May at 13:54 UTC (upper plot) during which wind speed was 7 m/s (same measurement period and geometry as data shown in Figs. 2, 7, and 8), and measurements made 1 June at 01:05 UTC (lower plot) during which wind speed was 5 m/s, compared with equivalent model. The source and receiver depths for the lower plot data are 25 and 52 m, respectively. The averaged envelope is the square root of a linear intensity average over 20 transmissions, and the amplitude is referenced to that of the peak value for the direct path.

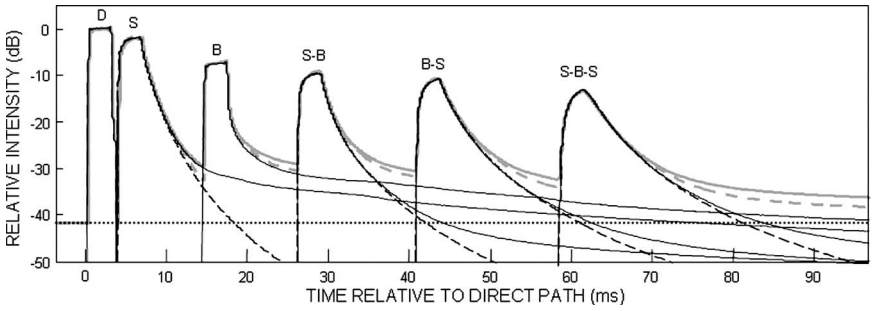

FIG. 11. Simulated total intensity level (gray line) and the contribution from each arrival (black line) for a 16-kHz CW pulse. Solid lines and dashed lines (except B path) represent the intensity level predicted with and without the effect of bubbles, respectively. The dotted line shows the noise level corresponding to the measurement set shown in Fig. 8, which is intensity summed for the total intensity level.

June beginning at 00:55 UTC and lasting about 2 h (Fig. 12). For these measurements the source and receiver depths were 50 and 26 m, respectively, wind speed was 1–2 m/s, and rms waveheight was 0.3 m. Note here that each signal represents a single transmission, and the sixth arrival, corresponding to the S-B-S path, is shaded for each case. The gross multipath time spreading clearly reduces with increasing range, yet six paths continue to dominate the arrival structure out to ranges of order 1 km (~97% of the energy in the received waveform at range 1024 m is transmitted by six paths[23]).

VI. SUMMARY

Results of measurements and modeling of the IIRF for the ASIAEX site in the East China Sea have been presented. The measurements were made in waters 105 m deep and at ranges between approximately 500 and 1000 m. The modeled IIRF, $I^c(t)$, is equivalent to a time-averaged response to an impulse and embodies the boundary scattering and reflection physics corresponding to the center frequency at which the computations are made. Upon convolving $I^c(t)$ with, for example, the squared envelope of a CW pulse, the result can be compared with field measurements of averaged intensity.

The numerical model representation of $I^c(t)$ consists of the incoherent addition of separate response functions, $I^p(t)$, associated with each eigenray, e.g., the direct path, the single-surface bounce (S), single-bottom bounce (B), plus paths involving multiple boundary interaction out to the sixth-arriving path. The impulse responses for S and B paths are described by the distribution of the bistatic cross section over the boundary surface. Responses for paths involving multiple boundary interactions such as the surface-bottom (S-B) path are computed in a similar manner but involve image reflection at the seabed; the S-B path invokes an image receiver and the B-S path invokes an image source. The sixth-arriving multipath is the surface-bottom-surface (S-B-S) path; by hypothesis, its response is constructed via the convolution of two partial impulse responses corresponding to the first and second interactions with the sea surface.

The model predictions compared reasonably well with the measurements involving CW pulses with center frequency of 8 and 16 kHz, and a linear frequency-modulated (FM) pulse of frequency range 8–16 kHz and duration 20 ms. For the FM pulse the matched filter response from measurements represents a band-limited approximation to the IIRF and these results compared well with a model representation generated by convolving $I^c(t)$ with the squared autocorrelation function of the transmitted waveform and taking the square root of the result.

It is found that six paths generally dominate the response at ranges 500 to 1000 m for this East China Sea channel, as shown by the measurements out to range ~1000 m, with the number of paths effectively limited by bottom loss. The basic structure of $I^c(t)$ is therefore set by seabed properties and acquisition geometry (source depth, receiver depth, range) with some differences in intrapath spreading dependent on sea surface conditions.

For the ASIAEX acquisition geometries studied here, for which the S path arrives before the B path, the intrapath time spread for the B path appears to be the major contributor to the background floor for multipath return. Note, however, that if the source and receiver are close to the seabed, such

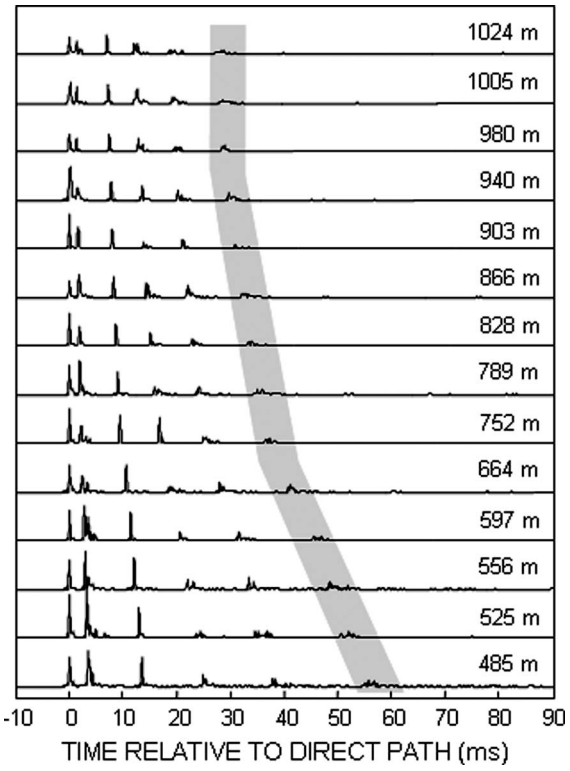

FIG. 12. The amplitude of the matched filter envelope response as a function of range for a single transmission of a FM pulse, frequency range 8–16 kHz. Timing for the arrivals are referenced to that of the direct path for each case (with source-receiver range noted on right) and the shaded gray area denotes the sixth arrival (S-B-S path). Measurements were taken on 6 June beginning at 00:55 UTC and lasting about 2 h during which the wind speed and rms waveheight were 1–2 m/s and ~0.3 m, respectively.

that the B path arrives before the S path, the modeling suggests that time spreading associated with near-surface bubbles will set the background floor.

(Received 23 June 2005; revised 28 October 2005; accepted 13 February 2006)

Thermoacoustic systems have very attractive features and possible wide applications in many areas, especially for cooling purposes. Inventions of traveling wave thermoacoustic engines and traveling wave thermoacoustic refrigerators with work recovery capability have greatly improved the thermodynamic efficiencies of the thermoacoustic systems. To fully utilize the advantages of traveling wave systems, a traveling wave work-recoverable thermoacoustic refrigerator has been designed and built that is driven by a traveling wave thermoacoustic engine, which is aimed at domestic refrigeration purposes. So far, the lowest temperature of −64.4 °C and 250 W cooling power at −22.1 °C are obtained by the system with 3.0 MPa helium gas and 57.7 Hz working frequency. Heat input into the system is 2.2 kW. Simulations based on linear thermoacoustic theory have also been done for comparison with experimental results, which shows reasonable agreement within a certain pressure wave amplitude range and cold end temperature range. The comparisons meanwhile imply some serious loss mechanism inside the traveling wave thermoacoustic refrigerator. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184267]

I. INTRODUCTION

Thermoacoustic systems use high-intensity sound waves to realize the conversion between heat and acoustic power. According to the direction of the conversion, they can be classified into two kinds of systems: thermoacoustic engines and thermoacoustic refrigerators (or coolers). The invention of traveling wave thermoacoustic engines[1] (TWTEs) and traveling wave thermoacoustic refrigerators with work recovery capability[2] (TWTRs) has greatly improved the thermodynamic efficiencies over previous standing-wave-based thermoacoustic systems. The main reason for the improvement is that traveling wave acoustic fields with high local impedance can be established inside the regenerators of these systems. Moreover, in the TWTRs, acoustic work coming from the cold end is recovered which further improves its efficiency especially within the domestic refrigeration temperature range. Naturally, combining the TWTE with the TWTR will lead to a highly efficient thermoacoustic refrigerator, which has other attractive features such as a heat-driven mechanism, no moving parts, environmental friendliness, etc. This system may find important applications in domestic refrigeration since present CFC- or HCFC-based technologies present serious threats to the environment. On the basis of our previous work on a TWTR driven by a standing wave thermoacoustic engine[3] and an improved design of the TWTE,[4] we have built an experimental setup of the TWTR driven by the TWTE and tested the cooling performance. In the second section, we introduce the details of the experiments. The third section introduces the simulation model and gives comparison between experiments and calculation results. Finally, conclusions and discussions are made.

II. EXPERIMENT DETAILS

A. Experimental setup

According to the computation results of our simulation program (to be introduced later), we have built an experimental setup which is illustrated in Fig. 1. It includes two subsystems: the TWTE and the TWTR, which is coupled at the second tee.

The TWTE loop mainly includes a feedback tube, a main water-cooled heat exchanger, a regenerator, a heater block, a thermal buffer tube, a secondary water-cooled heat exchanger, and a resonance tube. Details of the part dimensions are listed in Table I. The TWTR loop mainly includes a feedback tube, a water-cooled heat exchanger, a regenerator, a cold end heat exchanger, a thermal buffer tube, and a flow straightener. Details of the part dimensions are listed in Table II. Core parts of all the heat exchangers use similar design.[5]

As is known in thermoacoustic theory, Gedeon streaming[6] imposes strong influence on the thermal performance of a thermoacoustic system where there exists a loop. For simplicity, we insert a piece of elastic membrane above the upper water-cooled heat exchangers inside both subsystems, where the amplitudes of volume flow rate are relatively small. The benefit of using membranes is that it enables us to fairly compare the system's experimental performance with numeric calculations without the interference of the Gedeon streaming which is very difficult to mea-

 0001-4966/2006/119(5)/2686/7/$22.50

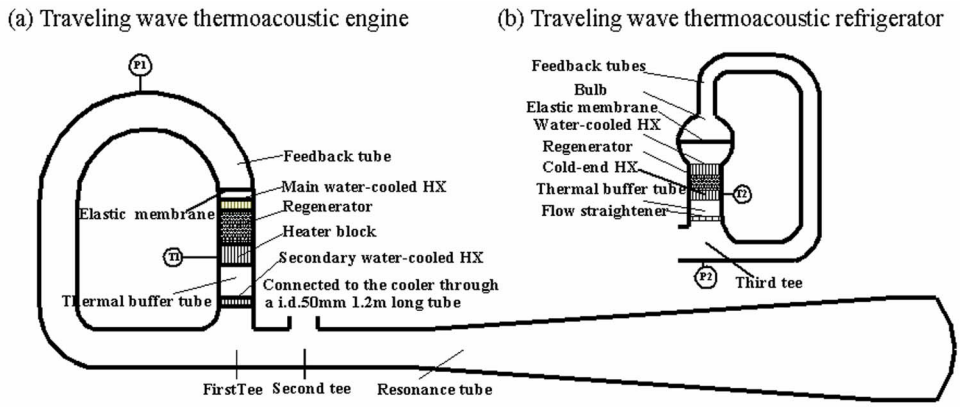

FIG. 1. Illustration of the traveling wave thermoacoustic refrigerator driven by the traveling wave thermoacoustic engine.

sure if it exists. Meanwhile, we use straight thermal buffer tubes in both the TWTE and TWTR without consideration of suppressing the Rayleigh streaming inside,[7] which could also be a big source of thermal loss.

One interesting feature of the system is that the cooler is not directly coupled to the engine at the second tee position but through a 50-mm i.d. 0.2-m-long globe valve and a 50-mm i.d. 1.0-m-long stainless steel tube connected in sequence. The purpose of this tube is to increase the pressure ratio available to the cooler, which is the result of our analysis and also has been verified through experiments. The globe valve is just for easy operation of the system.

For the TWTE, electric heaters are used for heat input into the heater block. Ceramic fiber bricks are used to thermally insulate the hot parts of the system from the surroundings. In the experiments, we found that the material is not so satisfying due to its softness and brittleness. *K*-type sheathed thermocouple T_1 is used to measure the temperature of a solid point on the outside shell of the heater block. For the TWTR, electric heaters are also used for cooling power measurements. Plastic foam is used to thermally insulate the cold parts from the surroundings. A Pt-100 resistance thermometer T_2 is used to measure the cold end temperature. Two pressure sensors P_1 and P_2 measure the pressure waves at the loop top of the TWTE and the inlet of the TWTR, respectively.

B. Experiment results

Generally, when heat is input through the TWTE's heater block, spontaneous oscillation will start once the temperature inside exceeds a critical value. The generated pressure wave will drive the cooler to cool down. With the setup charged with helium gas, we have done a series of experiments with different average pressures and heating powers. Maximum heating power is limited due to the material limitation of the heater block, where the temperature is always controlled around 650 °C by closely observing the temperature sensor T_1. Under all the working conditions, the system frequency slightly changes around 57.5 Hz with variations smaller than 0.5 Hz.

Figures 2(a)–2(c) gives the cooling power versus cold end temperature with different average pressures and heating powers. Generally speaking, a higher average pressure makes it possible for a larger heat input without breaking the temperature limit set by the heater block materials. This increases the acoustic power density within the system and thus leads to a larger maximum cooling power and a lower no-load cold end temperature within the above-mentioned high temperature limit. So far, a lowest temperature of −64.4 °C and a cooling power of 250 W at −22.1 °C are obtained with 2.2 kW heating power and 3.0 MPa average

pressure as shown in Fig. 2(c). The pressure ratio at the inlet of the cooler is about 1.14, which is the maximum value among all the experiment data.

Furthermore, Fig. 3 gives the comparison between the data with different average pressures but with the same heating power of 1.0 kW. It can be seen that lower average pressure leads to a lower values of lowest temperature and a larger cooling power at a certain temperature. But this does not mean that the relative thermal efficiency (the ratio between the practical thermal efficiency and the Carnot efficiency) is also better, since a lower average pressure gives a higher heater block temperature which leads to a higher value of ideal Carnot efficiency.

With these experimental data, we start the numeric simulation and compare the calculated results with experiments.

III. SIMULATION DETAILS

A. Linear thermoacoustic model

The computational model is based on linear thermoacoustic theory, the details of which have been given in Refs. 8 and 9 Minor losses and turbulence influence are not included in the model. For conciseness, the main control equations in complex form are

$$\frac{d\hat{U}}{dx} + R_1\hat{p} - R_3\hat{U} = 0, \tag{1}$$

$$\frac{d\hat{p}}{dx} + R_2\hat{U} = 0, \tag{2}$$

$$\frac{dH}{dx} = Q, \quad H = c_1 + c_2\frac{dT_x}{dx}, \tag{3}$$

where $\hat{p}, \hat{U}$ are complex pressure wave and volume flow rate, T_x is the mean temperature of the gas, H is the total energy including integrated enthalpy flow over the fluid passage cross section and static heat conduction, and Q is the heat input to the gas from the outside of the system (e.g., heat input at the heater block, heat brought away by the water passing the water heat exchanger). R_1, R_2, R_3, c_1, c_2 are complex coefficients, which are functions of the fluid passage geometry, frequency, average pressure, volume flow rate, temperature distribution, etc.

With these equations, simulation can be done with given boundary conditions. Different from DeltaE,[10] we use a mixed algorithm combining the advantages of both analytical and numeric methods. First, the whole system is divided into a certain number of cells. Analytically solving Eqs. (1) and (2) gives the relationship of two neighboring cells in the form of a transfer matrix:

$$\begin{bmatrix} \hat{p}(n+1) \\ \hat{U}(n+1) \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} \hat{p}(n) \\ \hat{U}(n) \end{bmatrix}, \tag{4}$$

where n is the sequence number of the cell. Each element in the 2×2 transfer matrix is a function of R_1, R_2, R_3. For Eq. (3), it can be written with a first-order accuracy on most computational cells in a discrete form,

$$B_1T_x(n-1) + B_2T_x(n) + B_3T_x(n+1) = B_4, \tag{5}$$

except for some special places (e.g., the tee) where a few more cells get involved. Here, $B_1 - B_4$ are coefficients related to the fluid passage geometry, frequency, average pressure, volume flow rate, temperature distribution, etc. Combining this form of equation of all the computational cells leads to a sparse matrix which can be easily solved using linear algebra algorithms.

B. Solving process

For thermoacoustic systems consisting of thermoacoustic engines, two parameters need to be guessed at the beginning of the computation: the frequency and the pressure amplitude at the starting cell. With the guessed values and assumed temperature distribution, $\hat{p}, \hat{U}$ of all cells can be

TABLE II. Details of the traveling wave thermoacoustic refrigerator.

Parts Name	Dimension	Other details
Feedback tube	32 mm i.d., 0.7 m long	
Water-cooled heat exchanger (HX)	35 mm long with about 0.09 m^2 heat exchange area with gas	Made from copper, housed in 50-mm-i.d. stainless steel tube[3]
Regenerator	50 mm i.d., length 35 mm	120 mesh stainless screens
Cold end heat exchanger	30 mm long with about 0.077 m^2 heat exchange area with gas	Made from copper
Thermal buffer tube	50 mm i.d., length 50 mm	Straight
Flow straightener	Several pieces of small mesh number stainless steel screens	

calculated from Eq. (4). Then Eq. (5) is used to calculate the new temperature values. According to the results, the temperature distribution of the system is modified. Since elements of the matrix in Eq. (4) are functions of temperature, $\hat{p}, \hat{U}$ needs to be recalculated. This iteration process should be continued until certain criteria are met. By comparing the calculated volume flow rate with the physical boundary conditions of the real system, we can judge whether the guessed frequency is reasonable. If not, we modify the frequency and do the calculations of $\hat{p}, \hat{U}$ again. Then the distribution of acoustic work flow can be evaluated to see if the guessed pressure amplitude at the starting cell is reasonable. If not, we do the calculations all over again with a new guessed pressure amplitude value. After these iteration steps, the final distributions of $\hat{p}, \hat{U}$ and T_x are obtained, as well as the acoustic work flow, total energy flow, and heat flow. Generally, the calculation time of an operating point is less than 5 min with relatively good initial guessed values.

In the model, helium gas is assumed as being ideal and has temperature-dependent heat conductivity and viscosity. The regenerator materials also have temperature-dependent heat conductivity and specific heat.

The definition of length axis according to Fig. 1 is given below. The origin is set at the first tee and the axis passes through the TWTE loop clockwise. Then it passes through a short 80-mm i.d. connecting tube, arrives at the second tee, and from there it passes through the 50-mm i.d. 1.2-m-long section and enters the TWTR loop counter-clockwise. When it returns to the inlet of the TWTR, the axis jumps to the position where the resonance tube is connected with the second tee and moves to the right end of the resonance tube. This jumping causes the rightmost abrupt changes in the curves of Fig. 4 and the acoustic power curve in Fig. 5.

C. Simulation results and comparison with experiment results

Due to the limitation of linear thermoacoustic theory when the pressure ratio is high, our comparisons focus on the operating conditions which have pressure ratios lower than 1.1 and TWTR cold end temperature around 270 K, thus influences of turbulence and Rayleigh streaming in the thermal buffer tube will not be serious.

After initializing the geometric parameters, boundary conditions, average pressure, and heat input, the calculation can start. It should be addressed here that due to the uncertainty of heat leakage through the insulation bricks at the TWTE's heater block, we input into the program with the measured heating power multiplied by a factor around 0.8–0.9, which depends on the heater block temperature.

Before discussing the calculation results, an important thermoacoustic concept of acoustic work W is defined as

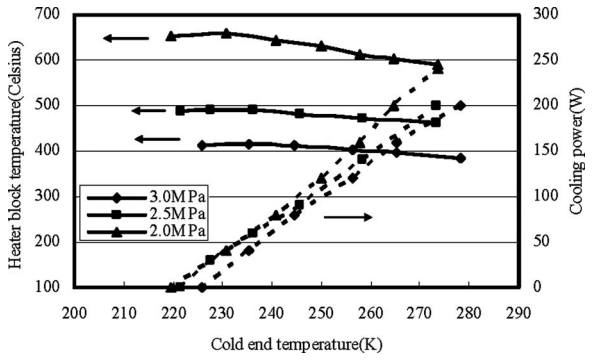

FIG. 3. Measured TWTE heater block temperature and TWTR cooling power versus TWTR cold end temperature, with heating power 1 kW and different average pressures.

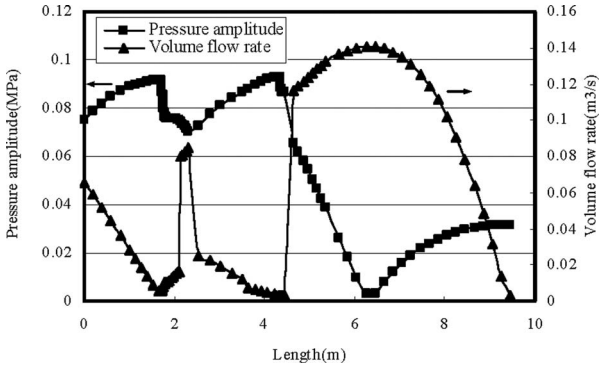

FIG. 4. Calculated distributions of pressure amplitudes and volume flow rates inside the system: average pressure 2.52 MPa, 58 Hz, heating power 500 W and TWTR cold end temperature 271.7 K.

TABLE III. Comparison between experimental results and calculated results with working conditions being 2.52 MPa average pressure, 500 W heating power, and 271.7 K TWTR cold end temperature.

	Frequency (Hz)	Pressure ratio at the TWTR inlet	Temperature at heater block (K)[a]	Cooling power of the TWTR(W)
Experiment	57.4	1.069	597	80
Calculation	58.0	1.071	515	90.3

[a]The measured temperature is on a solid point near the outer surface of the heater block, while the calculated temperature gives the highest gas temperature inside the heater block, which may cause big errors

$$W = \tfrac{1}{2}\mathrm{Re}(\hat{P}\hat{U}^{*}) \tag{6}$$

where Re means taking real part and * means complex conjugation. In analogy with the work done by a sinusoidally moving mechanical piston, this concept denotes how much work the virtual gas pistons at any x position can do. Most importantly, the magnitude of the acoustic work at the cold end of TWTR's thermal buffer tube roughly determines how much gross cooling power can be obtained.

First, we calculate an operating point with average pressure 2.52 MPa, the TWTR's cold end temperature 271.7 K, and heating power 500 W. Table III lists the comparison between experimental values and calculated values. The calculated results agree surprisingly well with experimental results, especially for frequency. With this good agreement, we believe that all the other calculated parameters will not deviate much from the reality. So, a deep look into the details of different parameters inside the system will help us to evaluate the system performance and find possible problems.

Figure 4 gives the distribution of the amplitudes of the oscillating pressures and volume flow rates. Except for the rightmost one, the other abrupt changes in volume flow rate curve are simply due to the bifurcation in the three tees shown in Fig. 1. It is clear that the pressure node and volume flow rate anti-node appear inside the resonance tube near the joint between the 1.5-m-long straight tube and the 3-m-long tapered tube. According to our analysis,[4] this is not a good operating condition for the resonance tube, which makes the tapered part much less useful. Figure 5 gives the distribution of temperature and acoustic work flow. Similarly, except for the rightmost one, the other abrupt changes in the acoustic power curve are simply due to the bifurcations at the three tees shown in Fig. 1. It can be seen in the figure that about 340 W of acoustic work comes out of the TWTE's heater block. At the first tee of the TWTE where the acoustic work gets dissipated to 336 W, most of the acoustic work ($\approx$272 W) is fed back through the feedback tube, flows through the regenerator, and is amplified to about 346 W. The remaining acoustic work ($\approx$64 W) flows rightward from the first tee, gets dissipated slightly, and arrives at the second tee where about 31 W goes to drive the cooler and 30 W gets dissipated inside the resonance tube. Inside the TWTR loop, 102 W acoustic work flows out of the cold end heat exchanger and, together with the 27 W (31 W minus 4 W due to the dissipation in the 50-mm i.d. tube) flows back to the ambient end of TWTR's regenerator. Then about 20 W of acoustic work is consumed to pump the heat from the cold end heat exchanger to the water-cooled heat exchanger. Furthermore, Fig. 6 shows the details of phase difference between pressure wave and volume flow rate inside the regenerators of both the TWTE and TWTR. It can be seen that the phase differences are generally larger than zero, especially for the regenerator of the TWTR. This is not good since we want to achieve an in-phase relationship in the middle of the regenerators for high efficiencies.

It should be noted that the above-mentioned case is only one of the few cases in which the calculations match well with the experiments. Keeping the same average pressure and heating power, Fig. 7 gives the comparison between calculation and experimental results of cooling powers and pressure wave amplitudes at the inlet of the TWTR when the cold end temperatures are lower. It can be seen that for the pressure wave amplitude, the differences between calculations and experiments are within 7%. In terms of acoustic

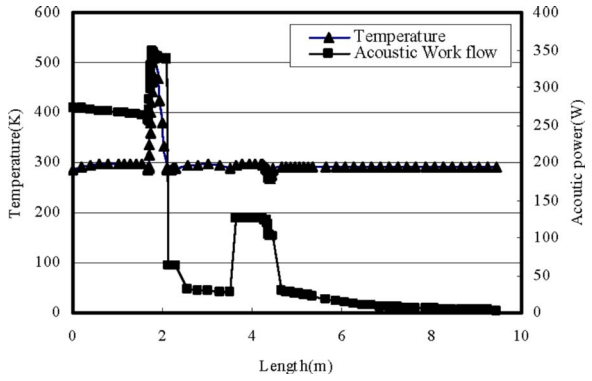

FIG. 5. Calculated distributions of temperatures and acoustic works inside the system: average pressure 2.52 MP, 58 Hz, heating power 500 W, and TWTR cold end temperature 271.7 K.

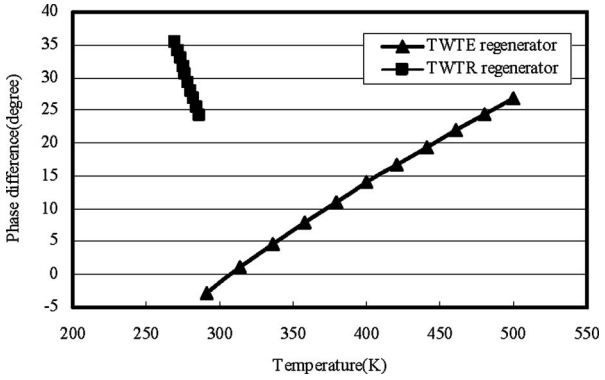

FIG. 6. Calculated distribution of phase relationship between pressure waves and volume flow rates inside the two regenerators. For clarity, the x axis uses temperatures which correspond to the positions inside the regenerators. Average pressure 2.52 MPa, 58 Hz, heating power 500 W, and TWTR cold end temperature 271.7 K.

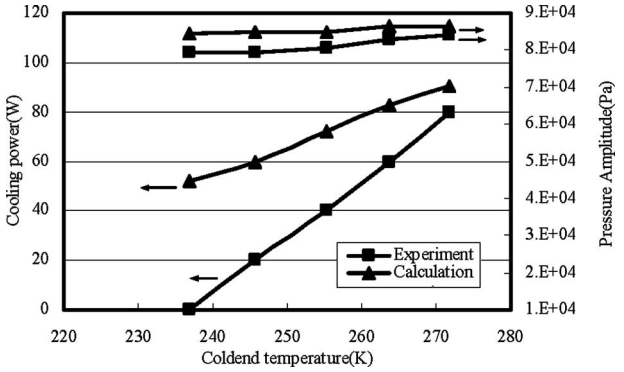

FIG. 7. Comparison between calculated and experimental results on TWTR's cooling power and inlet pressure amplitude versus TWTR cold end temperature, average pressure 2.52 MPa, and heating power 500 W.

power delivered to the cooler (proportional to the squared pressure wave amplitude), this means only about 15% difference, which cannot explain the large discrepancy between calculated and experimental cooling powers at temperatures below 265 K. The reason can only be found in the TWTR subsystem itself. Indeed, it is shown in Fig. 7 that the curve slope of the calculated cooling power is apparently smaller than that of the experiments, which meanwhile implies that the TWTR should be able to generate much lower temperature than that of experiments. Since pressure amplitude at the inlet of the TWTR varies only slightly with the cold end temperature in both experiments and calculations and the two curves gets rather close at around 270 K, this may indicate that some serious loss mechanism related to the cold end temperature exists in the experimental setup. Similar comparisons done with other operating conditions show the same phenomenon.

On the other hand, as we try to simulate other working conditions with larger pressure ratios, the deviation of calculated pressure amplitudes from experimental values also becomes more apparent, which, in addition to the possible losses addressed above, leads to a larger discrepancy of calculated cooling powers from experimental ones. Table IV gives comparisons of measured and calculated TWTR inlet pressure amplitudes under several typical operating conditions. The relative differences are not so big, but in terms of acoustic power, which is proportional to the squared pressure amplitude, the power difference can be as high as 54% for the first data point. This large discrepancy is not surprising since we have neglected the influence of nonlinear behavior (especially the turbulence) in our linear model.

IV. CONCLUSIONS

We have designed and built up an experimental setup of a traveling wave thermoacoustic refrigerator driven by a traveling wave thermoacoustic engine. Many experiments are done to test the performance with different average pressures and heating powers. So far, lowest temperature of −64.4 °C and highest cooling power of 250 W at −22.1 °C are obtained with 2.2 kW heating power, 3.0 MPa average pressure, and pressure ratio of 1.14 at the inlet of the cooler. The results show good application potential for the system in the field of domestic refrigeration, especially when the cooling power is required at around −20 °C or even lower.

For comparison, we have used a simulation program with a different algorithm from DeltaE to study the system with the corresponding experimental parameters. The working frequency can always be accurately predicted. For the others, the calculations agree with the experimental results rather well within a certain pressure wave amplitude range and cold end temperature range. A deep look into parameter distributions inside the system shows that there is a good potential of further improving the system's performance.

Smaller slopes of the calculated curves of TWTR cooling power versus cold end temperature compared with the measured curves may indicate that some loss mechanisms strongly related to the TWTR's cold end temperature are seriously underestimated. One of the most possible reasons is the Rayleigh streamings inside the TWTR's thermal buffer tube since we have not taken any special measures to suppress them. Besides, the dimension of the thermal buffer tube and arrangement of the flow straightener should also be carefully checked. The flow resistance and heat transfer inside the regenerators may need to be more reasonably evaluated. On the other hand, study of stand-alone TWTE and TWTR are necessary for a thorough understanding of the sources of the difference between experiments and calculations, especially when highest pressure ratios exceed 1.1.

With the experimental results, we will further modify and improve the program (mainly to include the turbulence effects and minor losses) for a better match and use it for future optimizations.

TABLE IV. Comparison between calculations and experiments of pressure amplitudes at the TWTR inlet with different operating conditions.

(Received 16 March 2005; revised 14 February 2006; accepted 14 February 2006)

Electromagnetic acoustic transducers (EMATs) generate ultrasonic waves in metals through an electromagnetic coupling mechanism. A concept for EMAT generation, using a coil alone without a permanent magnet, but with a pulse generator and a sample, is introduced. A simplified equivalent coil circuit is given and has been validated by experimental measurements. Such an equivalent circuit can be used for variations in excitation current calculations, which have often been neglected in previous publications in this area but have proved to be of great importance in considering the efficiency and frequency characteristics of ultrasonic generation. The equivalent coil inductance is dependent on the distance between the coil and the sample, due to coil interactions with eddy currents and the Ampere current of the magnetization mechanism. Analytical solution for an annular coil above metal samples is given, and the influences of the lift-off, coil radius, material magnetic permeability and electrical conductivity on the equivalent coil inductance are discussed. Experimental measurements agree well with predictions. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Electromagnetic acoustic transducers (EMATs) are one of several types of noncontact ultrasonic transducers.[1–16] They are noncontact, work at elevated temperatures, and are fairly insensitive to misalignment, and hence are suitable for measurements on-line and are less subject to coupling problems than traditional piezoelectric transducers (PTs).

Within a traditional PT there is an active piezoelectric element or array of elements. Its thickness and vibration mode determine the ultrasonic center frequency. The internal electrical elements (resistance, capacitance, and inductance) together with the backing layers determine the frequency bandwidth. If a pulse generator has bandwidth wider than that of the transducer, the ultrasonic waves generated by the transducer driven by the pulse generator are independent of the internal parameters of the pulse generator used.[6]

At present, the term EMAT is almost always taken to denote a coil with or without the presence of a permanent magnet. Ultrasonic waves are generated through the Lorentz force and/or magnetic mechanisms only when the coil is held close to a metal sample. The important point to bear in mind is that the frequency characteristics and generation efficiency of the ultrasound are dependent on both the sample and the pulse generator.[1–3,5] When a coil is designed, the pulse generator and sample to be measured must be taken into account in order to achieve the required frequency characteristics and optimize generation efficiency. It is well known that the lift-off, which is the distance between a coil and a sample, has an influence on eddy current and ultrasound generation,[1–3,7–16] however, the mechanism has not been addressed thoroughly and it is necessary to address this problem in detail.

The mechanism of ultrasonic generation by EMATs has been studied previously,[7–16] however, the influence on the excitation current through a coil from the rest of the system is typically ignored. The contribution of Ampere current of magnetization mechanism is ignored,[7] therefore the model cannot be used for ferromagnetic materials such as steel, iron, and ferrite. The contribution of eddy current is not fully considered, therefore it is only suitable for very low frequency. In previous studies using the finite element method (FEM), where attention has been focused on the optimal spatial design of the coil and the influence of lift-off,[13–16] the excitation current is usually assumed constant. However, the excitation current changes with lift-off or the load, not only in amplitude but also in frequency. Once the excitation current is obtained, we can calculate the eddy current, Lorentz force, and the ultrasonic generation analytically or numerically.[1–3,7–16]

In this paper, we first give an equivalent coil circuit and equivalent EMAT ultrasonic generation circuit, which can be used to calculate the excitation current, where equivalent inductance and equivalent capacitance are introduced. However, the equivalent inductance of a coil is dependent on the lift-off or load. The physical insight into the EMAT performance is given, and analytical expressions of equivalent inductance and the temporal function of Lorentz force for an annular coil are given that have taken both the eddy current and Ampere current into account. With the temporal function of Lorentz force, we can clearly see how excitation current is related to the frequency characteristics of the generated ultrasonic wave. In Sec. II, experimental measurements are reported which validate our equivalent circuit and predictions of the equivalent coil inductance with respect to frequency and lift-off. Section III gives the conclusions and a discussion of the results.

II. THEORY

EMAT ultrasonic generation and eddy current inductance have been investigated analytically for a few specific

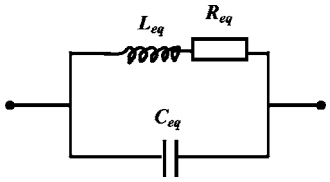

FIG. 1. Simplified equivalent coil circuit.

designs, such as annular coil, and numerically by finite element method (FEM), where the excitation current is assumed as continuous or transient. However, the excitation current changes with the load (close to electrical conductor) in both frequency characteristics and amplitude. EMAT generates ultrasonic waves in the electric conductor by means of Lorentz force due to the interaction of the induced eddy current with external static magnetic and dynamic magnetic field which is induced by the excitation current. The temporal function of the eddy current and dynamic magnetic field, as well as the Lorentz force, is dependent on that of the excitation current through the coil.

How the excitation current changes is of interest for us to investigate the characteristics of the generated ultrasonic waves. We should take the whole excitation system including the pulse generator, coil, and electrical conductor into account. First, we propose an equivalent circuit for the excitation system, based on which the excitation current can be calculated. An analytical expression for the equivalent coil inductance is given. The equivalent coil inductance is reduced by the eddy current induced in the electrical conductor, which tends to decrease the rate of change of the magnetic flux through the excitation coil and is increased for a ferrite where the relative magnetic permeability is a number much larger than 1, due to the magnetization apparently strengthening the magnetic flux through the excitation current so as to raise the rate of change of the magnetic flux through the coil. Finally, the temporal function of Lorentz force is given, which is the convolution of excitation current.

A. Coil equivalent circuit

Generally, an EMAT coil has many turns for optimal ultrasonic generation or receiving.[1–3] There is capacitance between the turns and between the coil and the metal sample, the value being dependent on coil configuration and lift-off. A coil also possesses a real resistive component to its impedance.

The impedance of a coil increases with the frequency of the excitation current flowing through the coil. The impedance is very small for direct current. The measured coil impedance has finite bandwidth around the frequency of the resonant impedance. When the bulk resistance is in series with the coil inductance, the quality factor of the coil circuit can be controlled by the bulk resistance. Therefore, the capacitance should be parallel to the coil inductance and the bulk resistance should be in series with the coil inductance. Such a circuit gives peak impedance around a particular frequency. A simplified equivalent circuit may be introduced to predict the behavior of a coil, as shown in Fig. 1, where L_{eq} is the equivalent inductance, R_{eq} is the internal bulk resistance of the coil, and C_{eq} is the equivalent capacitance representing all potential sources.

However, it is very difficult to give a circuit to simulate the behavior of a real coil exactly because the inductance process and capacitance process are not completely separate. The whole coil may be divided into many circuit elements connecting in series. Each circuit element is of similar structure as shown in Fig. 1. It would be very difficult to assess all the parameters and evaluate the behavior of a coil based on the parameters, so we choose the simple equivalent circuit to predict the behavior of a coil and have validated it by fitting experimental data to our predictions.

The equivalent impedance and equivalent phase of the equivalent coil circuit can be given by

$$Z_{\mathrm{eq}} = \frac{R_{\mathrm{eq}} + j((1-\omega^2 L_{\mathrm{eq}} C_{\mathrm{eq}})\omega L_{\mathrm{eq}} - \omega C_{\mathrm{eq}} R_{\mathrm{eq}}^2)}{(1-\omega^2 L_{\mathrm{eq}} C_{\mathrm{eq}}) - (\omega C_{\mathrm{eq}} R_{\mathrm{eq}})^2}, \tag{1}$$

$$\theta_{\mathrm{eq}} = \tan^{-1}\left(\frac{(1-\omega^2 L_{\mathrm{eq}} C_{\mathrm{eq}})\omega L_{\mathrm{eq}} - \omega C_{\mathrm{eq}} R_{\mathrm{eq}}^2}{R_{\mathrm{eq}}}\right). \tag{2}$$

We can measure the equivalent coil impedance and phase with an HP Vector Impedance Meter:

$$\omega_{\mathrm{reson}} = \frac{1}{\sqrt{L_{\mathrm{eq}} C_{\mathrm{eq}}}}. \tag{3}$$

When $\omega < \omega_{\mathrm{reson}}$, the phase angle is positive; when $\omega > \omega_{\mathrm{reson}}$, the phase angle is negative. From Eqs. (1) and (2), we can calculate the equivalent resistance (or in-phase voltage component) of the equivalent coil circuit, the real part of the equivalent impedance, Z_{eq}, by

$$\mathrm{real}(Z_{\mathrm{eq}}) = \frac{R_{\mathrm{eq}}}{(1-\omega^2 L_{\mathrm{eq}} C_{\mathrm{eq}}) - (\omega C_{\mathrm{eq}} R_{\mathrm{eq}})^2} \approx \frac{R_{\mathrm{eq}}}{1-\omega^2 L_{\mathrm{eq}} C_{\mathrm{eq}}}. \tag{4}$$

When $\omega < \omega_{\mathrm{reson}}$, and the equivalent inductance of the coil circuit decreases for some reason such as the coil approaching a metal sample, the real part of the equivalent coil impedance, real(Z_{eq}), decreases. But when $\omega > \omega_{\mathrm{reson}}$, a decrease in the equivalent inductance L_{eq} will make the equivalent resistance, real(Z_{eq}), increase. Note that the dc bulk resistance of the coil does not change and the ac bulk resistance of the coil increases with increasing frequency.

The discharge circuit on connecting a coil to a pulse generator is shown in Fig. 2, where C_0 and R_0 are the internal capacitance and electrical resistance of the pulse generator. Based on the discharge circuit, the excitation current through the coil can be calculated.[2,3] We first set

$$r = \sqrt{\frac{R^2 C_0}{4 L_{\mathrm{eq}}}}, \tag{5}$$

where the total resistance is given by $R = R_0 + R_{\mathrm{eq}}$. When $r = 1$ for a critically damped circuit, the current through the coil is given by[3]

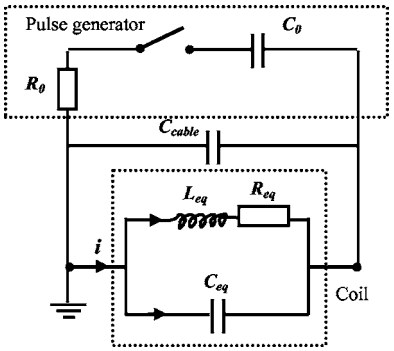

FIG. 2. Discharge circuit for a pulse EMAT.

$$i(t) \approx -I_0(r\omega_0 t)e^{-r\omega_0 t}, \tag{6}$$

where $I_0=\omega_0 C_0 U_{\max}$, $U_{\max}$ is the maximum voltage to which the capacitor C_0 is charged, and $\omega_0=1/\sqrt{L_{\text{eq}}C_0}$ is the natural resonant angular frequency of the circuit. When $r<1$ for the underdamped case, the current is given by[3]

$$i(t) = -\omega_0 C_0 U_{\max}\left(\frac{\sin(\omega_0 t\sqrt{1-r^2})}{\sqrt{1-r^2}}\right)e^{-r\omega_0 t}. \tag{7}$$

When $r>1$ for the overdamped case, the current is given by[3]

$$i(t) = -\omega_0 C_0 U_{\max}\left(\frac{e^{\omega_0 t\sqrt{r^2-1}} - e^{-\omega_0 t\sqrt{r^2-1}}}{2\sqrt{r^2-1}}\right)e^{-r\omega_0 t}. \tag{8}$$

B. Coil inductance

When an excitation current flows through a transmitting coil above an electrical conductor, an eddy current is induced within the skin depth. The eddy current is mainly in the opposite direction to the excitation current and reduces the rate of change of the magnetic flux through the excitation coil. Surface and volume Ampere currents are also to be generated due to the magnetization mechanism. The direction of the Ampere current is dependent on the magnetic characteristics of the sample and the external magnetic field. For paramagnetic and diamagnetic materials, the Ampere current is very small, and therefore the contribution to the magnetic flux through the excitation coil can be ignored. For ferromagnetic materials, the Ampere current is strong and is in the same direction as the excitation current provided that the frequency of the current is not so high that the magnetic domains cannot move at the same rate. The Ampere current increases the rate of change of the magnetic flux through the excitation coil and thus increases the inductance of the coil.

The total rate change of the magnetic flux through the excitation coil is expressed by

$$\frac{d\Phi}{dt} = \frac{d\Phi_{\text{air}}}{dt} - \frac{d\Phi_{\text{eddy}}}{dt} + \frac{d\Phi_{\text{Ampere}}}{dt}, \tag{9}$$

where

$$\frac{d\Phi}{dt} \equiv L_{\text{eq}}\frac{di}{dt}, \tag{10}$$

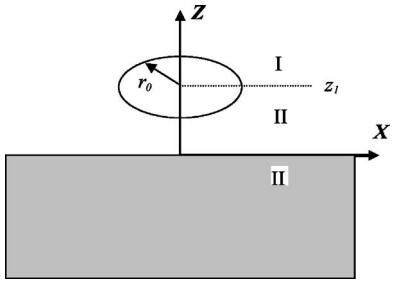

FIG. 3. A coordinate system for the analysis of a coil coupling mechanism. An annular coil is parallel to an electrical conductor with lift-off z_1. Partial differential equations at three regions are solved with the consideration of boundary conditions between each two connecting regions. The annular coil is of radius r_0 with its axis overlapping with the z axis.

$$\frac{d\Phi_{\text{air}}}{dt} \equiv L_{\text{air}}\frac{di}{dt}, \tag{11}$$

$$\frac{d\Phi_{\text{eddy}}}{dt} \equiv L_{\text{eddy}}\frac{di}{dt}, \tag{12}$$

$$\frac{d\Phi_{\text{Ampere}}}{dt} \equiv L_{\text{Ampere}}\frac{di}{dt}. \tag{13}$$

Equation (9) can be rewritten as

$$L_{\text{eq}} = L_{\text{air}} - L_{\text{eddy}} + L_{\text{Ampere}}. \tag{14}$$

L_{eq} is the equivalent inductance of the coil. L_{air}, L_{eddy}, and L_{Ampere} are the coil inductance in the absence of metal, the inductance contribution from eddy currents, and the inductance contribution from the Ampere current of magnetization, respectively. From Eq. (14), an induced eddy current tends to reduce the equivalent coil inductance, while the Ampere current tends to increase the equivalent coil inductance. It is noted that the excitation current, the induced eddy current, and the Ampere current are related to each other by the governing Maxwell's equations. The analytical expression for the equivalent coil inductance can be deduced only for a very few cases. We consider an annular coil above an electrical conductor as shown in Fig. 3, with a sinusoidal current of $\mathbf{i}(t)=\mathbf{i}_0 e^{j\omega t}$ flowing in the coil.

The differential equation for the magnetic vector potential, $\boldsymbol{A}$, in an isotropic, linear, and homogeneous medium due to an applied current is given by[2,3,7–16]

$$\nabla^2\boldsymbol{A} = -\mu\boldsymbol{i} + \mu\sigma\frac{\partial\boldsymbol{A}}{\partial t} + \mu\varepsilon\frac{\partial^2\boldsymbol{A}}{\partial t^2}. \tag{15}$$

Equation (15) is rewritten into the polar coordinate system,

$$\frac{\partial^2\boldsymbol{A}}{\partial r^2} + \frac{1}{r}\frac{\partial\boldsymbol{A}}{\partial r} + \frac{\partial^2\boldsymbol{A}}{\partial z^2} - \frac{\boldsymbol{A}}{r^2} = -\mu\boldsymbol{i} + \mu\sigma\frac{\partial\boldsymbol{A}}{\partial t} + \mu\epsilon\frac{\partial^2\boldsymbol{A}}{\partial t^2}. \tag{16}$$

With axial symmetry, there is only a tangential component of current $i(t)$ and therefore of vector potential $\boldsymbol{A}$. Vector potential $\boldsymbol{A}$ in Eqs. (15) and (16) will be replaced with the tangential component, A.

The vector potentials in the areas I, II, and III as shown in Fig. 3 can be obtained by solving the partial differential

equations with the boundary conditions, where the N turns of an annular coil are assumed to occupy same space.[7] Canceling out the term $e^{j\omega t}$, the vector potentials are given by

$$A_I(r,z,\omega) = \frac{\mu_1 r_0 N i_0}{2} \int_0^\infty J_1(\alpha_1 r_0) J_1(\alpha_1 r) \times \left[e^{\alpha_1 z_1} - \frac{\alpha_r - \mu_r}{\alpha_r + \mu_r} e^{-\alpha_1 z_1} \right] \frac{\alpha}{\alpha_1} e^{-\alpha_1 z} \, d\alpha, \quad (17)$$

$$A_{II}(r,z,\omega) = \frac{\mu_1 r_0 N i_0}{2} \int_0^\infty J_1(\alpha r_0) J_1(\alpha r) e^{-\alpha_1 z_1} \frac{\alpha}{\alpha_1} \times \left[e^{+\alpha_1 z} - \frac{\alpha_r - \mu_r}{\alpha_r + \mu_r} e^{-\alpha_1 z} \right] d\alpha, \quad (18)$$

$$A_{III}(r,z,\omega) = \mu_1 r_0 N i_0 \int_0^\infty J_1(\alpha r_0) J_1(\alpha r) \frac{\mu_r}{\alpha_r + \mu_r} \frac{\alpha}{\alpha_1} \times e^{\alpha_2 z - \alpha_1 z_1} \, d\alpha, \quad (19)$$

where

$$\alpha_1 = \sqrt{\alpha^2 - \omega^2 \mu_1 \varepsilon_1}, \quad (20)$$

$$\alpha_2 = \sqrt{\alpha^2 + j\omega \mu_2 \sigma_2}, \quad (21)$$

$$\mu_r = \frac{\mu_2}{\mu_1}, \quad (22)$$

$$\alpha_r = \frac{\alpha_2}{\alpha_1}, \quad (23)$$

where μ_1 and ε_1 are the magnetic permeability and dielectric permittivity in the air, and μ_2 and σ_2 are the permeability and conductivity of the conductor. The voltage over a single loop of wire of radius r_0 at $z=z_1$ due to magnetic coupling (the voltage due to current over bulk resistance is ignored) is given by

$$V(\omega) = \oint_{r_0} \mathbf{E} \, d\boldsymbol{l} = \oint_{r_0} -\frac{\partial \boldsymbol{A}_{II}}{\partial t} \, d\boldsymbol{l} = -j\omega 2\pi r_0 A_{II}(r_0, z_1). \quad (24)$$

So the total voltage over the coil of N turns is

$$V(\omega) = -jN\omega 2\pi r_0 A_{II}(r_0, z_1). \quad (25)$$

The impedance of a coil is defined by

$$Z(\omega) \equiv \frac{V(\omega)}{i_0}. \quad (26)$$

The equivalent inductance of a coil is defined by

$$L_{\text{eq}}(\omega) \equiv \frac{Z(\omega)}{-j\omega} = \frac{V(\omega)}{-j\omega i_0}. \quad (27)$$

Substituting Eq. (24) into Eq. (27), the inductance of a coil is obtained by

$$L_{\text{eq}}(\omega) = \pi \mu_1 r_0^2 N^2 \int_0^\infty J_1(\alpha r_0)^2 \frac{\alpha}{\alpha_1} \left[1 - \frac{\alpha_r - \mu_r}{\alpha_r + \mu_r} e^{-2\alpha_1 z_1} \right] d\alpha \quad (28)$$

When z_1/r_0 is very large, Eq. (28) can be rewritten as

$$L_{\text{eq}}(\omega) \approx L_{\text{air}}(\omega) = \pi \mu_1 r_0^2 N^2 \int_0^\infty J_1(\alpha r_0)^2 \frac{\alpha}{\alpha_1} \, d\alpha, \quad (29)$$

where $L_{\text{air}}(\omega)$ is the self-inductance of a coil in air, which is proportional to the radius of the coil and the square of the coil turn number, but independent of frequency, and the impedance of the coil increases linearly with angular frequency.

$$L_{\text{eq}}(\omega) = L_{\text{air}}(\omega) - (L_{\text{eddy}}(\omega) - L_{\text{Ampere}}(\omega)), \quad (30)$$

$$L_{\text{eddy}}(\omega) - L_{\text{Ampere}}(\omega) = \pi \mu_1 r_0^2 N^2 \int_0^\infty J_1(\alpha r_0)^2 \frac{\alpha_r - \mu_r}{\alpha_r + \mu_r} \frac{\alpha}{\alpha_1} e^{-2\alpha_1 z_1} \, d\alpha. \quad (31)$$

When z_1/r_0 is close to zero, Eq. (28) can be rewritten as

$$L_{\text{eq}}(\omega) \approx L_0(\omega) = \pi \mu_1 r_0^2 N^2 \int_0^\infty J_1(\alpha r_0)^2 \frac{2\mu_r}{\alpha_r + \mu_r} \frac{\alpha}{\alpha_1} \, d\alpha. \quad (32)$$

$L_0(\omega)$ denotes the equivalent inductance of a coil when the coil contacts the metal directly. In case that $\mu_r \gg \alpha_r$ for a ferrite material, Eq. (32) is rewritten as

$$L_0(\omega) \approx 2L_{\text{air}}(\omega). \quad (33)$$

The increase of the coil inductance is due to the strengthening of the magnetic flux through the coil. In the case that $\mu_r \approx 1$ for a nonferromagnetic material, such as aluminum and copper, Eq. (32) is rewritten as

$$L_0(\omega) = \pi \mu_1 r_0^2 N^2 \int_0^\infty J_1(\alpha r_0)^2 \frac{2}{\alpha_r + 1} \frac{\alpha}{\alpha_1} \, d\alpha. \quad (34)$$

The decrease of the coil inductance is due to the contribution of the induced eddy current in the electrical conductor, which reduces the rate of change of the magnetic flux through the coil.

Taking the derivative of the coil inductance in Eq. (28) over the lift-off z_1, we get

$$\frac{\partial L_{\text{eq}}(\omega)}{\partial z_1} = 2\pi \mu_1 r_0^2 N^2 \int_0^\infty J_1(\alpha r_0)^2 \frac{\alpha_r - \mu_r}{\alpha_r + \mu_r} e^{-2\alpha_1 z_1} \alpha \, d\alpha. \quad (35)$$

It is found that the ratio of the lift-off to the coil radius, z_1/r_0, determines the coil inductance sensitivity to the lift-off.

C. Temporal function of Lorentz force

Approximately, the Lorentz force can be expressed by[2,3]

$$\boldsymbol{F}(r,z,t) = \boldsymbol{F}_\delta(r,z) F_t(t), \quad (36)$$

where $\boldsymbol{F}_\delta(r,z)$ and $\boldsymbol{F}_t(t)$ are the spatial distribution function and temporal function of the Lorentz force, respectively. An

ultrasonic wave generated by a Lorentz force can be expressed by[2,3]

$$\boldsymbol{u}(r,z,t) = \boldsymbol{u}_{\delta}(r,z,t) \otimes F_t(t), \tag{37}$$

where $\boldsymbol{u}_{\delta}(r,z,t)$ is the ultrasonic wave generated by a Lorentz force of the spatial distribution described by $\boldsymbol{F}_{\delta}(r,z)$ of the delta temporal function.

The frequency characteristics of the generated ultrasonic wave are dependent on the temporal function and the spatial distribution functions of the corresponding Lorentz forces. From Maxwell's equation, the eddy current density in the electrical conductor directly under the excitation coil is given by

$$J_{\text{eddy}}(r_0,z,\omega) = -\sigma_2 \frac{\partial A_{III}(r_0,z,\omega)}{\partial t}. \tag{38}$$

Considering an excitation current pulse of temporal function $i(t)$, its frequency spectrum is described by

$$I(\omega) = \text{FFT}(i(t)), \tag{39}$$

where FFT is Fast Fourier Transform operator. Replacing i_0 with $I(\omega)$ in Eqs. (17)–(19) and (38), the eddy current density due to the current pulse is obtained by performing inverse FFT operation,

$$J_{\text{eddy}}(r_0,z,t) = \text{FFT}^{-1}(J_{\text{eddy}}(r_0,z,\omega)). \tag{40}$$

The magnetic flux density directly under the excitation current has mainly radial components given by

$$B_d(r_0,z,\omega) = \frac{\partial A_{III}(r_0,z,\omega)}{\partial z}. \tag{41}$$

The dynamic magnetic flux densities in time domain can be given by performing an inverse FFT operation,

$$B_d(r_0,z,t) = i(t) \otimes B_{d,\delta}(r_0,z,t), \tag{42}$$

where

$$B_{d,\delta}(r_0,z,t) = \text{FFT}^{-1}\left(r_0 N \int_0^{\infty} J_1(\alpha r_0)^2 \frac{\alpha \alpha_r \mu_2}{\alpha_r + \mu_r} e^{\alpha_2 z - \alpha_1 z_1}\, d\alpha \right). \tag{43}$$

The Lorentz force due to the eddy current interacting with the dynamic magnetic field induced has mainly component in negative Z-axis direction and is given by

$$F_d(r_0,z,t) = J_{\text{eddy}}(r_0,z,t) B_d(r_0,z,t). \tag{44}$$

Similarly, the Lorentz force due to the eddy current interacting with an external static magnetic field is dependent on the static magnetic field and is given by

$$\boldsymbol{F}_s(r_0,z,t) = \boldsymbol{J}_{\text{eddy}}(r_0,z,t) \times \boldsymbol{B}_s. \tag{45}$$

When eddy current $J_{\text{eddy}}(r_0,z,t)$ and dynamic magnetic field $B_d(r_0,z,t)$ have similar frequency characteristics, an enhanced Lorentz force can be obtained to generate ultrasonic waves more efficiently.[2,3] The coil is optimized for ultrasonic wave generation with specific frequency characteristics.

TABLE I. Sizes of annular coils used in this paper.

Coil label	AN1	AN2	AN3
Size (mm)[a]	11	11	11
Turns	3	6	9

[a]Internal diameter of coils.

III. EXPERIMENTAL MEASUREMENTS

Measurements were done using annular coils. All of the coils were made from copper wire of diameter 0.22 mm. The structures of the coils are described in Table I. Aluminum, copper, and steel samples were used. Aluminum is paramagnetic and copper is diamagnetic, and both have magnetic susceptibility χ_m of the order of 10^{-5}. The steel sample contains 0.5% chromium, molybdenum, and vanadium in total, and has been treated at temperature 980 °C for 1 h. The steel is ferromagnetic and of high magnetic susceptibility χ_m. The electrical conductivities and relative magnetic permeability of the materials are shown in Table II and will be used in later calculations. Please note that the relative permeability of steel and ferrite given in Table II are for direct current. The relative permeability of an alternating current is dependent on the frequency, but such information is not available in the literature. In this paper, the relative permeability of steel for frequencies above 30 kHz is given by $\mu_r = \mu_{r0} e^{-(f-30\,000)/800}$, and the relative permeability of ferrite for frequencies above 30 kHz is given by $\mu_r = \mu_{r0} e^{-(f-30\,000)/300}$, in order to achieve best agreement between the calculation and the measurement, where μ_{r0} is the relative permeability of dc given in Table II.

The experimental measurement setup is shown in Fig. 4. The pulse generator used in this work has an internal resistance of 2Ω and a maximum charge voltage of 850 V on the capacitor (1 μF). The capacitances of two cables of length 500 and 1150 mm used to connect a coil and the pulse generator are 12 and 53 pF, respectively. For an EMAT working at a frequency ranging from 200 kHz to 1 MHz, the influence of the cable capacitances can be neglected.

In order to accurately control the lift-off, a micrometer is used. The coil is attached to a nonmetallic block in parallel and the block is put on a platform controlled using a micrometer. The coil together with the fixed nonmetallic block moves with the micrometer platform. In this paper, coil impedance is measured with an HP Vector Impedance Meter for frequency ranging from 0.4 to 110 MHz, and by an Impedance Card installed in a computer for frequency ranging from 1 kHz to 1 MHz. The excitation current through the coil is

TABLE II. Material properties.

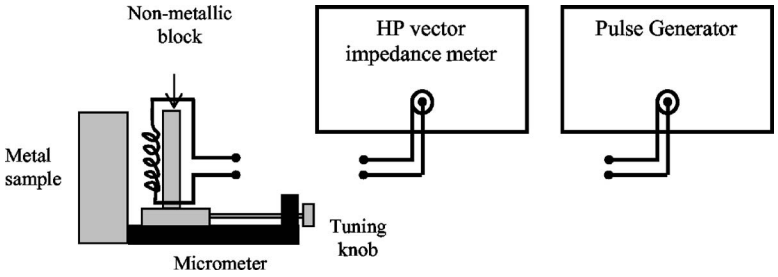

FIG. 4. Measurement setup for impedance and excitation current measurements.

measured using a LeCroy oscilloscope with a digitalization rate of 100 MHz and an analog bandwidth of 400 MHz.

A. Validation of equivalent coil circuit

We now consider the capacitance in the simplified equivalent coil circuit shown in Fig. 1. The resonant frequency of such an LCR circuit is given by[3]

$$f_R \approx \frac{1}{2\pi\sqrt{L_{\mathrm{eq}}C_{\mathrm{eq}}}}. \tag{46}$$

At the resonant frequency, the input current approaches zero. The coil impedance, which is inversely proportional to the current, achieves a maximum around frequency f_R.

Figure 5 shows the measured and calculated impedance for the annular coil labeled AN3 based on the simplified coil equivalent LCR circuit and the LR circuit for frequencies ranging from 400 kHz to 100 MHz for annular and linear coils. We choose values for capacitance, resistance, and inductance for the coil equivalent circuit such that the difference between the measured and simulated impedance with respect to frequency is close to the minimum. The simulation based on the simplified coil equivalent circuit agrees well with the measurements, while the calculation based on an LR circuit does not agree with the measurements. This confirms the existence of a significant capacitance within the coil. The effective inductance, capacitance, and resistance of coil AN3 in the presence of air, aluminum, copper, and steel are calculated based on the equivalent circuit and are shown in Table III.

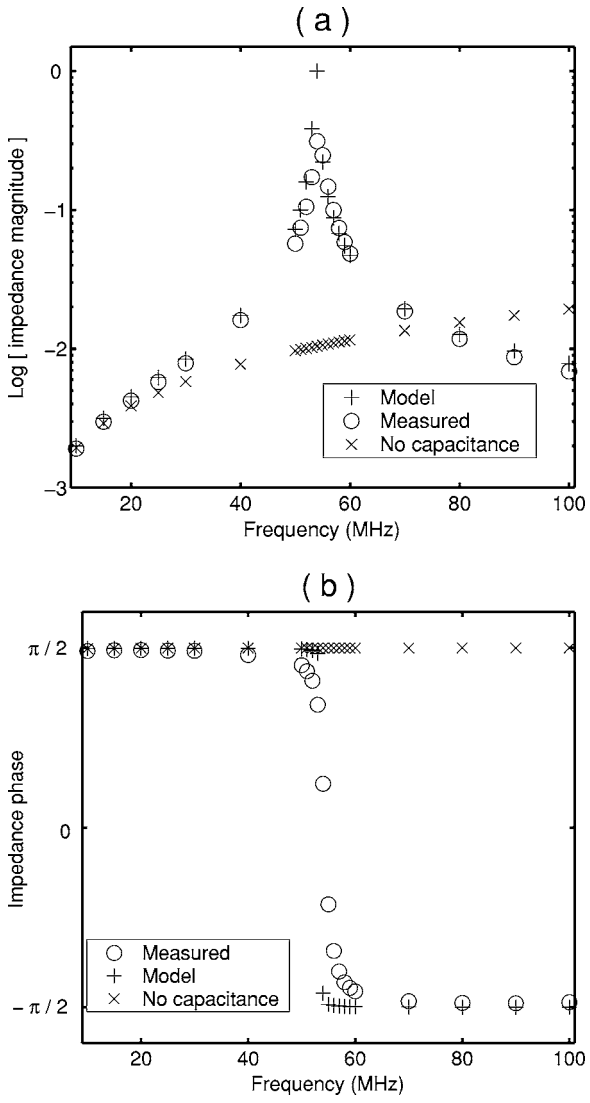

FIG. 5. Magnitude (a, plotted on a logarithm scale) and phase (b, plotted on a linear scale) of the impedance of coil AN3 with respect to frequency. The impedance magnitude in (a) is divided by the maximum magnitude of the calculated impedance peak. Circle is measured, plus sign is calculated based on the model of this paper, and cross is calculated where capacitance is not considered.

B. Eddy current and magnetization

Aluminum is paramagnetic while copper is diamagnetic, and both have a very small magnetic susceptibility χ_m. Therefore the magnetic field generated by magnetization can be ignored for these materials. All coils described in Table I were used with these samples, and the impedance was taken for each coil in three situations: without a sample present (surrounded by air), contacting the aluminum block, and contacting the copper sample. No peak impedance is found in the frequency range 0–100 MHz for the presence of both aluminum and copper because the equivalent inductance is too small. The maximum impedance is predicted to be around 100–110 MHz. The peak maximum impedance and phase reversal frequency appear at a higher frequency than

TABLE III. Effective inductance, capacitance, and resistance of annular coils with the presence of varied samples.

Coil label	Sample	L_{eq} (μH)	R_c (Ω)	Z_χ(Ω)	C_{eq} (pF)	f_{R} (MHz)
AN3	Air	1.38	0.6	0	6.36	53.6
	Aluminum	0.356	0.6	0	7.22	99.2
	Copper	0.355	0.6	0	6.90	102
	Steel	0.62	0.6	2.5	5.1	89.5

TABLE IV. Effective equivalent coil inductance (μH).

Coil label	AN1	AN2	AN3
Air	0.26	0.72	1.38
Aluminum	0.12	0.32	0.36
Steel	0.20	0.53	0.62

that in air (over 100 MHz, as opposed to 53 MHz). Table IV shows the equivalent coil inductances with and without steel and copper samples. These results prove that the eddy current tends to decrease the equivalent coil inductance.

The steel sample used in these measurements is ferromagnetic. Based on the simplified equivalent coil circuit, the equivalent inductance and capacitance of coil AN3 are calculated and are given in Table III. Through comparison with those of air and copper samples, it is found that the equivalent inductance of steel is smaller than that of air but bigger than that of copper. Same conclusion can be drawn from the results of coils AN1 and AN2 shown in Table IV.

Figure 6 shows the measured and calculated impedance of coil AN3 with the presence of air with no nearby magnetic or electrically conducting materials and in close proximity to ferrite, steel, and copper samples. The impedance measured with the ferrite present, where only the Ampere current of magnetization contributes to increase the coil inductance, is always higher than that of air. The impedance in the presence of copper, where only the eddy current contributes to reduce the coil inductance, is always lower than that of air. For steel, both the eddy current and Ampere current of magnetization contribute to coil inductance. The influence of eddy current increases faster with the frequency of the excitation current than the contribution from the Ampere current. At low frequencies, the coil inductance in the presence of steel is higher than that in air. When the frequency of the excitation current is above about 350 kHz, the coil inductance in the presence of steel becomes lower than that in air. This is related to the mobility of magnetic domains in the material.

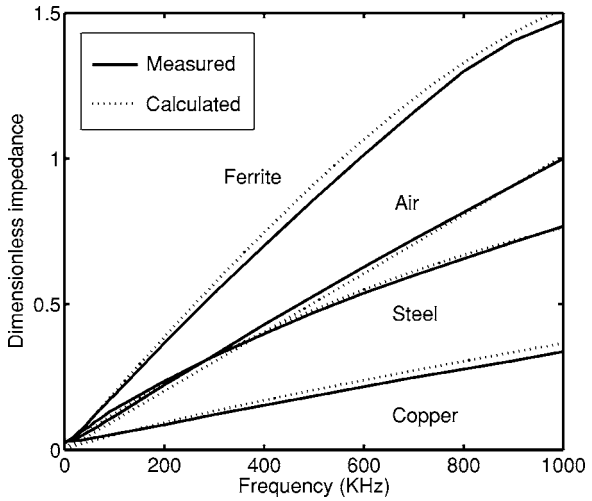

FIG. 6. Measured (solid lines) and calculated (dotted lines) impedances of the coil AN3 with respect to frequency at low frequency. For better comparison, the measured and calculated impedances are divided by the measured impedance of the coil at a frequency of 1 MHz in the presence of air.

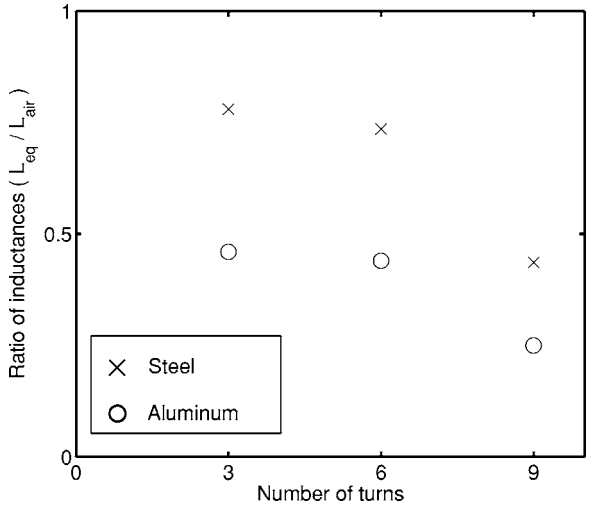

FIG. 7. Ratio of the measured inductances of coils AN1 (three turns), AN2 (six turns), and AN3 (nine turns) in the presence of aluminum (circle) or steel (cross) to that in the absence of a metal. Here L_{eq} or L_{air} denotes the impedances of a coil in the presence of a metal or air.

C. Lift-off sensitivity

Figure 7 shows the experimentally measured ratio of the equivalent coil inductance with aluminum and steel samples to that without any nearby sample (air), $L_{eq\text{-}metal}/L_{eq\text{-}air}$, for annular coils at a frequency of 500 kHz. The equivalent coil inductance with the steel sample is higher than that with the aluminum sample. The coil inductance of coil AN3 of nine turns is more influenced by the eddy current or eddy current and Ampere current than coil AN1 of three turns.

From Eqs. (28), (29), and (32), the ratio of coil inductance in the presence of metal to that in the absence of metal is not influenced by the number of coil turns. Figure 8 shows the ratio of the coil inductance in the presence of metal to that in the absence of metal calculated based on Eqs. (32) and (29), respectively, at frequency 300 kHz. The coil induc-

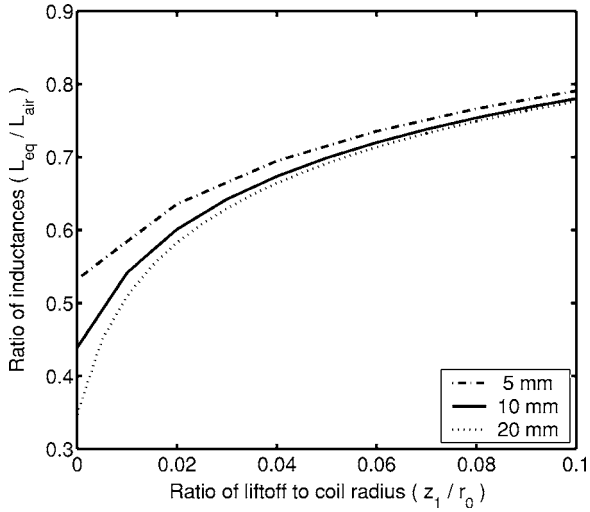

FIG. 8. Ratio of calculated inductance of annular coils in the presence of aluminum to that in the absence of aluminum with respect to the ratio of the lift-off to the coil radius. Dotted line, solid line, and dashed-dotted line are for coil radius of 20, 10, and 5 mm, respectively. Here L_{eq} or L_{air} denotes the impedances of a coil in the presence of a metal or air; z_1 and r_0 are the lift-off and the radius of the annular coil, respectively.

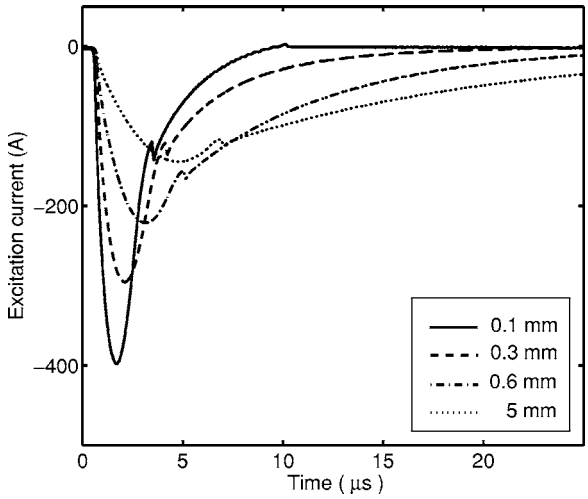

FIG. 9. Measured transient currents through an excitation coil at various lift-offs of 0.1 mm (solid line), 0.3 mm (dashed line), 0.6 mm (dashed-dotted line), and 5 mm (dotted line).

tance changes with respect to the ratio of lift-off to coil radius. For practical measurements, shown in Fig. 7, the lift-off may be assumed to be the same for coils AN1, AN2, and AN3. The internal radii of the three coils are the same, but their average radii are different. A coil of more turns has a larger overall width. These two factors explain the measured differences of the coils of varied number of turns.

With equivalent coil inductance, we can calculate coil excitation current based on the equivalent circuit as shown in Fig. 2. We give measured results in Fig. 9 to demonstrate the change of excitation current in amplitude and shape with respect to lift-off, where the excitation currents flowing in coil AN3 at lift-offs of 0.1, 0.3, 0.6, and 5 mm are measured. Rayleigh waves were observed with a reasonably high ratio of signal to noise at all of these current levels except that of 140 A at lift-off 5 mm.[2,3] The amplitude of the excitation current decreases dramatically with respect to lift-off, and the temporal width of the current pulse increases with lift-off, showing that the frequency bandwidth of the generation source drops significantly. Lift-off changes the frequency bandwidth of the excitation current, and, accordingly, the temporal function of the Lorentz force, which determines the frequency characteristics of the generated ultrasonic waves.[3]

IV. CONCLUSIONS AND DISCUSSION

In this paper, we have demonstrated why an EMAT must be considered from the point of view of a whole system, including a pulse generator, a transmitting coil, and a metal sample. The advantage of this concept is that the ultrasonic frequency characteristics and generation efficiency are considered systematically.

A coil and a metal sample are coupled by means of an electromagnetic coupling mechanism. An equivalent coil circuit is given, which includes the internal electrical resistance, self-inductance, and capacitance. The former two factors are well known. The capacitance between the coil and the metal sample and the capacitance of interwinding has a significant effect on the EMAT behavior. The influence of the coil capacitance becomes more significant for high-frequency wideband ultrasonic generation up to 30 MHz.[2,3] Due to the eddy current and magnetization mechanisms, the equivalent inductance is dependent on the magnetic susceptibility, the electrical conductivity of the metal sample, and the configuration of the coil. When a transmitting coil approaches a metal sample, a dynamic magnetic field and an eddy current are induced in the metal. Transient eddy currents produce dynamic magnetic fluxes passing through the transmitting coil, which oppose the change caused by the transient excitation current flowing in the coil. This results in the reduction of the equivalent coil inductance, making the excitation current more temporally sharp and enhancing the bandwidth. Magnetization mechanisms tend to increase or decrease the magnetic flux depending on the magnetic susceptibility of the metal sample, also resulting in an increase or decrease in the equivalent inductance. This is obvious for ferromagnetic materials.

An analytical expression of for equivalent coil inductance of an annular coil is given, which states the relative contribution from the eddy current and Ampere current on the equivalent inductance. The calculated impedances of an annular coil in air away from any nearby magnetic or electrically conducting samples, and then in close proximity to steel, ferrite, and copper, agree well with the measurements. The temporal function of Lorentz force is also given, which shows the relationship between the excitation current and can be used to predict the frequency characteristics of the ultrasonic wave that is generated by the annular coil. Experimental and calculated data can be found in our two references (Refs. 2 and 3) demonstrating ultrasonic waves of reasonably high ratio of signal to noise.

An active headrest for personal audio

Stephen J. Elliott and Matthew Jones[a)]

(Received 21 September 2005; revised 7 February 2006; accepted 20 February 2006)

There is an increasing need for personal audio systems, which generate sounds that are clearly audible to one listener but are not audible to other listeners nearby. Of particular interest in this paper are listeners sitting in adjacent seats in aircraft or land vehicles. Although personal audio could then be achieved with headsets, it would be safer and more comfortable if loudspeakers in the seat headrests could be actively controlled to generate an acceptable level of acoustic isolation. In this paper a number of approaches to this problem are investigated, but the most successful involves a pair of loudspeakers on one side of the headrest, driven together to reproduce an audio signal for a listener in that seat and also to attenuate the pressures in the adjacent seat. The performance of this technique is investigated using simple analytic models and also with a practical implementation, tested in an anechoic chamber and a small room. It is found that significant attenuations, of between 5 and 25 dB, can be achieved in the crosstalk between the seats for frequencies up to about 2 kHz. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188814]

I. INTRODUCTION

When two people are listening to different audio channels in adjacent seats in an aircraft or road vehicle, each person wants to hear their own channel faithfully reproduced, with a minimum of interference from the other person's channel. Figure 1 shows a diagram of the problem. Although this could be achieved if each person wore a headset, there may be comfort or safety issues with such devices and it would be more convenient if the audio channels could be reproduced through loudspeakers in the headrests of the seats. The safety implications of using headsets instead of headrest loudspeakers are concerned with the wiring to the headset and the fact that headsets can restrict communication with the wearer.

This paper investigates various approaches to actively improving the acoustic isolation between adjacent seats with headrest loudspeakers, so that the two people experience personal audio. Two strategies are investigated, initially using a simple free-field acoustic model. The first configuration is where the loudspeakers in one seat are used to control the sound from the loudspeaker in an adjacent seat. Such an arrangement has already been investigated using a finite element method by Hashimoto *et al.*[1] The second method, in general, employs a closely spaced array of acoustic sources to maintain a large pressure in one region of its near field while minimizing the pressure in another region. In this initial investigation, however, the loudspeaker array consists of just a pair of sources located in one side of the headrest in which the levels are maintained. Arrays of loudspeakers are commonly used to generate desired far-field directivity patterns using various beamforming techniques[2,3] and such a far-field array has also been investigated with a similar aim to the current paper by Druyvesteyn and Garas,[4] who emphasized that conventional active control systems could only be effectively used at low frequencies.

Another possible technology for the generation of personal audio may be the "audio spotlight"[5] in which the nonlinear interaction between two ultrasonic signals is used to generate a highly directional audio source in a similar way to an underwater parametric array.[6] These devices may, however, have unacceptable distortion properties for audio applications, because of their nonlinear generation mechanism, and there are questions about the safety of the high levels of ultrasound of such devices,[7] particularly in the near field if they were used in headrests.

Both of the control strategies using loudspeakers in the headrests could be implemented using feedforward control techniques,[8] since the audio channel provides a reference signal for a feedforward filter. An initial experimental investigation of the system is reported which uses an array of two closely spaced loudspeakers in the headrest of one of a pair of aircraft seats. Measurements of the frequency response from the loudspeakers to an array of microphones were first taken in an anechoic chamber and used to predict the performance in this experimental arrangement. A real-time implementation is then described, together with some measurements in a small room, which confirm that results very similar to those predicted from the anechoic measurements can be achieved in practice. Preliminary versions of this work were reported in Refs. 9–12.

II. SIMULATION STUDY

The simplest method of controlling the sound from a loudspeaker in one seat, in an adjacent seat, would be to use the loudspeakers already present in the seat as secondary sources. This is illustrated in Fig. 2 in which s is the audio signal used to drive the loudspeaker in the right-hand seat,

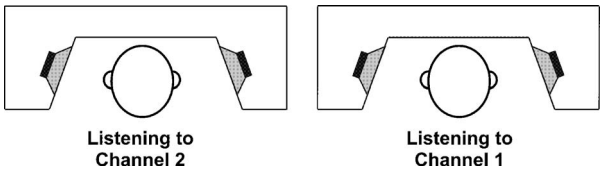

FIG. 1. Plan view of the physical arrangement in which listeners in adjacent seats are listening to different audio channels radiated by loudspeakers in the seat headrests.

with volume velocity q_p, which is also fed via filters H_1 and H_2 to the two loudspeakers on the left-hand seat which then have volume velocities q_{s1} and q_{s2}.

In order to quantify the potential acoustic behavior of such a system, a performance criterion that can be optimized needs to be defined. A convenient criterion would be to minimize the sum of the squared pressures at a number of locations in the left-hand headrest while keeping the sum of the squared pressures at locations in the right-hand headrest constant. This is equivalent to maximizing the ratio of the sum of squared pressures in the right-hand headrest to the sum of squared pressures in the left-hand headrest, which Choi and Kim[13] refer to as the acoustic contrast. The complex pressures at the locations that we are required to maintain at a high sound level, which may be termed the bright zone, p_1-p_4 in Fig. 2, can be written, for single frequency excitation, as elements of the vector

$$\mathbf{p}_B = \mathbf{Z}_B\mathbf{q}, \tag{1}$$

where $\mathbf{q}$ is a vector containing all the source strengths, which are q_p, q_{s1}, and q_{s2} in this case, and $\mathbf{Z}_B$ is a matrix of acoustic impedances from each source to every point at which the pressure is sampled in the bright zone. Similarly we can write the vector of complex pressures in the region where we want to reduce the levels, which may be termed the dark zone, p_5-p_8 in Fig. 2, as

$$\mathbf{p}_D = \mathbf{Z}_D\mathbf{q}. \tag{2}$$

The acoustic contrast, C, which is the ratio of the sum of squared pressures in the bright and dark zones, may thus be defined as

$$C = \frac{\mathbf{p}_B^H\mathbf{p}_B}{\mathbf{p}_D^H\mathbf{p}_D} \tag{3}$$

where the superscript H denotes Hermitian, complex conjugate, transpose. The acoustic contrast is a scalar quantity that we seek to maximize by adjusting q_{s1} and q_{s2} with respect to

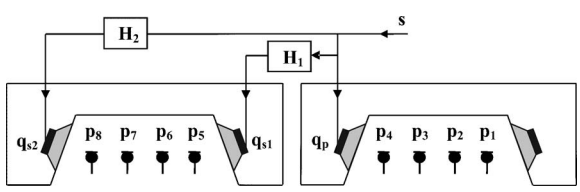

FIG. 2. Feedforward control strategy in which the loudspeakers in the left-hand headrest are used to control the sound in that seat due to a loudspeaker in the right-hand seat being driven by audio channel 1, shown here as the signal s.

q_p. Using Eqs. (1) and (2) the acoustic contrast may also be written as

$$C = \frac{\mathbf{q}^H\mathbf{Z}_B^H\mathbf{Z}_B\mathbf{q}}{\mathbf{q}^H\mathbf{Z}_D^H\mathbf{Z}_D\mathbf{q}}, \tag{4}$$

which Choi and Kim[13] show is maximized if $\mathbf{q}$ is the eigenvector of the matrix $[\mathbf{Z}_D^H\mathbf{Z}_D]^{-1}\mathbf{Z}_B^H\mathbf{Z}_B$ that corresponds to its largest eigenvalue. Once this optimum value of the vector $\mathbf{q}$ is calculated at a number of frequencies, the ratio of q_{s1} and q_{s2} to q_p can be calculated to determine the frequency responses of the filters H_1 and H_2 in Fig. 2.

An initial simulation has been performed for this geometry assuming that each of the acoustic sources behave as monopoles in free space. The distance between the two sources in one headrest, q_{s1} and q_{s2}, taken to be 27 cm, the distance between the closest sources in adjacent headrests, q_{s1} and q_p, was taken to be 22.4 cm, and four microphones were used to define the bright and dark zones each 4 and 7 cm from their nearest source. (The 4 cm distance is composed of a physical separation of about 1 cm and a correction for the finite size of the loudspeaker of one quarter of its diameter, as discussed in the Appendix.) These dimensions approximate those of the practical arrangement described in Sec. III. The sources and microphones are thus arranged in a line, although arrays that are not linear have also been investigated with similar results.

The results of this simulation are a pressure distribution for the optimized source strengths, whose contour plots in a two-dimensional plane running through the sources and microphones are shown in Fig. 3 for various frequencies of excitation. Although the performance is good at low frequencies, the sound field becomes more complicated and localized at high frequencies so that small changes in listening position cause large changes in acoustic pressure.

The reason why only local attenuations in pressure are achieved at high frequencies is that the secondary sources are a significant distance from the primary compared with the acoustic wavelength.[13] In order to be able to control the pressure over a larger region of the dark zone at high frequencies, a secondary source must be used which is close to the primary. One such arrangement is illustrated in Fig. 4. In this arrangement a single secondary source, q_s, located in the same headrest as q_p is fed via a filter H_1 from the primary source, and the frequency response of H_1 that maximizes the acoustic contrast can again be calculated using the abovementioned theory, except that the vector $\mathbf{q}$ now only contains q_p and q_s.

The results of monopole simulations with this geometry, where the primary and secondary are assumed to be 5 cm apart, are shown as contour plots in Fig. 5 for various frequencies of excitation. It can be seen that the region over which the pressure has been reduced by 20 dB compared with the pressure in the bright zone is considerably larger at high frequencies than it was in Fig. 3. The far-field directivity of this pair of monopoles is approximately cardioid below about 4 kHz, indicating that useful reductions in the sound from the right-hand headrest have been produced at all points to the left of it up to this frequency.

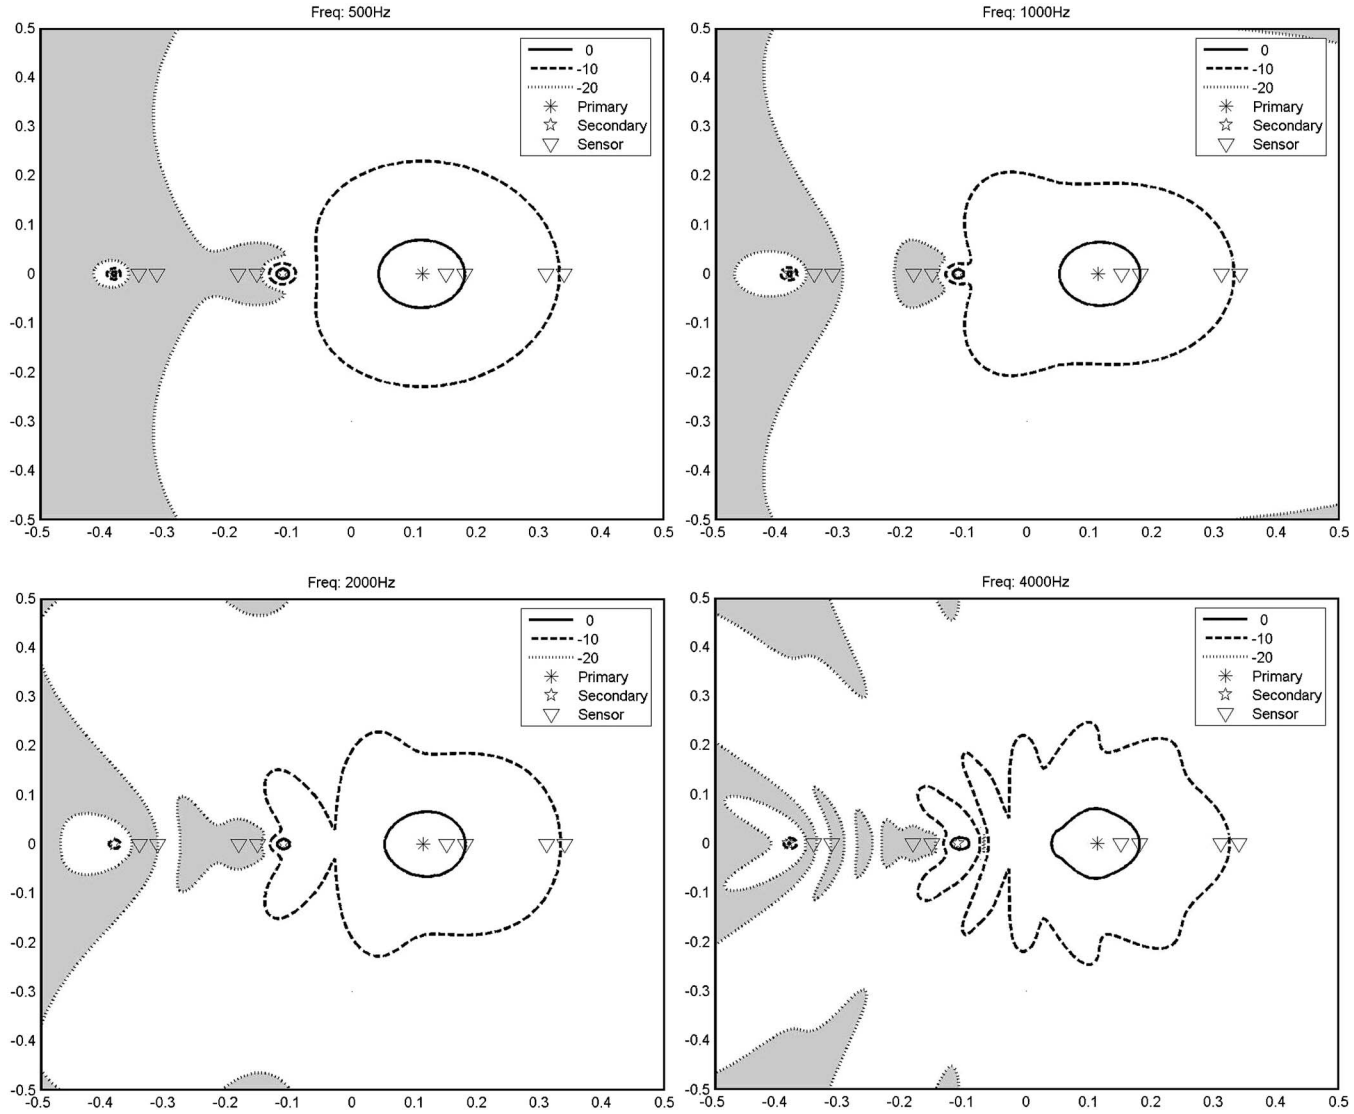

FIG. 3. Contour plots of the pressure levels at excitation frequencies of 500 Hz, 1, 2, and 4 kHz in a free-field acoustic model. Two secondary sources q_{s1} and q_{s2} (at $x=-0.11$ and -0.38 m) are used, remote from q_p (at $x=0.11$ m), to maximize the acoustic contrast between the pressures in the two seat positions. This maximization is done with respect to the microphones denoted by triangles. The shaded area indicates a reduction of 20 dB compared with the pressure at a point in the right-hand seat.

More subtle behavior can be revealed if the pressure distribution along the axis of the sources and microphones is plotted, and compared with that generated when q_s is adjusted to cancel the pressure in the far-field. These levels are plotted, at 500 Hz, as the solid and dashed lines in Fig. 6 and the former can be considered as a horizontal slice through the corresponding contour plot in Fig. 5. When q_s is adjusted to cancel the far-field pressure, the pressure field to the left of the sources falls off monotonically as $1/r^2$, where r is the distance from the sources. When q_s is adjusted to maximize the acoustic contrast between the two seats, the pressure field goes to zero at about the position of the microphone measuring P6 in Fig. 4 but then rises before falling off as $1/r$ at larger distances than are shown in this figure. The maximum level to the left of this dip is still about 40 dB down on the level in the bright zone, however, so although the far-field attenuation is not as great as when the far-field pressure is canceled, it is still probably sufficient for audio purposes.

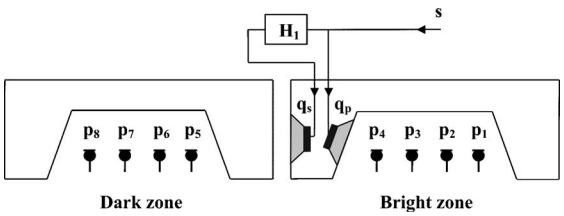

FIG. 4. Feedforward control strategy in which the outer loudspeaker of a pair mounted on one side of the headrest in the right-hand seat is used to control the sound in the left-hand seat due to the inner loudspeaker, which is driven by the audio signal s.

An important implication of the level curve in Fig. 6, which is confirmed by separate simulations, is that with just two sources, the optimal result for contrast maximization can be closely approximated by placing a null at a point in the dark zone. With such a simple geometry the system is unable to produce a complicated zone of silence, and just a single null can be created whose center point may be adjusted to maximize the contrast. An almost identical pressure distribu-

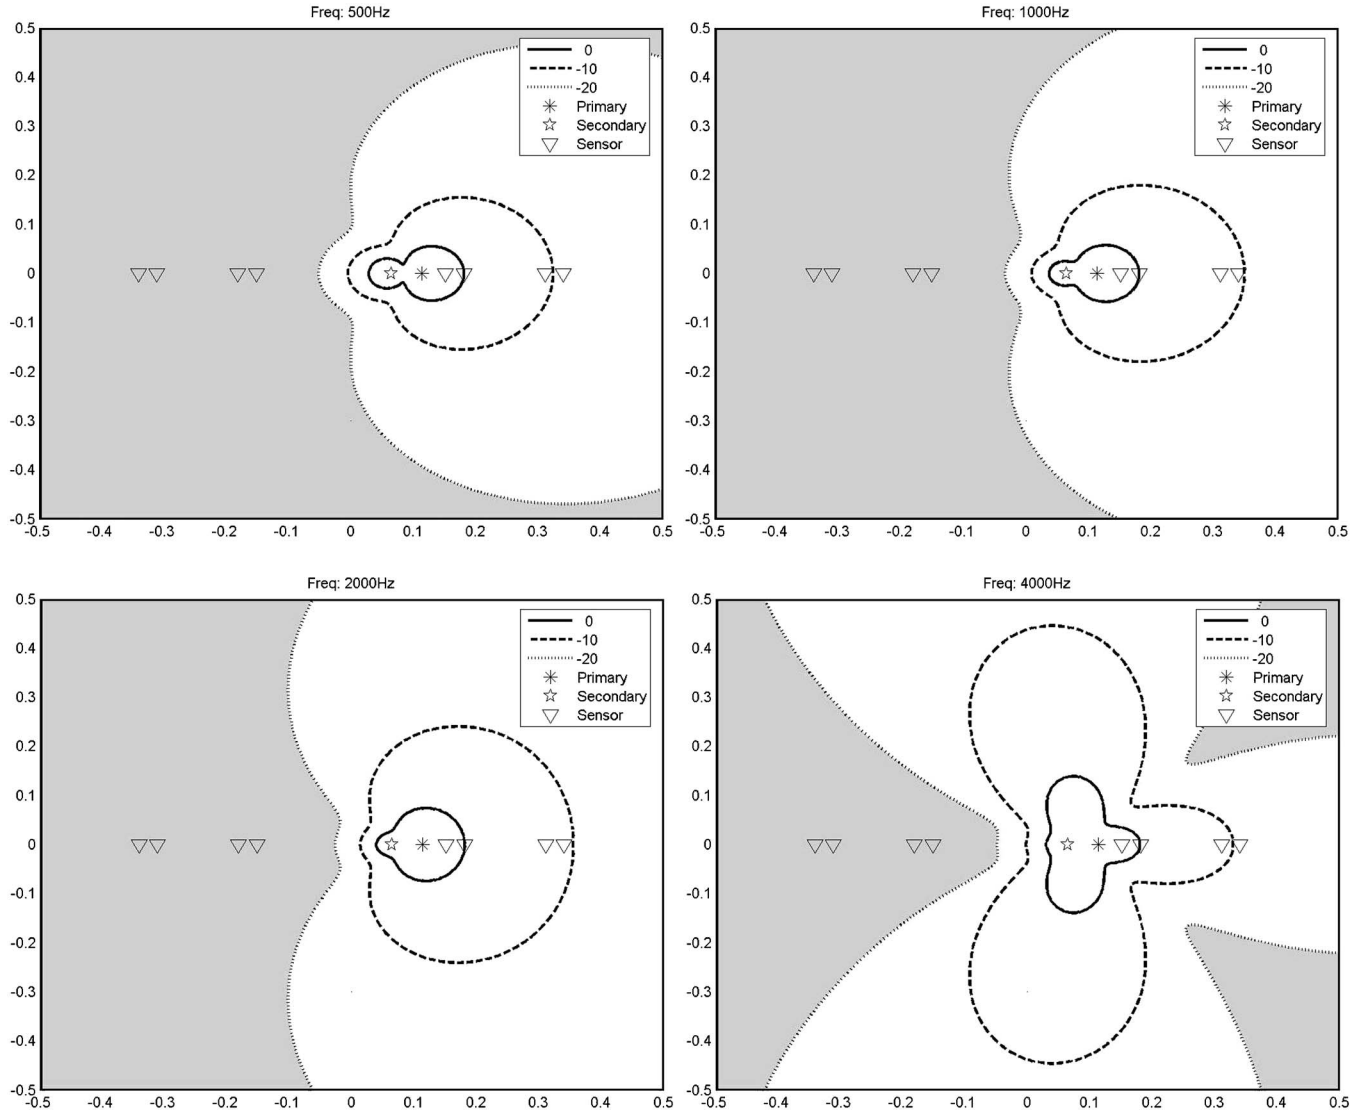

FIG. 5. Contour plot of the pressure levels at 500 Hz, 1, 2, and 4 kHz in a free-field acoustic model simulating the use of the secondary acoustic source q_s (at $x=0.06$ m) to maximize, close to q_p (at $x=0.11$ m), the acoustic contrast between the pressures in the two seat positions. The microphones over which the contrast is maximized are denoted here as triangles. The shaded area indicates a reduction of 20 dB compared with the pressure at a point in the right-hand seat.

tion could be achieved by adjusting q_s to simply cancel the pressure at a single point in the dark zone. This is a control strategy that would be considerably simpler to implement in a practical arrangement than contrast maximization, and is investigated further in the following section.

III. EXPERIMENTAL IMPLEMENTATION

Figure 7 shows a photograph of the experimental arrangement in which a pair of aircraft seats is fitted with prototype headrests containing loudspeakers. Dummy heads with microphones at the ear positions were arranged in the two seats to measure the pressures. In the inner headrest of the furthermost seat a pair of loudspeakers is fitted, mounted together facing each other, as shown in the right-hand side of Fig. 7. The loudspeakers had a diameter of 11.5 cm and were selected because their thickness was only 4.2 cm, so that a pair only had a depth of 8.4 cm when fitted into the headrest.

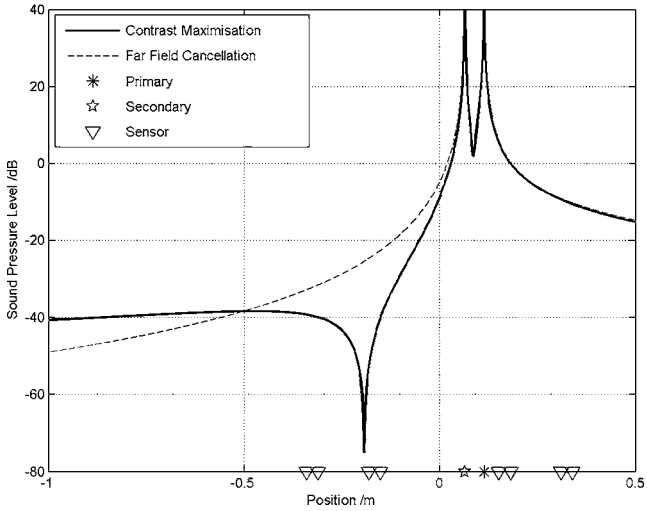

FIG. 6. Pressure level along the line joining the sources and microphone positions in Fig. 5 when the secondary source is adjusted to maximize the acoustic contrast, solid line, and when it is adjusted to cancel the far-field pressure, dashed line.

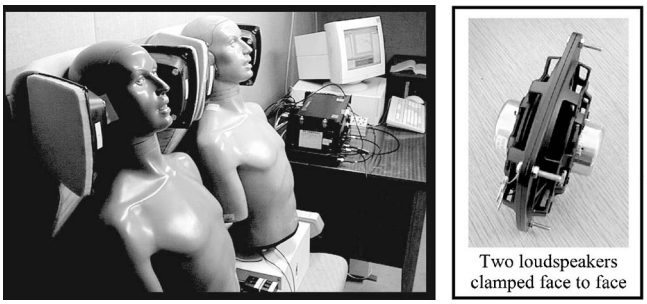

FIG. 7. Practical headrest arrangement with dummy heads in the two listening positions, left, and the two face-to-face loudspeakers to be mounted in the left-hand headrest of the right-hand seat, right.

The remaining headrests were only fitted with a single loudspeaker, of a similar type, in this preliminary setup.

Initially experiments were conducted in an anechoic chamber, in which the frequency response was measured from each loudspeaker to the microphones in each of the dummy heads, and also to microphones attached to the sides of the headrests, about 1 cm from the facing loudspeaker. The sum of the squared signals from the microphones both in the dummy head and on the surface of the headrest were used to define the overall level in the bright zone in the right-hand seat, and in the dark zone, in the left-hand seat. By manipulating the set of measured frequency responses, the optimum drive signals to the loudspeaker pair required to maximize the acoustic contrast was calculated, frequency by frequency, using the theoretical formulation discussed in Sec. II. The results in terms of this acoustic contrast are shown in Fig. 8, where the contrast without control, passive, and the contrast with control, active, are shown. Even when the outer loudspeaker is not being driven electrically, its cone moves

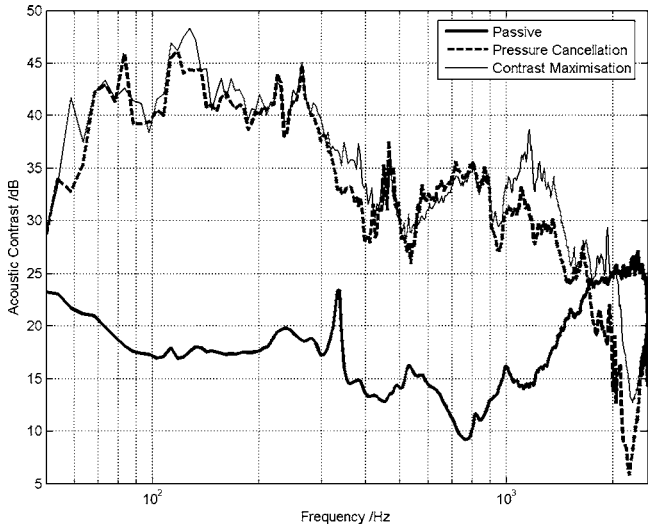

FIG. 8. Predictions of the acoustic contrast calculated as a function of frequency from the individual frequency response measurements between the loudspeakers and microphones in the anechoic chamber. The solid line is when only the single loudspeaker in the closed-back enclosure is driven, passive, the dashed line is when the outer loudspeaker in the open-backed pair is driven to cancel the pressure at a point in the adjacent seat, and the feint line is when this outer loudspeaker is driven to maximize the acoustic contrast. These results are almost identical if the control filters are constrained to be causal and truncated to 320 coefficients, which is the length used in the real-time implementation.

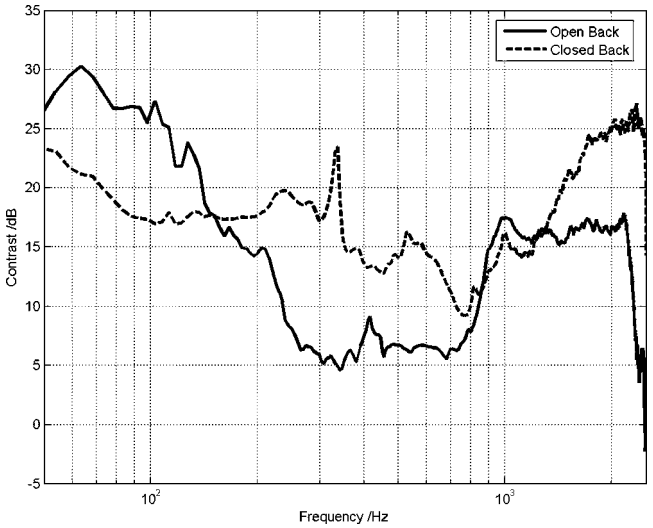

FIG. 9. Predictions of the acoustic contrast calculated from the individual frequency responses from a single loudspeaker and the microphones in the anechoic chamber. The solid line is when driving the inner loudspeaker of the loudspeaker pair mounted in an open-back enclosure, and the dashed line is when driving a single loudspeaker mounted in a closed-back enclosure in the same position.

due to acoustic coupling with the inner loudspeaker. In order to compare the actively controlled results with a passive system that approximated a single source, the open-backed loudspeaker pair was replaced by a single loudspeaker in a sealed enclosure, and all the pressure measurements repeated, in order to calculate the "passive" response with no control.

The acoustic contrast predicted using the simple monopole model for this geometry with no control is about 14 dB, independent of frequency. The measured acoustic contrast of the passive system is clearly worse than this from about 400 to 1 kHz, which is thought to be due to the presence of reflecting objects and local acoustic effects like resonant cavities. The passive acoustic contrast gets even worse in this frequency range when the back of the loudspeaker is removed and the second loudspeaker introduced, so that although the secondary loudspeaker in the pair is not driven electrically in the passive condition, it is acoustically excited by the primary loudspeaker so that the loudspeaker pair shows significant backward radiation. Figure 9 shows the results comparing the contrast without control using the loudspeaker pair, which is mounted in an open-backed enclosure, with that using only the single loudspeaker in a closed-backed enclosure. Apart from the peak at about 300 Hz, the calculated contrast with the single loudspeaker in the closed backed enclosure is more uniform than that of the loudspeaker pair in the open backed enclosure, which is particularly poor from about 200 to 800 Hz.

Of more significance than the absolute level of the contrast before control, however, is the improvement in acoustic contrast when the second loudspeaker is optimally driven. The improvement in acoustic contrast predicted by the monopole model when using a pair of monopoles rather than a single one is about 25–30 dB in this frequency range up to 2 kHz. The contrast calculated from the measured data, when the contrast is maximized, is shown as the feint line in Fig. 8.

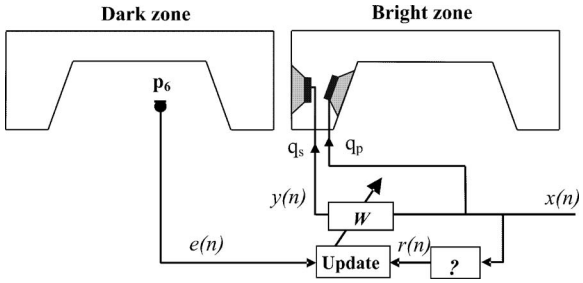

FIG. 10. Practical arrangement for the real-time implementation of an adaptive filter, **W**, driving the outer loudspeaker from the reference signal driving the inner loudspeaker, x, using the filtered reference LMS algorithm. The filter $\widehat{G}$ is the estimate of the plant response. Data converters and smoothing filters have not been included for clarity.

The improvement in contrast over the single loudspeaker result is about 20 dB below 300 Hz, falling to about 15 dB up to about 1 kHz. The frequency range was limited to 2 kHz in these experiments, but measurements on a similar arrangement by Chung[10] indicated that the predicted improvements in contrast became small above 2 kHz. The simple monopole model thus provides useful guidance on the performance of such systems up to 2 kHz, even though accurate prediction is not possible because the physical presence of the headrests and the heads of the listeners complicate the details of the sound field in the practical case.

Also shown by the dashed line in Fig. 8 is the acoustic contrast predicted from the anechoic measurements when the pressure at the ear of the right-hand dummy head closest to the adjacent seat was set to zero. This control strategy is inspired by the zero in the predicted pressure field in Fig. 6, and results in contrast values which are almost as high as those predicted under optimal conditions over the whole of the frequency range. The results from contrast maximization and pressure cancellation become even more similar when the control filter driving the second loudspeaker is constrained to be causal and of finite length. These results suggest that for this geometry near-optimal performance can be obtained using a rather simple control strategy.

Motivated by this similarity, a real time digital control system was implemented, using a dSPACE hardware/software system,[14] whose block diagram is shown in Fig. 10. The original audio signal driving the inner loudspeaker of the pair, $x(n)$, is passed through the adaptive filter W before being used to drive the outer loudspeaker. The filter is adapted using the filtered reference LMS algorithm[8] to minimize the pressure at one ear of the dummy head in the adjacent seat. The adaptive FIR filter used in this implementation has 320 coefficients and the sample rate used is 5 kHz. Once adapted, the coefficients of W are fixed, and the performance measured using a spectrum analyzer to estimate the combined frequency response of both sources to all the microphone positions. For these results the pair of seats is located in a small room approximately 6 m $\times$ 5 m $\times$ 2 m in size which had a reverberation time, T_{60}, of between 420 and 550 ms in the third octaves from 200 Hz to 2.5 kHz.

Figure 11 shows the acoustic contrast measured in the small room when driving only a single closed-back loudspeaker, and also the contrast when the pair of loudspeakers

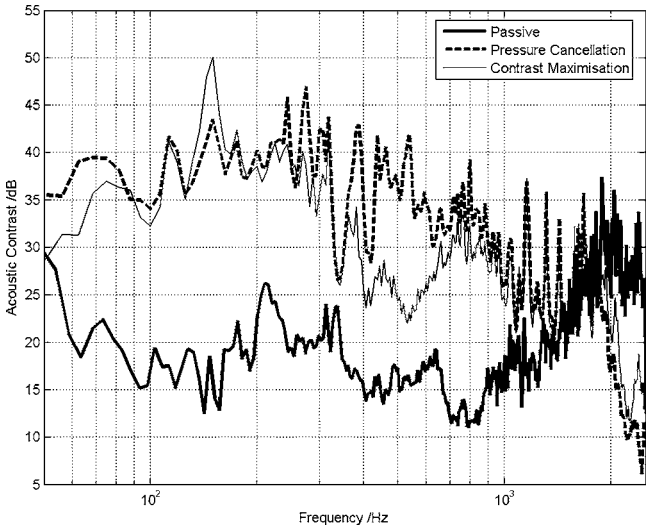

FIG. 11. The acoustic contrast as a function of frequency measured in a small room when driving only a single loudspeaker in a closed-back enclosure, solid, when the feedforward filter is implemented with a real-time system adapted to cancel the pressure at a point in the adjacent headrest (using the loudspeaker pair mounted in the open-back enclosure), dashed, and when the individual frequency responses are used to calculate the optimum performance for contrast maximization, feint.

mounted in the open-backed loudspeaker are driven, once the adaptive filter has fully converged. It is worth noting how similar these curves, measured with a real-time implementation in the small room, are to the corresponding curves in Fig. 8, calculated from the measurements made in the anechoic chamber. The passive contrast with the closed-back loudspeaker is greater in the room compared to that predicted in the anechoic chamber, which is probably due to increased levels in the bright zone due to reflections from nearby surfaces. There are also some additional dips and peaks that occur both before and after control in the small room, Fig. 11, due to individual modes in the room. It can be seen, however, that the general enhancement in contrast achieved using active control, and the variation with frequency, is similar for the two acoustic conditions. This is because the individual frequency responses between the loudspeakers and microphones are dominated by the direct response of the loudspeakers rather than the reflections off the walls, and are thus similar in the anechoic chamber and the small room. Most importantly, the levels of contrast using direct cancellation, implemented as shown in Fig. 10, are similar to those predicted from the anechoic chamber results and still show a significant improvement over the passive results. The feint line in Fig. 11 shows the predicted performance calculated from the individual frequency responses measured in the small room when the estimated contrast is maximized offline. It is interesting to note that at some frequencies the predicted optimal performance is worse than the performance measured after adaptive cancellation. This is thought to be due to the accumulation of errors in the calculation of the optimal performance from the measured frequency responses, which inevitably are not all measured simultaneously, and the ill conditioning of the matrix $\mathbf{Z}_D^H\mathbf{Z}_D$, which is inverted in the calculation of the filter that maximizes the

contrast in Eq. (4). The adaptive system is able to compensate for these small errors and thus achieve a better performance in this frequency range.

Informal listening tests indicate that the reduction in acoustic cross-talk between the seats is perceived as being very striking. The subjective impression when the active control system was switched on was that instead of the interfering sound appearing to come directly from the adjacent seat, it became more diffuse and noninvasive, and seemed to originate from many locations in the room. This is consistent with the control system operating to cancel the direct sound transmission, but not being able to cancel the reflected sound transmission, which will vary as people move about in the room. If the person in the left-hand seat was listening to a separate music channel or there was a reasonable level of background noise in the room, the audibility of the sound from the adjacent seat, when played at normal listening levels for a listener in that seat, would be significantly reduced when the control system was switched on.

Most importantly, however, was that good subjective impressions were maintained even if the listener moved their head side-to-side by the 5 cm or so distance allowed by the presence of the headrest, and up to about 15 cm forward and back or up and down. This suggests that the initial predictions from the monopole model, Fig. 5, that the sound is reduced over a significant region of space, also hold true in a practical implementation on a real headrest.

IV. CONCLUSIONS AND DISCUSSION

A number of arrangements of loudspeakers in the headrests of adjacent seats have been investigated to improve the acoustic isolation of reproduced sound between the seats. These were initially investigated using a simple free field model. An arrangement in which the loudspeakers in one seat were used to control the sound from an adjacent seat was predicted to give rather small zones of quiet so that the attenuation would be significantly affected by movements of the listener's head. A second arrangement looked more promising, in which a closely spaced pair of loudspeakers was used in one side of the headrest to both reproduce the sound in the seat to which it is attached and to cancel the sound radiated to the adjacent seat. This was predicted to produce much larger zones of quiet at higher frequencies, because the sound fields from the two loudspeakers would be much more closely matched if they were spaced close together compared with an acoustic wavelength. With a spacing of 5 cm the sources are within a tenth of a wavelength of each other, which is the spacing required for 10 dB of global control,[15] up to about 700 Hz.

These predictions were then investigated experimentally using a pair of thin loudspeakers mounted face to face in one side of the headrest. Measurements in the anechoic chamber confirmed that improvements in isolation of the order of those predicted should be possible, and also that this could be closely approximated by the practical strategy of adjusting a filter driving the outer loudspeaker from the signal driving the inner one to cancel the pressure at a point in the adjacent seat. An adaptive digital filter was then used to adjust such a filter in a real-time implementation. When the acoustic isolation was measured in a small room, the results were similar to those predicted from the anechoic chamber measurements, indicating that it is the direct field of the interfering sound which is dominant, even in a small room. Improvements in acoustic isolation of between 5 and 25 dB were measured from about 50 Hz to 2 kHz. These values are defined by comparing the contrast when the system is switched on with the passive contrast when only a single closed-back loudspeaker is driven.

Informal listening tests indicated that the reduction in crosstalk between the seats was impressive, that the residual sound was less intrusive, and that the subjective impression was maintained even for significant head movements.

The frequency response of the inner loudspeaker at the original listening position will be affected by such a cancellation system. However, it would always be possible to compensate for these effects at a single point by using a second filter to act on the signal $x(n)$ in Fig. 10 before it is fed to the inner loudspeaker. More formal listening tests are required to quantify the effects of such a system on the sound heard by two listeners in the adjacent seats.

It is not yet certain whether the control filter needs to be adapted for different environments, or whether a filter with a single fixed frequency response will give acceptable performance. If a fixed filter were acceptable, a simple modular system could be incorporated into each side of the headrest that only required a single input signal.

APPENDIX: EQUIVALENT MONOPOLE SOURCE POSITION FOR NEAR FIELD OF PISTON

The complex pressure a distance r along on the axis of a baffled piston of complex volume velocity q and radius a is given, assuming an $e^{j\omega t}$ time dependence, by[16]

$$p(r) = \frac{\rho_0 c_0 q_0}{\pi a^2}\left[e^{-jkr} - e^{-jk\sqrt{r^2+a^2}}\right]. \tag{A1}$$

Note that the piston velocity U_0 in Ref. 16 has been replaced by the volume velocity q_0 using the relation $U_0 = q_0/\pi a^2$, where πa^2 is the piston surface area.

If the pressure is measured very close to the piston, so that $r \ll a$, and the frequency is low enough that $kr \ll 1$, so that e^{-jkr} is almost unity, then

$$p \approx \frac{\rho_0 c_0 q_0}{\pi a^2}\left[1 - e^{-jka}\right]. \tag{A2}$$

Expanding the exponential into three terms of its infinite series, assuming $(ka)^3$ is negligible, Eq. (A2) can be written as

$$p \approx \frac{\rho_0 c_0 q_0}{\pi a^2}\left[1 - 1 + jka + \frac{(ka)^2}{2}\right], \tag{A3}$$

so that

$$p \approx \frac{j\omega\rho_0 q_0}{\pi a}\left[1 - j\frac{ka}{2}\right] \approx \frac{j\omega\rho_0 q}{\pi a}e^{-jkal/2}. \tag{A4}$$

This expression may be compared with the pressure a distance of d from a monopole source of strength q in an infinite baffle given by[16]

$$p = \frac{j\omega\rho_0 q_0}{2\pi d}e^{-jkd}. \tag{A5}$$

The magnitude and phase of the pressure in the near field of the piston are thus the same as that of an equivalent monopole source at a distance of

$$d = \frac{a}{2}, \tag{A6}$$

i.e., the distance from the equivalent monopole is half the piston radius, or one quarter of its diameter.

(Received 17 November 2005; revised 24 February 2006; accepted 24 February 2006)

This paper provides evidence for electrical $1/f$ noise as the dominant source of excess noise in piezoresistive microelectromechanical systems (MEMS) microphones. In piezoresistors, the fundamental noise sources may be divided into frequency independent thermal noise and frequency dependent $1/f$ excess noise dominating at low frequencies. Noise power spectra are presented for both commercial and research-prototype MEMS piezoresistive microphones as a function of applied voltage bias for both free and blocked membranes. The contributions of various mechanical and electrical noise sources are compared using a lumped noise equivalent circuit of the piezoresistive microphone. The bias dependence and membrane independence of the output noise indicate that the primary source of the excess noise is electrical in origin. © *2006 Acoustical Society of America.*

I. INTRODUCTION

The reduction of acoustic microphone size using microelectromechanical systems (MEMS) technology enables increased spatial resolution. However, whether the small size can be effectively utilized depends on the bandwidth, linearity, and the minimum detectable signal (MDS) of the microphone. The MDS is proportional to the total root-mean-square (rms) output noise due to all (acoustic, mechanical, and electrical) noise sources and inversely proportional to the overall sensitivity which depends on the transduction method and geometry.

The focus of this paper is on noise sources in piezoresistive MEMS microphones.[1–6] Piezoresistive transduction exhibits favorable scaling for small size compared to capacitive techniques.[7] Internal noise sources in piezoresistive microphones are divided into two categories. The first consists of noise sources present in all diaphragm-based microphones, pressure fluctuation noise due to the acoustic vent resistance, and mechanical thermal noise resulting from molecular agitation and structural damping of the diaphragm.[8] The second comprises noise sources specific to piezoresistive transduction, electrical thermal noise,[9,10] and electrical excess (or low frequency or $1/f$) noise in the piezoresistor.[11,12] Recently, there have been suggestions of a mechanical $1/f$ noise source that is correlated with the mechanical diaphragm damping resistance in condenser, piezoelectric, and piezoresistive microphones.[13,14] However, in contrast, electrical $1/f$ noise has been observed to be the dominant noise source in small piezoresistive cantilevers used in atomic force microscopy,[15,16] piezoresistive accelerometers,[17] and piezoresistive microphones.[3]

This present study investigates the dependence of output noise power spectra on bias voltage and membrane structure to elucidate the primary contribution to the measured low frequency noise in piezoresistive microphones. Both commercial and research prototype piezoresistive microphones are examined. The organization of this paper is as follows. First, noise mechanisms in piezoresistors are identified and the piezoresistive microphone structure and lumped noise equivalent circuit are reviewed. Next, the electrical noise measurement setup and method for extracting sensor noise from the amplifier setup noise are described. Experimental results using a metal film resistor with known noise spectra are presented and compared to theory. Then, output noise power spectra for commercial and research prototype piezoresistive MEMS microphones are measured as a function of bias voltage for free and fixed membrane structures. The paper concludes with a discussion of the dominant noise sources in piezoresistive microphones.

II. NOISE

In general, random fluctuations in a sensor output that do not originate in the input signal compose noise. In the electrical domain, nonrandom fluctuations (deterministic interference) caused by capacitively or inductively coupled electromagnetic interference may be present in the output signal, most commonly at 50 or 60 Hz and its harmonics due to interference from external power lines. These externally sourced deterministic fluctuations may be reduced through adequate shielding and proper grounding. However, intrinsic random fluctuations that originate from the sensor itself or the downstream amplifier circuit cannot be avoided by

[a)]Portions of this work were presented in "Sources of Excess Noise in Silicon Piezoresistive Microphones" at the 148th Meeting of the Acoustical Society of America, San Diego, CA, November 2004.

 0001-4966/2006/119(5)/2710/11/$22.50

shielding. These interfering random signals can be large enough to mask the signal of interest. Intrinsic noise sources are classified next in terms of the thermodynamic state and energy domain.

A. Noise sources

Noise in MEMS sensors can be classified by the absence (equilibrium) or presence (non-equilibrium) of external stimuli (voltage, light, thermal gradient, and strain). The magnitude of the noise depends on the material properties and the sensor geometry. Contributions of external amplifiers to the measured output noise will be discussed in Sec. IV on the noise experimental setup.

1. Electrical noise

Equilibrium thermal noise. Random scattering of charge carriers in thermodynamic equilibrium with the lattice give rise to voltage fluctuations at the terminals of a conductor or semiconductor piezoresistor. This equilibrium electrical noise was modeled by Nyquist[9] via a thermal noise voltage power spectral density (PSD),

$$S_{th} = 4k_B RT\,[V^2/\mathrm{Hz}], \tag{1}$$

where k_B is the Boltzmann constant, R is the resistance, and T is the temperature in Kelvin and was experimentally verified by Johnson.[10] Electrical thermal noise is independent of bias voltage since the agitation of the charge carriers by thermal lattice vibrations is present regardless of bias voltage. However, an increase in the temperature induces more agitation of the charge carriers, hence the Johnson (thermal) noise PSD is temperature dependent. Furthermore, Johnson noise is frequency independent because lattice vibrations are random, and thus are not related to any time constants.

Nonequilibrium $1/f$ *noise.* When an external voltage or current bias is applied to imperfect electrical conductors such as silicon with interfacial or bulk defects, an excess noise above the thermal equilibrium noise floor is observed that exhibits an inverse frequency $(1/f)$ dependence. The mechanism that generates electrical $1/f$ noise is still an active area of research. The two widely accepted mechanisms of electrical $1/f$ noise are the fluctuation in the bulk mobility $(\Delta\mu)$ described by Hooge[11] and the fluctuation in the number of carriers (Δn) developed by McWhorter.[12]

Hooge originally conducted noise experiments on homogeneous metal and semiconductor samples at low frequency.[11] The noise PSD in semiconductor samples exhibited an inverse frequency $(1/f)$ dependence, which he suggested was due to mobility fluctuations $(\Delta\mu)$ (Ref. 18) in the bulk semiconductor. He gave an empirical formula for the noise PSD of $1/f$ noise

$$S_V = \frac{\alpha V_{\mathrm{bias}}^2}{Nf}[V^2/\mathrm{Hz}], \tag{2}$$

where α is the Hooge parameter (an empirical material parameter varying from 1×10^{-6} to 1×10^{-3}), V_{bias} is the bias voltage, and N is the number of carriers. Since α is process dependent, α includes the effect of bulk defects. It is important to note that this nonequilibrium noise source is only observable when a voltage is applied across the resistor. In addition, the noise PSD is inversely proportional to the number of carriers N. Thus, the low frequency noise depends on the piezoresistor doping concentration N_{doping} and piezoresistor volume.

McWhorter[12] postulated that $1/f$ noise is caused by fluctuations of the number of surface charge carriers, due to trapping and detrapping of charge carriers at these traps. At the semiconductor surfaces and interfaces, physical defects give rise to electronic traps that capture and emit charge. Both Hooge's and McWhorter's $1/f$ noise models are actively used for modeling low frequency noise in electronic devices. The excess noise defined within the Hooge model can be expressed in terms of an effective α parameter which is a convenient figure of merit for device noise comparison between devices.[19] Thus, Hooge's model will be used to analyze the measured low frequency noise PSD of the MEMS piezoresistive microphone.

2. Mechanical noise

Equilibrium mechanical thermal noise. Mechanical thermal noise is the mechanical analog of electrical thermal noise. By the fluctuation-dissipation theorem, any dissipative mechanism that results in mechanical damping must be balanced by a fluctuation force to maintain macroscopic energy balance.[8] In analogy with Eq. (2), mechanical thermal noise is given by

$$S_{mth} = 4k_B R_m T\,[N^2/\mathrm{Hz}], \tag{3}$$

where R_m is the equivalent mechanical resistance.[8] An example of a fluctuation-dissipation mechanism in MEMS pressure sensors is thermal agitation of molecules impinging the diaphragm.[20]

Nonequilibrium mechanical $1/f$ *noise.* A mechanical $1/f$ noise correlated with the mechanical diaphragm damping resistance in condenser, piezoelectric, and piezoresistive microphones has been suggested.[13,14] In Ref. 14, the output noise of a condenser microphone was measured in an acoustic isolation vessel that maintained the microphone at constant temperature and pressure. The membrane noise was extracted by subtracting the preamplifier noise power (obtained when no external voltage was applied across the capacitor) from the total noise power of the biased capacitive condenser microphone. The resulting $1/f$ noise power spectrum was attributed to the mechanical diaphragm damping resistance. In Ref. 13, in addition to the well-known noise mechanisms present in piezoresistive microphone (mechanical thermal noise, Johnson noise, and electrical $1/f$ noise), a mechanical $1/f$ noise, correlated to the diaphragm damping resistance, was proposed.

III. PIEZORESISTIVE MICROPHONE

Before describing the noise measurement, the piezoresistive microphone structure,[3] operation, and lumped equivalent circuit are reviewed. When a pressure fluctuation impinges on the microphone, the diaphragm deflects producing a mechanical strain field. In a Wheatstone bridge circuit (Fig. 1) comprised of four silicon piezoresistors located at the diaphragm edge where the stress is maximum, the pressure-induced strain is transduced into an output voltage signal as discussed below. For a balanced bridge, the nominal unstressed resistances are equal, $R_1=R_2=R_3=R_4=R$, such that at zero pressure, the output bridge voltage is zero. Top and cross-sectional views of a circular diaphragm piezoresistive microphone (UF1) are shown, respectively, in Figs. 2(a) and

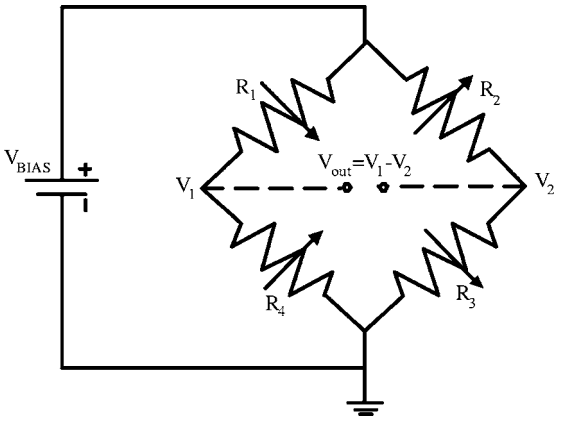

FIG. 1. Piezoresistors configured in Wheatstone bridge.

2(b).[3] Two tapered piezoresistors are positioned radially to sense the stress parallel to the current flow while the other two arc piezoresistors are placed tangentially to sense the stress perpendicular to the current flow. In a piezoresistor, the normalized resistance change $\Delta R/R$ is proportional to the longitudinal stress σ_l and transverse stress σ_t (defined with respect to the direction of current flow) through the longitudinal and transverse piezoresistance coefficients π_l and π_t, respectively,[21]

$$\frac{\Delta R}{R} = \sigma_l \pi_l + \sigma_t \pi_t. \tag{4}$$

When pressure is incident on a circular diaphragm microphone, the corresponding diaphragm pressure load p_d produces radial and tangential stresses $\sigma_r(r,\theta)$ and $\sigma_t(r,\theta)$ that are linearly related to p_d if the pressure-induced deflection is small.[22] Here, r and θ are the radius and polar angle, respectively. Noting that σ_l is longitudinal to current flow in the tapered resistor and transverse to current flow in the arc resistor, tapered and arc piezoresistors are designed with equal but opposite polarity resistance change[23]

$$\left.\frac{\Delta R(p_d)}{R}\right|_{\text{arc}} = -\left.\frac{\Delta R(p_d)}{R}\right|_{\text{tapered}}. \tag{5}$$

When the piezoresistors are arranged in a fully active Wheatstone bridge, these equal but opposite polarity resistance changes produce a differential output voltage $\Delta V_{\text{out}} = V_1 - V_2$ across the bridge that is proportional to the diaphragm pressure-induced resistance change $\Delta R(p_d)/R$ and the applied bias voltage V_{bias}

$$\Delta V_{\text{out}} = \frac{\Delta R(p_d)}{R} V_{\text{bias}}. \tag{6}$$

For use in the lumped element model of the piezoresistive microphone described below in Sec. III A, we define the mechanical voltage sensitivity

$$S_{\text{me}} = \left.\frac{\Delta R(p_d)}{R}\right|_{\text{arc}} \frac{V_{\text{bias}}}{p_d}. \tag{7}$$

A. Lumped element model

The dynamic input-output behavior of the piezoresistive microphone is modeled using an equivalent lumped two-port network circuit as shown in Fig. 3(a). Here, the distributed kinetic and potential energy in each energy domain of the microphone is lumped as an effective inertance and compliance[24] which is valid as long as the length scale of the microphone is much smaller than the acoustic wavelength. The lumped impedances are identified using two subscripts, the first refers to the energy domain, indicated by the subscript "a", for the acoustic domain, and the second refers to the specific component of the microphone. Given an input pressure $p_{\text{in}}(t)$ referenced to the microphone back cavity, there are two volumetric flow paths, (1) through the vent channel q_v and (2) through the deformation of the compliant diaphragm q_d. In the vent channel, dissipation via friction is modeled as a vent resistance R_{av}. The deformation of the compliant lossy diaphragm, induced by the volumetric flow,

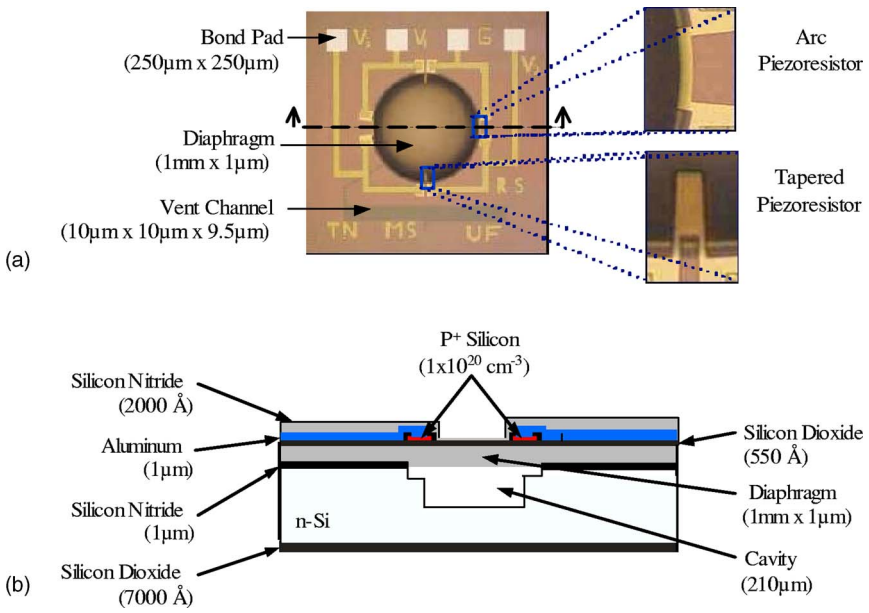

FIG. 2. (Color online) (a) Top view and (b) cross section of a piezoresistive microphone (Ref. 3).

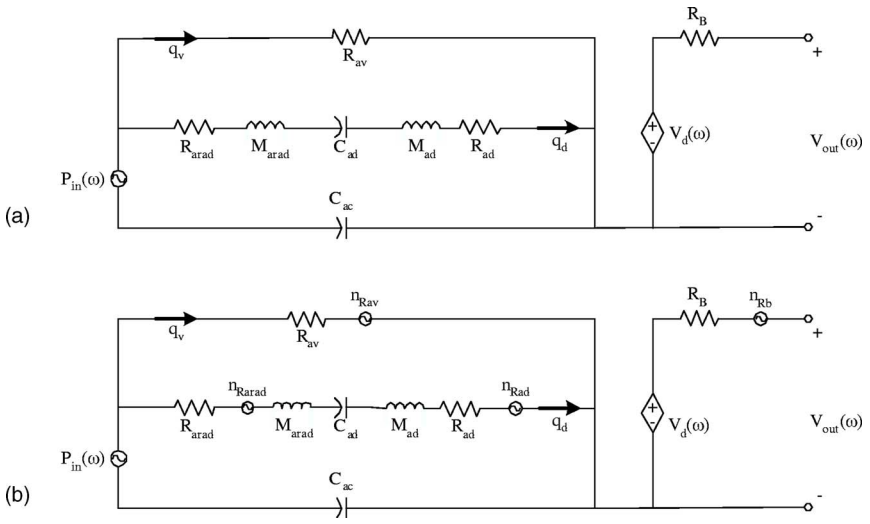

FIG. 3. (a) Lumped element model of a piezoresistive microphone, (b) noise equivalent circuit of a piezoresistive microphone.

is lumped in terms of an effective lumped mass of the diaphragm M_{ad}, damping resistance R_{ad}, and compliance of the diaphragm C_{ad}. In addition, the effect of the ambient fluid interaction with the membrane is modeled through the radiation mass of the diaphragm M_{arad} and the radiation resistance R_{arad}. The transduction of pressure to an output voltage is modeled as a dependent voltage source $V_d(\omega)$ in series with the bridge output resistance R_B. The dependent source shown in Fig. 3(a) is a function of the volumetric flow q_d instead of the bias voltage[25] since q_d is the flow variable in the acoustic domain part of the lumped equivalent circuit.

$$V_d(\omega) = \left(\frac{q_d}{j\omega C_{\mathrm{ad}}}\right) S_{\mathrm{me}}. \tag{8}$$

However, it is clear from the bias voltage dependence of S_{me} in Eq. (7) that there is no coupling between the acoustic input and the piezoresistive microphone electrical output if there is no applied bias voltage. Calculated values of the lumped parameters for the MEMS piezoresistive microphone shown in Fig. 2 are listed in Table I.[23,26]

B. Noise equivalent circuit

The noise equivalent circuit shown in Fig. 3(b) is obtained from the lumped element circuit [Fig. 3(a)] by shorting the input pressure, i.e., setting the acoustic pressure input to zero and replacing each dissipation element by an ideal noiseless dissipation element in series with its noise source.[27] Therefore, $n_{R_{\mathrm{av}}}(t)$ is the noise associated with R_{av}, $n_{R_{\mathrm{ad}}}(t)$ is the noise associated with R_{ad}, $n_{R_{\mathrm{arad}}}(t)$ is the noise associated with R_{arad}, and $n_{R_B}(t)$ is the noise associated with R_B. Also, M_{eff} is defined as $M_{\mathrm{av}}+M_{\mathrm{arad}}$. This noise equivalent circuit will be used to evaluate the relative contributions of the different noise sources in Sec. V.

IV. EXPERIMENTAL NOISE SETUP

Since the noise disturbance that limits the minimum detectable signal (MDS) of the microphone is small, special attention must be placed on the experimental noise setup, particularly to distinguish the noise in the device under test (DUT) from the noise present in the measuring equipment

and inadvertently picked up in the experimental setup. The setup noise PSD must be subtracted from the total measured noise PSD to determine the output noise of the DUT. The setup noise PSD is the contribution to the measured noise PSD by electromagnetic and acoustic interference as well as the noise present in the low-noise preamplifier (SRS560), the spectrum analyzer (SRS 785), and the power source. Electromagnetic interference is minimized by using three nested Faraday cages made up aluminum (3.48 mm thick), iron (1.46 mm thick), and high permeability magnetic foil (Less EMF Inc. - A276), single-point ground, and use of a lead acid battery (Panasonic - LC-R127R2P1) for biasing the MEMS microphones and the low noise preamplifier. The current and voltage noise PSD of the setup are measured, respectively, via open and short circuit of the preamplifier inputs. The preamplifier is ac coupled to block the dc bias. Differential input is employed to increase dynamic range through improved common mode noise rejection. When the SRS 560 is used during measurement, the filter is set as a bandpass filter with lower and higher limits set at 0.03 Hz and 300 kHz with ±6 dB/octave roll off. The gain is set to 1000 ensuring that the output signal of the preamplifier is higher than the noise floor of the spectrum analyzer ($<$10 nV_{rms} above 200 Hz) allowing accurate noise measurement. The spectrum analyzer is ac coupled with Hanning window selected to provide good selectivity and reduced power spectral density leakage. Overlapping frequency spans of 800 fast Fourier transform (FFT) lines are chosen in accordance to the degree of resolution desired. For instance, at low frequencies, a span of 12.5 Hz gives a frequency resolution of 15.625 mHz. At low frequencies, the binwidth is small to ensure good frequency resolution and therefore accurate measurements. At high frequencies, a larger frequency span of 12 800 Hz is used resulting in 16 Hz frequency resolution. Overall, the PSD is obtained by overlapping approximately the first 10% of each measurement span to minimize error due to leakage at the lowest frequencies since the digital window filter Hanning is not infinitely sharp. LABVIEW is used to automate the measurements. The experimental dc setup of the noise measurement is illustrated in Fig. 4.

The verification of the noise measurement setup is accomplished by using a 1 kΩ metal film resistor R_{dut} as the DUT since $1/f$ noise is minimal in metals at low current densities, thus its theoretical noise PSD is determined solely by the well-known thermal noise for a 1 kΩ resistance [4 $nV_{rms}/\sqrt{Hz}$ from Eq. (1)]. A small signal representation of the noise measurement setup is shown in Fig. 5. In this figure, S_{VRdut} is the thermal noise PSD associated with R_{dut}, and the input referred voltage and current noise sources of the preamplifier are represented by S_{va} and S_{ia}, respectively. The voltage noise source S_{va} of the preamplifier is obtained by shorting the input of the preamplifier, which allows the cancellation of S_{ia}. To measure the current noise power spectral density of the setup, the input of the preamplifier is open circuited. This permits cancellation of the voltage noise source S_{va}, allowing measurement of the current power spectral density S_{ia}. The voltage noise PSD of the DUT R_{dut} is extracted by subtracting the noise PSD contribution of the setup from the raw measured voltage PSD. The plot of the noise voltage PSD of the setup and raw PSD of a 1 kΩ metal film resistor without subtraction of the equipment setup noise

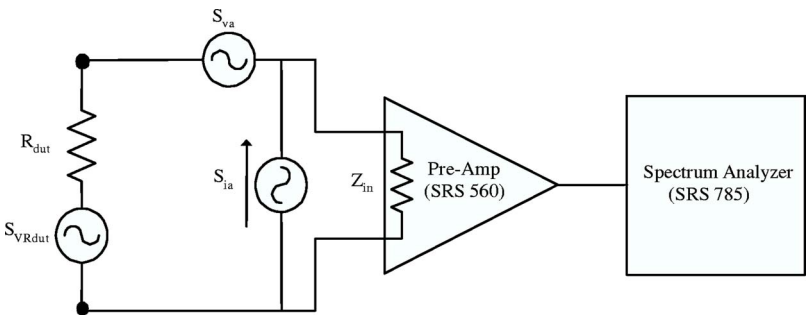

FIG. 5. Small signal representation of the setup with a 1 kΩ metal film resistor.

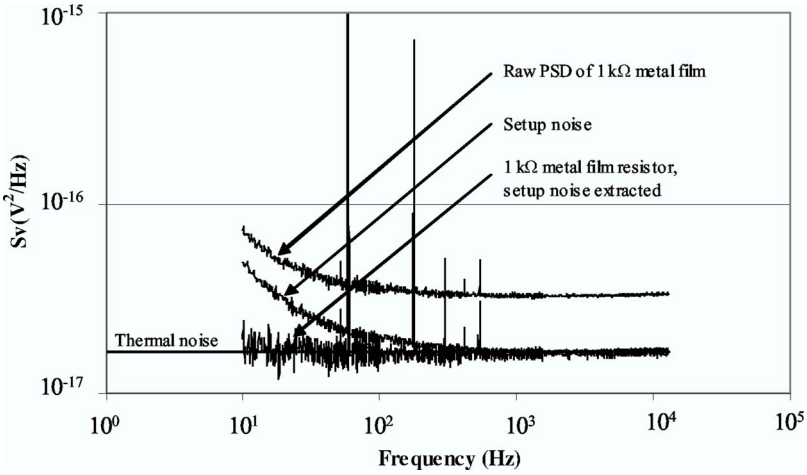

FIG. 6. Voltage noise PSD of a 1-kΩ metal film resistor without and with the subtraction of the equipment setup noise.

PSD is shown in Fig. 6. Once the setup noise PSD is subtracted from the raw noise PSD, the noise PSD of the 1 kΩ metal film resistor DUT is obtained. The noise PSD of the 1 kΩ metal film resistor, after the setup noise has been subtracted, also shown in Fig. 6, agrees well with the theoretical thermal noise PSD of a 1 kΩ metal film resistor, verifying the experiment noise setup and small signal model.

The preamplifier noise can be a limiting factor to a dc bridge noise measurement. If the preamplifier noise is larger than the DUT noise, the DUT noise PSD cannot be extracted from the raw measured noise PSD. To overcome this impediment, the microphone may be biased using an ac bias voltage to modulate the microphone low frequency noise to a frequency higher than the corner frequency of the preamplifier where it can be detected and measured. Figure 7 shows the setup for an ac bridge measurement.[28] Here, an ac modulation with carrier frequency f_c results in noise PSD at frequencies f_c-f_n and f_c+f_n, where f_n is the frequency component of the noise PSD. The ac bridge noise measurement method is useful when the measured low frequency noise PSD is dominated by the preamplifier noise at low frequencies. However, the measured ac modulated low frequency noise PSD must be multiplied by a factor of four to obtain the correct magnitude,[28] and there is a discontinuity of the PSD at the corner frequency since the frequency independent thermal noise cannot be ac modulated. Hence, the dc bridge noise measurement is preferred when the low frequency noise of the DUT is larger than the preamplifier noise so that a smooth, continuous noise PSD can be obtained.

V. MICROPHONE NOISE MEASUREMENT

In order to investigate the origin of the primary low frequency noise source in MEMS piezoresistive microphones, the noise PSD of four piezoresistive microphones was measured under equilibrium and varying nonequilibrium conditions. The four DUT consist of two commercial piezoresistive microphones [Kulite MIC-093 (Ref. 6) and Endevco 8510B-1 (Ref. 5)] and two research prototypes [piezoresistive microphone UF1) (Ref. 3) and piezoresistive

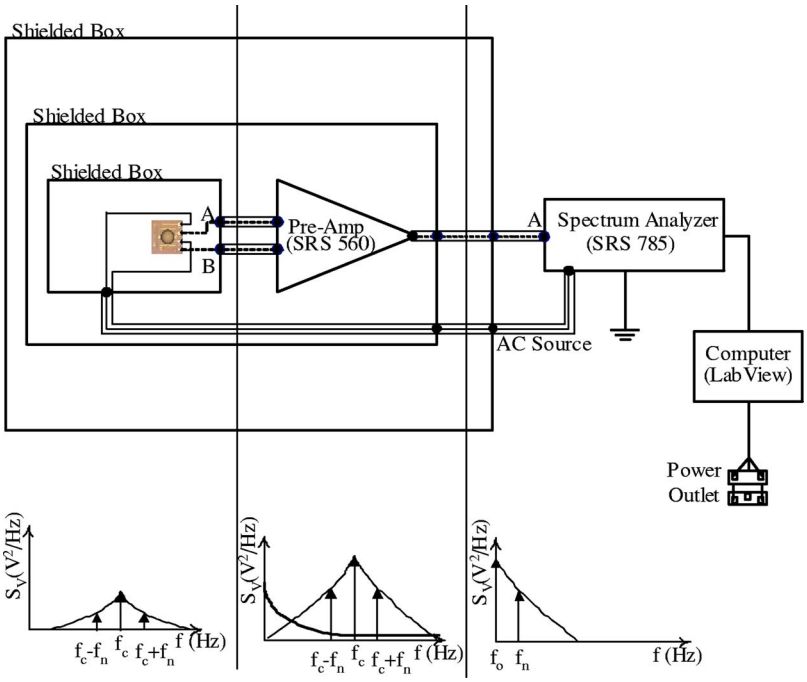

FIG. 7. (Color online) Experimental setup for an ac bridge measurement.

TABLE II. Measured input and output impedances and overall sensitivity of UF1 piezoresistive microphone, UF2 piezoresistive proximity sensor, and Kulite and Endevco piezoresistive microphones.

Microphones	Rin (Ω)	Rout (Ω)	Normalized overall sensitivity (μV/Pa V) at 1 kHz
UF1 piezoresistive microphone[a]	578	579	0.56
UF2 piezoresistive proximity sensor[b]	9623	9634	0.71
Kulite MIC-093[c] (with temperature compensation module)	3102	1148	0.42
Endevco 8510B-1[d]	2057	1820	2.69

proximity sensor UF2) (Ref. 4)]. The measured input and output impedances and overall normalized sensitivities (μV/Pa V) of the microphones are listed in Table II. Note that the Kulite microphone includes a temperature compensation module. The noise PSD of the piezoresistive microphones are evaluated using the experimental noise setup and procedures developed in Sec. IV. However, for the Kulite piezoresistive microphone, instead of a dc bias voltage, an ac bias voltage is used to extract the noise PSD since the low frequency noise of the Kulite microphone is less than the setup noise at low frequency.

A. Electrical bias dependence of 1/*f* noise

1. Excess noise under zero bias condition

Under zero bias, the excess noise coincides with the thermal noise as shown in Fig. 8(a) for research prototype UF1. In this case, the excess noise corresponds to the excess noise of the low noise preamplifier (SRS 560). The extracted noise PSD for UF1 at equilibrium after the setup noise PSD is subtracted, Fig. 8(a), shows good agreement with the theoretical thermal noise corresponding to the microphone output resistance. The UF1 noise PSD at zero bias is shown starting around 90 Hz since at lower frequencies the preamplifier noise dominates the UF1 noise PSD, thus it is impossible to proceed to the subtraction of the UF1 noise PSD from the raw measured noise PSD. The other three microphones show similar equilibrium noise PSD characteristics.

2. Excess noise under bias condition

Piezoresistive microphone (UF1). The voltage noise PSD of UF1 at different bias voltages is shown in Fig. 8(b). One can observe from Fig. 8(b) that as the bias voltage increases, the magnitude of the excess noise at low frequencies increases. At zero bias, there is no excess noise, and the noise PSD coincides with the thermal noise predicted by the device resistance (Table II). However, at high frequencies regardless of the bias voltage, the noise PSD asymptotically coincides with the Johnson noise of the DUT. The corner frequency between $1/f$ and thermal noise is approximately 1×10^4 Hz for the UF1 microphone. The Hooge parameter is extracted from the measured PSD at a low frequency (where $1/f$ noise is dominant) as a function of external bias using Eq. (2). This may be accomplished when the geometry of the piezoresistor and the doping concentration profile are known which is the case for the two research prototype MEMS microphones (UF1 and UF2). The average Hooge parameter extracted at 12 Hz using the three external bias voltages shown in Fig. 8(b) is $(3.2\pm0.3)\times10^{-3}$ for UF1.

Piezoresistive proximity sensor (UF2). The PSD of the piezoresistive proximity sensor (UF2) is measured with the same equipments and settings as the piezoresistive microphone (UF1). However, a bias is applied to the substrate since the piezoresistors in UF2 are junction isolated while

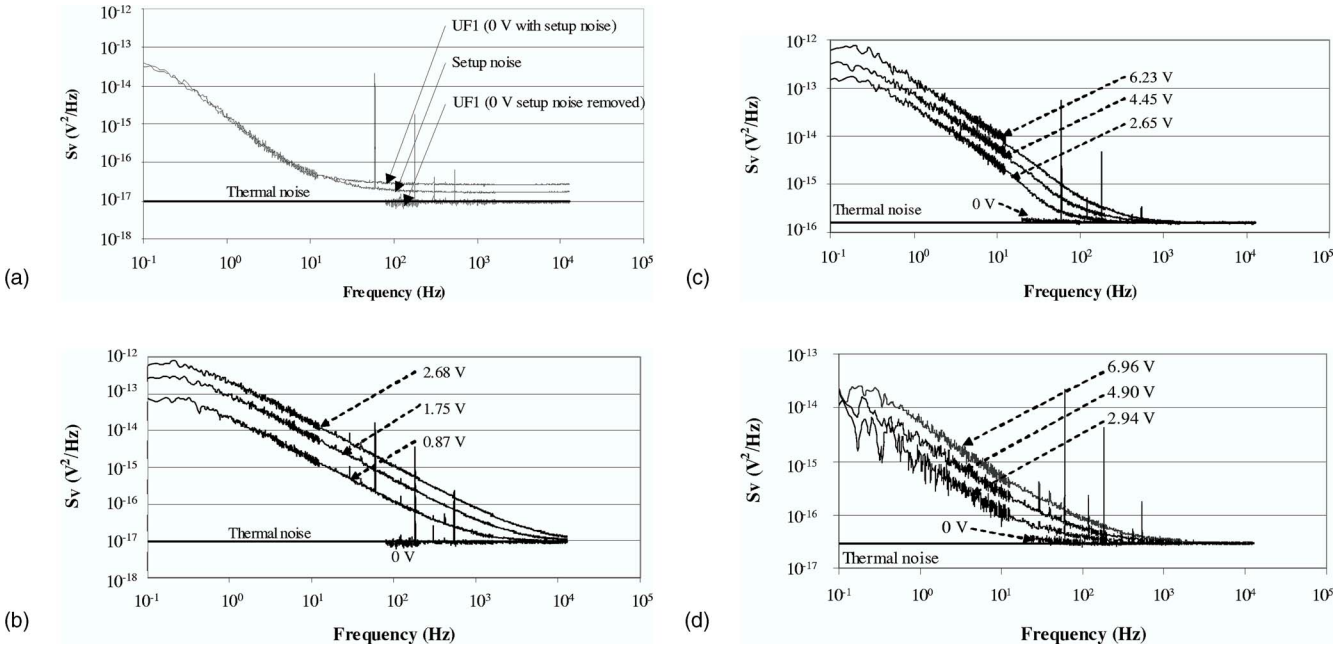

FIG. 8. (a) Power spectral density of UF piezoresistive microphone at zero bias voltage, (b) power spectral density of UF piezoresistive microphone at different bias voltages, (c) power spectral density of UF proximity sensor at different bias voltage (constant reverse bias of −0.5 V), and (d) power spectral density of Endevco microphone (Model 8510B-1) at different bias voltage.

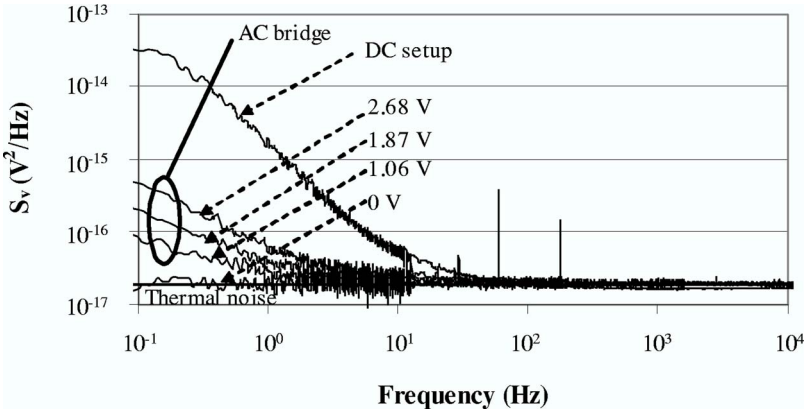

FIG. 9. Power spectral density of Kulite microphone (MIC-093) at different bias voltage compared to the dc setup noise.

the piezoresistors in UF1 are dielectrically isolated. The substrate is biased at 6.71, 4.99, and 3.15 V when the sensor is biased, respectively, at 6.23, 4.45, and 2.65 V. This leads to a reverse bias voltage of about −0.5 V that corresponds to a relatively small isolation leakage current of 0.96 nA. Since the shot noise PSD is directly proportional to the leakage current $S_v = 2qI$, the contribution of shot noise is negligible. The voltage noise PSD curves of UF2 with different bias voltages are shown in Fig. 8(c) at a constant reverse bias of −0.5 V. A similar behavior is observed, that is, the excess noise increases as the bias voltage is increased. The corner frequency is approximately 100 Hz, and the Hooge parameter estimated using Eq. (2) and Fig. 8(c) is $(6.1 \pm 0.6) \times 10^{-5}$.

Endevco piezoresistive microphone. The noise measurements are conducted on the commercial Endevco 8510B-1 piezoresistive microphone using the same conditions as the previous microphones. The noise power spectral density obtained is shown in Fig. 8(d). The excess noise again shows a voltage bias dependence. The corner frequency is approximately 100 Hz.

Kulite piezoresistive microphone. The noise power spectral density of the Kulite microphone (MIC-093) is obtained using an ac bridge because the low frequency noise is less than the dc setup noise. The noise measurements are conducted with an ac bias frequency of 50 kHz and different peak voltage bias amplitudes of 1.06, 1.87, and 2.68 V. The noise PSD of the Kulite microphone is shown in Fig. 9. As seen in Fig. 9, the measured noise PSD at low frequency is less than the dc setup noise, hence an ac bridge is required. The corner frequency is 10 Hz.

In summary, all four piezoresistive MEMS microphones, both commercial and research prototypes, show a voltage bias dependence of the excess noise. The acoustic interference contribution to the measured electrical noise is discussed next.

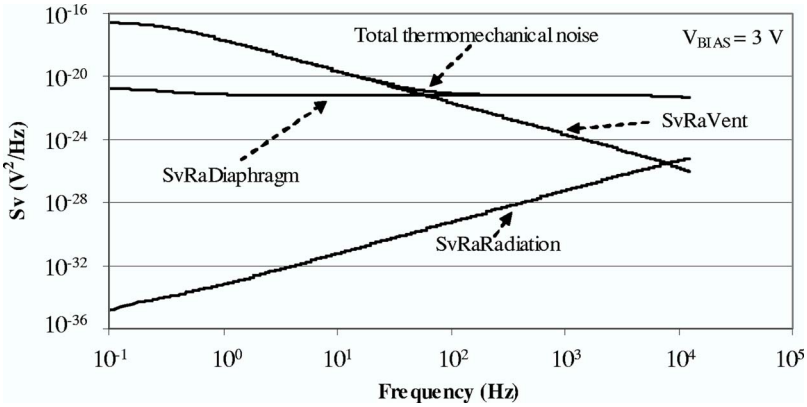

FIG. 11. Power spectral densities of noise sources due to the damping resistance, the radiation resistance, and the vent resistance.

3. Acoustic isolation test

The purpose of the acoustic isolation test is to quantify the acoustic sound pressure in the Faraday cage using a sensitive Bruel and Kjaer (B&K) microphone (model 4138) during the electrical noise measurement. The 1/8-in. Bruel and Kjaer 4138 condenser microphone at 1 kHz has a noise level of about 26 dB for a 3.16 Hz bin.[29] Figure 10(a) plots the measured acoustic pressure PSD for the Bruel and Kjaer 4138 condenser microphone and the UF1 microphone that were measured simultaneously. The measured acoustic PSD using the Bruel and Kjaer 4138 condenser microphone is approximately two orders of magnitude smaller than the measured acoustic PSD of the piezoresistive MEMS microphone UF1 in the triple nested Faraday cage. The coherence between the acoustic signal of the Bruel and Kjaer 4138 condenser microphone and the UF1 piezoresistive microphone (electrical noise in UF1 since the actual acoustic signal is two orders of magnitude smaller), shown in Fig. 10(b) is small for most frequencies. Although the acoustic isolation is not as elaborate as in Ref. 30, the acoustic isolation is sufficient such that the acoustic interference contribution to the measured electrical noise is negligible.

B. Membrane contribution to 1/*f* noise

To investigate whether the dominant source of the measured $1/f$ noise of the four piezoresistive microphones is mechanical or electrical in origin, two tests are applied. First, the output noise due to thermomechanical noise sources is computed using the noise equivalent circuit developed in Fig. 3(b) and compared to the measured output voltage noise PSD. Second, the dependence of the output noise on the membrane (fixed versus free) is measured as a function of applied voltage bias.

1. Thermomechanical contribution

The output voltage noise PSD due to thermomechanical fluctuation dissipation in the vent resistance, diaphragm damping resistance, and radiation resistance are calculated using the noise equivalent circuit shown in Fig. 3(b) and compared to the measured output voltage noise PSD. Since the detailed geometry is known for UF1, the thermomechanical contribution to the output voltage noise PSD is estimated for the piezoresistive microphone UF1, using values of the lumped element parameters given in Table I and the mechanical voltage sensitivity, S_{me} (2.9 μV/Pa at 1 kHz and 3 V dc bias) which is extracted from the measured overall sensitivity given in Table II at a specific frequency and bias voltage.

The output noise voltage PSD due to three thermomechanical noise courses (fluctuation dissipation in the vent resistance, diaphragm damping resistance, and radiation resistance) are calculated using the noise equivalent circuit in Fig. 3(b) and plotted in Fig. 11 for UF1. Among the thermomechanical noise sources, the output voltage noise PSD due to the vent resistance is seen to be dominant at low frequencies and frequency shaped by the noise equivalent circuit. The total estimated thermomechanical output voltage noise PSD is the sum of the three thermomechanical noise source contributions to the output voltage PSD. Although the ther-

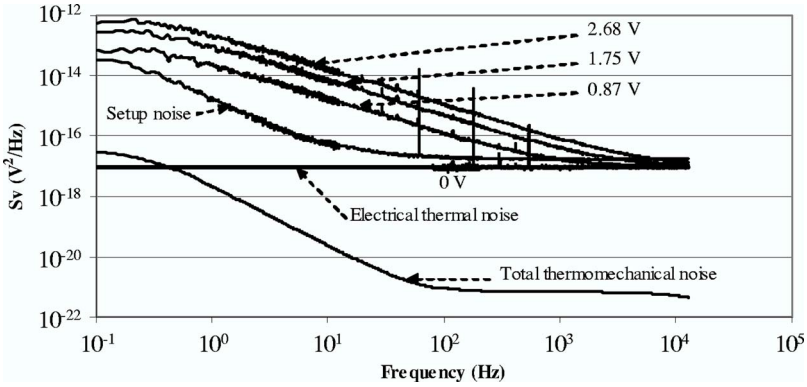

FIG. 12. Power spectral densities comparison of total thermomechanical noise to setup noise, electrical thermal noise, and electrical $1/f$ noise.

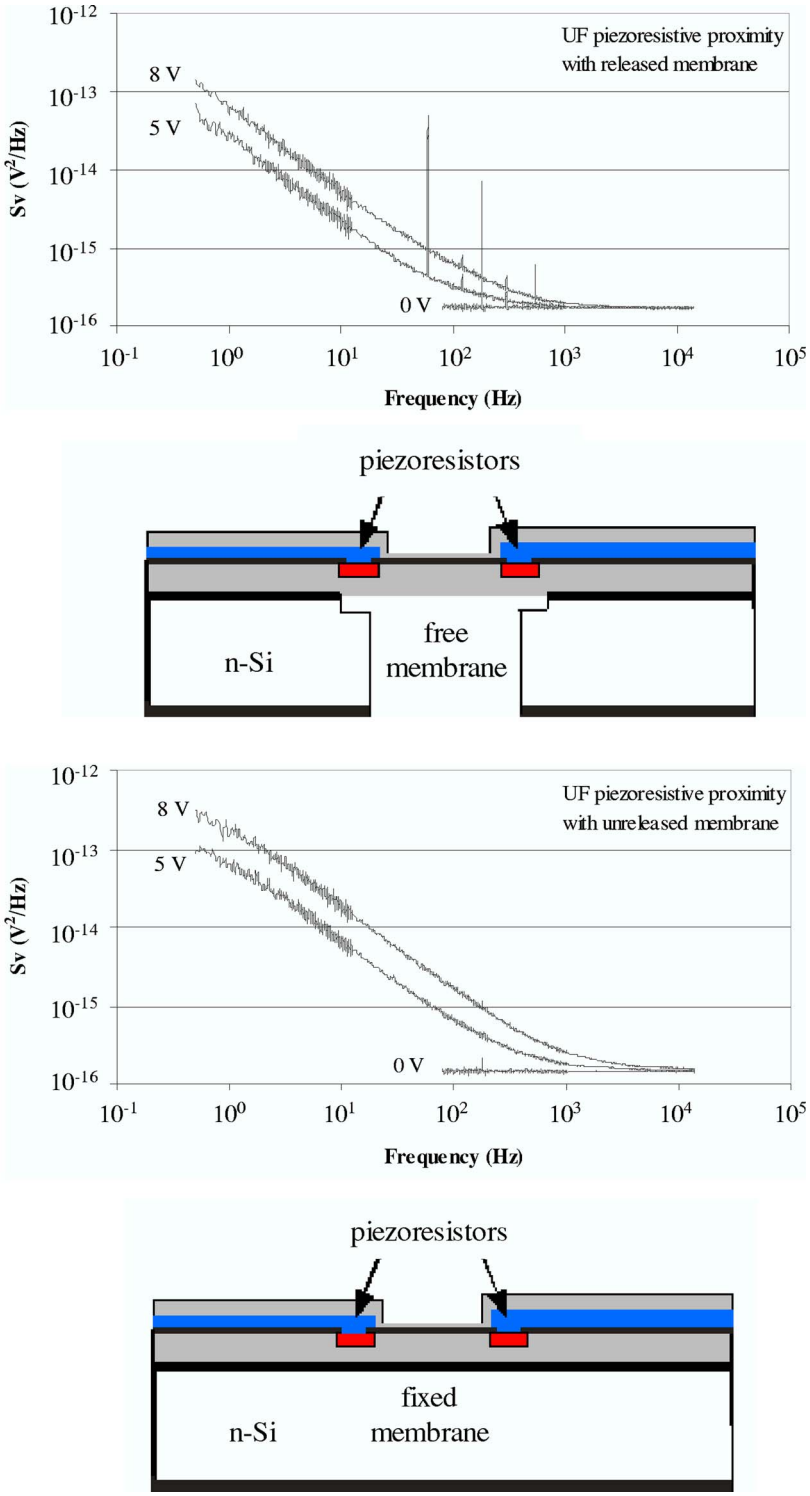

FIG. 13. (Color online) (a) Power spectral density of the UF piezoresistive proximity sensor with free diaphragm and (b) power spectral density of the UF piezoresistive proximity sensor with fixed diaphragm.

momechanical noise sources are not functions of frequency, their respective output voltage noise spectra are frequency shaped by their location in the noise equivalent circuit. When compared to the setup noise PSD, electrical thermal noise PSD, and the electrical $1/f$ noise PSD in Fig. 12, thermomechanical noise is seen to be negligible with respect to the aforementioned electrical noise sources for the biased piezoresistive MEMS microphones investigated in this study. This suggests that the dominant source of the measured $1/f$ noise of the four piezoresistive microphones is electrical in origin.

2. Membrane contribution

As a second test, the output voltage noise PSD is measured on two identical piezoresistive devices (UF2) except that one has a free membrane and the other has a fixed membrane. If the noise is primarily mechanical in origin, then a $1/f$ noise PSD characteristic must be present on the microphone with the free membrane but not on the fixed membrane, independent of electrical bias. Figure 13(a) shows the PSD of UF2 with a free diaphragm, and Fig. 13(b) shows the PSD of UF2 with a fixed diaphragm. Comparing Figs. 13(a)

and 13(b), excess noise is measured on both the mechanically free and fixed diaphragms. In addition, as the bias voltage increases, the PSD at low frequencies increases for both devices. The bias dependence and membrane independence of the output noise and negligible thermomechanical contribution indicate that the primary source of the excess noise observed in the four commercial and research-prototype piezoresistive MEMS microphones studied is electrical in origin.

VI. CONCLUSIONS

Using a validated noise setup, the noise PSD for four piezoresistive microphones has been investigated: two commercial piezoresistive microphones [Kulite (MIC-093) and Endevco (8510B-1)] and two research prototypes [piezoresistive microphone (UF1) (Ref. 3) and piezoresistive proximity sensor (UF2) (Ref. 4)]. Each of these measurements reveals a voltage bias dependence of the excess noise which is indicative of an electrical $1/f$ noise source. At zero bias, the DUT noise reduces to the thermal noise limit at equilibrium as expected. Using a noise equivalent circuit, the thermomechanical output voltage noise PSD due to the vent resistance, diaphragm damping resistance, and radiation resistance is found to be negligible compared to the setup noise PSD, electrical thermal noise PSD, and the electrical $1/f$ noise PSD. In addition, a bias-dependent low frequency noise was also observed on both fixed and free diaphragm piezoresistive microphones. The bias dependence and membrane independence of the output noise indicate that the primary source of the excess noise observed in the four commercial and research-prototype piezoresistive MEMS microphones studied is electrical in origin.

(Received 11 July 2005; revised 16 February 2006; accepted 19 February 2006)

Sound field reproduction finds applications in music or audio reproduction and experimental acoustics. For audio applications, sound field reproduction can be used to artificially reproduce the spatial character of natural hearing. The general objective is then to reproduce a sound field in a real reproduction environment. Wave field synthesis (WFS) is a known open-loop technology which assumes that the reproduction environment is anechoic. For classical WFS, the room response thus reduces the quality of the physical sound field reproduction. In this paper, adaptive wave field synthesis (AWFS) is analytically investigated as an adaptive sound field reproduction system combining WFS and active control with a limited number of reproduction error sensors to compensate the response of the listening environment. The primary point of this paper is the definition of AWFS. Therefore, the fundamental behavior of AWFS is illustrated by analytical considerations and simple free-field simulation results. As demonstrated, AWFS is fundamentally related to WFS and "Ambisonics." The paper introduces independent adaptive control of sound field reproduction on the basis of radiation modes, via the singular value decomposition of the transfer impedance matrix. Possible practical independent control of radiation modes for AWFS is discussed. [DOI: 10.1121/1.2186514]

I. INTRODUCTION

Sound field reproduction finds applications in music or audio reproduction (multisensory immersion for teaching, concerts, etc. (Woszczyk *et al.*, 2005), and experimental acoustics and psychoacoustics. For audio applications, sound field reproduction can be used to artificially reproduce the spatial character of natural hearing. Such a challenge has always fascinated both inventors and sound artists (Poulin, 1957; Malham and Myatt, 1995; Davis, 2003; AES Staff Writer, 2005). The general objective is to reproduce a sound field in a real reproduction environment. [See AES Staff Writer (2005) for a review of spatial and multichannel audio.]

Wave field synthesis (WFS) is an open-loop sound field reproduction technology which assumes that the reproduction environment is anechoic (Berkhout, 1988, 1993; Verheijen, 1997). For objective sound field reproduction, classical WFS thus does not perform well in a real reproduction space (Gauthier *et al.*, 2005b). Typical physical inaccuracies are caused by the room resonant response at low frequencies along with reflections and reverberation at higher frequencies. Adaptive wave field synthesis (AWFS) is investigated as a potential solution for room compensation with a limited number of acoustic sensors. The primary point of this paper is the theoretical analysis of AWFS. Therefore, the fundamental behavior of AWFS is illustrated by analytical considerations and simple free-field simulations. Other research has been devoted to in-room sound field reproduction or local sound reproduction using various approaches often derived from adaptive control (Kirkeby and Nelson, 1993; Nelson, 1994; Asano and Swanson, 1995; Uto and Hamada, 1995; Kirkeby *et al.*, 1996; Garas, 1999; Ise, 1999; Santillań, 2001; Corteel *et al.*, 2002; Nelson, 2002; Spors *et al.*, 2003; Epain *et al.*, 2004; Gauthier *et al.*, 2005a; Schobben and Aarts, 2005; Spors *et al.*, 2005; Fuster *et al.*, 2005).

This paper theoretically introduces AWFS which is a combination of optimal control and open-loop wave field synthesis designed for active sound field reproduction. The adaptive nature of AWFS comes from the use of reproduction error sensors that observe the system performance and adapt the input of the reproduction sources. What differentiates AWFS from classical active control is that the regularization is not included as a quadratic effort-penalty term in the cost function, but as a quadratic departure penalty from the WFS solution.

Although AWFS can be applied to any source and sensor configuration, numerical results are presented here for a small, central and compact sensor array that provides WFS compensation without occupying the reproduction space with a large and impractical sensor array. As discussed in previous reports (Gauthier *et al.*, 2005a), such a reduced sensor array is used as a practical compromise. However, the use of a limited number of reproduction sensors results in interesting properties of AWFS.

A compact sensor array is investigated here as a practical alternative to larger or circular sensors arrays that have

[a)]Portions of this work were presented in "Wave field synthesis, adaptive wave field synthesis and ambisonics using decentralized transformed control: Potential applications to sound field reproduction and active noise control," 150th ASA meeting, Minneapolis MN, October 2005.

[b)]Electronic mail: philippe_aubert_gauthier@hotmail.com

been previously proposed. They were suggested for applications such as sound field recording (Hulsebos *et al.*, 2003; Poletti, 2005). WFS room compensation (Spors *et al.*, 2003, 2005); and active sound field reproduction (Betlehem and Abhayapala, 2005).

As introduced by Spors *et al.* (2003; 2005), one approach to active compensation in WFS is to work in a transformed domain which can potentially uncouple the problem. In the present paper, it is shown that AWFS can be achieved in a transformed domain based on the source modes and pressure modes derived from the singular value decomposition (SVD) of the source-sensor transfer impedance matrix. SVD has found various applications in acoustics (Nelson, 2001; Nelson and Kahana, 2001; Nelson, 2002; Williams *et al.*, 2003; Bai and Kwuen-Yieng, 2005).

Recently, Bai and Elliott (2004) used a plant transfer matrix SVD to define an uncoupled adaptive system. This was motivated by the need to accelerate the convergence of standard LMS adaptive multichannel algorithms and the results are illustrated in the context of binaural sound field reproduction with cross-talk cancelation. The authors used two complementary methods: (1) prewhitening of the reference and (2) plant uncoupling via SVD of the transfer impedance matrix in the frequency domain and time-domain realization of the resulting uncoupled multichannel system. This proved to accelerate the LMS convergence rate at the cost of a processing delay.

Section II of the paper presents the radiation, WFS and AWFS models. Section III introduces a first interpretation of the AWFS mechanism. Numerical simulations are introduced in Sec. IV. Section V expands the theoretical behavior of AWFS on the basis of the SVD of the transfer impedance matrix including room effects. Section VI specifically shows the link between AWFS and closed-loop "Ambisonics." Practical considerations for independent radiation mode control are discussed in Sec. VII.

II. RADIATION, WFS AND CONTROL MODELS FOR AWFS

Let an active sound field reproduction system be represented by L monopole reproduction sources located at $\{\mathbf{x}_1^{(l)} \cdots \mathbf{x}_L^{(l)}\}$ and M sound pressure sensors located at $\{\mathbf{x}_1^{(m)} \cdots \mathbf{x}_M^{(m)}\}$ where $\mathbf{x}$ are position vectors expressed in rectangular coordinates (see Fig. 1 for an explanatory sketch). In the frequency domain, the sound pressure field radiated by the reproduction sources is defined as follows at radial frequency ω [rad/s]

$$\mathbf{p}^{(\mathrm{rep})}(\omega) = \mathbf{Z}(\omega)\mathbf{q}(\omega), \tag{1}$$

where $\mathbf{p}^{(\mathrm{rep})}(\omega)$ is a M coefficients column vector comprising the reproduced complex sound pressures [Pa] at sensor locations, $\mathbf{Z}(\omega)$ is a $M \times L$ transfer impedance matrix and $\mathbf{q}(\omega)$ [m^3/s] is the L coefficients reproduction source strength column vector. The frequency dependance may be omitted. All components in Eq. (1) are complex. For practical reasons, it is assumed that $M < L$ since a convenient system should not introduce a large number of sensors in the reproduction space. For free-field radiation, the

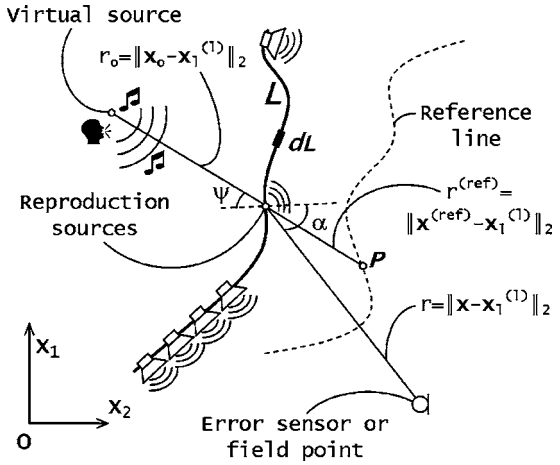

FIG. 1. Symbol convention for the WFS operators definition. The virtual source is located in $\mathbf{x}_o$. The reproduction source l is located in $\mathbf{x}_l^{(l)}$. $\mathbf{x}^{(\mathrm{ref})}$ describes points which belong to the reference line. $\mathbf{x}$ describes any field point and $\mathbf{x}_m^{(m)}$ is the m sensor position. L is the reproduction source line, the virtual source is on the left of the source line and the reproduction space is on the right of the source line. All sources and sensors are located in the x_1-x_2 plane.

transfer impedance matrix coefficients are defined by the free-field Green's function $G(\mathbf{x}|\mathbf{x}_l^{(l)})$ (Pierce, 1991; Nelson and Elliott, 1992)

$$Z_{ml} = -j\omega\rho G(\mathbf{x}_m^{(m)}|\mathbf{x}_l^{(l)}) \tag{2}$$

with

$$G(\mathbf{x}|\mathbf{x}_l^{(l)}) = \frac{e^{jk|\mathbf{x}-\mathbf{x}_l^{(l)}|}}{4\pi|\mathbf{x}-\mathbf{x}_l^{(l)}|}, \tag{3}$$

where $\mathbf{x}$ [m] is the field point, $\mathbf{x}_l^{(l)}$ [m] the l source position, $k=\omega/c$ [rad/m] the wave number (with sound speed $c=331$ m/s) and ρ [kg/m^3] the air density ($\rho=1.18$ kg/m^3). The time convention is $e^{-j\omega t}$ [$p(\mathbf{x},t)=p(\mathbf{x},\omega)e^{-j\omega t}$]. Without loss of generality, the following analytical developments can also be applied to Green's functions defined for semi-infinite or finite spaces. Free-field Green's functions are used here to illustrate general results of the fundamental AWFS behavior, through simple simulations. With these simulations, our primary objective is to clarify and illustrate the theoretical properties of AWFS.

The reproduction goal is defined as a target pressure field produced by a virtual source located at $\mathbf{x}_o$ [m]

$$p^{(\mathrm{im})}(\mathbf{x},\omega) = A(\omega)\frac{e^{jk|\mathbf{x}-\mathbf{x}_o|}}{|\mathbf{x}-\mathbf{x}_o|}, \tag{4}$$

where k is the wave number and $A(\omega)$ is the virtual source monopole amplitude, which is set to unity. Such a specific target wave field is used for simulation purposes. It could be replaced by any other target field definition (plane or directive fields, for example) and the remaining analytical developments would still be valid. Indeed, a part of the main points presented in this paper relies on analytical developments where no assumptions about the nature of $p^{(\mathrm{im})}(\mathbf{x},\omega)$ or $G(\mathbf{x}|\mathbf{x}_l^{(l)})$ are included. The virtual source position is arbitrary. A virtual source "in front" of the source array (i.e., on the same side as the listening space) is often cited

as an interesting practical possibility of sound field reproduction. In this paper, virtual sources are always located "behind" the array (with respect to the listening space).

A. WFS operators

WFS is an open-loop technology for sound field reproduction which assumes a free-field reproduction space (Berkhout, 1993; Verheijen, 1997). The WFS operators are defined from the Kirchhoff-Helmholtz integral theorem. These operators are then used to drive a reproduction source array according to the virtual source definition and to the reproduction source array geometry. In free-field conditions, using these WFS operators along with the source array would then approximately reproduce the target field produced by the virtual source. The WFS problem is usually limited to reproduction in the horizontal plane by means of a finite number of discrete sources using appropriate simplifications of the integral formulation (Verheijen, 1997; Nicol and Emerit, 1999; Spors *et al.*, 2005). A monopole array for WFS would be fed by the normal virtual sound pressure gradient evaluated along the reproduction source line. This is obtained using the monopole radiation part of the Kirchhoff-Helmholtz integral with the stationary phase approximation (Junger, 1993; Verheijen, 1997). Both the stationary phase approximation and the source line discretization introduce reproduction errors. Moreover, usage of a truncated reproduction array or piecewise linear array in practical WFS implementation causes finite aperture and corner effects which produce reproduction errors (Verheijen, 1997). The above WFS reproduction errors are readily observable in free field but they are masked in rooms by the comparatively large room effects. [This was observed by time- and frequency-domain numerical simulations in comparison with objective WFS sound field reproduction measurements in a real studio (Gauthier *et al.*, 2005b).]

On the one hand, the inherent free-field assumption of WFS reduces the objective accuracy of the sound field reproduction in real situations, thus suggesting the need for a closed-loop compensation (Spors *et al.*, 2003; Gauthier *et al.*, 2005b). On the other hand, WFS provides satisfactory results for sound localization by the human auditory system since the WFS direct field approaches the target field (Gauthier *et al.*, 2005b). (It is possible to decompose the WFS reproduced field as the superposition of a direct field and a field which is reverberated by the room walls and furniture surfaces.) Direct-field reproduction is critical for accurate subjective localization (Blauert, 1999). Therefore, the active compensation introduced by AWFS includes a departure penalty from the WFS operators, thus motivating the adaptive WFS terminology. The WFS operators are defined as follows (Verheijen, 1997):

$$Q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega) = -A(\omega)j\sqrt{\frac{jk}{2\pi}}\cos\Psi\frac{e^{jkr_o}}{\sqrt{r_o}} \times\sqrt{r^{(\mathrm{ref})}/(r^{(\mathrm{ref})}+r_o)}\Delta_l \tag{5}$$

and

$$q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega) = -\frac{4\pi Q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega)}{j\omega\rho}, \tag{6}$$

where $A(\omega)$ is the virtual source monopole amplitude, Ψ [rad] is the angle between the virtual source and the normal to the reproduction line at the reproduction source position $\mathbf{x}_l^{(l)}$, $r_o=\|\mathbf{x}_o-\mathbf{x}_l^{(l)}\|_2$ is the distance [m] between the virtual source (in $\mathbf{x}_o$) and the reproduction source (in $\mathbf{x}_l^{(l)}$) and $r^{(\mathrm{ref})}=\|\mathbf{x}^{(\mathrm{ref})}-\mathbf{x}_l^{(l)}\|_2$ is the distance [m] between the reproduction source and the reference line along the line r_o. These geometric parameters are illustrated in Fig. 1. In Eq. (5), Δ_l [m] is the reproduction source separation ($\Delta_l=\|\mathbf{x}_l^{(l)}-\mathbf{x}_{l+1}^{(l)})\|_2$). Equation (5) expresses the WFS monopole source amplitude $Q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega)$ to produce $p^{(\mathrm{im})}(\mathbf{x},\omega)$ while Eq. (6) transforms WFS monopole amplitudes in source strength amplitudes $q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega)$ (Pierce, 1991).

The stationary phase approximation in WFS also leads to the definition of a "reference line" (Verheijen, 1997) on which the amplitude of the reproduction error should theoretically be zero in comparison with points outside the reference line, again for free field. Indeed, the stationary phase approximation in WFS implies that the reproduced sound field would be effectively reproduced only on a line in front of the reproduction source array. For WFS, this line is arbitrarily chosen and this corresponds to the WFS reference line. This line is shown in Fig. 1. In this paper, the reproduction source line L is defined as a circle, and the reference line is also defined as a circle, centered on the virtual source position $\mathbf{x}_o$ and passing through the source array center. The choice of a given reference line definition is not relevant to the AWFS fundamental idea, but it remains an important choice for the WFS definition (for numerical results reproducibility) since the reference line influences the WFS operators of Eq. (5).

For WFS, a reproduction source is active if $|\Psi|<\pi/2$ radian (see Fig. 1 for Ψ definition). An active source implies that $Q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega)\neq 0$. Other sources, with $|\Psi|\geqslant\pi/2$, are not active [artificially forced to $Q_{\mathrm{WFS}}(\mathbf{x}_l^{(l)},\omega)=0$]. This highlights the fact that WFS solution implies that only a part of the reproduction source array is active for a given virtual source. A spatial weighting window is also used to progressively reduce the WFS strength amplitudes. This is applied to the reproduction sources closer to the end of the active part of the source WFS array. Such spatial windowing limits the finite aperture effects of the reproduction array. Here, the spatial weighting window is a rectangular window with half Hanning windows at its ends. The half Harming window extends over 0.5 m (Verheijen, 1997).

B. Definition of AWFS

Using the radiation model of Eqs. (1)–(3) with the target pressure field of Eq. (4), AWFS (adaptive wave field synthesis) is introduced as an optimal control approach with this cost function

$$J_{\mathrm{AWFS}} = \mathbf{e}^H\mathbf{e} + \lambda(\mathbf{q}-\mathbf{q}_{\mathrm{WFS}})^H(\mathbf{q}-\mathbf{q}_{\mathrm{WFS}}) \tag{7}$$

which must be minimized with λ being a real positive scalar. Superscript H denotes Hermitian transposition. Equation (7)

introduces the reproduction error vector $\mathbf{e}=\mathbf{p}^{(\mathrm{im})}-\mathbf{p}^{(\mathrm{rep})}=\mathbf{p}^{(\mathrm{im})}-\mathbf{Z}\mathbf{q}$, where $\mathbf{p}^{(\mathrm{im})}$ is the complex column vector of the target sound pressure at the M sensor locations, defined by Eq. (4) with $\mathbf{x}_m^{(m)}$ replacing $\mathbf{x}$. The first term in Eq. (7) represents the summation of the quadratic reproduction errors with respect to the target reproduced sound field, observed at the sensor locations. The second term in Eq. (7) is weighted by the regularization parameter λ and it represents a quadratic departure penalty of the solution $\mathbf{q}$ with respect to the fixed WFS solution $\mathbf{q}_{\mathrm{WFS}}$.

J_{AWFS} is a quadratic function of $\mathbf{q}$,

$$J_{\mathrm{AWFS}}=\mathbf{q}^H[\mathbf{Z}^H\mathbf{Z}+\lambda\mathbf{I}]\mathbf{q}-\mathbf{q}^H[\mathbf{Z}^H\mathbf{p}^{(\mathrm{im})}+\lambda\mathbf{q}_{\mathrm{WFS}}]-[\mathbf{p}^{(\mathrm{im})^H}\mathbf{Z}+\lambda\mathbf{q}_{\mathrm{WFS}}^H]\mathbf{q}+[\mathbf{p}^{(\mathrm{im})^H}\mathbf{p}^{(\mathrm{im})}+\lambda\mathbf{q}_{\mathrm{WFS}}^H\mathbf{q}_{\mathrm{WFS}}], \quad (8)$$

where $\mathbf{I}$ is the $L\times L$ identity matrix.

Although the reproduction system of Eq. (1) is underdetermined ($M<L$) (Nelson and Elliott, 1992), the WFS departure penalty term, weighted by λ, ensures that there will be a unique minimum of Eq. (7). That is, the Hessian matrix ($[\mathbf{Z}^H\mathbf{Z}+\lambda\mathbf{I}]$) of the quadratic Eq. (8) is positive definite provided that $\lambda>0$. This optimum source strength vector minimizes the cost function (Nelson and Elliott, 1992)

$$\mathbf{q}^{(\mathrm{opt})}=[\mathbf{Z}^H\mathbf{Z}+\lambda\mathbf{I}]^{-1}[\mathbf{Z}^H\mathbf{p}^{(\mathrm{im})}+\lambda\mathbf{q}_{\mathrm{WFS}}]. \quad (9)$$

When $\lambda\to\infty$ the solution reduces to the WFS operators $\mathbf{q}_{\mathrm{WFS}}$, when $\lambda\to 0$ the solution is the optimal control solution that minimizes the reproduction error in a least-mean-square (LMS) sense. These two situations are the limiting cases of AWFS.

III. INTERPRETATION OF AWFS

Equations (7) and (9) lead to insightful observations about the behavior of AWFS. It first should be noted that the second term of the cost function (7) includes a standard effort penalty obtained by $\lambda\mathbf{q}^H\mathbf{q}$ and a projection term $-2\lambda\mathbf{q}_{\mathrm{WFS}}^H\mathbf{q}$. The first term acts like a standard regularization while the second introduces a contribution of $\mathbf{q}_{\mathrm{WFS}}$ in the solution.

Rewriting Eq. (9) and extracting the $\mathbf{q}_{\mathrm{WFS}}$ contribution, one finds

$$\mathbf{q}^{(\mathrm{opt})}=[\mathbf{Z}^H\mathbf{Z}+\lambda\mathbf{I}]^{-1}[\mathbf{Z}^H\mathbf{e}_{\mathrm{WFS}}]+\mathbf{q}_{\mathrm{WFS}}, \quad (10)$$

where $\mathbf{e}_{\mathrm{WFS}}=\mathbf{p}^{(\mathrm{im})}-\mathbf{Z}\mathbf{q}_{\mathrm{WFS}}$ is the reproduction error of WFS at the sensors. This potentially includes the inherent WFS approximation errors reviewed in Sec. II A, along with the room effects.

Equation (10) illustrates that the optimal solution $\mathbf{q}^{(\mathrm{opt})}$ is the superposition of the optimal correction $[\mathbf{Z}^H\mathbf{Z}+\lambda\mathbf{I}]^{-1}[\mathbf{Z}^H\mathbf{e}_{\mathrm{WFS}}]$ on the fixed WFS solution $\mathbf{q}_{\mathrm{WFS}}$. The optimal correction matches a standard optimal solution for active control (including effort penalization), the difference is that the target is the WFS reproduction error $\mathbf{e}_{\mathrm{WFS}}$ replacing the target wave field $\mathbf{p}^{(\mathrm{im})}$. Although the WFS contribution $\mathbf{q}_{\mathrm{WFS}}$ activates only a limited set of sources, the optimal contribution ($[\mathbf{Z}^H\mathbf{Z}+\lambda\mathbf{I}]^{-1}[\mathbf{Z}^H\mathbf{e}_{\mathrm{WFS}}]$) will activate all the reproduction sources.

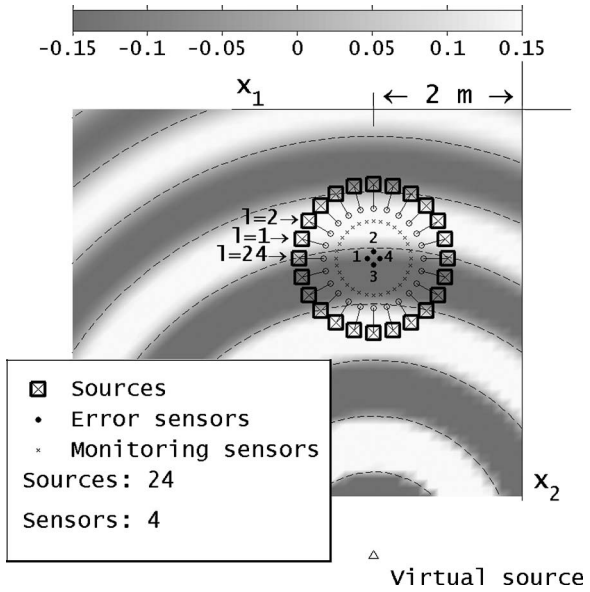

FIG. 2. System configuration in free field and real part of the target wave field at 220 Hz. Dashed lines represent zero-pressure contours of the target pressure field $p^{(\mathrm{im})}(\mathbf{x},w)$. —○, the normals to the source line. Δ, virtual source $\mathbf{x}_o=[2,6,0]$ meters.

IV. SIMULATION RESULTS

Simulation results are reported for a relatively small and compact hypothetical error sensor array prototype. (Such a prototype is currently under development for practical AWFS.) Simulations are performed in free field to illustrate the fundamental AWFS mechanisms.

The system configuration and the target pressure field $\mathbf{p}^{(\mathrm{im})}$ (at 220 Hz) are shown in Fig. 2. As illustrated, the system includes 24 sources, four error sensors, and 32 monitoring sensors used to quantify the reproduction quality outside the control region defined by the error sensor locations. The error sensors are separated by 0.175 m along x_1 and x_2. The source array has a diameter of 2 m and the source separation is 0.2611 m. The monitoring sensor array has a diameter of 1 m and the monitoring sensor separation is 0.098 m. All the arrays are centered around $x_1=x_2=2$ m. The virtual source is located at $\mathbf{x}_o=[2,6,0]$ meters.

Simulation results are globally quantified by E_{LS}

$$E_{\mathrm{LS}}=\frac{\mathbf{e}^H\mathbf{e}}{\mathbf{p}^{(\mathrm{im})^H}\mathbf{p}^{(\mathrm{im})}}. \quad (11)$$

E_{LS} is the global residual quadratic reproduction error normalized by the summation of the quadratic target pressures at the error sensor locations. $E_{\mathrm{LS}}=0$ characterizes perfect reproduction and $E_{\mathrm{LS}}=1$ corresponds to an error as large as the target field.

E_{LS} can also be computed for the M_m monitoring sensors using the reproduction errors at the monitoring sensor locations $\{\mathbf{x}_1^{(\mathrm{mon})}\cdots\mathbf{x}_{M_m}^{(\mathrm{mon})}\}$. The monitoring sensors are introduced to monitor the reproduction error outside the error sensor locations.

Results in terms of E_{LS} are shown in Figs. 3 and 4 for the configuration of Fig. 2 and others. Configuration (b) corresponds to Fig. 2. Configuration (a) corresponds to a unique

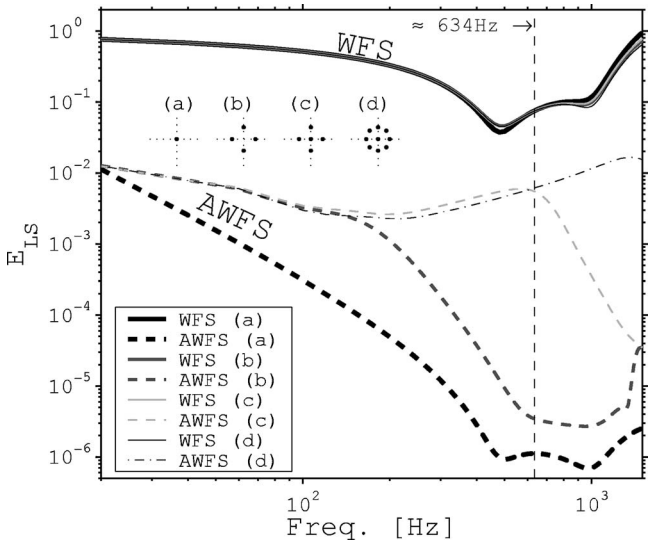

FIG. 3. E_{LS} at the error sensors for various approaches (WFS and AWFS) and error sensor configurations (shown as dot plots). Configuration (b) corresponds to Fig. 2; (a) corresponds to a unique sensor located at the center of the source array; (c) corresponds to configuration (b) plus an additional sensor at the center of the source array; (d) includes nine sensors approaching two tesseral quadrupolelike dispositions (45 degrees apart) plus a centered sensor.

sensor located at the center of the source array (at $x_1=x_2=2$ m). Configuration (c) is similar to (b) plus an additional sensor at the center of the source array. Configuration (d) includes nine sensors forming two tesseral quadrupoles [$\pi/4$ radian apart, the separation distance is the same as in case (b)] plus a centered sensor. In Fig. 3, WFS produces slightly different E_{LS} because the error sensor locations change: The WFS reproduced field is the same for the four configurations. In each case, the regularization parameter λ for AWFS was set to different values to take into account that an increased number of sensors reduces the importance of the penalization term in J_{AWFS} with a fixed λ. Case (a) was simulated with $\lambda=50$ while the other values were (b) $\lambda=200$, (c) $\lambda=250$, and (d) $\lambda=450$. Here, the λ values are not optimally chosen

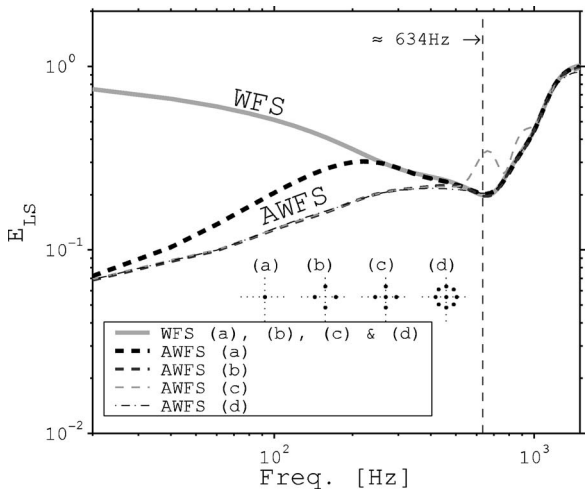

FIG. 4. E_{LS} at the monitoring sensors for the cases of Fig. 3 (the error sensor configurations are shown as dot plots).

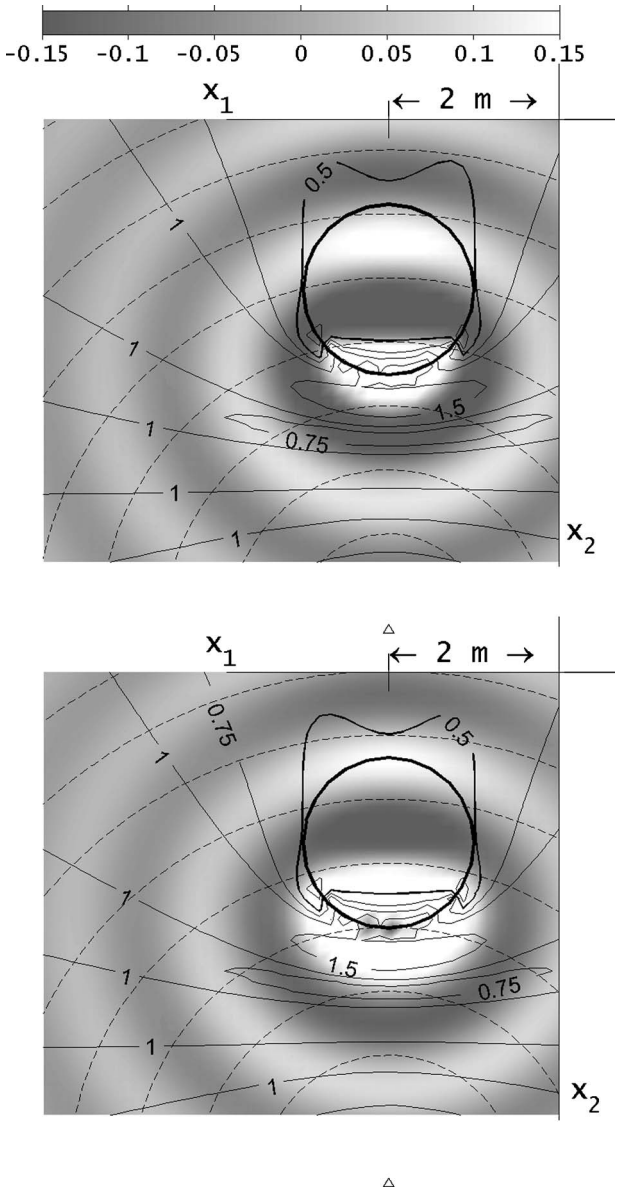

FIG. 5. Reproduced sound field at 220 Hz in free field WFS (real part on top, imaginary part on bottom). Dashed lines show zero-pressure contours of the target pressure field. Local normalized quadratic residual error is represented as continuous line contour plots. Reproduction sources are replaced by a thick source line for clarity. Δ, virtual source.

[with respect to inverse problem criteria such as the L-curve (Hansen, 1998; Nelson, 2001)], they were set to an arbitrary value multiplied by the number of sensors.

As shown in Fig. 3, E_{LS} at the error sensors is larger with WFS than AWFS. Also, the reproduction quality at the monitoring sensors with AWFS converges to the WFS results above approximately 634 Hz (Fig. 4). This frequency corresponds to the WFS spatial aliasing frequency which is defined in a first approximation by the source separation distance (Verheijen, 1997). WFS requires at least two reproduction sources per wavelength to avoid spatial aliasing.

Reproduced sound fields at 220 Hz for WFS, AWFS and reproduction error regularized minimization [$\lambda=50$ and $\mathbf{q}_{WFS}=\mathbf{0}$ in Eq. (9), that is optimal sound field reproduction without the WFS *a priori* solution] are shown in Figs. 5–7 for the configuration (b) shown in Fig. 2. $\lambda=50$ for all these

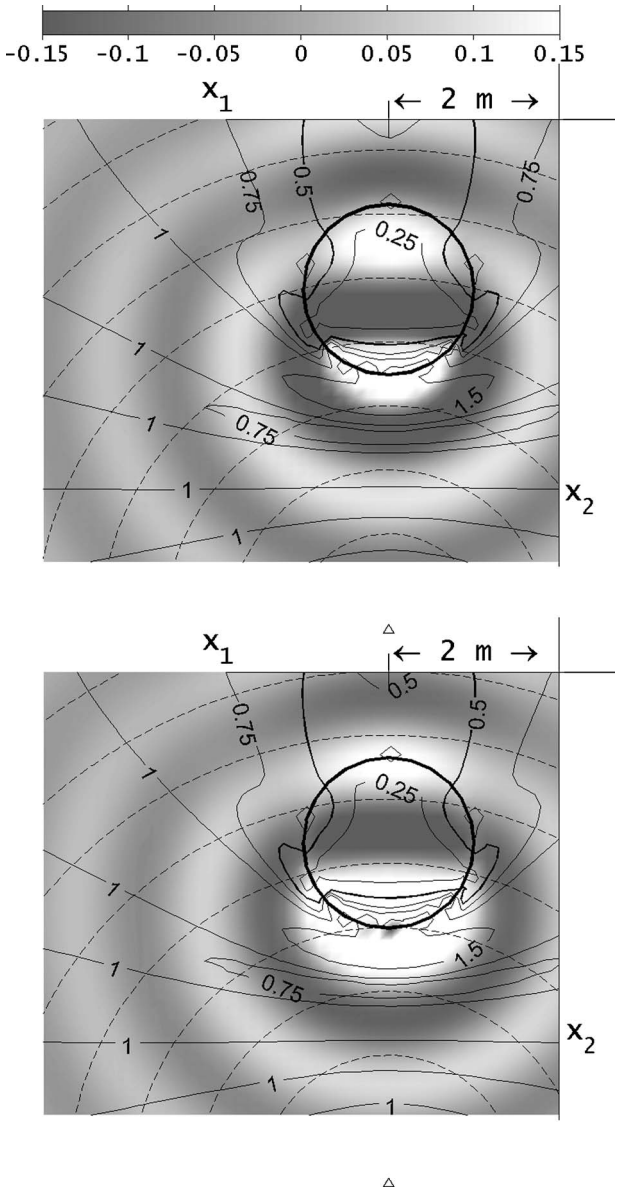

FIG. 6. Reproduced sound field at 220 Hz in free field by AWFS with $\lambda = 50$ (real part on top, imaginary part on bottom). Dashed lines show zero-pressure contours of the target pressure field. Local normalized quadratic residual error is represented as continuous line contour plots. Reproduction sources have been replaced by a thick source line for clarity. Δ, virtual source.

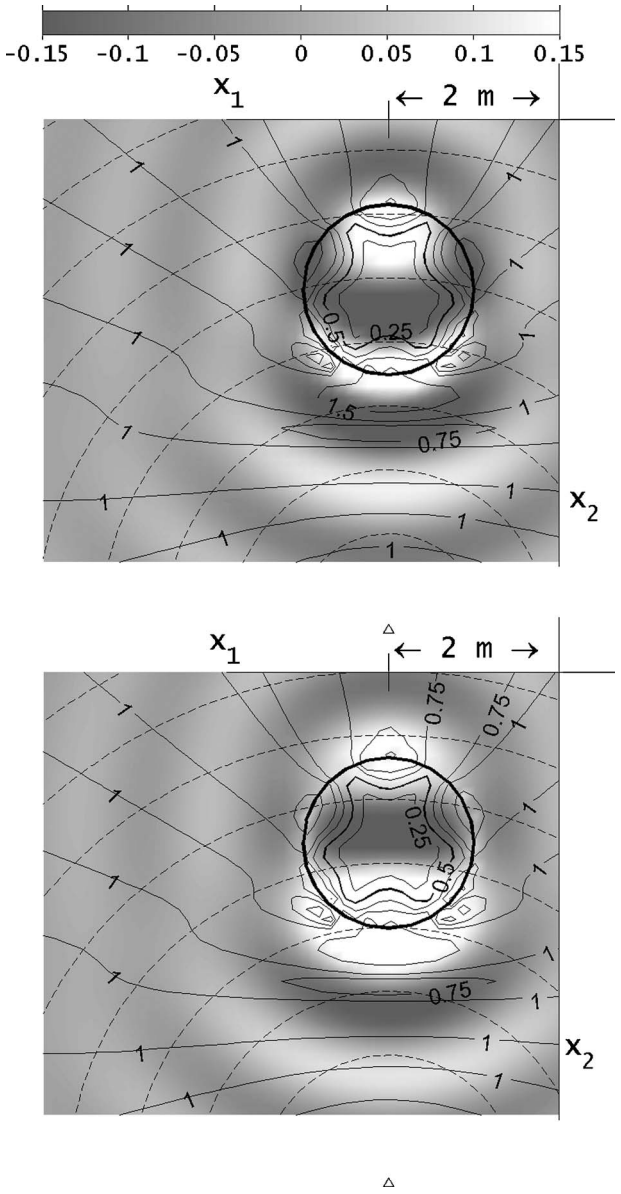

FIG. 7. Reproduced sound field in free field at 220 Hz by reproduction error minimization with $\lambda = 50$ and $\mathbf{q}_{\mathrm{WFS}} = \mathbf{0}$ (real part on top, imaginary part on bottom). Dashed lines show zero-pressure contours of the target pressure field. Local normalized quadratic residual error is represented as continuous line contour plots. Reproduction sources have been replaced by a thick source line for clarity. Δ, virtual source.

reproduced fields. The reproduced sound fields approach the target wave field. On these three figures, the spatial extent of effective reproduction is also shown. The size of this region varies with frequency. The spatial extent of effective reproduction is displayed via contour plots of the local quadratic normalized error $(|p^{(\mathrm{im})}(\mathbf{x},\omega) - p^{(\mathrm{rep})}(\mathbf{x},\omega)|^2 / |p^{(\mathrm{im})}(\mathbf{x},\omega)|^2)$. Contours are plotted only for the 0.25, 0.5, 0.75, 1, and 1.5 levels. The 0.5 level is suggested as the acceptable reproduction region limit for comparison purposes (Kirkeby and Nelson, 1993; Gauthier *et al.*, 2005a). AWFS introduces lower reproduction error than WFS in the source array center and the effective reproduction region is somewhat larger than the WFS effective region. AWFS in Fig. 6 also produces a more extended reproduction area (based on the 0.5 error level) than when simply minimizing the reproduction error at the error sensors with a control effort penalty (Fig. 7).

One of the benefits of AWFS is that it is possible to adjust the solution between a pure WFS realization (using a large penalization parameter) to a simple reproduction error minimization (with $\lambda \to 0$). This is shown in Fig. 8 on the basis of E_{LS} variations as a function of the penalization term λ. WFS, AWFS and reproduction error minimization regions are defined in Fig. 8. The E_{LS} values for regularization parameter $\lambda = \sigma_i^2$ (where σ_i are the transfer impedance matrix singular values) are plotted as circles. WFS corresponds to a large value of λ and E_{LS} does not significantly change with λ in this region. Reproduction error minimization corresponds to small values of λ and E_{LS} does not significantly change with λ in this region. The AWFS region is defined by the

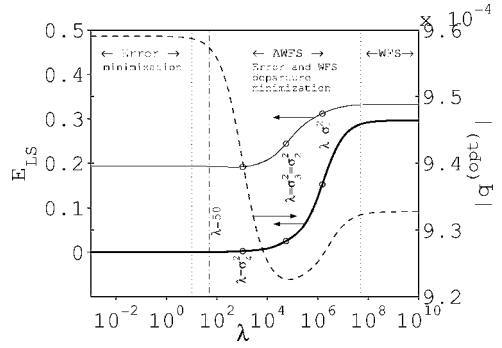

FIG. 8. E_{LS} at the error sensors (thick line) and at the monitoring sensors (thin line) and $(|\mathbf{q}^{(\mathrm{opt})}|)=\sqrt{\mathbf{q}^{(\mathrm{opt})H}\mathbf{q}^{(\mathrm{opt})}}$ (dashed line) at 220 Hz as a function of the regularization parameter λ. E_{LS} values for $\lambda=\sigma_i^2$ are shown as circles.

transition region between WFS and reproduction error minimization. The points for $\lambda=\sigma_i^2$ belong to this transition region.

For near-coincident error sensor arrays (relative to the wavelength) such as shown in Fig. 2, an under-regularized AWFS ($\lambda\rightarrow 0$) system can be regarded as a "closed-loop Ambisonics" reproduction system ("Ambisonics" systems are usually implemented as a open-loop systems, that is without any feedback or compensation), because such sensor arrays can be used to evaluate the pressure and two perpendicular pressure gradients in the horizontal plane. This relation between "Ambisonics" reproduction and AWFS is examined in Sec. VI A.

These simple simulations were used as an exemplary illustration of a simple AWFS behavior in free field. The more general underlying AWFS behavior, independent of the reproduction space, is exposed in the following section.

V. AWFS AND SINGULAR VALUE DECOMPOSITION OF Z

The singular value decomposition of the transfer impedance matrix is (Golub and van Loan, 1996)

$$\mathbf{Z}=\mathbf{U}_{M\times M}\boldsymbol{\Sigma}_{M\times L}\mathbf{V}^H_{L\times L}, \tag{12}$$

where subscripts indicate matrix dimensions. $\mathbf{U}$ is the matrix whose columns are the left singular vectors $\mathbf{u}_i$ of $\mathbf{Z}$, $\mathbf{V}$ is the matrix whose columns are the right singular vectors $\mathbf{v}_i$ of $\mathbf{Z}$ and $\boldsymbol{\Sigma}$ is the rectangular matrix of $\mathbf{Z}$ real positive singular values σ_i

$$\boldsymbol{\Sigma}=\begin{bmatrix}\sigma_1 & 0 & \cdots & & & 0\\ 0 & \sigma_2 & 0 & \cdots & & 0\\ & & \ddots & & & \\ 0 & \cdots & 0 & \sigma_M & \cdots & 0\end{bmatrix}_{M\times L}, \tag{13}$$

where $\sigma_i>\sigma_{i+1}$. The rank r of $\mathbf{Z}$ ($r\leqslant M<L$) is equal to the number of nonzero singular values. In Eq. (13) it was assumed that $r=M$ for convenience.

The matrices $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices ($\mathbf{U}^H\mathbf{U}=\mathbf{U}\mathbf{U}^H=\mathbf{V}^H\mathbf{V}=\mathbf{V}\mathbf{V}^H=\mathbf{I}$) since the left and right singular vectors are orthonormal vectors. SVD has well-known properties (Golub and van Loan, 1996; Hansen, 1998). Examples of SVD in acoustics are described by Nelson (2001); Williams *et al.* (2003); Bai and co-workers (2004; 2005). The span of the left singular vectors $\mathbf{u}_i$ constitutes the range of the matrix $\mathbf{Z}$ and the span of the last $L-r$ right singular vectors $\mathbf{v}_i$ is the null space of $\mathbf{Z}$ ($\mathbf{Z}\mathbf{v}_i=\mathbf{0}$ for $i>r$ and $i\leqslant L$) (Lancaster, 1985; Golub and van Loan, 1996) In order to explicitly relate left and right singular vectors to physical parameters, right singular vectors $\mathbf{v}_i$ and left singular vectors $\mathbf{u}_i$ will hereafter be, respectively, identified as "source modes" and "pressure modes." Each source and pressure modes pair with the corresponding singular value is here defined as a "radiation mode." This AWFS-specific terminology is different from the terminology introduced by Photiadis (1990) and from the more common definition of a radiation mode being a source distribution which radiates sound power independently from the other radiation modes.

Equations (1) and (12) result in this transformed radiation equation

$$\tilde{\mathbf{p}}^{(\mathrm{rep})}=\boldsymbol{\Sigma}\tilde{\mathbf{q}} \tag{14}$$

with the transformed source strengths $\tilde{\mathbf{q}}$ and acoustic pressures $\tilde{\mathbf{p}}$,

$$\tilde{\mathbf{p}}^{(\mathrm{im})}=\mathbf{U}^H\mathbf{p}^{(\mathrm{im})},\quad \tilde{\mathbf{p}}^{(\mathrm{rep})}=\mathbf{U}^H\mathbf{p}^{(\mathrm{rep})},\ \tilde{\mathbf{q}}=\mathbf{V}^H\mathbf{q}. \tag{15}$$

Since $\boldsymbol{\Sigma}$ is a pseudodiagonal rectangular matrix (the elements are nonzero only on the main diagonal), the radiation problem of Eq. (14) is a set of independent acoustical radiation between source modes $\mathbf{v}_i$ and pressure modes $\mathbf{u}_i$.

A. Nature of the under-determined set of equations $\mathbf{Zq}=\mathbf{p}^{(\mathrm{im})}$

In Sec. II B we treated the equation $\mathbf{Zq}=\mathbf{p}^{(\mathrm{im})}$ as a quadratic minimization. We now discuss the under-determined set of equations $\mathbf{Zq}=\mathbf{p}^{(\mathrm{im})}$. Since there are more unknown variables than equations ($L>M$), the set of equations $\mathbf{Zq}=\mathbf{p}^{(\mathrm{im})}$ cannot be solved in this form: there exists an infinite set of source strength values that will produce $\mathbf{p}^{(\mathrm{im})}$. Such under-determination is expressed as the contribution of left singular vectors in the solution

$$\mathbf{q}=\sum_{i=1}^{r}\frac{\tilde{p}_i^{(\mathrm{im})}}{\sigma_i}\mathbf{v}_i+\sum_{i=r+1}^{L}\alpha_i\mathbf{v}_i, \tag{16}$$

where α_i represents arbitrary coefficients which, with the vector basis of the null space of $\mathbf{Z}$, define the under-determined nature of $\mathbf{Zq}=\mathbf{p}^{(\mathrm{im})}$. Inserting (16) in $\mathbf{Zq}$ will effectively produce $\mathbf{p}^{(\mathrm{im})}$ regardless of α_i. A solution to such an under-determined problem is to cast it in a new quadratic minimization form which seeks to reduce the departure between the solution $\mathbf{q}$ and a given solution $\mathbf{q}_o$. If this *a priori* solution (Hansen, 1998) is simply 0 then the pseudoinversion can be applied to solve $\mathbf{Zq}=\mathbf{p}^{(\mathrm{im})}$ (Golub and van Loan, 1996). If the *a priori* solution $\mathbf{q}_o$ is not zero, a more general rule is obtained: the α_i in Eq. (16) correspond to the projection of $\mathbf{q}_o$ on $\mathbf{v}_i$

$$\alpha_i=\mathbf{v}_i^H\mathbf{q}_o\ \forall\ i>r\quad\text{and } i\leqslant L \tag{17}$$

and the first r contributions of $\mathbf{v}_i$ are determined by the first term in Eq. (16). This minimizes the cost function

$$J(\alpha_i) = \sum_{i=1}^{r} (\tilde{p}_i^{(\mathrm{im})}/\sigma_i - \mathbf{v}_i^H \mathbf{q}_o)^2 + \sum_{i=r+1}^{L} (\alpha_i - \mathbf{v}_i^H \mathbf{q}_o)^2. \quad (18)$$

In the next section, we proceed to show how the AWFS solution [expressed by Eq. (9)] corresponds to a modified version of Eqs. (16) and (17) where $\mathbf{q}_{\mathrm{WFS}}$ replace $\mathbf{q}_o$.

B. Independent radiation mode control for AWFS

Taking the AWFS solution of Eq. (9) and using the SVD of $\mathbf{Z}$, the AWFS solution can be expanded over the source modes $\mathbf{v}_i$, $\mathbf{q}^{(\mathrm{opt})} = \sum_{i=1}^{L} \tilde{q}_i \mathbf{v}_i$, as follows:

$$\tilde{q}_i = \begin{cases} \dfrac{\sigma_i}{(\sigma_i^2 + \lambda_i)} \tilde{p}_i^{(\mathrm{im})} + \dfrac{\lambda_i}{(\sigma_i^2 + \lambda_i)} \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}} \quad \forall \quad i \leqslant r \leqslant M, \\ \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}} \quad \forall\, \lambda_i > 0, \quad \forall\, i > r \text{ and } i \leqslant L, \\ 0 \quad \forall\, \lambda_i = 0, \quad \forall\, i > r \text{ and } i \leqslant L, \end{cases} \quad (19)$$

where the independent contributions of $\mathbf{v}_i$ in $\mathbf{q}^{(\mathrm{opt})}$ were individually regularized with λ_i. AWFS thus proceeds to control each radiation mode independently. The AWFS solution of Eq. (9) implicitly assumed an identical regularization parameter for all sources modes, $\lambda_i = \lambda \ \forall i$. Note that Eq. (19) was slightly modified in comparison to Eq. (9) for the particular case $\lambda_i = 0$: Eq. (19) is forced to the pseudoinverse definition by the addition of the third case in Eq. (19) (Hansen, 1998). The reproduction error is expanded

$$\mathbf{e} = \sum_{i=1}^{M} \tilde{e}_i \mathbf{u}_i \quad (20)$$

with

$$\tilde{e}_i = \frac{\lambda_i (\tilde{p}_i^{(\mathrm{im})} - \sigma_i \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}})}{(\sigma_i^2 + \lambda_i)} \quad \forall\, i \leqslant r. \quad (21)$$

Equation (19) shows that even if the multichannel system must generate the L source inputs in $\mathbf{q}^{(\mathrm{opt})}$, the total number of degrees of freedom is in fact r. In the first case [$i \leqslant r \leqslant M$ in Eq. (19)], the $\tilde{q}_i$ are a combination of reproduction error minimization with $\mathbf{q}_{\mathrm{WFS}}$ projection on the corresponding source mode $\mathbf{v}_i$. This combination is weighted by λ_i. When $\lambda_i = 0$, Eq. (19) provides the same solution as Eqs. (16) and (17) for $i \leqslant r \leqslant M$. In the second case [$i > r$ and $i \leqslant L$ in Eq. (19)], the corresponding $\tilde{q}_i$ are solely defined by the projection of $\mathbf{q}_{\mathrm{WFS}}$ on $\mathbf{v}_i$ if $\lambda_i > 0$. This shows that even if such source modes produce no sound pressure at sensor locations, they contribute to the solution in order to better match the WFS sound field reproduction outside the control region. These results explain how a part of the WFS operators is modified by AWFS and how the other fixed part is defined by the projection of $\mathbf{q}_{\mathrm{WFS}}$ on the null space vector basis. Since these observations stem from an analytical development and since the SVD exist for any complex matrix $\mathbf{Z}$, it is possible to extent this interpretation to a any real situation.

Equation (19) shows the discontinuity in the solution $\mathbf{q}^{(\mathrm{opt})}$ as $\lambda \to 0$, specifically in the components $\tilde{q}_i$ corresponding to the null space of $\mathbf{Z}$. This discontinuity in the solution would not be observable in the reproduced field at the error sensors, because the span of these source modes is the null space of the transfer impedance matrix. However, anywhere else such discontinuity would be observable in the reproduced sound field.

Equations (19) and (21) give insights into how each radiation modes are affected by $\lambda_i = \lambda$. Rewriting these equations for $i \leqslant r$ in terms of transformed WFS reproduction error ($\tilde{e}_{i\mathrm{WFS}} = \mathbf{u}_i^H \mathbf{p}^{(\mathrm{im})} - \sigma_i \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}} = \mathbf{u}_i^H (\mathbf{p}^{(\mathrm{im})} - \mathbf{Z}\mathbf{q}_{\mathrm{WFS}})$), one finds

$$\tilde{q}_i = \frac{\sigma_i}{(\sigma_i^2 + \lambda_i)} \tilde{e}_{i\mathrm{WFS}} + \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}} \quad \forall\, i \leqslant r \quad (22)$$

and

$$\tilde{e}_i = \frac{\lambda_i}{(\sigma_i^2 + \lambda_i)} \tilde{e}_{i\mathrm{WFS}} \quad \forall\, i \leqslant r. \quad (23)$$

When $\lambda_i \ll \sigma_i^2$, the solution $\tilde{q}_i$, for the control of the radiation mode i, is dominated by WFS reproduction error $\tilde{e}_{i\mathrm{WFS}}$ minimization ($\tilde{q}_i - \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}}$ is large and $\tilde{e}_i$ is small). When $\lambda_i \gg \sigma_i^2$, the solution $\tilde{q}_i$ is dominated by WFS departure penalty ($\tilde{q}_i - \mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}}$ is small and $\tilde{e}_i$ is large). This illustrates that for a regularization parameter λ as in Eqs. (7) and (9), the amount of penalization is different for each radiation mode; some radiation modes can be over-penalized ($\lambda \geqslant \sigma_i^2$) and some others under-penalized ($\lambda \leqslant \sigma_i^2$). This suggests that the behavior of AWFS with a global penalization ($\lambda_i = \lambda$) is a complex contribution of the radiation modes. This defines the AWFS transition band in Fig. 8.

VI. ANALYSIS OF SIMULATION RESULTS WITH SVD

The behavior of independent AWFS is illustrated through numerical results shown in Figs. 9–14 for free-field situations. Our goal is to simply exemplify the analytical results presented in the preceding section.

Figure 9 shows the first four source and pressure modes for the configuration of Fig. 2 at 220 Hz. There is 24 sources modes and four pressure modes in this configuration. The last 20 source modes produce no sound pressure at the sensor array. Figure 9 shows that the source modes have a single circumferential harmonic component, and the corresponding pressure modes provide a multipole expansion of the sound field at the sensor array. Moreover, one notes that the third source mode has a $\pi/4$ radian spatial phase difference with the second source mode (a similar trend is observed for the corresponding pressure modes). The source modes producing the $\mathbf{Z}$ null space are shown in Fig. 10. The null space source modes are spatially high-pass filtered impulses. This filtering removes the low-order source mode components from the spatial impulses.

Figure 11 shows the produced sound field for the first six source modes $\mathbf{v}_i$ at 220 Hz. The first source mode produces uniform sound pressure at the sensor array [subfigure (a)]. The next two source modes [subfigures (b) and (c)] produce perpendicular pressure gradients. The next source mode [subfigure (d)] produces a tesseral quadrupole field compo-

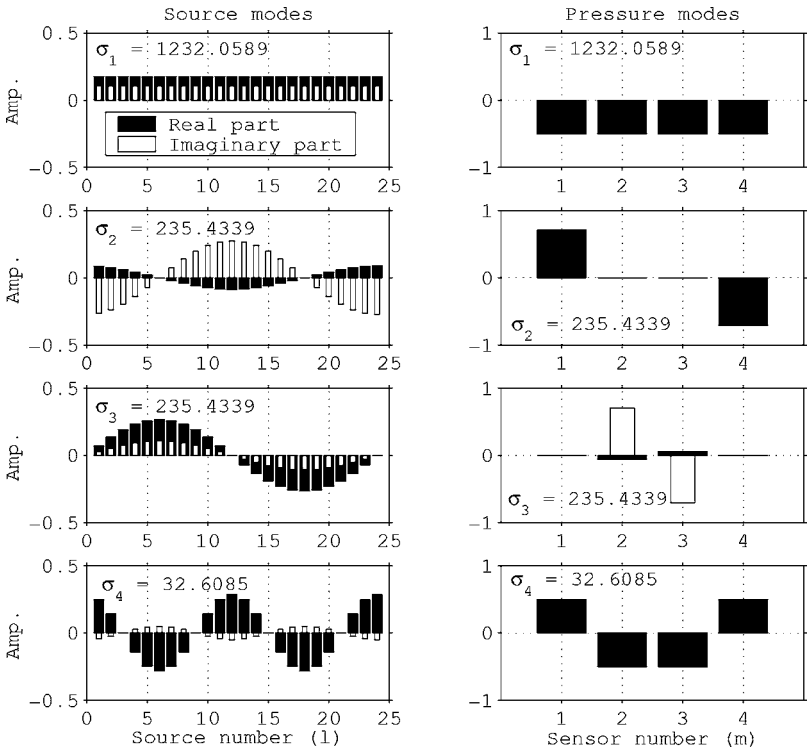

FIG. 9. Source modes $\mathbf{v}_i$ at 220 Hz on the left-hand side and corresponding pressure modes $\mathbf{u}_i$ (for $\sigma_i \neq 0$, that is $i \leqslant r = M$) on the right-hand side. Source and sensor numbers are shown in Fig. 2.

nent. The last two source modes produce no sound pressure at the sensors [subfigures (e) and (f)] since the corresponding source modes belong to the nullspace. These two source modes are shown on the first line in Fig. 10.

Figure 12 shows multipole representations of the pressure modes $\mathbf{u}_i$ at 220 Hz. The corresponding free-field directivities are also shown as polar plots. These directivity patterns were computed with plane wave responses at the sensors weighted by the complex pressure modes $\mathbf{u}_i^H$ as sensor gains. This figure illustrates that the $i=1$ pressure mode corresponds to sound pressure, the $i=2$ pressure mode approximates pressure gradient along x_1 (dipole sensitivity in the low frequency limit), the $i=3$ pressure mode gives a pressure gradient along x_2 (dipole sensitivity in the low frequency limit) and the $i=4$ pressure mode corresponds to a tesseral quadrupole finite approximation. Since Eq. (19) sug-

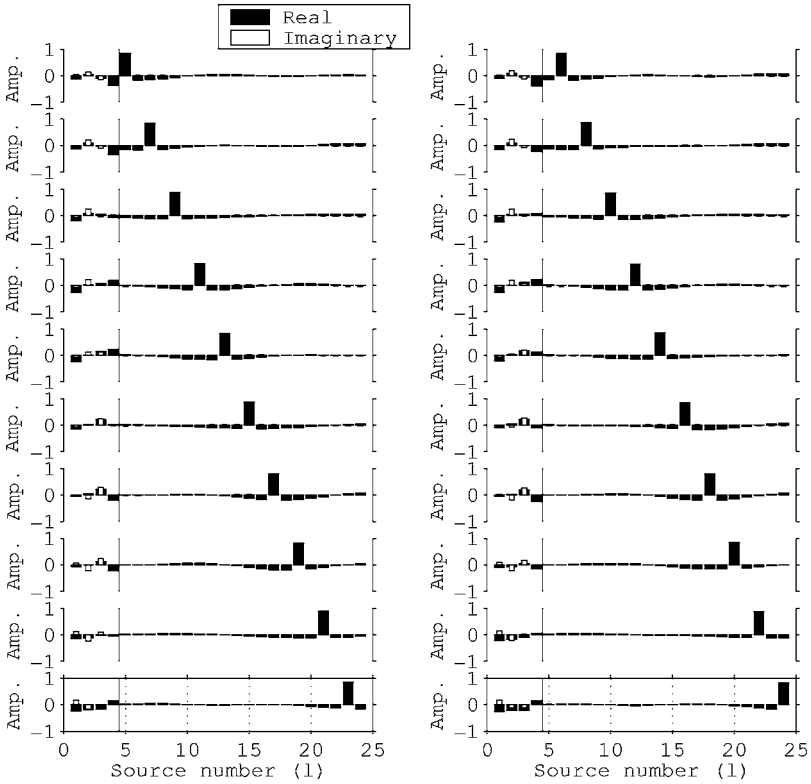

FIG. 10. The null space source modes $\mathbf{v}_i$ at 220 Hz. Increasing i proceeds from left to right and from top to bottom.

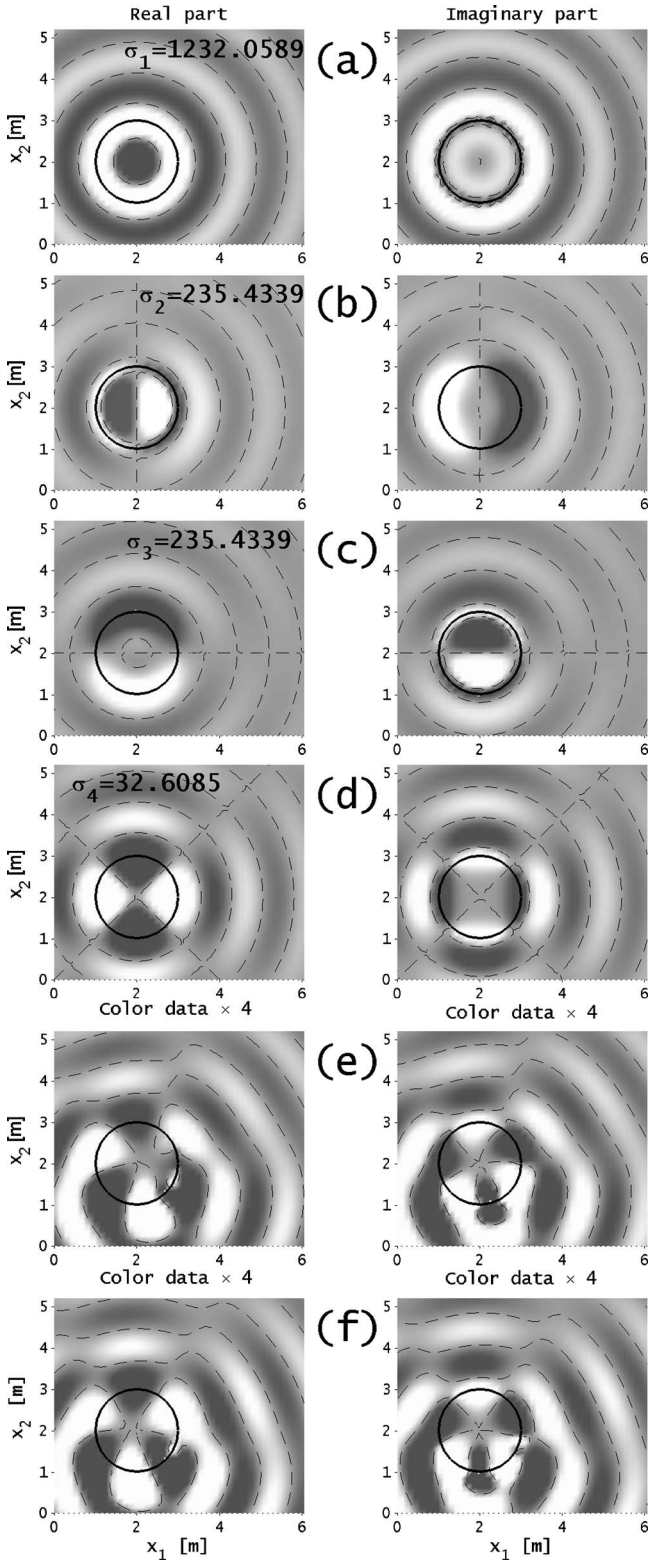

FIG. 11. Sound field radiated by the first six source modes. Source modes (a)–(d) generate the range of the transfer impedance matrix. Source modes (e) and (f) belong to the null space of the transfer impedance matrix. Dashed lines show zero-pressure contours of the pressure fields.

gests independent control of the reproduced pressure modes, one can conclude, from the pressure mode shapes of Fig. 12, that AWFS [Eqs. (7) and (9)] effectively operates on the independent control of pressure, pressure gradients and tesseral quadrupole pressure modes at the sensor array.

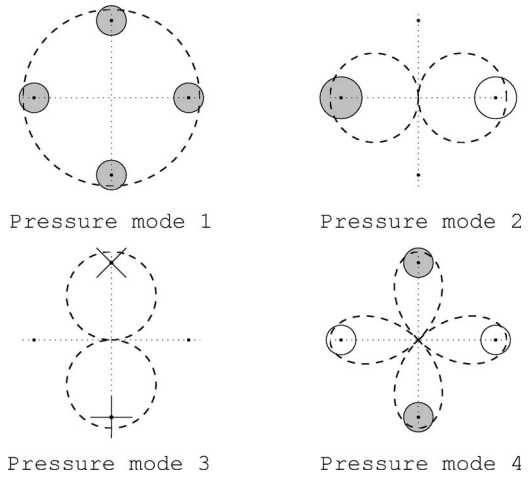

FIG. 12. Multipole representations of the first $M=4$ pressure modes and corresponding free field directivity.· sensor position; ○, positive real part; filled ○, negative real part; +, positive imaginary part; ×, negative imaginary part. Symbol diameter illustrates the magnitude of the corresponding value. Dashed lines, free field directivity.

Figure 13 shows the source strength vectors for WFS and AWFS used to produce the sound fields in Figs. 5 and 6 along with the projections of $\mathbf{q}_{\mathrm{WFS}}$ and $\mathbf{q}^{(\mathrm{opt})}$ on the source modes $\mathbf{v}_i$. By comparing the left graphs of Fig. 13, it is clear that WFS activates only a part of the reproduction sources while AWFS significantly activates nearly all sources. This illustrates the additive combination of WFS and reproduction error minimization. As shown in the right graphs of Fig. 13, AWFS only changes the first $r=M$ source mode contributions $\tilde{q}_i$ in comparison with WFS, this was shown in Eq. (19). This illustrates that the general AWFS minimization [Eqs. (7) and (9)] effectively gives the SVD solution of Eq. (19). Even if deriving (19) from (9) is straightforward using SVD, this numerical example is used to illustrate this equivalence.

A. AWFS and "Ambisonics"

The next simulations are introduced to draw the link between AWFS, using a compact centered sensor array as shown in Fig. 2, and "Ambisonics".

For the first simulation, the regularization parameter λ was set to the small value of 1×10^{-4} and the WFS solution $\mathbf{q}_{\mathrm{WFS}}$ was set to 0 in Eq. (9). A small penalization parameter λ is one of the limiting cases of AWFS. This corresponds to the minimization of the reproduction errors with a small penalty of the control effort. The optimal source strengths $\mathbf{q}^{(\mathrm{opt})}$ at 220 Hz and the corresponding projections on the source modes $\mathbf{v}_i$ are shown in Fig. 14(a). Figure 14(a) shows that only the first $r=M$ source modes are active, this is consistent with Eq. (19) when $\mathbf{q}_{\mathrm{WFS}}=0$. As explained below, such a type of source distribution is somewhat related to "Ambisonics" panning functions.

A short description of "Ambisonics" is introduced here. A more complete theoretical development is included in the appendix. "Ambisonics" is an open-loop reproduction technology from the 1970s introduced by Gerzon (Rumsey, 2001). In the most simple case, the target wave field $p^{(\mathrm{im})}(\mathbf{x},\omega)$ is defined as a plane wave in free field

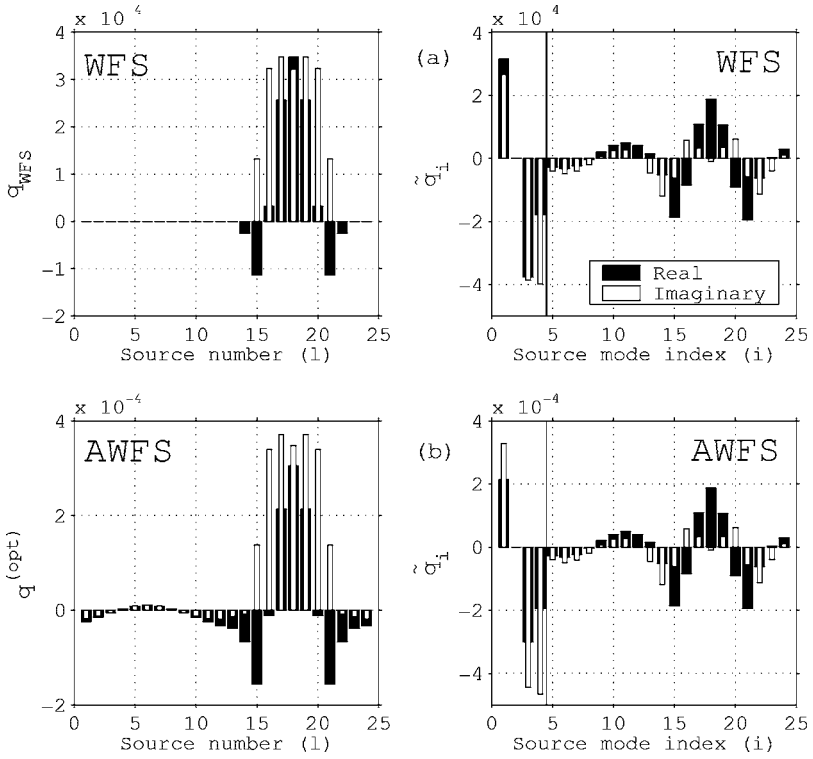

FIG. 13. Left, complex source strengths for (a) WFS ($\mathbf{q}_{\mathrm{WFS}}$ corresponding to Fig. 5) and (b) AWFS ($\mathbf{q}^{(\mathrm{opt})}$ corresponding to Fig. 6). Right, complex source mode contributions $\tilde{q}_i$ of (a) WFS and (b) AWFS solutions obtained from the orthogonal projection ($\tilde{q}_i=\mathbf{v}_i^H\mathbf{q}^{(\mathrm{opt})}$ or $\tilde{q}_i=\mathbf{v}_i^H\mathbf{q}_{\mathrm{WFS}}$) of the source strengths on the source modes.

$$p^{(\mathrm{im})}(R,\phi,\omega)=A(\omega)e^{jkR\cos(\phi-\theta)}, \tag{24}$$

where space coordinates are now described in terms of cylindrical coordinates (R,ϕ,z), and θ is the direction of propagation of the plane wave.

The reproduction system is assumed to be in free field and the reproduction sources (uniformly distributed over 2π radians) produce a set of plane waves at the origin of the coordinate system

$$p^{(\mathrm{rep})}(R,\phi)=\sum_{l=1}^{L}A_l e^{jkR\cos(\phi-\phi_l)}, \tag{25}$$

where A_l is the unknown contribution of the plane reproduction wave l whose direction of propagation is ϕ_l.

Using Fourier-Bessel series for both the target sound pressure field [Eqs. (24) and (A2)] and the reproduced field [Eqs. (25) and (A8)], it is possible to minimize (in an LMS

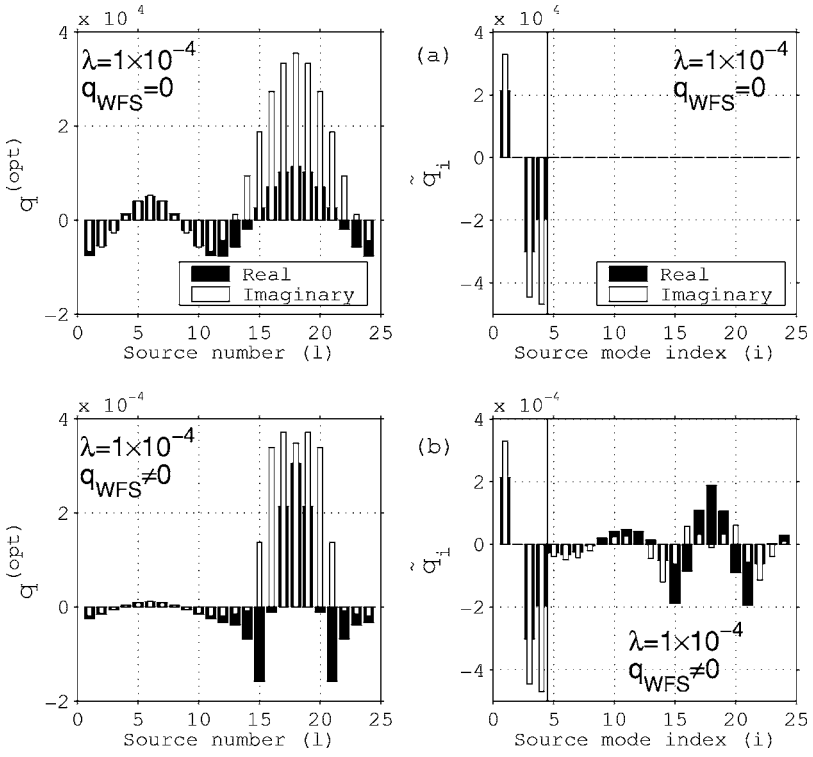

FIG. 14. Left, complex source strengths for optimal control (a) $\mathbf{q}^{(\mathrm{opt})}$ with $\lambda=1\times10^{-4}$ and $\mathbf{q}_{\mathrm{WFS}}=\mathbf{0}$, (b) $\mathbf{q}^{(\mathrm{opt})}$ with $\lambda=1\times10^{-4}$ and $\mathbf{q}_{\mathrm{WFS}}\neq\mathbf{0}$. Right, corresponding source mode contributions $\tilde{q}_i$ obtained from the orthogonal projections ($\tilde{q}_i=\mathbf{v}_i^H\mathbf{q}^{(\mathrm{opt})}$) of the source strengths on the source modes.

sense) the reproduction error over each of the coefficient of the Fourier-Bessel series. This gives a panning function (amplitude A_l of plane waves reproduction sources as function of θ and ϕ_l)

$$A_l = \frac{A}{L}\left[1 + 2\sum_{n=1}^{N} \cos(n(\theta - \phi_l))\right]. \tag{26}$$

This is a circular *sinc* function of ϕ_l for which the series truncature order N defines the number and amplitudes of the side lobes.

From this, one gets a panning function as to how (in an *a posteriori* operation) distribute a given signal to a circular source array to create, under the free field and plane wave assumptions, the target wave field. Since the Fourier-Bessel coefficients [see Eq. (A5)] correspond to low-order directivity patterns of microphones (first order "Ambisonics," $N=1$, gives three coefficients in the two series: monopole and two perpendicular dipole patterns), it is possible to consider the limiting case of AWFS with $\lambda \to 0$ as a "closed-loop Ambisonics" realization. The "closed-loop" appears since AWFS would be implemented with real microphones for reproduction error minimization while "Ambisonics" is a LMS solution that is implemented as an open-loop system. This is first supported by the pressure modes of Fig. 12 which shows that AWFS in this case corresponds to independent reproduction control of pressure, two perpendicular sound pressure gradients and a tesseral quadrupole approximation of the sound field at the error sensors in the low frequency limit. However, this connection between "Ambisonics" and AWFS using compact sensor array is essentially conceptual. This arises from that AWFS and "Ambisonics" use (1) different radiation models (spherical waves and plane waves for the reproduction system, respectively) and (2) different sensing devices (discrete sensor array for AWFS and perfectly coincident directive patterns for "Ambisonics").

The previous remarks show that AWFS (while letting $\lambda \to 0$ and forcing the WFS solution to zero) can be interpreted as a closed-loop "Ambisonics" realization. In the next example, we proceed in explaining how the AWFS realization (with $\mathbf{q}_{\mathrm{WFS}} \neq 0$ and for the specific sensor configuration shown in Fig. 2) is an hybrid solution between WFS and a "closed-loop Ambisonics" realization. This corresponds to "closed-loop modified Ambisonics." The "modified Ambisonics" arises from the superposition of the filtered WFS solution and the low-order closed-loop "Ambisonics" solution.

Figure 14(b) corresponds to the limiting case of AWFS with a vanishing regularization parameter $\lambda = 1 \times 10^{-4}$ and $\mathbf{q}_{\mathrm{WFS}}$ corresponding to the WFS solution [Eqs. (5) and (6)]. For the first four source modes contributions ($\tilde{q}_t$ with $i = 1,2,3,4$), the solution with $\mathbf{q}_{\mathrm{WFS}} \neq \mathbf{0}$ is almost identical to the solution with $\mathbf{q}_{\mathrm{WFS}} = \mathbf{0}$. This was to be expected from Eq. (19) since when $\lambda \to 0$, $\tilde{q}_i \approx \tilde{p}_i^{(\mathrm{im})}/\sigma_i$ for $i \leqslant r$. The higher-order source mode ($r < i \leqslant L$) contributions $\tilde{q}_i$ are the WFS projections ($\mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}}$) on $\mathbf{v}_i$ and are independent of λ. This appears when comparing the two graphs on the right-hand side of Fig. 14.

The previous results suggested a conceptual connection between AWFS in the configuration of Fig. 2 and "Ambisonics." In the next example, the nearly exact correspondence of AWFS, using Eq. (19), and the "Ambisonics" panning function of Eq. (26) will be shown. For this simulation, the AWFS radiation model is replaced with a reproduction source radiation model consistent with the "Ambisonics" formalism (plane waves as reproduction sources). The sensor array is however kept identical to the one shown in Fig. 2. Eq. (19) is also applied in the following conditions: First, the *a priori* solution $\mathbf{q}_{\mathrm{WFS}}$ is set to $\mathbf{0}$. Second, the effort penalization parameter λ is set to 0. Third, the $\tilde{q}_i$ components are only computed for $i = 1,2,3$ (these first three pressure modes correspond to uniform pressure and two pressure gradients sensing at the sensor array). This would correspond to first order "Ambisonics" using $N=1$ in Eq. (26). Fourth, the target wave field is a plane wave [see Eq. (24)] for which the direction of propagation corresponds to reproduction source number 12, see Fig. 2 for the angular plane source distributions which correspond to the reproduction source angular positions). The corresponding AWFS and "Ambisonics" solutions are shown in Fig. 15. The AWFS and "Ambisonics" source distributions are almost identical and correspond to a raised cosine [see Eq. (26) with $N=1$]. Despite appearances, the solutions are not exactly the same. The difference is due to the AWFS sensor array which can only provide a finite approximation to monopole and dipole sensitive patterns. The AWFS solution of Eq. (19) matches the "Ambisonics" solution of Eq. (A16) when the radiation models are consistent.

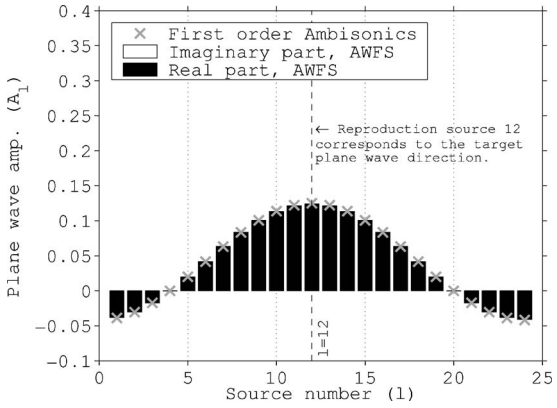

FIG. 15. Reproduction source amplitudes for plane wave reproduction with first order "Ambisonics" and truncated modified AWFS.

In summary, when the regularization parameter λ is large, AWFS simply converges towards WFS. When λ is small, the first ($i \leqslant r$) source modes contributions $\tilde{q}_i$ approach a closed-loop "Ambisonics" realization with a small WFS departure penalty, while all the other source modes (which create the nullspace) contributions are determined by the projection of WFS solution $\mathbf{q}_{\mathrm{WFS}}$ on the corresponding source modes $\mathbf{v}_i$. This precisely defines what was described earlier as "closed-loop modified Ambisonics." Briefly stated, the limiting cases of AWFS implementation produce (1) the WFS solution or (2) a closed-loop "Ambisonics" solution superposed to the spatially filtered WFS solution.

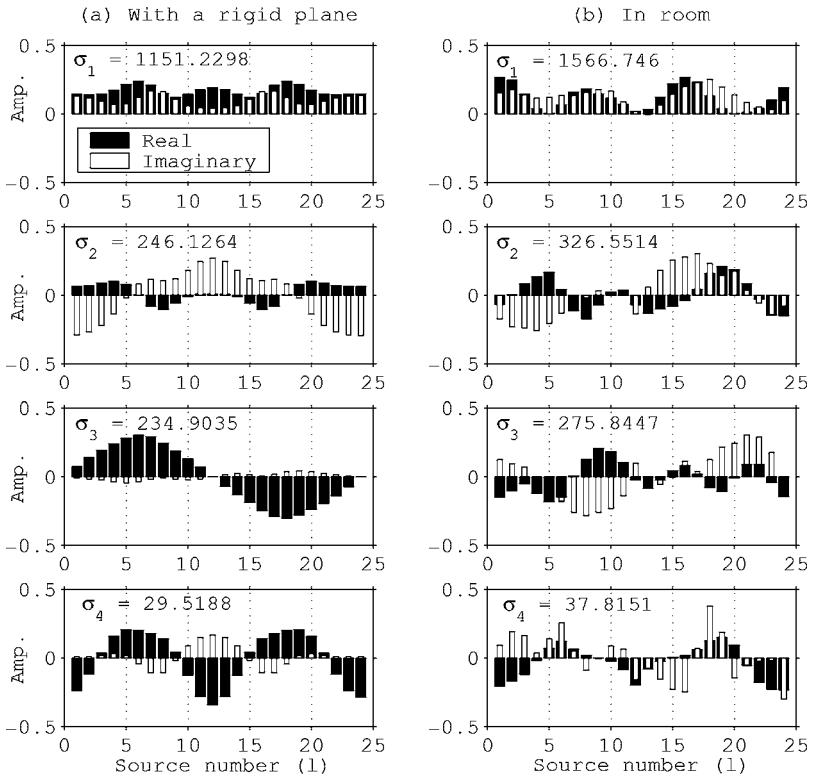

FIG. 16. First four source modes and singular values. (a) with a rigid plane in x_2-x_3. (b) in a room of 6.05 $\times 5.2 \times 2$ m with a reverberation time of approximately 0.28 s.

B. Including reflections and room effects

The preceding paragraphs showed the fundamental theoretical mechanisms of AWFS on the basis of analytical developments and illustrative simulation results in free field. However, AWFS has the potential to compensate for the effects of the listening space. Although this paper does not primarily address AWFS in room situation, some details are introduced to extend the significance of the preceding sections. In room, the compensation is more significant since the free-field assumptions of WFS are no longer respected and the accuracy of the reproduction by WFS is reduced (Gauthier *et al.*, 2005b).

The main goal of this section is to illustrate that even if both source modes and singular values are altered by the presence of boundaries, the pressure modes still provide pressure and pressure gradients estimates at the error sensors. Interestingly, this, with Eq. (19) (which is valid for any **Z**), extends the relation between AWFS and "Ambisonics" to sound field reproduction in rooms: independent control of pressure, pressure gradients and tesseral quadrupole pressure modes is achieved by AWFS in the configuration shown in Fig. 2 even in theoretical non-free-field conditions.

Figure 16(a) shows the first four source modes at 220 Hz when a rigid wall replaces the x_2-x_3 plane. The transfer impedance matrix was computed using the method of images. The corresponding pressure modes are shown as multipole representations in Fig. 17. Even if the pressure modes of Fig. 17 are slightly different to the free-field source modes of Fig. 12, the pressure modes still give finite difference approximations of pressure, pressure gradients and tesseral quadrupole as shown in Fig. 17. Figure 16(b) shows the first source modes when the system is located in a room for which the transfer impedance is based on a modal model including 6137 modes [the model is fully described by Gauthier *et al.* (2005a), see also Morse and Ingard (1968)]. The room is rectangular and its dimensions are $6.05 \times 5.2 \times 2$ m the room corner is located at $x_1=x_2=x_3=0$. The source and sensor plane is at $x_3=1.2192$ m. The reverberation time is approximately 0.28 s. The corresponding pressure modes are shown as a multipole representation in Fig. 18. Even though the source modes are distorted in comparison with the free field or rigid wall situation, the pressure modes still give finite difference approximations of pressure, perpendicular pressure gradients and tesseral quadrupole at the sensor array as shown in Fig. 18. By comparing Figs. 9

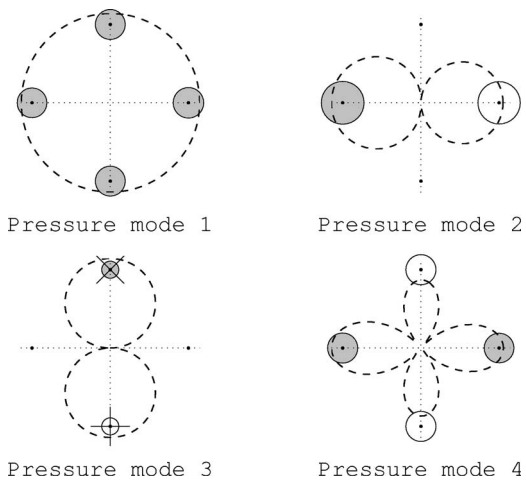

FIG. 17. Multipole representations of the first $M=4$ pressure modes and corresponding free field directivity for the source modes in Fig. 16(a). ·, sensor position; ○, positive real part; filled ○, negative real part; +, positive imaginary part; ×, negative imaginary part. Symbol diameter illustrates the magnitude of the corresponding value. Dashed lines, free field directivity.

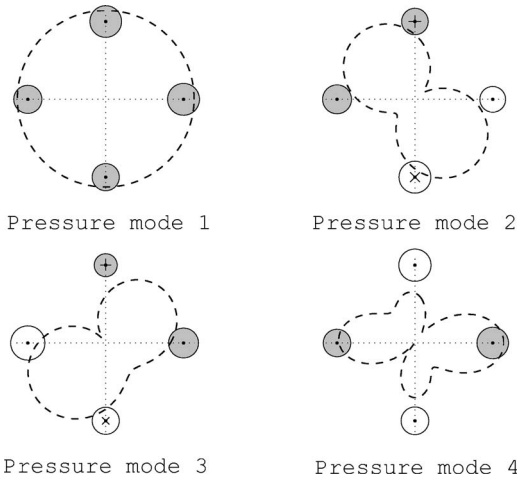

FIG. 18. Multipole representations of the first $M=4$ pressure modes and corresponding free field directivity for the source modes in Fig. 16(b). ·, sensor position; ○, positive imaginary part; filled ○, negative real part; +, positive imaginary part; ×, negative real part. Symbol diameter illustrates the magnitude of the corresponding value. Dashed lines, free field directivity.

and 16(b), one notes that the room singular values are significantly higher than the free-field and the semi-infinite space singular values. This demonstrates that for a given source strength vector $\mathbf{q}$, the sound pressures $\mathbf{p}^{(\mathrm{rep})}$ produced in a closed volume are larger than in free field.

According to these examples, independent control of radiation mode as pressure and higher-order sound pressure field derivatives is still a valid fundamental interpretation of Eq. (19) in the presence of a wall or a room. This suggests that AWFS based on independent radiation mode control as shown by Eq. (19) is a promising avenue for practical adaptive sound field reproduction which should somehow keep a link with "Ambisonics" and WFS.

VII. IMPLEMENTATION OF AWFS BY INDEPENDENT FEEDFORWARD CONTROL OF RADIATION MODES

This section describes a possible implementation of AWFS based on adaptive signal processing. As noted in Eq. (19), each source mode contribution in $\tilde{q}_i$ in $\mathbf{q}^{(\mathrm{opt})}$ is solely defined by the corresponding $\tilde{p}^{(\mathrm{im})}, \sigma_i, \lambda_i$ and $\mathbf{v}_i^H \mathbf{q}_{\mathrm{WFS}}$. It is possible to exploit this independence of the radiation modes for practical implementations of AWFS.

In a classical adaptive minimization of Eq. (7), a centralized multichannel adaptive algorithm would be implemented (Elliott, 2001) using a feedforward architecture. This is illustrated in Fig. 19. A set of z-transformed adaptive filters $\mathbf{w}(z)$ are adapted to reduce the quadratic summation of the M reproduction errors $\mathbf{e}_M(n)$. The discrete filters $\mathbf{w}(z)$ are fed by a reference signal $x(n)$ and produce the L command signals $\mathbf{y}_L(n)$ for the L reproduction sources. Here, $\mathbf{Z}(z)$ is the only physical system: All other operations are achieved in a signal processing domain. This includes $\hat{\mathbf{Z}}(z)$ which is an identified approximation of $\mathbf{Z}(z)$. The target field definition at the error sensors is obtained by passing the reference signal $x(n)$ through the target pressure modeler $\mathbf{a}(z)$. The WFS solution departure penalty [see Eq. (7)] is automatically taken into

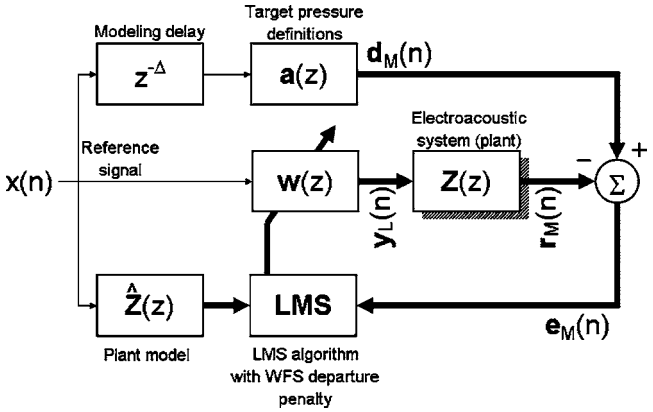

FIG. 19. Block diagram of a possible AWFS least-mean-square adaptive digital processing implementation using FXLMS multichannel algorithm. Subscripts denote signal dimensions.

account by the LMS adaptation which is based on a discrete time representation of the AWFS cost function of Eq. (7). Using M sensors, this will be a multiple-input-multiple-output (MIMO) $L \times M$ system. The computational burden involved in the block diagram of Fig. 19 becomes prohibitive as L, M and the adaptive filters order increase (Elliott, 2001; Bai and Elliott, 2004). Moreover, this may slow down the gradient LMS algorithm convergence as L and M increase (Bai and Elliott, 2004).

Another approach is illustrated as a block diagram in Fig. 20. $\mathbf{Z}(z)$ is again the only physical system. With this diagram, we seek to produce a set of M (with $M \leqslant L$) independent SISO (single-input–single-output) adaptive systems $\tilde{\mathbf{w}}_i(z)$. Here, each independent adaptive system generates the signal sent to each source mode $\mathbf{v}_i$ for $i < r \leqslant M$. This type of independent control using SVD was investigated by Bai and Elliott (2004) for cross-talk cancelation but without any *a priori* solution like $\mathbf{q}_{\mathrm{WFS}}$. This independent radiation mode-control of AWFS is also a modification of the principal-component LMS (PC-LMS) for active noise control of tonal disturbance (Cabell and Fuller, 1999; Elliott, 2000; Cabell *et al.*, 2001). The PC-LMS is based on SVD, but for AWFS

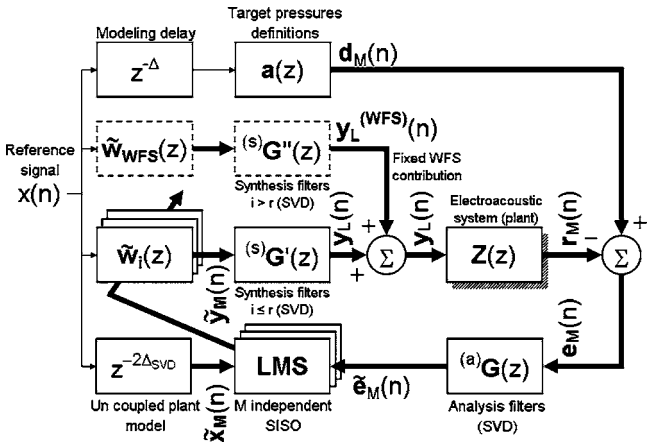

FIG. 20. Block diagram of a possible AWFS least-mean-square adaptive digital processing implementation based on independent radiation mode control. Subscripts denote signal dimensions.

the SVD decoupling must operate over the entire frequency range of interest (Bai and Elliott, 2004).

This implementation requires additional MIMO (multiple-input–multiple-output) synthesis and MIMO analysis filters, ${}^{(s)}\mathbf{G}'(z)$ and ${}^{(a)}\mathbf{G}(z)$, respectively, which must be generated in *a priori* identification stage. In this case, an identification of frequency response functions (FRF) $\hat{Z}_{ml}(\omega)$ between each source l and each sensor m must be achieved. The SVD of the corresponding transfer matrix for each frequency provides source modes $\mathbf{v}_i(\omega)$ and corresponding pressure modes $\mathbf{u}_i(\omega)$. The inverse Fourier transform of $\mathbf{v}_i(\omega)/\sigma_i(\omega)\,\forall\, i \leqslant r \leqslant M$ and $\mathbf{u}_i(\omega)$ generates the z-transformed discrete-time impulse responses (IR) matrices ${}^{(s)}\mathbf{G}'(z)$ and ${}^{(a)}\mathbf{G}(z)$, respectively. The ${}^{(s)}\mathbf{G}'(z)$ matrix generates the inputs of the individual reproduction sources from the source mode inputs with a delay of Δ_{SVD} samples (Bai and Elliott, 2004). Note that division by $\sigma_i(\omega)$ implies plant whitening along uncoupling. Conversely, the ${}^{(a)}\mathbf{G}(z)$ matrix is used to generate the pressure mode errors from the individual sensor errors, again with a delay of Δ_{SVD} samples (Bai and Elliott, 2004). The second synthesis filter matrix ${}^{(s)}\mathbf{G}''(z)$ is created from the null space source modes to produce the fixed part of the AWFS solution. The delay block (Fig. 20) of $2\Delta_{\mathrm{SVD}}$ samples then represents the uncoupled plant model. This type of realization was more extensively described by Bai and Elliott (2004) for cross-talk cancelation. Also, because of the WFS departure penalty in the AWFS definition, an additional set of fixed filters produce the outputs for the $i > r$ (and $i \leqslant$)L WFS fixed source mode contributions $\tilde{q}_i$. This *a priori* solution creates a difference with the work of Bai and Elliott (2004).

All the preceding remarks should be subject of further investigations and experimental verifications. This is topic of current research on practical AWFS in a real reproduction space, that is including a reflective environment.

VIII. CONCLUSION AND PERSPECTIVES

This paper introduced AWFS in the physical domain for active sound field reproduction. AWFS is based on the minimization of the quadratic reproduction errors with a quadratic departure penalty from the WFS solution. Although the AWFS practical interest would be for room compensation, this theoretical paper was mainly concerned with the fundamental AWFS behavior via general analytical considerations and simple free-field simulations.

AWFS can be interpreted as an additive combination of (1) a fixed WFS solution and (2) an optimal regularized solution which seeks to minimize the WFS reproduction error. Contrary to WFS, the AWFS active contribution is spread over the entire source array.

SVD of the transfer impedance matrix shown that, for AWFS, independent control operates on each radiation mode. In the case of a four sensor array, this leads to independent control of a multipole expansion of the sound field at the error sensor locations. For a transfer impedance matrix including either a rigid wall reflection or room effects, the pressure modes still provide finite difference approximations of pressure, pressure gradients and tesseral quadrupole as pressure modes. In real situation, we thus expect that AWFS control will effectively and independently work on similar pressure modes at the sensor array since the analytical results of Sec. V B apply for any transfer impedance matrix $\mathbf{Z}$.

A practical usefulness of AWFS arises from the possibility to move from WFS to closed-loop modified "Ambisonics." AWFS converges toward (1) WFS when the regularization parameter λ is large and (2) closed-loop modified "Ambisonics" when λ is low. In the latter case, it was shown that low order source mode contributions approach an "Ambisonics" problem and that higher order source mode (creating the null space) contributions are imposed by the projection of the WFS solution on the null space basis of $\mathbf{Z}$.

SVD of the transfer impedance matrix suggests an independent radiation mode control implementation of AWFS. This could be achieved with $r \leqslant M$ independent LMS adaptive algorithms which would independently control the source mode contributions in a real adaptive control application. Work is in progress to implement AWFS using the currently developed AWFS adaptive algorithms for a configuration like the one shown in Fig. 2. AWFS performance in-room situation is being therefore investigated from a practical and signal processing view point.

Most of the analytical developments for AWFS can be applied to active noise or vibration control. To the authors knowledge, the use of *a priori* solution like $\mathbf{q}_{\mathrm{WFS}}$ have not been used for active control, this could be of potential interest. Eqs. (7) and (16) to (18) are also typically encountered in inverse problems theory (Hansen, 1998). Inverse problems are of importance in acoustics (Nelson, 2001; Gérard *et al.*, 2005), where the use of *a priori* solutions could also be applied.

APPENDIX: "AMBISONICS" REVIEW

The target wave field $p^{(\mathrm{im})}(\mathbf{x},\omega)$ is defined as a plane wave in free field

$$p^{(\mathrm{im})}(R,\phi,\omega) = A(\omega)e^{jkR\cos(\phi-\theta)} \tag{A1}$$

with cylindrical coordinates (R,ϕ,z), and θ is the direction of propagation of the plane wave. This target plane wave field is represented by a Fourier-Bessel series,

$$p^{(\mathrm{im})}(R,\phi,\omega) = A(\omega)J_0(kR) + 2A(\omega)\sum_{n=1}^{\infty} j^n J_n(kR)\cos(n(\phi-\theta)), \quad \text{(A2)}$$

where J_n is the Bessel function of the first kind and order n. Rewriting Eq. (A2) gives

$$p^{(\mathrm{im})}(R,\phi) = AJ_0(kR) + 2A\sum_{n=1}^{\infty} j^n J_n(kR)\cos(n\theta)\cos(n\phi) + 2A\sum_{n=1}^{\infty} j^n J_n(kR)\sin(n\theta)\sin(n\phi). \quad \text{(A3)}$$

In practice, this series is truncated and expressed in vector form

$$p^{(\mathrm{im})}(R,\phi) = A\mathbf{c}^T\mathbf{h} \quad \text{(A4)}$$

with

$$\mathbf{c}^T = \sqrt{2}[1/\sqrt{2} \quad \cos(\theta) \quad \sin(\theta) \quad \cdots \quad \cos(n\theta) \quad \sin(n\theta) \quad \cdots] \quad \text{(A5)}$$

and

$$\mathbf{h}^T = \sqrt{2}[J_0(kR)/\sqrt{2} \quad j\cos(\phi)J_1(kR) \quad j\sin(\phi)J_1(kR) \quad \cdots \quad j^n\cos(n\phi)J_n(kR) \quad j^n\sin(n\phi)J_n(kR) \quad \cdots], \quad \text{(A6)}$$

where T denotes real transposition. Equation (A6) is independent of the target wave field definition while Eq. (A5) includes the target wave field direction θ. The Fourier-Bessel coefficients $\mathbf{c}$ are proportional to the outputs produced by harmonic directivity patterns on which the plane target field would impinge [see Eq. (A5)]. In $\mathbf{c}$, the first coefficient produces omnidirectional sensing, the second and the third produce perpendicular dipole patterns and this continues with higher order circumferential harmonics.

The reproduction system is assumed to be in free field and the reproduction sources (uniformly distributed over 2π radians) produce a set of plane waves at the origin of the coordinate system

$$p^{(\mathrm{rep})}(R,\phi) = \sum_{l=1}^{L} A_l e^{jkR\cos(\phi-\phi_l)}, \quad \text{(A7)}$$

where A_l is the unknown contribution of the plane reproduction wave l whose direction of propagation is ϕ_l. The reproduced field is also expressed as truncated Fourier-Bessel series

$$p^{(\mathrm{rep})}(R,\phi) = \sum_{l=1}^{L} A_l\mathbf{c}_l^T\mathbf{h} = \mathbf{A}^T\mathbf{C}^T\mathbf{h} \quad \text{(A8)}$$

with

$$\mathbf{A}^T = [A_1 \cdots A_L], \quad \text{(A9)}$$

$$\mathbf{C} = [\mathbf{c}_1 \cdots \mathbf{c}_L] \quad \text{(A10)}$$

$$\mathbf{c}_l = \sqrt{2}[1/\sqrt{2} \quad \cos(\phi_l) \quad \sin(\phi_l) \quad \cdots \quad \cos(n\phi_l) \quad \sin(n\phi_l) \quad \cdots]^T. \quad \text{(A11)}$$

The final step is the minimization of the sum of the quadratic reproduction error $|(\mathbf{A}\mathbf{c}^T - \mathbf{A}^T\mathbf{C}^T)\mathbf{h}|^2$, that is the reproduced wave field Fourier-Bessel coefficients $\mathbf{A}^T\mathbf{C}^T$ must approach, in a least-mean-square (LMS) sense, the target wave field Fourier-Bessel coefficients $A\mathbf{c}^T$. The minimization problem can readily be solved using the generalized pseudo-inverse (Golub and van Loan, 1996) denoted by †

$$\mathbf{A} = A\mathbf{C}^\dagger\mathbf{c} \quad \text{(A12)}$$

with

$$\mathbf{C}^\dagger = \mathbf{V}_c\boldsymbol{\Sigma}_c^+\mathbf{U}_c^H, \quad \text{(A13)}$$

where the SVD of the matrix $\mathbf{C}$ is $\mathbf{U}_c\Sigma_c\mathbf{V}_c^H$ and

$$[\boldsymbol{\Sigma}_c^+]^T = \begin{bmatrix} 1/\sigma_{1_c} & 0 & \cdots & & & 0 \\ 0 & 1/\sigma_{2_c} & 0 & \cdots & & 0 \\ & & \ddots & & & \\ 0 & \cdots & 0 & 1/\sigma_{N_c} & \cdots & 0 \end{bmatrix}_{N\times L}, \quad \text{(A14)}$$

where it was assumed that $N \leqslant L$. $\sigma_{1_c}, \ldots, \sigma_{N_c}$ are the singular values of $\mathbf{C}$. When all the "Ambisonics" reproduction sources are uniformly distributed over 2π radians, Eq. (A12) becomes

$$\mathbf{A} = A\frac{\mathbf{C}^T}{L}\mathbf{c} \quad \text{(A15)}$$

and this gives the following panning function (amplitude A_l of plane waves reproduction sources as function of θ and ϕ_l):

$$A_l = \frac{A}{L}\left[1 + 2\sum_{n=1}^{N}\cos(n(\theta-\phi_l))\right]. \quad \text{(A16)}$$

This corresponds to circular sinc function of ϕ_l.

Transient response of a hollow cylinder with radial and axial material inhomogeneity

Michael El-Raheb
ATK Mission Research, Laguna Hills, California 92653

(Received 3 August 2005; revised 24 January 2006; accepted 13 February 2006)

The transient response of a hollow finite cylinder with radial and axial material inhomogeneity to a pulse of short duration is analyzed. The problem is solved in two steps. Radial inhomogeneity is treated first by dividing the cylinder into coaxial segments each with a constant modulus E which is allowed to vary from segment to segment. Transfer matrices relating variables at the two radial interfaces of a segment combine to satisfy continuity of stress and displacement at these interfaces. The Galerkin method is then utilized to treat the general case with both radial and axial inhomogeneity adopting the eigenfunctions of the radially inhomogeneous cylinder as trial functions. Features of both static and transient responses resemble that for a weakening material along the axis: displacement increases and stress reduces in proportion to the reduction in modulus. Spatial attenuation of transient stress cannot be replicated when geometric dimensionality is reduced from 3-D axisymmetric to 2-D plane-strain. © *2006 Acoustical Society of America.*

I. INTRODUCTION

The dynamic response of solid and hollow elastic cylinders has been studied extensively in the literature as it applies to a variety of engineering and science problems. Vibrations of homogeneous hollow plane-strain cylinders were analyzed by Gasis[1] and Bird *et al.*[2] The frequency response of finite cylinders was analyzed by Grishenko and Meleshko,[3] Batard *et al.*,[4] and Grinchenko.[5] Soldatos and Ye[6] treated anisotropic laminated cylinders, and Hussein and Heyliger[7] considered layered piezoelectric cylinders. Cheung *et al.*[8] analyzed the 3-D vibration of solid and hollow cylinders by the Chebyshev-Ritz method. The free vibration of a hollow infinite multilayered cylinder was addressed by Sastry and Munjal[9] and Wang *et al.*[10] The free vibration of finite multilayered hollow cylinders was treated by Heyliger and Jilani[11] and Wang and Gong.[12] Whittier and Jones[13] studied the propagation of longitudinal and torsional waves in a bimaterial solid cylinder composed of an inner homogeneous core bonded to an outer homogeneous annular cylinder of different properties. Reuter[14] studied flexural waves in bimaterial cylinders. Keck and Armenakas[15] presented an exact solution for longitudinal waves in an infinitely long composite hollow cylinder made of three different transversely isotropic layers. The transient response of a multilayered hollow cylinder with time-dependent boundary conditions was treated by Lee[16] using a hybrid numerical method. Paul and Murali[17] determined the axisymmetric dynamic response of poro-elastic cylinders. Soldatos[18] presented a compilation of more than 150 references on the frequency response of solid and annular elastic cylinders. Yin and Yue[19] analyzed the plane-strain axisymmetric problem with multiple annular layers using Laplace transforms to integrate time dependence. Steinberg[20] formulated the inverse spectral problem to determine properties of a cylinder with inhomogeneous materials. No references were found treating the transient response of a finite hollow cylinder with both radial and axial inhomogeneity.

Analytical treatment of transient wave propagation in finite cylinders with radial and axial material inhomogeneity was not found in the literature. The reason is that these applications usually involve complicated geometries and constitutive laws that can be readily handled by general-purpose computer programs based on finite element, finite difference, finite volume, and smooth particle hydrodynamics (SPH). A comparison of results from these numerical programs with an independent analysis is needed to provide insight into the physics of the problem and phenomena that may not be gained from a purely numerical model. For transient phenomena following external loads of short duration, one simulation may take several hours on a fast workstation. To quickly validate results from these laborious models, engineers tend to simplify geometry and properties by considering limiting cases like that of a homogeneous plane-strain cylinder. Understanding the validity of these approximations is necessary since comparing results from a discretization model with narrowly valid approximations may lead to more uncertainty in the results. An overly simplified model does not always yield a valid result, yet a complicated discretization model needs consistent verification. The middle ground of an analysis that is neither a "black box" nor a simplification helps validate trends and, most importantly, provide understanding. Balancing the degree of simplification by including realistic physical effects in the analytical model rapidly increases its mathematical complexity.

Over the past 5 years, use of wave mechanics to explain mechanisms of tissue trauma has generated interest among researchers in bioengineering and medicine. Unfortunately, experimental measurements of tissue properties and their response to rapid transients with high strain rates are difficult if not impossible to achieve with acceptable accuracy. The

 0001-4966/2006/119(5)/2738/12/$22.50

standard predictive tool for this problem is a nonlinear finite element model. Comparison with a fundamentally different approach like analysis adds confidence to and understanding of results. While the analytical model is not a substitute for a general numerical model, it serves to understand and verify its results. When uncertainty arises from a peculiar numerical result, an independent analytical confirmation becomes necessary.

An analytical model for propagation of transient stress waves in tissue during projectile penetration was developed by El-Raheb.[21] The model consisted of a hollow homogeneous cylinder with radial velocity prescribed at the cylinder's inner boundary over a fixed axial footprint equal to the projectile's length. As long as the projectile's speed is much smaller than the speed of stress waves in the material, the approximation of a time-independent footprint is valid. Such is the case when projectile speed is 100 m/s while dilatational speed in tissue material is 1.7 km/s. However, for a projectile speed in excess of 500 m/s, projectile motion must be considered by allowing the footprint to lengthen with time at the projectile's speed. El-Raheb[22] extends the analysis in Ref. 21 to include a time-delayed prescribed radial displacement where length of the footprint varies with time.

This work addresses the effect on propagation of axial and radial material inhomogeneity from layers and radial tearing. Since real tissue inhomogeneity is too complicated to model, the analysis is restricted to axial symmetry. The problem is solved in two steps. First, radial or $E(r)$ inhomogeneity is treated in Sec. II by dividing the cylinder into coaxial segments each with constant modulus E_j that is allowed to vary from segment to segment. Transfer matrices relating variables at the two radial interfaces of a segment combine to satisfy continuity of stress and displacement at these interfaces. The Galerkin method is then utilized to treat the general problem with both radial and axial inhomogeneity or $E(r,z)$ adopting the eigenfunctions of the radially inhomogeneous cylinder as trial functions. The coupled problem is developed in Sec. III. Transient strain histories calculated with a nonlinear finite-element model compared favorably with the present analysis that is based on linear small displacement theory. This surprising result may be attributed to the tissue's comparative weakness.

Since the projectile's strength and acoustic impedance are much greater than those of tissue, the excitation transmitted over the inner cylinder boundary at the projectile-tissue interface can be approximated by prescribed radial and axial time-dependent motions rather than an unknown pressure excitation. In turn, the excited boundary is mixed meaning that part of the boundary over the footprint has a prescribed motion while the other part is traction-free. The influence method developed by El-Raheb[21] is employed to convert the segment of boundary where motion is prescribed to one where traction is prescribed. A summary of the steps is presented in Sec. VI.

The method of static-dynamic superposition developed by Berry and Naghdi[23] is applied to solve for transient response from each ring traction. The static solution and static-dynamic projection integral are developed in Secs. IV and V. This method accurately predicts stresses near and at the excited boundary and also converges rapidly with the number of terms in the modal expansion.

Section VII discusses results of the static and dynamic models. A comparison of histories from the different models explains how radial and axial inhomogeneities affect response.

Although the Galerkin method is standard, most treatments do not include the techniques in the present analysis and listed below:

(a) transfer matrices for segmenting radial inhomogeneity,
(b) influence method for modeling prescribed motion rather than prescribed pressure, and
(c) static-dynamic superposition for accurately representing the forcing function.

II. RADIAL INHOMOGENEITY

Consider a hollow cylinder with radial and axial coordinates (r,z) with origin on the cylinder's axis at its left face, inner and outer radii (r_p, r_o), length l, radial and axial displacements $\mathbf{u}=\{u,w\}^T$, Lamé constants (λ,μ), and mass density ρ. In all equations to follow subscripts to variables denote components and not partial derivatives. Also for conciseness, a bracket subscripted by j implies that in that bracket parameters λ,μ,k_e,k_s,C_k and functions φ_{mn},ψ_{mn} are also subscripted by j. Assume that Young's modulus $E(r,z)$ is the product of two functions in the form

$$E(r,z)=E_o\xi(r)\eta(z). \tag{1}$$

For radial inhomogeneity only, i.e., $\eta(z)=1$, the problem is solved analytically by dividing the region $r_p\leqslant r\leqslant r_o$ into N_r coaxial segments

$$r_j\leqslant r\leqslant r_{j+1},\quad 1\leqslant j\leqslant N_r,$$

$$\Delta r_j=r_{j+1}-r_j,\quad r_j=(r_o-r_p)/N_r. \tag{2}$$

Assume that $\xi(r)$ is constant over each segment but varies from segment to segment. Since axial symmetry holds, the linear elasto-dynamic equations of the jth segment are

$$\mathbf{D}_j\mathbf{u}_j-\rho\partial_{tt}\mathbf{u}_j=\mathbf{0},$$

$$D_{11,j}=[(\lambda+2\mu)\hat{\nabla}_1^2+\mu\partial_{zz}]_j,\quad D_{12,j}=(\lambda+\mu)_j\partial_{rz},$$

$$D_{21,j}=[(\lambda+\mu)\partial_z(\partial_r+1/r)]_j,$$

$$D_{22,j}=[\mu\hat{\nabla}_0^2+(\lambda+2\mu)\partial_{zz}]_j, \tag{3}$$

$$\lambda_j=\lambda_o\xi(r_j),$$

$$\mu_j=\mu_o\xi(r_j),\quad \hat{\nabla}_n^2\equiv\partial_{rr}+1/r\partial_r-n^2/r^2,\quad n=0,1.$$

λ_o,μ_o are Lamé constants that depend on E_o only, and t is time. For harmonic motions in time with radian frequency ω and simply supported boundary conditions at $z=0$ and $z=l$, Eq. (3) admits the solution (Ref. 21)

$$\{u(r,z,t),w(r,z,t)\}_j^T=\{\bar{u}(r)\sin(k_zz),\bar{w}(r)\cos(k_zz)\}_j^Te^{\hat{i}\omega t},$$

$$\bar{u}_j(r) = -k_{e,j}(C_1 J_1(k_e r) + C_2 Y_1(k_e r))_j + k_z(C_3 J_1(k_s r) + C_4 Y_1(k_s r))_j,$$

$$\bar{w}_j(r) = k_z(C_1 J_0(k_e r) + C_2 Y_0(k_e r))_j + k_{s,j}(C_3 J_0(k_s r) + C_4 Y_0(k_s r))_j, \tag{4a}$$

$$k_{e,j}^2 = \omega^2/c_{d,j}^2 - k_z^2, \quad c_{d,j}^2 = (\lambda + 2\mu)_j/\rho,$$
$$k_{s,j}^2 = \omega^2/c_{s,j}^2 - k_z^2, \quad c_{s,j}^2 = \mu_j/\rho. \tag{4b}$$

(c_d, c_s) are dilatational and shear speeds of sound, J_n and Y_n are Bessel functions of the first and second kind, $\hat{i}=\sqrt{-1}$, $k_z = m\pi/l$, where m is an integer axial wave number, and C_{kj} are independent constants in the solution of the jth coaxial segment.

The constitutive relations are

$$\sigma_{rr,j} = \lambda_j \Delta_j + 2\mu_j \partial_r u_j, \quad \sigma_{\theta\theta,j} = \lambda_j \Delta_j + 2\mu_j u_j/r,$$
$$\sigma_{zz,j} = \lambda_j \Delta_j + 2\mu_j \partial_z w_j, \quad \tau_{rz,j} = \mu_j(\partial_z u_j + \partial_r w_j), \tag{5}$$
$$\Delta_j = \partial_r u_j + u_j/r + \partial_z w_j.$$

Substituting (4a) in (5) yields

$$\begin{Bmatrix} \sigma_{rr} \\ \sigma_{\theta\theta} \\ \sigma_{zz} \\ \tau_{rz} \end{Bmatrix}_j (r,z,t) = \begin{Bmatrix} \bar{\sigma}_{rr}(r)\sin(k_z z) \\ \bar{\sigma}_{\theta\theta}(r)\sin(k_z z) \\ \bar{\sigma}_{zz}(r)\sin(k_z z) \\ \bar{\tau}_{rz}(r)\cos(k_z z) \end{Bmatrix}_j e^{\hat{i}\omega t}, \tag{6a}$$

$$\begin{aligned}\bar{\sigma}_{rr,j}(r) = {} & [-((\lambda+2\mu)k_e^2 + \lambda k_z^2)J_0(k_e r) \\ & + 2\mu k_e^2 J_1(k_e r)/(k_e r)]_j C_{1j} + [-((\lambda+2\mu)k_e^2 \\ & + \lambda k_z^2)Y_0(k_e r) + 2\mu k_e^2 Y_1(k_e r)/(k_e r)]_j C_{2j} \\ & + 2\mu_j k_{s,j} k_z [J_0(k_s r) - J_1(k_s r)/(k_s r)]_j C_{3j} \\ & + 2\mu_j k_{s,j} k_z [Y_0(k_s r) - Y_1(k_s r)/(k_s r)]_j C_{4j},\end{aligned} \tag{6b}$$

$$\begin{aligned}\bar{\sigma}_{\theta\theta,j}(r) = {} & -[\lambda(k_z^2 + k_e^2)J_0(k_e r) + 2\mu k_e^2 J_1(k_e r)/(k_e r)]_j C_{1j} \\ & -[\lambda(k_z^2 + k_e^2)Y_0(k_e r) + 2\mu k_e^2 Y_1(k_e r)/(k_e r)]_j C_{2j} \\ & + 2\mu_j k_{s,j} k_z [C_3 J_1(k_s r) + C_4 Y_1(k_s r)]_j/(k_{s,j} r),\end{aligned} \tag{6c}$$

$$\begin{aligned}\bar{\sigma}_{zz,j}(r) = {} & -((\lambda+2\mu)k_z^2 + \lambda k_e^2)_j [C_1 J_0(k_e r) + C_2 Y_0(k_e r)]_j \\ & - 2\mu_j k_{s,j} k_z [C_3 J_0(k_s r) + C_4 Y_0(k_s r)]_j,\end{aligned} \tag{6d}$$

$$\begin{aligned}\bar{\tau}_{rz,j}(r) = {} & -2\mu_j k_{e,j} k_z [C_1 J_1(k_e r) + C_2 Y_1(k_e r)]_j \\ & - \mu_j(k_{s,j}^2 - k_z^2)[C_3 J_1(k_s r) + C_4 Y_1(k_s r)]_j.\end{aligned} \tag{6e}$$

The functional form along z in (4a) and (6a) assumes that $\sigma_{zz} \equiv u = 0$ at the two axial ends of the cylinder $z = 0, l$. Although this condition is an approximation to a traction-free boundary where $\sigma_{zz} \equiv \tau_{rz} = 0$ at $z = 0, l$, nevertheless the effect of boundary conditions on stress waves remote from these boundaries is negligible prior to reflections from these boundaries, especially when the material's sound speed is low.

For each coaxial segment, express the state vector $\mathbf{S}_j = \{\bar{\sigma}_{rr}, \bar{\tau}_{rz}, \bar{u}, \bar{w}\}_j^T$ in terms of the constant vector $\mathbf{C}_j = \{C_1, C_2, C_3, C_4\}_j^T$:

$$\mathbf{S}_j(r) = \mathbf{B}_j(r)\mathbf{C}_j. \tag{7}$$

$\mathbf{B}_j(r)$ is a matrix with coefficients the functions multiplying $\{C_1, C_2, C_3, C_4\}_j^T$ in (4) and (6). Evaluating (7) at the two interfaces $r = r_j$ and $r = r_{j+1}$ of the jth segment and then eliminating $\mathbf{C}_j$ determines the 4×4 transfer matrix $\mathbf{T}_j$ relating state vectors at the two interfaces of a segment:

$$\mathbf{S}_j(r_{j+1}) = \mathbf{T}_j \mathbf{S}_j(r_j), \quad \mathbf{T}_j = \mathbf{B}_j^{-1}(r_j)\mathbf{B}_j(r_{j+1}), \tag{8a}$$

$$\mathbf{C}_j = \mathbf{B}_j^{-1}(r_j)\mathbf{S}_j(r_j). \tag{8b}$$

Enforcing continuity of $\mathbf{S}_j$ at interfaces of segments and homogeneous traction boundary conditions at $r = r_p$ and $r = r_o$,

$$\bar{\sigma}_{rr}(r_p) = \bar{\tau}_{rz}(r_p) = 0,$$
$$\bar{\sigma}_{rr}(r_o) = \bar{\tau}_{rz}(r_o) = 0, \tag{9}$$

yields the global transfer matrix $\mathbf{T}_G$ in tri-diagonal block form and the corresponding global $\mathbf{S}_G$ which is the ensemble of all $\mathbf{S}_j$:

$$\mathbf{T}_G \cdot \mathbf{S}_G = \mathbf{0} \Rightarrow \det|\mathbf{T}_G| = 0,$$
$$\mathbf{S}_G = \{\mathbf{S}_1(r_1), \mathbf{S}_2(r_2), \ldots, \mathbf{S}_j(r_j), \ldots, S_{N_r}(r_{N_r})\}^T. \tag{10}$$

Equation (10) determines the eigenset $\{\mathbf{S}_G; \omega\}$ and in turn $\mathbf{C} = \{\mathbf{C}_1, \mathbf{C}_2, \ldots, \mathbf{C}_j, \ldots, \mathbf{C}_{N_r}\}^T$ from (8b). For the jth coaxial segment, the eigenfunction expansions for u_j and w_j take the form

$$u_j(r,z,t) = \sum_n \sum_m a_{mn}(t)\varphi_{mn,j}(r)\sin(k_{zm} z),$$
$$w_j(r,z,t) = \sum_n \sum_m a_{mn}(t)\psi_{mn,j}(r)\cos(k_{zm} z). \tag{11}$$

$\phi_{mn,j} = \{\varphi_{mn}, \psi_{mn}\}_j^T$ is the displacement subvector of $\mathbf{S}_j$ corresponding to the nth eigenfunction with m axial half waves of the jth segment while their functional form is given by (4a).

III. RADIAL AND AXIAL INHOMOGENEITIES

When adding axial inhomogeneity, the equations of the jth coaxial segment become

$$\mathbf{D}_j \mathbf{u}_j + \tilde{\mathbf{D}}_j \mathbf{u}_j - \rho \partial_{tt} \mathbf{u}_j = \mathbf{0}. \tag{12}$$

$\mathbf{D}_j$ is similar to the differential operator matrix defined in (3) with the constants λ_j and μ_j replaced by the functions $\lambda_j \eta(z)$ and $\mu_j \eta(z)$, and $\tilde{\mathbf{D}}_j$ is the differential operator matrix defined by

$$\tilde{D}_{11,j} = \mu_j \eta'(z)\partial_z, \quad \tilde{D}_{12,j} = \mu_j \eta'(z)\partial_r,$$
$$\tilde{D}_{21,j} = \lambda_j \eta'(z)(\partial_r + 1/r), \quad \tilde{D}_{22,j} = (\lambda_j + 2\mu_j)\eta'(z)\partial_z. \tag{13}$$

$(\,)'$ is the derivative with respect to the argument. The Galerkin method is utilized to solve (12). Eigenfunctions of the radially inhomogeneous cylinder developed in Sec. II are

utilized as trial functions. Substituting (11) in (12) and noting that $\mathbf{D}_j\boldsymbol{\phi}_{mn,j}=-\rho\omega_{mn}^2\boldsymbol{\phi}_{mn,j}$ yields equations of the jth coaxial segment

$$\sum_l\sum_k [-\rho(\ddot{a}_{kl}+\eta(z)\omega_{kl}^2 a_{kl})\varphi_{kl,j}\sin(k_{zk}z) + a_{kl}\mu_j(k_{zk}\varphi_{kl}+\psi'_{kl})_j\eta'(z)\cos(k_{zk}z)] = p_r\bar{\delta}(r-r_p)(H(z-z_1)-H(z-z_2))f_p(t), \tag{14a}$$

$$\sum_l\sum_k [-\rho(\ddot{a}_{kl}+\eta(z)\omega_{kl}^2 a_{kl})\psi_{kl,j}\cos(k_{zk}z) + a_{kl}(\lambda(\varphi'_{kl}+\varphi_{kl}/r) - (\lambda+2\mu)k_{zk}\psi_{kl})_j\eta'(z)\sin(k_{zk}z)] = 0. \tag{14b}$$

$\dot{(\,)}$ is time derivative. a_{kl} and ω_{kl} are not subscripted by j because these modal quantities are the same for all segments. Multiplying (14a) by $\varphi_{mn,j}\sin(k_{zm}z)$ and (14b) by $\psi_{mn,j}\cos(k_{zm}z)$, adding the two equations, and then integrating over the cylinder volume including all segments while enforcing orthogonality of the $\{\varphi_{mn}(r),\psi_{mn}(r)\}^T$ set produces

$$\mathbf{Ka}+\mathbf{M}\ddot{\mathbf{a}}=\mathbf{0}, \tag{15a}$$

$$M_{mn,kl}=-0.5\rho l\delta_{mn,kl}\sum_j\int_{r_j}^{r_{j+1}}(\varphi_{mn}^2+\psi_{mn}^2)_j r\,dr \tag{15b}$$

$$K_{mn,kl}=\sum_{q=1}^{4}R_{mn,kl}^{(q)}Z_{mk}^{(q)}, \tag{15c}$$

$$\begin{aligned}
R_{mn,kl}^{(1)}&=-\rho\sum_j\int_{r_j}^{r_{j+1}}\omega_{kl}^2\varphi_{kl,j}\varphi_{mn,j}r\,dr,\\
R_{mn,kl}^{(2)}&=-\rho\sum_j\int_{r_j}^{r_{j+1}}\omega_{kl}^2\psi_{kl,j}\psi_{mn,j}r\,dr,\\
Z_{mk}^{(1)}&=\int_0^l\eta(z)\sin(k_{zk}z)\sin(k_{zm}z)dz,\\
Z_{mk}^{(2)}&=\int_0^l\eta(z)\cos(k_{zk}z)\cos(k_{zm}z)dz,\\
R_{mn,kl}^{(3)}&=\sum_j\int_{r_j}^{r_{j+1}}\mu_j(k_{zk}\varphi_{kl}+\psi'_{kl})_j\varphi_{mn,j}r\,dr,\\
R_{mn,kl}^{(4)}&=\sum_j\int_{r_j}^{r_{j+1}}[\lambda(\varphi'_{kl}+\varphi_{kl}/r)-(\lambda+2\mu)k_{zk}\psi_{kl}]_j\psi_{mn,j}r\,dr,\\
Z_{mk}^{(3)}&=\int_0^l\eta'(z)\cos(k_{zk}z)\sin(k_{zm}z)dz,\\
Z_{mk}^{(4)}&=\int_0^l\eta'(z)\sin(k_{zk}z)\cos(k_{zm}z)dz=Z_{km}^{(3)}.
\end{aligned} \tag{15d}$$

$\delta_{mn,kl}$ is the Kronecker delta. Equation (15a) is diagonalized by solving the eigenvalue problem

$$[\mathbf{K}-\mathbf{M}\omega^2]\mathbf{a}=\mathbf{0}. \tag{16}$$

This determines the coupled eigenfrequencies ω_{ci}, coupling coefficients a_{mni}, and orthogonal set $\{\Phi_{ci},\Psi_{ci}\}$ of the ith coupled mode. In terms of coupled modes, the eigenfunction expansion takes the form

$$\begin{aligned}
u(r,z,t)&=\sum_i c_i(t)\Phi_{ci}(r,z),\\
w(r,z,t)&=\sum_i c_i(t)\Psi_{ci}(r,z),
\end{aligned} \tag{17a}$$

$$\begin{aligned}
\Phi_{ci}(r,z)&=\sum_n\sum_m a_{mn,i}\sum_j\varphi_{mn,j}(r)(H(r-r_j)-H(r-r_{j+1}))\sin(k_{zm}z),\\
\Psi_{ci}(r,z)&=\sum_n\sum_m a_{mn,i}\sum_j\psi_{mn,j}(r)(H(r-r_j)-H(r-r_{j+1}))\cos(k_{zm}z).
\end{aligned} \tag{17b}$$

Consider the inhomogeneous boundary conditions at $r=r_p$:

$$\begin{aligned}
\sigma_{rr}(r_p,z;t)&=p_r[H(z-z_1)-H(z-z_2)]f_p(t),\\
\tau_{rz}(r_p,z;t)&=0,\\
\sigma_{rr}(r_o,z;t)&=\tau_{rz}(r_o,z;t)=0.
\end{aligned} \tag{18}$$

H is the Heaviside function, $f_p(t)$ is the time dependence of the forcing function, and p_r is the magnitude of the uniform applied pressure. To satisfy (23), the static-dynamic superposition method developed by Berry and Naghdi[23] is utilized. Total displacement is expressed as a superposition of two solutions

$$\mathbf{u}_T(r,z;t)=\mathbf{u}_s(r,z)f_p(t)+\mathbf{u}(r,z,t). \tag{19}$$

$\mathbf{u}_s$ is static displacement satisfying the inhomogeneous boundary conditions

$$\begin{aligned}
\sigma_{rrs}(r_p,z)&=[H(z-z_1)-H(z-z_2)],\\
\tau_{rzs}(r_p,z)&=0,\\
\sigma_{rrs}(r_o,z)&=0,\quad \tau_{rzs}(r_o,z)=0
\end{aligned} \tag{20}$$

(see Sec. V), and $\mathbf{u}$ is the dynamic eigenfunction expansion (17a). In this way, the first term yields finite σ_{rr} at $r=r_p$. In addition to accuracy of variables at and near the boundary, this method converges rapidly. Substituting (19) in (15a) and enforcing orthogonality of $\{\Phi_{ci},\Psi_{ci}\}$ determines uncoupled equations in $c_i(t)$:

$$\ddot{c}_i(t)+\omega_{ci}^2c_i(t)=p_rN_{cfi}\ddot{f}_p(t)/N_{cii}, \tag{21a}$$

$$\begin{aligned}
N_{cii}&=\rho\int_0^l\int_{r_p}^{r_o}(\Phi_{ci}^2+\Psi_{ci}^2)r\,dr\,dz\\
&=0.5\rho l\sum_n\sum_m a_{mn,i}^2\sum_j\int_{r_j}^{r_{j+1}}(\varphi_{mn}^2+\psi_{mn}^2)_j r\,dr,
\end{aligned}$$

$$N_{cfi} = -\rho \sum_j \int_{r_j}^{r_{j+1}} \int_0^l (\Phi_{ci} u_s + \Psi_{ci} w_s) r \, dr \, dz. \tag{21b}$$

The static-dynamic projection integral N_{cfi} is derived in Sec. V.

The effect of material visco-elasticity may be approximated in Eq. (21a) by including a velocity proportional term factored by frequency-dependent viscous damping coefficients $2\zeta_i(\omega_{ci})\dot{c}_i(t)$. A rigorous treatment of dynamic visco-elasticity would require computing a complex stiffness matrix **K** in Eq. (16) as it includes a complex frequency-dependent modulus. This yields the evaluation of a complex eigenvalue problem (see Ref. 24) which is beyond the scope of the present study.

IV. STATIC SOLUTION

The static-dynamic superposition method expressed by Eq. (19) requires the static solution $\mathbf{u}_s$ of the inhomogeneous cylinder. A method similar to the dynamic solution in Sec. III is adopted to solve the static problem. For the jth coaxial segment, express displacement as

$$u_{s,j}(r,z) = \left[u_{sr}(r,z) + \sum_n \sum_m \tilde{a}_{smn} \varphi_{mn}(r) \sin(k_{zm} z) \right]_j,$$
$$w_{s,j}(r,z) = \left[w_{sr}(r,z) + \sum_n \sum_m \tilde{a}_{smn} \psi_{mn}(r) \cos(k_{zm} z) \right]_j, \tag{22}$$

where static displacement (u_{sr}, w_{sr}) and eigenfunction $(\varphi_{kl}, \psi_{kl})$ are those of the radially inhomogeneous cylinder. The static equations are

$$[\mathbf{D}_j + \tilde{\mathbf{D}}_j] \mathbf{u}_{s,j} = \mathbf{0}. \tag{23}$$

The differential operators $\mathbf{D}_j$ and $\tilde{\mathbf{D}}_j$ are given by Eqs. (3) and (13), respectively. Substituting (28) in (29) yields

$$\sum_l \sum_k \tilde{a}_{skl} [-\rho \eta(z) \omega_{kl}^2 \varphi_{kl,j} \sin(k_{zk} z) + \mu_j (k_{zk} \varphi_{kl} + \psi'_{kl})_j \eta'(z) \cos(k_{zk} z)] = -[\tilde{D}_{11} u_{sr} + \tilde{D}_{12} w_{sr}]_j, \tag{24a}$$

$$\sum_l \sum_k \tilde{a}_{skl} [-\rho \eta(z) \omega_{kl}^2 \psi_{kl,j} \cos(k_{zk} z) + (\lambda(\varphi'_{kl} + \varphi_{kl}/r) - (\lambda + 2\mu) k_{zk} \psi_{kl})_j \eta'(z) \sin(k_{zk} z)] = -[\tilde{D}_{21} u_{sr} + \tilde{D}_{22} w_{sr}]_j. \tag{24b}$$

Note that in (24) $\mathbf{D}_j \mathbf{u}_{srj} = \mathbf{0}$ since $\mathbf{u}_{srj}$ is the static solution of the radially inhomogeneous cylinder. Multiplying (24a) by $\varphi_{mn,j} \sin(k_{zm} z)$, (24b) by $\psi_{mn,j} \cos(k_{zm} z)$, integrating over the cylinder's volume, and then adding the two equations produces

$$\mathbf{K} \tilde{\mathbf{a}}_s = \mathbf{p}_s, \tag{25}$$

where the stiffness matrix **K** is given by (15c) and the right-hand vector $\mathbf{p}_s$ is defined by

$$p_{s,mn} = -\sum_j \int_0^l \int_{r_j}^{r_{j+1}} [\tilde{D}_{11} u_{sr} + \tilde{D}_{12} w_{sr}]_j \varphi_{mn,j} \times \sin(k_{zm} z) r \, dr \, dz - \sum_j \int_0^l \int_{r_j}^{r_{j+1}} \times [\tilde{D}_{21} u_{sr} + \tilde{D}_{22} w_{sr}]_j \psi_{mn,j} \cos(k_{zm} z) r \, dr \, dz. \tag{26}$$

Equation (25) yields the coupling coefficient vector $\mathbf{a}_s = \{a_{skl}\}_j^T$. Static displacement (u_{sr}, w_{sr}) of a coaxial segment is derived by El-Raheb[1] and given below for completeness:

$$u_{sr,j}(r,z) = \sum_m \varphi_{srm,j}(r) \sin(k_{zm} z), \tag{27a}$$
$$\varphi_{srm,j}(r) = [C_1 I_1(k_z r) + C_2 K_1(k_z r) + C_3(k_z r I_0(k_z r) - I_1(k_z r)) - C_4(k_z r K_0(k_z r) + K_1(k_z r))]_{m,j},$$
$$w_{sr,j}(r,z) = \sum_m \psi_{srm,j}(r) \cos(k_{zm} z),$$
$$\psi_{srm,j}(r) = [C_1 I_0(k_z r) - C_2 K_0(k_z r) + C_3(\alpha_1 I_0(k_z r) + k_z r I_1(k_z r)) + C_4(-\alpha_1 K_0(k_z r) + k_z r K_1(k_z r))]_{m,j}, \tag{27b}$$
$$\alpha_{1j} = (\lambda + 3\mu)_j / (\lambda + \mu)_j.$$

I_n and K_n are the modified Bessel functions of the first and second kind. The transfer matrix approach utilized in Sec. II is applied to the radially inhomogeneous static problem. Since the z functions are orthogonal, solutions for each k_{zk} decouple and coefficients $C_{q,k}$ $(q=1,4)$ are determined by satisfying boundary conditions (20).

V. STATIC-DYNAMIC PROJECTION INTEGRAL

Substituting (17), (22), and (27) in (21b) and enforcing orthogonality of the z functions yields an expression for N_{cfi} in terms of constituent functions, i.e., modes and static solution of the radially inhomogeneous problem

$$N_{cfi} = \sum_n \sum_m (a_{mn,i} N_{rfmn} - \tilde{a}_{smn} a_{mn,i} N_{rmn}),$$
$$N_{rfmn} = -0.5 \rho l \sum_j \int_{r_j}^{r_{j+1}} (\varphi_{srm} \varphi_{mn} + \psi_{srm} \psi_{mn})_j r \, dr, \tag{28}$$
$$N_{rmn} = 0.5 \rho l \sum_j \int_{r_j}^{r_{j+1}} (\varphi_{mn}^2 + \psi_{mn}^2)_j r \, dr.$$

N_{rfmn} and N_{rmn} are the static-dynamic projection integral and generalized mass of the cylinder with purely radial inhomogeneity developed in Sec. II. This is the limit when $\tilde{a}_{smn} = 0$ and $a_{mn,i} = \delta_{mn,i}$ in (28), and with generalized coordinates a_{mn} in (11) satisfying

$$\ddot{a}_{mn}(t) + \omega_{mn}^2 a_{mn}(t) = p_r N_{rfmn} f_p(t) / N_{rmn}. \tag{29}$$

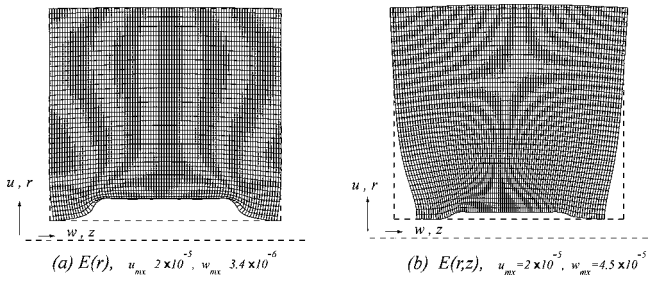

FIG. 1. Static deformation from prescribed u at $r=r_p$. (a) $E=E(r)$. (b) $E=E(r,z)$.

VI. PRESCRIBED MOTION WITH TIME DELAY

When the forcing function is a radial motion prescribed over part of the inner cylindrical boundary while the remaining part of the boundary is traction-free, the problem converts to a mixed boundary value whose solution is briefly outlined below while details may be found in Ref. 21.

Divide the cylindrical surface $\{r=r_p, z_a \leqslant z \leqslant z_b\}$ into n_p+1 equidistant ring stations with constant increment Δz_p

$$z_1, z_2, \ldots, z_l, \ldots, z_{n_p+1}, \quad z_l = z_a + (l-1)\Delta z_p,$$
$$\Delta z_p = (z_b - z_a)/n_p, \quad z_1 = z_a, \quad z_{n_p+1} = z_b. \tag{30}$$

Assume a uniform pressure of unit intensity to act over each ring segment $z_l \rightarrow z_{l+1}$ with arbitrary time dependence $\tilde{f}_p(t)$. For the kth pressure segment, evaluating $u_{lk}(r_p, z_{cl}; t) \equiv U_{clk}(t)$ at the central point $z_{cl}=(z_l+z_{l-1})/2$ of the lth segment yields coefficients of the influence matrix $U_{clk}(t)$. Total displacement at the boundary $r=r_p$ is then

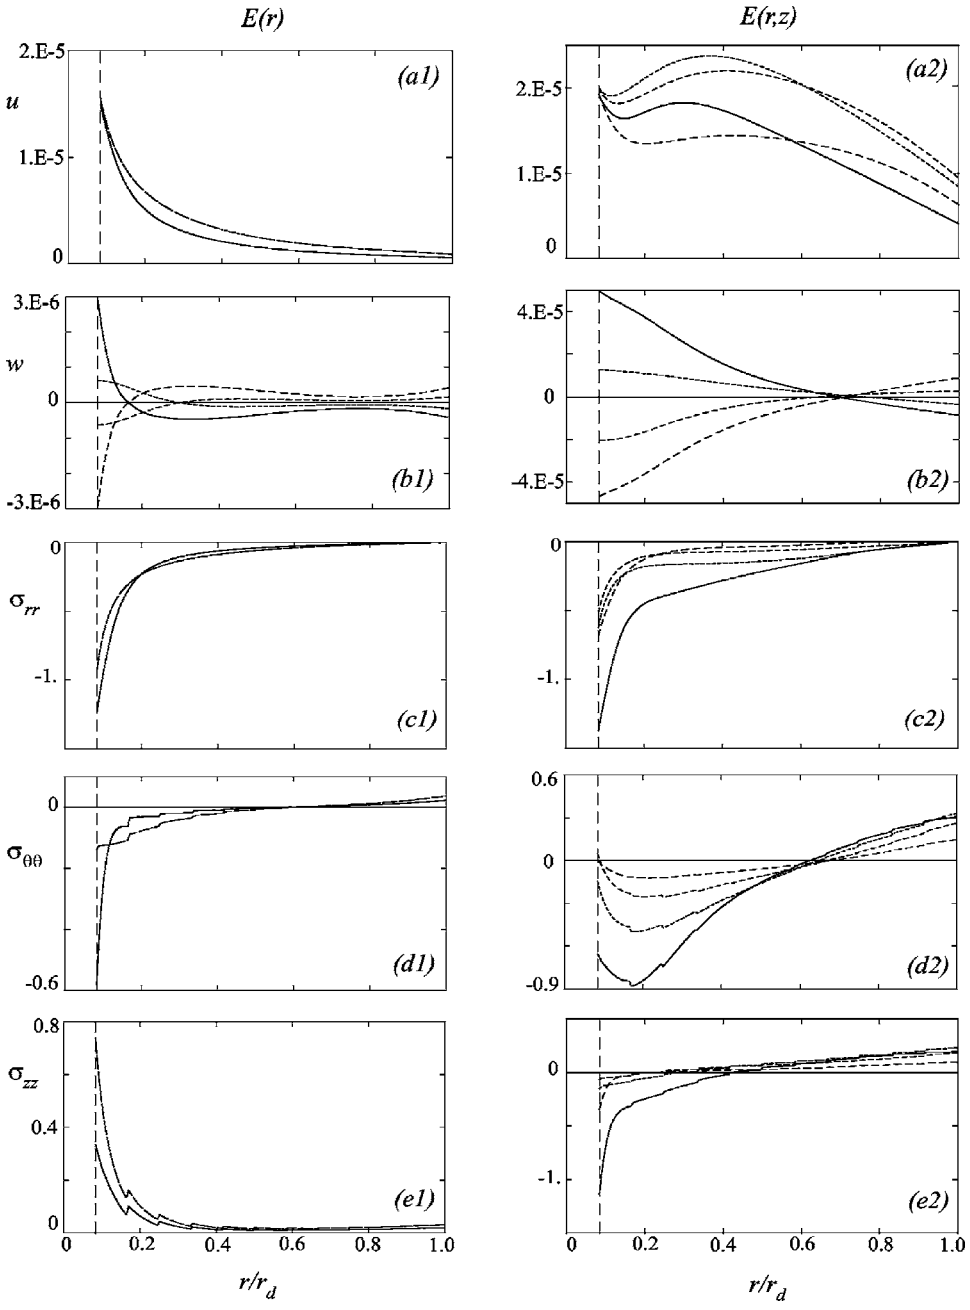

FIG. 2. Distribution of static variables along r from prescribed u at $r=r_p$. (a1)–(e1) $E=E(r)$. (a2)–(e2) $E=E(r,z)$.———z/l=0.2, --- 0.4, - - - - 0.6, - - - 0.8.

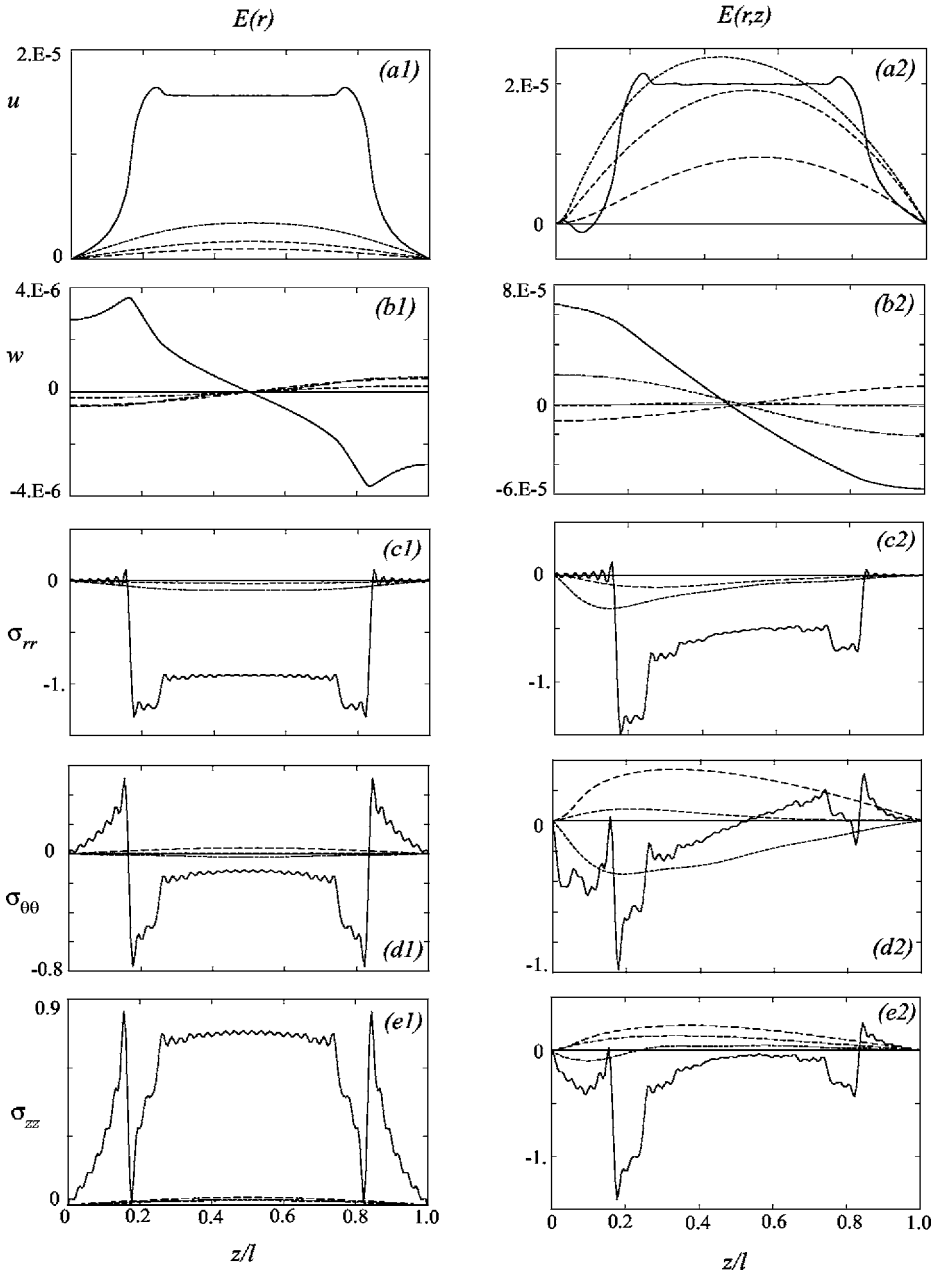

FIG. 3. Distribution of static variables along z from prescribed u at $r=r_p$. (a1)–(e1) $E=E(r)$. (a2)–(e2) $E=E(r,z)$.———$r/r_p=1$, --- 5, - - - - 8, - - - 12.

$$u(r_p,z_{cl};t)=\sum_{k=1}^{n} U_{clk}(t)\tilde{p}_k(t), \quad 1\leqslant l\leqslant n. \tag{31}$$

$\tilde{p}_k(t)$ are time-dependent weights determined from the constraint that $u(r_p,z_{cl};t)=u_p(t)$ where $u_p(t)$ is instantaneous prescribed displacement. This superposition applies to all dependent variables $\mathbf{S}$,

$$\mathbf{S}(r,z;t)=\sum_{k=1}^{n} \mathbf{S}_{\mathbf{k}}(r,z;t)\tilde{p}_k(t), \quad 1\leqslant l\leqslant n, \tag{32}$$

where $\mathbf{S}_k$ is the value of the variable from the kth pressure segment. Since $\tilde{f}_p(t)$ is arbitrary, numerical experiments have shown that a simple ramp is appropriate:

$$\tilde{f}_p(t)=(t/\Delta t_1)[H(t)-H(t-\Delta t_1)]+H(t-\Delta t_1), \tag{33}$$

where Δt_1 is a rise time in the prescribed motion profile. Enforcing the condition of prescribed displacement $u_p(t)$ at each time step yields a set of simultaneous equations in the instantaneous weights $\tilde{p}_k(t)$:

$$\sum_{k=1}^{n_p} U_{clk}(t)\tilde{p}_k(t)=u_p(t), \quad 1\leqslant l\leqslant n_p. \tag{34}$$

When the projectile moves, the axial length of the footprint varies instantaneously. Then, $f_p(t)$ in (21a) is modified to a time-delayed form that depends not only on t but also on z as follows:

$$f_p(\hat{t}), \quad \hat{t} = (t - z/V_p)H(t - z/V_p). \tag{35}$$

V_p is projectile speed. The significance of (35) is that at some station z, $f_p(\hat{t})$ acts only when $t \geqslant z/V_p$, otherwise it vanishes, thus the term "time-delayed."

VII. RESULTS

Before discussing results of tissue response, a comparison of the present analysis with an example by Yin and Yue[19] is appropriate although their analysis concerns the special case of a plane-strain bi-material cylinder. In this example, the inner annulus is made of steel and the outer annulus of aluminum. Inner radius a_1 and thickness of each layer h_1, h_2 are all equal. The ratio of extensional propagation speeds is $c_{d1}/c_{d2}=1.1$, the density ratio is $\rho_1/\rho_2=2.724$, and the Poisson ratio for both layers is $\nu=0.25$. An axisymmetric prescribed pressure with a step function time dependence $p(t)=p_oH(t)$ is applied at the inner perimeter $r=a_1$ while the outer perimeter is traction-free, where $H(t)$ is the Heaviside function. Plots of normalized radial displacement $\tilde{u}=u(\lambda_1+2\mu_1)/(a_1p_o)$ and normalized circumferential stress $\tilde{\sigma}_{\theta\theta}=\sigma_{\theta\theta}/(2(1-\nu)p_o)$ along the normalized radius $\tilde{r}=(r-a_1)/(2h_1)$ at the normalized time $\tilde{t}\equiv t/(h_1/c_{d1}+h_2/c_{d2})=1$ are identical to the solid thick lines in the second and third plots of Fig. 2 of Ref. 19. In the present analysis, 150 terms were used in the modal expansion. This large number is needed since in this example the rise time of $H(t)$ is zero, meaning that its frequency content is infinite. In spite of this demanding requirement, the present analysis converges rapidly. Although this comparison is limited to the case of plane strain, it validates the radial dependence of a segmented infinite cylinder adopting the transfer matrix method.

In all numerical results to follow, the geometry and material properties of the hollow gelatin cylinder are

$$r_p = 0.635 \text{ cm } (=0.25 \text{ in.}), \quad r_o = 7.62 \text{ cm } (=3 \text{ in.}), \tag{36a}$$

$$l = 7.62 \text{ cm } (=3 \text{ in.}),$$

$$E_o = 3.1 \times 10^9 \text{ dyn/cm}^2 \ (=4.5 \times 10^4 \text{ lb/in.}^2)$$

$$\rho = 0.93 \text{ g/cm}^3 \ (=8.7 \times 10^{-5} \text{ lbs}^2/\text{in.}^4), \quad \nu = 0.48 \tag{36b}$$

$$c_d = 1.71 \text{ km/s } (=6.74 \times 10^4 \text{ in./s}),$$

$$c_s = 0.34 \text{ km/s} (=1.32 \times 10^4 \text{ in./s}).$$

E_o is Young's modulus of the homogeneous cylinder. This low modulus and the choice of $\nu=0.48$ for an almost incompressible material are consistent with a gelatin simulent of biological tissue used in experiments. Motion prescribed over the inner boundary extends over the interval $z_a \leqslant z \leqslant z_b$ where $z_a=1.27$ cm (=0.5 in.) and $z_b=6.35$ cm (=2.5 in.). This interval is divided into 14 equidistant ring segments needed in the influence method.

Functions $\xi(r)$ and $\eta(z)$ in Eq. (1) defining radial and axial material inhomogeneity are given by

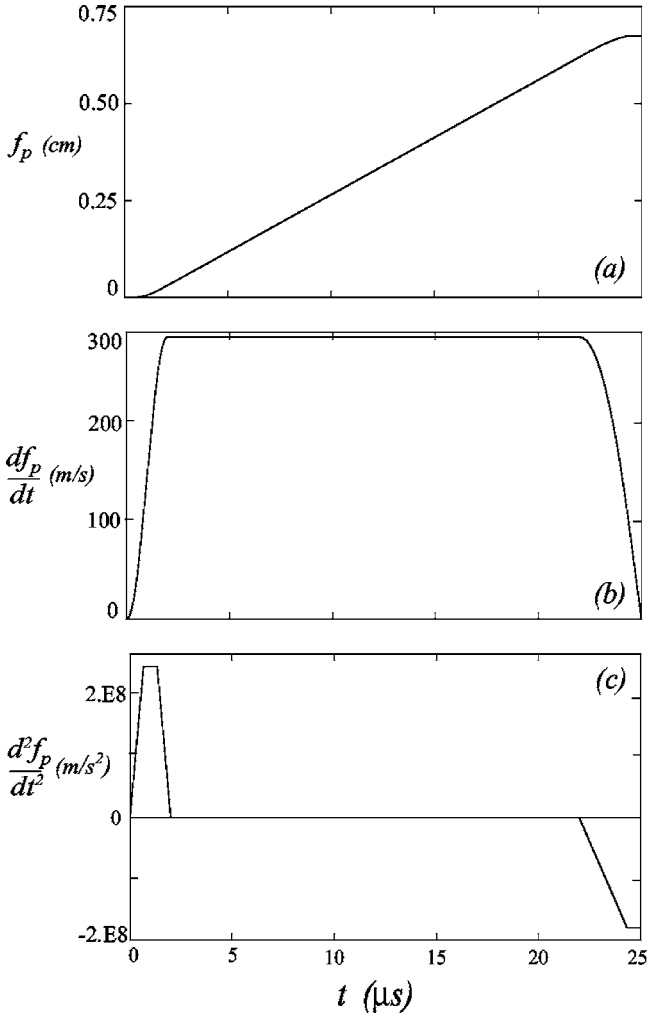

FIG. 4. Prescribed motion. (a) f_p, (b) df_p/dt, and (c) d^2f_p/dt^2.

$$E(r,z) = E_o\xi(r)\eta(z),$$

$$\xi(r) = \alpha + (1-\alpha)(r - r_p)/(r_o - r_p), \quad \alpha = 0.444, \tag{36c}$$

$$\eta(z) = 1 - 0.75(z/l) + 0.18(z/l)^2.$$

$\xi(r)$ is discretized into $N_r=12$ steps of equal interval

$$\xi(r) = \xi(r_{cj})[H(r - (j-1)\Delta r) - H(r - j\Delta r)],$$

$$(j-1)\Delta r \leqslant r \leqslant j\Delta r, \tag{36d}$$

$$r_{cj} = (2j-1)\Delta r/2, \quad \Delta r = (r_o - r_p)/N_r, \quad 1 \leqslant j \leqslant N_r.$$

The reduced modulus at $r=r_p$ accounts for radial tearing caused by the projectile's motion weakening the material locally. The reduction in modulus axially accounts for weaker tissue behind muscle.

Since the static solution is needed for determining transient response, static results are discussed first. Figures 1(a) and 1(b) show the static deformed cylinder's generator for prescribed radial displacement with $E(r)$ and $E(r,z)$. Note that for the same magnitude of prescribed u_o, w_{mx} from $E(r,z)$ is an order of magnitude larger than that from $E(r)$ because of reduced stiffness along the axis. At $r=r_p$, w is such that it shortens cylinder length while at $r=r_o$ the reverse

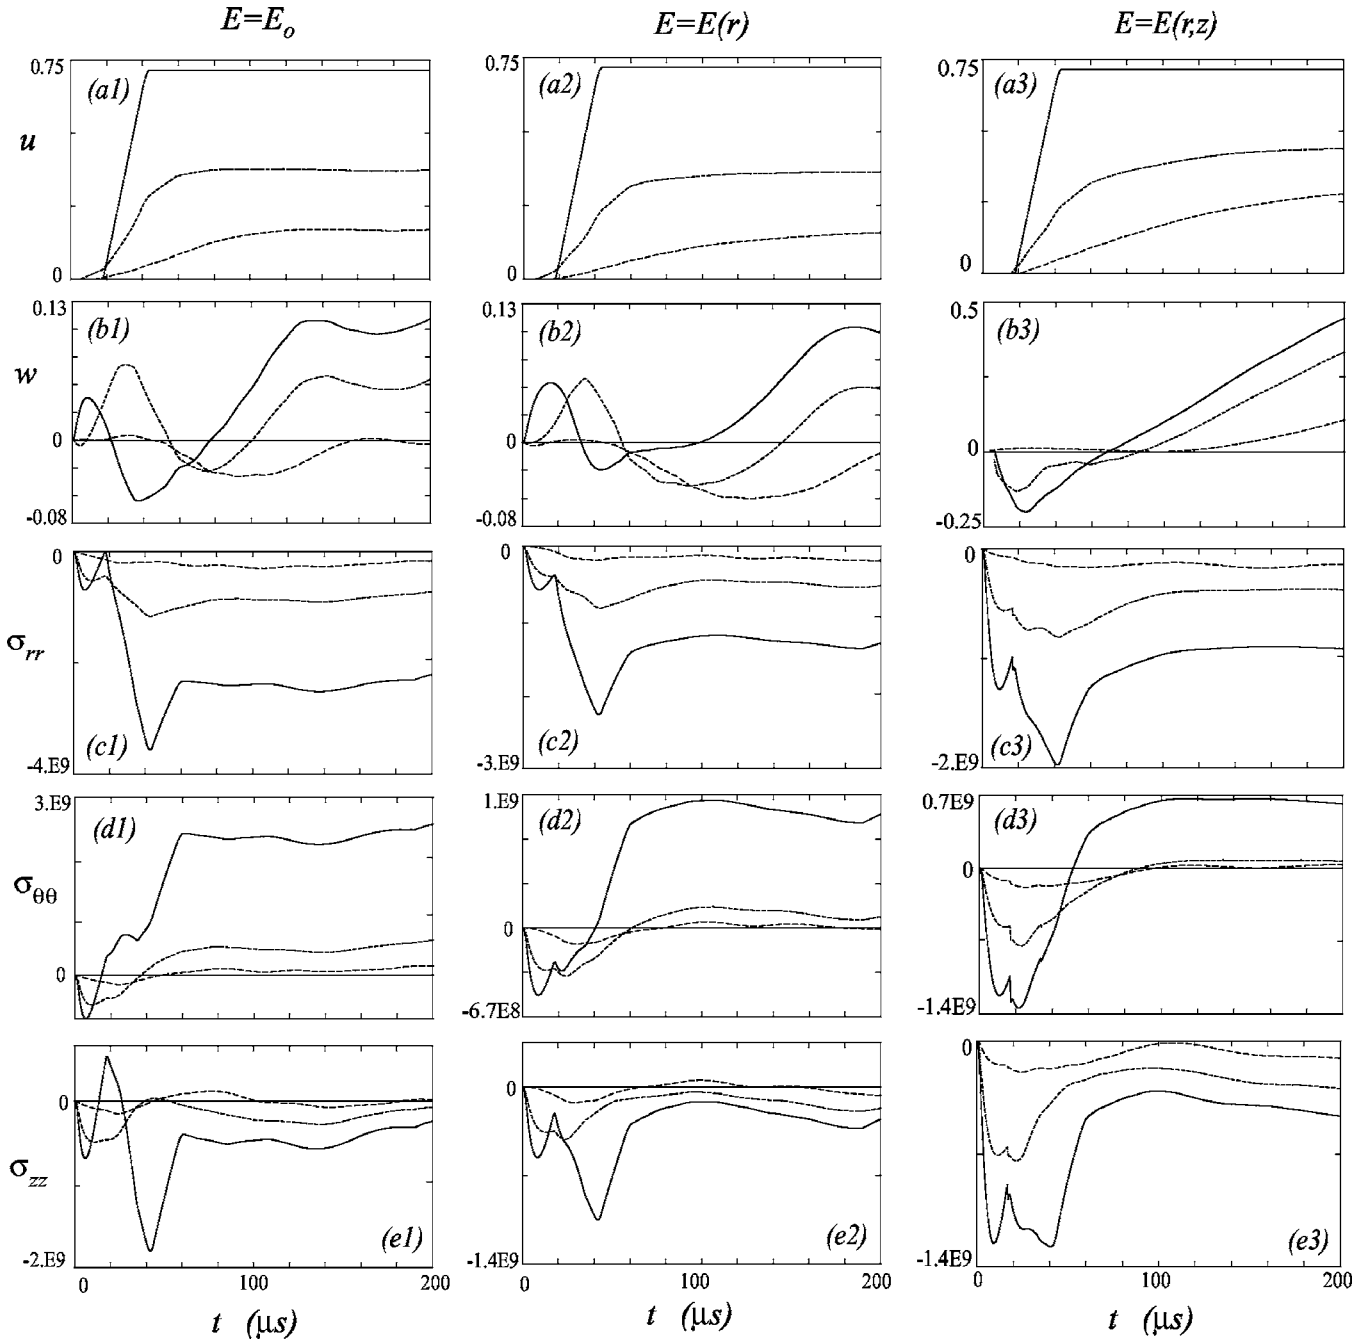

FIG. 5. Histories of cylinder at $z=2$ cm.———$r/r_p=1$, --- 2, - - - 4. (a1)–(e1) $E=E_o$. (a2)–(e2) $E=E(r)$. (a3)–(e3) $E=E(r,z)$.

holds. A clearer interpretation of static results comes from distribution of the dependent variable along r and z.

Figure 2 plots variables along r with z as a parameter for both $E(r)$ and $E(r,z)$. In order to satisfy the prescribed u condition at $r=r_p$, the resulting applied traction varies along z. For comparative purposes, the magnitude of applied traction is then adjusted by a constant factor so that in both cases average pressure is unity. For $E(r)$, u [Fig. 2(a1)] is symmetric about $z=l/2$ and diminishes steeply along r reaching small values at $r=r_o$. For $E(r,z)$, u [Fig. 2(a2)] is asymmetric about $z=l/2$ from modulus asymmetry and maintains its magnitude throughout l. The same applies to w [Fig. 2(b1,b2)] except that for $E(r,z)$, w_{mx} is an order of magnitude larger than its value for $E(r)$. σ_{rr} is comparable for both $E(r)$ and $E(r,z)$ cases [Fig. 2(c1,c2)], while $\sigma_{\theta\theta}$ follows the same trend as u [Fig. 3(d1,d2)]. Comparing Fig. 2(e1) to (e2) reveals that although σ_{zz}'s magnitude remains almost the same, it changes from tensile for $E(r)$ to compressive for $E(r,z)$.

Figure 3 plots static variable along z with r as a parameter. u [Fig. 3(a1,a2)] follows the uniform prescribed u_o. Magnitude differs for each case due to the normalization explained earlier. At $r>r_p$, u_{mx} in Fig. 3(a2) is almost an order of magnitude larger than that in Fig. 3(a1) and the same applies to w_{mx} in Fig. 3(b1,b2). σ_{rr} in Fig. 3(c1) is symmetric about $z=l/2$ while σ_{rr} in Fig. 3(c2) is not. Note the steep rise in magnitude of σ_{rr} near z_a and z_b typical of the traction distribution necessary to achieve a uniform pre-

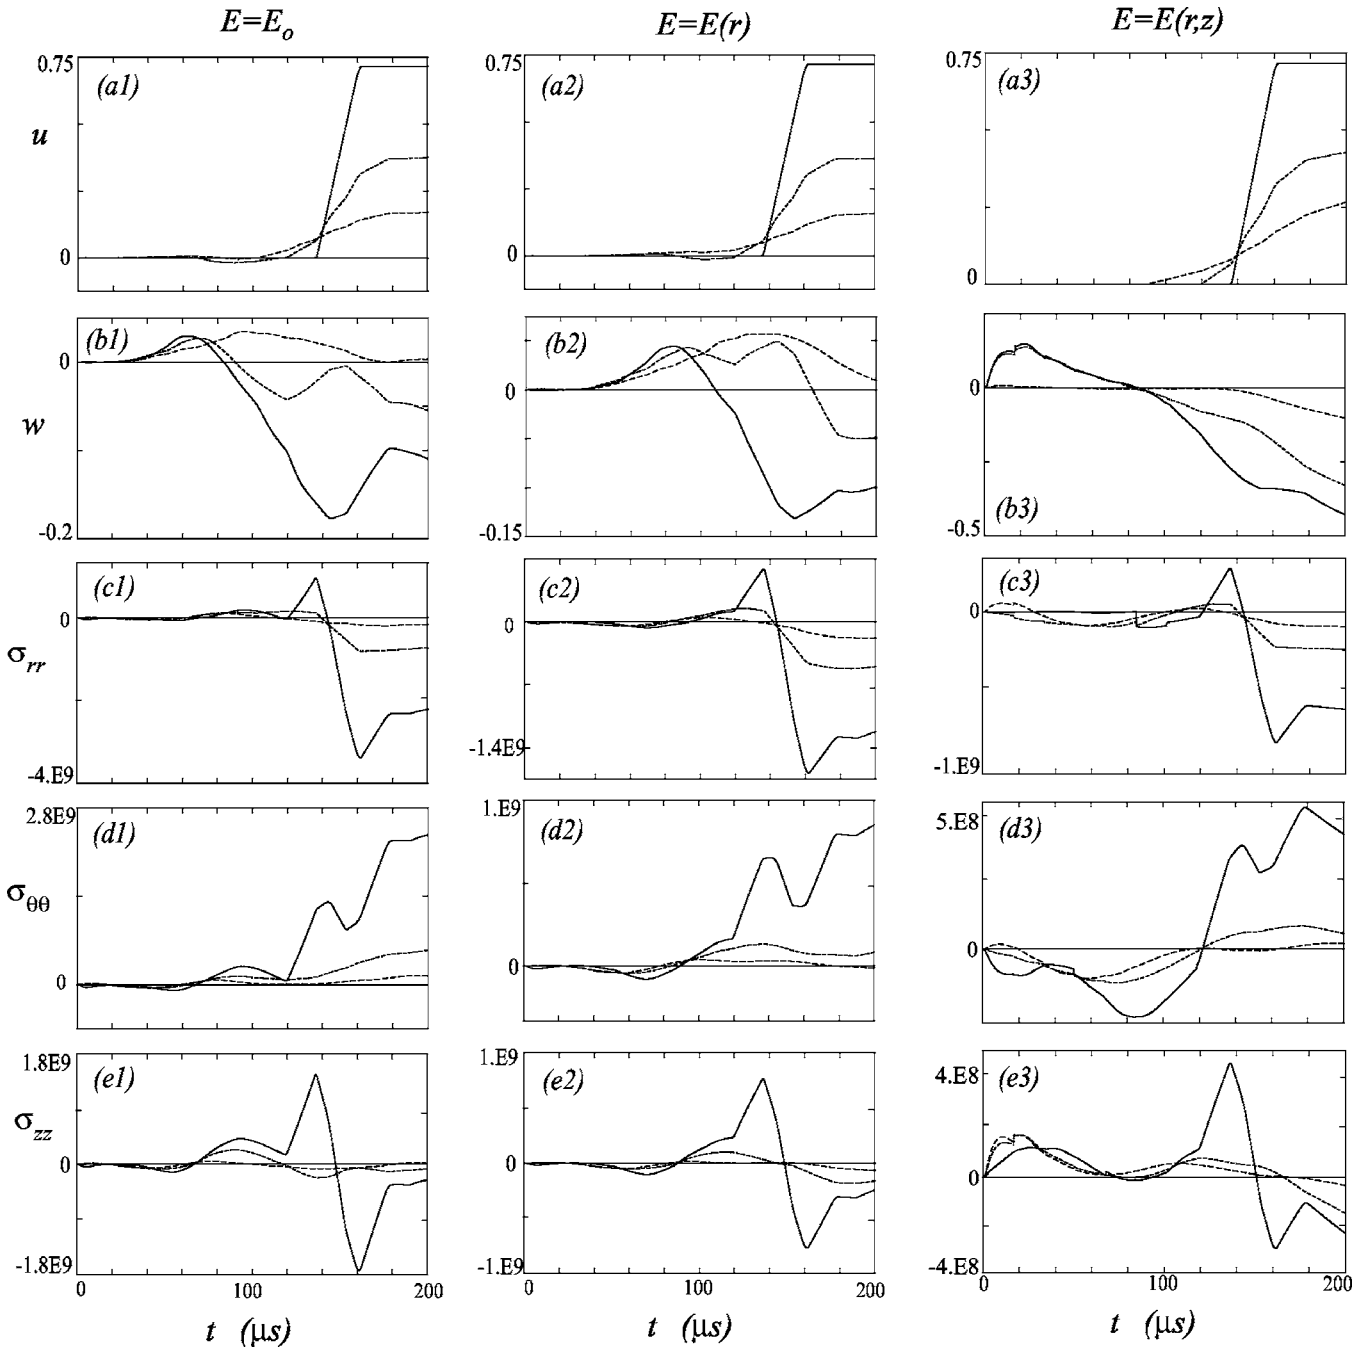

FIG. 6. Histories of cylinder at $z=5.6$ cm.———$r/r_p=1$, --- 2, - - - 4 (a1)–(e1) $E=E_o$. (a2)–(e2) $E=E(r)$. (a3)–(e3) $E=E(r,z)$.

scribed u_o (see Ref. 1, Fig. 1). $\sigma_{\theta\theta}$ [Fig. 3(d1, d2)] is discontinuous at z_a and z_b while its magnitude follows the same steep rise as σ_{rr} near these limits. As noted in Fig. 2(e1, e2), σ_{zz} changes from tensile for $E(r)$ to compressive for $E(r,z)$ and is discontinuous at z_a and z_b. For $z_a<z<z_b$ magnitude of σ_{zz} for $E(r)$ is almost ten times larger than that for $E(r,z)$.

In calculating transient response, prescribed motion follows the profiles in Figs. 4(a)–4(c) where the maximum uniform velocity attained after a 2-μs transient is $V_p=300$ m/s (=984 ft/s). The acceleration profile is made of six linear segments:

(1) Linear acceleration: $\ddot{f}_{p1}(t)=\alpha_1 t, \quad 0\leqslant t\leqslant t_1,$

(2) Constant acceleration: $\ddot{f}_{p2}(t)=\alpha_1 t_1, \quad t_1\leqslant t\leqslant t_2,$

(3) Linear deceleration: $\ddot{f}_{p3}(t)=\ddot{f}_{p2}(t_2)-\alpha_2(t-t_2),$

$t_2\leqslant t\leqslant t_3,$

(4) Constant velocity: $\ddot{f}_{p4}(t)=0, \quad \dot{f}_{p4}(t_3)=V_p,$

$t_3\leqslant t\leqslant t_4,$

(5) Linear deceleration: $\ddot{f}_{p5}(t)=-\alpha_3(t-t_4),$

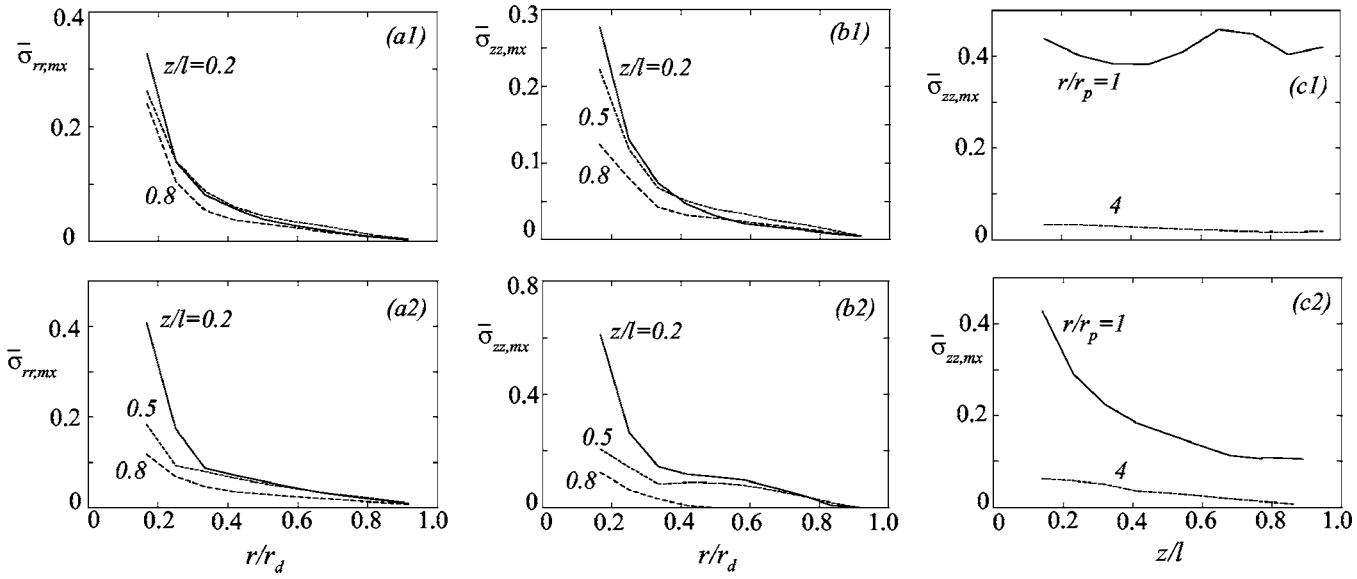

FIG. 7. Peak stress attenuation in 3-D axisymmetric model. (a1), (b1), (c1) Homogeneous $E=E_o$. (a2), (b2), (c2) Inhomogeneous $E=E_o\xi(r)\eta(z)$.

$$t_4 \leqslant t \leqslant t_5,$$

(6) Constant deceleration: $\ddot{f}_{p6}(t) = -\alpha_3(t_5 - t_4)$,

$$t_5 \leqslant t \leqslant t_6.$$

t_6 is the time when $\dot{f}_p(t)=0$. Assuming that the first three time intervals are equal ($\Delta t_1=\Delta t_2=\Delta t_3$, $\Delta t_i=t_i-t_{i-1}$) and $\alpha_2=\alpha_1$, then α_1 is determined by assigning the constant velocity V_p to $\dot{f}_{p4}(t_3)$. In the analysis to follow $\Delta t_{1,3}\equiv\Delta t_1+\Delta t_2+\Delta t_3=2\ \mu s$, $\Delta t_{3,4}=20\ \mu s$, and $\alpha_3=1/3\alpha_1$.

Figure 5 plots the history of variables at $z/l=0.266$ for three cases:

(1) Case A, Fig. 5(a1)–(e1), homogeneous cylinder with $E=E_o$.
(2) Case B, Fig. 5(a2)–(e2), radial inhomogeneity with $E=E(r)$.
(3) Case C, Fig. 5(a3)–(e3), radial and axial inhomogeneity $E=E(r,z)$.

At $r=r_p$, u [Fig. 5(a1, a2, a3)] follows the time-delayed prescribed $f_p(t)$ in Fig. 4(a) for all cases. For $r>r_p$, u for case C is larger than the other two cases. The same applies to w [Fig. 5(b1)–(b3)] where for case C it is an order of magnitude larger than the other two cases as observed for the static case in Fig. 3(a2) and (b2). This follows the reduction in modulus along z as prescribed by (36c). σ_{rr} (Fig. 5(c1)–(c3)) peaks at 10 μs, then at 40 μs, and then follows an almost flat plateau. Its magnitude is largest for case A, followed by case B and case C, since stiffness of these cases follows the same order. The second peak happens 20 μs after arrival time of the time-delayed prescribed motion. $\sigma_{\theta\theta}$ follows the same trend as σ_{rr} in magnitude and shape [Fig. 5(d1)–(d3)]. Unlike the static case in Figs. 2(e2) and 3(e2), σ_{zz} [Fig. 5(e1)–(e3)] is compressive for all cases. After the second peak at 40 μs, σ_{zz} reaches an almost flat plateau with magnitude for case A the same as case C, trailed by that for case B. The first peak at 10 μs occurs during an almost hydrostatic stress state where $\sigma_{rr}\approx\sigma_{\theta\theta}\approx\sigma_{zz}$.

Figure 6 plots the history of variables for the three cases when $z/l=0.733$. At $r=r_p$, u [Fig. 6(a1)–(a3)] follows the time-delayed prescribed motion that reaches $z/l=0.733$ at the arrival time of 140 μs. For cases A and B at $r>r_p$, u starts rising near 120 μs just before arrival time. The same observation applies to w [Fig. 6(b1)–(b3)]. For case C, the magnitude of w is four times larger than the other two cases. σ_{rr} peaks at 160 μs following arrival time [Fig. 6(c1)–(c3)] with largest magnitude for case A, followed by case B, then case C. For case C, σ_{rr} is four times smaller than in case A. The same observation applies to $\sigma_{\theta\theta}$ [Fig. 6(d1)–(d3)] and σ_{zz} [Fig. 6(e1)–(e3)]. An observation common to all variables is quiescence prior to arrival time.

The effect on peak transient stresses of inhomogeneity is shown in Fig. 7. For the homogeneous cylinder with $E=E_o$, Figs. 7(a1) and (b1) plot $\bar{\sigma}_{rr,mx}=\sigma_{rr,mx}(r,z_s)/\sigma_{rr,mx}(r_p,z_s)$ and $\bar{\sigma}_{zz,mx}=\sigma_{zz,mx}(r,z_s)/\sigma_{zz,mx}(r_p,z_s)$ versus r/r_d for $r>r_p$ at three axial positions $z_s/l=0.2,0.5,0.8$, while Fig. 7(c1) plots $\bar{\sigma}_{zz,mx}=\sigma_{zz,mx}(r_s,z)/\sigma_{zz,mx}(r_s,0)$ versus z/l at two radial positions $r_s/r_p=1$ and 4. An explanation that $\bar{\sigma}_{rr,mx}$ and $\bar{\sigma}_{zz,mx}$ are substantially higher at $r=r_p$ and $z=0$ is that immediately following impact, a hydrostatic state of stress prevails which disperses quickly. The hydrostatic condition replicates the one-dimensional environment, thus explaining the higher stresses. Both $\bar{\sigma}_{rr,mx}$ and $\bar{\sigma}_{zz,mx}$ fall steeply with r as with the static case [Figs. 2 (c1) and (e1)]. As expected, after a sharp fall from the value at $z=0$, $\bar{\sigma}_{zz,mx}$ is almost constant along z for a fixed value of r_s as with the static case [Fig. 3(e1) for $0.25\leqslant z/l\leqslant 0.75$]. For the inhomogeneous cylinder [Figs. 7(a2)–(b2)] $\bar{\sigma}_{rr,mx}$ and $\bar{\sigma}_{zz,mx}$ are higher than those of the homogeneous cylinder with greater sensitivity to z_s. Moreover, $\bar{\sigma}_{zz,mx}$ [Fig. 7(c2)] falls along z as with the static case [Fig. 3(e2) for $0.25\leqslant z/l\leqslant 0.75$].

A simplification to the 3-D axisymmetric models in Secs. II and III are the radial and axial plane-strain models

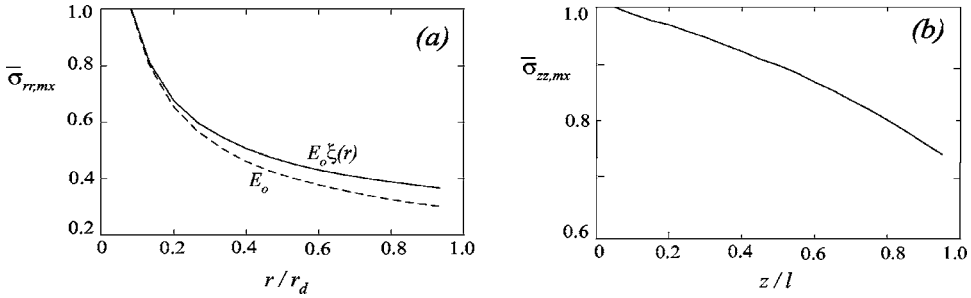

FIG. 8. Peak stress attenuation in plane-strain models. (a) Radial model.———$E=E_o\xi(r)$, --- $E=E_o$. (b) Axial model.———$E=E_o\eta(z)$.

which are limits when either axial or radial dependences are eliminated. The radial plane-strain model has the same r_p and r_o as the cylinder with $E(r)=E_o\xi(r)$. The axial plane-strain model has the same l as the cylinder with $E(z)=E_o\eta(z)$. Figure 8(a) plots distribution of $\bar{\sigma}_{rr,mx}$ along r for the inhomogeneous case (solid line) and the homogeneous case (dashed line). Comparing Fig. 8(a) with Fig. 7(a1, a2) reveals that in plane-strain stress falls more gradually than in 3-D. The greater attenuation in 3-D is caused by dispersion. It is evident that coupling between axial and radial motions makes the cylinder's response features unique in that the plane-strain models cannot duplicate.

VIII. CONCLUSION

The effect on transient response of radial and axial inhomogeneity is analyzed. Radial inhomogeneity is treated adopting transfer matrices of coaxial segments each with constant modulus. Axial inhomogeneity is then included employing the eigenfunctions of the radially inhomogeneous problem as a trial function in a Galerkin procedure. Noteworthy results are the following:

(1) Static response includes the principal features of transient response concerning stress and displacement.
(2) Static stress reduces sharply with r for the homogeneous and radially inhomogeneous cases. However, in the case of axial inhomogeneity stress maintains its value at the excited boundary further along r.
(3) A reduction in modulus along r and z reduces transient stress proportionately and increases w substantially.
(4) All transient variables are quiescent prior to arrival time of the time-delayed prescribed motion.
(5) In both static and dynamic response, prescribed motion raises radial boundary traction near the edges of the footprint along the cylinder's inner boundary.
(6) The simplified plane-strain models cannot replicate transient stress attenuation of the inhomogeneous cylinder as coupling between axial and radial motions makes the cylinder unique in response features.

Three-dimensional simulation of electron-acoustic detections

Chun-ming Gao, Shu-yi Zhang, Zhong-ning Zhang, and Xiu-ji Shui
Lab of Modern Acoustics, Institute of Acoustics, Nanjing University, Nanjing 210093, China

(Received 29 April 2005; revised 9 January 2006; accepted 15 February 2006)

In electron-acoustic (EA) detection, a periodically modulated electron beam is impinging on a sample to excite thermo-acoustic signals, and a PZT transducer bonded on the back surface of the sample is used to detect the thermo-acoustic signals. Based on the conditions of the EA detection experiment, theoretical analyses of 3-D temperature distributions in the sample, 3-D elastic fields in the sample and piezoelectric transducer, and piezoelectric output signals of the transducer are given. Generally, the vibration modes and the electrical output signals of the transducer are hard to calculate because of the complicated structures, i.e., complicated boundary conditions, thus a finite element method (FEM) is used to simulate the electron-acoustic signals. According to the corresponding FEM model, the frequency spectra of the detected EA signals can be calculated. Meanwhile, the related experimental measurements for several homogeneous samples are carried out. Comparing the theoretical simulated results with those of the experiments, it shows that both are in good agreement with each other. Finally, using this FEM model, the dependences of the electron-acoustic signals on the thermal and elastic properties of several samples are investigated.

I. INTRODUCTION

Scanning electron-acoustic microscopy (SEAM) was established by Brandis *et al.*[1] and Cargill III[2] independently in 1980. Since then, the applications of SEAM for characterizing the microstructures of materials and devices have been widely developed, such as doping regions in semiconductors,[3] magnetic domains in ferromagnetic and microwave materials,[4] ferroelectric domains in ferroelectric ceramics,[5] residual stresses in ceramics[6] and metals,[7] surface and subsurface structures in biological materials,[8–10] and so on. The advantages of SEAM are the special imaging abilities for local different thermal or elastic features of surface and subsurface structures with high resolution, by which laminated images of micro-inhomogeneous materials can be obtained nondestructively.[7,10] It is well known that the similar results can also be obtained by conventional acoustic microscopy (AM).[11] However, due to the thermal wavelength being about one thousand times smaller than the acoustic wavelength and operating in the same frequency and the same material, the operating frequency in SEAM can be decreased three orders of magnitude for obtaining the same special resolution.[12]

On the other hand, several theoretical studies on electron-acoustic (EA) signal generation have been performed. Bresse *et al.*[13,14] evaluated the electron-acoustic signal generation in semiconductors and metallic layers by one-dimensional model; Rosencwaig *et al.*[15] and Qian *et al.*[16,17] analyzed the mechanisms of the acoustic signal generation by focused electron beam in a three-dimensional model, but did not give the numerically calculated results. Comparing with the successful SEAM imaging experiments, the theoretical research is quite deficient.

In this work, based on the experimental conditions of SEAM,[7,10] 3-D analyses of the temperature distributions in the sample, the elastic fields in the sample, and the piezoelectric transducer induced by focused electron beam impinging are given, and then a finite element method (FEM) is used for simulating the EA signals detected by a PZT transducer. Meanwhile, several experiments for homogeneous samples have also been carried out. Comparisons of the experimental measurements and theoretical simulations, which verify the theoretical modeling and the simulation results of EA signals, are available. Finally, the dependences between the EA signals on the properties of the samples are obtained, which illustrate that the EA signals can display different structures and properties of materials, and then the imaging mechanisms of inhomogeneous materials by SEAM can be demonstrated. In addition, the properties and parameters of the materials can also be evaluated by SEAM signals.

II. THEORY

Based on the experimental method, the theoretical model of the EA detection with the cylindrical coordinate is shown in Fig. 1, in which a periodically modulated electron beam with frequency f is impinging on the surface of the sample to excite the thermo-acoustic waves, and the thermo-acoustic waves are detected by a circular piece of PZT transducer.

In Fig. 1, L_s and r_s are the thickness and radius of the sample, L_t and r_t are the thickness and radius of the transducer, P_1 and P_2 are the pressure on the upper and back sides of the transducer, respectively, and r_p is the aperture radius of the brass cap.

 0001-4966/2006/119(5)/2750/8/$22.50

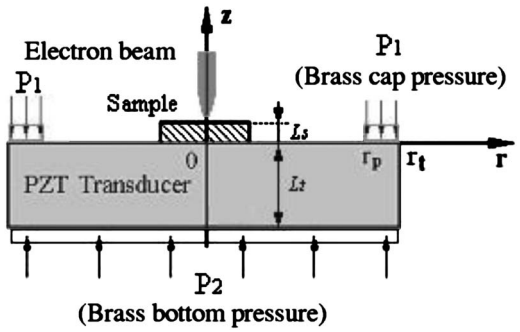

FIG. 1. Theoretical model of EA detection.

The thermal diffusion equation in the sample can be expressed as

$$\nabla^2 T_s(r,z) - \frac{i\omega}{D_s} T_s(r,z) = -\frac{1}{k_s} H(r,z),$$
$$D_s = k_s/\rho_s c_s, \tag{1}$$

where $T_s(r,z)$ is the temperature variation induced by the electron beam, D_s, k_s, ρ_s, and c_s are the thermal diffusivity, thermal conductivity, density, and specific heat of the sample, respectively, and $H(r,z)$ is the power density of the heat source,[16]

$$H(r,z) = \frac{\eta P_0 \beta}{2\pi r_0^2} \exp(-\beta|z - z_0|)\exp(-r^2/r_0^2), \tag{2}$$

where P_0 is the power and r_0 is the focused radius of the electron beam, η is the efficiency of the incident electron beam converted to heat, β is the electron energy attenuation coefficient, and z_0 is the electron penetration depth in the sample.

In the SEAM detection, the sample is placed under vacuum at room temperature, therefore the thermal boundary conditions at the upper and lateral surfaces of the sample are assumed to be adiabatic. Meanwhile, the thermal wave in the samples is damping very quickly and the propagation distance is about one wavelength. In our experimental situation, the modulation frequency is several hundreds kHz, the wavelength of the thermal wave is approximately several μm, and the thickness and radius of the sample are several hundreds to several thousands of μm, which is much larger than the wavelength of the thermal wave. Thus the boundary conditions can be written as

$$\left.\frac{\partial T_s(r,z)}{\partial z}\right|_{z=0} = 0, \qquad \left.\frac{\partial T_s(r,z)}{\partial z}\right|_{z=Is} = 0,$$
$$\left.\frac{\partial T_s(r,z)}{\partial r}\right|_{r=r_s} = 0. \tag{3}$$

Using the boundary conditions (3), the temperature distributions in the sample can be obtained by solving Eq. (1).

For an isotropic solid sample, the thermoelastic equation can be expressed as[16]

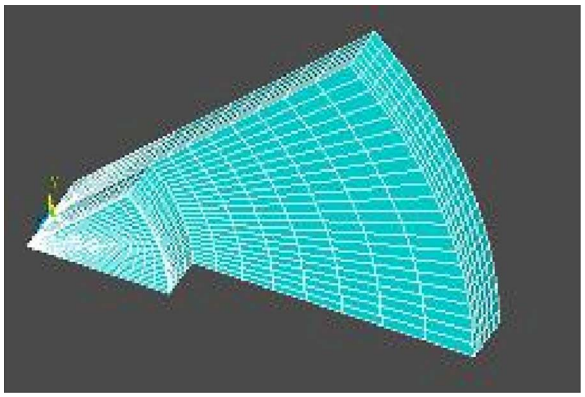

FIG. 2. (Color online) Meshed model of detection component.

$$\mu_s \nabla^2 \bar{u}_s(r,z) + (\lambda_s + \mu_s)\nabla[\nabla \cdot \bar{u}_s(r,z)] + \rho_s \omega^2 \bar{u}_s(r,z) = \alpha_{TS}(3\lambda_s + 2\mu_s)\nabla T_s(r,z), \tag{4}$$

where $\bar{u}_s(r,z)$ is the displacement field, λ_s and μ_s are the Lamé constants, and α_{TS} is the thermal expansion coefficient of the sample.

For the piezoelectric transducer made by PZT-5 ceramic, due to the elastic constants of the material[18] approach to those of isotropic materials, the transducer can be approximately assumed as elastic isotropic, thus the elastic equation can be expressed as

$$\mu_t \nabla^2 \bar{u}_t(r,z) + (\lambda_t + \mu_t)\nabla[\nabla \cdot \bar{u}_t(r,z)] + \rho_t \omega^2 \bar{u}_t(r,z) = 0, \tag{5}$$

where $\bar{u}_t(r,z)$ is the displacement field, λ_t and μ_t are the Lamé constants, and ρ_t is the density of the transducer. Based on Eqs. (1)–(5) and the boundary conditions of continuous displacement and stress in the interface of the sample and transducer, the displacement and stress fields in the transducer can be determined.

In addition, for the PZT transducer with axial polorization, the piezoelectric equations are[18]

$$\bar{\tau} = K\bar{u}_t - K^z\bar{E},$$
$$\bar{D}_e = K^z\bar{u}_t + K^d\bar{E}, \tag{6}$$

where $\bar{\tau}$ is the stress, $\bar{u}_t$ is the strain, $\bar{E}$ is the electric field, $\bar{D}_e$ is the electric displacement, K, K^z, and K^d are the stiffness coefficients, the piezoelectric constants, and dielectric coefficients of the transducer, respectively. Then the output voltage of the PZT transducer can be obtained.

According to the experimental conditions, the boundary conditions can be written as follows:

The stresses are free on both the upper surface of the sample and a part of the upper surface of the transducer (see Fig. 1), i.e.,

$$\tau_{zs} = \tau_{rzs} = 0 \quad (\text{at } z = L_s \text{ and } 0 < r < r_s),$$
$$\tau_{zt} = \tau_{rzt} = 0 \quad (\text{at } z = 0 \text{ and } r_s < r < r_P), \tag{7}$$

where τ_{zs} and τ_{rzs} are the normal and shear stress components of the sample and τ_{zt} and τ_{rzt} are the normal and shear

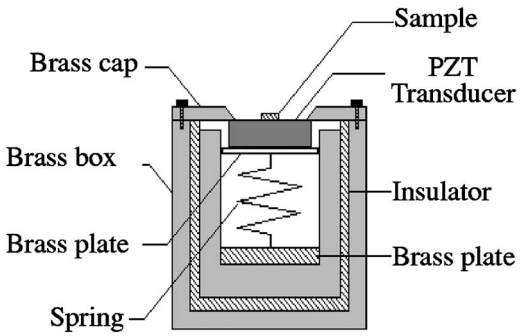

FIG. 3. Structure of piezoelectric detection component.

stress components of the transducer, respectively.

The stresses at the upper surface and the backside of the PZT transducer can be expressed as

$$\begin{aligned}
&\tau_{zt} = p_1 \quad (\text{at } z = 0 \text{ and } r_P < r < r_t),\\
&\tau_{rzt} = 0 \quad (\text{at } z = 0 \text{ and } r_P < r < r_t),\\
&\tau_{zt} = -p_2 \quad (\text{at } z = -L_t \text{ and } 0 < r < r_t),\\
&\tau_{rzt} = 0 \quad (\text{at } z = -L_t \text{ and } 0 < r < r_t).
\end{aligned} \tag{8}$$

At the interface between sample and transducer, the displacements and stresses are considered continuous,

$$\begin{aligned}
&u_{rs} = u_{rt}, \quad u_{zs} = u_{zt} \quad (\text{at } z = 0 \text{ and } 0 < r < r_s),\\
&\tau_{rs} = \tau_{rt}, \quad \tau_{zs} = \tau_{zt} \quad (\text{at } z = 0 \text{ and } 0 < r < r_s),
\end{aligned} \tag{9}$$

where the subscripts r, z represent r and z directions, and s, t represent the sample and transducer. According to the temperature distribution in the sample obtained from Eqs. (1)–(3) and the complicated boundary conditions shown in Eqs. (7)–(9), the thermo-elastic equations (4) and (5) are difficult to solve by analytical method, and then the EA signals cannot be obtained analytically.

Therefore, a finite element method (FEM) is employed to solve the temperature distributions, displacement fields, and EA signals numerically.

III. FEM ANALYSIS

The general FEM form of the thermal diffusivity equation can be written by[19]

$$\begin{bmatrix} C_1 & 0 & \cdots & 0 \\ 0 & C_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \\ 0 & 0 & \cdots & C_m \end{bmatrix} \begin{bmatrix} \dot{\phi}_1 \\ \dot{\phi}_2 \\ \vdots \\ \dot{\phi}_m \end{bmatrix} + \begin{bmatrix} K_1 & 0 & \cdots & 0 \\ 0 & K_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \\ 0 & 0 & \cdots & K_m \end{bmatrix} \times \begin{bmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_m \end{bmatrix} = \begin{bmatrix} P_1 \\ P_2 \\ \vdots \\ P_m \end{bmatrix}, \tag{10}$$

where C_i is the heat-capacity matrix, $\dot{\phi}_i = d\phi_i/dt$, ϕ_i is the temperature array, K_i is the heat-conduction matrix, and P_i is the temperature-load array. The K_i, C_i, and P_i can be expressed as[20]

$$\begin{aligned}
K_i &= \sum \int_{V_i} k_i \left(\left(\frac{\partial N}{\partial r} \right)^* \left(\frac{\partial N}{\partial r} \right) + \left(\frac{\partial N}{\partial z} \right)^* \left(\frac{\partial N}{\partial z} \right) \right.\\
&\quad \left. - \left(\frac{\partial N}{\partial z} \right)^* \left(\frac{N}{r} \right) \right) dV_i,\\
C_i &= \sum \int_{V_i} \rho_i c_i N^* N \, dV_i,\\
P_i &= \sum \int_{V_i} \rho_i Q_i N^* \, dV_i,
\end{aligned} \tag{11}$$

where the k_i, ρ_i, and c_i are the heat conductivity, density, and specific heat, respectively, Q_i is the heat energy absorbed from the electron beam, V_i is the volume of the ith element, N is the interpolation function array, and * is the transposed operator.

The general FEM form of the thermo-elastic couple equation can be written by

$$\begin{bmatrix} [M] & [0] \\ [0] & [0] \end{bmatrix} \begin{Bmatrix} \{\ddot{u}\} \\ \{\ddot{T}\} \end{Bmatrix} + \begin{bmatrix} [D] & [0] \\ [0] & [D^t] \end{bmatrix} \begin{Bmatrix} \{\dot{u}\} \\ \{\dot{T}\} \end{Bmatrix} + \begin{bmatrix} [K] & [0] \\ [0] & [K^t] \end{bmatrix} \begin{Bmatrix} \{u\} \\ \{T\} \end{Bmatrix} = \begin{Bmatrix} \{F\} \\ \{Q\} \end{Bmatrix},$$

$$\dot{u} = \partial u/\partial t, \quad \ddot{u} = \partial^2 u/\partial t^2,$$

$$\dot{T} = \partial T/\partial t, \quad \ddot{T} = \partial^2 T/\partial t^2,$$

$$[K^t] = [K^{tb}] + [K^{tc}], \tag{12}$$

$$\{F\} = \{F^{nd}\} + \{F^{th}\} + \{F^{pr}\} + \{F^{ac}\},$$

$$\{Q\} = \{Q^{nd}\} + \{Q^g\} + \{Q^c\},$$

where M is structural mass matrix; u is displacement vector; T is temperature vector; D is structural damping matrix; K, K^t, K^{tb}, and K^{tc} are the structural stiffness matrix, the total thermal conductivity matrix, the thermal conductivity matrix of material, and the thermal conductivity matrix of surface convection, respectively; F is the force vector; F^{nd} is applied nodal force vector; F^{th} is the thermal strain force vector; F^{pr} is the pressure load vector; F^{ac} is the force vector due to acceleration effects; Q^{nd} is the applied nodal heat flow rate vector; Q^g is the heat generation rate vector for causing other than Joule heating; and Q^c is the convection surface vector.

The general FEM form of the piezoelectric couple equation can be written by

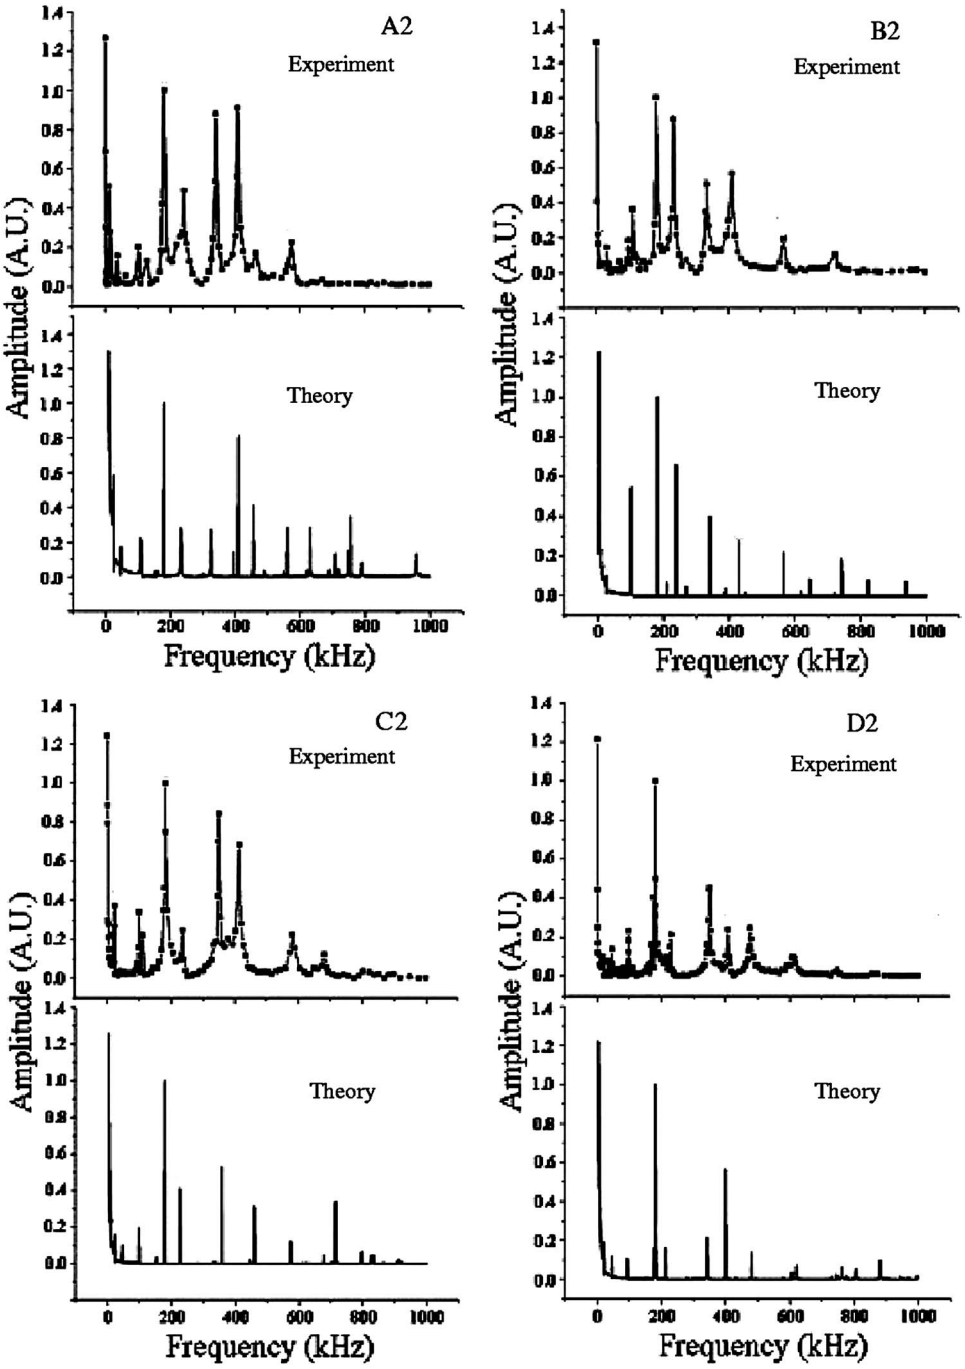

FIG. 5. EA Amplitude versus modulation frequency for transducer 2.

$$\begin{bmatrix} [M] & [0] \\ [0] & [0] \end{bmatrix} \begin{Bmatrix} \{\ddot{u}\} \\ \{\ddot{V}'\} \end{Bmatrix} + \begin{bmatrix} [D] & [0] \\ [0] & [0] \end{bmatrix} \begin{Bmatrix} \{\dot{u}\} \\ \{\dot{V}'\} \end{Bmatrix} + \begin{bmatrix} [K] & [K^z] \\ [K^z]^* & [K^d] \end{bmatrix} \begin{Bmatrix} \{u\} \\ \{V'\} \end{Bmatrix} = \begin{Bmatrix} \{F\} \\ \{L\} \end{Bmatrix}, \tag{13}$$

$$\dot{V}' = \partial V'/\partial t, \quad \ddot{V}' = \partial^2 V'/\partial t^2,$$

$$\{L\} = \{L^{nd}\} + \{L^c\} + \{L^{sc}\},$$

where V' is the output voltage; K, K^z, and K^d are the stiffness coefficient matrix, the piezoelectric coefficient matrix, and the dielectric coefficient matrix of the transducer, respectively; and L, L^{nd}, L^c, and L^{sc} are the load vector, applied nodal charge vector, charge density load vector, and surface charge density load vector, respectively.

Since the detection component is cylindrical symmetric, in order to simplify the calculation, $\frac{1}{8}$ of the detection component can be simulated by the FEM, in which a FEM model is shown in Fig. 2. Using the FEM model, the EA signals can be calculated numerically by Eqs. (10)–(13).

IV. EXPERIMENTAL DETECTION

The piezoelectric detection component is shown in Fig. 3, in which the sample is bonded on the surface of the piezoelectric transducer. In the experiments, in order to verify the theoretical FEM simulation model, copper samples with

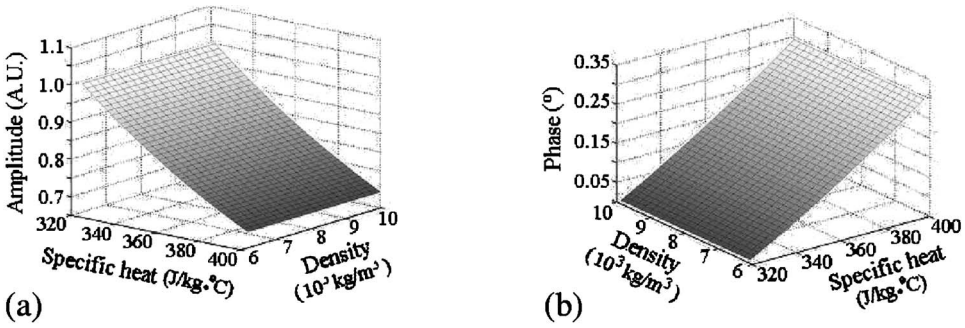

FIG. 6. Dependences of EA signal on the specific heat and density of sample: (a) amplitude and (b) phase.

four different sizes composite with PZT transducers with two different sizes are measured. The different compositions of the samples and transducers are listed in Table I. The distributions of the EA signals versus frequencies obtained by the experimental measurements for the different compositions are shown in Figs. 4 and 5, in which the accelerating voltage and focused radius of the electronic beam are adjusted to 30 KV and 1 μm, respectively.

V. NUMERICAL SIMULATION RESULTS AND DISCUSSIONS

A. EA signals at different frequencies

Based on the experimental conditions, the dependences of the amplitude of the EA signals on the frequency are numerically calculated by using the FEM model, which are also shown in Figs. 4 and 5. In the simulation, the pressures P_1 and P_2 are taken as 10 N/m^2.

Comparing the experimental results with those of the theoretical simulations, it can be seen that the signal peaks observed by the experiments also appear in the simulated curves by the FEM model except a few peaks that appeared in the calculated curves have not been observed in the experiments. From Figs. 4 and 5, it can be illustrated that for most experimental peaks the corresponding frequencies are in good agreement with those of calculated peaks. The frequency deviations between both results are less than 5%, and they are listed in the Appendix. Therefore, the EA signals can be calculated by using the FEM model.

However, except for the strong peaks at around 200 KHz, which are evidently corresponding to the radial resonance frequency of the transducer that appeared in both experimental and theoretical results, the vibration modes of the transducers are very complicated due to the complicated detection structures, i.e., the complicated boundary conditions, which make the mode identification very difficult.

On the other hand, there are a few deviations between the experimental and calculated results including the altitudes and frequencies of the signal peaks. The deviations are probably induced by the following reasons: (1) the material parameters of the sample and transducer may not be adopted precisely in the calculation; (2) the influences of the structures of the detection system, such as the spring, brass electrodes, and other accessories, on the vibrations of the transducer have not been considered; (3) some micro-disbonds between the sample and the transducer may exist in experiment; and (4) the sensitivity of the experimental system needs to be improved to detect very small peaks that appear in the theoretical calculations. In addition, the larger widths of the peaks observed in the experiments, which may be induced by the damping effects of the detection system, are not displayed in the theoretical simulations because the damping effects have not been considered in the theory. Meanwhile, the experimental widening peaks cause several peaks observed in theory to be merged.

B. Influence of the thermal and elastic properties of the samples on EA signals

In order to study the influences of the thermal and elastic characters of the samples on EA signals, the composition system of sample A and transducer 1 is taken as an example to be simulated.

(1) The dependences of the amplitude and phase of the EA signal on the density and specific heat of the sample are shown in Figs. 6(a) and 6(b), respectively. It show that the amplitude of the EA signal decreases and the phase

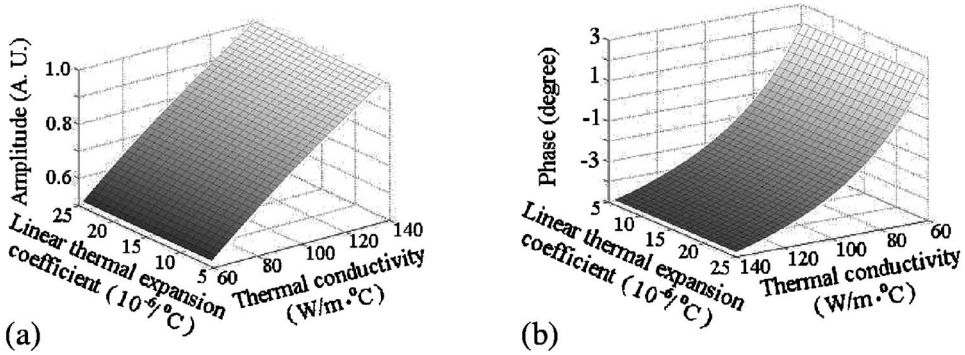

FIG. 7. Dependences of the EA signal on the linear thermal expansion coefficient and thermal conductivity of sample: (a) amplitude and (b) phase.

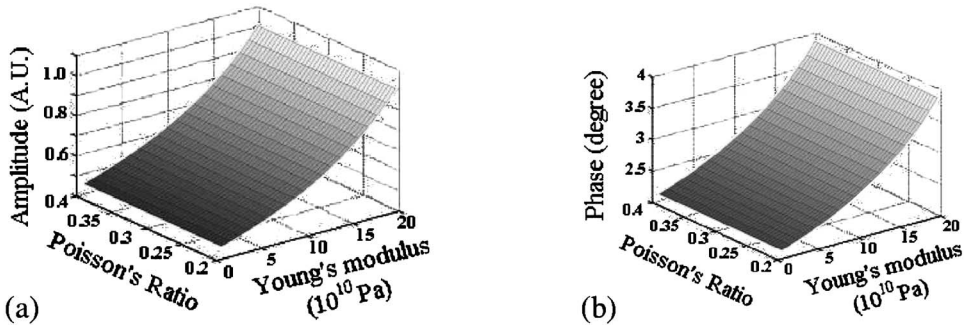

FIG. 8. Dependences of the EA signal on Poisson's ratio and Young's modulus of sample: (a) amplitude and (b) phase.

of the EA signal increases monotonously with the specific heat increase, but there is little influence with the density increase of the sample.

(2) The dependences of the amplitude and phase of the EA signal on the linear thermal expansion coefficient and thermal conductivity of the sample are shown in Figs. 7(a) and 7(b), respectively. It shows that the amplitude and phase of the EA signal increase monotonously with the thermal conductivity increase, and there is little influence with the linear thermal expansion coefficient increase of the sample.

(3) The dependences of the amplitude and phase of the EA signal on Poissons ratios and Young's modules of the sample are shown in Figs. 8(a) and 8(b), respectively, which show that the amplitude and phase of the EA signal increase monotonously with the Young's modules increase, but has influence little on the Poisson's ratios variation of the sample.

(4) Generally, the EA signals change with the variations of the specific heat, thermal conductivity, and Young's modules of the sample sensitively. If the electron beam is focused on the surface of the sample and the thermal wavelength is very small, the EA signal can reveal the local properties of the sample. Therefore, for an inhomogeneous sample, in which the local thermal and/or elastic properties are different from neighboring structures, as the focused electron beam is scanning on the surface of the sample, the EA signal will display different amplitude and phase and then the mechanism of SEAM imaging can be illustrated. On the other hand, it can be pointed out that the properties and parameters of the materials can also be evaluated by EA detections.

VI. CONCLUSIONS

In order to theoretically analyze the EA detections, a 3-D FEM model is used for simulating the EA signals. Comparing the experimental measurements and numerical calculations, several conclusions can be obtained.

(1) In EA detection, the 3-D theoretical relations of the thermal field, elastic field, and piezoelectric signal under complicated boundary conditions are given. Due to the theoretical relations being very complicated, the output signals of EA detection are always difficult to obtain by analytical method. Thus a 3-D FEM model is established to simulate the EA signals.

(2) The experimental measurements of the EA signals in different compositions of the samples and circular PZT transducers are carried out. From the dependences of the amplitude of the EA signals on the modulation frequency, there exist a lot of peaks located at the resonance (harmonic) frequencies and/or their superposition as the frequency lower than 1 MHz.

i	575	560	3				803	827	3	748	746	0
j	670	640	4				900	912	1			

(3) In order to compare the theoretical results with those of the experiments, the theoretical simulations according to the experimental conditions are given. They show that the calculated results are in good agreement with the experimental results although there are a few deviations.
(4) The numerical calculations can be used to find the dependences of the EA signals on the thermal and elastic properties of the sample. It shows that the output signals are sensitive to the specific heat, thermal conductivity, and Young's modulus of the sample, even influenced a little by the density, linear expansion coefficient, and Poisson's ratio of the sample. Therefore, the changes of the thermal and/or elastic properties and parameters of the samples can be reflected by the EA signals, and then the mechanism of the SEAM images for inhomogeneous materials can be demonstrated.
(5) The properties and parameters of the samples can be evaluated by the EA detections.

Cluster control of acoustic potential energy in a structural/acoustic cavity

Nobuo Tanaka[a] and Kozue Kobayashi
Department of Mechanical Engineering, Tokyo Metropolitan Institute of Technology, 6-6 Asahigaoka, Hino-city, Tokyo 191-0065, Japan

(Received 1 February 2005; revised 27 February 2006; accepted 28 February 2006)

This paper is concerned with cluster control of acoustic potential energy in a cluster coupled structural/acoustic cavity using both active noise control (ANC) and active vibration control (AVC). First, fundamental characteristics of a cluster coupled cavity are discussed, intriguing phenomena being confirmed: the coupling is strictly selective; structural modes and acoustic modes interfere with each other *if and only if* they fall into the same cluster, and hence termed *cluster coupling*. It is found that acoustic potential energy is a resultant from each cluster contribution, and thus clustered acoustic potential energy in a cavity may be extracted via *cluster filtering* without causing observation spillover, and may also be controlled independently using *cluster actuation* without causing control spillover. Employing both cluster filtering and cluster actuation, an optimal cluster control law using both ANC and AVC for minimizing clustered acoustic potential energy is derived. Based upon the control law, cluster control may be achieved, enabling the implementation of a multi-SISO system that may significantly mitigate computation load, as opposed to a MIMO system, on a controller. Finally, a numerical simulation is conducted, demonstrating the cluster control effect for suppressing acoustic potential energy in the cluster coupled cavity. [DOI: 10.1121/1.2188815]

I. INTRODUCTION

For the purpose of suppressing noise pollution, much research has been done in the past. Summarizing the active control approaches reported so far, they are classified into two categories; active noise control[1] (ANC) and active vibration control[2,3] (AVC). ANC aims to suppress the noise at sensor locations directly by employing secondary sound sources, while AVC attempts to suppress the structural vibration, the cause of noise radiation, by installing control actuators directly to the target structure. In the active noise control community, noise suppression in an open space seems to be a topic of much research interest, however, noise suppression in a closed space observed in such as aircrafts, automobiles, trains, and so on still needs to be tackled especially for a structure/acoustic coupled cavity.

The term "coupling" indicates the interference between a structural field and an acoustic field of the cavity, resulting in changing the modal frequencies and modal functions of both field systems. Depending on the degree of coupling, coupled cavities can be divided into two categories. A weakly coupled cavity falls into the first category, which is normally used and provides accurate model of the system response if the fluid medium is nondense, and the structure is not "small." Based upon modal coupling theory,[4,5] the cavity dynamics are generally expressed. In this case, eigenfrequencies of both structural field and acoustic field vary. Furthermore, eigenfunctions of acoustic cavity are affected by coupling; however the approach stands on the premise that eigenfunctions of the cavity remain the same as those of an acoustically rigid walled cavity while only the eigenfrequencies of the cavity change. In practice, it is understandable that the eigenfrequencies of the cavity are likely to vary while the eigenfunctions change little. Structural/acoustic systems displaying weak modal coupling characteristics are common amongst sound transmission problems targeted for active noise control: Pan *et al.*[6,7] discussed, analytically and experimentally, the mechanism for controlling noise transmission through a panel of the weakly (modal) coupled cavity; Snyder and Hansen[8,9] showed a theoretical and experimental framework suitable for aiding in the design of active control of sound transmission into the cavity; Snyder and Tanaka[10] investigated the sound transmission control using a shaped modal sensor; Sampath and Balachandran[11,12] studied the performance functions for the interior noise control analytically as well as experimentally; and Kim and Brennan[13] investigated the active control of harmonic sound transmission.

When cavity walls become thin and its size becomes small, such assumption is no longer valid, and this case falls into the second category called a strongly coupled cavity.[14–21] If this is the case, eigenfrequencies and eigenfunctions of structural and acoustic fields change. As a result, complexity in dealing with a cavity model substantially arises: orthogonality of acoustic modal functions is not guaranteed; eigenfunctions and eigenfrequencies of the cavity must be numerically obtained through a complicated procedure even for a simplistic model. With a view to investigating the characteristics of a strongly coupled cavity, an effort has been undertaken: Lyon[14] examined the possibility of estimating the noise reduction in various frequency ranges of the strongly coupled rectangular cavity; Dowell and Voss[15]

 0001-4966/2006/119(5)/2758/14/$22.50

studied fundamental characteristics of the cavity or cavity-backed panel; Pretlove[16,17] derived an exact solution of the acoustic velocity potential in a strongly coupled rectangular cavity with one flexible wall; Kihlman[18] investigated the relation between wall vibration and sound pressure; Battacharya and Crocker[19] derived a purely analytical general solution of the wave equation with inhomogeneous boundary conditions; Guy and Bhattacharya[20] studied the influence of a finite cavity backing a finite panel on the sound transmission; and Guy[21] presented a multimodal solution of the airborne sound transmission.

This paper is concerned with cluster control of acoustic potential energy of a cluster coupled cavity when a flexible panel is subjected to external forces. Cluster coupling is tantamount to conventional modal coupling, however this paper adopts the term "cluster" as the authors utilized it in Refs. 22 and 23. First, this paper begins by confirming the fundamental characteristics of the cluster coupled cavity. The coupling is strictly selective; structural modes and the acoustic modes interfere with each other *if and only if* they fall into the same cluster, and hence are termed *cluster coupling*. It is found that acoustic potential energy is a resultant from each cluster contribution, and thus clustered acoustic potential energy in a cavity may be extracted via *cluster filtering*[22,23] without causing observation spillover,[24] and may also be controlled independently using *cluster actuation*[23] without causing control spillover. Furthermore, employing both cluster filtering and cluster actuation, the optimal cluster control law based upon ANC and AVC for minimizing the acoustic potential energy in a cluster coupled enclosure is derived. Using the control law, cluster control may be achieved, enabling the implementation of a multi-SISO system that may significantly mitigate computation load, as opposed to a MIMO system, on a controller. Finally, a numerical simulation is conducted, demonstrating the cluster control effect for suppressing acoustic potential energy in the cluster coupled cavity.

II. A CLUSTER COUPLED STRUCTURAL/ACOUSTIC ENCLOSURE

A. Vibration field system

Consider some generic coupled structural/acoustic enclosure as shown in Fig. 1, subject to excitation by unspecified N_d point disturbance forces and N_c point control forces. Then the equation of motion of a two-dimensional, lossless, distributed paameter structure is expressed as

$$\mathbf{L}[w(\mathbf{x},t)] + m(\mathbf{x})\frac{\partial w^2(\mathbf{x},t)}{\partial t^2} = -p(\mathbf{x},t) + \sum_{i=1}^{N_d} f_{d,i}(t)\,\delta(\mathbf{x}-\mathbf{x}_{d,i}) + \sum_{i=1}^{N_c} f_{c,i}(t)\,\delta(\mathbf{x}-\mathbf{x}_{c,i}), \tag{1}$$

where $\mathbf{L}$, $w(\mathbf{x},t)$, $m(\mathbf{x})$, $p(\mathbf{x},t)$, $f_d(\mathbf{t})$, $f_c(t)$, and δ are the self-adjoint differential operator, deflection of the panel at $\mathbf{x}=(x,y)$, mass density of the panel, sound pressure at $\mathbf{x}$ of a cavity, a disturbance force at $\mathbf{x}_d$, a control force at $\mathbf{x}_c$, and a Dirac delta function, respectively. Note that the panel is subjected to the influence of the cluster coupled circumstances, hence the sound pressure term on the right-hand side of Eq. (1).

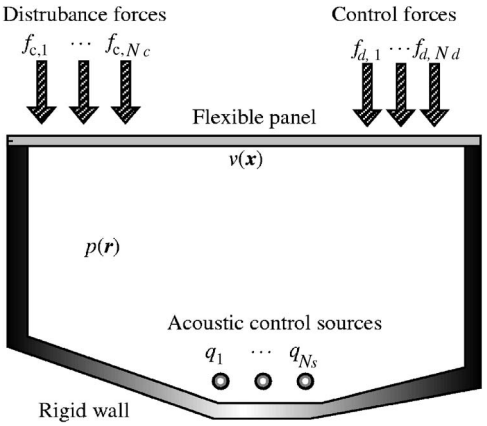

FIG. 1. Enclosure consisting of a flexible wall and rigid walls where active vibration control actuators, disturbance forces, and acoustic control sources are located.

When a disturbance force excites the panel harmonically with the driving frequency ω, the deflection of the panel is then given by

$$w(\mathbf{x},t) = w(\mathbf{x})e^{j\omega t}. \tag{2}$$

For a uniform panel, the equation of motion in Eq. (1) therefore becomes

$$D\nabla^4 w(\mathbf{x}) - \omega^2\rho_h h w(\mathbf{x}) = -p(\mathbf{x}) + \sum_{i=1}^{N_d} f_{d,i}\delta(\mathbf{x}-\mathbf{x}_{d,i}) + \sum_{i=1}^{N_c} f_{c,i}\delta(\mathbf{x}-\mathbf{x}_{c,i}), \tag{3}$$

where D is the bending stiffness of the panel, ρ_h is the density of the structure material, h is the thickness of the panel, and ∇^4 is defined as

$$\nabla^4 = \nabla^2\nabla^2 = \frac{\partial^4}{\partial x^4} + 2\frac{\partial^4}{\partial x^2\partial y^2} + \frac{\partial^4}{\partial y^4}. \tag{4}$$

The deflection $w(\mathbf{x})$ of the panel, limiting consideration to M_s structural modes, is then expressed as

$$w(\mathbf{x}) = \sum_{m=1}^{\infty} \varphi_m(\mathbf{x})w_m \approx \boldsymbol{\varphi}^T(\mathbf{x})\mathbf{w}, \tag{5}$$

where the superscript T denotes the transpose of the expression, $\varphi_m(\mathbf{x})$ $(m=1,2,\ldots,M_s)$ is the mth eigenfunction of the target panel, w_m is the associated modal coefficient, $\mathbf{w} \in \mathfrak{C}^{M_s}$ where $\mathfrak{C}^{M_s}$ denotes the set of all ordered M_s tuples of complex numbers, is the structure modal displacement vector, and $\boldsymbol{\varphi}(\mathbf{x}) \in \mathfrak{R}^{M_s}$ where $\mathfrak{R}^{M_s}$ denotes the set of all ordered M_s-tuples of real numbers, is the modal function vector at $\mathbf{x}$ of the panel, and are given by

$$\boldsymbol{\varphi}(\mathbf{x}) = (\varphi_1(\mathbf{x})\varphi_2(\mathbf{x})\cdots\varphi_M,(\mathbf{x}))^T, \tag{6}$$

and

$$\mathbf{w} = (w_1 w_2, \ldots, w_{M_s})^T, \tag{7}$$

so that the velocity $v(\mathbf{x})$ at some location $\mathbf{x}$ on the enclosing structure yields

$$v(\mathbf{x}) = j\omega w(\mathbf{x}) = \boldsymbol{\varphi}^T(\mathbf{x})\mathbf{v}. \tag{8}$$

Furthermore, the sound pressure $p(\mathbf{r})$ at $\mathbf{r}=(x,y,z)$ in the enclosed space can be expressed in terms of the acoustic mode shape functions of the cavity,

$$p(\mathbf{r}) = \sum_{i=1}^{\infty} p_i \phi_i(\mathbf{r}) \approx \boldsymbol{\phi}^T(\mathbf{r})\mathbf{p}, \tag{9}$$

where p_i is the sound pressure amplitude of the ith acoustic mode and $\phi_i(\mathbf{r})$ is the associated mode shape function at the location $\mathbf{r}$ in space. $\mathbf{p} \in \mathfrak{C}^{M_a}$ and $\boldsymbol{\phi}(\mathbf{r}) \in \mathfrak{R}^{M_a}$ are the acoustic modal amplitude vector and the acoustic modal function vector where they are, respectively, defined as

$$\mathbf{p} = (p_1 p_2, \ldots, p_{M_a})^T, \tag{10}$$

and

$$\boldsymbol{\phi}(\mathbf{r}) = (\phi_1(\mathbf{r})\phi_2(\mathbf{r})\cdots\phi_{M_a}(\mathbf{r}))^T. \tag{11}$$

Note that, as a result of modal orthogonality,

$$\int_V \phi_i(\mathbf{r})\phi_j(\mathbf{r})d\mathbf{r} = V_i\delta_{ij}, \tag{12}$$

where V_i is the volume normalization of the ith acoustic mode and δ_{ij} is the Kronecker delta.

Multiplying Eq. (3) with the ith structure modal function $\varphi_i(\mathbf{x})$ and integrating it over the domain of the plate leads to

$$v_i = \frac{j\omega}{\omega_{s,i}^2 - \omega^2}\left(-\int_s \varphi_i(\mathbf{x})p(\mathbf{x})d\mathbf{x} + \sum_{k=1}^{N_d}\varphi_i(\mathbf{x}_{d,k})f_{d,k} + \sum_{k=1}^{N_c}\varphi_i(\mathbf{x}_{c,k})f_{c,k}\right), \tag{13}$$

where j and $\omega_{s,i}$ are the imaginary unit and the ith structure modal frequency, respectively. Substituting Eq. (9) into the integration term in Eq. (13) leads to

$$-\int_s \varphi_i(\mathbf{x})p(\mathbf{x})d\mathbf{x} = -\int_s \varphi_i(\mathbf{x})\boldsymbol{\phi}^T(\mathbf{x})d\mathbf{x}\mathbf{p} = -\bar{\boldsymbol{\beta}}_i^T\mathbf{p}, \tag{14}$$

where

$$\bar{\boldsymbol{\beta}}_i = (\beta_{1i}\beta_{2i}, \ldots, \beta_{M_a i})^T \tag{15}$$

and where β_{ij} is the modal coupling coefficient[19] for the ith acoustic mode and jth structural mode,

$$\beta_{ij} = \int_s \phi_i(\mathbf{x})\varphi_j(\mathbf{x})d\mathbf{x}. \tag{16}$$

Substituting Eq. (14) into Eq. (13) and after some manipulations of the formulas, the modal velocity vector becomes

$$\mathbf{v} = \tilde{\boldsymbol{\Lambda}}_s(-\mathbf{B}_{\text{couple}}^T\mathbf{p} + \mathbf{Z}_c\mathbf{f}_c + \mathbf{Z}_d\mathbf{f}_d), \tag{17}$$

where

$$\tilde{\boldsymbol{\Lambda}}_s = \begin{pmatrix} \frac{j\omega}{\omega_{s,1}^2-\omega^2} & 0 & \cdots & 0 \\ 0 & \frac{j\omega}{\omega_{s,2}^2-\omega^2} & 0 & \vdots \\ \vdots & 0 & \ddots & 0 \\ 0 & \cdots & \cdots & \frac{j\omega}{\omega_{s,M_s}^2-\omega^2} \end{pmatrix} \in \mathfrak{I}^{M_s\times M_s}, \tag{18}$$

$$\mathbf{B}_{\text{couple}} = \begin{pmatrix} \boldsymbol{\beta}_1^T \\ \boldsymbol{\beta}_2^T \\ \vdots \\ \boldsymbol{\beta}_{Ma}^T \end{pmatrix} = (\bar{\boldsymbol{\beta}}_1\ \bar{\boldsymbol{\beta}}_2\ \bar{\boldsymbol{\beta}}_{Ms}) \in \mathfrak{R}^{M_a\times M_s}, \tag{19}$$

$$\mathbf{Z}_c = \begin{pmatrix} \varphi_1(\mathbf{x}_{c1}) & \varphi_1(\mathbf{x}_{c2}) & \cdots & \varphi_1(\mathbf{x}_{cN_c}) \\ \varphi_2(\mathbf{x}_{c1}) & \varphi_2(\mathbf{x}_{c2}) & \cdots & \varphi_2(\mathbf{x}_{cN_c}) \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{M_s}(\mathbf{x}_{c1}) & \varphi_{M_s}(\mathbf{x}_{c2}) & \cdots & \varphi_{M_s}(\mathbf{x}_{cN_c}) \end{pmatrix} \in \mathfrak{R}^{M_s\times N_c}, \tag{20}$$

$$\mathbf{Z}_d = \begin{pmatrix} \varphi_1(\mathbf{x}_{d1}) & \varphi_1(\mathbf{x}_{d2}) & \cdots & \varphi_1(\mathbf{x}_{dN_d}) \\ \varphi_2(\mathbf{x}_{d1}) & \varphi_2(\mathbf{x}_{d2}) & \cdots & \varphi_2(\mathbf{x}_{dN_d}) \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{M_s}(\mathbf{x}_{d1}) & \varphi_{M_s}(\mathbf{x}_{d2}) & \cdots & \varphi_{M_s}(\mathbf{x}_{dN_d}) \end{pmatrix} \in \mathfrak{R}^{M_s\times N_d}, \tag{21}$$

$$\mathbf{f}_c = (f_{c,1}\ f_{c,2}\ \cdots\ f_{c,N_c})^T \in \mathfrak{C}^{N_c}, \tag{22}$$

$$\mathbf{f}_d = (f_{d,1}\ f_{d,2}\ \cdots\ f_{d,N_d})^T \in \mathfrak{C}^{N_d}, \tag{23}$$

and where $\mathfrak{I}^{M_s\times M_s}$ and $\mathfrak{R}^{M_a\times M_s}$ denote the class of all $M_s \times M_s$ matrices with pure imaginary number elements and all $M_a \times M_s$ matrices with real number elements, respectively.

B. Acoustic field system

Sound pressure $p(\mathbf{r})$ that is a resultant from the surface velocity of the enclosing structure and N_s sound sources for ANC with the volume velocity q_i at $\mathbf{r}_i$ is defined by the Green's function response equation,

$$p(\mathbf{r}) = j\omega\rho_0\int_s \mathrm{G}(\mathbf{x}|\mathbf{r})v(\mathbf{x})d\mathbf{x} + j\omega\rho_0\sum_{i=1}^{N_s}\mathrm{G}(\mathbf{r}_i|\mathbf{r})q_i, \tag{24}$$

where $\mathrm{G}(\mathbf{x}/\mathbf{r})$ is the Green's function of the enclosed space, and is defined as

$$G(\mathbf{x}|\mathbf{r}) = \sum_{i=1}^{\infty} \frac{c_0^2 \phi_i(\mathbf{x}) \phi_i(\mathbf{r})}{V_i(\omega_{a,i}^2 - \omega^2)}, \tag{25}$$

where $\omega_{a,i}$ is the eigenvalue of the ith acoustic mode, c_0 is the speed of sound in the acoustic medium, and the integration in Eq. (24) is over the surface S of the panel. Consequently, the complex amplitude of the ith acoustic mode is found to be

$$p_i = j\omega\rho_0 c_0^2 \int_s \frac{\phi_i(\mathbf{x})}{V_i(\omega_{a,i}^2 - \omega^2)} v(\mathbf{x}) d\mathbf{x} + j\omega\rho_0 c_0^2 \sum_{j=1}^{N_s} \frac{\phi_i(\mathbf{x}_j)}{V_i(\omega_{a,i}^2 - \omega^2)} q_j, \tag{26}$$

where the surface velocity $v(\mathbf{x})$ of the panel may be expanded in terms of the mode shape functions, enabling the amplitude of the ith acoustic mode to be expressed as

$$p_i = \frac{j\omega\rho_0 c_0^2}{V_i(\omega_{a,i}^2 - \omega^2)} (\boldsymbol{\beta}_i^T \mathbf{v} + \bar{\boldsymbol{\phi}}_i^T \mathbf{q}), \tag{27}$$

where

$$\bar{\boldsymbol{\phi}}_i = (\phi_i(\mathbf{r}_1) \phi_i(\mathbf{r}_2) \cdots \phi_i(\mathbf{r}_{N_s}))^T, \tag{28}$$

and

$$\mathbf{q} = (q_1 q_2 \cdots q_{N_s})^T. \tag{29}$$

From Eq. (27), the acoustic modal amplitude vector is given by

$$\mathbf{p} = \tilde{\boldsymbol{\Lambda}}_a (\mathbf{B}_{\text{couple}} \mathbf{v} + \boldsymbol{\Phi} \mathbf{q}), \tag{30}$$

where

$$\tilde{\boldsymbol{\Lambda}}_a = \begin{pmatrix} \frac{j\rho_0 c_0^2 \omega}{V_1(\omega_{a,1}^2 - \omega^2)} & 0 & \cdots & 0 \\ 0 & \frac{j\rho_0 c_0^2 \omega}{V_2(\omega_{a,2}^2 - \omega^2)} & 0 & \vdots \\ \vdots & 0 & \ddots & 0 \\ 0 & \cdots & 0 & \frac{j\rho_0 c_0^2 \omega}{V_{M_a}(\omega_{a,M_a}^2 - \omega^2)} \end{pmatrix} \in \mathfrak{I}^{M_a \times M_a}, \tag{31}$$

and

$$\boldsymbol{\Phi} = \begin{pmatrix} \bar{\boldsymbol{\phi}}_1^T \\ \bar{\boldsymbol{\phi}}_2^T \\ \vdots \\ \bar{\boldsymbol{\phi}}_{M_a}^T \end{pmatrix} = (\boldsymbol{\phi}(\mathbf{r}_1)\ \boldsymbol{\phi}(r_2)\ \cdots\ \boldsymbol{\phi}(\mathbf{r}_{M_a})) = \begin{pmatrix} \phi_1(\mathbf{r}_1) & \phi_1(\mathbf{r}_2) & \cdots & \phi_1(\mathbf{r}_{N_s}) \\ \phi_2(\mathbf{r}_1) & \phi_2(\mathbf{r}_2) & \cdots & \phi_2(\mathbf{r}_{N_s}) \\ \vdots & \vdots & \vdots & \vdots \\ \phi_{M_a}(\mathbf{r}_1) & \phi_{M_a}(\mathbf{r}_2) & \cdots & \phi_{M_a}(\mathbf{r}_{N_s}) \end{pmatrix} \in \mathfrak{R}^{M_a \times N_s}. \tag{32}$$

C. Cluster coupled structural/acoustic system

A cluster coupled structural/acoustic system equation may be obtained by combining both the vibration field equation in Eq. (17) and the acoustic field equation in Eq. (30). By substituting Eq. (30) into Eq. (17), the modal amplitude velocity vector is given by

$$\mathbf{v} = (\mathbf{I}_{M_s} + \tilde{\boldsymbol{\Lambda}}_s \mathbf{B}_{\text{couple}}^T \tilde{\boldsymbol{\Lambda}}_a \mathbf{B}_{\text{couple}})^{-1} \times \tilde{\boldsymbol{\Lambda}}_s (-\mathbf{B}_{\text{couple}}^T \tilde{\boldsymbol{\Lambda}}_a \boldsymbol{\Phi} \mathbf{q} + \mathbf{Z}_c \mathbf{f}_c + \mathbf{Z}_d \mathbf{f}_d), \tag{33}$$

where $\mathbf{I}_{M_s}$, denotes the identity matrix with the order of M_s. Similarly, substituting Eq. (17) into Eq. (30), the acoustic modal amplitude vector yields

$$\mathbf{p} = (\mathbf{I}_{M_a} + \tilde{\boldsymbol{\Lambda}}_a \mathbf{B}_{\text{couple}} \tilde{\boldsymbol{\Lambda}}_s \mathbf{B}_{\text{couple}}^T)^{-1} \times \tilde{\boldsymbol{\Lambda}}_a \{\boldsymbol{\Phi} \mathbf{q} + \mathbf{B}_{\text{couple}} \tilde{\boldsymbol{\Lambda}}_s (\mathbf{Z}_c \mathbf{f}_c + \mathbf{Z}_d \mathbf{f}_d)\}. \tag{34}$$

From Eqs. (33) and (34), it can be found that the properties of a cluster coupled structural/acoustic enclosure are governed by the following characteristic equation:

$$\det(\mathbf{I}_{M_a} + \tilde{\boldsymbol{\Lambda}}_a \mathbf{B}_{\text{couple}} \tilde{\boldsymbol{\Lambda}}_s \mathbf{B}_{\text{couple}}^T) = \det(\mathbf{I}_{M_s} + \tilde{\boldsymbol{\Lambda}}_s \mathbf{B}_{\text{couple}}^T \tilde{\boldsymbol{\Lambda}}_a \mathbf{B}_{\text{couple}}) = 0. \tag{35}$$

Assume that all the structural modes of a rectangular panel are classified into four clusters[22,23]—A_s, B_s, C_s, and D_s. The clustered structure modal function vector in Eq. (6) may then be written as

$$\boldsymbol{\varphi}(\mathbf{x}) = (\boldsymbol{\varphi}_{\mathrm{A}_s}(\mathbf{x})\ \boldsymbol{\varphi}_{\mathrm{B}_s}(\mathbf{x})\ \boldsymbol{\varphi}_{\mathrm{C}_s}(\mathbf{x})\ \boldsymbol{\varphi}_{\mathrm{D}_s}(\mathbf{x}))^T, \tag{36}$$

where $\boldsymbol{\varphi}_{\mathrm{A}_s}(\mathbf{x}) \in \mathfrak{R}^{M_{s\mathrm{A}}}$, $\boldsymbol{\varphi}_{\mathrm{B}_s}(\mathbf{x}) \in \mathfrak{R}^{M_{s\mathrm{B}}}$, $\boldsymbol{\varphi}_{\mathrm{C}_s}(\mathbf{x}) \in \mathfrak{R}^{M_{s\mathrm{C}}}$ and $\boldsymbol{\varphi}_{\mathrm{D}_s}(\mathbf{x}) \in \mathfrak{R}^{M_{s\mathrm{D}}}$. Similarly, when all the acoustic modes of a rectangular cavity are grouped into the clusters: A_a, B_a, C_a, and D_a, the acoustic modal amplitude vector in Eq. (11) is given by

$$\boldsymbol{\phi}(\mathbf{r}) = (\boldsymbol{\phi}_{\mathrm{A}_a}(\mathbf{r})\ \boldsymbol{\phi}_{\mathrm{B}_a}(\mathbf{r})\ \boldsymbol{\phi}_{\mathrm{C}_a}(\mathbf{r})\ \boldsymbol{\phi}_{\mathrm{D}_a}(\mathbf{r}))^T, \tag{37}$$

where $\boldsymbol{\phi}_{\mathrm{A}_a}(\mathbf{r}) \in \mathfrak{R}^{M_{s\mathrm{A}}}$, $\boldsymbol{\phi}_{\mathbf{B}_a}(\mathbf{r}) \in \mathfrak{R}^{M_{s\mathrm{B}}}$, $\boldsymbol{\phi}_{\mathrm{C}_a}(\mathbf{r}) \in \mathfrak{R}^{M_{s\mathrm{C}}}$ and $\boldsymbol{\phi}_{\mathrm{D}_a}(\mathbf{r}) \in \mathfrak{R}^{M_{s\mathrm{D}}}$.c

Note that the acoustic modal indices of the rectangular cavity are described by three indices in the x, y, and z axes, and the two in the x and y axes are used as they meet in the x-y plane of the cavity.

Cluster coupling means that when structural modes and acoustic modes fall into the same common cluster; $\mathrm{A} \equiv \mathrm{A}_s \equiv \mathrm{A}_a$, $\mathrm{B} \equiv \mathrm{B}_s \equiv \mathrm{B}_a$, $\mathrm{C} \equiv \mathrm{C}_s \equiv \mathrm{C}_a$, and $\mathrm{D} \equiv \mathrm{D}_s \equiv \mathrm{D}_a$, the modal pair in each cluster interferes with each other, resulting in changing the eigenvalues of each cluster coupling system independently, as will be discussed shortly.

If this is the case, the coupling coefficient β_{ij} in Eq. (16) with respect to the modal pair becomes nonzero. For example, the odd/odd structural modes do not couple with the acoustic odd/odd or odd/even or even/odd modes, thereby causing the nullification of the modal coupling coefficient. As noted by Pretlove[16,17] and Bhattacharya,[19] the modal coupling or parity-dependent coupling of the cavity modes and the panel modes is so selective that the radiation or coupling may be divided into sub-domains containing only those matched parity modes. Khilman[18] also estimated the parity-dependent coupling coefficient of a panel mode with all the possible cavity modes. Thus the terminology "cluster coupling" used in the work is tantamount to the "modal coupling" or "parity-dependent coupling" used in the work is tantamount to the "modal coupling" or "parity-dependent coupling" used in the former arts; however, in order to maintain the consistency as it is already utilized in the authors' relevant papers,[22,23] this paper employs the label "cluster."

Hence, all the structural/acoustic modal combinations are summarized as follows:

Cluster A: It consists of all the odd/odd structural modes, $\varphi_{\mathrm{odd/odd}}(\mathbf{x})$, and all the even/even acoustic modes, $\phi_{\mathrm{even/even}}(\mathbf{x})$.

Cluster B: It consists of all the odd/even structural modes, $\varphi_{\mathrm{odd/even}}(\mathbf{x})$, and all the even/odd acoustic modes, $\phi_{\mathrm{even/odd}}(\mathbf{x})$.

Cluster C: It consists of all the even/odd structural modes, $\varphi_{\mathrm{even/odd}}(\mathbf{x})$, and all the odd/even acoustic modes, $\phi_{\mathrm{odd/even}}(\mathbf{x})$.

Cluster D: It consists of all the even/even structural modes, $\varphi_{\mathrm{even/even}}(\mathbf{x})$, and all the odd/odd acoustic modes, $\phi_{\mathrm{odd/odd}}(\mathbf{x})$.

Boundary conditions of the structural modes of a rectangular panel satisfying the above-mentioned properties are, for instance, simple support of four edges of the plate (SSSS), clamped support (CCCC), free support (FFFF), and combinations thereof such as (SCSC), (FCFC), and (SFSF), where an eigenfunction is expressed as a symmetrical or skew-symmetrical function with respect to the x and y axes. Thus all the structural/acoustic modes of a rectangular panel/cavity system are classified into four kinds of clusters.

Suppose that all structural modes are orthogonal, and then the clusters consisting of those modes are also orthogonal to each other. Furthermore, taking into consideration the modal orthogonality between the structural modes and acoustic modes, the modal coupling matrix defined in Eq. (19) is written as

$$\mathbf{B}_{\mathrm{couple}} = \begin{pmatrix} \mathbf{B}_{\mathrm{A}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_{\mathrm{B}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{B}_{\mathrm{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{B}_{\mathrm{D}} \end{pmatrix}. \tag{38}$$

Similarly, the matrices $\tilde{\mathbf{\Lambda}}_s$ and $\tilde{\mathbf{\Lambda}}_a$ may also be decoupled into the following:

$$\tilde{\mathbf{\Lambda}}_s = \begin{pmatrix} \tilde{\mathbf{\Lambda}}_{s\mathrm{A}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{\Lambda}}_{s\mathrm{B}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \tilde{\mathbf{\Lambda}}_{s\mathrm{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{\Lambda}}_{s\mathrm{D}} \end{pmatrix}, \tag{39}$$

and

$$\tilde{\mathbf{\Lambda}}_a = \begin{pmatrix} \tilde{\mathbf{\Lambda}}_{a\mathrm{A}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{\Lambda}}_{a\mathrm{B}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \tilde{\mathbf{\Lambda}}_{a\mathrm{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{\Lambda}}_{a\mathrm{D}} \end{pmatrix}. \tag{40}$$

Substituting Eqs. (38)–(40) into Eq. (35), the cluster coupling characteristic equation expands to

$$\begin{aligned} &\det(\mathbf{I}_{M_s} + \tilde{\mathbf{\Lambda}}_a \mathbf{B}_{\mathrm{couple}} \tilde{\mathbf{\Lambda}}_s \mathbf{B}_{\mathrm{couple}}^T) \\ &= \det\begin{pmatrix} \mathbf{\Delta}_{\mathrm{A}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{\Delta}_{\mathrm{B}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{\Delta}_{\mathrm{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{\Delta}_{\mathrm{D}} \end{pmatrix} \\ &= \begin{pmatrix} \det(\mathbf{\Delta}_{\mathrm{A}}) & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \det(\mathbf{\Delta}_{\mathrm{B}}) & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \det(\mathbf{\Delta}_{\mathrm{C}}) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \det(\mathbf{\Delta}_{\mathrm{D}}) \end{pmatrix} = 0, \end{aligned} \tag{41}$$

where

$$\mathbf{\Delta}_{\mathrm{A}} = \mathbf{I}_{\mathrm{A}} + \tilde{\mathbf{\Lambda}}_{a\mathrm{A}} \mathbf{B}_{\mathrm{A}} \tilde{\mathbf{\Lambda}}_{s\mathrm{A}} \mathbf{B}_{\mathrm{A}}^T, \tag{42}$$

$$\mathbf{\Delta}_{\mathrm{B}} = \mathbf{I}_{\mathrm{B}} + \tilde{\mathbf{\Lambda}}_{a\mathrm{B}} \mathbf{B}_{\mathrm{B}} \tilde{\mathbf{\Lambda}}_{s\mathrm{B}} \mathbf{B}_{\mathrm{B}}^T, \tag{43}$$

$$\mathbf{\Delta}_{\mathrm{C}} = \mathbf{I}_{\mathrm{C}} + \tilde{\mathbf{\Lambda}}_{a\mathrm{C}} \mathbf{B}_{\mathrm{C}} \tilde{\mathbf{\Lambda}}_{s\mathrm{C}} \mathbf{B}_{\mathrm{C}}^T, \tag{44}$$

$$\boldsymbol{\Delta}_{\mathrm{D}} = \mathbf{I}_{\mathrm{D}} + \tilde{\boldsymbol{\Lambda}}_{a\mathrm{D}}\mathbf{B}_{\mathrm{D}}\tilde{\boldsymbol{\Lambda}}_{s\mathrm{D}}\mathbf{B}_{\mathrm{D}}^{T}. \tag{45}$$

Moreover, the inverse matrix of $(\mathbf{I}_{M_s} + \tilde{\boldsymbol{\Lambda}}_a\mathbf{B}_{\mathrm{couple}}\tilde{\boldsymbol{\Lambda}}_s\mathbf{B}_{\mathrm{couple}}^{T})$ becomes

$$\boldsymbol{\Delta}_{a,\mathrm{inv}} = (\mathbf{I}_{M_s} + \tilde{\boldsymbol{\Lambda}}_a\mathbf{B}_{\mathrm{couple}}\tilde{\boldsymbol{\Lambda}}_s\mathbf{B}_{\mathrm{couple}}^{T})^{-1} = \begin{pmatrix} \boldsymbol{\Delta}_{\mathrm{A}}^{-1} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Delta}_{\mathrm{B}}^{-1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\Delta}_{\mathrm{C}}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \boldsymbol{\Delta}_{\mathrm{D}}^{-1} \end{pmatrix}. \tag{46}$$

Clearly from Eq. (46), the eigenvalues of each cluster are independently determined by the cluster characteristic equation, thus causing no spillover on the other clusters.

III. ACOUSTIC POTENTIAL ENERGY IN A CLUSTER COUPLED CAVITY

A. Acoustic potential energy

Acoustic potential energy E_p in a cavity may be described by

$$E_p = \frac{1}{4\rho_0 c_0^2}\int_V |p(r)|^2 d\mathbf{r}, \tag{47}$$

where V is the volume of the enclosure. By substituting Eq. (9) into Eq. (47), the potential energy E_p becomes

$$E_p = \frac{1}{4\rho_0 c_0^2}\int_V \mathbf{p}^H \boldsymbol{\phi}(r)\boldsymbol{\phi}^T(r)\mathbf{p}\, d\mathbf{r}, \tag{48}$$

where the superscript H represents the Hermitian (conjugate transpose). Furthermore, considering the orthogonality of acoustic modal functions in Eq. (12), the acoustic potential energy E_p is therefore described as

$$E_p = \mathbf{p}^H \boldsymbol{\Lambda}_V \mathbf{p}, \tag{49}$$

where

$$\boldsymbol{\Lambda}_V = \frac{1}{4\rho_0 c_0^2}\begin{pmatrix} V_1 & 0 & \cdots & 0 \\ 0 & V_2 & 0 & \vdots \\ \vdots & 0 & \ddots & 0 \\ 0 & \cdots & 0 & V_{M_a} \end{pmatrix} \in \mathfrak{R}^{M_a \times M_a}. \tag{50}$$

As discussed before, the matrix $\boldsymbol{\Lambda}_V$ can further be grouped into the four cluster blocks,

$$\boldsymbol{\Lambda}_V = \begin{pmatrix} \boldsymbol{\Lambda}_{V\mathrm{A}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Lambda}_{V\mathrm{B}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\Lambda}_{V\mathrm{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \boldsymbol{\Lambda}_{V\mathrm{D}} \end{pmatrix}. \tag{51}$$

Substituting Eq. (34) into Eq. (49), the acoustic potential energy E_p is given by

$$E_p = \mathbf{q}^H\mathbf{A}_p\mathbf{q} + \mathbf{f}_C^H\mathbf{B}_p^H\mathbf{q} + \mathbf{f}_d^H\mathbf{C}_p^H\mathbf{q} + \mathbf{q}^H\mathbf{B}_p\mathbf{f}_c + \mathbf{f}_c^H\mathbf{D}_p\mathbf{f}_c + \mathbf{f}_d^H\mathbf{E}_p^H\mathbf{f}_c + \mathbf{q}^H\mathbf{C}_p\mathbf{f}_d + \mathbf{f}_c^H\mathbf{E}_p\mathbf{f}_d + E_{p,\mathrm{without}}, \tag{52}$$

where the matrices in Eq. (52) are defined as follows:

$$\mathbf{A}_p = \Phi^T\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a\boldsymbol{\Phi} \in \mathfrak{R}^{N_s\times N_s}, \tag{53}$$

$$\mathbf{B}_p^H = \mathbf{Z}_c^T\tilde{\boldsymbol{\Lambda}}_s^*\mathbf{B}_{\mathrm{couple}}^T\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a\boldsymbol{\Phi} \in \mathfrak{I}^{N_s\times N_c}, \tag{54}$$

$$\mathbf{C}_p^H = \mathbf{Z}_c^T\tilde{\boldsymbol{\Lambda}}_s^*\mathbf{B}_{\mathrm{couple}}^T\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a\boldsymbol{\Phi} \in \mathfrak{I}^{N_s\times N_c}, \tag{55}$$

$$\mathbf{D}_p = \mathbf{Z}_c^T\tilde{\boldsymbol{\Lambda}}_s^*\mathbf{B}_{\mathrm{couple}}^T\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a\mathbf{B}_{\mathrm{couple}}\tilde{\boldsymbol{\Lambda}}_s\mathbf{Z}_c \in \mathfrak{R}^{N_c\times N_c}, \tag{56}$$

$$\mathbf{E}_p = \mathbf{Z}_c^T\tilde{\boldsymbol{\Lambda}}_s^*\mathbf{B}_{\mathrm{couple}}^T\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a\mathbf{B}_{\mathrm{couple}}\tilde{\boldsymbol{\Lambda}}_s\mathbf{Z}_d \in \mathfrak{R}^{N_c\times N_d}, \tag{57}$$

$$E_{p,\mathrm{without}} = \mathbf{Z}_d^T\tilde{\boldsymbol{\Lambda}}_s^*\mathbf{B}_{\mathrm{couple}}^T\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a\mathbf{B}_{\mathrm{couple}}\tilde{\boldsymbol{\Lambda}}_s\mathbf{Z}_d \in \mathfrak{R}^{1\times 1}, \tag{58}$$

and where the asterisk and $E_{p,\mathrm{without}}$ denote complex conjugate and the acoustic potential energy in the cavity without control, respectively.

Here the common term $\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a$ in Eqs. (53)–(58) further expands to

$$\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a = \begin{pmatrix} \tilde{\boldsymbol{\Lambda}}_{\mathrm{A}}^*\boldsymbol{\Delta}_{\mathrm{A}}^{T,-1}\boldsymbol{\Lambda}_{V,\mathrm{A}}\boldsymbol{\Delta}_{\mathrm{A}}^{-1}\tilde{\boldsymbol{\Lambda}}_{\mathrm{A}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \tilde{\boldsymbol{\Lambda}}_{\mathrm{B}}^*\boldsymbol{\Delta}_{\mathrm{B}}^{T,-1}\boldsymbol{\Lambda}_{V,\mathrm{B}}\boldsymbol{\Delta}_{\mathrm{B}}^{-1}\tilde{\boldsymbol{\Lambda}}_{\mathrm{B}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \tilde{\boldsymbol{\Lambda}}_{\mathrm{C}}^*\boldsymbol{\Delta}_{\mathrm{C}}^{T,-1}\boldsymbol{\Lambda}_{V,\mathrm{C}}\boldsymbol{\Delta}_{\mathrm{C}}^{-1}\tilde{\boldsymbol{\Lambda}}_{\mathrm{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\boldsymbol{\Lambda}}_{\mathrm{D}}^*\boldsymbol{\Delta}_{\mathrm{D}}^{T,-1}\boldsymbol{\Lambda}_{V,\mathrm{D}}\boldsymbol{\Delta}_{\mathrm{D}}^{-1}\tilde{\boldsymbol{\Lambda}}_{\mathrm{D}} \end{pmatrix}. \tag{59}$$

Thus, due to the structure of the matrix $\tilde{\boldsymbol{\Lambda}}_a^*\boldsymbol{\Delta}_{a,\mathrm{inv}}^T\boldsymbol{\Lambda}_V\boldsymbol{\Delta}_{a,\mathrm{inv}}\tilde{\boldsymbol{\Lambda}}_a$, acoustic potential energy is decomposed into the four clusters, so that the matrices $\mathbf{A}_p$, $\mathbf{B}_p$, $\mathbf{C}_p$, $\mathbf{D}_p$, and $\mathbf{E}_p$ are partitioned into four cluster matrices, and hence the acoustic potential energy may be expressed as the sum of the acoustic potential energy in each cluster,

$$E_p = E_A + E_B + E_C + E_D. \tag{60}$$

B. Cluster filtering of acoustic potential energy

Employing cluster filtering,[22,23] a way to estimate the acoustic potential energy is presented. Assume that the acoustic point sensors at $\mathbf{r}_{s1}-\mathbf{r}_{s4}$ are situated such that the following descriptions are satisfied:

$$\mathbf{r}_{s1} = (x_s, y_s, z_s), \tag{61}$$

$$\mathbf{r}_{s2} = (L_x - x_s, y_s, z_s), \tag{62}$$

$$\mathbf{r}_{s3} = (L_x - x_s, L_x - y_s, z_s), \tag{63}$$

$$\mathbf{r}_{s4} = (x_s, L_x - y_s, z_s), \tag{64}$$

where

$$x_s \ll L_x, y_s \ll L_y, z_s \ll L_z. \tag{65}$$

By combining the four sound sensor outputs (sound pressure output) into the sound pressure vector $\mathbf{p}_c$, we have

$$\mathbf{p}_c = \begin{pmatrix} p(\mathbf{r}_{s1}) \\ p(\mathbf{r}_{s2}) \\ p(\mathbf{r}_{s3}) \\ p(\mathbf{r}_{s4}) \end{pmatrix} = \begin{pmatrix} p_1 \\ p_2 \\ p_3 \\ p_4 \end{pmatrix}. \tag{66}$$

Introducing the Hadamard matrix $\mathbf{T}$, the sound pressure vector $\mathbf{p}_c$ is transformed into

$$\tilde{\mathbf{p}} = \begin{pmatrix} \tilde{p}_A \\ \tilde{p}_B \\ \tilde{p}_C \\ \tilde{p}_D \end{pmatrix} = \mathbf{T}\mathbf{p}_c, \tag{67}$$

where

$$\mathbf{T} = (\mathbf{t}_A\ \mathbf{t}_B\ \mathbf{t}_C\ \mathbf{t}_D) = \begin{pmatrix} \mathbf{t}_A^T \\ \mathbf{t}_B^T \\ \mathbf{t}_C^T \\ \mathbf{t}_D^T \end{pmatrix} \tag{68}$$

and where

$$\mathbf{t}_A = (1\ 1\ 1\ 1)^T, \tag{69}$$

$$\mathbf{t}_B = (1\ 1\ -1\ -1)^T, \tag{70}$$

$$\mathbf{t}_C = (1\ -1\ -1\ 1)^T, \tag{71}$$

$$\mathbf{t}_D = (1\ -1\ 1\ -1)^T. \tag{72}$$

Taking into consideration the properties of acoustic eigenfunction, the elements of $\tilde{\mathbf{p}}$ in Eq. (67) are expressed as

$$\tilde{p}_A = \sum_{i=1}^{\infty} p_{i,\text{even/even}} \phi_{i,\text{even/even}} \approx \boldsymbol{\phi}_A^T \mathbf{p}_A, \tag{73}$$

$$\tilde{p}_B = \sum_{i=1}^{\infty} p_{i,\text{even/odd}} \phi_{i,\text{even/odd}} \approx \boldsymbol{\phi}_B^T \mathbf{p}_B, \tag{74}$$

$$\tilde{p}_C = \sum_{i=1}^{\infty} p_{i,\text{odd/even}} \phi_{i,\text{odd/even}} \approx \boldsymbol{\phi}_C^T \mathbf{p}_C, \tag{75}$$

$$\tilde{p}_D = \sum_{i=1}^{\infty} p_{i,\text{odd/odd}} \phi_{i,\text{odd/odd}} \approx \boldsymbol{\phi}_D^T \mathbf{p}_D. \tag{76}$$

Clearly from Eqs. (73)–(76), $\tilde{p}_A$, $\tilde{p}_B$, $\tilde{p}_C$, and $\tilde{p}_D$ express the summation of all the sound pressure belonging to clusters A, B, C, and D, respectively. Thus, it may extract each cluster attributes by introducing the cluster filtering processing.

Therefore, estimated acoustic potential energy of each cluster may be given by

$$\hat{E}_A = \frac{V}{4\rho_0 c_0^2} |\tilde{p}_A|^2, \tag{77}$$

$$\hat{E}_B = \frac{V}{4\rho_0 c_0^2} |\tilde{p}_B|^2, \tag{78}$$

$$\hat{E}_C = \frac{V}{4\rho_0 c_0^2} |\tilde{p}_C|^2, \tag{79}$$

$$\hat{E}_D = \frac{V}{4\rho_0 c_0^2} |\tilde{p}_D|^2. \tag{80}$$

C. Structural cluster actuation of acoustic potential energy

Suppose that the vibration control forces $f_{c1}-f_{c4}$, the amplitude of which is unity, are located at $\mathbf{x}_{c1}-\mathbf{x}_{c4}$ such that the following descriptions are satisfied:

$$\mathbf{x}_{c1} = (x_c, y_c), \tag{81}$$

$$\mathbf{x}_{c2} = (L_x - x_c, y_c), \tag{82}$$

$$\mathbf{x}_{c3} = (L_x - x_c, L_y - y_c), \tag{83}$$

$$\mathbf{x}_{c4} = (x_c, L_y - y_c), \tag{84}$$

where

$$x_c \ll L_x, L_c \ll L_y. \tag{85}$$

Incorporating the four control forces into the control force vector $\mathbf{f}$, we have

$$\mathbf{f} = \begin{pmatrix} f_{c1}(\mathbf{x}_{c1}) \\ f_{c2}(\mathbf{x}_{c2}) \\ f_{c3}(\mathbf{x}_{c3}) \\ f_{c4}(\mathbf{x}_{c4}) \end{pmatrix} = \begin{pmatrix} \delta(\mathbf{x} - \mathbf{x}_{c1}) \\ \delta(\mathbf{x} - \mathbf{x}_{c2}) \\ \delta(\mathbf{x} - \mathbf{x}_{c3}) \\ \delta(\mathbf{x} - \mathbf{x}_{c4}) \end{pmatrix}. \tag{86}$$

When driving these four control forces in phase with the amplitude f_A, the resultant force is then given by

$$\tilde{f}_{\mathrm{A}} = f_{\mathrm{A}}\{f_{c1}(\mathbf{x}_{c1}) + f_{c2}(\mathbf{x}_{c2}) + f_{c3}(\mathbf{x}_{c3}) + f_{c4}(\mathbf{x}_{c4})\}$$
$$= f_{\mathrm{A}}\{\delta(\mathbf{x}-\mathbf{x}_{c1}) + \delta(\mathbf{x}-\mathbf{x}_{c2}) + \delta(\mathbf{x}-\mathbf{x}_{c3}) + \delta(\mathbf{x}-\mathbf{x}_{c4})\}. \quad (87)$$

Then, as a result of applying $\tilde{f}_{\mathrm{A}}$ to excite the panel, the velocity modal amplitude v_i of the panel in Eq. (13) yields

$$v_i^{\mathrm{A}} = \frac{j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{A}}\{\varphi_i(\mathbf{x}_{c1}) + \varphi_i(\mathbf{x}_{c2}) + \varphi_i(\mathbf{x}_{c3}) + \varphi_i(\mathbf{x}_{c4})\}$$
$$= \frac{4j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{A}}\varphi_i^{\mathrm{A}}(\mathbf{x}_{c1}), \quad (88)$$

where the superscript A denotes a whole collection of the cluster "A" elements. Apparently from Eq. (88), only the odd/odd structural modes belonging to the cluster "A" are excited as a result of applying the transformed force $\tilde{f}_{\mathrm{A}}$ in Eq. (87). Note that all the odd/odd structural modes interfere with all the even/even acoustic modes as both of them belong to the same cluster "A," and hence exciting the panel via $\tilde{f}_{\mathrm{A}}$ leads to the direct activation of even/even acoustic modes without causing spillover.

In the same way, exciting the panel with the four point forces with an appropriate phase arrangement as described in the following permits one to activate the following cluster: For cluster B (odd/even structural modes),

$$\tilde{f}_{\mathrm{B}} = f_{\mathrm{B}}\{f_{c1}(\mathbf{x}_{c1}) + f_{c2}(\mathbf{x}_{c2}) - f_{c3}(\mathbf{x}_{c3}) - f_{c4}(\mathbf{x}_{c4})\}$$
$$= f_{\mathrm{B}}\{\delta(\mathbf{x}-\mathbf{x}_{c1}) + \delta(\mathbf{x}-\mathbf{x}_{c2}) - \delta(\mathbf{x}-\mathbf{x}_{c3}) - \delta(\mathbf{x}-\mathbf{x}_{c4})\} \quad (89)$$

then

$$v_i^{\mathrm{B}} = \frac{j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{A}}\{\varphi_i(\mathbf{x}_{c1}) + \varphi_i(\mathbf{x}_{c2}) - \varphi_i(\mathbf{x}_{c3}) - \varphi_i(\mathbf{x}_{c4})\}$$
$$= \frac{4j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{B}}\varphi_i^{\mathrm{B}}(\mathbf{x}_{c1}). \quad (90)$$

For cluster C (even/odd structural modes),

$$\tilde{f}_{\mathrm{C}} = f_{\mathrm{C}}\{f_{c1}(\mathbf{x}_{c1}) - f_{c2}(\mathbf{x}_{c2}) - f_{c3}(\mathbf{x}_{c3}) + f_{c4}(\mathbf{x}_{c4})\}$$
$$= f_{\mathrm{C}}\{\delta(\mathbf{x}-\mathbf{x}_{c1}) - \delta(\mathbf{x}-\mathbf{x}_{c2}) - \delta(\mathbf{x}-\mathbf{x}_{c3}) + \delta(\mathbf{x}-\mathbf{x}_{c4})\}, \quad (91)$$

then

$$v_i^{\mathrm{C}} = \frac{j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{C}}\{\varphi_i(\mathbf{x}_{c1}) - \varphi_i(\mathbf{x}_{c2}) - \varphi_i(\mathbf{x}_{c3}) + \varphi_i(\mathbf{x}_{c4})\}$$
$$= \frac{4j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{C}}\varphi_i^{\mathrm{C}}(\mathbf{x}_{c1}). \quad (92)$$

For cluster D (even/even structural modes),

$$\tilde{f}_{\mathrm{D}} = f_{\mathrm{D}}\{f_{c1}(\mathbf{x}_{c1}) - f_{c2}(\mathbf{x}_{c2}) + f_{c3}(\mathbf{x}_{c3}) - f_{c4}(\mathbf{x}_{c4})\}$$
$$= f_{\mathrm{D}}\{\delta(\mathbf{x}-\mathbf{x}_{c1}) - \delta(\mathbf{x}-\mathbf{x}_{c2}) + \delta(\mathbf{x}-\mathbf{x}_{c3}) - \delta(\mathbf{x}-\mathbf{x}_{c4})\}, \quad (93)$$

then

$$v_i^{\mathrm{D}} = \frac{j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{D}}\{\varphi_i(\mathbf{x}_{c1}) - \varphi_i(\mathbf{x}_{c2}) + \varphi_i(\mathbf{x}_{c3}) - \varphi_i(\mathbf{x}_{c4})\}$$
$$= \frac{4j\omega}{\omega_{s,i}^2-\omega^2} f_{\mathrm{D}}\varphi_i^{\mathrm{D}}(\mathbf{x}_{c1}). \quad (94)$$

Combining the transformed forces into the cluster force vector $\tilde{\mathbf{f}}$, we have

$$\tilde{\mathbf{f}} = \begin{pmatrix} \tilde{f}_{\mathrm{A}} \\ \tilde{f}_{\mathrm{B}} \\ \tilde{f}_{\mathrm{C}} \\ \tilde{f}_{\mathrm{D}} \end{pmatrix} = \mathbf{FTf}, \quad (95)$$

where $\mathbf{F}$ is the gain matrix and defined as

$$\mathbf{F} = \begin{pmatrix} f_{\mathrm{A}} & 0 & 0 & 0 \\ 0 & f_{\mathrm{B}} & 0 & 0 \\ 0 & 0 & f_{\mathrm{C}} & 0 \\ 0 & 0 & 0 & f_{\mathrm{D}} \end{pmatrix}. \quad (96)$$

Thus, the control force vector $\mathbf{f}$ is transformed into the cluster force vector $\tilde{\mathbf{f}}$ using the Hadamard matrix $\mathbf{T}$ assigned with a gain matrix $\mathbf{F}$, and hence termed a structural cluster actuation.

D. Acoustic cluster actuation of acoustic potential energy

Place four acoustic sources q_1-q_4 with the unity amplitude at $\mathbf{r}_{a1}-\mathbf{r}_{a4}$ such that the following descriptions are satisfied:

$$\mathbf{r}_{a1} = (x_a, y_a, z_a), \quad (97)$$

$$\mathbf{r}_{a2} = (L_x - x_a, y_a, z_a), \quad (98)$$

$$\mathbf{r}_{a3} = (L_x - x_a, L_x - y_a, z_a), \quad (99)$$

$$\mathbf{r}_{a4} = (x_a, L_x - y_a, z_a), \quad (100)$$

where

$$x_a \ll L_x, y_a \ll L_y, z_a \ll L_z. \quad (101)$$

Incorporating the four point forces into the sound source vector $\mathbf{q}$, we have

$$\mathbf{q} = \begin{pmatrix} q(\mathbf{r}_{a1}) \\ q(\mathbf{r}_{a2}) \\ q(\mathbf{r}_{a3}) \\ q(\mathbf{r}_{a4}) \end{pmatrix} = \begin{pmatrix} \delta(\mathbf{r}-\mathbf{r}_{a1}) \\ \delta(\mathbf{r}-\mathbf{r}_{a2}) \\ \delta(\mathbf{r}-\mathbf{r}_{a3}) \\ \delta(\mathbf{r}-\mathbf{r}_{a4}) \end{pmatrix}. \quad (102)$$

When driving these four sound sources in phase with the amplitude q_{A}, the resultant sound source is then given by

$$\tilde{q}_{\mathrm{A}} = q_{\mathrm{A}}\{q(\mathbf{r}_{a1}) + q(\mathbf{r}_{a2}) + q(\mathbf{r}_{a3}) + q(\mathbf{r}_{a4})\}$$
$$= q_{\mathrm{A}}\{\delta(\mathbf{r}-\mathbf{r}_{s1}) + \delta(\mathbf{r}-\mathbf{r}_{s2}) + \delta(\mathbf{r}-\mathbf{r}_{s3}) + \delta(\mathbf{r}-\mathbf{r}_{s4})\}, \quad (103)$$

and the sound pressure modal amplitude p_i in Eq. (26), be-

cause of the characteristics of the acoustic modal function, yields

$$p_i^{\mathrm{A}} = \frac{j\omega\rho_0 c_0^2}{V_i(\omega_{a,i}^2 - \omega^2)} q_{\mathrm{A}}\{\phi_i(\mathbf{r}_{s1}) + \phi_i(\mathbf{r}_{s2}) + \phi_i(\mathbf{r}_{s3}) + \phi_i(\mathbf{r}_{s4})\} = \frac{4j\omega\rho_0 c_0^2}{V_i(\omega_{a,i}^2 - \omega^2)} q_{\mathrm{A}}\phi_i^{\mathrm{A}}(\mathbf{r}_{s1}). \quad (104)$$

Apparently from Eq. (104), only the even/even acoustic modes belonging to the cluster "A" are excited as a result of applying the transformed sound source $\tilde{q}_{\mathrm{A}}$ in Eq. (103) whereas the other acoustic modes are not.

In the same way, driving the four point sound sources with an appropriate phase arrangement as described in the following permits one to excite the following a acoustic cluster: For cluster B (even/odd acoustic modes),

$$\tilde{q}_{\mathrm{B}} = q_{\mathrm{B}}\{q(\mathbf{r}_{a1}) + q(\mathbf{r}_{a2}) - q(\mathbf{r}_{a3}) - q(\mathbf{r}_{a4})\} = q_{\mathrm{B}}\{\delta(\mathbf{r}-\mathbf{r}_{a1}) + \delta(\mathbf{r}-\mathbf{r}_{a2}) - \delta(\mathbf{r}-\mathbf{r}_{a3}) - \delta(\mathbf{r}-\mathbf{r}_{a4})\}. \quad (105)$$

For cluster C (odd/even acoustic mode),

$$\tilde{q}_{\mathrm{C}} = q_{\mathrm{C}}\{q(\mathbf{r}_{a1}) - q(\mathbf{r}_{a2}) - q(\mathbf{r}_{a3}) + q(\mathbf{r}_{a4})\} = q_{\mathrm{C}}\{\delta(\mathbf{r}-\mathbf{r}_{a1}) - \delta(\mathbf{r}-\mathbf{r}_{a2}) - \delta(\mathbf{r}-\mathbf{r}_{a3}) + \delta(\mathbf{r}-\mathbf{r}_{a4})\}. \quad (106)$$

For cluster D (odd/odd acoustic mode),

$$\tilde{q}_{\mathrm{D}} = q_{\mathrm{D}}\{q(\mathbf{r}_{a1}) - q(\mathbf{r}_{a2}) + q(\mathbf{r}_{a3}) - q(\mathbf{r}_{a4})\} = q_{D}\{\delta(\mathbf{r}-\mathbf{r}_{a1}) - \delta(\mathbf{r}-\mathbf{r}_{a2}) + \delta(\mathbf{r}-\mathbf{r}_{a3}) - \delta(\mathbf{r}-\mathbf{r}_{a4})\}. \quad (107)$$

Thus, combining the transformed sound sources into the cluster sound vector $\tilde{\mathbf{q}}$ leads to

$$\tilde{\mathbf{q}} = \begin{pmatrix} \tilde{q}_{\mathrm{A}} \\ \tilde{q}_{\mathrm{B}} \\ \tilde{q}_{\mathrm{C}} \\ \tilde{q}_{\mathrm{D}} \end{pmatrix} = \mathbf{QTq}, \quad (108)$$

where $\mathbf{Q}$ denotes the gain matrix, and is defined as

$$\mathbf{Q} = \begin{pmatrix} q_{\mathrm{A}} & 0 & 0 & 0 \\ 0 & q_{\mathrm{B}} & 0 & 0 \\ 0 & 0 & q_{\mathrm{C}} & 0 \\ 0 & 0 & 0 & q_{\mathrm{D}} \end{pmatrix}. \quad (109)$$

Here the sound source vector $\mathbf{q}$ is transformed via the Hadamard matrix into the cluster sound source vector $\tilde{\mathbf{q}}$, and hence termed an acoustic cluster actuation.

IV. CLUSTER CONTROL OF ACOUSTIC POTENTIAL ENERGY IN A CLUSTER COUPLED CAVITY

A. Optimal control law for minimizing clustered acoustic potential energy

Now, sound pressure modal amplitude vector in Eq. (34) is partitioned into the four cluster vectors as

$$\mathbf{p} = \begin{pmatrix} \mathbf{p}_{\mathrm{A}} \\ \mathbf{p}_{\mathrm{B}} \\ \mathbf{p}_{\mathrm{C}} \\ \mathbf{p}_{\mathrm{D}} \end{pmatrix}. \quad (110)$$

Substituting Eq. (110) into Eq. (34), the clustered sound pressure modal amplitude vector may then be written as

$$\mathbf{p}_{\mathrm{A}} = \boldsymbol{\Delta}_{\mathrm{A}}^{-1}\tilde{\boldsymbol{\Lambda}}_{a\mathrm{A}}\{q_{\mathrm{A}}\boldsymbol{\Phi}_{\mathrm{A}}\mathbf{t}_{\mathrm{A}} + \mathbf{B}_{\mathrm{A}}\tilde{\boldsymbol{\Lambda}}_{s\mathrm{A}}(f_{\mathrm{A}}\bar{\boldsymbol{\Phi}}_{\mathrm{A}}\mathbf{t}_{\mathrm{A}} + \hat{\boldsymbol{\Phi}}_{\mathrm{A}}\mathbf{f}_d)\}, \quad (111)$$

$$\mathbf{p}_{\mathrm{B}} = \boldsymbol{\Delta}_{\mathrm{B}}^{-1}\tilde{\boldsymbol{\Lambda}}_{a\mathrm{B}}\{q_{\mathrm{B}}\boldsymbol{\Phi}_{\mathrm{B}}\mathbf{t}_{\mathrm{B}} + \mathbf{B}_{\mathrm{B}}\tilde{\boldsymbol{\Lambda}}_{s\mathrm{B}}(f_{\mathrm{B}}\bar{\boldsymbol{\Phi}}_{\mathrm{B}}\mathbf{t}_{\mathrm{B}} + \hat{\boldsymbol{\Phi}}_{\mathrm{B}}\mathbf{f}_d)\}, \quad (112)$$

$$\mathbf{p}_{\mathrm{C}} = \boldsymbol{\Delta}_{\mathrm{C}}^{-1}\tilde{\boldsymbol{\Lambda}}_{a\mathrm{C}}\{q_{\mathrm{C}}\boldsymbol{\Phi}_{\mathrm{C}}\mathbf{t}_{\mathrm{C}} + \mathbf{B}_{\mathrm{C}}\tilde{\boldsymbol{\Lambda}}_{s\mathrm{B}}(f_{\mathrm{C}}\bar{\boldsymbol{\Phi}}_{\mathrm{C}}\mathbf{t}_{\mathrm{C}} + \hat{\boldsymbol{\Phi}}_{\mathrm{C}}\mathbf{f}_d)\}, \quad (113)$$

$$\mathbf{p}_{\mathrm{D}} = \boldsymbol{\Delta}_{\mathrm{D}}^{-1}\tilde{\boldsymbol{\Lambda}}_{a\mathrm{D}}\{q_{\mathrm{D}}\boldsymbol{\Phi}_{\mathrm{D}}\mathbf{t}_{\mathrm{D}} + \mathbf{B}_{\mathrm{D}}\tilde{\boldsymbol{\Lambda}}_{s\mathrm{D}}(f_{\mathrm{D}}\bar{\boldsymbol{\Phi}}_{\mathrm{D}}\mathbf{t}_{\mathrm{D}} + \hat{\boldsymbol{\Phi}}_{\mathrm{D}}\mathbf{f}_d)\} \quad (114)$$

where $\boldsymbol{\Phi}_{\mathrm{A}}$–$\boldsymbol{\Phi}_{\mathrm{D}}$, $\bar{\boldsymbol{\Phi}}_{\mathrm{A}}$–$\bar{\boldsymbol{\Phi}}_{\mathrm{D}}$, and $\hat{\boldsymbol{\Phi}}_{\mathrm{A}}$–$\hat{\boldsymbol{\Phi}}_{\mathrm{D}}$ are the partitioned sub-matrices of $\boldsymbol{\Phi}$ in Eq. (32), $\mathbf{Z}_c$ in Eq. (20), and $\mathbf{Z}_d$ in Eq. (21), respectively, and hence

$$\boldsymbol{\Phi} = \begin{pmatrix} \boldsymbol{\Phi}_{\mathrm{A}} \\ \boldsymbol{\Phi}_{\mathrm{B}} \\ \boldsymbol{\Phi}_{\mathrm{C}} \\ \boldsymbol{\Phi}_{\mathrm{D}} \end{pmatrix}, \quad (115)$$

$$\mathbf{Z}_c = \begin{pmatrix} \bar{\boldsymbol{\Phi}}_{\mathrm{A}} \\ \bar{\boldsymbol{\Phi}}_{\mathrm{B}} \\ \bar{\boldsymbol{\Phi}}_{\mathrm{C}} \\ \bar{\boldsymbol{\Phi}}_{\mathrm{D}} \end{pmatrix}, \quad (116)$$

$$\mathbf{Z}_d = \begin{pmatrix} \hat{\boldsymbol{\Phi}}_{\mathrm{A}} \\ \hat{\boldsymbol{\Phi}}_{\mathrm{B}} \\ \hat{\boldsymbol{\Phi}}_{\mathrm{C}} \\ \hat{\boldsymbol{\Phi}}_{\mathrm{D}} \end{pmatrix}. \quad (117)$$

As such, the clustered acoustic potential energy is expressed as

$$\hat{E}_{\mathrm{A}} = \frac{V}{4\rho_0 c_0^2}|\tilde{p}_{\mathrm{A}}|^2 = \frac{4V}{\rho_0 c_0^2}\mathbf{p}_{\mathrm{A}}^H\boldsymbol{\Psi}_{\mathrm{A}}(\mathbf{r}_{s1})\mathbf{p}_{\mathrm{A}}, \quad (118)$$

$$\hat{E}_{\mathrm{B}} = \frac{V}{4\rho_0 c_0^2}|\tilde{p}_{\mathrm{B}}|^2 = \frac{4V}{\rho_0 c_0^2}\mathbf{p}_{\mathrm{B}}^H\boldsymbol{\Psi}_{\mathrm{B}}(\mathbf{r}_{s1})\mathbf{p}_{\mathrm{B}}, \quad (119)$$

$$\hat{E}_{\mathrm{C}} = \frac{V}{4\rho_0 c_0^2}|\tilde{p}_{\mathrm{C}}|^2 = \frac{4V}{\rho_0 c_0^2}\mathbf{p}_{\mathrm{C}}^H\boldsymbol{\Psi}_{\mathrm{C}}(\mathbf{r}_{s1})\mathbf{p}_{\mathrm{C}}, \quad (120)$$

$$\hat{E}_{\mathrm{D}} = \frac{V}{4\rho_0 c_0^2}|\tilde{p}_{\mathrm{D}}|^2 = \frac{4V}{\rho_0 c_0^2}\mathbf{p}_{\mathrm{D}}^H\boldsymbol{\Psi}_{\mathrm{D}}(\mathbf{r}_{s1})\mathbf{p}_{\mathrm{D}}, \quad (121)$$

where

$$\boldsymbol{\Psi}_i(\mathbf{r}_{s1}) = \boldsymbol{\phi}_i(\mathbf{r}_{s1})\boldsymbol{\phi}_i^T(\mathbf{r}_{s1}) \quad (i = \mathrm{A,B,C,D}). \quad (122)$$

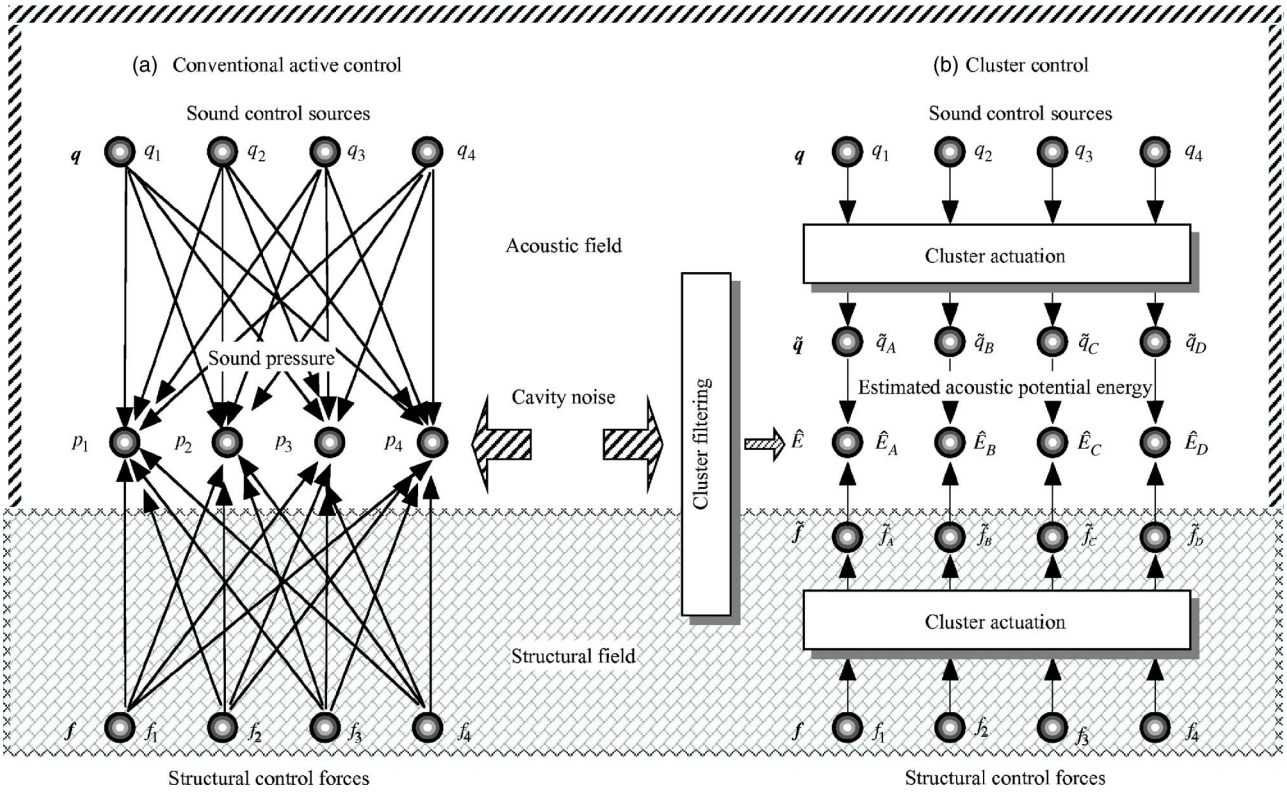

FIG. 2. Schematic signal flow diagram of (a) a conventional active control and (b) cluster control with cluster filtering and cluster actuation.

By substituting Eqs. (111)–(114) into Eqs. (118)–(121), the potential energy further expands to

$$\hat{E}_i = a_i q_i^2 + 2b_i q_i f_i + 2c_i q_i + d_i f_i^2 + 2e_i f_i + f_0 \quad (i = \mathrm{A,B,C,D}), \tag{123}$$

where

$$a_i = \mathbf{t}_i^T \boldsymbol{\Phi}_i^T (\boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai})^H \boldsymbol{\Psi}_i \boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai} \boldsymbol{\Phi}_i \mathbf{t}_i, \tag{124}$$

$$b_i = \mathbf{t}_i^T \boldsymbol{\Phi}_i^T (\boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai})^H \boldsymbol{\Psi}_i \boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai} \bar{\boldsymbol{\Phi}}_i \mathbf{t}_i, \tag{125}$$

$$c_i = \mathbf{t}_i^T \boldsymbol{\Phi}_i^T (\boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai})^H \boldsymbol{\Psi}_i \boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai} \hat{\boldsymbol{\Phi}}_i \mathbf{f}_d, \tag{126}$$

$$d_i = \mathbf{t}_i^T \bar{\boldsymbol{\Phi}}_i^T (\boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai})^H \boldsymbol{\Psi}_i \boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai} \bar{\boldsymbol{\Phi}}_i \mathbf{t}_i, \tag{127}$$

$$e_i = \mathbf{t}_i^T \bar{\boldsymbol{\Phi}}_i^T (\boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai})^H \boldsymbol{\Psi}_i \boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai} \hat{\boldsymbol{\Phi}}_i \mathbf{f}_d, \tag{128}$$

$$f_0 = \mathbf{f}_d^H \hat{\boldsymbol{\Phi}}_i^T (\boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai})^H \boldsymbol{\Psi}_i \boldsymbol{\Delta}_i^{-1} \tilde{\boldsymbol{\Lambda}}_{ai} \hat{\boldsymbol{\Phi}}_i \mathbf{f}_d. \tag{129}$$

Taking the derivative of Eq. (123) with respect to q_i and f_i, respectively, and setting them to zero, we have

$$\frac{\partial \hat{E}_i}{\partial q_i} = 2a_i q_i + 2b_i f_i + 2c_i = 0, \tag{130}$$

$$\frac{\partial \hat{E}_i}{\partial f_i} = 2b_i q_i + 2d_i f_i + 2e_i = 0. \tag{131}$$

Solving Eqs. (130) and (131) simultaneously, the optimal control law for minimizing the clustered acoustic potential energy is given by

$$q_i = -\frac{c_i d_i - b_i e_i}{a_i d_i - b_i^2}, \tag{132}$$

$$f_i = -\frac{a_i e - b_i c_i}{a_i d_i - b_i^2}. \tag{133}$$

B. Cluster control system arrangement

With a view to achieving global noise suppression, it is required to increase the number of sensors and actuators. However, the large number of sensors required as input to the control algorithm would quickly overtax the controller CPU and reduce the performance of the system even with the ever-increasing capabilities of microprocessors. Figure 2(a) illustrates the schematic diagram of a conventional active control system with eight inputs (four sound control sources and four structural control forces) and four outputs (four sound pressures). As seen from the figure, control signals intersect each other, a complicated control system being constructed. On the contrary, as shown in Fig. 2(b), cluster control enables the independent control of each cluster without crosstalk, thereby substantially reducing computational burden. More importantly, the cluster filtering outputs are no longer the sound pressure *per se* at sensor locations but the

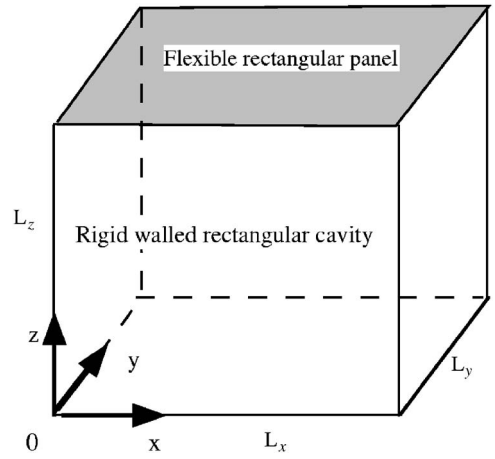

FIG. 3. A rectangular cavity with a top simply supported panel and rigid walls.

set of all acoustic modes with the same attributes of each cluster, which is responsible for the total acoustic potential energy. Thus, the suppression of the cluster filtering outputs via cluster actuation leads to the suppression of the global noise attenuation. Furthermore, an eight input four output control system is regarded as 8 SISO (single input single output) systems in Fig. 2(b) as opposed to MIMO (multi-input multi-output) in Fig. 2(a), thus reducing significantly the computation load. Even in the worst case when the cluster control fails to be implemented, the cluster control system turns into a conventional MIMO system.

V. NUMERICAL SIMULATION

In an effort to investigate the fundamental characteristics of cluster coupling as well as the cluster control effect for suppressing the acoustic potential energy in a cluster coupled structural/acoustic enclosure, an orthorhombic enclosure, as shown in Fig. 3, with the dimensions of 0.917 m $\times$0.707 m$\times$0.6 m is employed. Among the six panels encompassing the enclosure, the top panel is assumed to be flexible whereas the other five are perfectly rigid. All four edges of the top steel panel of thickness h are simply supported, the panel being subjected to a point disturbance force of 1 N at $\mathbf{r}_d=(0.2,0.2,0.6\ \text{m})$. Four cluster filtering sensors for estimating acoustic potential energy are placed with the origin at $\mathbf{r}_{s1}=(0.1,0.1,0\ \text{m})$, four cluster control actuators for AVC actuators and four cluster sound sources for ANC are located with the base at $\mathbf{r}_{c1}=(0.1,0.1,0.6\ \text{m})$ and $\mathbf{r}_{a1}=(0.15\ \text{m},0.15\ \text{m},0)$, respectively. Table I lists the structural and acoustic modes grouped into the four clusters A, B, C, and D in the frequency range up to 200 Hz.

Consider the cluster filtering for extracting the designated acoustic potential energy into an appropriate cluster. Figure 4(a) shows the frequency characteristics of acoustic potential energy E_p of the cavity with the thickness of the panel $h=1$ mm and estimated acoustic potential energy $\hat{E}_\text{A}$. Aside from approximately 20 dB discrepancy between the two curves, these dynamical properties look significantly similar, implying the validity of the cluster filtering for estimating the acoustic potential energy in a cluster coupled cavity using four point sound sensors as will be discussed shortly. Illustrated in Fig. 4(b) are the cluster filtering outputs for cluster from A through D, each property being depicted separately in Fig. 4(c). It is interesting to note that the degenerate resonance, for instance, at 22.1 Hz, consisting of the (1,1) and (2,1) modes, is successfully filtered out in each cluster. Thus, as a result of applying cluster filtering, four clusters are extracted perfectly without causing observation spillover.

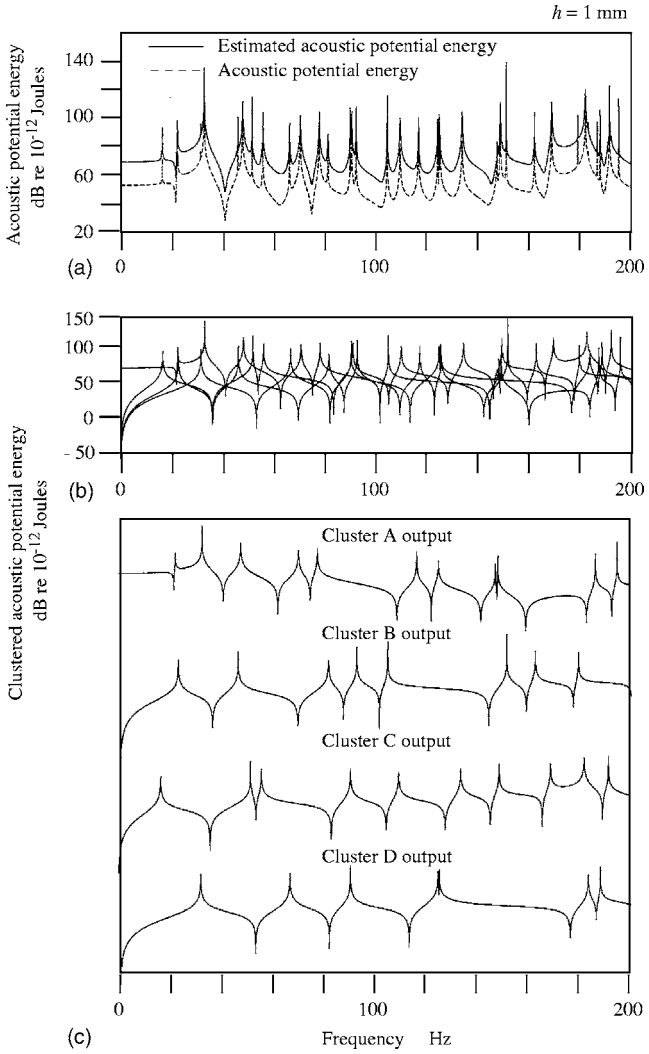

FIG. 4. Acoustic potential energy in a cluster coupled cavity with the panel of $h=1$ mm; (a) acoustic potential energy E_p and estimated acoustic potential energy $\hat{E}_p$; (b) cluster filtering outputs; (c) components of each cluster output.

Figure 5 depicts the cluster control effect for suppressing the acoustic potential energy belonging to cluster A in the cavity with the panel thickness $h=1$ mm using both AVC and ANC. The control laws derived in Eqs. (132) and (133) are designed so as to minimize the estimated acoustic potential energy $\hat{E}_\text{A}$ consisting of all odd/odd structural modes and even/even acoustic modes in the cavity. Figures 5(b) and 5(c) show the estimated acoustic potential energy $\hat{E}_p$ and the estimated acoustic potential energy reduction achieved by minimizing the contribution of $\hat{E}_\text{A}$ to total acoustic potential

TABLE I. Clustered structural and acoustic modes and their modal indices of a weekly coupled rectangular cavity with a simply supported top panel of dimensions of 0.917 m $\times$0.707 m $\times$0.6 m (h=1 mm).

5 5	195.3						

energy in the cavity. As seen from Fig. 5(c), only the resonant modes in terms of cluster A are suppressed whereas the other modes remain unaffected.

Figure 5(a) illustrates the plot of E_p obtained when minimizing the estimated potential energy $\hat{E}_A$. Comparing the curve with that of the estimated potential energy $\hat{E}_p$ in Fig. 5(b), there seems little discrepancy between both of them, implying that the control law in terms of $\hat{E}_p$ is valid even for suppressing E_p. The reason for this is clear if the frequency properties of E_p and $\hat{E}_p$ in Fig. 4(a) are considered; the curve of $\hat{E}_p$ roughly overlaps that of E_p as a result of raising the base line of E_p, and thus E_p is expressed approximately by multiplying $\hat{E}_p$ with some constant value. If this is the case, the derivative of $\hat{E}_p$ with respect to control forces becomes the same as that of E_p, and hence the control law for minimizing $\hat{E}_p$ is commensurate with that for minimizing E_p. Fig-

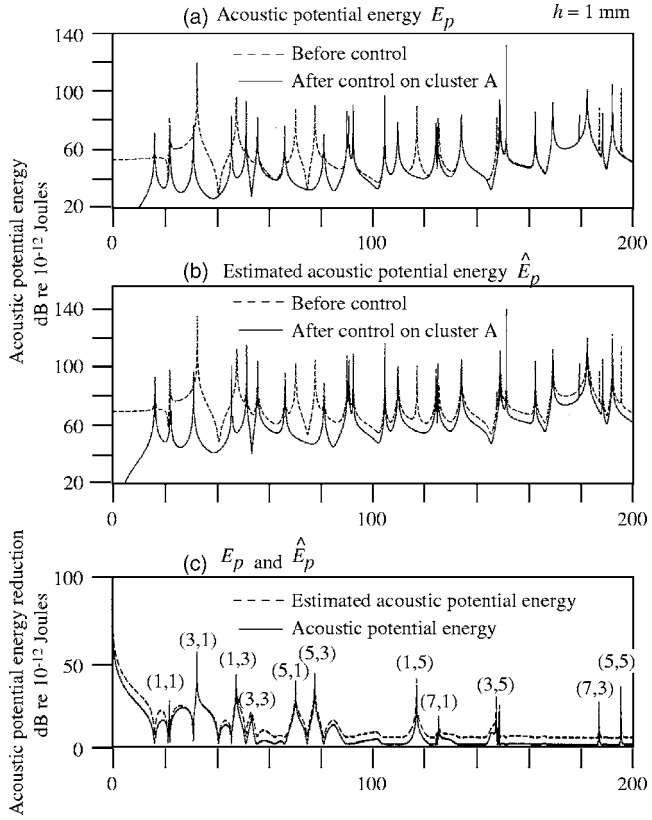

FIG. 5. Cluster control effect for minimizing cluster A of a cluster coupled cavity with the panel of h=1 mm; (a) E_p before and after cluster control on cluster A; (b) $\hat{E}_p$ before and after cluster control on cluster A; (c) reduction in E_p and $\hat{E}_p$.

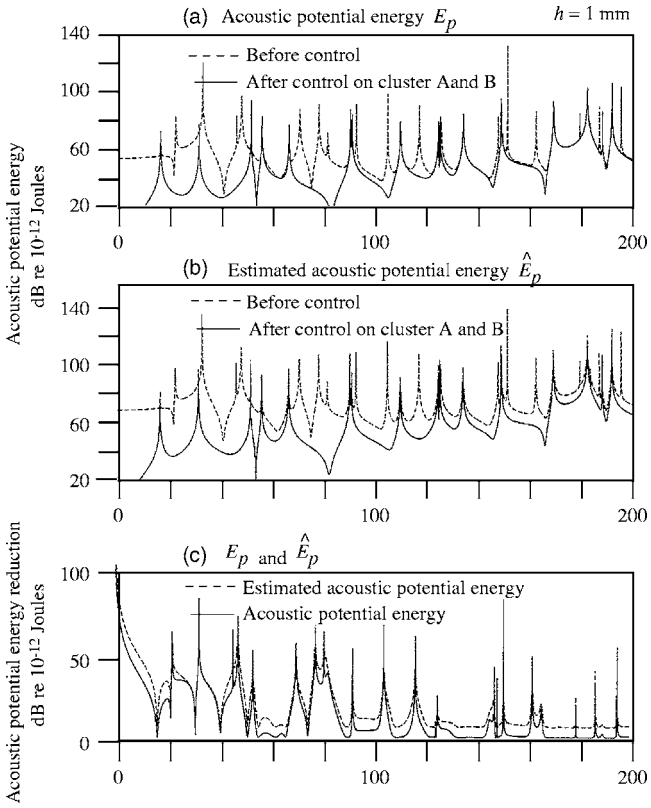

FIG. 6. Cluster control effect for minimizing clusters A and B of a cluster coupled cavity with the panel of h=1 mm; (a) E_p before and after cluster control on clusters A and B; (b) $\hat{E}_p$ before and after cluster control on clusters A and B; (c) reduction in E_p and $\hat{E}_p$.

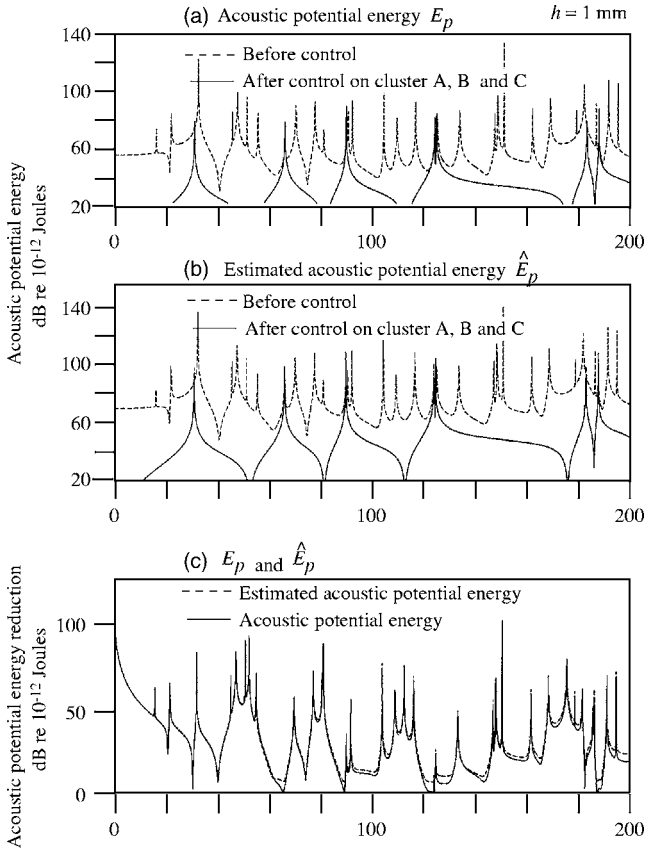

FIG. 7. Cluster control effect for minimizing clusters A, B, and C of a cluster coupled cavity with the panel of $h=1$ mm; (a) E_p before and after cluster control on clusters A, B, and C; (b) $\hat{E}_p$ before and after cluster control on clusters A, B, and C; (c) reduction in E_p and $\hat{E}_p$.

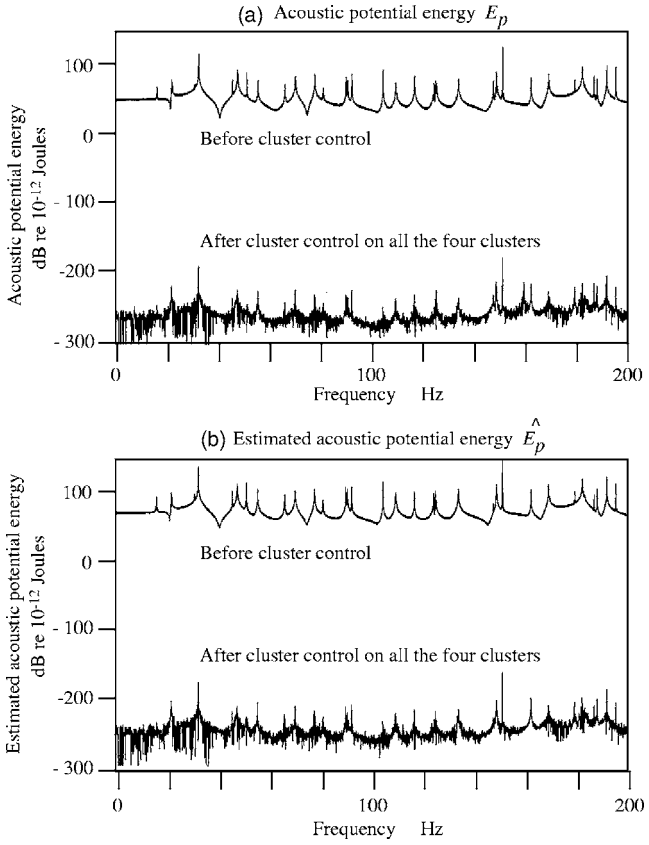

FIG. 8. Cluster control effect for minimizing clusters A, B, C, and D of a cluster coupled cavity with the panel of $h=1$ mm; (a) E_p before and after cluster control on all the four clusters; (b) $\hat{E}_p$ before and after cluster control on all the four clusters.

ure 5(c) shows the acoustic potential energy reduction in E_p and $\hat{E}_p$, demonstrating a small amount of inconsistency between the two because of $\hat{E}_p$ still being the approximation of acoustic potential energy. To evaluate quantitatively the control effect for suppressing the acoustic potential energy, an overall level based upon acoustic potential energy reduction in Fig. 5(c) is introduced, the results being as follows: 9.6 and 12.9 dB for the reduction of E_p and $\hat{E}_p$, respectively, via cluster control on the cluster A.

Depicted in Figs. 6(a) and 6(b) are, respectively, the curves of E_p and $\hat{E}_p$ obtained when minimizing both $\hat{E}_\mathrm{A}$ and $\hat{E}_\mathrm{B}$ in Eqs. (118) and (119). Comparing the plots with those in Fig. 5, it is found that the number of resonant peaks decreases since the attribute of E_p after the cluster control is governed only by that of clusters C and D. In contrast, acoustic potential energy reduction in Fig. 6(c) consists of the suppressed clusters, A and B, with the result that an overall level indicating the control effect further improves; 23.4 dB for the reduction of E_p and 28.6 dB in $\hat{E}_p$.

In addition to the performance index in the above, $\hat{E}_C$ is further included, hence the minimization of $\hat{E}_\mathrm{A}$, $\hat{E}_\mathrm{B}$, and $\hat{E}_\mathrm{C}$. Illustrated in Figs. 7(a) and 7(b) are the acoustic potential energy before and after the cluster control. The acoustic potential energy E_p in this case is dominated by cluster D only, so that the resonant peaks appearing in the figures refer to those of cluster D, whereas the number of resonant peaks in the acoustic potential energy reduction in Fig. 7(c) further increases, resulting in enhancement of control effect. Observe that the curve in Fig. 7(a) coincides with that of the bottom picture in Fig. 4(c) that shows the frequency characteristics of cluster D extracted by cluster filtering. Therefore, the acoustic potential energy in the cluster coupled cavity after control is now dictated by the attribute of cluster D. An overall value quantitatively indicating control effect for suppressing acoustic potential energy is found to be 41.4 dB in E_p and 44.8 dB in $\hat{E}_p$.

Note that acoustic potential energy may be grouped into four clusters, each cluster possessing the same properties in common, and hence the suppression of all four clusters leads to the suppression of total acoustic potential energy in the cavity. Figure 8 shows the control effect obtained by suppressing all the estimated acoustic potential energy; $\hat{E}_\mathrm{A}$, $\hat{E}_\mathrm{B}$, $\hat{E}_\mathrm{C}$, and $\hat{E}_\mathrm{D}$ using both AVC and ANC. Figures 8(a) and 8(b) show, respectively, the frequency properties of E_p and $\hat{E}_p$ before and after the cluster control. As is seen from the figures, control effect for suppressing the acoustic potential energy in the cluster coupled cavity is outstanding. It may be of little significance to depict the frequency characteristics, the gain of which is under −200 dB; however it is still helpful to grasp the control effect.

VI. CONCLUSIONS

For the purpose of minimizing acoustic potential energy in a cluster coupled structural/acoustic cavity, cluster control comprising both cluster filtering and cluster actuation has been presented. Acoustic potential energy in a cluster coupled cavity was found to be expressed as a resultant from each cluster contribution, and hence cluster potential energy may be controlled independently without causing control spillover. This fact enables one to implement a multi-SISO system whereby computation load may significantly be alleviated. More important, the cluster filtering outputs are no longer the sound pressure *per se* at sensor locations but the set of all acoustic modes with the same attributes of each cluster, which is responsible for the total acoustic potential energy. Thus, the suppression of the cluster filtering outputs via cluster actuation leads to the suppression of the global noise attenuation. Even in the worst case when the cluster control fails to be implemented, the cluster control system turns into a conventional MIMO system. Furthermore, cluster control law to suppress clustered potential energy using ANC and AVC has also been derived. Based upon the cluster control law, a numerical simulation was carried out, demonstrating the validity of cluster control for suppressing acoustic potential energy in a cluster coupled cavity.

(Received 3 November 2005; accepted 11 February 2006)

The Institute of Aerospace Medicine at the German Aerospace Center (DLR) investigated the influence of nocturnal aircraft noise on sleep in polysomnographic laboratory and field studies between 1999 and 2004. The results of the field studies were used by the Regional Council of Leipzig (Germany) for the establishment of a noise protection plan in the official approval process for the expansion of Leipzig/Halle airport. Methods and results of the DLR field study are described in detail. Special attention is given to the dose-response relationship between the maximum sound pressure level of an aircraft noise event and the probability to wake up, which was used to establish noise protection zones directly related to the effects of noise on sleep. These protection zones differ qualitatively and quantitatively from zones that are solely based on acoustical criteria. The noise protection plan for Leipzig/Halle airport is presented and substantiated: (1) on average, there should be less than one additional awakening induced by aircraft noise, (2) awakenings recalled in the morning should be avoided as much as possible, and (3) aircraft noise should interfere as little as possible with the process of falling asleep again. Issues concerned with the representativeness of the study sample are discussed. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184247]

I. INTRODUCTION

Between 1999 and 2004, the DLR–Institute of Aerospace Medicine (IAM) in Cologne, Germany, performed extensive laboratory and field studies on the effects of aircraft noise on sleep, mood, and performance in the DLR/HGF project "Quiet Air Traffic."[2–4] The Regional Council of Leipzig (RCL) asked the IAM to propose a concept for the protection of airport residents against the adverse effects of nocturnal aircraft noise on sleep based on the findings of these studies.

Leipzig/Halle airport is planned to be extended to an international freight hub with air traffic predominantly occurring during the night. In order to be able to handle the prognosticated traffic volumes, the southern runway will be turned and extended to a length of 3600 m. Together with the northern runway, this independent parallel runway system will allow for simultaneous takeoffs and landings on both runways. The traffic volume is predicted with 81 000 aircraft movements during the six busiest months in the year 2015.[1] Of these, 45 600 will take place during the day between 6:00 and 22:00 and 35 400 will occur during the night between 22:00 and 6:00. Thus, a large part of the aircraft movements will take place during the night. This situation distinguishes Leipzig/Halle airport from most other airports worldwide.

After an extensive course of consideration the RCL decided to develop a plan for the protection of airport residents against the adverse effects of nocturnal aircraft noise primarily based on the results of the DLR field study,[2] and therefore on the newest available scientific data. On 4 November 2004 the noise protection plan was presented for approval.[1] A few days later, DHL decided to move its international cargo hub from Brussels to Leipzig.

In this publication, methodological aspects of the DLR field study will be reported. The most important findings on the effects of nocturnal aircraft noise on sleep in general and on the probability of noise-induced awakenings in particular will be presented. Based on these results, it will be shown that noise protection plans based on number above threshold (NAT) and/or L_{eq} criteria are not suitable for an adequate description of the effects of nocturnal aircraft noise on sleep. Finally, a noise protection plan based on the findings of the DLR field study will be presented and substantiated.

II. METHODS

The DLR–Institute of Aerospace Medicine investigated the influence of nocturnal aircraft noise on human sleep, mood, and performance in a laboratory and a field study. The concepts of the noise protection plan for Leipzig/Halle airport are mainly based on the results of the field study. Therefore, study design and methods used in the field study will be briefly described. For a detailed description the reader is

asked to refer to the executive summary of the study.[2] The field study was conducted between September 2001 and November 2002 with 64 residents of Cologne-Bonn airport, which is one of the German airports with the highest nighttime traffic densities and mainly used for freight traffic during the night. Subjects were investigated for nine consecutive nights, starting on Mondays.

Participants, selected in a multi-level process, were between 19 and 61 years old (average: 38 years). Fifty-six percent of the participants were female. Subjects had to be free of intrinsic sleep disorders and had to have normal hearing thresholds according to age. A detailed description of the selection process can be found in the report DLR-FB 2004/7E.[2] Consequences of the selection process for the representativeness of the sample are discussed in detail in Sec. V F. The study protocol was approved by the ethics committee of the Medical Board of the district North Rhine. Subjects were instructed according to the Helsinki declaration, participated voluntarily, and were free to discontinue their participation at any time without explanation.

The electroencephalogram (brain current diagram, EEG), the electrooculogram (eye movements, EOG), the electromyogram (muscle tension, EMG), the electrocardiogram (ECG), respiratory movements, finger pulse amplitude, position in bed, and actigraphy were sampled continuously during the night. With the EEG, EOG, and EMG signals (also called polysomnography), sleep can be classified into different sleep stages.[5]

Wake is differentiated from sleep. Sleep itself is classified in REM sleep, with its typical rapid eye movements, and nonREM sleep. NonREM sleep can be further divided in the four sleep stages S1, S2, S3, and S4. Because of high arousal thresholds,[6] stages S3 and S4 are also called "deep sleep." Deep sleep as well as REM sleep are known to be very important for the restorative power of sleep.[7] Wake and stage S1, on the other hand, do not seem to contribute to recuperation, or only very little.[8]

Historically, each night is usually divided into 30-s epochs. A trained scorer then assigns one of the sleep stages or "awake" to each of the epochs. Since reliable procedures for an automatic sleep stage analysis do not yet exist, sampling and analysis of polysomnographic data are sumptuous, and therefore have only been applied in studies with relatively small sample sizes (see Sec. V F). However, only polysomnography allows the assessment of structural aspects of sleep. Studies using actigraphy try to draw conclusions on sleep quality and quantity based on movements of the wrist of one arm, and are therefore obviously inferior to polysomnography according to the informational value. With 64 subjects and 576 subject nights, the DLR study is the largest polysomnographic field study on the effects of nocturnal aircraft noise so far.

In the field study, sound pressure levels (SPL) and the actual sounds were recorded inside the bedroom (at the sleeper's ear) and outside (2 m in front of the window) with class-1 sound level meters. All events (e.g., aircraft noise, road traffic noise, snoring, etc.) were identified by a human scorer. The beginning and the end of each event were marked. The simultaneous recording of acoustical and electrophysiological signals allowed for an event-correlated analysis with a maximum resolution of 125 ms.

Aircraft noise is intermittent noise. An event-correlated analysis establishes a direct temporal association between the occurrence of an aircraft noise event (ANE) and the reaction of the investigated subject to the ANE. This is only possible because of the synchronous sampling of electrophysiological and acoustical signals. Variables like the nocturnal secretion rate of stress hormones, the annoyance of study subjects asked for in the morning by questionnaires, or the amounts of the different sleep stages are represented in a single datum, which summarizes the effects of all nocturnal ANEs. These integrative measures are unsuitable for an event-correlated analysis, because the connection to single noise events cannot be made.

The reactions of sleeping humans to aircraft noise are nonspecific, since they may also be observed during natural sleep otherwise undisturbed by external stimuli. Hence, reactions observed during an ANE cannot be differentiated from spontaneous reactions according to electrophysiological criteria. Therefore, it is necessary to use an event-correlated analysis to distinguish spontaneous reactions from reactions observed during an ANE. Furthermore, spontaneous reactions occur irregularly. Therefore, if there is a reaction during an ANE, it is important to ask how often this reaction would have taken place spontaneously anyway, i.e., without the influence of aircraft noise. In epidemiology the term *attributable risk* is often used in this context. The probability of a reaction induced by aircraft noise is calculated as

$$P_{\text{induced}} = P_{\text{ANE}} - P_{\text{spontaneous}}. \tag{1}$$

As the physiological reactions may not immediately start after the beginning of an ANE, a certain time interval is screened for reactions of the sleeper. This time interval is called a "noise window." With a size of three epochs (90 s) after the beginning of an ANE, the length of the noise window was chosen to maximize the probability of reactions induced by aircraft noise [P_{induced} in Eq. (1)].

Several potential indicators for noise-induced sleep disturbances have been identified and proposed in the past. Brief EEG and EMG activations are called **arousals**.[9] Because of their short duration they are not classified as stage "awake" according to the rules of Rechtschaffen and Kales.[5] **Awakenings** are longer arousals, defined as EEG and EMG activations that last for at least 15 s and therefore lead to a classification of the sleep stage as "awake." **Sleep stage changes** are defined as transitions from one sleep stage to a different sleep stage. In the context of noise effects research, commonly only those sleep stage changes leading to a lighter sleep are considered, e.g., changes from deep sleep stage S4 to the light sleep stage S2.

Polysomnographic studies conducted in the past predominantly used awakenings as the primary indicator of sleep disturbances induced by environmental noise.[10,11] Because of the following reasons awakenings are appropriate indicators for sleep disturbances induced by environmental noise:

(i) The awakening is the **strongest form of activation**

of the sleeping organism. The consequences for the restorative functions of sleep are accordingly severe.

(ii) Awakenings are relatively **specific**, i.e., the frequency of spontaneous awakenings is relatively low compared to other indicators. In the 112 baseline nights of the experimental group in the laboratory study, on average about 24 spontaneous awakenings were observed.[4,2] Spontaneous sleep stage changes were seen more than twice as often (on average about 52 changes per night). Mathur and Douglas[12] investigated the spontaneous onset of EEG arousals according to ASDA criteria.[9] They found on average about 21 arousals per hour of sleep. If the mean sleep period time (SPT) of 411.5 min of the noise-free baseline nights of the laboratory study is taken as a basis, this value corresponds to about 144 spontaneous EEG arousals per night.

(iii) In contrast to arousal, awakenings are usually accompanied by prolonged and unimodal increases in heart frequency.[13] We observed in our own investigations that the amplitude and/or the frequency of heart frequency accelerations are relatively low if there is no simultaneous awakening. But especially the regular occurrence of these nocturnal **vegetative reactions** seems to be a possible cause for the development of high blood pressure and the associated diseases of the cardiovascular system (myocardial infarction, stroke).[14] The degree of vegetative reactions accompanied by sleep stage changes or short arousals alone is low compared to reactions associated with awakenings.

(iv) The majority of awakenings last for exactly one epoch (15 to 45 s) and, therefore, are too short to be remembered on the next day. On the other hand, single awakenings may last longer and, therefore, be associated with the occurrence of waking consciousness. As a consequence, these longer awakenings may be recalled on the next day. In this case, they will also dominate the subjective assessment of sleep quality and quantity on the next day. Sleep stage changes and arousals will not be remembered on the next day as they do not lead to the occurrence of waking consciousness.

Sleep stage S1 does not contribute or only little contributes to the recuperative value of sleep. On the contrary, increased fractions of sleep stage S1 were identified as typical effects of sleep fragmentation in the past.[8] Hence, in this analysis not only changes to stage awake were regarded as relevant sleep stage changes, but also changes to sleep stage S1. This preventive measure increased the fraction of reactions associated with ANEs without significantly lowering the specifity of the proposed indicator, which is also called the sleep fragmentation index (SFI). Other authors also prefer to use this indicator in noise effects research.[15] The SFI was shown to correlate highly with the arousal index following ASDA criteria.[16,14] Therefore, in this publication the term "awakenings" implicitly means transitions from sleep stages REM, S4, S3, or S2 to the sleep stages S1 or awake.

Awakening probability does not solely depend on the maximum SPL of the ANE. On the one hand, other acoustical characteristics of the noise event (spectral content, duration, etc.) play an important role. On the other hand, situative and individual factors moderate the reactions to aircraft noise.[2] Therefore, in order to assess the influence of the maximum SPL, the other moderating factors have to be controlled for, which is called adjustment. Since an awakening represents a dichotomous dependent variable (yes/no), logistic regression was used for the analyses. As every subject was exposed to multiple ANEs, the observed reactions within one subject were not independent. Hence, random effects logistic regression was used, which is able to handle clustered data.[17]

Environmental conditions are less controlled in field studies compared to laboratory studies. The emergence of an ANE from the background noise level was identified as an important factor for the incidence of noise-induced awakenings. Therefore, in the field the background noise level was estimated for the minute preceding each ANE. The $L_{AS,eq}$ varied between 16.4 und 58.3 dB with a median of 27.1 dB.

Other noises originating from inside or outside the bedroom may occur during an ANE or between two ANEs. They were identified in the field study. An ANE contributed only to the final analysis if the following conditions were met: (1) In the minute before or during the ANE currently analyzed, only noises that were caused by the subject (except snoring) or by another ANE were allowed. Here, eliminating data with other ANEs in the minute before the start of the ANE currently analyzed could have led to a systematic underestimation of awakening probabilities in times of high air traffic. (2) Noises produced by the subject during the ANE currently analyzed were explicitly not discarded from the analysis, as they could have been caused by a reaction to the ANE. For each ANE, every of the other investigated nights was checked for ANEs in the same period according to the elapsed time after sleep onset. If there was no ANE, this period was used for the estimation of spontaneous awakening probability.

III. RESULTS

In total, 61 of 64 subjects contributed to the final analysis with 483 subject nights, in which 15 556 ANEs were recorded. The data of three subjects had to be discarded because of constant snoring (two subjects) or an intrinsic sleep disorder (one subject). The first night was not analyzed because of the so-called first-night effect.[18] In total, 10 658 ANEs met the inclusion criteria (see above) and contributed to the regression analyses.

Table I summarizes the results of a multivariable random effects logistic regression model (software Egret, Version 2.0.31, Cytel Corp.). The model contains the maximum A-weighted SPL ($L_{AS,max}$) and the background noise level in the minute preceding the ANE ($L_{eq_}1$min) as well as their interaction term $L_{AS,max} \times L_{eq_}1$min as statistically significant variables. Additionally, the sleep stage prior to the occur-

TABLE I. Results of a random effects logistic regression based on 61 subjects, 483 subject nights, and 10 658 ANEs. −2 log L=6659.8 with 10 650 degrees of freedom.

rence of an ANE (indicator variables prior stage S3 and stage S4 and prior REM) as well as elapsed sleep time are incorporated as statistically significant moderators in the model.

Awakening probability increases with maximum SPL $L_{AS,max}$ of the ANE, with background noise level $L_{eq_}$1min as well as with elapsed sleep time (positive coefficients). Awakening probability is lower from deep sleep (stages S3 and S4) and higher from REM sleep compared to stage S2. Nevertheless, stage S2 constitutes the most vulnerable sleep stage according to noise-induced awakenings, as the probability of spontaneous awakenings was much higher from REM sleep than from stage S2 sleep [see Eq. (1)]. The statistically significant interaction of maximum SPL $L_{AS,max}$ and background noise level $L_{eq_}$1min corroborates the importance of the emergence of an ANE from the background noise level.

Figure 1 illustrates the relationship between the maximum SPL of an ANE and the percentage awakened based on results of the regression model presented in Table I (black line). The background noise level was assumed constant with 27.1 dB (median). For preventive reasons, the sleep stage prior to the ANE was assumed to be stage S2 in all cases, i.e., the most sensitive sleep stage. Likewise, elapsed sleep time was set to the middle of the more sensitive second half of the night (epoch 601, about 5 h after sleep onset in the field study).

The highest SPL measured in the field inside the bedroom was 73.2 dB. Spontaneous changes to awake or stage S1 occurred with a probability of 8.6% (dashed line). A threshold value of about 33 dB was found in the field study, i.e., awakening probability increased only for ANEs with maximum SPL above 33 dB compared to spontaneous awakening probability (see Fig. 1). This threshold was only 6 dB above the background noise level, which seems physiologically plausible: First noise-induced awakenings should be observed once the human auditory system is able to differentiate the ANE from the background noise. Nevertheless, it must be pointed out that the awakening probability just above the threshold is accordingly very low. Only 2 of 1000 people exposed to an ANE with a maximum SPL of 34 dB will show a noise-induced awakening. Due to the large number of subjects and ANEs, the precision of the point estimate is very high, i.e., the width of the 95% confidence interval is very low (3.1% at 39 dB and 10.5% at 73.2 dB).

As already mentioned, awakenings are not specific for aircraft noise, as they also occur spontaneously. The probability of noise-induced awakenings is calculated by sub-

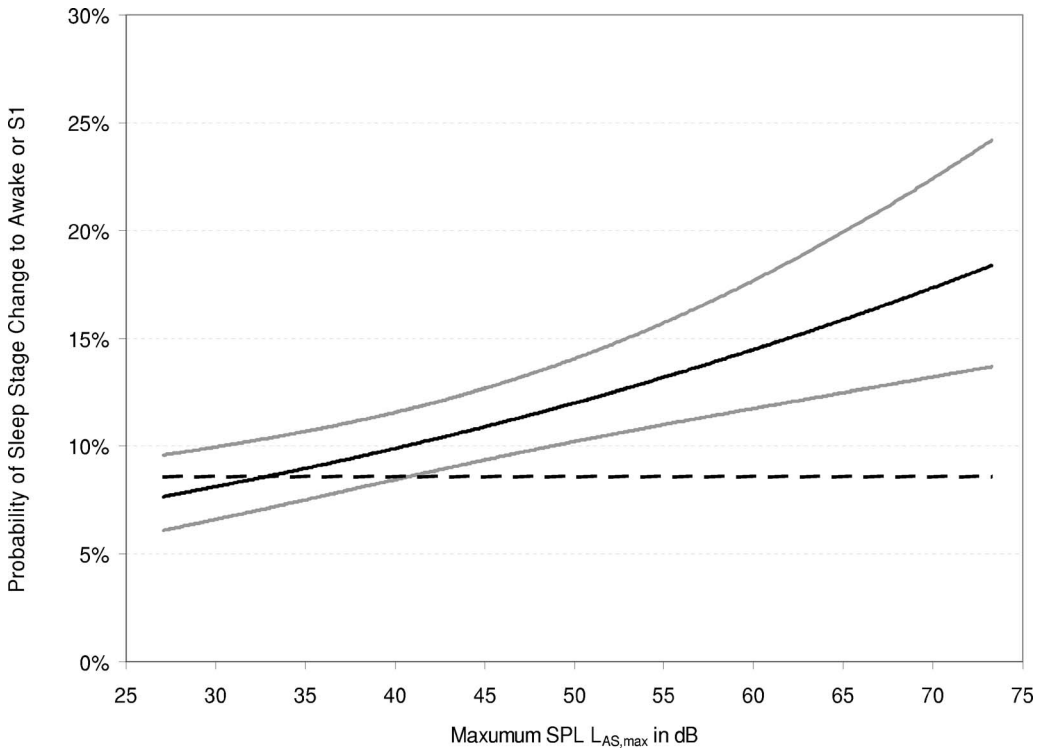

FIG. 1. Probability of sleep stage change to stage S1 or awake depending on maximum SPL $L_{AS,max}$ based on the regression results from Table I. Assumptions: Background noise level L_{eq-}1min=27.1 dB constant (median), prior sleep stage = stage 2, elapsed sleep time = 601 epochs (middle of second half of the night). Point estimates (black line), 95% confidence limits (gray lines), and spontaneous reaction probabilities (dashed line) are shown.

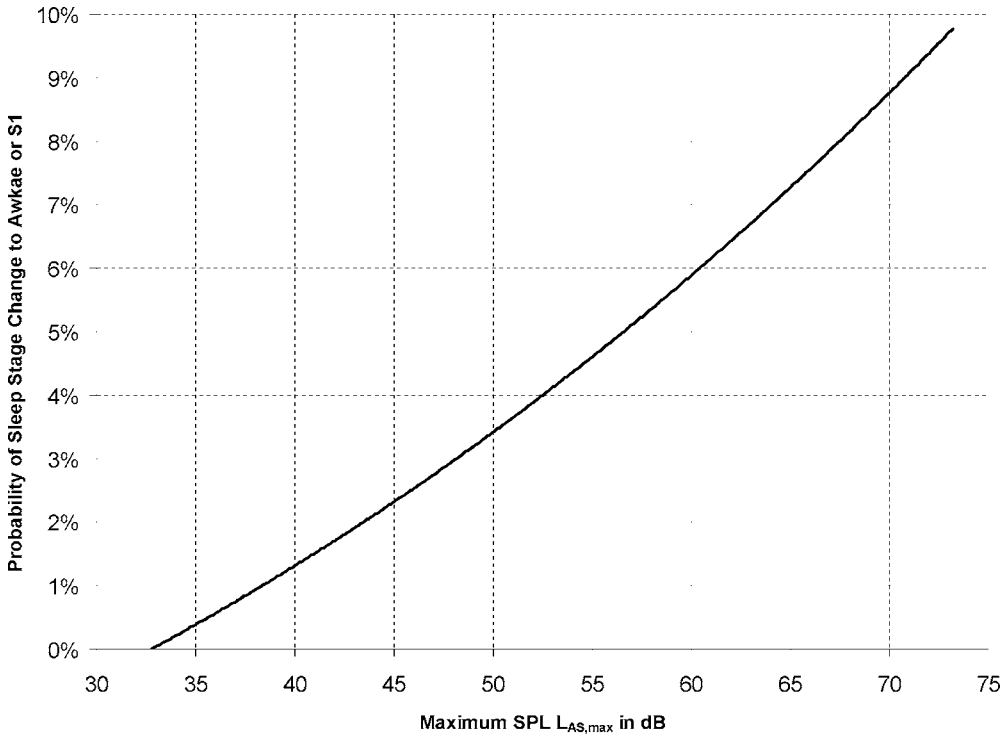

FIG. 2. Probability of aircraft-noise-induced awakenings depending on maximum SPL of ANEs. First reactions occur above maximum SPLs of 32.7 dB. This threshold exceeds the assumed background noise level of 27.1 dB only by 5.6 dB.

tracting spontaneous awakening probability (dashed line in Fig. 1) from awakening probability observed under the influence of aircraft noise (black line in Fig. 1) as indicated in Eq. (1). Aircraft-noise-induced awakening probability depending on the maximum SPL of an ANE is shown in Fig. 2.

The regression line can be approximated with a second-degree polynomial between 32.7 and 73.2 dB. Awakening probability in % is calculated as

$$P_{\mathrm{AWR}} = 1.894 \times 10^{-3} L_{\mathrm{AS,max}}^2 + 4.008 \times 10^{-2} L_{\mathrm{AS,max}} - 3.3243. \quad (2)$$

The awakening probabilities calculated by the polynomial deviate less than 0.1% from the original regression line within the specified interval.

Both the number and the duration of aircraft-noise-induced awakenings play an important role for the evaluation of the effects of aircraft noise on sleep, because the probability of a recalled awakening in the morning increases with the awakening duration. Thus, the results of the DLR laboratory study showed that awakening duration increased with the maximum SPL of an ANE (see Fig. 3).

Awakenings induced by ANEs with maximum SPLs of 65 dB or lower were relatively short. After 1.5 min, descriptively no difference in the percentage of subjects having fallen asleep again compared to spontaneous awakenings was observed. In contrast to that, awakenings induced by ANEs with maximum SPLs of 70 dB or higher were markedly longer than spontaneous awakenings.

IV. DISCUSSION OF NOISE PROTECTION STRATEGIES

In Germany, the most recent proposal for the protection against aircraft noise effects on sleep is based on a combination of *number above threshold* (NAT) and equivalent continuous sound level (L_{eq}) criteria ("Beschluss zur Novelle des Fluglärmgesetzes" from 25 May 2005). Pros and cons of NAT and L_{eq} criteria will be briefly discussed here based on the findings of the DLR field study. Both criteria are calculated from acoustical parameters (maximum SPL, time integrated SPL, or noise duration).

A. Number above threshold (NAT) criteria

NAT criteria are based on the assumption that below a defined threshold value no or only negligible effects of aircraft noise on sleep can be found. It was shown in Sec. III that first noise-induced awakenings can be expected if the maximum SPL exceeds 33 dB. Current proposals recommend limit values for NAT criteria between 52 and 55 dB, i.e., markedly above the threshold found in the DLR field study. Awakenings induced by ANEs with maximum SPLs between 33 dB and the proposed limit value are therefore not taken into account by the corresponding NAT criterion. Theoretically, an arbitrary number of ANEs with maximum SPLs below the NAT limit value are permitted without violating the NAT criterion, but simultaneously inducing relevant sleep disturbances.

NAT criteria also limit the number of ANEs above the threshold value, but without a definition of how much this threshold value may be exceeded by single ANEs. For example, a NAT criterion of 4×52 dB states that a maximum

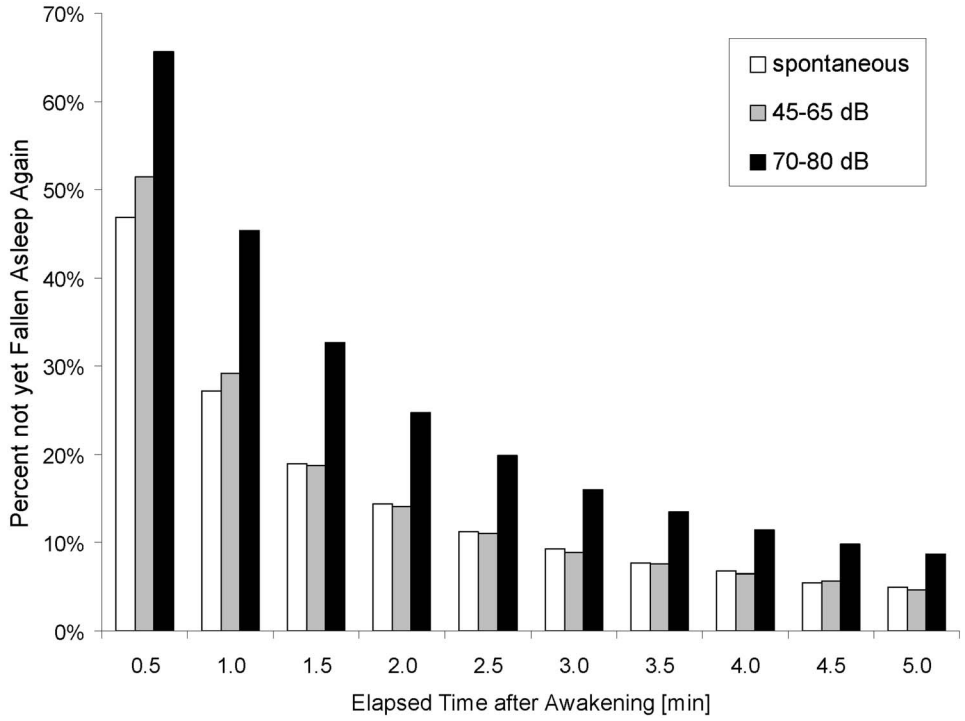

FIG. 3. Duration of noise-induced awakenings compared to spontaneous awakenings. Parameter is maximum SPL.

SPL of 52 dB may be exceeded no more than four times. Therefore, the criterion is neither violated by four ANEs with maximum SPLs of 53 dB nor by four ANEs with maximum SPLs of 73 dB. Calculations based on the dose-response relationship established in the DLR field study expect that 16 of 100 airport residents will be woken up by four events with 53 dB, whereas 39 of 100 residents, i.e., more than twice as many, will be woken up by four events with 73 dB (see Fig. 2).

B. L_{Aeq} criteria

Reducing the number of ANEs by 50% without changing the aircraft types means that the energy equivalent continuous sound level L_{Aeq} will decrease by 3 dB. Criteria solely depending on L_{Aeq} therefore implicitly assume that the effects of aircraft noise on sleep are simultaneously diminished by 50%, e.g., that the number of awakenings induced by aircraft noise is halved. Figure 4 demonstrates that this is not true. Following the epidemiologic concept of *numbers needed to harm*, it shows, depending on the maximum SPL of single ANEs, how many ANEs are needed to induce one additional awakening on average, where independent events were assumed.

If the maximum SPL of single ANEs is reduced by 3 dB from 72 to 69 dB, the permitted number of ANEs inducing one additional awakening may not be doubled but only in-

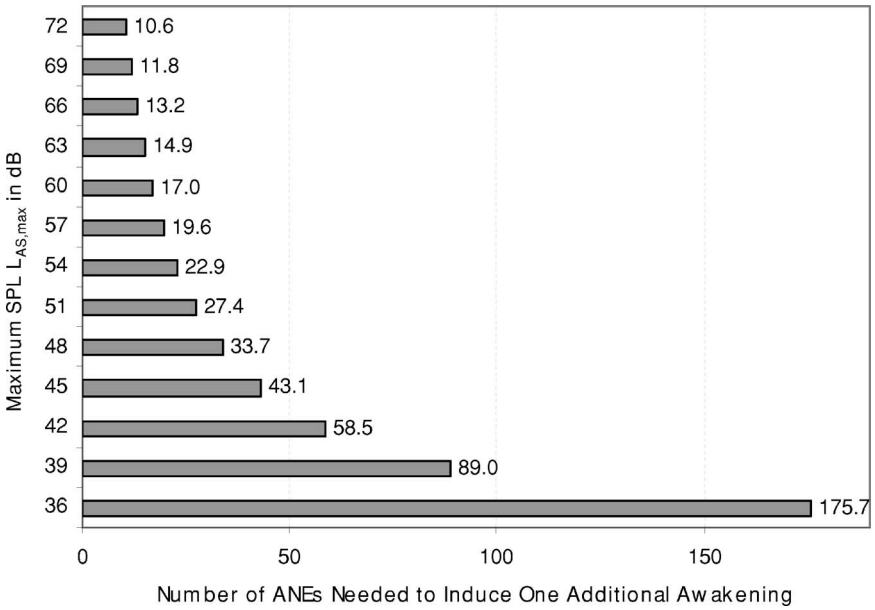

FIG. 4. Number of ANEs needed to induce one additional awakening on average and depending on the maximum SPL. Results are based on the dose-response relationship found in the field study (see Table I).

creased by 11% from 10.6 to 11.8 movements. The allowable change in the number of ANEs following reductions in maximum SPL of 3 dB increases continuously from 11% (decrease from 72 to 69 dB) to 97% (decrease from 39 to 36 dB), i.e., the number of ANEs may be nearly doubled only very close to the threshold value of 33 dB.

C. Combinations of NAT and L_{Aeq} criteria

Potentially, there are two main advantages of combining NAT and L_{Aeq} criteria:

(i) The L_{Aeq} is mainly influenced by events with high SPLs. If ANEs are much louder than the limit value of the NAT criterion, the L_{Aeq} criterion will be violated quickly.

(ii) The number of ANEs with maximum SPLs between the physiological threshold (33 dB) and the limit value of the NAT criterion cannot be increased at will without violating the L_{Aeq} criterion. Especially in the case of high traffic volumes, the L_{Aeq} criterion will dominate the combined criterion, although there is a strong dependence on the actual limit values for both criteria.

Nevertheless, the problems associated with each of the criteria are not completely solved by the combination of both criteria. There are several constellations concerning the number and the maximum SPL of ANEs with maximum SPLs between the physiological threshold and the limit value of the NAT criterion that violate neither the L_{Aeq} criterion nor the NAT criterion, but lead to a relevant number of noise-induced awakenings nevertheless. A publication of the Health Council of the Netherlands states that, given a certain L_{night}, the least favorable situation regarding a direct biological effect occurs if maximum SPLs of single ANEs are about 5 dB higher than the physiological effect threshold.[19] Of course, this noise pattern constitutes an unrealistic *worst case scenario*.

D. A physiological noise effects criterion

As mentioned above, combinations of the acoustical NAT and L_{Aeq} criteria dominate current proposals of concepts for the protection of sleep against adverse effects of aircraft noise. Practically, noise protection zones around airports are represented by noise contours, i.e., curves on which a certain noise descriptor has a constant value. Such contours are usually estimated by calculations rather than by measurements. They are derived from the maximum SPL as well as the duration and number of ANEs, which again are based upon the airport's traffic description. This description, which can be a forecast, specifies the number and types of aircraft operating at the airport during a well defined time period. Until now, noise contours around German airports were solely based on acoustical criteria, i.e., areas where a certain L_{Aeq} is exceeded (e.g., 50 dB outside) or a certain maximum SPL is exceeded too often (e.g., 6×75 dB outside). By establishing these purely acoustical contours, it was implicitly assumed that aircraft-noise-induced sleep disturbances are acceptable outside the contours without additional sound insulation measures.

The dose-response relationship established in the DLR field study (see Fig. 2) can be combined with the estimation of immission values in order to explicitly specify the effects of aircraft noise on sleep around airports. The average number of aircraft-noise-induced awakenings at a certain location in the airport environment is calculated from the distribution of A-weighted maximum SPLs $n(L_{AS,max})$ at this location:

$$N_{AWR} = \int_{-\infty}^{\infty} f_{AWR}(L_{AS,max}) n(L_{AS,max})\, dL. \tag{3a}$$

The function f_{AWR} follows from Eq. (2) as

$$f_{AWR}(L_{AS,max}) = \max(1.894 \times 10^{-5} L_{AS,max}^2 + 4.008 \times 10^{-4} L_{AS,max} - 3.3243 \times 10^{-2}; 0). \tag{4}$$

The max-function assures that there are no negative contributions of maximum SPLs below the threshold of 33 dB. The assumption that the function f_{AWR} is still valid above the range of 73 dB is arbitrary. In practice, there are no problems associated with this assumption, as maximum SPLs of this magnitude inside the bedroom only occur in highly exposed areas close to the airport.

These equations can easily be implemented in any calculation procedure capable of providing distributions of maximum SPLs (e.g., the German AzB procedure, which was used for the calculations in this publication). In practice level distributions are realized by SPL classes of a certain width rather than by a distribution function $n(L_{As,max})$. In that case, Eq. (3a) migrates to the following equation:

$$N_{AWR} = \sum_i f_{AWR}(L_{AS,max,i}) n(L_{AS,max,i}). \tag{3b}$$

The summation has to be performed over all level classes denoted by the index i. It is likely that there will be an influence of the class width. In order to minimize this effect, the calculations performed for this investigation were carried out with a class width of 0.2 dB. Additionally, normally distributed maximum SPLs with a standard deviation of 3 dB were assumed instead of the discrete maximum SPL values provided by the AzB algorithm for the particular aircraft categories. This is currently also a common approach for the calculation of NAT contours. There is some potential to improve the implementation of the N_{AWR}-calculation scheme into existing aircraft noise calculation tools. Such optimizations are currently the subject of further investigations.

With the method described above, the number of aircraft-noise-induced awakenings can be predicted for each location around the airport. Hence, the need for protective measures against the adverse effects of aircraft noise can be quantified explicitly and precisely. This is illustrated in Fig. 5 for Frankfurt airport. Two areas based on L_{Aeq} criteria are compared with three areas outside of which less than one, two, or three additional noise-induced awakenings are expected.

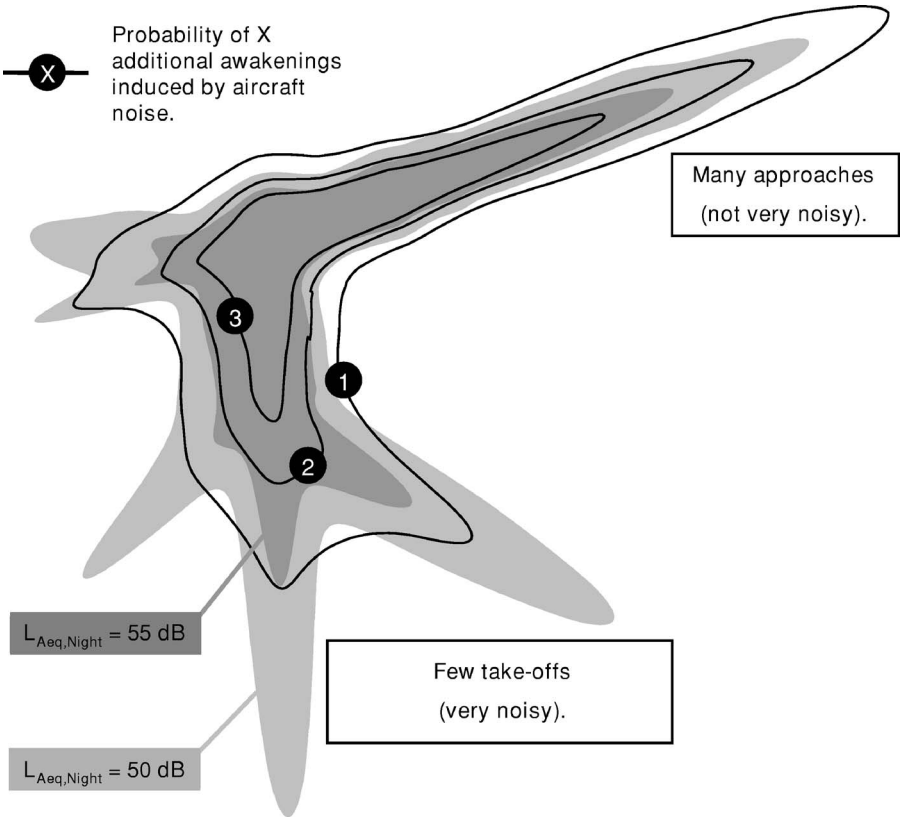

FIG. 5. Prognosis of noise effects for Frankfurt airport: on average one, two, or three additional awakenings induced by aircraft noise (black lines), L_{Aeq}=55 dB (dark gray), and L_{Aeq} =50 dB (light gray). Calculations are based on 25 000 nocturnal aircraft movements in the busiest six months of the year.

Apparently, there are qualitative differences: On the one hand, the contours for additional awakenings extend into areas with many but relatively quiet fly-overs (approaching aircrafts). On the other hand, in areas with few but relatively loud fly-overs (departures) they are not as pronounced as the L_{Aeq} contours. This illustrates the fact that L_{Aeq} criteria are not suitable for an adequate description of the effects of nocturnal aircraft noise on sleep.

The introduction of a physiological measure for sleep disturbances (i.e., the probability of awakenings) reflects a more medical- and health-related position than acoustical dimensions can do. The combination of a physiological reaction and an acoustical event, represented in a dose-response curve, and the calculation of acoustical immissions at a given location in the vicinity of airports provides a powerful tool for the protection of the affected population. Therefore, an easily applicable concept for the protection against adverse effects of nocturnal aircraft noise on sleep has been developed.

V. CONCEPT FOR THE PROTECTION AGAINST ADVERSE EFFECTS OF NOCTURNAL AIRCRAFT NOISE

The DLR concept for the protection against adverse effects of nocturnal aircraft noise on sleep will be presented and substantiated. Potential restrictions of the concept will also be discussed.

A. Objectives of the concept

The adequate protection of people affected by nocturnal aircraft noise has to be the main objective of a protective concept in order to prevent negative health consequences. Changes in sleep structure that may lead to a nonrestorative sleep are the primary effects of nocturnal aircraft noise. Sleepiness and impaired mental capacities are two of the possible immediate consequences. Furthermore, annoyance may be induced by consciously perceived noise events during the night. It is also being discussed whether repeatedly (over years) occurring noise-induced sleep disturbances may lead to other health impairments, such as an increased risk for high blood pressure or myocardial infarction.[20–22] If established, these noise impacts on health would be of major societal importance. However, in practice it is very difficult to substantiate a causal link between noise and long-term health effects, as many different and well-proven risk factors lead to the same diseases and induction periods are usually very long. Until now, there is no study corroborating this causal link for nocturnal aircraft noise.[19]

In order to overcome this dilemma, the DLR concept is based on two assumptions:

(1) Because of biological plausibility, it is hypothesized that a causal link between noise-induced sleep disturbances and long-term health effects exists. Vice versa, long-term health effects can be prevented with a high probability if noise-induced sleep disturbances are minimized.
(2) It is assumed that humans—like any organism—represent an adaptive system, which is able to compensate for certain strains without negative effects for the organism. Hence, it is not necessary to eliminate strains completely. It is simultaneously assumed that there are very sensitive subjects, who fail to compen-

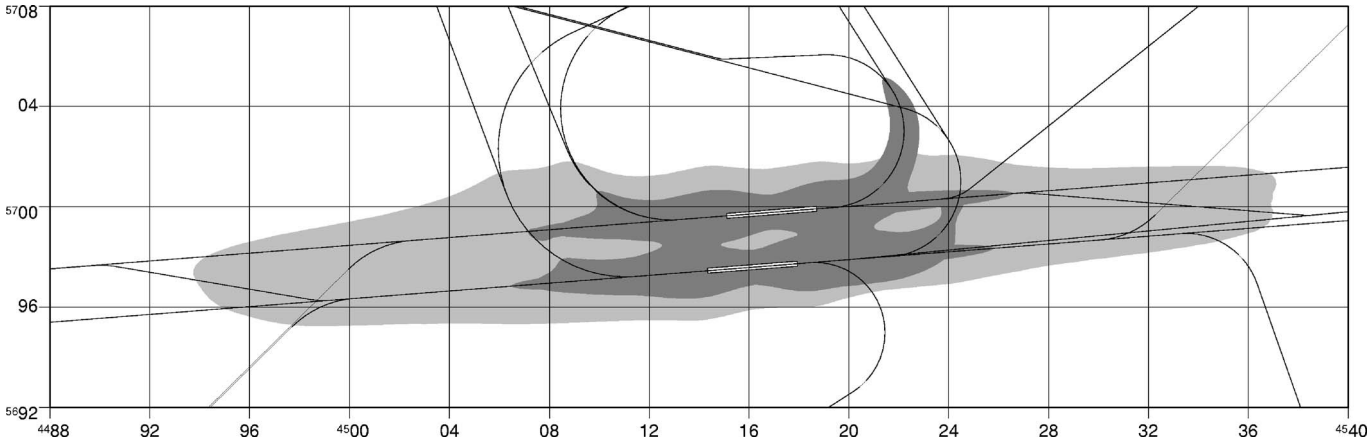

FIG. 6. Noise protection zone for Leipzig/Halle airport (traffic prognosis for 2015) consisting of the combination of two areas: (1) area outside of which less than one additional awakening induced by aircraft noise is expected on average (light gray) and (2) area outside of which maximum SPLs of 80 dB or higher (measured outside) occur less than once (dark gray, envelope of two contours calculated separately for 100% flight movements in each direction).

sate for small strains, as well as there are very robust subjects, who endure strong strains without negative consequences.

From a medical point of view, sound insulation should only be used if all other measures fail. Methods for the reduction of noise emissions are an active research field (e.g., silent engines, noise reduced takeoff and landing procedures, etc.). They should be consequently and quickly applied in practice.

B. Description of the concept

The DLR concept is based on three objectives, which reflect three highly correlated dimensions of sleep:

(1) On average, there should be less than one additional awakening induced by aircraft noise. Here, awakenings are defined as an electrophysiological phenomenon classified according to the rules of Rechtschaffen *et al.*[5]
(2) Awakenings recalled in the morning should be prevented as much as possible.
(3) There should be no relevant impairment of the process of falling asleep again.

Figure 6 illustrates the proposed noise protection zone for Leipzig/Halle airport for the night (22:00 until 06:00), based on a traffic prognosis for 2015. Two contours are combined: Outside of the light gray area on average less than one additional awakening induced by aircraft noise is expected. This contour is based on the expected, average distribution of flight movements on the two operation directions. Outside of the dark gray area, maximum SPLs of 80 dB or higher (measured outside) occur less than once. This contour is the envelope of two contours estimated for a 100% distribution of flight movements in both operating directions. This leads to an overestimation of effects, which was intended as awakenings recalled in the morning are regarded as especially severe sleep disturbances. The three columns of the DLR concept will be discussed in detail in Secs. V C to V E.

C. Less than one additional awakening induced by aircraft noise on average (first criterion)

Self-evidently, humans either wake up or they do not, i.e., on the individual level and within one night noninteger values for the number of additional awakenings do not make sense. However, they do if one refers to more than one night or to more than one subject (i.e., to averages). The criterion "on average less than one awakening per night" would be violated if a subject is woken up by aircraft noise 365 times in one year. However, it would just not be violated if the subject is woken up by aircraft noise 364 times in one year. When interpreting these numbers it has to be kept in mind that about 24 spontaneous awakenings can be expected per night on average and therefore about 8760 spontaneous awakenings can be expected per year.[2]

If and how often a subject is actually woken up by aircraft noise depends on the amount of air traffic in the special night, other situative and individual factors, as well as on chance. Therefore, in single nights it is possible that a subject is woken up more than once, e.g., two times. If the criterion should not be violated it has to be guaranteed that the subject is not woken up by aircraft noise in one other night, thus compensating for the two awakenings. The same is true for an even higher number of noise-induced awakenings: If a subject is woken up four times by aircraft noise in one night, this has to be compensated for by three nights with no additional awakenings, otherwise the criterion would be violated in the long run.

A Monte Carlo Markov chain (MCMC) simulation was used to calculate how the numbers of noise-induced awakenings per night are distributed over the 365 nights of one year: Maximum SPLs were randomly drawn from the maximum SPL distribution found in the DLR field study. For each SPL, awakening probabilities were calculated according to the dose-response relationship shown in Fig. 2. With a random number generator and based on the derived awakening probability it was determined whether the simulated human subject woke up or did not wake up induced by aircraft noise. This procedure was repeated and awakening probabilities were summed until the criterion of one additional aircraft-

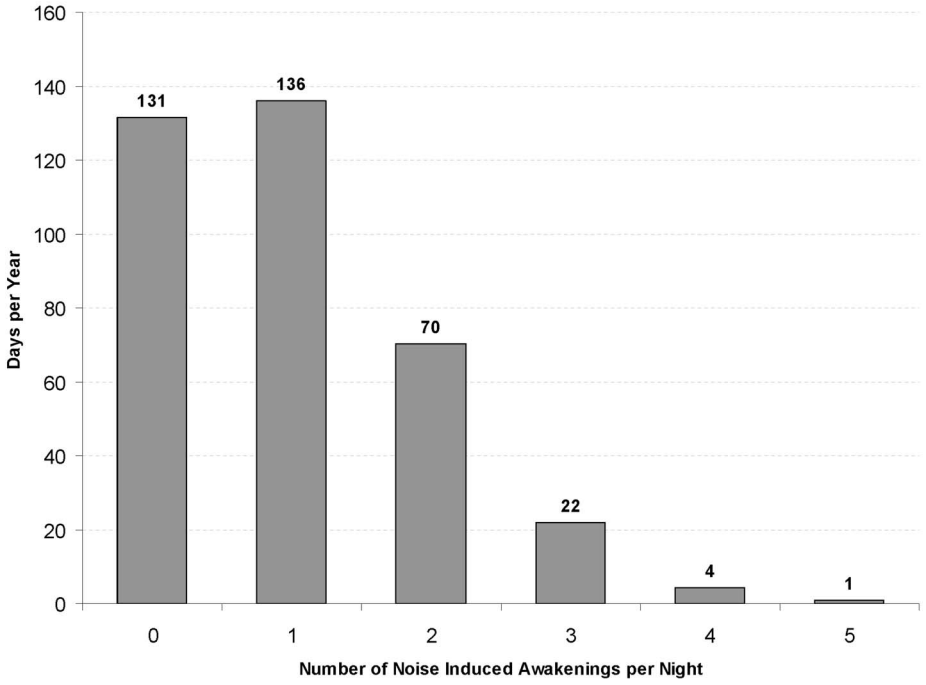

FIG. 7. Distribution of aircraft-noise-induced awakenings over the 365 days of one year if the criterion "on average less than one noise-induced awakening" is just not violated.

noise-induced awakening was just violated. This noise event was the last event counted, unless the sum of awakening probabilities up to the previous noise event, that just did not violate the criterion, was closer to the limit value in absolute terms. In that case, the previous noise event was the last event counted. With this method, 1 000 000 noise nights were simulated.

The expected distribution of aircraft noise-induced awakenings over the 365 days of one year is shown in Fig. 7.

In 131 nights there is no, in 136 nights there is one, in 70 nights there are two, and in 22 nights there are three additional awakenings. Four or five noise-induced awakenings per night occur extremely seldomly, and six or more awakenings practically do not occur.

These reactions are electrophysiological awakenings based on the definition by Rechtschaffen and Kales.[5] They are usually too short to be remembered on the next day (see above). From a preventive point of view, however, the number of electrophysiological awakenings induced by aircraft noise should be restricted as much as possible,[23] although the impact of electrophysiological awakenings on health, quality of life, and psychological outcomes remains a matter of scientific debate and therefore uncertain.[24] As electrophysiological awakenings go along with vegetative arousal reactions (e.g., increases in heart frequency and blood pressure), it is at least biologically plausible that repeatedly occurring noise-induced awakenings over years may impact health.[13] It is currently not known how many noise-induced awakenings are tolerable without leading to middle- or long-term impairments of well-being and health. With the high number of spontaneous awakenings and the high variability in several nights of the same person in mind, it is not deemed necessary from a medical point of view to completely avoid additional awakenings induced by aircraft noise. It is rather assumed that impacts of aircraft noise on health can be excluded in areas where less than one additional awakening is expected to be induced by aircraft noise on average.

D. Recalled awakening (second criterion)

The risk of recalled awakening increases with the duration of the awakening. Recalled awakenings are correlated with the subjective evaluation of sleep quality and sleep quantity: The higher the number of recalled awakenings, the worse is the evaluation of sleep quality (field study: $r_{\text{Spearman}}=-0.316$) and sleep quantity (field study: $r_{\text{Spearman}}=-0.269$). Additionally, ANEs occurring in the sleep period influence the assessment of annoyance only when they are perceived consciously by airport residents, and longer awakenings are a prerequisite for regaining consciousness.[19]

Recalled awakenings not only fragment sleep: They go along with psychological disadvantages as well and therefore constitute a major sleep disturbance. Psychosomatic disorders cannot be excluded if recalled awakenings are induced over longer time periods. Therefore, special attention has to be drawn to recalled awakenings in the process of evaluating the impacts of aircraft noise on sleep. From a medical point of view, recalled awakenings induced by aircraft noise should be prevented as much as possible.

The first criterion limits the number of noise-induced awakenings irrespective of the duration of the awakenings. Therefore, the number of recalled awakenings is limited as well. Most of the spontaneous awakenings are too short to be remembered on the next day. Analyses of the laboratory study showed that the duration of noise-induced awakenings increases with the maximum SPL of ANEs. Relevant differences compared to spontaneous awakenings were observed for maximum SPLs of more than 65 dB (see Fig. 3).

For this reason, maximum SPLs of more than 65 dB should be avoided in the bedroom. For a partly opened window with an assumed difference in SPLs of 15 dB between inside and outside, the 1×80 $dB_{outside}$ contour of Fig. 6 (dark gray) assures that outside this area maximum SPLs of 65 dB are exceeded less than once inside the bedroom on average. As recalled awakenings should be avoided as much as possible, this contour is based on a 100% flight movement in one direction estimation, i.e., a worst case.

E. Falling asleep again (third criterion)

The problem of falling asleep again is practically not considered in the literature of noise effects on sleep, disregarding the fact that about 7% of the sleep period is spent awake.[13] ANEs can prevent the sleeper from falling asleep again in these situations, and therefore have a negative impact on sleep structure.[2]

The traffic prognosis for Leipzig/Halle airport in 2015 forecasts two very busy periods during the night caused by freight handling. Between 0:00 and 1:30 up to 60 approaches per hour and between 4:00 and 5:30 up to 50 starts per hour are expected. The short time period of 1 to 1.5 min between two noise events in these peak hours leads to an increased risk of preventing the affected population from falling asleep again. If a subject already regained consciousness, annoyance reactions may result from consciously perceived noise events. Indeed, many airport residents complain about ANEs in early morning hours. At this time of the night, sleep pressure and awakening thresholds are low: Falling asleep again is difficult anyhow and aggravated by aircraft noise events.

Extensive analyses based on the data of the DLR field study were performed to assess the impact of aircraft noise on falling asleep again. The analyses are complicated by the fact that people who are prevented from falling asleep again stay awake and may be repeatedly prevented from falling asleep again by additional ANEs. In statistical terms, probabilities are no longer independent, but they are conditional on what happened in the past.

The results of these analyses will be presented elsewhere. They are based on a Markov state transition model which differentiates between two states only: awake and sleep. In the model, transitions between these two states depend on maximum SPL $L_{AS,max}$ of the ANE, elapsed sleep time, the current state (awake/sleep), and the elapsed time spent in the same sleep stage and estimated with autoregressive logistic regression based on the data of the field study. The Markov model was used to predict the number of awakenings, the duration of wake periods, the number of awakenings recalled in the morning, and the percentage of highly annoyed subjects. The results indicated that maximum SPLs of ANEs in the second half of the night should receive a malus of 1.4 dB, i.e., they should be artificially elevated by 1.4 dB, in order to assure an undisturbed process of falling asleep again similarly in all regions around Leipzig/Halle airport.

TABLE II. Relevant polysomnographic field studies on the effects of aircraft noise on sleep. In the study of Hume *et al.*[15] SPLs were measured outside the bedroom only.

Study	No. of subjects	No. of subject nights	Age range (years)
Basner *et al.*[2] (2004)	64	576	19–61
Hume *et al.*[15] (2003)	46	178	20–70
Flindell *et al.*[11] (2000)	18	90	30–40
Ehrenstein *et al.*[26] (1982)	3	30–45	8–10
Vallet *et al.*[25] (1980)	40	160	20–55

F. Transferring study results to the population level

Polysomnography is the only method that allows us to draw conclusions on structural aspects of sleep. At the same time, data acquisition and analysis are cumbersome, time consuming, and therefore expensive. Hence, polysomnographic studies on the impact of aircraft noise on sleep are scarce and were usually based upon small samples. These studies differed considerably in study design and the methods applied, thus complicating comparisons or meta-analyses between them. As there is considerable intersubject variability in noise sensitivity, small studies may per chance investigate only very sensitive or only very insensitive subjects according to aircraft-noise-induced changes in sleep structure. Hence, transferring the results of small studies to the population level is not possible or limited.

The sample size of the DLR field study is compared to other relevant field studies using polysomnography in Table II.

Vallet[25] investigated the effects of aircraft noise on sleep in the field on 40 subjects aged 20 to 55 years (160 subject nights). Flindell *et al.*[11] examined 18 subjects aged 30 to 40 years on five consecutive nights (90 subject nights). The authors call their study a pilot study for a potential extension of the Ollerhead *et al.* study.[10] Ehrenstein[26] investigated three children aged 8 to 10 years in the vicinity of Munich airport. As there was no air traffic after 21:30, only ANEs between 20:00 and 21:30 could be analyzed. Ollerhead *et al.*[10] performed an actigraphic study in the vicinity of several British airports. Polysomnography was additionally performed on 46 of the 178 subjects. The results of the polysomnographic data were published by Hume *et al.*[15] in 2003. In this study, the SPL was measured only outside of the dwellings, restricting the validity of the results. None of the studies investigated nonhealthy subjects.

In the DLR field study, 64 subjects were studied for 576 subject nights, resulting in the largest polysomnographic study with identical methodological approach so far. Nevertheless, the study does not claim representativeness for the whole population. It is impossible to be representative for a whole population in a study with huge methodological expenses for a single subject like the DLR study. Additionally, some inclusion criteria had to be met in order to be eligible for study participation, leading to a higher internal validity of the results. This is a prerequisite for external validation, but also it restricts it to some extent.[2]

Therefore, the results of the field study were not trans-

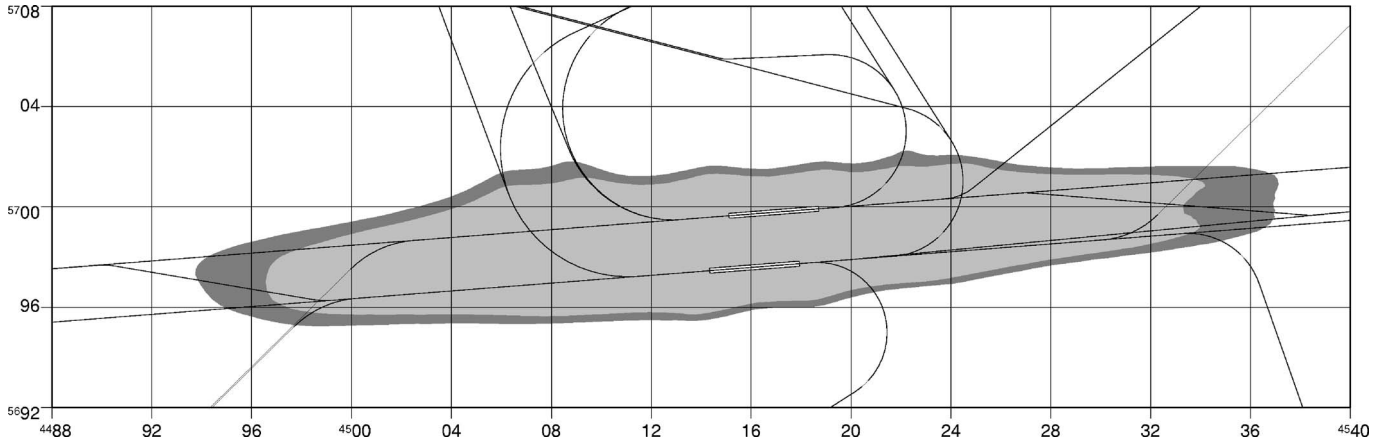

FIG. 8. Areas outside of which less than one awakening is additionally induced by aircraft noise. Comparison of preventive approach (sleep stage S2, middle of second half of the night, outer dark gray area) with approach based on actual data found in the field study (inner light gray area). By the preventive approach the noise protection zone is increased by 28% (=43 km^2).

ferred 1:1 to the population living in the vicinity of Leipzig/Halle airport. Instead, several preventive measures were taken in order to protect those parts of the population that were not represented in the DLR field study and that are more sensitive to aircraft noise at the same time. Some of these measures shall be briefly summarized:

(i) Subjects assessing themselves as sensitive to and annoyed by aircraft noise were included preferably into the study. Seventy-five percent of study subjects assessed themselves as moderately, strongly, or very strongly annoyed, compared to 15% of a representative German survey.[27]

(ii) Not only awakenings but also sleep stage changes to stage S1 were counted as relevant noise-induced sleep disturbances, increasing the probability of reactions to aircraft noise.

(iii) For the calculation of the dose-response curve based on the regression results it was assumed that the sleeper spent the whole night in the most sensitive sleep stage S2 and in the middle of the more sensitive second half of the night. In reality, an average night contains only about 50% of sleep stage S2. Hence, the dose-response curve is shifted to higher probabilities compared to calculations where the actual sleep stage distribution is used. Because of this measure alone the noise protection zone increases from 156 km^2 by 28% to 199 km^2 (see Fig. 8).

(iv) Subjects with illnesses leading to a lower noise sensitivity (e.g., hypakusis, hypersomnolence) were excluded from study participation.

(v) The calculations for the noise protection zone were based on the six busiest months of the year according to air traffic.

(vi) Sound insulation was increased by 3 dB for sensitive institutions (e.g., hospitals) and individuals with relevant diseases accompanied by a higher noise sensitivity.

(vii) The proposal of allowing only one additional awakening induced by aircraft noise makes sense in terms of preventive medicine. It has to be taken into account that on average 24 spontaneous awakenings can be observed in an otherwise undisturbed night anyway.

VI. CONCLUSIONS

The DLR-Institute of Aerospace Medicine investigated the influence of aircraft noise on sleep, mood, and performance in an extensive polysomnographic field study between 1999 and 2004 as part of the DLR/HGF-project "Quiet Air Traffic." The dose-response relationship developed in this study was used to establish a concept for the protection of subjects against the adverse effects of nocturnal aircraft noise on sleep. Advantages of this new concept compared to conventional NAT criteria, L_{eq} criteria, or combinations of NAT and L_{eq} criteria were discussed.

It is planned to extend Leipzig/Halle airport to a freight hub with an independent parallel runway system. Major parts of air traffic will take place during the night. The Regional Council of Leipzig decided to use the results of the DLR field study for a new noise protection concept at Leipzig/Halle airport. This concept culminates in the three propositions presented and discussed in Sec. V and reflects three correlated dimensions of sleep: There should be on average less than one additional awakening induced by aircraft noise, noise-induced awakenings recalled in the morning should be prevented as much as possible, and no relevant impairments of the process of falling asleep again should occur. These three provisions have been proposed in order to consider the special conditions under which Leipzig/Halle airport will operate: (1) construction of a second independent runway, (2) settlement of a night cargo hub for a big service integrator, (3) heavy air traffic during night including peak hours with up to 60 movements per hour, and (4) practically no nocturnal air traffic in the present. These circumstances necessitate a special concept for the protection of the affected population against the adverse effects of nocturnal aircraft noise on sleep.

With the decision for the implementation of the results of the DLR field study, fresh ground was broken, as noise

protection zones solely depended on acoustical criteria so far. The noise protection zone for nocturnal air traffic proposed by DLR exceeds the one of the current law amendment under discussion, which should come in force in 2011, by 60 km^2, and will be correspondingly accompanied by additional financial burdens for the airport resulting from the installation of sound insulation.

Shortly after the publication of the official documents of the approval process for the extension of Leipzig/Halle airport in November 2004, the integrator DHL decided to move its European freight hub from Brussels to Leipzig/Halle. In the long run, this could lead to several thousands of new jobs in this region. Despite the very conservative approach taken in constructing the noise protection zones, some residents living in the vicinity of Leipzig/Halle airport were still not satisfied with the concept: They sued in order to prevent the start of construction at the airport. The Federal Administrative Court rebutted this legal action in May 2005 in the first instance, and the construction measures started without delay in August 2005.

ACKNOWLEDGMENTS

We would like to thank all subjects who agreed to participate in our studies as well as the investigators from the DLR flight physiology department for their extraordinary effort in sampling and analyzing the data.

(Received 27 September 2005; revised 22 February 2006; accepted 24 February 2006)

Acoustic impedance of perforations in contact with fibrous material, as well as air alone, is experimentally determined in the absence of mean flow. Different porosities (2.1, 8.4, 13.6, and 25.2 %) and hole diameters (0.249 and 0.498 cm) are applied for perforations, along with two fiber filling densities (100 and 200 kg/m^3) to illustrate the effect of variations in such parameters on the perforation impedance. A modified impedance tube setup is developed for the measurement of the acoustic impedance of perforations in contact with fibrous material, and the air alone. The complex wave-number and characteristic impedance of the fibrous material are also experimentally obtained in this study to utilize such properties for the calculation of acoustic impedance of perforations in contact with the material. The experimental results show that both resistance and reactance of the perforations in contact with air decrease as the porosity increases. It is also shown that the fibrous material significantly increases both the resistance and reactance. For a given filling density, both resistance and reactance decrease as the porosity increases, except for the specific samples with highest porosity (25.2%). © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188354]

I. INTRODUCTION

Perforated ducts are often used in reactive silencers to control the acoustic performance, guide the flow and reduce the flow losses, and influence the sound quality through suppression of flow noise from abrupt cross-sectional area changes. In dissipative silencers, perforated ducts are also utilized to protect the absorbing material, while modifying the acoustic characteristics by adding mainly reactance to the impedance. The predictions for both types of silencers rely on the acoustic impedance of perforations. This impedance is dependent on the perforation geometry (porosity, shape and size of holes, wall thickness, and distance between holes), the flow field (grazing and through flow), sound pressure level, and the medium in contact with the perforation. The complexity of the perforation impedance confines the analytical approaches only to simple perforations, and experimental methods are often used to obtain the impedance. While the acoustic characteristics of perforations in contact with air alone are relatively well established primarily by experimental work (refer, for example, to Sullivan and Crocker, 1978), only limited studies on perforations facing absorbing material are available.

The acoustic impedance of perforations in contact with air alone has been extensively investigated, for example, by Ingard (1953), Sullivan and Crocker (1978), Melling (1973), Dickey *et al.* (2000, 2001), Dean (1974), Rao and Munjal (1986), and Cummings (1986). An empirical formulation of the perforation impedance by Sullivan and Crocker (1978) has been widely used in the linear regime in the absence of mean flow. Melling (1973) and Dickey *et al.* (2000) considered the impact of high amplitudes on the perforation impedance. In the nonlinear regime, the resistance and reactance of the perforation impedance are shown to increase and decrease, respectively, with the acoustic velocity. The effect of grazing mean flow on the impedance was studied by Dean (1974), Rao and Munjal (1986), Cummings (1986), and Dickey *et al.* (2001). Grazing flow is generally observed to decrease reactance and increase resistance of the perforation impedance.

Studies have also been conducted on the acoustic impedance of perforations facing fibrous material in the absence of mean flow, which may be categorized as analytical, experimental, and semiempirical. The analytical work has considered the effect of fibrous material on the perforation impedance. For example, Bolt (1947) considered the mass reactance of perforations facing the absorbing material. He concluded that the addition of perforations to the absorbing material generally increased the absorption coefficient at low frequencies, while decreasing it at high frequencies. Later, Ingard and Bolt (1951) illustrated the effectiveness of perforations at low frequencies through an increase of the resistance. They concluded that a combination of absorbing material and perforations formed a Helmholtz resonator. Ingard (1954) emphasized the increase of resistance by the addition of perforations and the effect of an air gap between the perforations and absorbing material. His analysis showed that the air gap between the perforations and facing material nar-

[a)]Electronic mail: Selamet.1@osu.edu

rowed the effective frequency range of absorption coefficients. The experimental work on the acoustic characteristics of perforations combined with an absorbent is confined to determining the surface acoustic impedance or the absorption coefficient, rather than the perforation impedance. Having considered the perforations facing absorbing material as a Helmholtz resonator, one of the earlier works by Callaway and Ramer (1952) showed that the air gap between the perforations and absorbing material increased the absorption coefficient for a very low duct porosity (1.23%). Later, Davern (1977) experimentally illustrated the effect of porosity and wall thickness of the perforations, absorbing material density, air space, and the impervious layer between perforations and absorbing material on the absorption coefficient. The semiempirical studies first measured the perforation impedance in the absence of fibrous material, then empirically incorporated the acoustic properties of the material to account for their effect on the perforation impedance. Kirby and Cummings (1998) presented a semiempirical impedance formulation for the perforation backed by absorbing material in the presence of grazing mean flow. They concluded that the absorbing material increased the perforation impedance and the results were strongly dependent on the density of absorbing material immediately adjacent to perforations. They also argued that the interaction among holes could be neglected and thus the formulation for single hole could be used for a multihole perforation. Selamet *et al.* (2001) adapted the concept of Kirby and Cummings by modifying the formulation of Sullivan and Crocker (1978) for the perforations facing air-fibrous material. They illustrated the significant impact of perforation impedance on the transmission loss of dissipative silencers particularly with low porosity. The foregoing studies with the absorbent, however, are limited to developing expressions for the acoustic impedance of perforations by intuitive modifications of the available no-fiber relationships. Hence, the predictive studies on the acoustic performance of dissipative silencers have thus far used the perforation impedance with air, or its alternatives with such heuristic modifications.

The present study experimentally determines the acoustic impedance of perforations facing air-air (air on both sides) and air-fibrous material (air on one side and fibrous material on the other side) directly in the absence of mean flow. First, the measurement methodology developed in this study is applied to the perforations facing air-air, and the results are compared with the available literature. Then, the impedance of perforation in contact with air-fibrous material of $\rho_f = 100$ and 200 kg/m^3 is also experimentally acquired. Since accurate acoustic properties of the fibrous material are necessary for the measurement of acoustic impedance of perforations in contact with the material, the characteristic impedance and wave number of the material are also experimentally obtained in this work.

Following this Introduction, Sec. II presents the definitions of perforation impedance and existing formulations and Sec. III describes the experimental setups and data reduction. Section IV gives the results of acoustic properties of fibrous material and acoustic impedance of perforations followed by the concluding remarks in Sec. V.

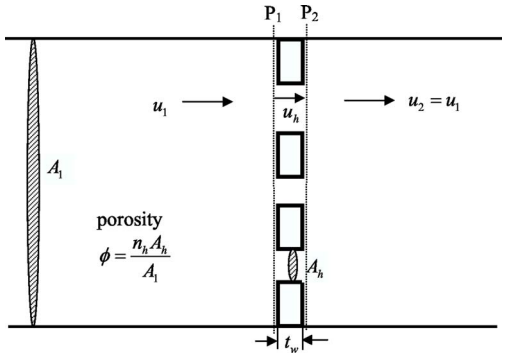

FIG. 1. A perforated plate in a duct.

II. DEFINITIONS OF PERFORATION IMPEDANCE AND EXISTING FORMULATIONS

A. Definitions of perforation impedance

The acoustic impedance is the ratio of the pressure difference across perforations to the particle velocity (Fig. 1). Two available definitions of the impedance differ by the way the particle velocity is specified. One uses the particle velocity u_h at the hole in Fig. 1, and the other the velocity u_1 or u_2 in the duct. These definitions and the relationship in between are introduced next.

The specific acoustic impedance of a hole is defined as

$$Z_h = \frac{p_1 - p_2}{u_h} = R_s + i\omega L_s = R_s + i\omega\rho_0 \ell_{\text{eff}} = R_s + ik_0\rho_0 c_0 \ell_{\text{eff}}, \tag{1}$$

where p_1 and p_2 are the acoustic pressures before and after the perforated plate, respectively, as shown in Fig. 1; ρ_0 the air density; c_0 the speed of sound in air; k_0 the wave number in air; R_s the specific resistance; L_s the specific inertance; and

$$\ell_{\text{eff}} = t_w + \alpha d_h \tag{2}$$

the effective length of the hole, where t_w is the wall thickness, d_h the hole diameter, and α the end correction coefficient. The coefficient α is dependent on the hole geometry and the characteristics of medium in contact with the hole. The nondimensional acoustic impedance of a hole is then given by

$$\zeta_h = \frac{p_1 - p_2}{Z_0 u_h} = R + ik_0(t_w + \alpha d_h), \tag{3}$$

where $Z_0 = \rho_0 c_0$ is the characteristic impedance of air and R is the dimensionless resistance.

The nondimensional acoustic impedance of a perforated plate can be defined as

$$\zeta_p = \frac{p_1 - p_2}{Z_0 u_1}, \tag{4}$$

where the particle velocity u_1 in the duct is related to u_h through conservation of mass by

$$u_1 = \frac{n_h A_h}{A_1} u_h = \phi u_h, \tag{5}$$

n_h being the number of holes, A_h the area of a hole, and ϕ the porosity. Equations (3)–(5) yield the relationships between the impedance of a hole and a plate as

$$\zeta_p = \frac{p_1 - p_2}{Z_0 u_h \phi} = \frac{\zeta_h}{\phi} = \frac{R + ik_0(t_w + \alpha d_h)}{\phi}. \tag{6}$$

While the impedance of a hole is representative of the acoustic characteristics of an isolated single perforation, it is the impedance of a plate typically used in the analyses, for example, in transmission loss predictions. The impedance of a plate ζ_p is usually measured first, the impedance of a hole ζ_h is then calculated using Eq. (6).

B. Existing formulations

The empirical relationship of Sullivan and Crocker (1978) given by

$$\zeta_p = \frac{0.006 + ik_0(t_w + 0.75 d_h)}{\phi} \tag{7}$$

has been widely used for the perforation impedance with air-air contact. This expression was obtained using a perforation with ϕ=4.2%. In Eq. (7), the coefficient 0.75 is associated with the end correction of the perforation. While the theoretical maximum value is $8/3\pi(\cong 0.85)$ for a single hole with an infinite flange, the coefficient may be smaller for multiholes due to the interaction among holes. Melling (1973) graphically illustrated such interaction between two holes.

Kirby and Cummings (1998) suggested a semiempirical acoustic impedance $\tilde{\zeta}_p$ for perforated plates facing air-fibrous material by modifying ζ_p that faces air-air as

$$\tilde{\zeta}_p = \zeta_p + \frac{ik_0 0.425\left(-1 + \frac{\tilde{Z}}{Z_0}\frac{\tilde{k}}{k_0}\right) d_h}{\phi}. \tag{8}$$

In Eq. (8), half of the end correction for a perforation facing air-air (the first term inside the parentheses) is combined with a second term to account for the effect of the fibrous material. However, the use of Eq. (8) for dissipative silencers leads to erroneous transmission loss predictions possibly due, according to Kirby (2001), to an overestimated perforation impedance. Such overestimation may be attributed to the ignored interaction among holes. Selamet *et al.* (2001) adapted the concept by applying Eq. (7) to the perforations facing air-fibrous material as follows:

$$\tilde{\zeta}_p = \frac{0.006 + ik_0\left[t_w + \frac{0.75}{2}\left(1 + \frac{\tilde{Z}}{Z_0}\frac{\tilde{k}}{k_0}\right) d_h\right]}{\phi}. \tag{9}$$

In Eq. (9), the effect of absorbent is considered with the complex characteristic impedance $\tilde{Z}$ and wave-number $\tilde{k}$ of the material, thus both real and imaginary parts of the impedance can be modified in Eq. (9). Since it is obtained by modifying Eq. (7) based on ϕ=4.2%, Eq. (9) is expected to be valid near this particular porosity.

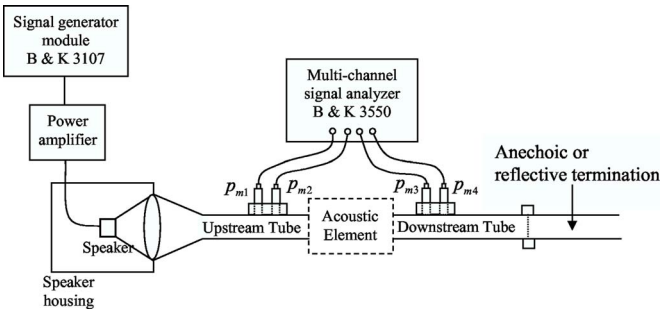

FIG. 2. Schematic of the impedance tube setup in the absence of mean flow.

III. EXPERIMENTAL SETUP AND DATA REDUCTION

An impedance tube setup shown in Fig. 2 (Refer, for example, to Dickey *et al.*, 2000 or Selamet *et al.*, 1994, for details) is modified for the measurements of characteristic impedance and wave number of the absorbing material, and the acoustic impedance of perforations in the absence of mean flow, particularly in contact with the material. The resulting setups and the data reduction for such measurements are described next.

A. Measurement of characteristic impedance and wave number of fibrous material

A transfer function method with two different termination conditions (Fig. 3) in conjunction with the impedance tube of Fig. 2 is developed to acquire experimentally the complex characteristic impedance and wave number of the fibrous material in the absence of mean flow. A sample of absorbing material is mounted inside the main duct bounded by wire screens with a porosity higher than 75% defining the locations a and b in Fig. 3. Transfer functions among the microphones and two measurements with distinctly different terminations are required in the present method to determine the complex characteristic impedance and wave number of the absorbing material in the frequency domain. Anechoic and fully reflective boundaries are applied as two different termination conditions.

The transfer matrix, which expresses the relationships between acoustic pressure and velocities at the surfaces a and b of the sample, is given for the first termination in terms of the complex characteristic impedance $\tilde{Z}$, the wave-number $\tilde{k}$, and the length of the sample ℓ_f as

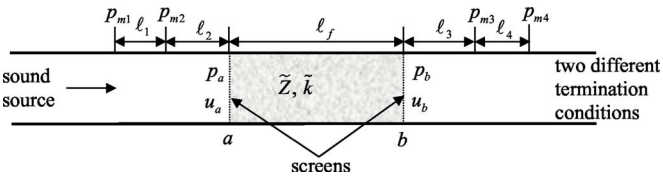

FIG. 3. Schematic of the experimental setup for obtaining the acoustic properties of absorbing material in the absence of mean flow.

$$\begin{bmatrix} p_a \\ u_a \end{bmatrix} = \begin{bmatrix} \cos(\tilde{k}\ell_f) & i\tilde{Z}\sin(\tilde{k}\ell_f) \\ i\dfrac{\sin(\tilde{k}\ell_f)}{\tilde{Z}} & \cos(\tilde{k}\ell_f) \end{bmatrix} \begin{bmatrix} p_b \\ u_b \end{bmatrix}, \tag{10}$$

and for the second termination (designated by prime)

$$\begin{bmatrix} p'_a \\ u'_a \end{bmatrix} = \begin{bmatrix} \cos(\tilde{k}\ell_f) & i\tilde{Z}\sin(\tilde{k}\ell_f) \\ i\dfrac{\sin(\tilde{k}\ell_f)}{\tilde{Z}} & \cos(\tilde{k}\ell_f) \end{bmatrix} \begin{bmatrix} p'_b \\ u'_b \end{bmatrix}. \tag{11}$$

Combining Eqs. (10) and (11) and rearranging yields

$$\begin{bmatrix} \cos(\tilde{k}\ell_f) \\ i\tilde{Z}\sin(\tilde{k}\ell_f) \\ i\dfrac{\sin(\tilde{k}\ell_f)}{\tilde{Z}} \\ \cos(\tilde{k}\ell_f) \end{bmatrix} = \begin{bmatrix} p_b & u_b & 0 & 0 \\ 0 & 0 & p_b & u_b \\ p'_b & u'_b & 0 & 0 \\ 0 & 0 & p'_b & u'_b \end{bmatrix}^{-1} \begin{bmatrix} p_a \\ u_a \\ p'_a \\ u'_a \end{bmatrix} = \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \end{bmatrix}, \tag{12}$$

where $T_1 = T_4$ is noted. In Eq. (12), acoustic pressures (p_a, p_b, p'_a, p'_b) and velocities (u_a, u_b, u'_a, u'_b) at the sample surfaces a and b can be calculated from the pressure measurements at four microphones $(p_{m1}, p_{m2}, p_{m3}, p_{m4}, p'_{m1}, p'_{m2}, p'_{m3}, p'_{m4})$ in Fig. 3. The transfer matrix between the sample surface a and microphone 2 [for a straight pipe of constant cross-sectional area (Munjal, 1987)] is given by, for the first termination

$$\begin{bmatrix} p_a \\ u_a \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_2) & iZ_0\sin(k_0\ell_2) \\ i\dfrac{1}{Z_0}\sin(k_0\ell_2) & \cos(k_0\ell_2) \end{bmatrix}^{-1} \begin{bmatrix} p_{m2} \\ u_{m2} \end{bmatrix}. \tag{13}$$

In Eq. (13), the acoustic velocity u_{m2} at microphone 2 can be expressed in terms of pressure measurements, p_{m1} and p_{m2} at microphones 1 and 2. In light of

$$\begin{bmatrix} p_{m2} \\ u_{m2} \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_1) & -iZ_0\sin(k_0\ell_1) \\ -i\dfrac{1}{Z_0}\sin(k_0\ell_1) & \cos(k_0\ell_1) \end{bmatrix} \begin{bmatrix} p_{m1} \\ u_{m1} \end{bmatrix}, \tag{14}$$

u_{m2} is given by

$$u_{m2} = \frac{p_{m1} - p_{m2}\cos(k_0\ell_1)}{iZ_0\sin(k_0\ell_1)}. \tag{15}$$

Substitution of Eq. (15) into Eq. (13) yields

$$\begin{bmatrix} p_a \\ u_a \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_2) & iZ_0\sin(k_0\ell_2) \\ i\dfrac{1}{Z_0}\sin(k_0\ell_2) & \cos(k_0\ell_2) \end{bmatrix}^{-1} \times \begin{bmatrix} p_{m2} \\ \dfrac{p_{m1} - p_{m2}\cos(k_0\ell_1)}{iZ_0\sin(k_0\ell_1)} \end{bmatrix}, \tag{16}$$

which expresses the acoustic pressure and velocity at the sample surface a in terms of pressures alone measured at microphones 1 and 2. Similarly, the acoustic pressure and velocity at the sample surface a for the second termination is given by

$$\begin{bmatrix} p'_a \\ u'_a \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_2) & iZ_0\sin(k_0\ell_2) \\ i\dfrac{1}{Z_0}\sin(k\ell_2) & \cos(k_0\ell_2) \end{bmatrix}^{-1} \times \begin{bmatrix} p'_{m2} \\ \dfrac{p'_{m1} - p'_{m2}\cos(k_0\ell_1)}{iZ_0\sin(k_0\ell_1)} \end{bmatrix}. \tag{17}$$

The acoustic pressure and velocity at sample surface b can be similarly expressed in terms of pressures measured at microphones 3 and 4 for the first termination as

$$\begin{bmatrix} p_b \\ u_b \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_3) & iZ_0\sin(k_0\ell_3) \\ i\dfrac{1}{Z_0}\sin(k_0\ell_3) & \cos(k_0\ell_3) \end{bmatrix} \times \begin{bmatrix} p_{m3} \\ \dfrac{p_{m3}\cos(k_0\ell_4) - p_{m4}}{iZ_0\sin(k_0\ell_4)} \end{bmatrix}, \tag{18}$$

and for the second termination

$$\begin{bmatrix} p'_b \\ u'_b \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_3) & iZ_0\sin(k_0\ell_3) \\ i\dfrac{1}{Z_0}\sin(k_0\ell_3) & \cos(k_0\ell_3) \end{bmatrix} \times \begin{bmatrix} p'_{m3} \\ \dfrac{p'_{m3}\cos(k_0\ell_4) - p'_{m4}}{iZ_0\sin(k_0\ell_4)} \end{bmatrix}. \tag{19}$$

The complex characteristic impedance and wave number of the sample can then be obtained from Eq. (12) and Eqs. (16)–(19). The complex characteristic impedance $\tilde{Z}$ is given, in terms of T_2 and T_3 of Eq. (12), by

$$\tilde{Z} = \sqrt{\frac{T_2}{T_3}} \tag{20}$$

and the complex wave number, in terms of T_1 or T_4 of Eq. (12), by

$$\tilde{k} = \frac{1}{\ell_f}\cos^{-1}(T_1) = \frac{1}{\ell_f}\cos^{-1}(T_4). \tag{21}$$

Measured T_1 and T_4 of Eq. (12) are expected to be identical. However, that may not be exactly true in experiments due,

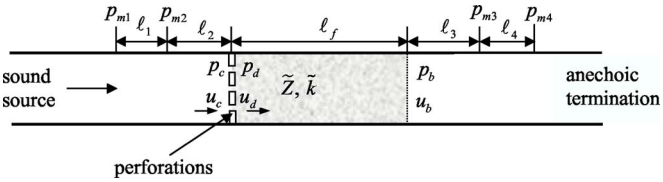

FIG. 4. Schematic of the experimental setup for obtaining the acoustic impedance of perforations in the absence of mean flow.

for example, to inhomogeneity in the filling and imperfect sample surfaces. Thus, the complex wave number is obtained in the present study using an average of T_1 and T_4 as

$$\tilde{k} = \frac{1}{\ell_f} \cos^{-1}\left(\frac{T_1 + T_4}{2}\right). \tag{22}$$

B. Measurement of acoustic impedance of perforations

Once the acoustic properties of the absorbing material are obtained, the acoustic impedance of perforations in contact with the absorbent on one side can be also determined experimentally. Unlike the acoustic properties of the absorbing material, only a single experiment with one termination is adequate for the measurement of perforation impedance. An anechoic termination is applied to reduce the interferences at microphones by the reflected wave from the termination. In view of Fig. 4, replacing u_1 of Eq. (4) by u_c gives the acoustic impedance of a perforated plate as

$$\tilde{\zeta}_p = \frac{p_c - p_d}{Z_0 u_c}, \tag{23}$$

where p_c and p_d are the acoustic pressures at the perforation surfaces contacting air and absorbing material, respectively, and u_c is the acoustic velocity in the duct at the perforation surface. The quantities p_c and u_c are determined in terms of pressures measured at microphones 1 and 2 from Eq. (16) as

$$\begin{bmatrix} p_c \\ u_c \end{bmatrix} = \begin{bmatrix} \cos(k_0\ell_2) & iZ_0\sin(k_0\ell_2) \\ i\frac{1}{Z_0}\sin(k_0\ell_2) & \cos(k_0\ell_2) \end{bmatrix}^{-1} \times \begin{bmatrix} p_{m2} \\ \frac{p_{m1} - p_{m2}\cos(k_0\ell_1)}{iZ_0\sin(k_0\ell_1)} \end{bmatrix}. \tag{24}$$

The acoustic pressure and velocity at the perforation surface in contact with the fibrous material are expressed in terms of a series of transfer matrices and the pressures measured at microphones 3 and 4 as

$$\begin{bmatrix} p_d \\ u_d \end{bmatrix} = [T_{ab}][T_{b3}] \begin{bmatrix} p_{m3} \\ \frac{p_{m3}\cos(k_0\ell_4) - p_{m4}}{iZ_0\sin(k_0\ell_4)} \end{bmatrix}, \tag{25}$$

where

$$[T_{ab}] = \begin{bmatrix} \cos(\tilde{k}\ell_f) & i\tilde{Z}\sin(\tilde{k}\ell_f) \\ i\frac{\sin(\tilde{k}\ell_f)}{\tilde{Z}} & \cos(\tilde{k}\ell_f) \end{bmatrix} \tag{26}$$

is the transfer matrix between surfaces a and b, and

$$[T_{b3}] = \begin{bmatrix} \cos(k_0\ell_3) & iZ_0\sin(k_0\ell_3) \\ i\frac{1}{Z_0}\sin(k_0\ell_3) & \cos(k_0\ell_3) \end{bmatrix} \tag{27}$$

is the transfer matrix between surface b and microphone 3. Finally, the perforation impedance can be determined from Eqs. (23)–(27) and sound pressure measurements at four microphones. In Eq. (23), experimentally determined acoustic velocities u_c and u_d at the perforation surface may not be exactly identical in experiments. Thus, an average of the two velocities is used for the calculation of perforation impedance as

$$\tilde{\zeta}_p = \frac{p_c - p_d}{Z_0\frac{(u_c + u_d)}{2}}. \tag{28}$$

The same setup and the data reduction technique are also used for the measurements of acoustic impedance of perforations without the fibrous material.

IV. ACOUSTIC PROPERTIES OF FIBROUS MATERIAL

A modified impedance tube setup described in the preceding section is used to experimentally obtain the complex characteristic impedance and wave number of fibrous material. The present study focuses on two filling densities ($\rho_f = 100$ and 200 kg/m^3 representing approximate bounds in practical applications), and experimentally determines their acoustic properties. These properties are then directly applied to the measurements of acoustic impedance of perforation in contact with the fibrous material. The precise measurements of the distances between the sample surfaces and microphones or among microphones are critical in the experiments. The accuracy within 0.1 mm for the materials with well-defined surfaces is recommended by ASTM 1050-98 (1998). However, such a precise physical measurement may not be possible due, for example, to the difficulty in finding the centers of the microphones with their diameter of 6.35 mm (1/4 in.). Thus, the distances ℓ_1 through ℓ_4 and the sample length ℓ_f in Figs. 3 and 4 are acoustically estimated using quarter wave resonances (Katz, 2000). The estimated distances by this method are as follows: $\ell_1 = \ell_4 = 3.55$ cm, $\ell_2 = 12.81$ cm, $\ell_3 = 12.71$ cm, and $\ell_f = 10.16$ cm. When ℓ_f is too short, the impact of inhomogeneous filling tends to magnify. On the other hand, too long of a sample is detrimental to transferring sufficient sound energy to the downstream microphones due to wave dissipation through the material, particularly at high frequencies. Therefore, ℓ_f was chosen to balance these competing factors. An accurate

estimation of speed of sound is also important for the measurements, which is calculated here by

$$c_0 = 20.047\sqrt{273.15 + T_C} \quad [\mathrm{m/s}], \tag{29}$$

as suggested by ASTM 1050-98 (1998). All experiments were performed at the room temperature, $T_C = 19 \pm 1\ ^\circ\mathrm{C}$.

A. Fiber samples

Advantex® continuous-strand glass fiber developed by Owens Corning (Novi, MI) is used in the experiments. The texturization process separates filament roving strands of fiber glass into individual filaments by turbulent air flow (Silentex™ process). The average diameter of the individual filaments in the roving strand is 24 μm. In addition to the acoustic properties, high thermal and corrosion resistance of the Advantex® glass fiber may also be desirable particularly for the exhaust systems. The physical and chemical properties of various absorptive materials and their relative durability in automotive silencer operations have been described by Beranek (1988) and Huff (2001).

Absorbent samples, 10 cm long and 4.9 cm in diameter and with two different filling densities $\rho_f = 100$ and 200 kg/m^3, are placed in the test tube (Fig. 2). Densities significantly lower than $\rho_f = 100$ kg/m^3 may cause the movement of fibers inside the silencers and higher than $\rho_f = 200$ kg/m^3 may be undesirable in terms of cost, weight, and in some cases acoustic attenuation.

Random filling is applied to achieve overall isotropic and homogeneous conditions. However, partially or locally nonisotropic or inhomogeneous regions may exist due, for example, to the hand filling of the absorbent into the test tube. Thus, experiments with five different samples for each filling density are performed to examine the effect of variations in filling conditions. An average of five individual experiments is then used as the final result. The present study uses a well-texturized condition, which has mostly individual filaments. The front surfaces of the absorbent sample also need to be well defined in the experiments. The surfaces of the sample perpendicular to the direction of wave propagation are identified by two screens. The screens have a high porosity not to influence the surface properties of the absorbent and sufficiently high tension to hold the absorbent flat at the surface.

B. Characteristic impedance and wave number

The normalized empirical complex characteristic impedance $\tilde{Z}$ and the wave-number $\tilde{k}$ of Delany and Bazley (1970) for fibrous materials in mks units

$$\frac{\tilde{Z}}{Z_0} = [1 + 0.0511(f/R_f)^{-0.75}] + i[-0.0768(f/R_f)^{-0.73}] \tag{30}$$

TABLE I. Fit coefficients of the measured characteristic impedance and wave number.

Filling density (kg/m^3)	a_1	b_1	a_2	b_2	a_3	b_3	a_4	b_4
100	33.20	0.7523	28.32	0.6512	39.20	0.6841	38.39	0.6285
200	25.69	0.5523	71.97	0.7072	56.03	0.6304	62.05	0.5980

$$\frac{\tilde{k}}{k_0} = [1 + 0.0858(f/R_f)^{-0.70}] + i[-0.1749(f/R_f)^{-0.59}] \tag{31}$$

have been widely used due to its simplicity and accuracy. Here f is the frequency in hertz and R_f the flow resistivity which is primarily dependent on the fiber diameter, layer orientation, and filling density. Although the Delany and Bazley formulation is well representative of the acoustic behavior of fibrous material in general, the present study experimentally determines the complex characteristic impedance and wave number of specific fibrous material since the process of data reduction for perforation impedance requires accurate (rather than simply somewhat representative) acoustic properties of the material in contact with the perforations. The present study has retained the forms of Eqs. (30) and (31), since they provide suitable fits. The curve-fitted complex characteristic impedance and wave number based on the averaged values of five experiments are expressed by

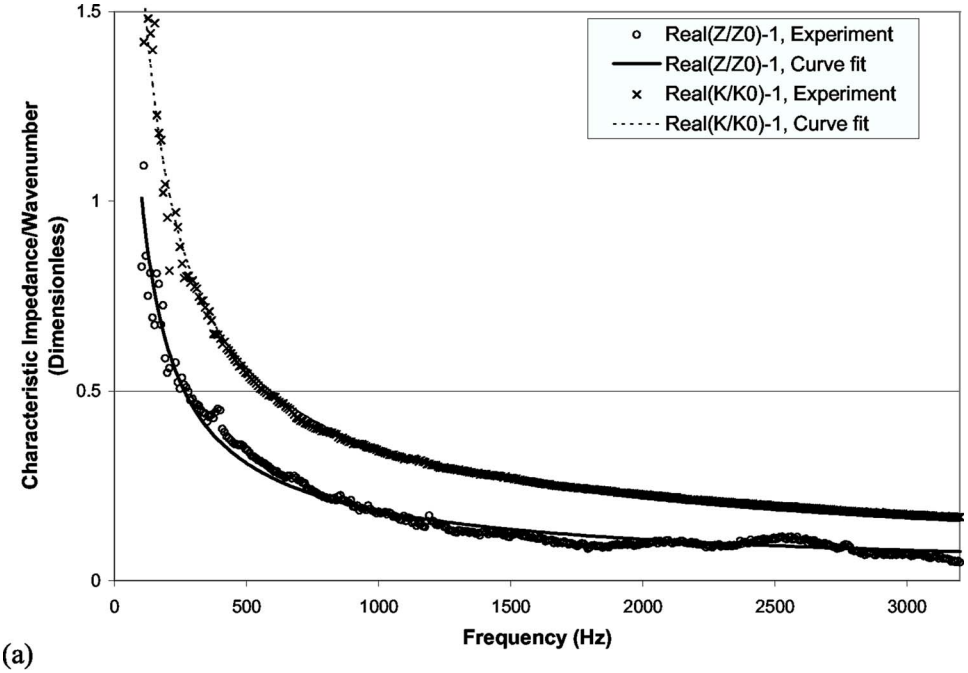
$$\frac{\tilde{Z}}{Z_0} = (1 + a_1 f^{-b_1}) - i a_2 f^{-b_2}, \tag{32}$$

$$\frac{\tilde{k}}{k_0} = (1 + a_3 f^{-b_3}) - i a_4 f^{-b_4}, \tag{33}$$

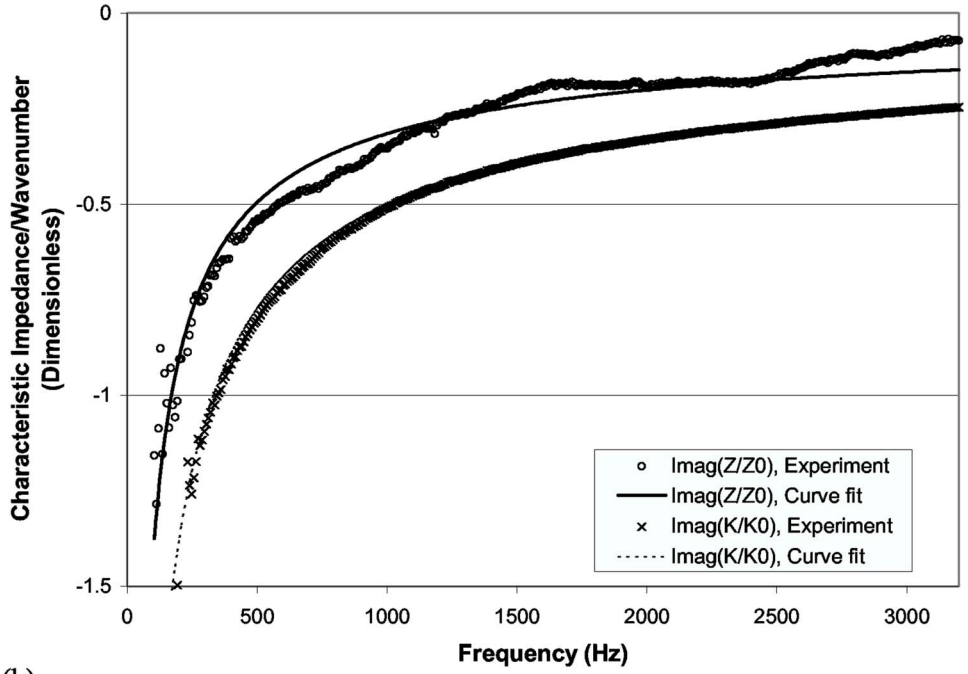
with the coefficients presented in Table I for both filling densities of $\rho_f = 100$ and 200 kg/m^3. The function "fit" of MATLAB® is applied for all curve fits in the frequency range of 100–3200 Hz. At lower frequencies, two distinct termination conditions may not be achieved, which are necessary for accurate results, due to the imperfect anechoic boundary. The accuracy of the measurement at low frequency is also limited by the microphone spacing (ASTM 1050-98, 1998). Figure 5 shows, for example, the characteristic impedance and wave number for $\rho_f = 100$ kg/m^3. The curve fits represent most of the data points well, particularly for the wave number.

V. ACOUSTIC IMPEDANCE OF PERFORATIONS

The acoustic impedance of perforations in contact with air-fibrous material is different than the one facing air-air due to the influence of absorbing material. The fiber filling density and texturization condition in contact with the perforation are particularly important. Ingard (1954) claims that the fiber properties only within a distance of one hole diameter are significant. Thus, the air gap between the perforation and the fibrous material may also alter the perforation impedance. The present study considers only the perforations directly in contact with the fibrous material without the air gap.



(a)



(b)

FIG. 5. Characteristic impedance and wave number of the fibrous material with $\rho_f = 100\,\mathrm{kg/m^3}$; (a) real part and (b) imaginary part.

Acoustic impedance of perforations facing air only and air-fibrous material is measured in the present study using the impedance tube presented in Fig. 4 and methodology described in Sec. II. The averaged results from five experiments with different fibrous material samples are utilized in the data reduction.

A. Perforation plate samples

Table II presents 11 samples of circular plates considered in this study with different porosity ϕ, wall thickness t_w, and hole diameter d_h to investigate the effect of such parameters on the perforation impedance. Figures 6 and 7 provide, respectively, the detailed dimensions and the photos of the circular perforated plates used in the present study. Perfora-

tions facing air-air with higher than 10% porosity have not been, in general, considered in the literature since the effect of varying perforations at high porosities on the transmission loss of perforated silencers is insignificant. However, with the fibrous material, the transmission loss may be affected by the perforation impedance even at higher porosities. Thus, four porosities (ϕ=2.1, 8.4, 13.6, and 25.2 %) are used in the present study, defined by the area ratio of all holes to the plate. The samples are categorized into three groups (Table II); (1) group A is the base with d_h=0.249 cm and t_w

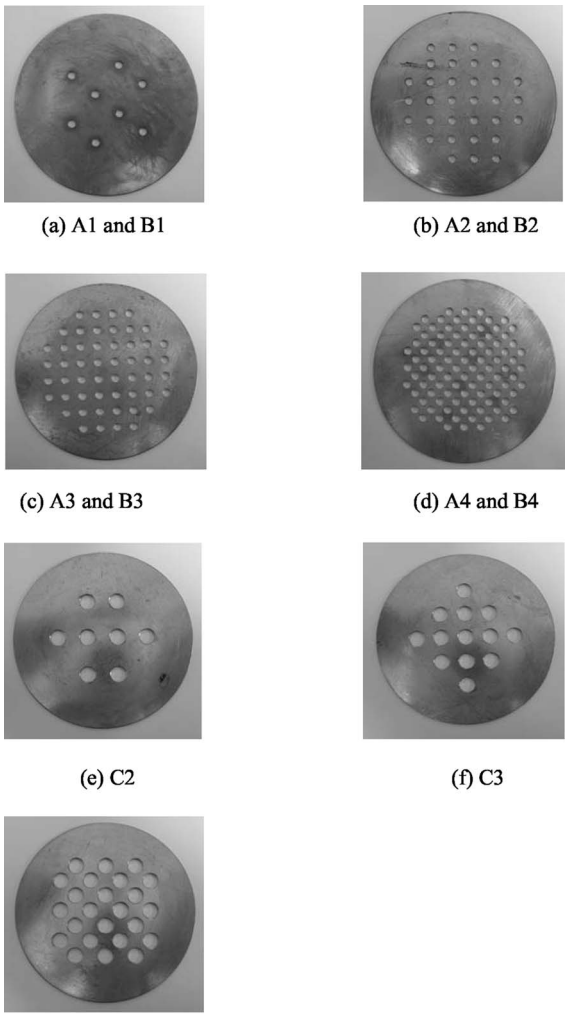

FIG. 7. Pictures of perforated plate samples.

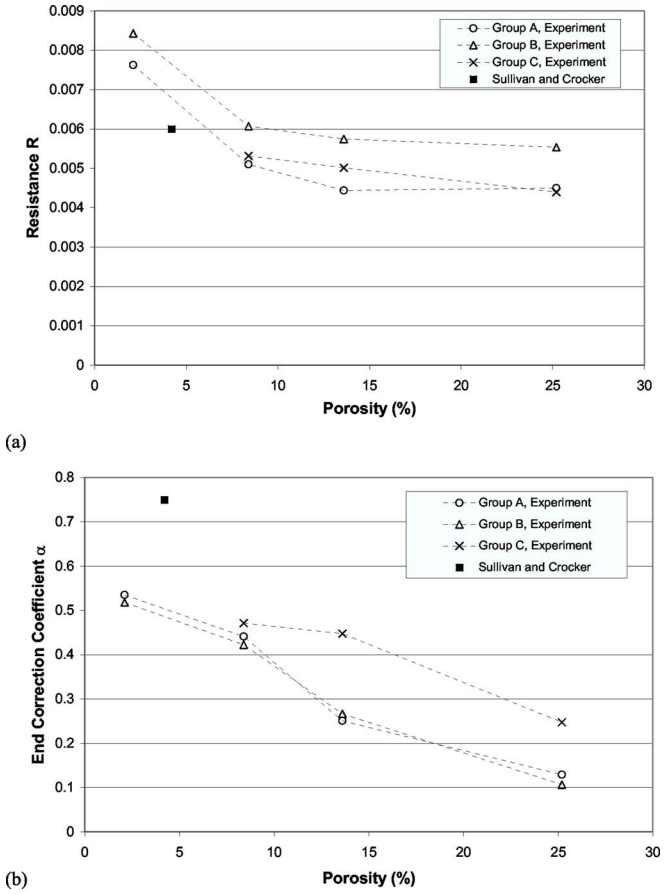

FIG. 8. Comparison of measurements of the acoustic impedance of a hole in contact with air-air; (a) resistance and (b) end correction coefficient.

=0.08 cm; (2) group B has the same hole diameter as group A and doubles the wall thickness to t_w=0.16 cm; and (3) group C has the same wall thickness as group A, while doubling the hole diameter to d_h=0.498 cm. The numbers (1–4) after the group identification by (A–C) in Table II designate different duct porosities. The holes on the plates are distributed to achieve similar distances between the holes in the vertical and horizontal directions. For impedance measurements, the circular sample plates are installed in the impedance tube of 4.9 cm inner diameter, as shown in Fig. 4. The distance from the tube wall to the nearest hole is chosen to be longer than the distance between holes in order to minimize the effect of the interaction between holes and the wall.

B. Acoustic impedance of perforations in contact with air alone

The dimensionless resistance R and the end correction coefficient α in Eq. (6) of the perforation samples with air-air contact are experimentally determined using the impedance tube setup depicted in Fig. 4. While this setup is originally designed to measure the impedance of perforation facing fibrous material, it can also be utilized for the perforation in contact with air only. For each perforation plate, five experiments are performed, and their averaged values are then used to obtain R and α. The end correction coefficients are calculated from the curve-fitted reactance in the frequency range of 100–3200 Hz for most samples. The only exception is A1 and B1 with ϕ=2.1% which are curve fitted in the range of 100–2600 Hz due to the unstable signals at frequencies higher than 2600 Hz. The mean values of resistance in the same frequency range are also obtained.

Figure 8 presents the measured R and α (also given in Table III) for the perforation samples of Table II, facing air-air. Figure 8(a) shows that the resistance R decreases as the porosity increases, particularly from ϕ=2.1 to 8.4 %. Group B (t_w=0.16 cm) has higher resistance than group A (t_w =0.08 cm), due to the doubled wall thickness. The resistance 0.006 obtained by Sullivan and Crocker (1978) for ϕ =4.2% falls in between the range of ϕ=2.1 and 8.4 % in Fig. 8(a). Figure 8(b) illustrates the effect of porosity, wall thickness, and hole diameter on α, thus reactance of the perforation impedance. As the porosity increases, α decreases because of the shorter distance between the holes, hence a stronger interaction among the holes. Groups A and B have similar values of α indicating that the end correction coefficient is essentially independent of the wall thickness. Group C has higher values of α than those of group A presumably

TABLE III. Measured R and α of the perforations.

Sample No.	R			α		
	Air alone	$\rho_f=100$ (kg/m^3)	$\rho_f=200$ (kg/m^3)	Air alone	$\rho_f=100$ (kg/m^3)	$\rho_f=200$ (kg/m^3)

B3	0.005744	0.02444	0.04142	0.2666	0.4661	0.5048
B4	0.005539	0.02657	0.05076	0.1066	0.3951	0.3980
C2	0.005318	0.04728	0.09015	0.4707	0.6206	0.7167
C3	0.005013	0.04598	0.09308	0.4473	0.6269	0.7142
C4	0.004395	0.03973	0.07604	0.2471	0.4504	0.4926

due to the larger hole diameter resulting in a longer distance among the holes, thereby reducing the interaction. The end corrections obtained in the present study are lower than 0.75 of Sullivan and Crocker (1978) for all porosities, possibly due to different distance between holes.

C. Acoustic impedance of perforations in contact with fibrous material

The experimental results for R and α of the perforations facing an absorbent with $\rho_f=100$ and 200 kg/m^3 as well as air alone are shown in Figs. 9–11, for groups A, B, and C, respectively, and Table III. Figures 9–11 show that fibrous material substantially increases both resistance and end correction coefficients for all three groups. The resistance R of $\rho_f=200$ kg/m^3 are higher than those of lower filling density $\rho_f=100$ kg/m^3 for all samples. The effect of different filling density on α diminishes for the samples A4 and B4. The average increases of R over all 11 samples (recall Table II) due to the fibrous material are reflected by factors of nearly 5 and 10 relative to the baseline with no fiber for $\rho_f=100$ and 200 kg/m^3, respectively, whereas the average α is approximately only doubled for both fiber densities. Thus, the impact of fibrous material on the resistance is more significant than on the end correction coefficient. The imaginary part of the perforation impedance depends also on the frequency, the hole diameter, and the wall thickness [recall Eq. (3)].

For groups A (Fig. 9) and B (Fig. 10), as the porosity increases, α decreases for both filling densities except for one sample (A4 with $\phi=25.2\%$ and $\rho_f=100$ kg/m^3). For the same groups, R decreases with porosity up to $\phi=13.6\%$, and then increases to that of $\phi=25.2\%$. Group C (Fig. 11) with $d_h=0.498$ cm exhibits some differences from groups A and B with $d_h=0.249$ cm; R of $\phi=25.2\%$ is lower than that of $\phi=13.6\%$, and the change of α from $\phi=13.6$ to 25.2 % is more dramatic than from $\phi=8.4$ to 13.6 %.

Table IV presents relative standard deviations (σ_R/R and σ_α/α) for R and α calculated from five repeat experiments with air alone and with fibrous material. σ_R/R is usually higher than σ_α/α, and both deviations, in general, increase with the porosity. σ_R/R and σ_α/α for $\rho_f=200$ kg/m^3 are, in most cases, greater than those for $\rho_f=100$ kg/m^3, possibly due to relatively nonhomogeneous filling conditions, including texturization of the fiber, for the higher density. The texturization of the absorbent may substantially affect the acoustic impedance of perforations in contact with this material (Lee, 2005). The present study has provided the impedance of perforation in contact with well texturized fibrous material.

VI. CONCLUSIONS

The understanding of the acoustic behavior of the fibrous material and perforations is critical for the design of dissipative silencers. Therefore, the present study has developed experimental setups to measure: (a) the complex characteristic impedance and the complex wave number of the fibrous material, and (b) the acoustic impedance of perforations, particularly in the presence of absorbing material.

The characteristic impedance and wave number of the fibrous material with two filling densities (ρ_f=100 and 200 kg/m^3) are obtained using a modified impedance tube setup with four microphones and two different termination conditions. The averaged values from five samples are curve fitted as a function of frequency. These curve fits represent most of the data points well, particularly for the wave number at both filling densities. The characteristic impedance and wave number inferred from the experiments are then used for the measurement of acoustic impedance of perforations in contact with the fibrous material.

A new experimental setup has been developed in the present study for the measurement of acoustic impedance of perforations in contact with the fibrous material as well as with air alone in the absence of mean flow. The resistance R and the end correction coefficient α of 11 perforation samples with different porosities (ϕ=2.1, 8.4, 13.6, and 25.2 %), hole diameters (d_h=0.249 and 0.498 cm), and wall thickness (t_w=0.08 and 0.16 cm) are measured along with the fibrous material of ρ_f=100 and 200 kg/m^3. For the perforations without fibrous material, the resistance R and the end correction coefficient α decrease as the porosity increases. The fibrous material significantly increases both R and α compared to the perforation in contact with air only. For both filling densities, both R and α decrease as the porosity increases, except for some of the samples with highest porosity (ϕ=25.2%).

TABLE IV. Standard deviations relative to R and α (%).

Sample No.	$\frac{\sigma_R}{R}$ Air alone	$\frac{\sigma_R}{R}$ ρ_f=100 (kg/m^3)	$\frac{\sigma_R}{R}$ ρ_f=200 (kg/m^3)	$\frac{\sigma_\alpha}{\alpha}$ Air alone	$\frac{\sigma_\alpha}{\alpha}$ ρ_f=100 (kg/m^3)	$\frac{\sigma_\alpha}{\alpha}$ ρ_f=200 (kg/m^3)
A1	24.5	16.1	25.4	7.4	3.4	7.7
A2	10.3	15.7	16.0	4.9	3.7	6.9
A3	11.3	25.4	31.8	8.9	7.2	13.8
A4	17.5	44.2	38.2	30.8	10.9	25.5
B1	7.3	15.3	18.1	3.4	4.2	4.6
B2	6.9	17.1	23.0	4.2	4.1	7.5
B3	9.4	21.8	31.8	8.4	9.2	16.1
B4	15.3	25.8	36.1	35.2	15.9	36.9
C2	18.7	19.4	22.1	3.0	4.2	5.9
C3	16.6	18.3	26.9	3.5	5.1	6.3
C4	20.7	29.0	35.9	10.0	7.8	13.9

The results obtained in the present study can be directly used for the predictions of acoustic behavior of silencers that use similar fibrous material and perforation geometry. When the material and geometry deviate substantially than those of the current work, caution should be exercised in the use of perforation impedance.

Nomenclature

A_1 = cross-sectional area of the duct before the perforated plate
A_h = cross-sectional area of a hole
$a_{1,2,3,4}$ $b_{1,2,3,4}$ = coefficients of wave number and characteristic impedance of fibrous material
$\tilde{c}$ = complex speed of sound in the absorbing material
c_0 = speed of sound in air
d_h = perforate hole diameter
f = frequency
i = imaginary unit ($=\sqrt{-1}$)
$\tilde{k}$ = complex wave number in the absorbing material
k_0 = wave number in air
L_s = specific inertance
ℓ_1 = length between microphones 1 and 2
ℓ_2 = length between microphone 2 and sample upstream surface
ℓ_3 = length between microphone 3 and sample downstream surface
ℓ_4 = length between microphones 3 and 4
ℓ_{eff} = effective length of a hole
ℓ_f = length of a fiber sample
n_h = number of holes
p_1 = acoustic pressure before the perforate plate
p_2 = acoustic pressure after the perforate plate
p_a = acoustic pressure at the upstream of the fiber sample with the first termination condition
p'_a = acoustic pressure at the upstream of the fiber sample with the second termination condition
p_b = acoustic pressure at the downstream of the fiber sample with the first termination condition
p'_b = acoustic pressure at the downstream of the fiber sample with the second termination condition
p_c = acoustic pressure at the perforations contacting air
p_d = acoustic pressure at the perforations contacting fiber
p_{m1} = acoustic pressure at microphone 1 with the first termination condition
p_{m2} = acoustic pressure at microphone 2 with the first termination condition
p_{m3} = acoustic pressure at microphone 3 with the first termination condition
p_{m4} = acoustic pressure at microphone 4 with the first termination condition
p'_{m1} = acoustic pressure at microphone 1 with the second termination condition
p'_{m2} = acoustic pressure at microphone 2 with the second termination condition
p'_{m3} = acoustic pressure at microphone 3 with the second termination condition
p'_{m4} = acoustic pressure at microphone 4 with the second termination condition
R = dimensionless resistance of perforation impedance
R_f = flow resistivity of the absorbing material
R_s = specific resistance
t_w = wall thickness of perforated duct
$[T_{ab}]$ = transfer matrix of a fiber sample
$[T_{b3}]$ = transfer matrix between the downstream of a fiber sample and microphone 3
T_C = room temperature
$T_{1,2,3,4}$ = matrix elements
u_1 = particle velocity before the perforated plate
u_2 = particle velocity after the perforated plate
u_h = particle velocity at a hole
u_{m1} = particle velocity at microphone 1 with the first termination condition
u_{m2} = particle velocity at microphone 2 with the first termination condition
u_a = particle velocity at upstream of the fiber sample with the first termination condition
u'_a = particle velocity at upstream of the fiber sample with the second termination condition
u_b = particle velocity at downstream of the fiber sample with the first termination condition
u'_b = particle velocity at downstream of the fiber sample with the second termination condition
u_c = particle velocity at perforations contacting air
u_d = particle velocity at perforations contacting fiber
Z_0 = $\rho_0 c_0$, characteristic impedance of air
$\tilde{Z}$ = $\widetilde{\rho c}$, complex characteristic impedance of the absorbing material
Z_h = acoustic impedance of a hole
α = end correction coefficient of perforation impedance
σ_α = one standard deviation of α
σ_R = one standard deviation of R
ϕ = porosity
ρ_0 = density of air
ρ_f = filling or bulk density of fibrous material
$\tilde{\rho}$ = effective density of the absorbing material

ω = angular velocity
ζ_p = nondimensionalized acoustic impedance of perforated plate
$\tilde{\zeta}_p$ = nondimensionalized acoustic impedance of perforated plate in contact with fibrous material
ζ_h = nondimensionalized acoustic impedance of a hole
$\tilde{\zeta}_h$ = nondimensionalized acoustic impedance of a hole in contact with fibrous material

Evaluation of a boss model and subtraction technique for predicting wideband scattering phenomena in room acoustics

Georgios Natsiopoulos[a] and Mendel Kleiner
Department of Civil and Environmental Engineering, Division of Applied Acoustics, Chalmers University of Technology, S-41296 Gothenburg, Sweden

(Received 6 October 2005; revised 20 February 2006; accepted 21 February 2006)

Scattering from a hard hemisphere on an infinite plane is studied experimentally and theoretically in a laboratory environment using a subtraction technique. With this technique, the scattered field is determined by subtracting the transient responses from the plane with and without the boss present. Scattering for different combinations of transducer and hemisphere positions are then classified into a number of cases, denoted in-plane/off-plane and back-/forward/mixed scattering. Theoretical and experimental results are compared and evaluated from an auralization point of view using a one-third octave band smoothing of the contribution from the hemisphere. With the smoothing used, average intensity level discrepancies typically less than 3 dB are obtained for a 6 octaves wide *ka*-interval, where *a* equals the hemisphere radius. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Acoustic scattering from isolated objects on planar surfaces, such as semicylindrical columns or hemispherical armatures on walls, is a common phenomenon in room acoustics. Therefore, fast and sufficiently accurate prediction models of this for auralization purposes are of great importance in the design, improvement, and analysis of auditoria.

Analytical solutions are rare[1,2] but generally preferred, especially since no spatial discretization is needed. In the middle of the last century, Twersky[3,4] developed analytical expressions for scattering from rigid semicylinders or hemispheres on a rigid infinite plane, where a boss model was used — a combination of image methods, separation of variables, and addition theorems for coupling phenomena. Later, Goodman and Stern[5] studied acoustic plane wave scattering from an elastic hemispherical shell on a rigid infinite plane, both analytically and numerically. They found that the external field was similar to that produced by a rigid hemisphere.

Comparisons with measurements were not made in the studies above, although they would elucidate several questions of practical importance. For example, possible turbulence effects at sharp edges will not be visible in the analytical solution, since they are derived by adding results for smooth spheres or cylinders in free space. In addition, theoretical results for hemispheres show strong focusing effects that may not be equally pronounced in reality. Moreover, the incident wave front is never perfectly plane or spherical, and this will also affect the agreement with situations encountered in practice.

An experiment with a hemispherical hardened plastic shell placed on a smooth concrete floor was carried out to investigate whether the boss model could be a candidate for applications in room acoustics. Microphone and loudspeaker were of a cylindrical shape and were pointed toward the hemisphere base center from distances $3a$ and $9a$, respectively, where $a=11.5$ cm is the hemisphere radius. Loudspeaker and microphone angles were varied in steps of 30° to include examples of in- and off-plane scattering, as well as back-, forward, and mixed scattering. Each measurement was made with and without the hemisphere present, making an estimate of the scattered part obtainable by subtraction. Details of all measurements have been documented.[6] Corresponding theoretical results were readily produced for comparison using the method of separation of variables[1] and the principle of superposition.[7]

II. THEORY

A. Scattering from a hard sphere

The problem has rotational symmetry about the axis that runs through the point source location $\boldsymbol{r}_0$ and the center of the sphere $\boldsymbol{r}_a$. Let $\boldsymbol{r}$ be the observation point. See Fig. 1. Note that

$$\cos\alpha = \frac{\boldsymbol{r}-\boldsymbol{r}_a}{|\boldsymbol{r}-\boldsymbol{r}_a|}\cdot\frac{\boldsymbol{r}_0-\boldsymbol{r}_a}{|\boldsymbol{r}_0-\boldsymbol{r}_a|}. \tag{1}$$

In the frequency domain, the exact analytical solution for a sphere present is written as a sum of the incident field $\hat{p}_{\mathrm{in}}$ and a scattered part $\hat{p}_{\mathrm{sc}}$, which satisfies the homogeneous Helmholtz equation

$$\hat{p}(\boldsymbol{r},\omega)=\hat{p}_{\mathrm{in}}(\boldsymbol{r},\omega)+\hat{p}_{\mathrm{sc}}(\boldsymbol{r},\omega), \tag{2}$$

$$\nabla^2\hat{p}_{\mathrm{in}}(\boldsymbol{r},\omega)+k^2\hat{p}_{\mathrm{in}}(\boldsymbol{r},\omega)=4\pi\delta(\boldsymbol{r}-\boldsymbol{r}_0)\hat{U}(\omega), \tag{3}$$

$$\nabla^2\hat{p}_{\mathrm{sc}}(\boldsymbol{r},\omega)+k^2\hat{p}_{\mathrm{sc}}(\boldsymbol{r},\omega)=0. \tag{4}$$

Here, δ is the Dirac delta function. The point source sends out a signal $U(t)$ and the Fourier transform pair used is

$$p(\boldsymbol{r},t)=\frac{1}{2\pi}\int_{\omega=-\infty}^{\infty}\hat{p}(\boldsymbol{r},\omega)e^{-i\omega t}d\omega, \tag{5}$$

[a]Electronic mail: georgios.natsiopoulos@chalmers.se

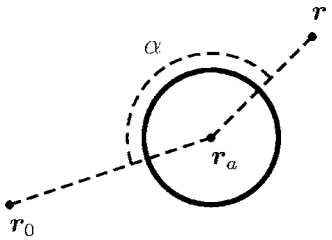

FIG. 1. Geometry for scattering from a sphere centered at $\boldsymbol{r}_a$. The source is located at $\boldsymbol{r}_0$ and the receiver at $\boldsymbol{r}$. By definition, $0^\circ \leqslant \alpha \leqslant 180^\circ$.

$$\hat{p}(\boldsymbol{r},\omega) = \int_{t=-\infty}^{\infty} p(\boldsymbol{r},t) e^{i\omega t} dt. \tag{6}$$

Neumann conditions demand that the normal derivative of the total field is zero at the boundary of the sphere:

$$[\boldsymbol{n}(\boldsymbol{r}) \cdot \nabla \hat{p}(\boldsymbol{r},\omega)]_{|\boldsymbol{r}-\boldsymbol{r}_a|=a} = 0. \tag{7}$$

Here, $\boldsymbol{n}$ is the normal vector of unit length. An explicit analytical solution exists[8] by separation of variables:

$$\hat{p}_{\mathrm{sc}}(\boldsymbol{r},\omega) = -ik\hat{U}(\omega) \sum_{m=0}^{\infty} Q_m(ka) h_m(k|\boldsymbol{r}-\boldsymbol{r}_a|) \times h_m(k|\boldsymbol{r}_0-\boldsymbol{r}_a|) P_m(\cos\alpha), \tag{8}$$

$$Q_m(ka) = (2m+1) \frac{m j_m(ka) - ka j_{m+1}(ka)}{m h_m(ka) - ka h_{m+1}(ka)}, \tag{9}$$

where P_m is the Legendre polynomial of degree m, j_m is the spherical Bessel function of order m, and h_m is the spherical Hankel function of the first kind and order m.

B. A hard hemisphere on a hard infinite plane

Let a hemisphere be situated on an infinite plane with unit normal $\boldsymbol{n}$ pointing into the room. Above the plane, the problem is mathematically equivalent to scattering from a sphere by two sources — the original source and a virtual mirror source.[3] See Fig. 2. The position of the minor source $\boldsymbol{r}_0^*$ is

$$\boldsymbol{r}_0^* = \boldsymbol{r}_0 - 2|(\boldsymbol{r}_0 - \boldsymbol{r}_a) \cdot \boldsymbol{n}|\boldsymbol{n}. \tag{10}$$

The exact analytical solution for a hemisphere present is

$$\hat{p}(\boldsymbol{r},\omega) = \hat{U}(\omega)\left[\frac{e^{ik|\boldsymbol{r}-\boldsymbol{r}_0|}}{|\boldsymbol{r}-\boldsymbol{r}_0|} + \frac{e^{ik|\boldsymbol{r}-\boldsymbol{r}_0^*|}}{|\boldsymbol{r}-\boldsymbol{r}_0^*|}\right] + \hat{p}_{\mathrm{sc}}(\boldsymbol{r},\omega) + \hat{p}_{\mathrm{sc}}^*(\boldsymbol{r},\omega), \tag{11}$$

where the sum of the scattered fields are

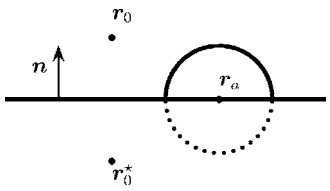

FIG. 2. The hemisphere with its base center at $\boldsymbol{r}_a$, the reflection plane with its unit normal vector $\boldsymbol{n}$, and the virtual mirror source $\boldsymbol{r}_0^*$.

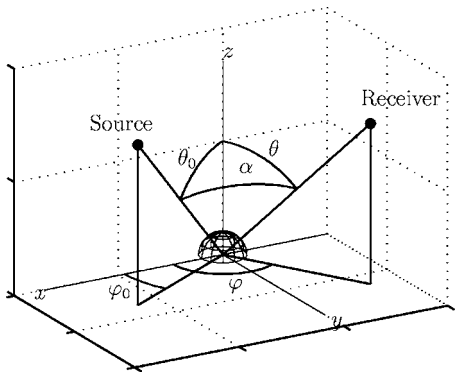

FIG. 3. Illustration that shows the coordinates used in specifying various measurement setups.

$$\hat{p}_{\mathrm{sc}}(\boldsymbol{r},\omega) + \hat{p}_{\mathrm{sc}}^*(\boldsymbol{r},\omega) = -ik\hat{U}(\omega) \sum_{m=0}^{\infty} Q_m(ka) \times h_m(k|\boldsymbol{r}-\boldsymbol{r}_a|) h_m(k|\boldsymbol{r}_0-\boldsymbol{r}_a|)[P_m(\cos\alpha) + P_m(\cos\alpha^*)], \tag{12}$$

since $|\boldsymbol{r}_0^*-\boldsymbol{r}_a| = |\boldsymbol{r}_0-\boldsymbol{r}_a|$. Here,

$$\cos\alpha^* = \frac{\boldsymbol{r}-\boldsymbol{r}_a}{|\boldsymbol{r}-\boldsymbol{r}_a|} \cdot \frac{\boldsymbol{r}_0^*-\boldsymbol{r}_a}{|\boldsymbol{r}_0^*-\boldsymbol{r}_a|}, \tag{13}$$

where α^* corresponds to the angle between the image source and the observation point, measured from the hemisphere base center. Compare with Eq. (1).

The principle of superposition can be used to take into account N point sources placed at $\boldsymbol{r}_n, n=1,2,\ldots,N$ instead of a single one at $\boldsymbol{r}_0$:

$$\hat{p}(\boldsymbol{r},\omega) = \sum_{n=1}^{N} \left[\hat{U}_n(\omega)\left\{\frac{e^{ik|\boldsymbol{r}-\boldsymbol{r}_n|}}{|\boldsymbol{r}-\boldsymbol{r}_n|} + \frac{e^{ik|\boldsymbol{r}-\boldsymbol{r}_n^*|}}{|\boldsymbol{r}-\boldsymbol{r}_n^*|}\right\} + \hat{p}_{\mathrm{sc},n}(\boldsymbol{r},\omega) + \hat{p}_{\mathrm{sc},n}^*(\boldsymbol{r},\omega)\right]. \tag{14}$$

III. MEASUREMENT RESULTS

Figure 3 introduces the coordinates used in the measurement setup, while Fig. 4 shows the equivalent situation from a mathematical point of view. See Appendix A for details regarding coordinate relations. Scattering from the hemisphere on the infinite plane was calculated with the help of Eq. (14) by modeling the loudspeaker as a cluster of monopoles, further discussed in Sec. IV A. The measured scattered part was determined by subtracting the result with the hemisphere present to the result with the hemisphere absent.

Loudness is roughly independent of the energy distribution inside critical bands,[9] whose width above 500 Hz approximates to one-third octave. In the comparison between measurement and model, a one-third octave smoothing was therefore applied, see Eq. (B1). Figure 5 shows typical results for comparisons in both the time and frequency domains. In Table I, results for all comparisons between the measured and modeled scattered parts are compiled in terms of a single value, ΔL_{MA}, see Eq. (B3). A compilation of

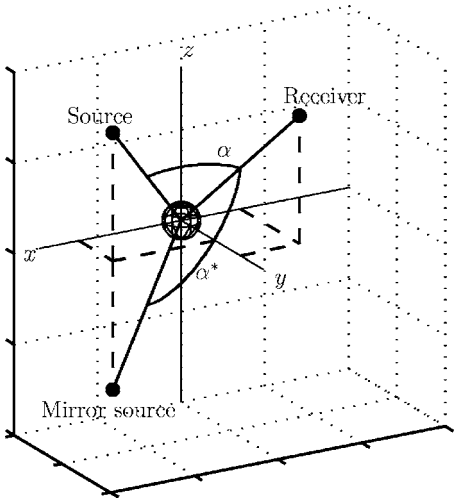

FIG. 4. A situation that is mathematically equivalent to the one in Fig. 3 for $z \geq 0$.

graphs similar to those in Fig. 5 for every measurement is available.[6] In order to analyze the measurements group wise, instead of individually, a number of scattering cases were defined:

- Backscattering: $\alpha \leq 90^\circ$ and $\alpha^* \leq 90^\circ$,
- Forward scattering: $\alpha \geq 90^\circ$ and $\alpha^* \geq 90^\circ$,
- Mixed scattering: $\alpha \leq 90^\circ$ and $\alpha^* \geq 90^\circ$, or $\alpha \geq 90^\circ$ and $\alpha^* \leq 90^\circ$,
- In-plane: $\boldsymbol{r}, \boldsymbol{r}_a, \boldsymbol{r}_0$, and $\boldsymbol{r}_0^*$ all in the same plane,
- Off-plane: $\boldsymbol{r}, \boldsymbol{r}_a, \boldsymbol{r}_0$, and $\boldsymbol{r}_0^*$ *not* in the same plane.

Moreover, focusing occurs for $\alpha^* = 180^\circ$. Table II shows ΔL_{MA} for different groups of measurements. The repeatability of measurements is studied in Table III in terms of standard deviations of ΔL_{MA} for measurements that ideally should yield identical results due to geometrical symmetry.

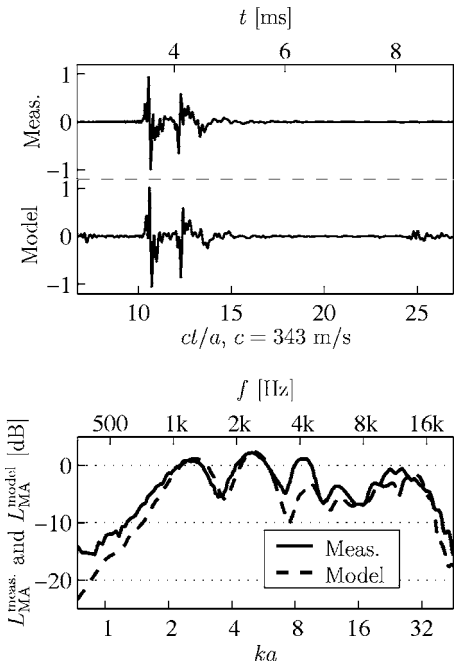

FIG. 5. Typical example of scattered field: $\theta_0 = 0^\circ$, $\theta = 30^\circ$, and $\varphi = 90^\circ$. Frequency response (arbitrary normalization): $L_{\mathrm{MA}}^{\mathrm{meas.}}$ (continuous) and $L_{\mathrm{MA}}^{\mathrm{model}}$(dashed). Transient response (normalized to $\max|p_{\mathrm{model}}|$): Measurement (upper) and model (lower).

IV. DISCUSSION

A. Directivity measurements

Equation (14) can be used to compare measurements with theory if the loudspeaker is modeled as a cluster of monopoles. In the scattering measurements, a cylindrical loudspeaker was used as a sound source. The transient response was measured a full circle around the loudspeaker at 5° steps in an anechoic chamber. Measurements showed that the loudspeaker directivity was approximately axially symmetric. For simplicity, the monopoles were therefore placed along the symmetry axis. Using a linear least-squares fit method,[10] the amplitudes and phases of the monopoles were adjusted to reproduce the directivity measurements. Figure 6 indicates that the cluster of monopoles could reproduce the

$\theta=90^\circ$	0.2	0.6	0.4	0.3	0.3	0.4	0.3

directivity well at the measurement positions. Since the loudspeaker was directed toward the hemisphere base center in all measurements, it was sufficient to use directivity measurements for the angles $0^\circ, 5^\circ, \ldots, 30^\circ$ relative to the loudspeaker front. This reduced the number of monopoles that needed to be used, and so reduced calculation time.

Although the amplitudes and phases have been adjusted to reproduce the directivity at the measurement positions, it is not certain that the cluster of monopoles may reproduce the loudspeaker directivity at other positions. This results in an error, whose contribution to the discrepancies in Table I is unknown. The method has been studied extensively,[7,11,12] but a definitive scheme for choosing the number and placement of the monopoles has not been proposed.[13]

B. The sphere — theoretical sensitivity study

A sensitivity study for small variations of transducer positions was made in order to assess what accuracy to expect when theory is to be compared with measurements. Figure 7 shows some typical results for the scattered part in the case of the sphere. Because of the principle of superposition, this applies for hemispheres on planes too, see Eq. (12). One notices that the scattered field becomes stronger and varies more as α increases. Because of symmetry, strong focusing occurs around $\alpha=180^\circ$, which may make scattering phenomena audible even at long distances for spheres.

Table IV shows that small variations in α ($\pm 5^\circ$ in steps of 1°) may result in large variations for the scattered field, especially for large values of α and high frequencies. One notices that the variations are largest around $\alpha_0=150^\circ$. This corresponds well to α_s, the angle that separates the optically illuminated region to the optical shadow:

$$\alpha_s = \arccos\frac{a}{|\boldsymbol{r}_0-\boldsymbol{r}_a|} + \arccos\frac{a}{|\boldsymbol{r}-\boldsymbol{r}_a|} = 154^\circ. \qquad (15)$$

To conclude, slightly inaccurate transducer positions in measurements may result in arge errors when comparing with theory, especially when either α and/or α^* is close to α_s.

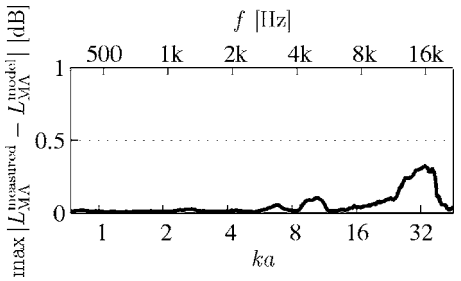

FIG. 6. Reproduction of the loudspeaker directivity with a cluster of monopoles. The graph shows $\max|L_{\mathrm{MA}}^{\mathrm{measured}}-L_{\mathrm{MA}}^{\mathrm{model}}|$ over all angles $0^\circ, 5^\circ, \ldots, 30^\circ$ re frontal.

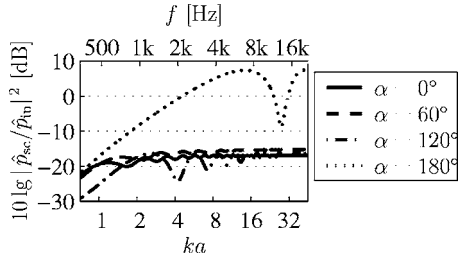

FIG. 7. $10\lg|\hat{p}_{\mathrm{sc}}/\hat{p}_{\mathrm{in}}|^2$ for the angles $\alpha=0^\circ, 60^\circ, 120^\circ$, and 180°, respectively. In all four cases, $|\boldsymbol{r}-\boldsymbol{r}_a|=3a, |\boldsymbol{r}_0-\boldsymbol{r}_a|=9a$, with $a=0.115$ m. Results for $1/\sqrt{2}\leq ka\leq 32\sqrt{2}$ (600 values, logarithmic spacing) where $k=2\pi f/c$ and $c=343$ m/s.

C. Scattering measurements

On average, the measurements and calculations show good agreement; with ΔL_{MA} typically less than 3 dB for most scattering cases. Therefore, although normal hearing subjects typically show a level-difference threshold around 1.5 dB for similar cases,[14] masking from other reflections suggests that this threshold is higher for applications in room acoustics. Since the scattered part $\hat{p}_{\mathrm{sc}}+\hat{p}_{\mathrm{sc}}^*$ is always accompanied by the incident field and the reflection from the infinite plane $\hat{p}_{\mathrm{in}}+\hat{p}_{\mathrm{in}}^*$, significant masking is expected. Except for focusing, i.e., around $\alpha^*=180^\circ$, the scattered sound pressure level is of the order of 20 dB weaker than the incident field, see Fig. 7.

Results are worse for forward scattering, which is expected since the results are sensitive for large angles α and

TABLE IV. Small angular variations may lead to large variations in $10\lg|\hat{p}_{\mathrm{sc}}/\hat{p}_{\mathrm{in}}|^2$. First, octave band averages (centered around $ka=1,2,4,8,16$, and 32) of $|\hat{p}_{\mathrm{sc}}/\hat{p}_{\mathrm{in}}|^2$ were calculated for $\alpha=0^\circ, 1^\circ, 2^\circ, \ldots, 180^\circ$. The table entries show (in decibels) how much these averages vary in the intervals $\alpha\in[\alpha_0-5^\circ, \alpha_0+5^\circ]$. In all calculations $|\boldsymbol{r}-\boldsymbol{r}_a|=3a, |\boldsymbol{r}_0-\boldsymbol{r}_a|=9a$, with $a=0.115$ m. Results for $1/\sqrt{2}\leq ka\leq 32\sqrt{2}$ (600 values, logarithmic spacing) where $k=2\pi f/c$ and $c=343$ m/s.

α^*. More surprising, from this point of view, is that backscattering results are worse than the total average, too. This could be related to the fact that the microphone generally is closer to the loudspeaker for backscattering in comparison with other cases, and that the loudspeaker enclosure itself may reflect sound. The loudspeaker is however modeled as a number of infinitesimally small monopole sources, that cannot by themselves scatter any secondary incident waves (see Fig. 8).

The number of samples are fewer for low octaves, since the measurements were made with constant sampling frequency. Larger discrepancies are therefore to be expected at the lower octave bands. Another factor that may affect the magnitude of the discrepancies is the averaging process.[15] In comparison with $\Delta L_{\mathrm{MA}}, \Delta L_{\mathrm{MG}}$ enhances peaks and ignores dips to a higher degree (see Appendix B). Table V shows that ΔL_{MG} produces better overall numerical agreement.

As a final comment, significantly better agreements could be achieved by assuming that the measurements for $\theta_0 = 60^\circ$ actually had been carried out for $\theta_0 = 55^\circ$. The improved statistics for those measurements are shown in Table VI and illustrates the sensitivity to small angular variations well.

V. CONCLUSION

Scattering phenomena play an important part in determining the acoustic quality of auditoria, although its relation to, e.g., diffusion is not yet understood.[16] Accurate scattering models are available through boundary element models for example, but they are not fast enough for use in prediction of concert halls acoustics,[17] whose size often exceeds 20000 m^3. As a result, the necessary accuracy needed for auralization purposes is largely unknown.

To address the mentioned challenges, scattering of sound from a hemisphere on a plane was measured and the results compared with the boss model — a combination of the method of images and separation of variables. The hemispherical shape was chosen partly because an analytical reference solution for Neumann boundary conditions with point source excitation exists. Together with the principle of superposition, the point source excitation model was sufficient, since the loudspeaker directivity was modeled as a cluster of point sources. Moreover, since many objects designed to scatter sound in auditoria are rigid and immobile, solutions for Neumann boundary conditions are applicable in many situations of practical interest. Another reason was that scattering from hemispheres may be significant even at long distances because it focuses sound from the virtual image source, and this may find useful applications in the design of auditoria.

Motivated by psychoacoustic results,[9] which states that loudness is roughly independent of the energy distribution inside critical bands, a moving one-third octave band level smoothing was applied for more relevant comparison between measured and theoretical results. In this case, mean intensity level errors typically less than 3 dB were obtained. These results are promising, but whether this accuracy is sufficient or not in each situation of practical interest can ultimately be answered only by psychoacoustic experiments. An important result was, however, that small variations in transducer positions could lead to large variations in the results; an inherent physical phenomenon that cannot be circumvented by alternative modeling methods.

ACKNOWLEDGMENTS

This work would not have been possible without the research funding provided by Vetenskapsrådet. The authors also wish to thank Christopher Cichetti and Jovanie Zayas at Worcester Polytechnic Institute who performed all the measurements during their stay at the department, and their major advisor, Professor Richard H. Campbell.

APPENDIX A: MEASUREMENT COORDINATE SYSTEM

A spherical coordinate system (x, y, z) is used to identify the microphone and loudspeaker center positions $\boldsymbol{r} = (r, \theta, \varphi)$ and $\boldsymbol{r}_0 = (r_0, \theta_0, \varphi_0)$, (see Figs. 3 and 4).

$$\begin{cases} x = r \sin\theta \cos\varphi, \\ y = r \sin\theta \sin\varphi, \\ z = r \cos\theta. \end{cases} \tag{A1}$$

The hemisphere base center lies in the origin, and the z axis (and $\boldsymbol{n}$) is pointing upward from the concrete floor. This implies that $\varphi_0^* = \varphi_0$ and $\theta_0^* = \pi - \theta_0$. The relations between $(\theta, \varphi), (\theta_0, \varphi_0), (\theta_0^*, \varphi_0^*), \alpha$, and α^* become

$$\cos\alpha = \sin\theta \sin\theta_0 \cos(\varphi - \varphi_0) + \cos\theta \cos\theta_0, \tag{A2}$$

$$\cos \alpha^* = \sin \theta \sin \theta_0 \cos(\varphi - \varphi_0) - \cos \theta \cos \theta_0. \quad \text{(A3)}$$

In all measurements, $r_0 = 9a, r = 3a, a = 11.5$ cm, and $\varphi_0 = 0°$.

APPENDIX B: VARIOUS LEVEL MEASURES

Let $\hat{u}$ be a function of ω and let $\hat{u}_{\text{ref}}$ be some reference value. We define the moving one-third octave band *arithmetic* mean level $L_{\text{MA}}[\hat{u}](\omega)$, a function of ω, as

$$L_{\text{MA}}[\hat{u}](\omega) = 10 \lg \left[\frac{1}{\omega \sqrt[3]{2}} \int_{\eta=\omega/\sqrt[6]{2}}^{\omega\sqrt[6]{2}} \left| \frac{\hat{u}(\eta)}{\hat{u}_{\text{ref}}} \right|^2 d\eta \right], \quad \text{(B1)}$$

An alternative is the moving one-third octave band *geometric* mean level $L_{\text{MG}}[\hat{u}](\omega)$:

$$L_{\text{MG}}[\hat{u}](\omega) = \frac{1}{\omega \sqrt[3]{2}} \int_{\eta=\omega/\sqrt[6]{2}}^{\omega\sqrt[6]{2}} 10 \lg \left| \frac{\hat{u}(\eta)}{\hat{u}_{\text{ref}}} \right|^2 d\eta. \quad \text{(B2)}$$

$\Delta L_{\text{MX}}[\hat{u}, \hat{v}]$ (X stands for either A or G) is a single number used to estimate the overall similarity between $\hat{u}(\omega)$ and $\hat{v}(\omega)$:

$$\Delta L_{\text{MX}}[\hat{u}, \hat{v}] = \frac{1}{\bar{\omega} - \underline{\omega}} \int_{\eta=\underline{\omega}}^{\bar{\omega}} |L_{\text{MX}}[\hat{u}](\eta) - L_{\text{MX}}[\hat{v}](\eta)| d\eta. \quad \text{(B3)}$$

(Received 16 August 2005; revised 15 February 2006; accepted 16 February 2006)

In this paper, a three-dimensional Laplace domain finite element model with four-node tetrahedral porous elements is developed and applied for the investigations. Without the incident acoustic field, the exact acoustical properties of a laterally infinite planar foam, which is backed with a rigid plane, are accurately predicted by assuming the circumferential edge constraints as rollers. It is found that the rigidity of the circumferential edge constraint has a profound effect on the predictions. If the circumferential edge constraints are all fixed, the amplitude of the first sound absorption peak is increased, and the peak is moved to a lower frequency as compared with the exact solutions. Measurements obtained by the two-microphone impedance tube method are bounded by the predictions of samples with roller as well as with fixed constraints. They are much closer to that predicted with fixed edge constraints. Upon increasing the diameter-to-thickness ratio of the sample, the influence of the fixed edge constraint is reduced. The measured acoustic results can be the representatives of the laterally infinite planar foam from which the sample was cut only if the roller edge constraint of the sample is managed or the diameter-to-thickness ratio of the sample is increased. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2185494]

I. INTRODUCTION

Acoustical properties (dynamic stiffness, acoustic impedance, reflection coefficient, and absorption coefficient) are indices for evaluating the quality of the sound absorption materials. Generally, the acoustical properties can be measured in free field,[1,2] in a reverberant room,[3] and in a tube.[4–7] Techniques of measurements in a tube mainly found are one-[4] and two-microphone[5] impedance tube techniques. The two-microphone impedance tube method is considerably automatically calibrated if the sensor switching procedure is performed. Other than the measurement techniques, analytical models generally achieved for predicting the acoustical properties of the sound absorption material are the equivalent fluid model and the sophisticated model based on Biot's theory of poroelasticity. The equivalent fluid model assumes the sound absorption material as an isotropic mixed fluid and the propagation of sound is determined by two complex quantities, the characteristic impedance and the wave number. These two quantities are empirically expressed by power law expressions of a single parameter, air resistance divided by frequency.[8,9] In the sophisticated model, the Biot theory[10–12] assumes the sound absorption material is constructed such that a solid material forms a skeleton that contains statistically distributed small pores that are filled with a Newtonian, viscous compressible fluid. The bulk material is assumed homogeneous on a macroscopic scale and the pores are assumed interconnected. The solid skeleton is taken to be linear elastic and undergoes small deformation, and the fluid inertia and the friction are characterized by the density, viscosity, and pore dimensions.

The exact acoustical property solutions to the sound absorption material are restricted to a laterally infinite, finite-thickness planar sheet.[13] Commonly, the acoustical properties of the sound absorption material with complex geometry are numerically pursued by applying the porous model coupled by an incident acoustic field with which the sound absorption material is in contact. The transmission and reflection waves that characterized acoustical properties are then solved. Based on the equivalent medium properties, the resistivity and the porosity, Craggs[14,15] examined a one-dimensional, axially symmetric acoustic absorption system for obtaining the absorption coefficient. Easwaran and Munjal[16] predicted the reflection characteristics of rectangular and conical wedges in an impedance tube. Subsequently, Chen *et al.*[17] investigated the acoustic absorption characteristics of porous materials with triangle, semicircle, and convex rectangular surface shapes. There is only one longitudinal wave to be examined, if the equivalent fluid model is applied. If the prediction and the design of acoustical properties of the sound absorption material are mainly considered, methods that combine the acoustic field with the Biot theory are more effective. Behaviors of two longitudinal waves and one shear wave in the porous material can be examined with the use of Biot theory.[11] Using the Biot complete poroelastic theory, Kang and Bolton[18–20] studied the optimal design of axisymmetric foam wedges and examined the effect of the circumferential edge constraint on the absorption coefficient as well as the vibration modes of a porous material sample placed in the standing wave tube. In any case, the incident acoustic field is needed to perform simulations.

Numerous researchers[6,7,19,21–23] have found the acoustical properties measured from an impedance tube strongly

dependent on the uniformity as well as the circumferential edge of the sample, and the backing between the sample and the end-cap of the tube. The measured results are different from those of the laterally infinite, finite-thickness planar sheet from which the samples were cut. It has been numerically and experimentally revealed[19,21] that with the edge constraint effects applied, the predictions are much closer to the measurements than those of the unconstrained predictions. Heretofore, the numerical methods usually applied are the two-dimensional finite element methods. However, with the influence of the circumferential edge constraint, it is unlikely that a two-dimensional result is representative of that of a sample of three-dimensional shape (a cylindrical porous column with low diameter-to-thickness ratio).

In this paper, a new approach using an impulse excitation to examine the influence of the circumferential edge constraint on the three-dimensional acoustic frequency response functions of a rigidly backed polyurethane foam sample placed in the impedance tube is presented. Using this method, the efforts on calculating the incident acoustic field can be omitted. During the analysis, Biot's poroelastic dynamic equation set is first transferred to the Laplace domain. Thereafter the four-node tetrahedral porous elements are used for deriving the three-dimensional finite element equations. After applying a uniformly distributed impulse pressure excitation to the surface of the foam sample, the displacement response at the surface is then calculated by the derived Laplace domain finite element equations. The acoustic response of the foam sample is characterized by a dynamic transfer function $[T(s)]$ that is defined as the ratio of the transformed impulsive pressure excitation $[I(s)]$ to the transformed displacement response $[O(s)]$. Upon obtaining the dynamic transfer function, frequency response functions of the sample representing the dynamic stiffness, surface impedance, reflection, and absorption coefficients in the frequency domain can be obtained by simply replacing the Laplace transform parameter s by $j\omega$ where ω is the radial frequency.[13,24,25] Subsequently, with the use of the roller circumferential edge constraint, the acoustical properties of a planar, laterally infinite, and rigidly backed open-cell polyurethane foam with permeable upper surface are validated first. Then, the influences of the fixed circumferential edge constraint and the diameter-to-thickness ratio on the acoustical properties of polyurethane foam samples are examined. Comparisons of results predicted with those measured by the two-microphone impedance tube method are made as well.

II. THEORY

A. Governing equations of foams

In this work, Biot's theory of poroelasticity is employed to simulate the dynamic behaviors of polyurethane foam samples placed in the impedance tube. The equations governing the deformation of poroelastic material are written as

$$N\nabla^2\mathbf{u} + \nabla[(A+N)e + Q\varepsilon] = \rho_{11}\ddot{\mathbf{u}} + \rho_{12}\ddot{\mathbf{U}} + b(\dot{\mathbf{u}} - \dot{\mathbf{U}}), \quad (1)$$

$$\nabla(Qe + R\varepsilon) = \rho_{12}\ddot{\mathbf{u}} + \rho_{22}\ddot{\mathbf{U}} - b(\dot{\mathbf{u}} - \dot{\mathbf{U}}), \quad (2)$$

where N, A, Q, R are elastic constants, b is the dissipation coefficient. $\mathbf{u}$ is the average solid skeleton displacement vector, and $\mathbf{U}$ is the average fluid displacement vector. Similarly, the solid dilatation e and the fluid dilatation ε are defined in the usual manner for small deformation. ∇^2 is the Laplacian and ∇ is the gradient. The quantities ρ_{11}, ρ_{22}, and ρ_{12} are apparent mass densities. ρ_{11} represents the total effective mass of the solid moving in the fluid, ρ_{22} represents the total effective mass of that part of the fluid, and ρ_{12} represents a mass coupling parameter between the fluid and the solid.[11] When there is no relative motion between the fluid and solid skeleton, it is found that $\rho = \rho_{11} + \rho_{22} + 2\rho_{12}$. Here, ρ denotes the total mass density of the fluid-saturated elastic foam. ρ can be expressed in terms of the mass density of solid ρ_s, the mass density of fluid ρ_f, and the porosity ϕ as $\rho = (1-\phi)\rho_s + \phi\rho_f$.

The dynamic behavior of the cylindrical polyurethane foam sample in the impedance tube is investigated by assuming its lower surface fixed on the infinite rigid end-cap and subjected to a uniform distributed impulsive sound pressure loading on its permeable upper surface. The cylindrical sample of diameter D and thickness H is presented in Fig. 1. In the figure, p_o is the amplitude of the pressure loading and $\delta(t)$ is the impulse at time t. The foam considered is assumed to be deformed from the initially un-deformed position and all stresses are zero if the foam is stress free at the initial state.

Taking the Laplace transform with respect to the time variable of Eqs. (1) and (2) and then using the initial condi-

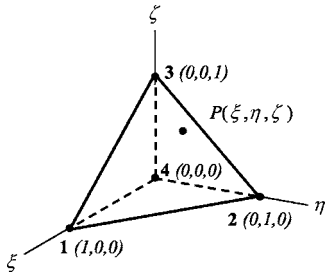

FIG. 3. Four-node master element in ξ, η, and ζ space.

tions mentioned and the Cartesian coordinates shown, the dynamic equations for the three-dimensional foam problems yields

$$L_1(\bar{u}_x,\bar{u}_y,\bar{u}_z,\bar{U}_x,\bar{U}_y,\bar{U}_z) = N\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\bar{u}_x + (A+N)\frac{\partial}{\partial x}\left(\frac{\partial \bar{u}_x}{\partial x}+\frac{\partial \bar{u}_y}{\partial y}+\frac{\partial \bar{u}_z}{\partial z}\right) + Q\frac{\partial}{\partial x}\left(\frac{\partial \bar{U}_x}{\partial x}+\frac{\partial \bar{U}_y}{\partial y}+\frac{\partial \bar{U}_z}{\partial z}\right) - s^2(\rho_{11}\bar{u}_x+\rho_{12}\bar{U}_x) - bs(\bar{u}_x-\bar{U}_x)=0, \quad (3)$$

$$L_2(\bar{u}_x,\bar{u}_y,\bar{u}_z,\bar{U}_x,\bar{U}_y,\bar{U}_z) = N\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\bar{u}_y + (A+N)\frac{\partial}{\partial y}\left(\frac{\partial \bar{u}_x}{\partial x}+\frac{\partial \bar{u}_y}{\partial y}+\frac{\partial \bar{u}_z}{\partial z}\right) + Q\frac{\partial}{\partial y}\left(\frac{\partial \bar{U}_x}{\partial x}+\frac{\partial \bar{U}_y}{\partial y}+\frac{\partial \bar{U}_z}{\partial z}\right) - s^2(\rho_{11}\bar{u}_y+\rho_{12}\bar{U}_y) - bs(\bar{u}_y-\bar{U}_y)=0, \quad (4)$$

$$L_3(\bar{u}_x,\bar{u}_y,\bar{u}_z,\bar{U}_x,\bar{U}_y,\bar{U}_z) = N\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\bar{u}_z + (A+N)\frac{\partial}{\partial z}\left(\frac{\partial \bar{u}_x}{\partial x}+\frac{\partial \bar{u}_y}{\partial y}+\frac{\partial \bar{u}_z}{\partial z}\right) + Q\frac{\partial}{\partial z}\left(\frac{\partial \bar{U}_x}{\partial x}+\frac{\partial \bar{U}_y}{\partial y}+\frac{\partial \bar{U}_z}{\partial z}\right) - s^2(\rho_{11}\bar{u}_z+\rho_{12}\bar{U}_z) - bs(\bar{u}_z-\bar{U}_z)=0, \quad (5)$$

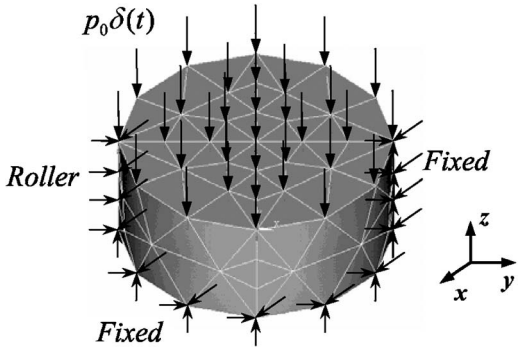

FIG. 4. Boundary conditions of a three-dimensional polyurethane foam.

$$L_4(\bar{u}_x,\bar{u}_y,\bar{u}_z,\bar{U}_x,\bar{U}_y,\bar{U}_z) = \frac{\partial}{\partial x}\left[Q\left(\frac{\partial \bar{u}_x}{\partial x}+\frac{\partial \bar{u}_y}{\partial y}+\frac{\partial \bar{u}_z}{\partial z}\right)+R\left(\frac{\partial \bar{U}_x}{\partial x}+\frac{\partial \bar{U}_y}{\partial y}+\frac{\partial \bar{U}_z}{\partial z}\right)\right] - s^2(\rho_{12}\bar{u}_x+\rho_{22}\bar{U}_x) + bs(\bar{u}_x-\bar{U}_x)=0, \quad (6)$$

$$L_5(\bar{u}_x,\bar{u}_y,\bar{u}_z,\bar{U}_x,\bar{U}_y,\bar{U}_z) = \frac{\partial}{\partial y}\left[Q\left(\frac{\partial \bar{u}_x}{\partial x}+\frac{\partial \bar{u}_y}{\partial y}+\frac{\partial \bar{u}_z}{\partial z}\right)+R\left(\frac{\partial \bar{U}_x}{\partial x}+\frac{\partial \bar{U}_y}{\partial y}+\frac{\partial \bar{U}_z}{\partial z}\right)\right] - s^2(\rho_{12}\bar{u}_y+\rho_{22}\bar{U}_y) + bs(\bar{u}_y-\bar{U}_y)=0, \quad (7)$$

$$L_6(\bar{u}_x,\bar{u}_y,\bar{u}_z,\bar{U}_x,\bar{U}_y,\bar{U}_z) = \frac{\partial}{\partial z}\left[Q\left(\frac{\partial \bar{u}_x}{\partial x}+\frac{\partial \bar{u}_y}{\partial y}+\frac{\partial \bar{u}_z}{\partial z}\right)+R\left(\frac{\partial \bar{U}_x}{\partial x}+\frac{\partial \bar{U}_y}{\partial y}+\frac{\partial \bar{U}_z}{\partial z}\right)\right] - s^2(\rho_{12}\bar{u}_z+\rho_{22}\bar{U}_z) + bs(\bar{u}_z-\bar{U}_z)=0, \quad (8)$$

where $\bar{u}_x$, $\bar{u}_y$, $\bar{u}_z$, $\bar{U}_x$, $\bar{U}_y$, and $\bar{U}_z$ are the Laplace transforms of displacement components of the solid skeleton (u_x,u_y,u_z) and the fluid (U_x,U_y,U_z), respectively. s above is the Laplace transform parameter.

B. Finite element model

The Galerkin finite element method is applied to obtain the acoustical properties of polyurethane foam samples in the study. Figure 2 shows a four-node tetrahedral porous element. $P(x,y,z)$ in Fig. 2 represents an arbitrary point within an element. If three Cartesian components of displacement of the solid skeleton and of fluid at each node are defined, the four-node tetrahedral porous element will have 24 degrees of freedom, given by the column vector of displacements $[\mathbf{q}]=[q_1,\ldots,q_{24}]^T$.

In terms of a natural coordinate system (ξ, η, ζ), the tetrahedral porous element defined with reference to the Cartesian coordinate system (x, y, z) can then be transformed into a master element as shown in Fig. 3. $P(\xi, \eta, \zeta)$ becomes the coordinate system transformation of $P(x, y, z)$. According to the natural coordinates defined, four Lagrange-type shape functions for the tetrahedral element can be written as

$$N_1 = \xi,$$

$$N_2 = \eta,$$

$$N_3 = \zeta, \tag{9}$$

$$N_4 = 1 - \xi - \eta - \zeta.$$

With the use of the column vector of displacements $[\mathbf{q}]$ and shape functions defined, solid skeleton and fluid displacement components can be written in a compact form as

$$[\mathbf{u}] = [\mathbf{N}][\mathbf{q}], \tag{10}$$

where $[\mathbf{u}]=[\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z]^T$ and $[\mathbf{N}]$ is the shape function matrix. The shape function matrix for the tetrahedral element can be written as

$$[\mathbf{N}] = \begin{bmatrix} [\mathbf{N}]_1 \\ [\mathbf{N}]_2 \\ [\mathbf{N}]_3 \\ [\mathbf{N}]_4 \\ [\mathbf{N}]_5 \\ [\mathbf{N}]_6 \end{bmatrix} = \begin{bmatrix} N_1 & & 0 & N_2 & & 0 & N_3 & & 0 & N_4 & & 0 \\ 0 & N_1 & 0 & 0 & N_2 & 0 & 0 & N_3 & 0 & 0 & N_4 & 0 \\ 0 & 0 & \cdots 0 & 0 & 0 & \cdots 0 & 0 & 0 & \cdots 0 & 0 & 0 & \cdots 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & N_1 & 0 & 0 & N_2 & 0 & 0 & N_3 & 0 & 0 & N_4 \end{bmatrix}.$$

Then, following the Galerkin approach, the equation governing the behavior of an element becomes

$$\begin{aligned} \sum_{e=1}^{n} \int_{V_e} & [\mathbf{N}]_1^T L_1(\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z) \\ & + [\mathbf{N}]_2^T L_2(\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z) \\ & + [\mathbf{N}]_3^T L_3(\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z) \\ & + [\mathbf{N}]_4^T L_4(\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z) \\ & + [\mathbf{N}]_5^T L_5(\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z) \\ & + [\mathbf{N}]_6^T L_6(\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z) dV = 0. \end{aligned} \tag{11}$$

If we integrate Eq. (11) by parts using the Green-Gauss theorem or the divergence theorem and then summarize the results, we obtain

$$\begin{aligned} \sum_{e=1}^{n} \int_{V_e} & [[N]_1^T, [N]_2^T, [N]_3^T, [N]_4^T, [N]_5^T, [N]_6^T] \\ & \times \begin{Bmatrix} s^2(\rho_{11}\bar{u}_x + \rho_{12}\bar{U}_x) + bs(\bar{u}_x - \bar{U}_x) \\ s^2(\rho_{11}\bar{u}_y + \rho_{12}\bar{U}_y) + bs(\bar{u}_y - \bar{U}_y) \\ s^2(\rho_{11}\bar{u}_z + \rho_{12}\bar{U}_z) + bs(\bar{u}_z - \bar{U}_z) \\ s^2(\rho_{12}\bar{u}_x + \rho_{22}\bar{U}_x) - bs(\bar{u}_x - \bar{U}_x) \\ s^2(\rho_{12}\bar{u}_y + \rho_{22}\bar{U}_y) - bs(\bar{u}_y - \bar{U}_y) \\ s^2(\rho_{12}\bar{u}_z + \rho_{22}\bar{U}_z) - bs(\bar{u}_z - \bar{U}_z) \end{Bmatrix} dV \\ & - \sum_{e=1}^{n} \int_{l_e} [[\mathbf{N}]_1^T, [\mathbf{N}]_2^T, [\mathbf{N}]_3^T, [\mathbf{N}]_4^T, [\mathbf{N}]_5^T, [\mathbf{N}]_6^T] \\ & \times \begin{Bmatrix} \bar{\sigma}_{xx} l_x + \bar{\tau}_{xy} l_y + \bar{\tau}_{xz} l_z \\ \bar{\tau}_{xy} l_x + \bar{\sigma}_{yy} l_y + \bar{\tau}_{yz} l_z \\ \bar{\tau}_{xz} l_x + \bar{\tau}_{yz} l_x + \bar{\sigma}_{zz} l_z \\ \bar{\sigma} l_x \\ \bar{\sigma} l_y \\ \bar{\sigma} l_z \end{Bmatrix} dl + \sum_{e=1}^{n} \int_{V_e} [\mathbf{k}]^T [\hat{\mathbf{q}}] dV = 0 \end{aligned} \tag{12}$$

where $\bar{\sigma}_{xx}$, $\bar{\sigma}_{yy}$, $\bar{\sigma}_{zz}$, $\bar{\tau}_{xy}$, $\bar{\tau}_{xz}$, $\bar{\tau}_{yz}$, and $\bar{\sigma}$ are the Laplace transforms of σ_{xx}, σ_{yy}, σ_{zz}, τ_{xy}, τ_{xz}, τ_{yz}, and σ, respectively. σ_{xx}, σ_{yy}, σ_{zz}, τ_{xy}, τ_{xz}, and τ_{yz} are stresses acting on the solid skeleton of the foam and σ is the stress of the air in the foam;

$$[\hat{\mathbf{q}}] = \left\{ \frac{\partial \bar{u}_x}{\partial x}, \frac{\partial \bar{u}_x}{\partial y}, \frac{\partial \bar{u}_x}{\partial z}, \frac{\partial \bar{u}_y}{\partial x}, \frac{\partial \bar{u}_y}{\partial y}, \frac{\partial \bar{u}_y}{\partial z}, \frac{\partial \bar{u}_z}{\partial x}, \frac{\partial \bar{u}_z}{\partial y}, \frac{\partial \bar{u}_z}{\partial z}, \right.$$
$$\left. \frac{\partial \bar{U}_x}{\partial x}, \frac{\partial \bar{U}_x}{\partial y}, \frac{\partial \bar{U}_x}{\partial z}, \frac{\partial \bar{U}_y}{\partial x}, \frac{\partial \bar{U}_y}{\partial y}, \frac{\partial \bar{U}_y}{\partial z}, \frac{\partial \bar{U}_z}{\partial x}, \frac{\partial \bar{U}_z}{\partial y}, \frac{\partial \bar{U}_z}{\partial z} \right\}^T,$$

$$[\mathbf{k}] = [k_1, k_2, k_3, k_4, k_5, k_6, k_7, k_8, k_9, k_{10}, 0, 0, 0, k_{11}, 0, 0, 0, k_{12}],$$

in which

$$k_1 = (A + 2N) \frac{\partial [N]_1^T}{\partial x} + A \left(\frac{\partial [N]_2^T}{\partial y} + \frac{\partial [N]_3^T}{\partial z} \right) + Q \left(\frac{\partial [N]_4^T}{\partial x} + \frac{\partial [N]_5^T}{\partial y} + \frac{\partial [N]_6^T}{\partial z} \right),$$

$$k_2 = k_4 = \left(\frac{\partial [N]_1^T}{\partial y} + \frac{\partial [N]_2^T}{\partial x} \right),$$

$$k_3 = k_7 = \left(\frac{\partial [N]_1^T}{\partial z} + \frac{\partial [N]_3^T}{\partial x} \right),$$

$$k_5 = (A + 2N) \frac{\partial [N]_2^T}{\partial y} + A \left(\frac{\partial [N]_1^T}{\partial x} + \frac{\partial [N]_3^T}{\partial z} \right) + Q \left(\frac{\partial [N]_4^T}{\partial x} + \frac{\partial [N]_5^T}{\partial y} + \frac{\partial [N]_6^T}{\partial z} \right),$$

$$k_6 = k_8 = \left(\frac{\partial [N]_2^T}{\partial z} + \frac{\partial [N]_3^T}{\partial y} \right),$$

$$k_9 = (A + 2N) \frac{\partial [N]_3^T}{\partial z} + A \left(\frac{\partial [N]_1^T}{\partial x} + \frac{\partial [N]_2^T}{\partial y} \right) + Q \left(\frac{\partial [N]_4^T}{\partial x} + \frac{\partial [N]_5^T}{\partial y} + \frac{\partial [N]_6^T}{\partial z} \right),$$

and

$$k_{10} = k_{11} = k_{12} = Q \left(\frac{\partial [N]_1^T}{\partial x} + \frac{\partial [N]_2^T}{\partial y} + \frac{\partial [N]_3^T}{\partial z} \right) + R \left(\frac{\partial [N]_4^T}{\partial x} + \frac{\partial [N]_5^T}{\partial y} + \frac{\partial [N]_6^T}{\partial z} \right).$$

Substituting shape functions [Eq. (9)] and displacement components [Eq. (10)] into Eq. (12) and rearranging terms gives

$$\sum_{e=1}^{n} \{ [\mathbf{K}^{(e)}][\mathbf{q}] - [\mathbf{F}^{(e)}] \} = 0, \tag{13}$$

where $[\mathbf{K}^{(e)}]$ is the stiffness coefficient matrix for the element and $[\mathbf{F}^{(e)}]$ may be viewed as the loading vector which contains boundary conditions.

The three-dimensional foam sample can be analyzed by discretizing it with finite elements. The equations of individual elements would then be assembled to form the equation of the foam. After manipulation, the Laplace domain finite element equation of the foam is simplified as

$$[\mathbf{K}^*][\mathbf{q}^*] = [\mathbf{F}^*], \tag{14}$$

where $[\mathbf{K}^*]$ is the global stiffness matrix, $[\mathbf{q}^*]$ is the global displacement vector, and $[\mathbf{F}^*]$ is the global loading vector. Once the Laplace transformed dynamic stiffness $\bar{K}$ of the foam sample is calculated, the Laplace transformed surface acoustic impedance $\bar{Z}$, the reflection coefficient R_0, and the sound absorption coefficient A_0 for the normal incidence case can be defined as

$$\bar{Z}(s) = \frac{-p_0}{(1-\phi) s \bar{\mathbf{u}}|_{z=\mathrm{H}} + \phi s \bar{\mathbf{U}}|_{z=\mathrm{H}}} = \frac{\bar{K}(s)}{s}, \tag{15}$$

$$R_0 = \frac{\bar{Z} - Z_{\mathrm{air}}}{\bar{Z} + Z_{\mathrm{air}}} = \frac{\bar{K}(s)/s - Z_{\mathrm{air}}}{\bar{K}(s)/s + Z_{\mathrm{air}}}, \tag{16}$$

$$A_0 = 1 - |R_0|^2, \tag{17}$$

where Z_{air} is the characteristic impedance of air. Frequency response functions of K, Z, R_0, and A_0 can then be rapidly obtained by replacing the Laplace transform parameter s that appears in Eqs. (15)–(17) by $j\omega$, where ω is the radial frequency.

C. Boundary conditions in Laplace domain

As shown in Fig. 4, the impulsive sound pressure loading applied on the upper surface of the foam sample is presented as $p = p_o \delta(t)$. If the top surface of the foam is permeable, the pressure loading is shared by the solid skeleton and the fluid of the three-dimensional sample depending on the porosity. Thus, the boundary conditions of the top surface after the Laplace transform can be described as $\bar{\sigma}_f = \phi p_o$ and $\bar{\sigma}_s = (1-\phi) p_o$. The lower surface is presumed to be fixed on an infinite rigid plane. Hence, the Laplace transformed solid skeleton and fluid displacements ($\bar{u}_x$, $\bar{u}_y$, $\bar{u}_z$, $\bar{U}_x$, $\bar{U}_y$, and $\bar{U}_z$) must be zero on this face.

The constraints on the circumferential edge of the foam sample can be set as rollers for simulating a laterally infinite, finite-thickness planar foam. The roller condition implies that the node can freely move up and down but not to the side as shown on the left of the foam sample in Fig. 4; hence, the Laplace transformed solid skeleton and fluid displacements in x and y coordinates, $\bar{u}_x$, $\bar{u}_y$, $\bar{U}_x$, and $\bar{U}_y$, are zero on the circumferential edge. For the case that the circumferential edge is fully constrained, the node constraint can be simulated as fixed as shown on the right of the foam sample. Same as the boundary conditions of the lower surface, fixed condition implies that the solid skeleton and fluid displacements are zero on the surface.

III. MATERIAL PROPERTIES OF POLYURETHANE FOAM

In order to predict the acoustical properties in terms of frequency response functions, the apparent mass densities ρ_{11}, ρ_{12}, ρ_{22}, the dissipation coefficient b, and the elastic constants N, A, Q, R that appeared in Eqs. (1) and (2) can all be related to the foam constituents, the mass density of solid ρ_s, the mass density of fluid ρ_f, porosity ϕ, tortuosity α_∞, pore cross-section shape correction factor c, and DC flow resistivity σ_0. The typical material properties of the polyurethane foam saturated with air are summarized by Tsay and Yeh[13] and presented as follows.

The coupling apparent mass ρ_{12} can be represented by porosity, tortuosity, and the mass density of fluid as

$$\rho_{12} = -\phi \rho_f (\alpha_\infty - 1). \tag{18}$$

The total effective masses of the solid ρ_{11} and fluid ρ_{22} are defined accordingly as

$$\rho_{11} = (1-\phi)\rho_s - \rho_{12}, \tag{19}$$

$$\rho_{22} = \phi \rho_f - \rho_{12}. \tag{20}$$

The porosity of polyurethane foam is around 0.75–0.99 and the density is in the range of 20–300 kg/m^3 usually.

TABLE I. Measured and estimated (*) material properties of polyurethane foams.[13]

	Porosity ϕ	Shear modulus N (10^4 N/m^2)	Poisson coefficient ν	DC flow resistivity σ_o (N.s/m^4)	Tortuosity α_∞	Density of frame ρ_s (kg/m^3)	Shape factor c	Thickness of foam H (m)
Foam 1	0.95	175(1+0.2i)	0.35*	5500	1.0*	45.7	1.0*	0.016
Foam 2	0.95	93(1+0.2i)	0.35*	5500	1.0*	45.7	1.0*	0.030
Foam 3	0.95	55(1+0.2i)	0.35*	5500	1.0*	45.7	1.0*	0.051

The Laplace transformed dissipation coefficient $\bar{b}$ defined in the dynamic poroelastic theory is formulated as

$$\bar{b} = \frac{-\bar{\sigma}_0}{4}\phi^2 \left\{ \frac{[m_{r_0} J_1(m_{r_0})]/[J_0(m_{r_0})]}{1-[2J_1(m_{r_0})]/[m_{r_0} J_0(m_{r_0})]} \right\}, \quad (21)$$

where $\bar{\sigma}_0$ is the DC flow resistivity and is expressed as $\bar{\sigma}_0 = (8c\mu\alpha_\infty)/(\phi r_0^2)$. c is a cross-section shape correction factor, μ is the viscosity of fluid (air), and r_0 is the radius of the pore. For pores of square, equilateral triangle, and rectangular slit, c is 1.07, 1.14, and 0.78, respectively. J_0 and J_1 are Bessel functions of the first kind of order zero and one. m_{r_0} in the Bessel functions is found as $m_{r_0} = c\sqrt{-8s\rho_{22}/(\bar{\sigma}_0\phi^2)}$ in which s is the Laplace transform parameter.

For most acoustic foams, elastic constants A, Q, and R can be expressed by the shear modulus of the solid skeleton in vacuum N, the bulk modulus of the solid skeleton K_b, and the bulk modulus of the air K_f as

$$A = \frac{(1-\phi)^2}{\phi}K_f + K_b - \frac{2}{3}N, \quad (22)$$

$$Q = (1-\phi)K_f, \quad (23)$$

$$R = \phi K_f. \quad (24)$$

N, K_b, and K_f are complex coefficients. K_b can be evaluated by

$$K_b = \frac{2N(1+\nu)}{3(1-2\nu)}, \quad (25)$$

where ν is the Poisson's ratio of the foam. K_f in pores inside the foam can be derived using the equation of state of air and the equation of thermal conduction of air. The Laplace transformed bulk modulus of air $\bar{K}_f$ is formulated as

$$\bar{K}_f = \frac{p_{\text{amb}}\gamma}{\gamma-(\gamma-1)\{1-2/Bm_{r_0}[J_1(Bm_{r_0})]/[J_0(Bm_{r_0})]\}}, \quad (26)$$

where p_{amb} is the ambient mean pressure, B is the square root of the Prandtl number, and $\gamma = c_p/c_v$. c_v and c_p are specific heats per unit mass at constant volume and pressure, respectively.

IV. MEASUREMENT SYSTEM

The two-microphone acoustic measurement system used for the earlier study[13] was applied for measuring the acoustical properties of foam samples. The measurement system was established according to the ASTM E1050-98 standard.[5] The system contains a driving signal generator (ACO 3024), a driving signal amplifier (LDS PA-100E), a 6-in. speaker, two impedance tubes of 0.0395- and 0.1268-m diameter, two pairs of acoustic microphones (B&K 4187) and amplifiers (Norsonic 336), and a dynamic signal analyzer (SD-390). When the reliable measurement errors are kept under 0.5 dB, the applicable frequency ranges of the small and large impedance tubes are from 100 to 4000 Hz and from 100 to 1600 Hz, respectively.

In the acoustic measurement system, the phasor of sound pressure measured at position 1 through microphone 1 can be derived as $A_1(\omega)e^{i\phi_1(\omega)}M_1(\omega)e^{i\varphi_1(\omega)}$, and the phasor of sound pressure measured at position 2 through microphone 2 is then found as $A_2(\omega)e^{i\phi_2(\omega)}M_2(\omega)e^{i\varphi_2(\omega)}$. Here, $A_1(\omega)e^{i\phi_1(\omega)}$ and $A_2(\omega)e^{i\phi_2(\omega)}$ are the phasors of the true sound pressure appeared in the positions 1 and 2. Accordingly, $M_1(\omega)e^{i\varphi_1(\omega)}$ and $M_2(\omega)e^{i\varphi_2(\omega)}$ are the phasors of the mechanical property of microphones 1 and 2, respectively. The transfer function H_{21}^o that describes the sound pressure ratio of position 2 to position 1 can be defined as $H_{21}^o(\omega) = [A_2(\omega)e^{i\theta_2(\omega)}M_2(\omega)e^{i\varphi_2(\omega)}]/[A_1(\omega)e^{i\theta_1(\omega)}M_1(\omega)e^{i\varphi_1(\omega)}]$. After the two microphones are switched and the second measurement of the same sample is performed, the phasor of sound pressure measured at position 1 through microphone 2 is $A_1(\omega)e^{i\theta_1(\omega)}M_2(\omega)e^{i\varphi_2(\omega)}$, and the phasor of sound pressure measured at position 2 through microphone 1 is $A_2(\omega)e^{i\theta_2(\omega)}M_1(\omega)e^{i\varphi_1(\omega)}$. A_1, A_2, M_1, and M_2 are amplitudes. θ_1, θ_2, φ_1, and φ_2 are phase angles. The sound pressure ratio of position 2 to position 1 after the switching of two microphones is $H_{21}^s(\omega) = [A_2(\omega)e^{i\theta_2(\omega)}M_1(\omega)e^{i\varphi_1(\omega)}]/[A_1(\omega)e^{i\theta_1(\omega)}M_2(\omega)e^{i\varphi_2(\omega)}]$. If H_{21}^o and H_{21}^s are multiplied, we can eliminate the mechanical influences of microphones 1 and 2 and receive the true sound pressure transfer function of position 2 to position 1 as $H_{21} = \sqrt{H_{21}^o H_{21}^s}$. With the use of this automatically calibrated transfer function, the reflection coefficient of the sample can be formulated[7] as

$$R_0(\omega) = \frac{H_{21} - e^{-ik_w d_m}}{e^{-ik_w d_m} - H_{21}} e^{i2k_w l_1}, \quad (27)$$

and the sound absorption coefficient is calculated subsequently ($A_0 = 1 - |R_0|^2$). In Eq. (27), k_w is the wave number of air, d_m is the length between positions 1 and 2, and l_1 is the distance measured from the base of the foam sample to position 1.

V. VALIDATION OF THE THREE-DIMENSIONAL LAPLACE DOMAIN FINITE ELEMENT METHOD

To validate the three-dimensional Laplace domain finite element method (3D LDFEM), the dynamic stiffness of a laterally infinite, finite-thickness, and planar foam backed with a rigid plane with its permeable upper surface subjected to an impulsive pressure excitation, $p_0\delta(t)$, is examined. Results predicted by the 3D LDFEM in comparison with that predicted by the 2D LDFEM[24] as well as the 1D exact results are performed. The 1D exact solution of the Laplace transformed dynamic stiffness $\bar{K}$ of the foam derived in a previous work[13] is rearranged as

$$\bar{K}(s) = \frac{-p_0}{(1-\phi)\bar{\mathbf{u}}|_{z=H} + \phi\bar{\mathbf{U}}|_{z=H}} = \frac{(\bar{P}\bar{R}-\bar{Q}^2)(C_3-C_1)}{[(1-\phi)\Delta_{11}+\phi\Delta_{31}][(1-\phi)(\bar{Q}+\bar{R}C_3)-\phi(\bar{P}+\bar{Q}C_3)]\delta_1\tanh(\delta_1 H)+[(1-\phi)\Delta_{13}+\phi\Delta_{33}][\phi(\bar{P}+\bar{Q}C_1)-(1-\phi)(\bar{Q}+\bar{R}C_1)]\delta_2\tanh(\delta_2 H)}, \tag{28}$$

where

$$\bar{P} = \bar{A} + 2\bar{N},$$

$$C_1 = \frac{-\bar{\rho}_{11}(s)^2 - \bar{b}s + \bar{P}(\delta_1)^2}{\bar{\rho}_{12}(s)^2 - \bar{b}s - \bar{Q}(\delta_1)^2},$$

$$C_3 = \frac{-\bar{\rho}_{11}(s)^2 - \bar{b}s + \bar{P}(\delta_2)^2}{\bar{\rho}_{12}(s)^2 - \bar{b}s - \bar{Q}(\delta_2)^2},$$

$$\delta_1 = \pm\sqrt{\frac{s\psi_4}{2\bar{\beta}_1}}, \quad \delta_2 = \pm s\sqrt{\frac{2\psi_2}{\psi_4}},$$

$$\psi_1 = \bar{\alpha}_1 s + \bar{\beta}_2,$$

$$\psi_2 = \bar{\rho}_0 s + \bar{b}\bar{\rho}, \quad \psi_3 = (\psi_1)^2 - 4\bar{\beta}_1 s(\psi_2), \quad \psi_4 = \sqrt{\psi_3} + \psi_1,$$

$$\alpha_1 = \bar{P}\rho_{22} + \bar{R}\rho_{11} - 2\bar{Q}\rho_{12},$$

$$\beta_1 = \bar{P}\bar{R} - \bar{Q}^2, \quad \beta_2 = (\bar{P} + \bar{R} + 2\bar{Q})\bar{b},$$

$$\bar{\rho}_0 = \bar{\rho}_{11}\bar{\rho}_{22} - \bar{\rho}_{12}^2, \quad \bar{\rho} = \bar{\rho}_{11} + \bar{\rho}_{22} + 2\bar{\rho}_{12},$$

$$\Delta_{11} = \frac{\Delta_1}{\Delta} + \frac{\Delta_2 C_1}{\Delta}, \quad \Delta_{13} = \frac{\Delta_1}{\Delta} + \frac{\Delta_2 C_3}{\Delta},$$

$$\Delta_{31} = \frac{\Delta_3}{\Delta} + \frac{\Delta_4 C_1}{\Delta}, \quad \Delta_{33} = \frac{\Delta_3}{\Delta} + \frac{\Delta_4 C_3}{\Delta},$$

$$\Delta = (\bar{\rho}_0 s + \bar{b}\bar{\rho})s^2,$$

$$\Delta_1 = (\bar{\rho}_{22}s + \bar{b})\bar{P} - (\bar{\rho}_{12}s - \bar{b})\bar{Q},$$

$$\Delta_2 = (\bar{\rho}_{22}s + \bar{b})\bar{Q} - (\bar{\rho}_{12}s - \bar{b})\bar{R},$$

$$\Delta_3 = (\bar{\rho}_{11}s + \bar{b})\bar{Q} - (\bar{\rho}_{12}s - \bar{b})\bar{P},$$

$$\Delta_4 = (\bar{\rho}_{11}s + \bar{b})\bar{R} - (\bar{\rho}_{12}s - \bar{b})\bar{Q}.$$

.

During the numerical comparisons, element models of polyurethane foam of thickness 0.016 m with diameters of 0.0395 m (diameter of small tube) and 0.1268 m (diameter of large tube) subjected to roller circumferential edge constraints are used to simulate the complex dynamic stiffness of the infinite foam 1. The material properties of foam 1 are presented in Table I. The real and imaginary parts of the complex dynamic stiffness predicted by the 2D and 3D LDFEMs for samples of different diameters and the exact solutions predicted from Eq. (28) for the infinite foam 1 are illustrated in Fig. 5. Nodes and elements for the analyses are shown in Table II. Since the constraints on the circumferential edge are assumed as rollers, the change of sample diameter as expected has no noticeable effect on the predictions of the acoustical properties of the infinite foam 1. All predicted results are complete matched with the exact solutions. This validates that the 3D LDFEM is suitable for the predictions of the acoustical properties of polyurethane foams.

VI. INFLUENCE OF EDGE CONSTRAINT ON THE ACOUSTICAL PROPERTY

Numerous researchers reported that if the sample is cut slightly undersize or slightly oversize, then either an air gap is created between the sample and the tube wall, or the circumferential edge of the sample is compressed after being pushed into the tube. Hence, the boundary conditions at the circumferential edge normally cannot be simulated precisely. In this section, the measured and the numerical simulated acoustic results of foams 1–3 (foams with the same constituents but different thicknesses) are shown to present this phenomena and to reveal that a porous material with nonzero Poisson's coefficient, the accuracy of predictions can be greatly enhanced through the three-dimensional simulations. The material properties of foams 1–3 are tabulated in Table I.

The sound absorption coefficients of the samples of diameter 0.0395 m with different thicknesses are shown in Figs. 6–8. In these figures, the exact solutions of foams with infinite extent, experimental data of exact cut (cut by a cylindrical cutter which has the same diameter as the tube) and

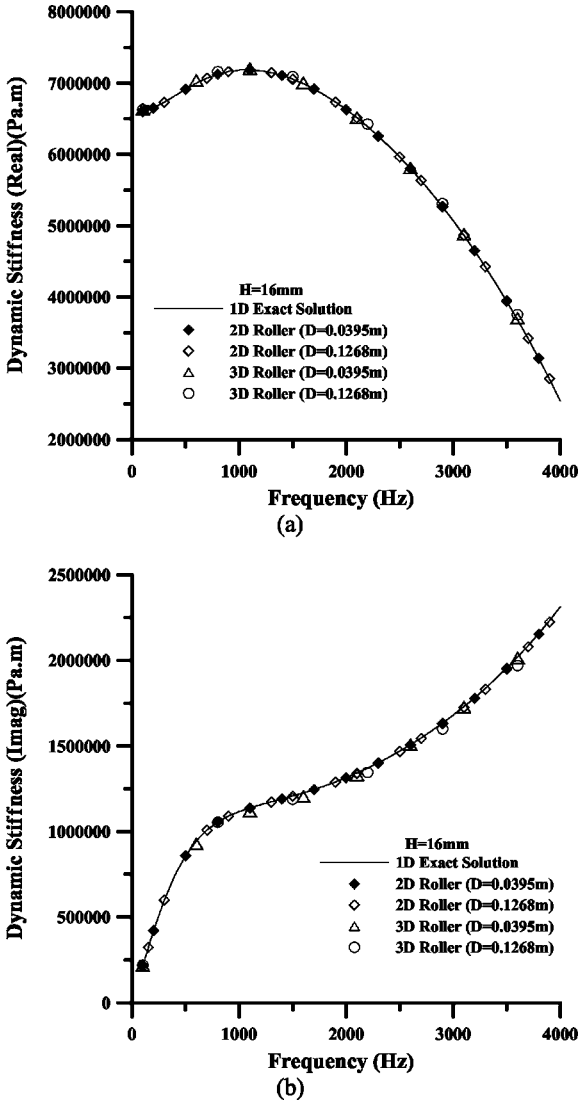

FIG. 5. Dynamic stiffness of foam 1 backed with a rigid wall. (a) Real part. (b) Imaginary part.

slightly undercut samples, and the predictions of samples with fixed as well as roller circumferential edge constraints simulated by the 2D and 3D LDFEMs are presented. It is clearly found that the experimental results are bounded by the predictions of 3D LDFEM with fixed and roller edge constraints. Before the first absorption peak occurred, the sound absorption coefficients of exact cut samples are better than that of undercut samples. The numerical predictions with fixed edge constraints are much closer to the measurements of exact cut samples than the predictions with roller edge constraints. Though the predictions of the 2D LDFEM can generally fit the results of the slightly undercut samples, underestimated predictions are found.

TABLE II. Nodes and elements of the finite element models of foam 1.

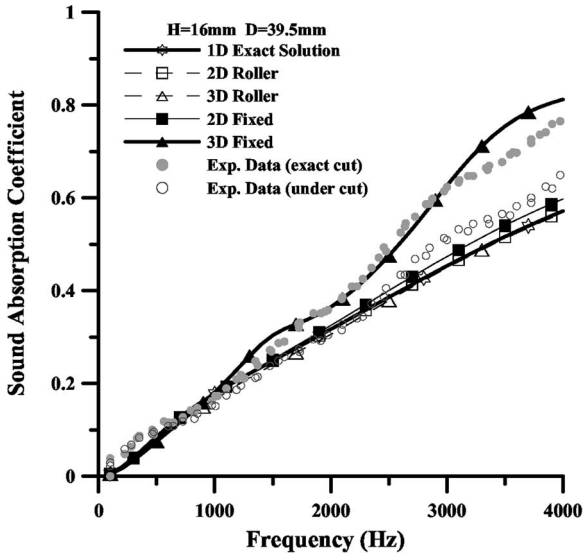

FIG. 6. Sound absorption coefficient of foam 1 backed with a rigid wall.

It is remarked that the unlikely simulations of the sound absorption coefficients reaching unity at low frequencies while reducing the rigidity of the edge constraint from fixed to roller, reported in the earlier study,[19] are not found in the present study. Owing to the influence of the fixed edge constraint, the results of Figs. 6–8 clearly show that the amplitude of the first sound absorption peak is increased and the frequency of this peak is shifted downwards. The sound absorption coefficient measured from a sample can be used to represent that of the infinite planar foam where it was cut from only if the ideal roller edge constraint is applied on the sample during the experiment. This conclusion also applied to the other acoustical properties. For demonstrations, the reflection coefficient, the acoustic impedance, and the dynamic stiffness of samples of foam 2 are presented in Figs. 9–11, respectively. It is further emphasized that if the results are presented in the form of the imaginary part of the normal incidence acoustic impedance, the variations in between the

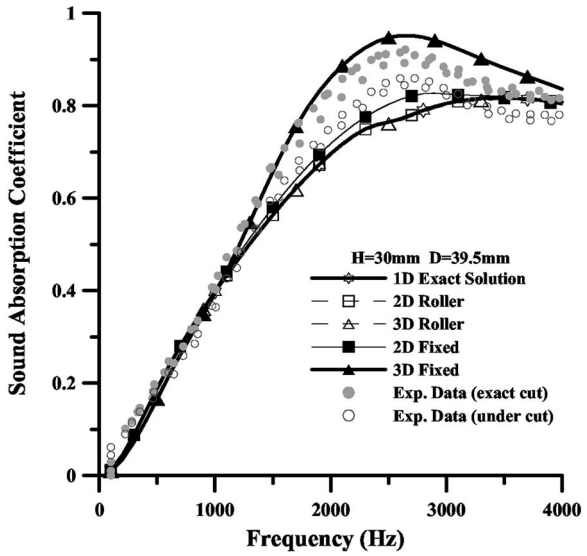

FIG. 7. Sound absorption coefficient of foam 2 backed with a rigid wall.

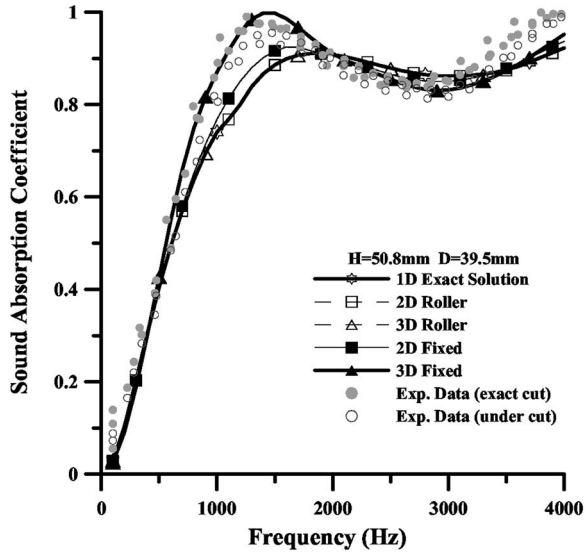

FIG. 8. Sound absorption coefficient of foam 3 backed with a rigid wall.

2D and 3D simulations become less. However, small discrepancies in the low-frequency regions can still be discovered.

VII. INFLUENCE OF SAMPLE DIAMETER ON THE ACOUSTICAL PROPERTY

It was validated that acoustic results of foams with roller edge constraints predicted by the 2D and 3D LDFEMs are completely matched with the 1D exact solutions. While the circumferential edge of a sample is fixed, the rigidity near the edge is increased accordingly. The averaged effect of the increasing of the local rigidity on the acoustical properties of the sample will become less if the diameter-to-thickness ratio (DTR) is raised. For illustration, the sound absorption results for samples of foam 2 of diameters of 0.0395 m (DTR =1.3) and 0.1268 m (DTR=4.2) predicted by the 3D LDFEM with fixed circumferential edge constraints applied, and the one-dimensional exact solutions are shown in Fig. 12. The results clearly show that the more the DTR is increased, the closer the predicted results are to the one-dimensional exact solutions. Generally, as the DTR approaches infinity, the predicted results of the model with fixed edge constraints on the circumferential edge will approach the exact solutions as well as the predicted results of the model with roller edge constraints.

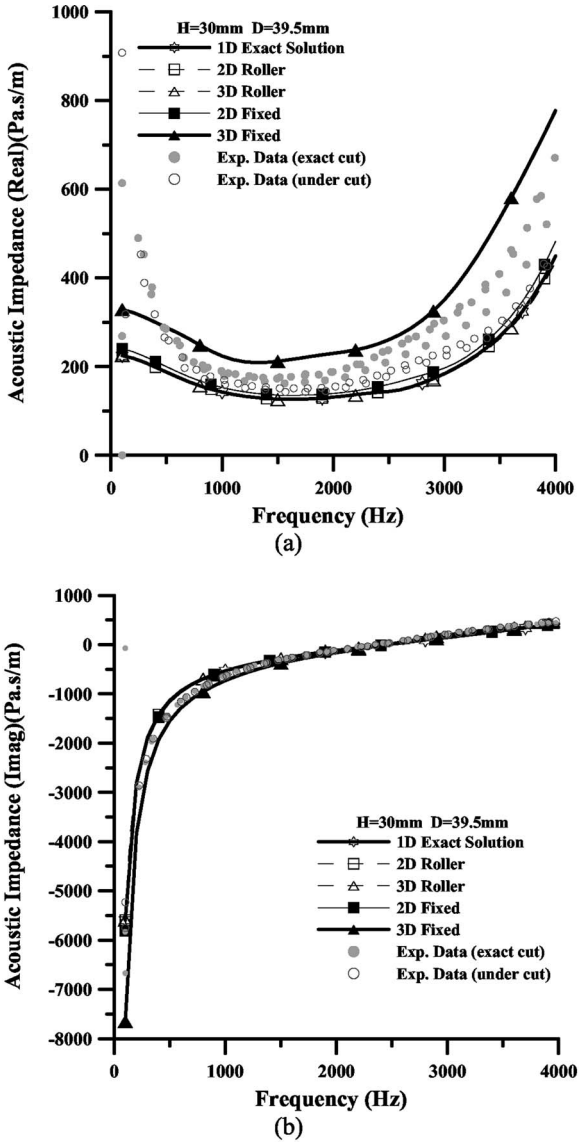

FIG. 10. Acoustic impedance of foam 2 backed with a rigid wall. (a) Real part. (b) Imaginary part.

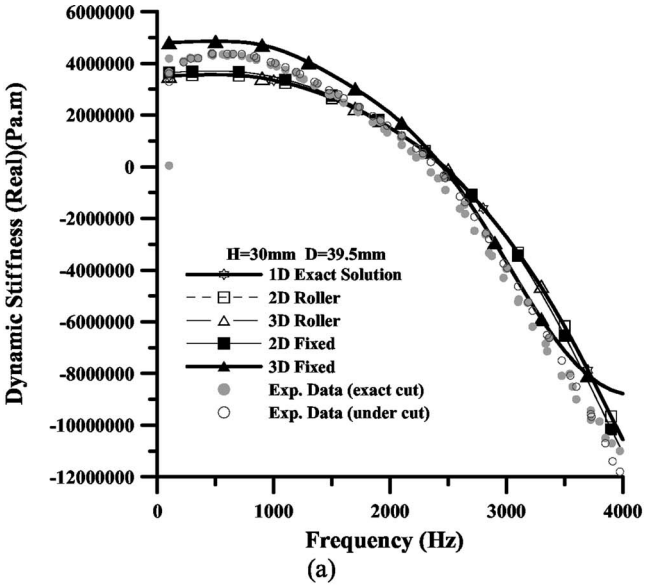
VIII. CONCLUSIONS

The three-dimensional Laplace domain finite element method, based on Biot's dynamic poroelasticity theory, for simulating the acoustical properties of foams with four-node tetrahedral porous elements was established in this study. Combined with the acoustic measurement system, the influences of circumferential edge constraint and the sample diameter on the foam sample placed in the impedance tube were examined. The experimental and predicted results obtained in this study lead to the following conclusions.



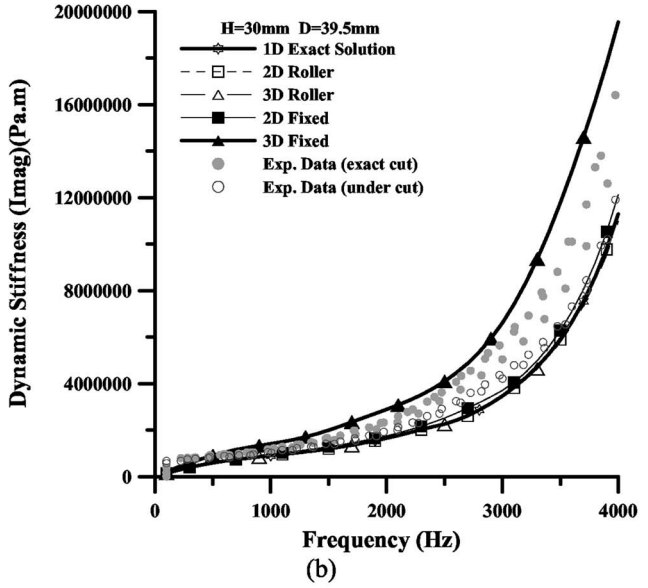


FIG. 11. Dynamic stiffness of foam 2 backed with a rigid wall. (a) Real part. (b) Imaginary part.

Without the use of the incident acoustic field, which was required in the earlier studies, the acoustic behaviors of the foam samples can be efficiently predicted by the three-dimensional Laplace domain finite method. Results predicted by the three-dimensional Laplace domain finite method for samples with roller circumferential edge constraints coincided with the one-dimensional exact solutions. However, in the circumstance of a foam with nonzero Poisson's coefficient and low diameter-to-thickness ratio, the rigidity of the circumferential edge constraint has profound effects on the acoustic predictions of the foam.

While the circumferential edge of the foam is fixed, the amplitude of the first sound absorption peak is increased and the peak is moved to a lower frequency as compared with that predicted with roller constraints. Measurements of samples are bounded by the predictions of samples with roller as well as fixed constraints and are much closer to that predicted with fixed edge constraints. Although the two-dimensional approach can predict the tendency of the acoustic results of samples, underestimations are often found. In summary, the measured acoustic results can be used to represent that of the laterally infinite planar foam from which the sample was cut only if the roller edge constraint is managed during the experiment.

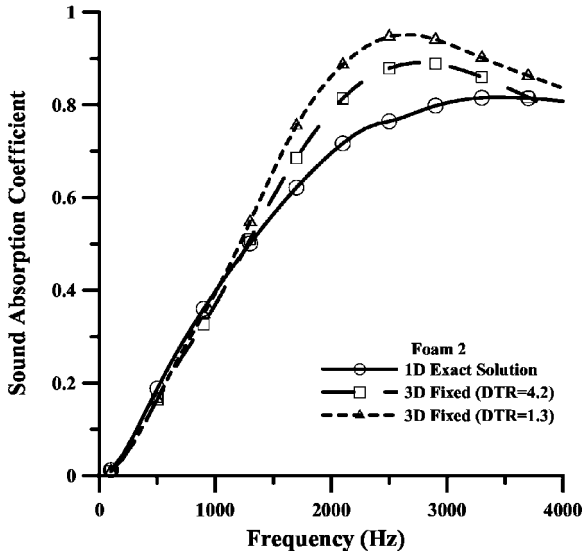

FIG. 12. Influence of sample diameter on the sound absorption coefficient.

The influence of the fixed circumferential edge constraint can be covered up by the increase of the diameter-to-thickness ratio. The more the diameter-to-thickness ratio is increased, the closer the predicted results are to that of the sample with roller edge constraints. When the diameter-to-thickness ratio approaches infinity, the predicted results of the sample with fixed edge constraints and that of the sample with roller edge constraints both approach the one-dimensional exact solutions.

(Received 19 May 2005; revised 1 February 2006; accepted 9 February 2006)

Synchronized switch damping (SSD) principle and derived techniques have been developed to address the problem of structural damping. Compared with standard passive piezoelectric damping, these new semi-passive techniques offer the advantage of self-adaptation with environmental variations. Unlike active damping systems, their implementation does not require any sophisticated signal processing nor any bulky power amplifier. This paper presents an enhancement of the SSD technique on voltage source (SSDV) which is the most effective of the SSD techniques. The former SSDV technique uses a constant continuous voltage sources whereas the proposed enhancement uses an adaptive continuous voltage source which permits fitting the mechanical braking force resulting from the SSDV process to the vibration level. A theoretical analysis of the SSDV techniques is proposed. Experimental results for structural damping under single frequency and for vibration control of a smart board under white noise excitation are presented and confirm the interest of the enhanced SSDV compared to other SSD techniques. Depending on the excitation type, a 4- to 10-dB damping gain can be achieved. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Several semi-passive vibration control techniques have been recently developed. The state switching method proposed by Clark (2000) is a variable stiffness technique in which piezoelements are periodically held in the open-circuit state, then switched and held in the short-circuit state, synchronously with the structure motion. Cunefare (2002) successfully adapted previous works of Larson *et al.* (1998) on the state-switching concept to vibration damping in a rather different way and these were proposed as the state-switching absorber (SSA).

This paper deals with particular nonlinear techniques which are known as SSD for synchronized switch damping (Richard, 1998, 2000). These techniques consist in a nonlinear processing of the voltage on a piezoelement bonded on the structure. It is implemented with a simple switch synchronously driven during short periods with the structure motion. The switch connects the piezoelement to a circuit which can be either a simple short circuit (SSDS), a small inductor (SSDI), or voltage sources (SSDV). Due to this process, a voltage magnification is obtained and a phase shift appears between the piezoelement strain and the resulting voltage, thus creating energy dissipation. This method offers several advantages: It is insensitive to environmental changes due to its self-adaptive broadband behavior and it requires only a very low external power for the switch control and the voltage source in the case of the SSDV.

It has been shown that dissipated energy depends in particular on the voltage amplitude across the electrodes of piezoelectric elements. The role of the additional constant voltage sources in the SSDV technique is thus to increase the voltage amplitude, which increases the damping effect. In the original SSDV technique, the sign of the continuous voltage source is changed so that it increased the piezovoltage during the inversion process (Lefeurve, 2005). However, its absolute value remains constant, which can lead to stability problems. Actually, when the vibration level is very low, the original SSDV approach may excite the structure instead of limiting its vibrations. The enhancement proposed in this paper consists in fitting the continuous voltage amplitude to the vibration level. SSD techniques are presented and theoretically developed in Sec. II. Section III presents experimental results under single frequency excitation. Vibration damping experiment under white noise excitation of a plate structure

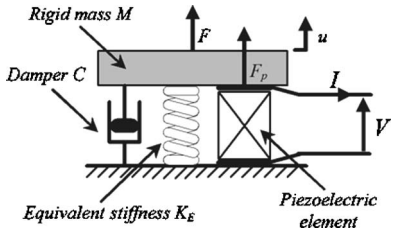

FIG. 1. Schematic representation of the electromechanical model.

exhibiting numerous modes on a 1-kHz frequency band is presented in Sec. IV and illustrates the broadband capability of the proposed enhanced SSDV technique.

II. SSD TECHNIQUES BASIS

This section briefly presents the different SSD techniques. For clarity reasons, a sinusoidal excitation is considered. In this simple case, if the structure is driven around one of its resonance frequency, it can be modeled using a second-order model.

A. Modeling

A mechanical model based on a spring-mass system having only one degree of freedom gives a good description of vibrating structure behavior near a resonance. The differential equation (1) is established assuming that the global structure including piezoelectric elements is linearly elastic. In this equation, M represents the equivalent rigid mass and C is the mechanical losses coefficient. K_E is the equivalent stiffness of the electromechanical structure when the piezoelectric elements are short-circuited, u is the rigid mass displacement and ΣF_i represents the sum of other forces applied to the equivalent rigid mass, comprising forces applied by piezoelectric elements. Piezoelectric elements bonded on the considered structure ensure the electromechanical coupling described by the equations (2) and (3), where F_p is the electrically dependent part of the force applied by piezoelectric elements on the structure, C_0 is the blocked capacitance of piezoelectric elements and α is the force factor. I is the outgoing current from piezoelectric elements. M, C_0, α, and K_E can be deduced from piezoelectric elements and structure characteristics and geometry, or starting from a few measurements, as shown in Sec. III A. A schematic representation of the model is given by Fig. 1:

$$M\ddot{u} + C\dot{u} + K_E u = \sum F_i, \tag{1}$$

$$F_p = -\alpha V, \tag{2}$$

$$I = \alpha\dot{u} - C_0\dot{V}. \tag{3}$$

Finally, ΣF_i applied to the rigid equivalent mass comprises F_p and an external excitation force F. Thus, the differential equation governing the mass motion can be written as Eq. (4). The energy equation (5) is obtained by multiplying both sides of Eq. (4) by the velocity and integrating over the time variable. The provided energy is divided into kinetic energy, potential elastic energy, mechanical losses, and transferred energy. The transferred energy corresponds to the part of the mechanical energy which is converted into electrical energy. Maximizing this energy amounts to minimizing the mechanical energy in the structure (kinetic + elastic):

$$M\ddot{u} + C\dot{u} + K_E u = F - \alpha V, \tag{4}$$

$$\int F\dot{u}\,dt = \frac{1}{2}M\dot{u}^2 + \frac{1}{2}K_E u^2 + \int C\dot{u}^2\,dt + \int \alpha V\dot{u}\,dt. \tag{5}$$

B. Open-circuit condition

It is considered that nothing is connected to the piezoelectric elements; the transferred energy is then clearly equal to zero. The current flowing out the equivalent piezo is null and then (3) written in the frequency domain leads to Eq. (6). Inserting Eq. (6) in Eq. (4) written in the frequency domain leads to the transfer function (7) linking the displacement to the driving force:

$$\tilde{V} = \frac{\alpha}{C_0}\tilde{u}, \tag{6}$$

$$\frac{\tilde{u}}{\tilde{F}} = \frac{1}{\left(K_E + \alpha^2/C_0 - M\omega^2 + jC\omega\right)}. \tag{7}$$

It is assumed that at the resonance frequency the force F and the speed $\dot{u}$ are in phase (this is a good approximation for structures with low viscous losses). The resonance angular frequency is then given by Eq. (8) and the amplitude of the displacement by Eq. (9) where F_M is this amplitude of the driving force:

$$\omega_0 = \sqrt{\frac{K_E + \alpha^2/C_0}{M}}, \tag{8}$$

$$u_M = \frac{F_M}{C\omega_0}. \tag{9}$$

C. SSDI technique

The SSDI technique consists of adding a switching device in parallel with the piezoelectric elements. This device is composed of a switch and an inductance L_I connected in series, as shown in Fig. 2. The switch is almost always open, except when a voltage extremum occurs, i.e., when a strain extremum occurs in the piezoelement. At this instant, the switch is closed. The capacitance C_0 of the piezoelectric elements and the inductance L_I then constitute oscillator. The switch S_W is kept closed until the voltage V on the piezoelectric elements has been reversed. It corresponds to a time t_i equal to a half period of the electric oscillator, as shown in Eq. (10):

$$t_i = \pi\sqrt{L_I C_0}. \tag{10}$$

When the switch is open and if no load is connected, the outgoing piezocurrent is null and then the voltage and the

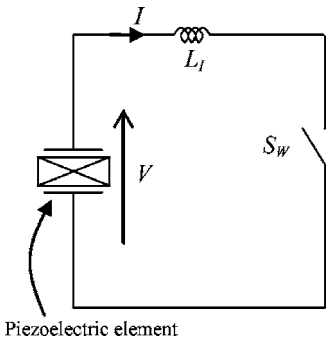

FIG. 2. SSDI electrical circuit.

displacement vary proportionally. The voltage and displacement typical waveforms are shown in Fig. 3.

The voltage inversion is not perfect, because a part of the energy stored on the piezoelectric element's capacitance is lost in the switching network (electronic switch +inductance). These losses are modeled by an electrical quality factor Q_I. The relation between Q_I and the voltage of the piezoelectric element before and after the inversion process is given by Eq. (11):

$$V_m = \gamma V_M = V_M e^{-\pi/2Q_I}. \tag{11}$$

The transferred energy can be expressed as the following integral function of voltage V and displacement u:

$$\int \alpha V \dot{u}\, dt = \int \alpha V\, du. \tag{12}$$

Considering a periodic motion of the structure, transferred energy can then be represented as the cycle shown in Fig. 4. Two open circuit phases and two voltage inversions phases can be distinguished on this cycle. In open circuit, voltage variations are proportional to displacement with a factor α/C_0, whereas there is no displacement variation during the voltage inversions, since the inversion time is much smaller than the mechanical motion period. The surface circumscribed by this cycle is the image of transferred energy with a factor $1/\alpha$. Between two voltage inversions, the voltage and the displacement vary proportionally, which leads to Eq. (13) where u_M is the displacement amplitude. The transferred energy E_t during a period is given by Eq. (14):

$$V_M = V_m + \frac{2\alpha}{C_0} u_M, \tag{13}$$

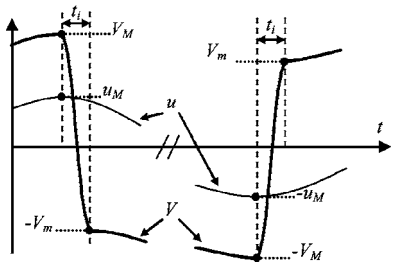

FIG. 3. Displacement and voltage typical waveforms.

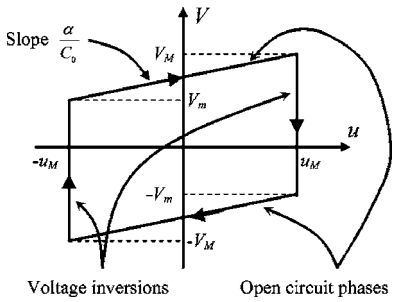

FIG. 4. Energy cycle.

$$E_t = \int_{\text{period}} \alpha V\, du = 2\alpha u_M (V_m + V_M). \tag{14}$$

E_t can be expressed as a unique function of the displacement amplitude using Eqs. (11), (13), and (14):

$$E_t = \frac{4\alpha^2}{C_0} \frac{1+\gamma}{1-\gamma} u_M^2. \tag{15}$$

It is assumed that the displacement remains purely sinusoidal. If the driving force angular frequency is ω, the displacement can be expressed by Eq. (16). The piezovoltage can be expressed as the sum of two functions, one which is an image of the displacement and one of which is a crenel function. This is summarized in Eq. (17), where h is the crenel function defined in Eq. (18). In the case of a periodic motion, h is also periodic and can be expressed as Fourier series, as shown in Eq. (19).

$$u(t) = u_M \sin(\omega t + \varphi), \tag{16}$$

$$V = \frac{\alpha}{C_0}(u + h), \tag{17}$$

$$h = u_M \frac{1+\gamma}{1-\gamma} \operatorname{signe}(\dot{u}), \tag{18}$$

$$h = u_M \frac{1+\gamma}{1-\gamma} \sum_{n=0}^{\infty} \left(\frac{4}{\pi(2n+1)} \cos((2n+1)\omega t + \varphi) \right). \tag{19}$$

Inserting Eq. (17) in Eq. (4) leads to Eq. (20). Since the displacement is assumed to remain sinusoidal, only the first harmonic of the crenel can be considered, which leads to the transfer function (21) linking the displacement to the driving force:

$$F = M\ddot{u} + \left(K_E + \frac{\alpha^2}{C_0}\right)u + C\dot{u} + \frac{\alpha^2}{C_0}h, \tag{20}$$

$$\frac{\tilde{u}}{\tilde{F}} = \frac{1}{\left(K_E + \alpha^2/C_0 - M\omega^2 + j\left(C\omega + (4\alpha^2/\pi C_0)(1+\gamma)/(1-\gamma)\right)\right)}. \tag{21}$$

It is assumed that at the resonance frequency the force F and the speed $\dot{u}$ are in phase. The resonance angular frequency is then given by Eq. (8) and the amplitude of the displacement by Eq. (22). Equation (23) gives the theoretical value of the SSDI damping

$$u_M = \frac{F_M}{C\omega_0 + (4\alpha^2/\pi C_0)(1+\gamma)/(1-\gamma)}, \tag{22}$$

$$A_{\mathrm{SSDI}} = 20\log\left(\frac{C\omega_0}{C\omega_0 + (4\alpha^2/\pi C_0)(1+\gamma)/(1-\gamma)}\right) \tag{23}$$

D. Original SSDV technique (Lefeuvre, 2006)

The electrical circuit of the original SSDV semi-passive damping technique is represented in Fig. 5. The difference between this circuit and the previously presented SSDI circuit is that the piezoelectric element is switched on a positive or a negative voltage source across the inductive shunt circuit. It has been shown that dissipated energy depends in particular on the voltage amplitude across the electrodes of piezoelectric elements. The role of these additional constant voltage sources is to increase the piezovoltage amplitude, thus increasing the damping effect.

The control strategy of the switches consists in closing S_{W1} when a maximum of the strain in the piezoelectric elements occurs, corresponding to a maximum of the voltage V. Closing S_{W1} starts a pseudo-periodic voltage oscillation, until S_{W1} is opened. The switch is kept closed during a time t_i equal to a half the pseudo-period of the electrical oscillator composed by the inductance and the capacitance of the piezoelectric elements. Thus, the voltage sign of V become negative when S_{W1} is opened.

The switch S_{W2} is controlled in a symmetrical way to S_{W1}: it is closed when a minimum of displacement strain occurs, corresponding to a minimum of the voltage V. This switch is then opened after a closing time t_i. Thus, the sign of V becomes positive. Theoretical corresponding waveforms of the strain and the voltage V are plotted in Fig. 6.

The transferred energy E_t during a period can be expressed as in the previous case by Eq. (14), since the energy cycle described in Fig. 4 also corresponds to the SSDV displacement and voltage waveforms. The voltage variation between two inversions still leads to Eq. (13) but the voltage inversion across the voltage source V_{cc} leads to Eq. (24). E_t can then be expressed as a function of u_M and V_{cc}, as shown by Eq. (25):

$$V_m - V_{cc} = \gamma(V_M + V_{cc}), \tag{24}$$

$$E_t = \left(4\frac{\alpha^2}{C_0}u_M^2 + 4\alpha u_M V_{cc}\right)\frac{1+\gamma}{1-\gamma}. \tag{25}$$

It is clearly shown that the SSDV technique increases the uV cycle along the voltage axis, which results in increasing the transferred energy.

As in the previous case, it is assumed that the displacement remains purely sinusoidal, thus Eqs. (16) and (17) are still valid. The crenel function h is now given by Eqs. (26) and (27) using Fourier series:

$$h = \frac{1+\gamma}{1-\gamma}\left(u_M + \frac{C_0}{\alpha}V_{cc}\right)\operatorname{signe}(\dot{u}), \tag{26}$$

$$h = \frac{1+\gamma}{1-\gamma}\left(u_M + \frac{C_0}{\alpha}V_{cc}\right) \times \sum_{n=0}^{\infty}\left(\frac{4}{\pi(2n+1)}\cos\left((2n+1)\omega t + \varphi\right)\right). \tag{27}$$

As in the previous case, only the first harmonic of the crenel can be considered, which leads to Eq. (28). For a given angular frequency ω, the displacement magnitude u_M as well as

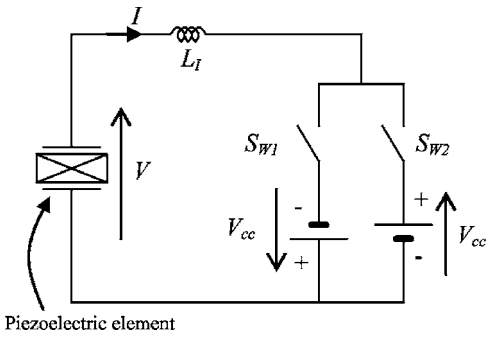

FIG. 5. Original SSDV electrical circuit.

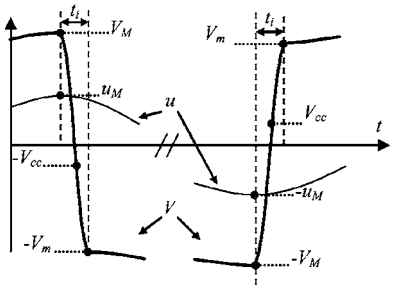

FIG. 6. Displacement and voltage typical waveforms.

its phase difference φ compared to the driving force can be obtained solving the system (29):

$$u_M \sin(\omega t+\varphi)\left(K_E+\frac{\alpha^2}{C_0}-\omega^2 M\right)+\cos(\omega t+\varphi) \times\left(u_M\left(C\omega+\frac{4}{\pi}\frac{\alpha^2}{C_0}\frac{1+\gamma}{1-\gamma}\right)+\frac{4}{\pi}\frac{1+\gamma}{1-\gamma}\alpha V_{cc}\right) = F_M \sin(\omega t), \tag{28}$$

$$u_M\left(K_E+\frac{\alpha^2}{C_0}-\omega^2 M\right)\sin\varphi + \left(u_M\left(C\omega+\frac{4}{\pi}\frac{\alpha^2}{C_0}\frac{1+\gamma}{1-\gamma}\right)+\frac{4}{\pi}\frac{1+\gamma}{1-\gamma}\alpha V_{cc}\right)\cos\varphi=0,$$

$$u_M\left(K_E+\frac{\alpha^2}{C_0}-\omega^2 M\right)\cos\varphi+\left(u_M\left(C\omega+\frac{4}{\pi}\frac{\alpha^2}{C_0}\frac{1+\gamma}{1-\gamma}\right)+\frac{4}{\pi}\frac{1+\gamma}{1-\gamma}\alpha V_{cc}\right)\sin\varphi=F_M. \tag{29}$$

At the resonance $\varphi=\pi/2$ and then the angular resonance frequency is still given by Eq. (8). In this case, the displacement amplitude can be expressed as a function of the force magnitude and of the continuous voltage, as shown by Eq. (30). The theoretical value of the SSDV damping is given by Eq. (31):

$$u_M=\frac{F_M(4/\pi)[(1+\gamma)/(1-\gamma)]\alpha V_{cc}}{C\omega_0+(4\alpha^2/\pi C_0)(1+\gamma)(1-\gamma)}, \tag{30}$$

$$A_{\mathrm{SSDV}}=20\log\left(\frac{C\omega_0}{C\omega_0+(4\alpha^2/\pi C_0)(1+\gamma)/(1-\gamma)} \times\left(1-\frac{4}{\pi}\frac{1+\gamma}{1-\gamma}\frac{\alpha V_{cc}}{F_M}\right)\right). \tag{31}$$

This equation shows that, under a given excitation force, a value- of the voltage V_{cc} that totally cancels the vibration can be found. The expression of this particular value of the voltage is given in Eq. (32). In this case, the force applied by the piezoelectric element on the structure, which is proportional to V_{cc}, totally compensates the effect of external excitation force. Applying a voltage higher than $V_{cc\,\max}$ leads to stability problems because in this case the voltage comes to have a driving instead of a braking effect. Moreover, when V_{cc} approaches this critical value, the previous theoretical development is no longer valid due to the displacement higher harmonics that cannot be neglected any longer compared to the fundamentals:

$$V_{cc\,\max}=\frac{\pi}{4\alpha}\frac{1-\gamma}{1+\gamma}F_M. \tag{32}$$

E. Enhanced SSDV technique

The enhancement proposed in this paper consists in adapting the voltage in order to fit the piezoelectric force due to the SSDV process to the vibration amplitude. This can be basically done by forcing the continuous voltage V_{cc} to be of opposite sign and proportional to the strain. The strain can be monitored using the voltage on an additional piezoelement bonded in the same area as the patches used for the vibration control. Considering the simple model previously described, the voltage on an additional piezoelement is given by Eq. (33), and V_{cc} by Eq. (34), where β is proportional coefficient set by the user. The electrical circuit of the enhanced SSDV is a represented in Fig. 7. As in the SSDI technique, the control strategy of the switch consists in closing S_w when an extremum of strain in the piezoelectric elements occurs, corresponding to an extremum of the voltage V. S_W is open after the voltage inversion. In the case of a sinusoidal steady-state excitation, the voltage V_{cc} during the voltage inversion is given by Eq. (35). Theoretical waveforms of the strain and the voltage V are similar to the ones plotted in Fig. 6:

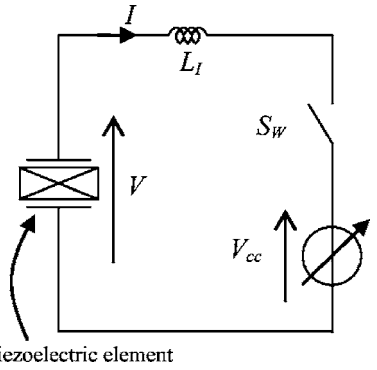

FIG. 7. Enhanced SSDV electrical circuit.

$$V_s=\frac{\alpha}{C_0}u, \tag{33}$$

$$V_{cc}=-\beta\frac{\alpha}{C_0}u, \tag{34}$$

$$V_{cc}=-\beta\frac{\alpha}{C_0}u_M \quad \text{on strain maximum},$$
$$V_{cc}=\beta\frac{\alpha}{C_0}u_M \quad \text{on strain minimum}. \tag{35}$$

The transferred energy E_t during a period can be expressed as in previous cases by Eq. (14), since the energy cycle described in Fig. 4 is still valid. The voltage variation between two inversions still leads to Eq. (13) and the voltage inversion across the voltage source V_{cc} leads to Eq. (36). E_t can then be expressed as a function of u_M, as shown by Eq. (37).

$$V_m-\beta\frac{\alpha}{C_0}u_M=\gamma\left(V_M+\beta\frac{\alpha}{C_0}u_M\right), \tag{36}$$

$$E_t=\frac{4\alpha^2}{C_0}(1+\beta)\frac{1+\gamma}{1-\gamma}u_m^2. \tag{37}$$

As the original SSDV technique, the enhanced SSDV increases the uV cycle along the voltage axis, which results in increasing the transferred energy.

As in previous cases, it is assumed that the displacement remains purely sinusoidal, thus Eqs. (16) and (17) are still

valid. The crenel function h is now given by Eqs. (38) and (39) using Fourier series. It is shown that, as in the SSDI case, the crenel function is proportional to the displacement amplitude, which is not the case with the original SSDV.

$$h = u_M(1+\beta)\frac{1+\gamma}{1-\gamma}\,\mathrm{signe}(\dot{u}), \tag{38}$$

$$h = u_M(1+\beta)\frac{1+\gamma}{1-\gamma}\sum_{n=1}^{\infty}\left(\frac{4}{\pi(2n+1)}\cos((2n+1)\omega t+\varphi)\right). \tag{39}$$

As previously, only the first harmonic of the crenel can be considered. Since the crenel function is very similar to the crenel function related to the SSDI technique, the transfer function linking the displacement to the driving force can easily be deduced and is given by Eq. (40). At the resonance frequency, still given by Eq. (8), the amplitude of the displacement is given by Eq. (41) and the related damping by Eq. (42):

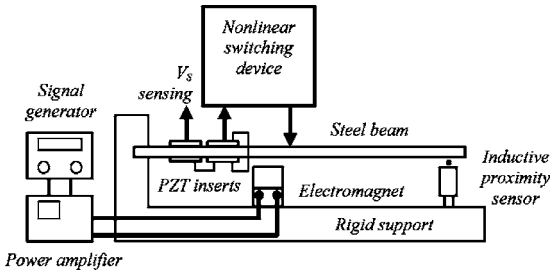

FIG. 8. Experimental setup.

$$\frac{\tilde{u}}{\tilde{F}} = \frac{1}{\left(K_E + (\alpha^2/C_0) - M\omega^2 + j\left(C\omega + (4\alpha^2/\pi C_0)(1+\beta)(1+\gamma)/(1-\gamma)\right)\right)}, \tag{40}$$

$$u_M = \frac{F_M}{C\omega_0 + (4\alpha^2/\pi C_0)(1+\beta)(1+\gamma)/(1-\gamma)}, \tag{41}$$

$$A_{\mathrm{SSDV_{enh}}} = 20\log\left(\frac{C\omega_0}{C\omega_0 + (4\alpha^2/\pi C_0)(1+\beta)(1+\gamma)/(1-\gamma)}\right). \tag{42}$$

This equation shows that, for a given parameter β, the damping is not sensitive to the amplitude of the applied force. This is the critical point of the SSDV enhancement. Using the original SSDV technique with a given continuous voltage amplitude leads to stability problems when reducing the driving force amplitude and to a lack of effectiveness when increasing it. These drawbacks are efficiently overpassed by the proposed enhancement. Actually, the enhanced SSDV technique is a closed loop process where the piezoelectric force is adjusted to the vibration amplitude, whereas the original SSDV is closer to an open loop process.

It must be noted that for high values of β, the previous theoretical development is no longer valid because the displacement higher harmonics cannot be neglected any longer compared to the fundamental.

III. EXPERIMENTS UNDER SINGLE FREQUENCY EXCITATION

A. Experimental setup

The experimental test structure is a cantilever beam clamped at one end in a rigid structure, as shown in Fig. 8. The beam vibrations are driven with an electromagnet that generates a periodic force. The piezoelectric ceramic inserts are bonded on the beam close to the clamped end where the bending radius is at minimum. The poling direction of the piezoelectric inserts is perpendicular to the plate and it is the lateral coupling k_{31} which mainly drives the piezoelectric response. The measurement of the cantilever free end displacement is obtained with an inductive proximity sensor. The characteristics of the beam and the piezoelectric inserts are summarized in Tables I and II II, respectively.

TABLE I. Steel beam characteristics.

Length L	180 mm
Width	90 mm
Thickness	2.05 mm

B. Model identification

The considered piezoelectric structure is more complex than the simple resonator described in Sec. II A. The various parameters cannot be simply obtained from the properties of the piezoelectric inserts. However, the structure presents all the features of a piezoelectric electromechanical device as defined in Sec. II A. Its properties can therefore be identified using the experimental measurements defined in Table III and Eqs. (43). The identified model corresponds then to the

actual setup around the considered resonance frequency which corresponds, in this case, to the first flexural mode. Numerical data corresponding to the experimental setup are summarized in Table IV:

$$\alpha = \lambda C_0, \quad K_E = \alpha\lambda \frac{f_0^2}{f_1^2 - f_0^2}, \quad M = \frac{K_E}{4\pi^2 f_0^2},$$
$$C = 4\pi\xi M f_1. \tag{43}$$

C. Results

The beam is driven around its first resonance frequency. The driving force amplitude is 0.086N. Without control and at the resonance frequency the displacement amplitude of the beam free end is 2.2 mm. Both theoretical and experimental normalized displacement amplitudes in dB are plotted in Fig. 9, versus the driving force frequency for the different techniques. The inversion quality factor Q_I is 2.1. It was artificially decreased adding a 1-kΩ resistance in series with the inductor for clarity reasons to highlight the damping enhancement due to the SSDV voltage magnification. For the original SSDV technique V_{cc} is set to 3 V and for the enhanced SSDV β is set to 0.95. Theoretical displacements are calculated using Eqs. (7), (21), (29), and (40).

V_{cc} and β were chosen so that the original and the enhanced SSDV techniques lead to the same displacement amplitude at the resonance frequency. The original and enhanced SSDV harmonic responses are shown to be very close. The original SSDV technique is slightly more effective out of the resonance frequency because in the case of the enhanced SSDV, V_{cc} decreases when moving away from the resonance frequency.

Experimental displacement and voltage waveforms are

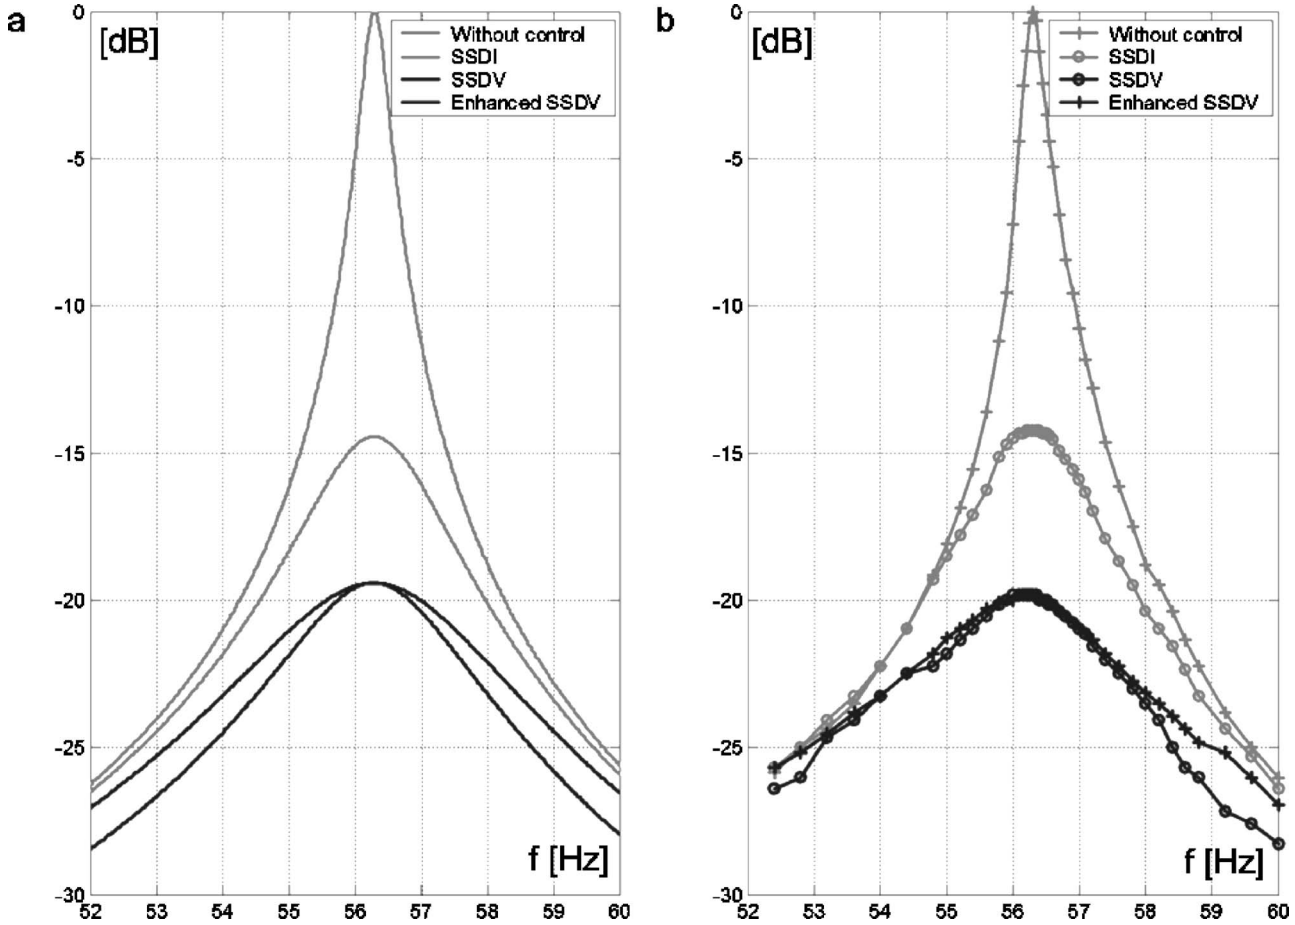

FIG. 9. Theoretical (a) and experimental (b) normalized harmonic responses for the different techniques.

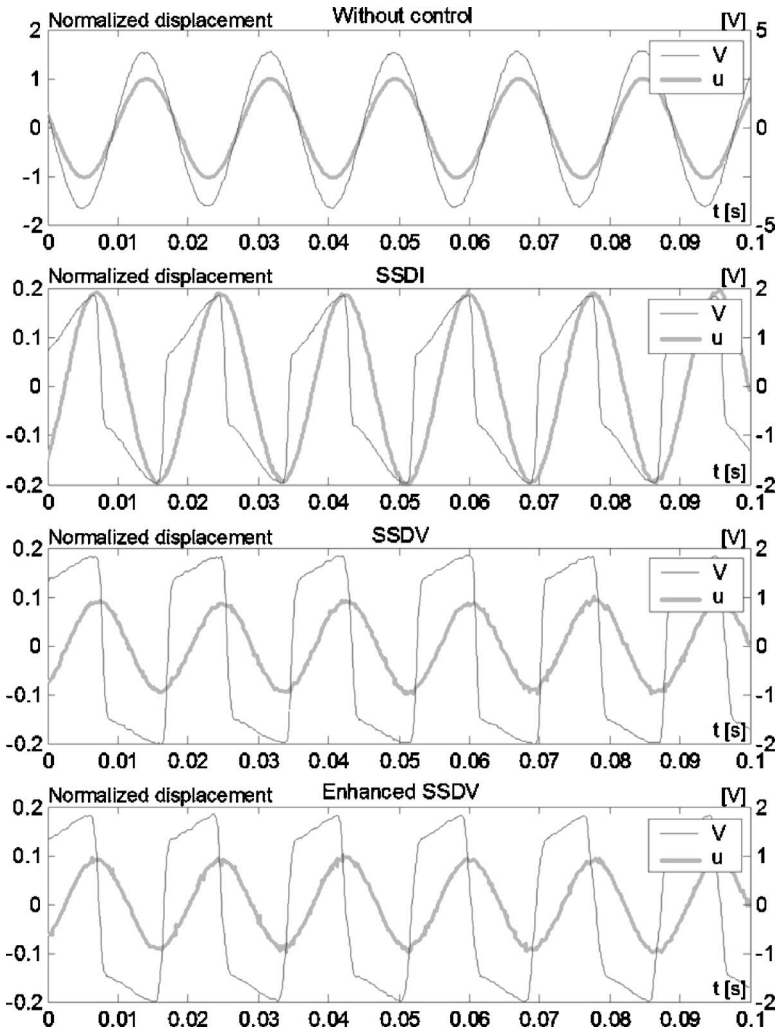

FIG. 10. Voltage and normalized displacement waveforms for the different technique.

plotted in Fig. 10. The voltage inversion induces a discontinuity in the force applied by the piezoelectric elements. This discontinuity leads to a small acceleration gap of the structure motion, but the displacement remains continuous, due to inertial effect. Moreover, the shape of the voltage induces excitation of the structure on odd multiples of the resonance frequency. In this particular case, the structure is highly resonant and no resonance frequency corresponds to odd multiples of the first bending mode. The displacement remains then almost sinusoidal (other lines of the displacement spectrum are at least −50 dB under the first resonance frequency line).

Figure 11 shows both theoretical and experimental damping for each technique as a function of the normalized driving force amplitude. The structure is driven at its resonance frequency; V_{cc} and β are unchanged. The driving force

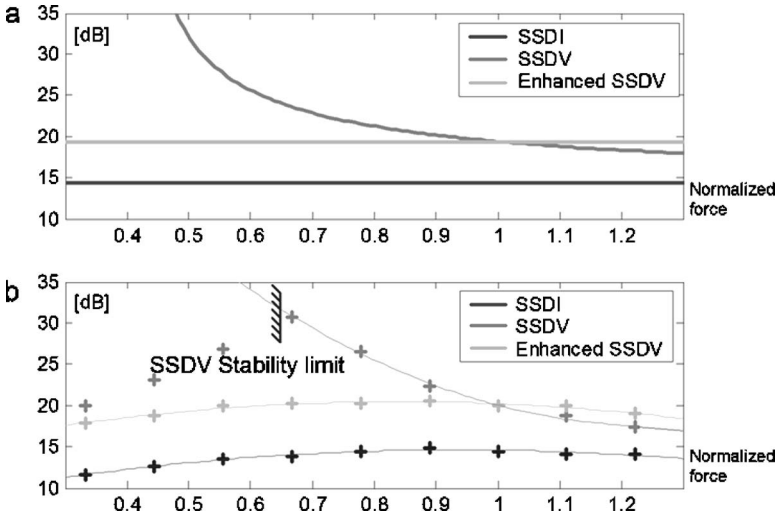

FIG. 11. Theoretical (a) and experimental (b) damping absolute value for the different techniques versus the normalized driving force $-V_{cc}=3$ V and $\beta=0.95$.

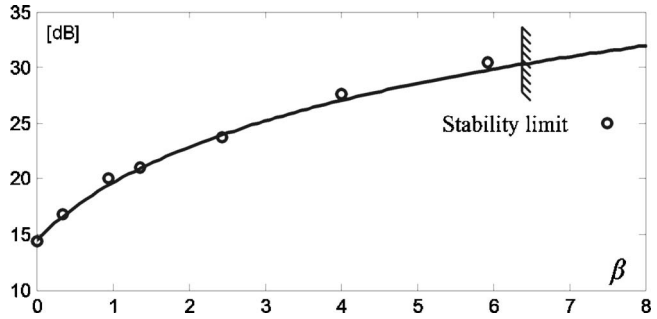

FIG. 12. Theoretical and experimental enhanced SSDV damping absolute value versus β.

is normalized so that 1 corresponds to the driving force of the previous harmonic analysis. SSDI and enhanced SSDV damping remain theoretically constant versus the driving force amplitude, which is confirmed experimentally. The original SSDV damping is logically a decreasing function of the driving force amplitude. The original SSDV damping is lower than the enhanced SSDV damping for normalized force amplitude greater than 1 and greater for normalized force amplitude lower than 1. The original SSDV technique leads to stability problems when the amplitude of the driving force is too low. In this case, the displacement higher harmonics cannot be neglected any more compared to the fundamental. New displacement extrema are induced which destabilize the switching control and lead to a lack of effectiveness compared to theoretical results. Actually, even if there were no higher harmonics excitations, stability problems would occur when the external driving force become lower than the force induced by the piezovoltage, i.e., when Eq. (32) is verified.

For $\beta=0.95$, the enhanced SSDV technique is stable whatever the amplitude of the driving force. Actually, β can be raised to increase the damping performance. Figure 12 shows the enhanced SSDV damping at the resonance frequency versus β. It is shown that the damping reaches -30 dB for $\beta=6$. It must also be highlighted that when $\beta=6$, the damping is almost -30 dB whatever the amplitude of the driving force.

The enhanced SSDV technique is inherently stable whatever the amplitude of the excitation because the voltage source level is continuously adapted in order to fit the piezoelectric generated control force to the mechanical excitation. Parameter β can be considered as a feedback gain allowing us to adjust the amplitude of the control force to the vibration amplitude. Theoretically, this closed loop process is stable for any value of β. However, as usual, a large value of the feedback gain limits the modulus margin and therefore instabilities may be observed when perturbations due to noise or harmonics are important compared to the excited mode. In the experimental case, noises and electronic implementation imperfections reach the margin modulus for β greater than 6. It is remarkable that under this practical limit, the system is stable and the damping is constant for any exciting force amplitude.

IV. EXPERIMENTS UNDER WIDEBAND EXCITATION

A. Experimental setup

The setup considered here is shown in Fig. 13. It is composed of a composite board with builtin piezoelectric elements (Qiu, 2003). This *smart board* is clamped on the extremity of a rectangular pipe. The piezoelectric elements are symmetrically located along the four clamped sides, where the strain is a maximum for almost all the modes. This geometry has been chosen because it exhibits a larger modal density than the previous cantilever beam. Actually eight lines almost regularly spaced are obtained on a 1-kHz frequency band. A speaker driven by a white noise electrical signal is used to excite simply and simultaneously the various modes. Practically the speaker is installed in a 60-cm pipe section, closed on one end by a rigid panel and by the equipped panel on the other end.

White noise is generated inside the pipe by the speaker and can only be transmitted to the outside via vibration of the composite board. This experimental setup is used to show that the SSDV technique is also effective for wideband excitation of a more complex and realistic structure than a cantilever beam. All piezoelectric patches are electrically connected together and then several vibration modes exhibit electromechanical couplings. The goal of this experiment is to show that, for those coupled mode, the SSD technique has multimodal vibration damping capabilities.

Most of the piezoelectric surface is connected to the nonlinear switching device, but a small part is used as a vibration sensor. Practically, the switch S_W is an electronic switch driven by a digital signal processor (DSP) which detects the main extrema of the sensing voltage V_S. The variable continuous voltage source V_{cc} is actually the output of a basic operational amplifier driven by the DSP. The amplitude

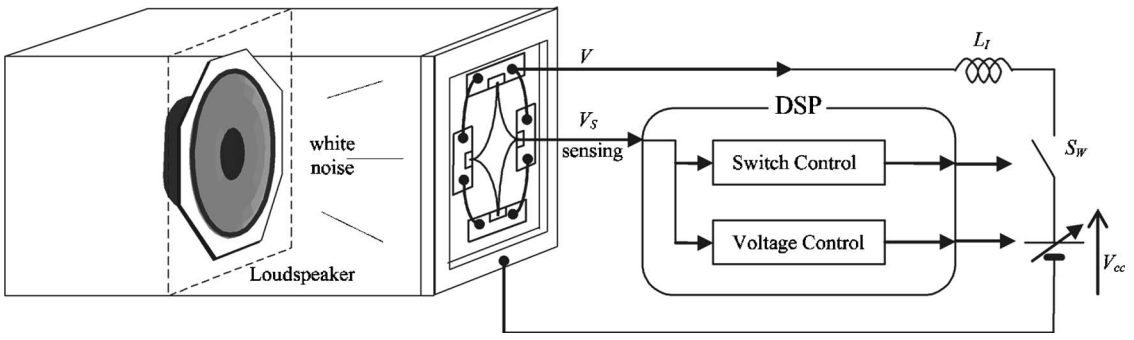

FIG. 13. Experimental setup.

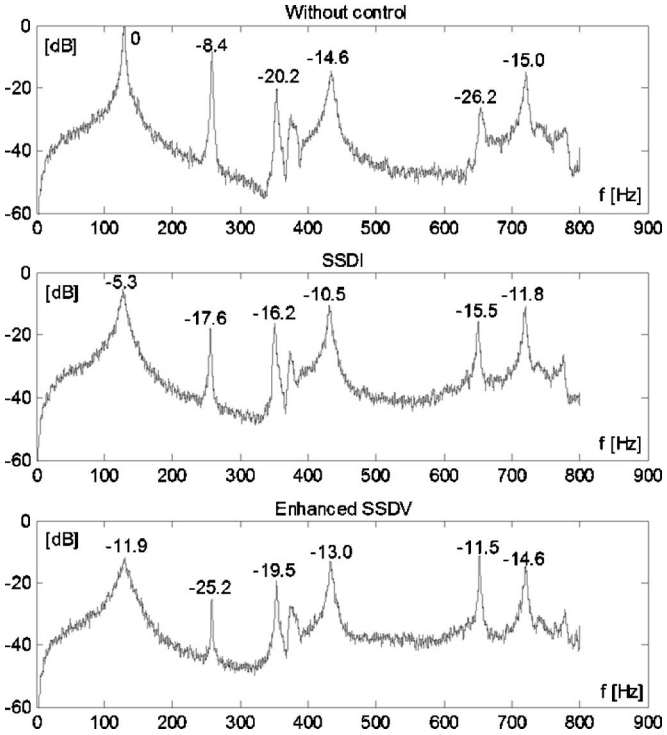

FIG. 14. Spectrum of sensing voltage temporal derivative without control, using the SSDI technique and using the enhanced SSDV technique.

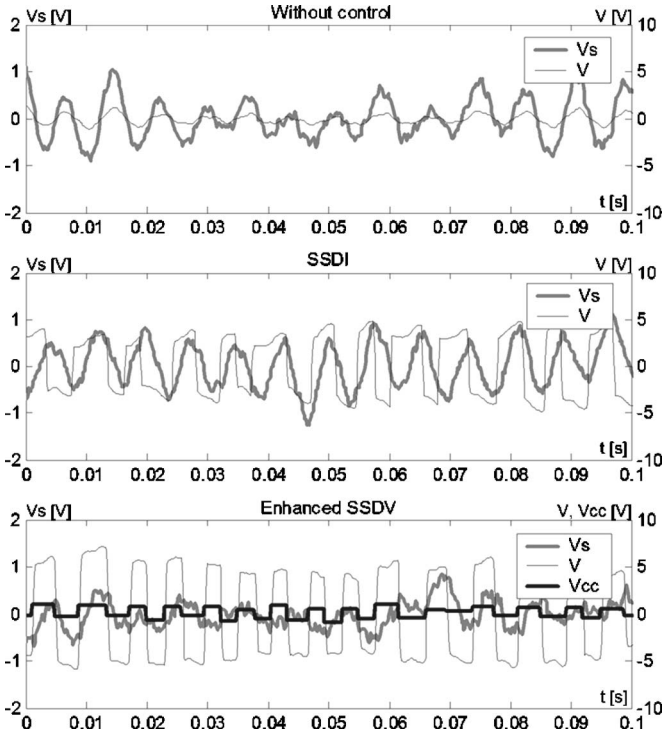

FIG. 15. Voltage and strain waveforms without control, using the SSDI technique and using the enhanced SSDV technique.

of V_{cc} is simply set to be proportional to the amplitude of V_S. The optimal gain coefficient β is fitted only one time. It is 2.2 in this experimental case.

In this first approach, only the coupled modes are considered and, thus, the sensing voltage V_S can be used to monitor the board vibrations on these particular modes.

B. Results

The vibration generated by the noise is related to the harmonic response of the board, and the voltage V_S, which is used for the monitoring of the board vibration for the coupled mode, is also related to the coupling coefficient corresponding to each mode.

Three cases are considered: vibration without control, SSDI control, and enhanced SSDV control. The spectrum of the temporal derivative of V_S is plotted in Fig. 14 in the three cases. The voltage temporal derivative is used instead of the voltage itself for clarity reasons, in order to emphasize the effect of the SSD techniques on higher frequencies. Without control, the first mode (130 Hz) exhibits the highest line, principally because it is the highest coupled mode. Characteristics of the first mode are given in Table V. The other modes are not as highly coupled and their squared coupling coefficients are between 0.1% and 0.5%. The uncontrolled voltage V_S is roughly harmonic, since the first mode is at least 8 dB higher than the other lines.

TABLE V. Characteristics of the board first mode (composite board).

Resonance frequency	130 Hz
Mechanical quality factor	30
Squared coupling coefficient k^2	1%

It is shown that using the SSDI technique leads to a −5.3 and −9.2-dB attenuation of the two main lines (the two first lines) of the spectrum without control. Other lines are increased, especially the 651-Hz one, but remain lower than the first line corresponding to the resonance frequency.

Using the enhanced SSDV technique leads to a −11.9 and −18.8-dB attenuation of the two main lines without control. It can be noticed that except for the 651-Hz line, which is greatly increased, the other lines remain almost constant. Actually, all lines are under −11.5 dB and the 651-Hz line is the most important line. It should also be noticed that the spectrum corresponds to the voltage temporal derivative and that the most important line would still be the first resonance frequency considering the voltage spectrum.

Actually the SSD techniques mainly control the first resonance frequency and its corresponding nonlinearity (the second line, which is twice the first resonance frequency). The SSD techniques lead then to a leveled down spectrum, since the first mode is mainly addressed. The switch frequency mainly corresponds to the first resonance frequency of the board. The sharp edges of the piezovoltage, resulting from the nonlinear processing, generate then excitations on odd multiples of the first resonance frequency. The 651-Hz line magnitude is increased because it corresponds to both a resonance frequency of the structure and an odd multiple of the first resonance frequency. The global damping effect of the SSD techniques can be evaluated by Eq. (44). The SSDI global damping effect is −2.3 dB whereas it is −6.1 dB using the enhanced SSDV approach:

$$A_{\mathrm{dB}} = 10 \log \left(\frac{(\int V_s^2 \, dt)_{\text{with control}}}{(\int V_s^2 \, dt)_{\text{without control}}} \right). \tag{44}$$

Figure 15 gives a representation of the sensing voltage V_S

and the processed voltage V for a small part of the whole recorded time. In the case of the enhanced SSDV technique the continuous voltage V_{cc} is also plotted. It clearly shows the voltage magnification due the SSDI technique and its enhancement using the voltage source.

The noise transmission control is not fully addressed in the first approach presented here. Further work will consist in using the SSD technique on several sets of piezoelectric patches, each coupled to a set of vibration modes. The control of the panel vibration will then reduce the noise transmitted through the board.

V. CONCLUSION

The enhanced SSDV technique allows us to tune the mechanical braking force resulting from the SSDV process to the vibration level. The continuous voltage source that amplifies the voltage inversion is proportional to the vibration amplitude. With the original SSDV technique, the absolute value of the continuous voltage remains constant which induces stability problems when the vibration amplitude tends to zero. Current work aims at clarifying the stability problems of the original SSDV technique. Several phenomena must be taken into account which reduce the system stability: higher harmonics excitation due to the sharp edges of the piezovoltage, technical difficulties to detect extrema for very low vibration level, overbalance of the external force when switching on too high voltage source, and practical delay between extrema occurrences and the moment they are detected.

These stability problems are bypassed using the enhanced SSDV. In the case of a single frequency excitation, it was shown that the enhanced SSDV technique gives a drastic constant and stable damping whatever the amplitude of the driving force (up to -30 dB when $\beta=6$). Experimental results also show that the enhanced SSDV technique is able to simultaneously control the different lower frequency modes of a composite plate. Ongoing work also aims at qualifying the panel sound transmission coefficient and its control using SSDI, SSDV, and enhanced SSDV techniques. Due to their simplicity and relative low cost, these SSD techniques could prove to be competitive for noise isolation.

(Received 20 October 2005; revised 17 February 2006; accepted 19 February 2006)

Acoustic surface impedance of sound absorbing materials can be measured by several techniques such as the impedance tube for normal impedance or the Tamura method for normal and oblique surface impedance. *In situ*, the acoustic impedance is mostly measured by use of impulse methods or by applying two-microphone techniques. All these techniques are based on the determination of the sound pressure at specific locations. In this paper, the authors use a method which is based on the combined measurement of the instantaneous sound pressure and sound particle velocity. A brief description of the measurement technique and a detailed analysis of the influence of the calibration, the source type, the source height, the sound incidence angle, and the sample size are included. I. INTRODUCTION

To model the performance of acoustic absorbing materials in practice, researchers are interested in the reflection coefficient of those materials for different angles of sound incidence. The acoustic surface impedance and the absorption coefficient of absorbing materials can be measured with the impedance tube[1] for normal sound incidence or the Tamura method[2,3] for normal and oblique incidence of sound. For *in situ* measurements, common techniques are the impulse method[4] or the two-microphone technique.[5] Allard *et al.*[6] present a method for measurements around grazing incidence *in situ*. All these techniques make use of the measurement of local sound pressure.

As mentioned before, a proven technique to determine the angle dependency of the surface impedance and the absorption coefficient is described by Tamura. In this method, sound pressure is measured in two planes parallel to the surface of interest and a two-dimensional Fourier transformation is used to calculate the angle dependent surface impedance. Thus, no assumptions about the exact nature of the wave field are made. However, a drawback of the method is the rather complicated measurement setup together with the need for large test samples and the time-consuming measurement procedure.

In this paper, a new method for determining the surface impedance and the absorption coefficient of an absorbing material in the free field is investigated. A brief description of the measurement technique and a detailed analysis of the influence of the calibration, the source type, the source height, the sound incidence angle, and the sample size is included. All time-varying quantities should obey the time dependence $e^{-i\omega t}$ with $i=\sqrt{-1}$.

II. MEASUREMENT DEVICE

A. Working principle of the particle velocity transducer

The transducer consists of two very closely spaced heated wires. The measurement principle is based on the detection of the temperature difference between these two resistive sensors.[7] A traveling acoustic wave causes a time varying heat transfer from one sensor element to the other. The subsequent temperature difference results in a time-dependent difference between both electrical resistance values, which quantifies the particle velocity in a linear matter. However, due to the effects of diffusion and heat capacity, the sensitivity of the particle velocity sensor decreases with frequency.[8] In the *p-u* measurement probe, commercially known as "Microflown," a particle velocity sensor (u) and a miniature pressure microphone (p) are placed close together. In that way, local field impedance can directly be measured. This combination was shown to be able to measure the absorption coefficient in an impedance tube accurately.[9]

B. Calibration methods

Depending on frequency, a calibration can be performed in a standing wave tube or alternatively a free field calibration can be used. The standing wave tube calibration is used for lower frequencies (100 Hz–4 kHz). The free field calibration is applicable in the frequency range 200 Hz–20 kHz.

[a]Electronic mail: reinhilde.lanoye@bwk.kuleuven.be

 0001-4966/2006/119(5)/2826/6/$22.50

1. Standing wave tube calibration

In a standing wave tube, the sound pressure at a distance x from the rigid ending is given by

$$p(x,t,\omega) = A(e^{ikx} + e^{-ikx})e^{-i\omega t} \tag{1}$$

at frequencies below the cut-off frequency.

The particle velocity at the same position is given by

$$u(x,t,\omega) = \frac{1}{i\omega\rho_0}\frac{\partial p(x,t,\omega)}{\partial x} = \frac{A}{\rho_0 c}(e^{ikx} - e^{-ikx})e^{-i\omega t}. \tag{2}$$

The calibration of the pressure and particle velocity sensor as well as their phase difference is done separately to allow for the use of the combined probe (p-u probe) not only as an impedance sensor but also for intensity and particle velocity measurements.

A reference microphone is mounted at the rigid reflecting ending of the standing wave tube with a length of 76 cm and a diameter of 4.7 cm. At the other end, a loudspeaker is placed. If the p-u probe is set at a distance l from the reflecting surface (l lies typically in the range of 50 cm in these measurements), the ratio between the pressure measured by the p-u probe and the pressure at the reflecting ending is given by

$$\frac{p_{\text{probe}}(\omega)}{p_{\text{ref}}(\omega)} = \cos(kl). \tag{3}$$

The ratio between the particle velocity measured by the p-u probe and the pressure at the reflecting ending equals

$$\frac{u_{\text{probe}}(\omega)}{p_{\text{ref}}(\omega)} = \frac{i}{\rho_0 c}\sin(kl). \tag{4}$$

To calibrate the phase difference between the particle velocity sensor and the miniature pressure microphone in the combined probe, the ratio of particle velocity and pressure is measured. Theoretically, the ratio between both at the same point in the standing wave tube is

$$\frac{u_{\text{probe}}(\omega)}{p_{\text{probe}}(\omega)} = \frac{i}{\rho_0 c}\tan(kl) \tag{5}$$

and thus, the phase difference has to be equal to

$$\text{phase}\left\{\frac{u_{\text{probe}}(\omega)}{p_{\text{probe}}(\omega)}\right\} = \pm 90^\circ. \tag{6}$$

The difference between the measured phase and the theoretical value is used for calibration of the phase.

To calculate the frequency dependent sensitivity of the pressure sensor (sens_p) and particle velocity sensor (sens_u), the measured (voltage) transfer function is multiplied by the reference microphone sensitivity and, for the particle velocity sensor, additionally with $\rho \cdot c$. Following from Eqs. (3) and (4), the local maxima of these scaled transfer functions mark the sensitivity of the sensors at the respective frequency. A spline interpolation is done to obtain calibration values for the whole frequency range. In Fig. 1, the scaled transfer function and the resulting sensitivity is shown for the particle velocity sensor.

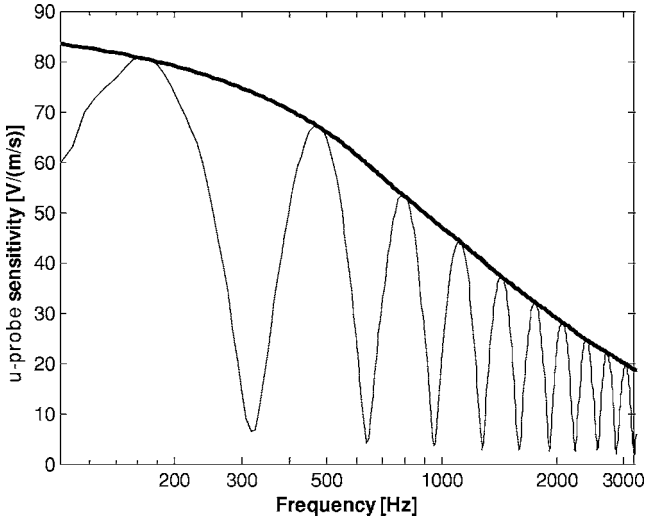

FIG. 1. Sensitivity of the Microflown element of the p-u probe. The thin line shows the measured ratio of the particle velocity at the p-u probe to the pressure at the rigid ending. The thick line marks the frequency dependent sensitivity in V/(m/s).

To obtain the phase correction function (phase_up), the local maxima and minima of the phase difference between the particle velocity sensor and the pressure microphone of the p-u probe are determined. Again, a spline interpolation is done to obtain calibration values for the whole frequency range. Following Eq. (6), the mean of the maximum and minimum values marks the deviation from ideal (zero phase) behavior and is used as correction function as shown in Fig. 2.

The preceding calibration method has the advantage of not requiring a precise value for l and c.

A correction function (CF) can be defined for the standing wave tube calibration. Later measurements have to be multiplied with this correction function to obtain calibrated measurement results. CF is defined in

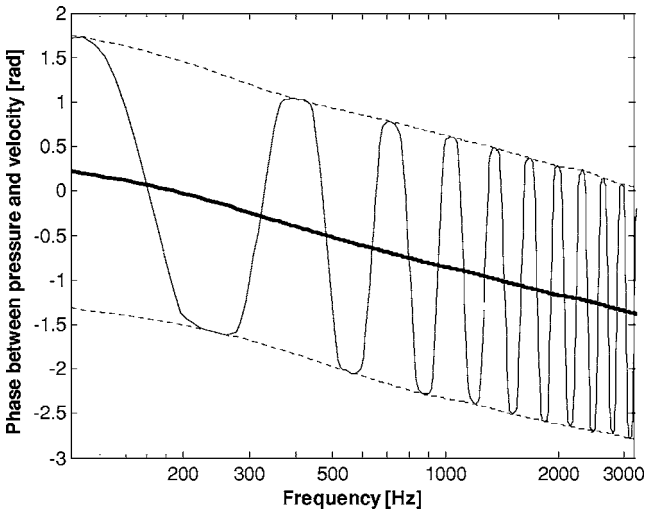

FIG. 2. Phase difference between the particle velocity sensor and the pressure element of the p-u probe. The thin line shows the measured phase between the particle velocity and the pressure at the p-u probe. The thick line marks the frequency dependent phase error.

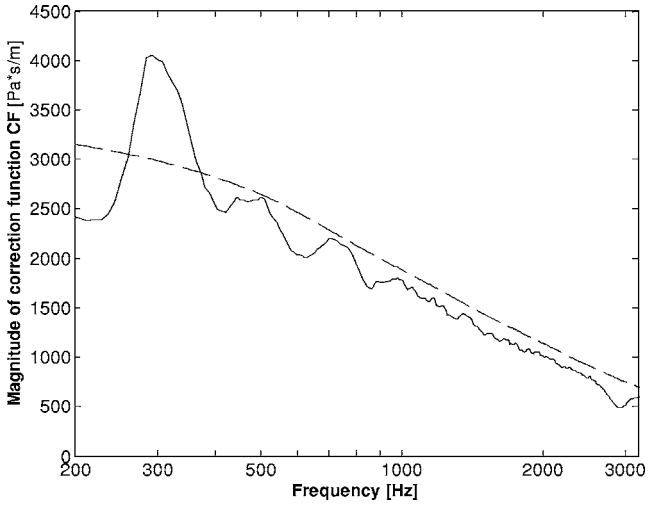

FIG. 3. Magnitude of the correction function (CF). Free field calibration (——) vs standing wave tube calibration (---).

$$\mathrm{CF} = \frac{\mathrm{sens\_}u}{\mathrm{sens\_}p} e^{i\cdot \mathrm{phase\_}up}. \tag{7}$$

Effects of damping along the tube could be shown to be negligible following an analysis based on Tijdeman's theory.[10]

2. Free field calibration

Free field calibration relies on the fact that the field impedance in a free field at a distance r is given by

$$Z_0(r,\omega) = \rho_0 c \frac{ikr}{ikr-1} \tag{8}$$

if sound is emitted by a point source.

The ratio between pressure and particle velocity is measured in free field conditions and equals Z_m. The ratio of the theoretical free field impedance to the measured impedance is the correction function,

$$\mathrm{CF} = \frac{Z_0}{Z_m}, \tag{9}$$

which is subsequently applied for calibration of all p-u measurements to obtain the calibrated field impedance. In contrast to the standing wave tube calibration, pressure and particle velocity probe cannot be calibrated separately.

The magnitude of the CF is represented in Fig. 3 for both the standing wave tube calibration [Eq. (7)] and the free field calibration [Eq. (9)]. The calibration function of the free field calibration is measured with use of a loudspeaker in a box and a probe-loudspeaker distance of 1.18 m. The probe is placed above absorbing wedges.

In the figure, a difference between both correction functions can be seen, especially at low frequencies. These deviations are due to unwanted reflections in the semi-anechoic room, e.g., coming from the floor. So, one can conclude that free field calibration is too sensitive to reflections for use at low frequencies.

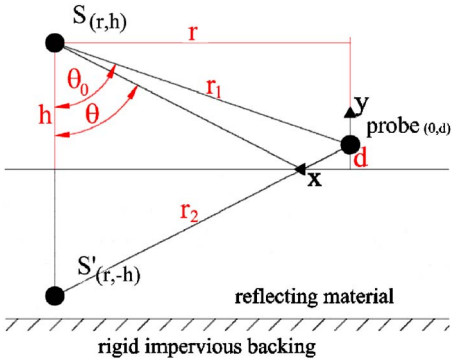

FIG. 4. (Color online) Mirror source model of the reflection of a spherical wave at an impedance plane.

III. CALCULATION TECHNIQUE

Two models are used to derive the surface impedance of a material from the measured field impedance at a certain single point above the surface. Both models assume a point source excitation of the air medium above the sample.

A. Mirror source model

This model assumes a plane-wave-like reflection. To include the reflection, a mirror source is placed behind the sample at the same distance as the physical source is placed from the sample, see Fig. 4.

This assumption is only valid if the source-sample distance is large compared to the wavelength.[11]

The angle dependent plane wave reflection coefficient $R_p(\omega,\theta)$, which can be calculated out of a measured impedance at a normal distance d above the surface, is given by

$$R_p(\omega,\theta) = e^{ik(r_1-r_2)} \frac{r_2}{r_1} \frac{Z(d,\omega)\dfrac{1-ikr_1}{-ikr_1}\cos\theta_0 - \rho_0 c}{Z(d,\omega)\dfrac{1-ikr_2}{-ikr_2}\cos\theta + \rho_0 c}. \tag{10}$$

r_1 equals the length of the direct path, r_2 is the length of the path mirror source-measurement point, and θ is the specular angle of incidence. θ_0 in this equation is the angle between the normal to the surface and the path which connects source and measurement point.

B. Asymptotic solution for locally reacting surfaces

The F-term solution of Nobile and Hayek[12] for the sound field above an impedance plane takes into account that a spherical wave is reflected differently from a plane wave. It assumes a locally reacting surface.

The velocity potential at a distance d above the impedance plane is given by

$$\phi(d) = \frac{e^{ikr_1}}{r_1} + Q\frac{e^{ikr_2}}{r_2} \tag{11}$$

in which Q denotes the spherical wave reflection coefficient

$$Q = R_p + (1-R_p)F. \tag{12}$$

R_p is the plane wave reflection coefficient, F the boundary loss function. This function F is determined by the geometry

TABLE I. Properties of the studied porous material.

Thickness (mm)	Density (kg/m^3)	Porosity (–)	Tortuosity (–)	Flow resistivity (Ns/m^4)	Viscous length (μm)	Thermal length (μm)
30	10	>0.95	1.09	10500	100	150

of the problem and the impedance of the absorbing surface. The pressure is given by

$$p(d) = \rho \frac{\partial \phi}{\partial t} = -i\rho\omega\phi, \tag{13}$$

the particle velocity by

$$u(d) = -\operatorname{grad} \phi(d). \tag{14}$$

This gradient is estimated by a finite difference approach,

$$u(d) = [\phi(d+\varepsilon) - \phi(d-\varepsilon)]/2\varepsilon \tag{15}$$

with a small ε.

With a minimum search, the surface impedance which minimizes the difference between the measured field impedance and the field impedance predicted by the model is found. The resulting surface impedance serves to calculate the plane wave absorption coefficient of the material.

If the source-sample distance and the measurement frequency are large enough, both calculation methods will be equivalent.

IV. MATERIAL DESCRIPTION

In this study, the measurement material is a 3 cm thick open-cell Melamine foam. The properties of this foam, given in Table I, are measured according to the appropriate methods. Descriptions of the methods to measure the characteristic lengths are given by Leclaire *et al.*[13] The techniques to measure porosity and tortuosity are described by Fellah *et al.*[14] The method to measure flow resistivity is given in ISO-9053.[15]

This material is assumed to behave as an equivalent fluid. To simulate the surface impedance and the absorption coefficient of this material, the theory of Johnson *et al.*[16] and Champoux and Allard[17] is used.

V. MEASUREMENT PROCEDURE

The measurements described in the following were performed in a semi-anechoic chamber with a lower limiting frequency of 150 Hz. The air in this semi-anechoic room was excited with two different sound sources, both driven with bandwith limited pseudorandom noise between 100 Hz and 6.4 kHz. The considered sound sources are a Monacor KU-156 compression driver with a 10 cm tube of $\frac{1}{2}$ in. diameter mounted on it ("point source") and a 20 cm woofer in a closed box. A Stanford Research System SR780 network analyzer was used for all measurements and postprocessing was done with MATLAB.

Samples of different sizes were placed on the rigid floor and the *p-u* probe was mounted above the surface at a height between 1.5 and 3 cm at a radial distance to the source equaling a sound incidence angle of up to 60°. The orientation of the *p-u* probe was carefully checked to agree with the normal of the sample surface.

VI. SENSITIVITY ANALYSIS

In the following, a detailed analysis of the influence of some measurement parameters is given. For the convenience of the reader and to provide a compact presentation of the results, the results are presented as absorption coefficients. Measurements are performed on a 1.8×1.2 m^2 sample, unless stated otherwise.

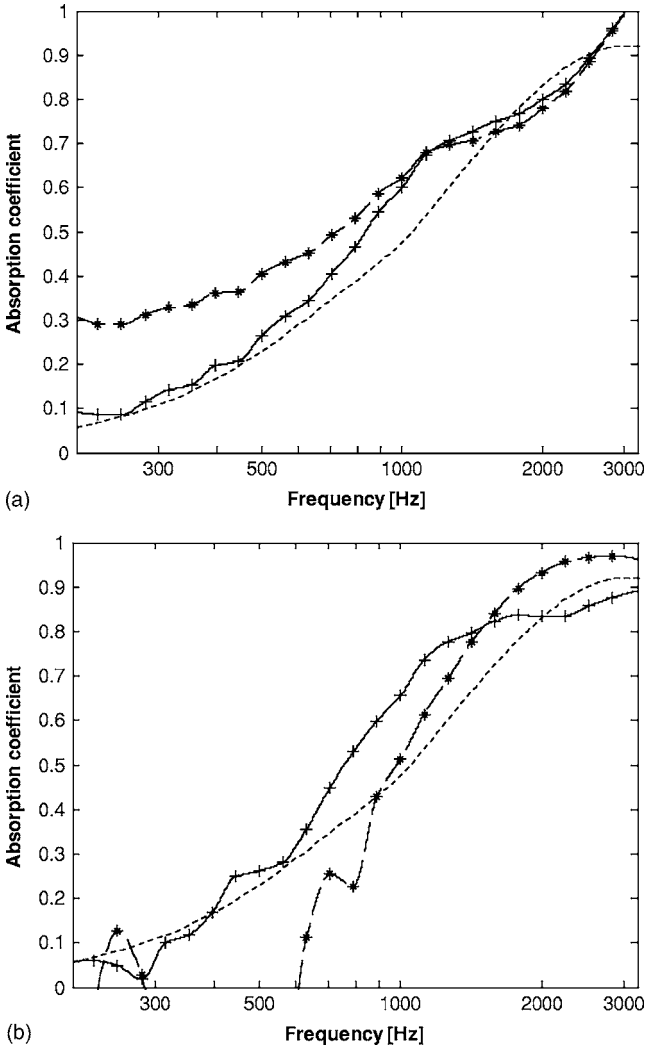

FIG. 5. Absorption coefficient of 3 cm Melamine foam for normal incidence. (a) Comparison of the mirror source model (*) and the asymptotic solution (+). Simulation results (···). (b) Comparison of the free field calibration (*) and the standing wave tube calibration (+). Simulation results (···).

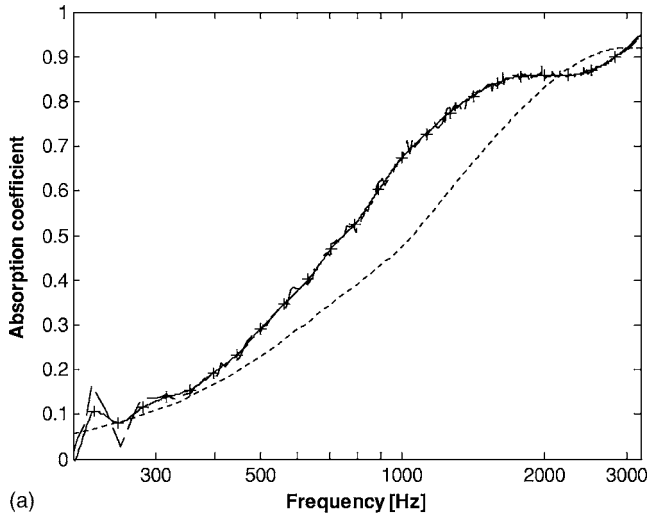

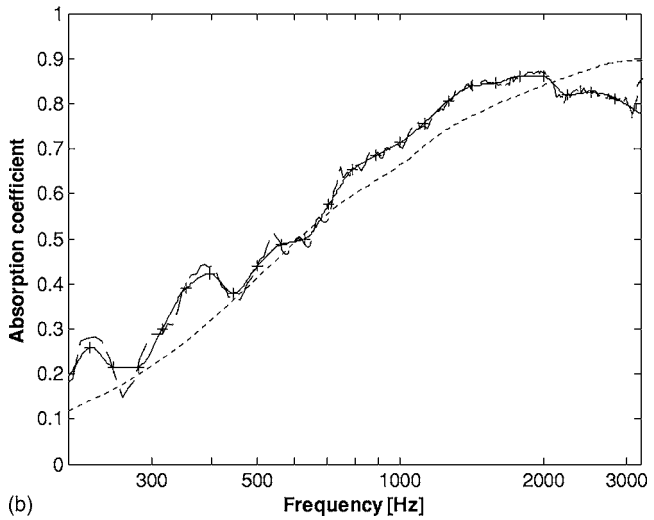

FIG. 6. Absorption coefficient of 3 cm Melamine foam. Measurement (---) with a woofer in a closed box at 1.21 m height. 1/6th octave average marked with (+). Simulation results (···). (a) Normal incidence, (b) 45° incidence.

A. Comparison of calculation models

In Fig. 5(a), a comparison is made between both above-described calculation methods. The same field impedance measurement, calibrated with a standing wave tube calibration, is used for this comparison. At low frequencies, the mirror source model differs significantly from the simulation. As shown in the experiments, the best agreement is found for the asymptotic model, which is further used as the reference.

B. Comparison of calibration methods

As can be seen in Fig. 5(b), a standing wave tube calibration allows more accurate measurements at low frequencies than a measurement with a free field calibration of the sensor probe. The surface impedance and absorption coefficient were calculated with the asymptotic solution.

C. Influence of source type

Comparison measurements were done with two different, above-described, sound sources. It could be concluded that the measurements with the loudspeaker in a box are the most accurate, especially at low frequencies, and this source will thus be used in further research. The good result for low frequencies is due to the high sound pressure that can be reached with a loudspeaker in a box. Therefore, the particle velocity at the surface of a material with high impedance is still measurable. This source has also the advantage of increasing directivity at higher frequencies and therefore avoids unwanted reflections.

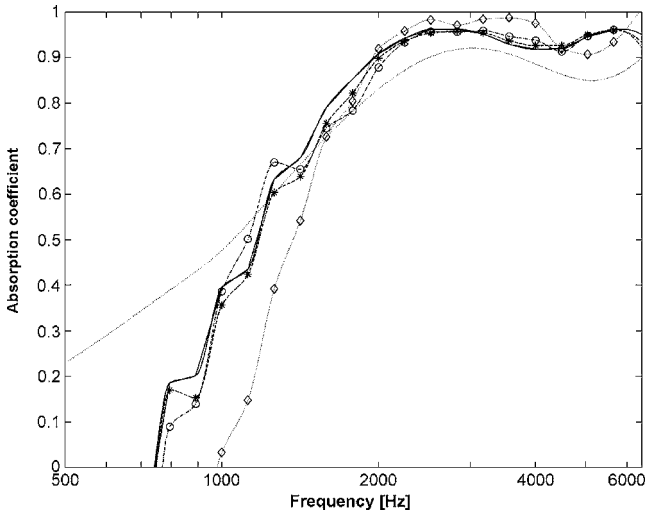

FIG. 7. Absorption coefficient of 3 cm Melamine foam for normal incidence: Influence of sample size. The size were 1.2×1.2 m^2 (---), 0.6×0.6 m^2 (*), 0.3×0.3 m^2 (°), and 0.15×0.15 m^2 ($\diamond$). Simulation results (···).

D. Influence of source height

The source was placed at different heights between 0.85 and 1.71 m above the absorbing material. If the solution of Nobile and Hayek is used to calculate the surface impedance, no significant differences can be found between the calculated absorption curves for different source heights. When the mirror source model is used, the solution below 1.2 kHz deviates more and more from the simulation when the source is placed closer to the surface.

E. Influence of incidence angle

Compared to the standing wave tube, one of the main advantages of this measurement technique is the possibility to measure the surface impedance for an arbitrary angle of sound incidence. The technique is also faster than the Tamura method. Measurements for a number of incidence angles were performed. The results for normal incidence and an angle of incidence of 45° are, respectively, shown in Figs. 6(a) and 6(b). The results for normal incidence are the best, since the phase between particle velocity and pressure is larger at normal incidence than at oblique incidence and hence the influence of the phase mismatch after calibration is smaller.

F. Influence of sample size

In this specific study, a point source was used. Knowing the required sample size is very important to know the *in situ*

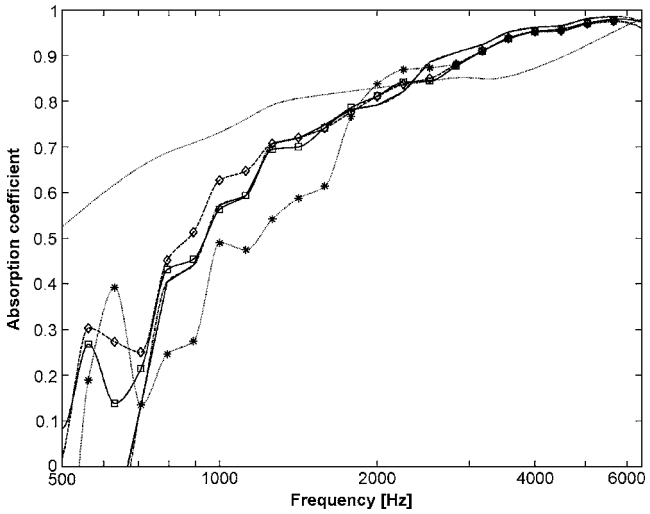

FIG. 8. Absorption coefficient of 3 cm Melamine foam for 60° incidence angle: Influence of sample size. The size were 2.4×1.2 m^2 (□), 1.8×1.2 m^2 (◇), 1.2×1.2 m^2 (---), and 0.6×0.6 m^2 (*). Simulation results (···).

applicability of the measurement device. The absorption coefficient from 200 Hz up to 6.4 kHz is measured. Results of these measurements are plotted in Figs. 7 and 8. One can clearly see that a larger sample size is necessary for more oblique angles of incidence. For 60°, there is even a sample size of 1.8×1.2 m^2 necessary to obtain good results. The poor quality of the measurements at low frequencies is due to the free field calibration, but thanks to this calibration method, one can plot higher frequency results.

VII. CONCLUSION

A new method for the measurement of the surface impedance in free field of a layer of absorbing material has been investigated in this paper. When using this method, a simultaneous measurement of the particle velocity and the pressure above the absorbing material is performed, so the field impedance close to the surface can be measured directly. The asymptotic solution for the calculation of the surface impedance has been shown to give the best results.

By means of the presented sensitivity analysis, it can be concluded that reasonably accurate and fast measurements can be performed with this new method, provided that the particle velocity-pressure transducer is adequately calibrated. Also oblique surface impedance measurements are possible with this technique. For normal to slightly oblique incidence, a rather small absorbing surface is sufficient and so the method could be applied for *in situ* analysis of local sound absorption.

(Received 1 September 2005; revised 14 February 2006; accepted 14 February 2006)

A field test was conducted on the accuracy of an eight-microphone acoustic location system designed to triangulate the position of duetting rufous-and-white wrens (*Thryothorus rufalbus*) in Costa Rica's humid evergreen forest. Eight microphones were set up in the breeding territories of 20 pairs of wrens, with an average intermicrophone distance of 75.2±2.6 m. The array of microphones was used to record antiphonal duets broadcast through stereo loudspeakers. The positions of the loudspeakers were then estimated by evaluating the delay with which the eight microphones recorded the broadcast sounds. Position estimates were compared to coordinates surveyed with a global-positioning system (GPS). The acoustic location system estimated the position of loudspeakers with an error of 2.82±0.26 m and calculated the distance between the "male" and "female" loudspeakers with an error of 2.12±0.42 m. Given the large range of distances between duetting birds, this relatively low level of error demonstrates that the acoustic location system is a useful tool for studying avian duets. Location error was influenced partly by the difficulties inherent in collecting high accuracy GPS coordinates of microphone positions underneath a lush tropical canopy and partly by the complicating influence of irregular topography and thick vegetation on sound transmission. I. INTRODUCTION

An acoustic location system consists of an array of microphones that facilitates spatial monitoring of animals based on the sounds they produce. Acoustic location systems offer special research advantages because animals' natural movement patterns are not inhibited by the passive monitoring process and animals can be located even in environments characterized by visual obstructions (McGregor *et al.*, 1997). Furthermore, the signals exchanged between animals are recorded as part of the acoustic location process, facilitating detailed studies of communication processes between multiple individuals simultaneously (McGregor *et al.*, 1997; Burt and Vehrencamp, 2005). Acoustic location systems have been used extensively to monitor the behavior of many marine organisms, with particular focus on large mammals (e.g., Stafford *et al.*, 1998; Mellinger and Clark, 2003; Clark and Clapham, 2004). In contrast, research employing terrestrial acoustic location systems is uncommon (but see Spiesberger, 1999; Hayes *et al.*, 2000; Mohl *et al.*, 2001; Wahlberg *et al.*, 2001, 2003; Bower and Clark, 2005; Burt and Vehrencamp, 2005). Here we test the accuracy of a passive acoustic location system for monitoring the position of duetting songbirds in neotropical forest.

Duets occur when two animals, usually breeding partners, coordinate their songs in overlapping or exactly alternating bouts of vocalizations. Duets are produced in many texa, including insects (Bailey, 2003), frogs (Emerson and Boyd, 1999), mammals (e.g., Geissmann, 2002), and birds (Hall, 2004). Duetting occurs in more than 220 species of birds and ranks among the most highly coordinated behaviors known in the animal kingdom (Thorpe, 1963; Hall, 2004). However, much controversy and little consensus surrounds the ecological and evolutionary significance of duetting, as well as the mechanics of vocal coordination by duetting partners. This is, in part, because many duetting birds live in densely vegetated tropical forest where traditional tools for following and observing animals, such as visual tracking or radiotelemetry, are difficult. Nevertheless, spatial analyses of duetting may allow for an advanced understand-

ing of the significance of this intriguing behavior. We were interested in studying duetting behavior in neotropical rufous-and-white wrens (*Thryothorus rufalbus*) from a spatial perspective. To that end, we developed an eight-microphone acoustic location system for spatial monitoring of the duetting behavior of birds in the humid forests of northwest Costa Rica. In this study we present a test of this system by quantifying the accuracy with which microphone array recordings allowed us to triangulate the position of loudspeakers broadcasting simulated rufous-and-white wren duets.

II. METHODS

A. Study species and study site

Rufous-and-white wrens live in forested and semi-forested habitat throughout much of Central America and northwestern South America. Males and females coordinate their songs to produce both antiphonal and polyphonal duets. The voices of the two sexes are similar, although male songs have significantly lower frequency characteristics and are significantly longer than female songs (Mennill and Vehrencamp, 2005). Rufous-and-white wrens are largely ground-dwelling songbirds (Ahumada, 2001) and typically remain in very low vegetation, occasionally ascending to higher perches to sing.

At Santa Rosa National Park in northwest Costa Rica (10°40′N, 85°30′W), our study population of rufous-and-white wrens inhabits the fragments of evergreen moist forest that remain within the mosaic of regenerating forests that constitute the Guanacaste Conservation Area. The study site is characterized by thick vegetation, including a rich vertical structure and a lush canopy dominated by guapinol (*Hymenea courbaril*), milk (*Brosiumu utile*), and chicle (*Manilkara chicle*) trees. The study site also has diverse topography—the wrens' territories follow the sloped stream-sides and small escarpments that are associated with the park's evergreen moist forest. These biotic and abiotic features of rufous-and-white wren territories provide a challenging model system in which to test an acoustic location system: rich understory vegetation complicates sound transmission, thick forest canopy makes high-accuracy survey coordinates difficult to obtain, and topographic diversity complicates both sound transmission and satellite reception. Therefore, if an acoustic location system can be used to accurately monitor the position of duetting birds in this habitat, it will be useful for monitoring animals in many other habitats as well.

B. Field methods

Our acoustic location system consisted of an array of eight omni-directional microphones which were connected by 1200 m of microphone cable to a centrally located computer. Microphone input was digitized using a multi-channel data acquisition card (model: National Instruments DAQ-6260). The microphones were housed in rain guards made of PVC tubing and speaker cloth, mounted on top of 3-m wooden poles via 30-cm shelf brackets. Stakes were elevated off the ground and attached to trees with bungee cords (Fig. 1). We attempted to space microphones evenly throughout each rufous-and-white wren territory, mounting microphones opportunistically where vegetation allowed. Within each array, the average between-microphone distance was 75.2±2.6 m (calculated pairwise for all microphones in each array), the maximum distance was 137.6±5.9 m, and the minimum distance was 31.5±1.4 m (mean±SE; $n=20$ array configurations).

FIG. 1. Photograph of one of the eight microphones used to record playback of rufous-and-white wren duets. Microphones were placed on 3.0-m wooden poles and attached to trees within wren territories. The average between-microphone distance within each of the 20 array configurations was 75.2±2.6 m.

Between 18 April and 8 July 2003 and 2004 we used the eight-channel microphone array to record duets played through stereo loudspeakers within the breeding territories of 20 different pairs of wrens. Recording sessions were conducted between 0630 and 0845 h. The left and right loudspeakers (model: Sony SRS-A37) were separated by a distance of 10 to 20 m (average distance between loudspeakers: 16.3±0.5 m), a distance within the observed range of distances between duetting rufous-and-white wrens. The left loudspeaker broadcast one bird's duet contribution and the right loudspeaker broadcast the partner's duet contribution. The loudspeakers were oriented upwards and mounted on poles at a height of 1.0 m. Stimuli were broadcast from a portable CD player (model: Sony D-SJ301). The volume of broadcast songs was held constant across all trials, at a natural sound pressure level of 80 dB at 1 m (measured at a horizontal distance from the upwards-oriented loudspeaker using a Realistic 33-2050 sound level meter on slow setting).

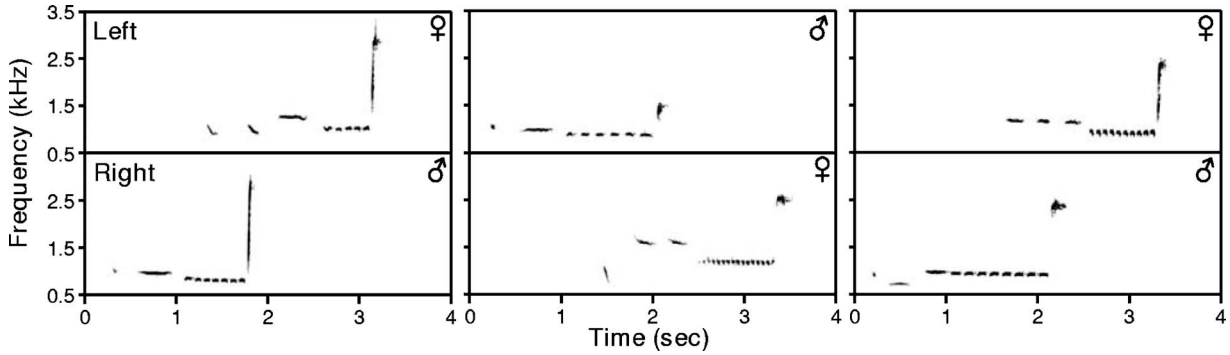

FIG. 2. Sound spectrograms of rufous-and-white wren duet stimuli broadcast within the acoustic location system. Spectrograms depict stereo sound files with the left channel on top and the right channel below. Examples of three different pairs' duets are shown.

The playback stimuli were duets recorded from the 20 resident pairs. We recorded stimuli as monaural WAV files (16 bit sampling, 22 050 Hz sample rate) with a directional microphone (model: Sennheiser MKH-70) and a solid state digital recorder (model: Marantz PMD-670) during spontaneous bouts of early-morning singing. The male and female duet components were isolated from each another using the "frequency cursor filter" function of Syrinx-PC (J. Burt, Seattle, WA). The amplitudes of both the male and female songs were then subtly adjusted to the same maximum amplitude using the "amplitude normalize" feature of CoolEdit 2000 (Syntrillium, Phoenix, AZ). Male and female songs were then pasted into the left and right channels of 16-bit stereo WAV files (Fig. 2). We alternated whether the male or female song was broadcast through the left or right channel from one playback session to the next. Rufous-and-white wren duets occur in several different varieties: the male may begin singing and the female may join in part way through the male song or immediately after it, the sex roles may be reversed, or both birds may begin singing at the same time. Male-initiated duets are the most common variety (Mennill and Vehrencamp, 2005) and for this reason we used male-initiated duets in this test of location accuracy. Within each array, we recorded the broadcast of six duets, as well as six male solos and six female solos for comparison. The solo stimuli were identical to the male and female contributions to the duet.

Traditional survey methods are difficult given the thick vegetation at our study site. We surveyed microphone and loudspeaker positions using an Ashtech ProMark II Global Positioning System (GPS; Thales Navigation, Santa Clara, CA). This system consists of twin receiver units with external antennae which collect data in tandem at two positions, allowing for differential correction based on the data collected at the two sites simultaneously. We mounted the GPS antennae on tripods at a height of 1.70 m. In an attempt to overcome the error introduced by GPS sampling underneath a thick forest canopy, we sampled points extensively and repeatedly, sampling each site two to six times between 2003 and 2005. Combined over three years of GPS sampling, we sampled the position of each microphone for 85.9 ± 1.3 min ($n=160$ microphone positions) and the position of each loudspeaker for 74.7 ± 1.6 min ($n=40$ loudspeaker positions). We used Ashtech Solutions Software (Thales Navigation, Santa Clara, CA) to calculate an average Universal Transverse Mercator (UTM) coordinate from each loudspeaker and microphone position. We report error around these coordinates as the standard error given as output by the Ashtech Solutions Software following postprocessing adjustment.

C. Array analysis

In the laboratory, we used Syrinx-PC to browse eight-channel spectrograms of field recordings. We used the time and frequency cursors of Syrinx-PC to draw a selection box around non-overlapping sections of male and female duet contributions. As is typical of rufous-and-white wren duets (Mennill and Vehrencamp, 2005), our broadcast stimuli involved duets where the terminal section of the male song was overlapped by the beginning section of the female song. Therefore, we selected only the introductory portion of male duet contributions and the terminal portion of the female duet contributions. For our analyses of the solo songs, in contrast, we were able to select the entire male or female song.

We used software written in MatLab (Mathworks Inc., Natick, MA) to estimate the location of the loudspeakers that broadcast male and female songs. The localization process consists of two components: computing cross-correlation functions and searching for the best location estimate. The correlation component begins by copying the sound data from the selected channel and applying a FIR filter to the data to restrict the signal energy to the frequency limits of the selection box. The digital samples that fall outside of the temporal bounds of the selected region are replaced with zeroes. This edited signal is cross correlated against the remaining seven channels. These correlations are resistant to the presence of other sounds within the data segment because the extent of the selection is used to mask out all the other signals in the selected channel. Twenty-one additional correlation functions are computed between all pairs of microphones that do not include the selected channel. For these correlations, it is advantageous to utilize the channels with the strongest signals to provide the masked template that is correlated against the remaining channels. The amplitudes of peaks in the initial seven correlations are used to order the seven channels in terms of estimated signal strength. The remaining correlations are computed as follows: the channel

with the highest correlation peak is correlated with the remaining six channels, the channel with the second highest correlation peak is correlated with the remaining five channels, etc. The locations of the correlation peaks are used to apply masking, to help reduce the impact of other signals that occur in the data segment. The software can deal with multiple correlation peaks that complicate the masking process, but this complication was not an issue in this study.

Once the correlation functions are computed, the estimated location of the selected sound is obtained by a stochastic search which involves the GPS coordinates of the eight microphones. For each candidate source location, the predicted time delays are computed using the Euclidean distances between the source location and the microphone locations, combined with the speed of sound. The values of the correlation functions associated with the predicted delays are extracted and these 28 values are summed. The location with the maximal sum of these correlation values provides the estimated location. This optimization criterion is algebraically identical to finding the point in space that produces the highest energy output from a delay-and-sum beamforming system (Johnson and Dudgeon, 1993). Our array analysis process assumes that the speakers lie in a plane (two-dimensional localization) and deviations from this assumption contribute to location errors. For all analyses we fixed the speed of sound at 348 m/s (corresponding to air temperature of 25 °C and 90% relative humidity, as is typical at our study site at the time of recording; see below). We evaluate how variation in air temperature and humidity—and therefore speed of sound—influenced position estimates by plotting temperature and humidity against location accuracy.

D. Location accuracy

To test the accuracy of the acoustic location system, we compared the loudspeakers' GPS coordinates to the positions estimated by the array analysis software. We report the difference as "location accuracy;" the Euclidean distance between the GPS coordinates of the loudspeaker and the array-estimated coordinates of the sound source (in meters).

To evaluate environmental variables that may have influenced the accuracy of our array-based location estimates, we compared location accuracy measurements across the 20 arrays to four features of the acoustic environment: (1) air temperature at the time of the recording, (2) relative humidity of the air at the time of the recording, (3) recording date (a rough measure of leaf phenology), and (4) variance in the height of the eight microphones within each array (a rough measure of topographic variation within each recording area). We measured temperature and humidity with a data logger (model: Hobo Pro, Onset Technology, Pocasset, MA), which was hung at a height of 1.0 m near the center of each array, and sampled the air condition every 5 min. We also compare our error measurements to two features of the microphone arrays themselves: (5) the density of microphones (measured as the average distance between all pairs of microphones in each array) and (6) the distance between the loudspeaker and the nearest microphone [a feature which has been shown to influence recording accuracy in a study of temperate microphone arrays (McGregor *et al.*, 1997)].

E. Statistical methods

All analyses were conducted in JMP 5.0 (SAS Institute, Cary, NC). We compare the location error of female versus male songs broadcast as solos versus duets with two-factor ANOVA. We test for associations between accuracy and environmental variables with Pearson correlations. All tests are two-tailed. All values are reported as mean±SE.

III. RESULTS

A. GPS accuracy

Using a global position system (GPS) to survey the positions of eight microphones within each of the 20 microphone arrays, we achieved a latitudinal accuracy of 1.26±0.05 m and a longitudinal accuracy of 1.36±0.05 m, for an average accuracy of 1.31±0.05 m (n=160 microphone positions). For loudspeaker positions, we achieved a latitudinal accuracy of 2.49±0.09 m and a longitudinal accuracy of 2.68±0.09 m, for an average accuracy of 2.59±0.09 (n=40 microphone positions; lower accuracy in loudspeaker coordinates arose from shorter sampling periods). The accuracy of all GPS coordinates was constrained by the thick canopy, as has been found in other studies involving GPS-based research in tropical forest environments (e.g., Phillips *et al.*, 1998; Dominy and Duncan, 2001).

B. Location accuracy

Using the eight-channel acoustic location system, we triangulated the position of loudspeakers broadcasting rufous-and-white wren song with an average location error of 2.82±0.26 m (n=40 loudspeakers, average location error calculated across all stimuli broadcast from each loudspeaker; Fig. 3). It is noteworthy that this value is fractionally larger than the estimated GPS location error for the speaker locations, suggesting that the combined effects of all errors in the acoustic location system are smaller than the GPS survey error for the speakers. The location error was similar for locations based on the broadcast of male solos, male duet contributions, female solos, and female duet contributions (Fig. 4; two-factor ANOVA: whole model $F_{3,76}$ =0.4, p=0.73) despite the significantly lower frequency characteristics of male songs (see Mennill and Vehrencamp, 2005). The six songs broadcast from each loudspeaker generated tightly clustered position estimates, demonstrating that our position estimates were repeatable.

Array recordings accurately estimated the distance between a pair of loudspeakers simulating the male and female duet contributions of a pair of rufous-and-white wrens. The discrepancy in the estimated distance between the male and female loudspeakers, as measured by GPS versus the acoustic location system, was 2.12±0.42 m (n=20).

C. Factors influencing location accuracy

None of the variables we measured showed a relationship with location accuracy (Fig. 5). Location accuracy did

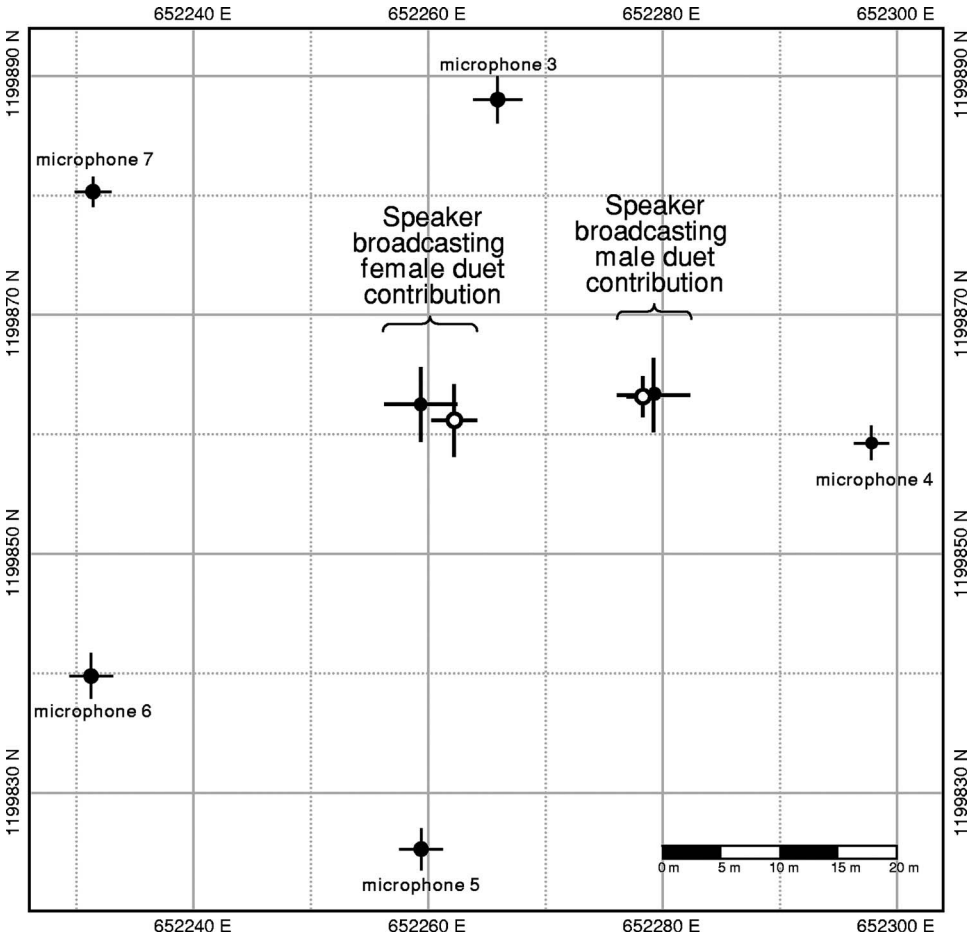

FIG. 3. Map of a portion of a microphone array, showing five microphones and two loudspeaker positions. Stereo loudspeakers were set up near the center of the area enclosed by the microphones and stereo duet stimuli were broadcast through the left and right channels. The solid circles show positions of loudspeakers and microphones measured by GPS. The open circles show the position of the loudspeakers estimated using the acoustic location system. Horizontal and vertical lines show standard error.

not vary significantly across a temperature range of 22.1 to 25.2 °C (r=0.07, p=0.67, n=40), a range typical of the early to mid morning at our study site. Location accuracy did not vary significantly across a humidity range of 58.3% to 99.2% (r=0.12, p=0.45, n=40). The acoustic location system was remarkably robust and functioned effectively even at the high humidity levels within this tropical forest.

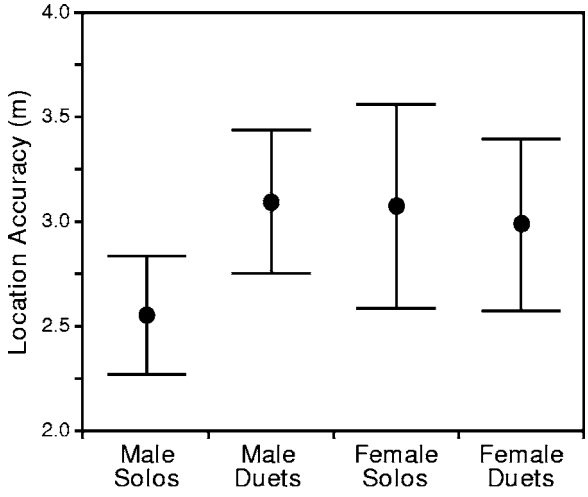

FIG. 4. Location accuracy for n=40 loudspeakers which broadcast rufous-and-white wren vocalizations and were recorded within 20 microphone arrays. Location accuracy was similar when loudspeakers broadcast male and female vocalizations, whether as solos or duets. Points show means and vertical bars show standard error.

Location accuracy did not change with the time of year (r =0.02, p=0.92, n=40), indicating that leaf phenology had little influence on the accuracy of the acoustic location system. This is not surprising, as the leaf structure of the study site remains similar throughout most of the year, varying primarily with bursts of leaf production in the canopy, as is the case for many tropical forests (van Schaik *et al.*, 1993). Despite the variation in topography at the study site, location accuracy did not show a significant relationship with topographic variation, measured as the variance in the heights of the microphones (r=0.18, p=0.26, n=40). Similarly, location accuracy did not vary significantly with microphone density (r=0.04, p=0.81, n=40) or the distance between the loudspeaker and the center of the array (r=0.09, p=0.59, n =40).

IV. DISCUSSION

The acoustic location system provided accurate estimates of the position of loudspeakers broadcasting rufous-and-white wren duets in neotropical humid forest. Triangulating the position of loudspeakers based on the delay in time with which eight microphones recorded playback stimuli, we achieved an average location error of 2.82 m. We estimated the distance between the loudspeakers broadcasting male and female duet components to within 2.12 m. Therefore, our test of acoustic location system accuracy establishes microphone array technology as a useful tool for spatial analysis of

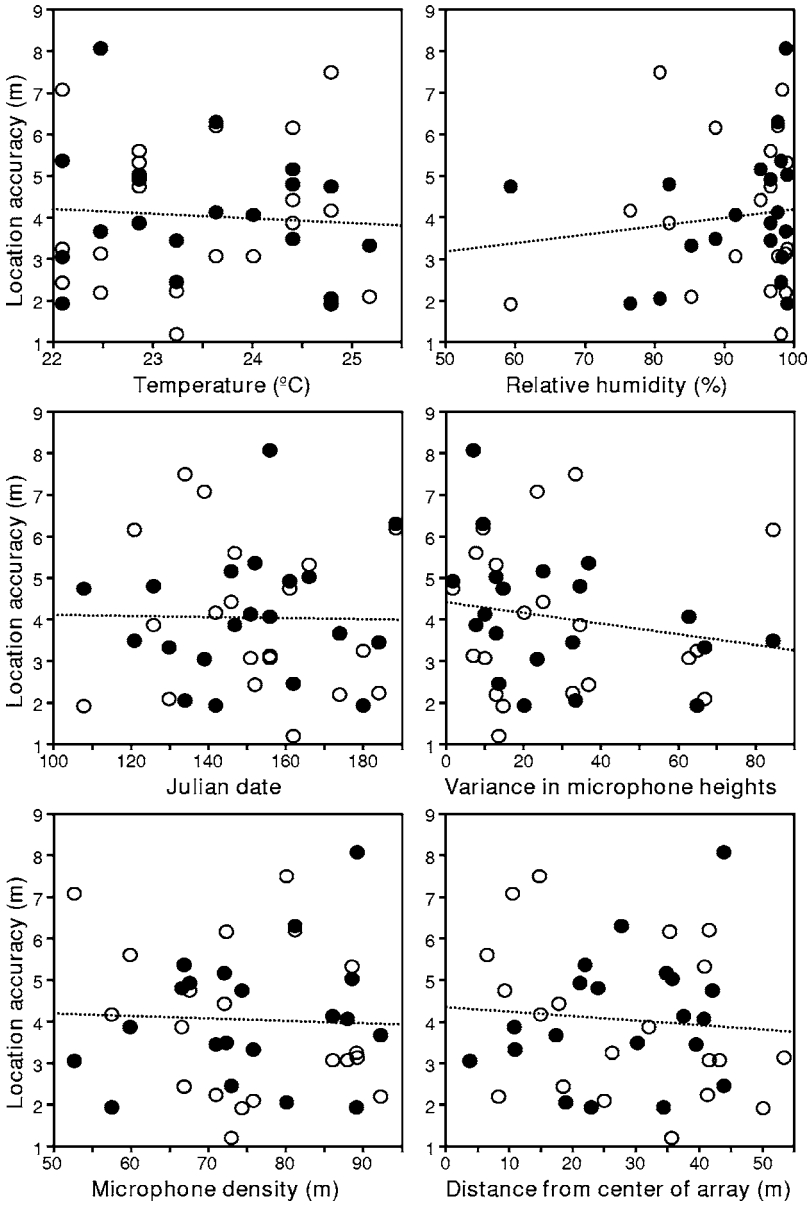

FIG. 5. Location accuracy did not show a strong relationship with four features of the recording environment or two features of the array configuration: air temperature, the relative humidity of the air, Julian date (a rough measure of leaf phenology), variance in microphone height (a rough measure of topographic variation), the density of microphones within the array (measured as the average distance between microphones), or the distance between the loudspeaker and the center of the array. Open circles show $n=20$ loudspeakers which broadcast female duet contributions and closed circles show $n=20$ loudspeakers which broadcast male duet contributions.

the vocal behavior of animals in tropical forests, even within areas characterized by dense vegetation, thick canopy cover, and irregular topography.

When participating in vocal duets, the distance between male and female rufous-and-white wrens varies tremendously (D. J. Mennill, unpublished data). Because the error of our acoustic location system is small, the accuracy of this acoustic location system will be revealing for monitoring duetting behavior in these neotropical wrens. Recording natural duets with the acoustic location system will allow us to test hypotheses for the function of avian duets by evaluating how close together birds are when they duet, whether birds approach one another during a bout of duetting, and where birds sing duets relative to territory boundaries and other habitat features. Whereas single-channel recordings are predicated on the idea of monitoring one individual at a time, a multi-microphone system may be used to monitor multiple individuals simultaneously, and therefore to understand behaviors such as duetting. Moreover, because multi-microphone recordings permit spatial analysis of animal vocal behavior, acoustic location systems can be used to monitor the movement and spacing of animals in habitats where traditional techniques are impractical.

Error in our ability to triangulate exactly the position of the loudspeakers arose from at least two sources. First, the accuracy of our acoustic location system is dependent on the accuracy with which we surveyed microphone positions. Our GPS coordinates of microphone positions were accurate to only 1.31 m despite extensive surveying across multiple years. Tropical forest ranks among the most challenging environments for collecting high-accuracy GPS coordinates because of the presence of dense canopy vegetation (Blake *et al.*, 2001; Phillips *et al.*, 1998; Dominy and Duncan, 2001). When surveying areas near our study site that lacked a dense canopy cover, we found that our GPS was capable of achieving submeter accuracy, supporting the idea that it is the canopy layer within the study site that made high-accuracy GPS coordinates difficult to obtain, not satellite geometry or any other feature of the tropics *per se*. When future research questions require more precise GPS coordinates for points

within canopied tropical forest, raising GPS antennae high into the canopy on telescoping poles may facilitate submeter level accuracy.

The second source of error in our location accuracy probably stemmed from the influence of dense vegetation and diverse topography on sound transmission within the study site. Our acoustic location system triangulates the position of animals in two dimensions, effectively treating the recorded area as a flat plane. In reality, the study site has many hills and valleys which are likely to influence patterns of sound reverberation for songs transmitted in this environment. We found no relationship between the variance in the height of the eight microphones in each array (a rough measure of the topographic variation within each array) and location accuracy. However, we do not interpret this as evidence that topography had no influence on the acoustic location system, but rather that topography had equivalent effects across all 20 array configurations. There are no analytical software tools yet developed to account for both three-dimensional transmission of sound together with a variable habitat surface. This is an important area for future enhancement in acoustic location system accuracy.

Both McGregor *et al.* (1997) and Bower and Clark (2005) evaluated the accuracy of a four-microphone array for triangulating the position of songbirds. By recording a variety of sounds in an open meadow and an open woodland in Europe, McGregor *et al.* (1997) evaluated the accuracy of an acoustic location system in two temperate environments. They report an average location error of 3.68 ± 0.29 m in open meadow and 6.76 ± 0.56 in open woodland, although accuracy improved substantially when the broadcast sound was closer to the center of their four-element arrays (McGregor *et al.* 1997). Bower and Clark (2005) recorded songbirds in a regrown farm field in North America with a similar array of four microphones. They report an average location error of 0.82 ± 0.29 m for birds recorded near the center of their four-element array and 2.13 ± 1.30 m for birds recorded just outside of their array. Both McGregor *et al.* (1997) and Bower and Clark (2005) report a relationship between location error and the distance between the loudspeaker and the center of the array. We did not find this effect in our analyses, however all of our stimuli were recorded from positions near the center of the 20 arrays, whereas these other analyses included sounds recorded outside the area bounded by their four microphones. We expect that location accuracy would decline if duets were recorded from outside of the area encompassed by the array of microphones. McGregor *et al.* (1997) and Bower and Clark (2005) recorded only on windless days in environments which induced little reverberation, whereas we conducted recordings through a variety of inclement weather conditions, including substantial winds and persistent dripping water, and in an environment which was likely to induce much reverberation. Our analyses provide a realistic test of the abilities of an acoustic location system and demonstrate that an acoustic location system can be used in suboptimal recording conditions.

Our understanding of the behavior and ecology of tropical animals remains poorly developed, despite the tremendous diversity of animal life in the tropics and the urgency for tropical research in light of the conservation threats to tropical forests (Kroodsma *et al.*, 1996). Acoustic location technology is a highly valuable tool for enhancing our understanding of the ecology and evolution of tropical animals. Microphone array recordings may be useful for studying extremely secretive animals or animals that are difficult to observe because of dense vegetation, large home ranges, or nocturnal activity. Microphone arrays also offer a valuable tool for studying network-level communication and have been used to study neighborhoods of song sparrows (Bower, 2000) and banded wrens (Burt and Vehrencamp, 2005). We believe that acoustic location technology may be used to study many other systems and provide ecologists and ethologists with a valuable and versatile tool for tropical research.

(Received 3 November 2005; accepted 28 February 2006)

The problem of imaging the intensity distribution of a subsurface acoustic source from passive measurements is considered. The source may be spatially extended, and is assumed to be random and spatially incoherent. Two passive imaging algorithms are examined and shown to be closely related. The first algorithm is based on time-domain migration in which signals recorded by an array of receivers are backpropagated to multiple source locations. The second algorithm is based on backprojecting cross-correlating signals computed between all pairs of receiving elements. When the latter algorithm is applied in two dimensions, the correlation peak can be shown to be the line-integral of the source intensity along a hyperbolic path whose foci are the receiving points. This suggests a filtered-backprojection procedure in which the backprojection is performed along multiple hyperbolic paths. The algorithm is easily generalized to three dimensions, in which the cross-correlated signals are backprojected over hyperboloids. Images using simulated and field data are presented as an illustration. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188667]

I. INTRODUCTION

We consider the problem of reconstructing images of subsurface acoustic sources generated either artificially within an underground facility or by the scattering of ambient seismic noise impinging upon a buried structure. One application identified as important by the military is source location within a buried facility based on the passive monitoring of acoustic emissions from both stationary and moving equipment within such a facility. Another potential objective is to identify the type of source on the basis of its noise spectrum, although source characterization is beyond the scope of this paper; rather, our goal is to examine source imaging algorithms, that is, to show how an intensity map, or image, of an extended source distribution can be reconstructed using signals passively recorded by a geophone array deployed above ground.

Several approaches to passive seismic imaging have been studied in recent years. A method investigated by Shuster *et al.*[1] and Wapenaar *et al.*,[2–5] termed "seismic interferometry," exploits the interference of a direct arrival with a scattered or secondary arrival, which may, for example, originate from backscattering from the surface. This approach is an elaboration of an idea by Claerbout[6] relating transmission and reflection seismograms using autocorrelated data in which one component originates from a free surface reflection. If the subsurface source is impulsive or very broadband, then the cross-correlation between the direct and secondary arrivals can bear a strong resemblance to a reflection seismogram.

An essential ingredient in the above methods is the interference between a direct and one or more secondary arrivals. The passive imaging methods investigated in this paper differ in that they employ only the direct arrivals; no interference with a "reference wave" is needed. In particular, two imaging algorithms of this kind have been published,[7,8] and one aim of this paper is to elucidate the relationship between these two techniques. The earliest of these algorithms was derived for imaging acoustic emission sources in materials,[8] while the second algorithm was intended for seismic imaging.[7] It is important to note that these algorithms do not use time delays across an array to "triangulate" on the source, which is inherently a nonlinear procedure. Rather, the algorithms are truly imaging methods, capable of mapping a spatially extended source. The imaging algorithms are linear in the intensity, and thus the source need not be spatially localized. In order for the algorithms to be linear, the assumption of a spatially incoherent source is required, meaning that the signals emitted from spatially distinct points within an extended source are assumed to be statistically uncorrelated. It should be noted that passive imaging, as defined here, differs from the seismic source characterization problem, in which the parameters of an isolated source are to be estimated, such as the source location, the seismic moment, the event time, and so on. Our objective is to map a single parameter, the source intensity.

In one imaging algorithm,[7] termed "time-exposure acoustics," passive data acquired by an array of geophones are used to reconstruct a source image by backpropagating the signals into image space. This procedure bears some resemblance to time-domain migration. But, in contrast to the active source problem in which signals are transmitted into the ground, in the passive problem no time origin exists with respect to which the propagation delays can be referenced. That is, the signals are assumed emitted from the source in a continuous and random fashion. The essential idea described in Ref. 7 is to average with respect to this time origin. In

 0001-4966/2006/119(5)/2840/8/$22.50

particular, multiple images are reconstructed, each with a different assumed time origin (the time at which the signal is emitted) and then these images are averaged on an intensity basis. This approach exploits the fact that the signal, either emitted from or scattered by a point in the subsurface, will create a wavefront that will manifest itself as a correlated signal across a receiving aperture on the surface. By coherently summing this signal and backpropagating to multiple source locations, one can develop an image of source intensity. As discussed in Ref. 7, image resolution is determined essentially by two factors: the source bandwidth and the array size.

The above method has been referred to as "time-exposure acoustics" (TEA) since the source is continuous and ever present, and, as a result, an image can be built up over time as data are continually accumulated. The underlying idea is to exploit the spatial coherence of signals that are correlated across an array to construct an image. When properly averaged, random fluctuations in an ensemble of images will diminish over time as new data are incorporated. Simulations in Ref. 7 illustrate this process.

In a second source reconstruction algorithm,[8] the source imaging problem is formulated as a tomographic reconstruction problem. Here, signals recorded by different pairs of geophones are cross correlated. The resultant correlation peak consists of an integration of the source intensity lying along a hyperbolic path [in a two-dimensional (2-D) problem] or on the surface of a hyperboloid (in a 3-D problem) in which the coordinates of the two geophones define the foci of the hyperbola or hyperboloid. In this formulation, the correlation peaks may be regarded as the line integral of source intensity over this hyperbolic path (in two dimensions) or as the surface integral of source intensity over a hyperboloid (in three dimensions). We shall see that this method is closely related to the TEA algorithm, although this relationship may not be immediately obvious.

In the analysis that follows, we shall assume a scalar wave (acoustic) problem. We shall also assume a constant velocity and neglect mode conversion effects at the Earth's surface. These assumptions are made for simplicity, but the essential ideas presented here can be generalized in principle to more complex (and realistic) earth models. In Secs. II and III, we analyze, respectively, the TEA and cross-correlation source imaging algorithms and examine their relationship. In Sec. IV we present images using simulated data and in Sec. V we show images derived from field data.

II. TIME-EXPOSURE ACOUSTICS (TIME-DOMAIN MIGRATION)

We first review the source imaging method known as time-exposure acoustics[7] and cast it in a form to facilitate later comparison to the cross-correlation algorithm.[8] Denote by $S(\mathbf{r},t)$ a random and spatially-varying subsurface source distribution. We assume that the source distribution is spatially incoherent, meaning that separate source points are statistically uncorrelated,[9] which we express by $\langle S(\mathbf{r},t)\, S(\mathbf{r}',t')^{*}\rangle = 0$ for $\mathbf{r} \neq \mathbf{r}'$, where the angle brackets denote an average with respect to time and * means complex conjugate.[10] Define the source intensity by $I(\mathbf{r}) = \langle |S(\mathbf{r},t)|^2 \rangle$. This is the quantity that we wish to image.

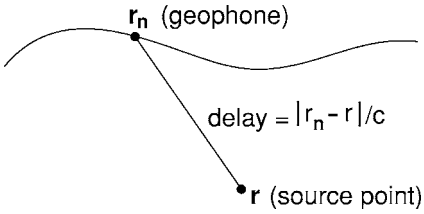

FIG. 1. The source point is located at $\mathbf{r}$, the geophone at $\mathbf{r}_n$, and the received signal denoted by $u(\mathbf{r}_n,t)$.

Suppose we have a two-dimensional array of N geophones above ground and let $u(\mathbf{r}_n,t)$ denote the signal recorded at the geophone location $\mathbf{r}_n$ (Fig. 1).

One could attempt to reconstruct an image, denoted $\hat{\mathcal{S}}_0(\mathbf{r})$, by backpropagating the received signals, $u(\mathbf{r}_n,t)$, to multiple source points, $\mathbf{r}$, and summing over the geophones. This is described by the formula

$$\hat{\mathcal{S}}_0(\mathbf{r}) = \sum_{n=1}^{N} |\mathbf{r} - \mathbf{r}_n| \bar{u}(\mathbf{r}_n, |\mathbf{r} - \mathbf{r}_n|/c), \tag{1}$$

where the overbar on $\bar{u}(\mathbf{r}_n,t)$ signifies a (possibly) filtered version of $u(\mathbf{r}_n,t)$, that is,

$$\bar{u}(\mathbf{r}_n,t) = u(\mathbf{r}_n,t) * b(t), \tag{2}$$

with $*$ denoting convolution and $b(t)$ a filter function. For example, $b(t)$ might be a whitening filter. In (1), the factor $|\mathbf{r}-\mathbf{r}_n|$ is included to compensate for signal loss due to geometric spreading of the wave originating from the point $\mathbf{r}$. If desired, we could replace this with a more general "gain" function, $a(|\mathbf{r}-\mathbf{r}_n|)$, to take into account a more complex model of signal attenuation (e.g., absorption in addition to geometric spreading). Note that in (1), the signal $\bar{u}(\mathbf{r}_n,t)$ is evaluated at the time $t=|\mathbf{r}-\mathbf{r}_n|/c$; this correctly describes backpropagation to the point $\mathbf{r}$ for a signal emitted from $\mathbf{r}$ at $t=0$. For a signal emitted at another time, say, t_0, then (1) should be replaced by

$$\hat{\mathcal{S}}(\mathbf{r}) = \sum_{n=1}^{N} |\mathbf{r} - \mathbf{r}_n| \bar{u}(\mathbf{r}_n, |\mathbf{r} - \mathbf{r}_n|/c + t_0). \tag{3}$$

The backprojection process is illustrated in Fig. 2 for a 2-D imaging problem. When imaging the point (x,z), backprojection is equivalent to coherently summing over a hyperbolic path in data space, (x_n,t), defined by $t=\sqrt{(x-x_n)^2+z^2}/c+t_0$ (the dashed line), where x_n is the coordinate of a geophone in a linear array. For a 3-D problem, when imaging the point $\mathbf{r}$, the summation is performed over a hyberboloid in data space, (r_n,t), defined by $t=|\mathbf{r}-\mathbf{r}_n|/c+t_0$.

Our approach is to average these images with respect to the "time origin," t_0, in a manner to be prescribed. For brevity, define

$$\bar{u}_n(\mathbf{r}) \equiv |\mathbf{r} - \mathbf{r}_n| \bar{u}(\mathbf{r}_n, |\mathbf{r} - \mathbf{r}_n|/c + t_0), \tag{4}$$

so that (3) is

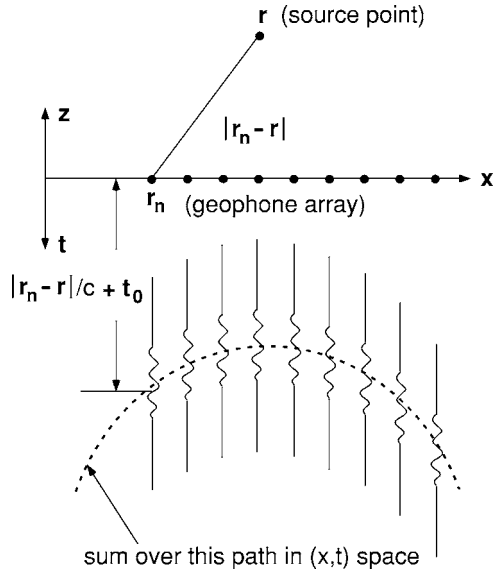

FIG. 2. When imaging the point (x,z) in two dimensions, backprojection is equivalent to coherent summation over the path $t=\sqrt{(x-x_n)^2+z^2}/c+t_0$ in (x_n,t) space, where x_n is the nth geophone coordinate in a linear array. When imaging the point (x,y,z) in three dimensions, backprojection is equivalent to coherent summation over the surface $t=\sqrt{(x-x_n)^2+(y-y_n)^2+z^2}/c+t_0$ in (x_n,y_n,t) space, where (x_n,y_n) is the nth geophone coordinate in a 2-D array.

$$\hat{\mathcal{S}}(\mathbf{r}) = \sum_{n=1}^{N} \bar{u}_n(\mathbf{r}). \tag{5}$$

Letting $\langle\cdot\rangle_{t_0}$ denote an ensemble average with respect to t_0, we see that $\langle\hat{S}(\mathbf{r})\rangle_{t_0}=0$ since the image $\hat{S}(\mathbf{r})$ is linear in the field $\bar{u}_n(\mathbf{r})$, which is a random variable with zero mean. This precludes averaging the images on an "amplitude" basis. We therefore consider averaging successive images on an intensity basis, i.e., computing as our image $\hat{\mathcal{I}}(\mathbf{r})=\langle|\hat{S}(\mathbf{r})|^2\rangle_{t_0}$. This, however, leads to a large "DC bias" in the image that builds up over time. An unbiased image estimator is obtained by subtracting the "DC component," as follows:

$$\hat{\mathcal{I}}(\mathbf{r}) = \left\langle \left| \sum_{n=1}^{N} \bar{u}_n(\mathbf{r}) \right|^2 \right\rangle_{t_0} - \left\langle \sum_{n=1}^{N} |\bar{u}_n(\mathbf{r})|^2 \right\rangle_{t_0}, \tag{6}$$

which can also be written as

$$\hat{\mathcal{I}}(\mathbf{r}) = \sum_{\substack{n=1 \\ n\neq m}}^{N} \sum_{m=1}^{N} \langle \bar{u}_n(\mathbf{r}) \bar{u}_m(\mathbf{r})^* \rangle_{t_0}. \tag{7}$$

Equation (7) shows that, if there is no correlation between distinct traces, $\bar{u}_n(\mathbf{r})$, then the image $\hat{I}(\mathbf{r})$ vanishes as desired.

In (6) and (7), the ensemble average is performed with respect to the time origin t_0. Let us rename this time origin t_k and define

$$\bar{u}_n^k(\mathbf{r}) \equiv |\mathbf{r}-\mathbf{r}_n| \bar{u}(\mathbf{r}_n, |\mathbf{r}-\mathbf{r}_n|/c + t_k). \tag{8}$$

We now average with respect to t_k, and (6) and (7) may be approximated by

$$\hat{\mathcal{I}}(\mathbf{r}) = \frac{1}{K}\sum_{k=1}^{K} \left\{ \left| \sum_{n=1}^{N} \bar{u}_n^k(\mathbf{r}) \right|^2 - \sum_{n=1}^{N} |\bar{u}_n^k(\mathbf{r})|^2 \right\} = \sum_{\substack{n=1 \\ n\neq m}}^{N} \sum_{m=1}^{N} \left(\frac{1}{K} \sum_{k=1}^{K} \bar{u}_n^k(\mathbf{r}) \bar{u}_m^k(\mathbf{r})^* \right), \tag{9}$$

where K is the number of averages.

Equation (9) represents our basic imaging algorithm. In the next section, we describe another algorithm based on a process of cross-correlation, filtering, and backprojection. To make the comparison between (9) and the cross-correlation algorithm easy, it will be convenient to rewrite (9) explicitly in terms of the correlation between the signals $\bar{u}(\mathbf{r}_n,t)$ and $\bar{u}(\mathbf{r}_m,t')$. Define the temporal correlation function

$$\Gamma_{\bar{u}\bar{u}}(\mathbf{r}_n,\mathbf{r}_m;t,t') = \langle \bar{u}(\mathbf{r}_n,t) \bar{u}(\mathbf{r}_m,t')^* \rangle_{t_0} \equiv \lim_{T\to\infty} \frac{1}{T} \int_0^T \bar{u}(\mathbf{r}_n,t+t_0) \bar{u}(\mathbf{r}_m,t'+t_0)^* \, dt_0. \tag{10}$$

The discrete-time version of this is

$$\Gamma_{\bar{u}\bar{u}}(\mathbf{r}_n,\mathbf{r}_m;t,t') = \frac{1}{K}\sum_{k=1}^{K} \bar{u}(\mathbf{r}_n,t+t_k) \bar{u}(\mathbf{r}_m,t'+t_k)^*, \tag{11}$$

where t_k is an indexed time sample. Substituting (8) into (9) and making use of (11), we have

$$\hat{\mathcal{I}}(\mathbf{r}) = \sum_{\substack{n=1 \\ n\neq m}}^{N} \sum_{m=1}^{N} |\mathbf{r}-\mathbf{r}_n||\mathbf{r}-\mathbf{r}_m| \times \Gamma_{\bar{u}\bar{u}}(\mathbf{r}_n,\mathbf{r}_m;|\mathbf{r}-\mathbf{r}_n|/c,|\mathbf{r}-\mathbf{r}_m|/c). \tag{12}$$

For a stationary process, $\Gamma_{\bar{u}\bar{u}}(\mathbf{r},\mathbf{r}';t,t')=\Gamma_{\bar{u}\bar{u}}(\mathbf{r},\mathbf{r}';t-t')$ and, in this case, (12) may be written as

$$\hat{\mathcal{I}}(\mathbf{r}) = \sum_{\substack{n=1 \\ n\neq m}}^{N} \sum_{m=1}^{N} |\mathbf{r}-\mathbf{r}_n||\mathbf{r}-\mathbf{r}_m| \Gamma_{\bar{u}\bar{u}}(\mathbf{r}_n,\mathbf{r}_m;\tau_{nm}), \tag{13}$$

where $\tau_{nm} \equiv |\mathbf{r}_n-\mathbf{r}|/c - |\mathbf{r}_m-\mathbf{r}|/c$ is the difference in the time delay between the source point, $\mathbf{r}$, and the two geophones locations, $\mathbf{r}_n$ and $\mathbf{r}_m$. This equation is now in a form that can be directly compared with the cross-correlation algorithm.

III. SOURCE IMAGING USING CROSS-CORRELATED SIGNALS

In this approach, signals between pairs of geophones are cross correlated. Here, the time-origin problem does not arise, because only relative delays are relevant; absolute delays with respect to a time origin do not play a role.

The signals arriving at two geophones from a particular source point will be delayed versions of each another with the delay proportional to the difference in pathlengths between the source and the two receivers. Cross correlating these two signals will yield a correlation peak with an offset, τ, equal to this relative delay. In particular, if the two geophones are located at $\mathbf{r}_n$ and $\mathbf{r}_m$ and the source location is $\mathbf{r}$,

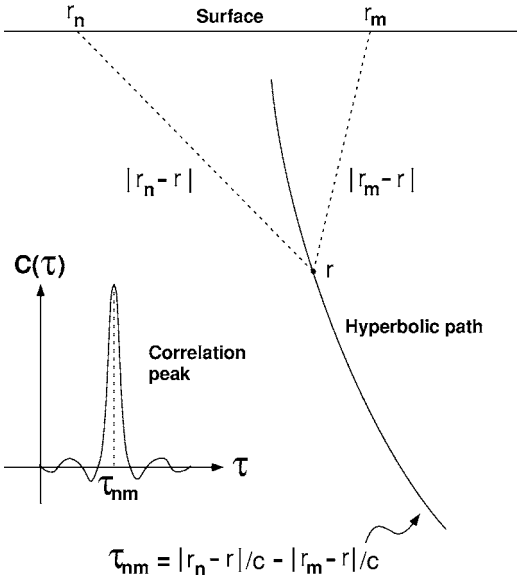

FIG. 3. The correlation peak at the delay τ_{nm} is the sum of contributions along the hyperbolic path whose foci are at the geophone locations $\mathbf{r}_n$ and $\mathbf{r}_m$.

then the correlation peak will occur at $\tau_{nm}=|\mathbf{r}_n-\mathbf{r}|/c-|\mathbf{r}_m-\mathbf{r}|/c$. The locus of points that contribute to this correlation peak (for a 2-D image) are all points that yield the same time difference τ_{nm}, that is, all points $\mathbf{r}$ that lie on a hyperbolic path whose foci are $\mathbf{r}_n$ and $\mathbf{r}_m$, as illustrated in Fig. 3.[11]

As a result, the cross correlation may be regarded as measuring the path integral of the source intensity along this hyperbolic path. The reconstruction problem is similar to the classic tomographic reconstruction problem that recovers an image from measurements of multiple overlapping line integrals of an unknown density function (in our case, source intensity). In this case, however, the line integrals are along different hyperbolas (defined by the receiver locations) rather than straight lines. This suggests a backprojection algorithm. That is, to reconstruct an image of the source intensity distribution, we filter and backproject the cross-correlated signals along these overlapping hyperbolic paths. In the 3-D version, the hyperbolic paths become surfaces (hyperboloids) and the filtered cross-correlated signals are backprojected over these surfaces. The optimal tomographic filter function will differ for the 2-D and 3-D problems.

We can justify such an approach as follows. Again, let $S(\mathbf{r},t)$ denote a random subsurface source distribution with an arbitrary spatial dependence. We assume that the source is spatially incoherent with some finite frequency bandwidth, ω_c. That is, we assume that $S(\mathbf{r},t)$ is a random process with a mutual coherence function, given by

$$\Gamma_{ss}(\mathbf{r},\mathbf{r}';t,t') \equiv \langle S(\mathbf{r},t)S(\mathbf{r}',t')^*\rangle = \sigma_s^2(\mathbf{r})\,\delta(\mathbf{r}-\mathbf{r}')C(t-t'). \tag{14}$$

Again, the angle brackets denotes a time average, $\delta(\mathbf{r}-\mathbf{r}')$ is a 3-D Dirac delta function, and $C(t-t')$ is a temporal correlation function whose frequency content is confined to $|\omega| < \omega_c$.[12] The delta function implies that the process is spatially incoherent (statistically uncorrelated from point to point). The spatial dependence $\sigma_s^2(\mathbf{r})$ may be regarded as a spatially varying source intensity. It is this function that we wish to image.

The random source generates an acoustic field, $u(\mathbf{r},t)$, that obeys the following time-dependent wave equation:

$$\nabla^2 u(\mathbf{r},t) - \frac{1}{c^2}\frac{\partial^2 u(\mathbf{r},t)}{\partial t^2} = -S(\mathbf{r},t), \tag{15}$$

where c is the speed of sound. The time dependent Green's function obeys the wave equation,

$$\nabla^2 g(\mathbf{r},t|\mathbf{r}',t') - \frac{1}{c^2}\frac{\partial^2 g(\mathbf{r},t|\mathbf{r}',t')}{\partial t^2} = -4\pi\delta(\mathbf{r}-\mathbf{r}')\,\delta(t-t'), \tag{16}$$

where the Green's function is given by[13]

$$g(\mathbf{r},t|\mathbf{r}',t') = \frac{1}{|\mathbf{r}-\mathbf{r}'|}\delta[|\mathbf{r}-\mathbf{r}'|/c-(t-t')]H(t-t'), \tag{17}$$

and $H(t)$ is the unit step function. Using standard techniques, (15) and (16) can be combined to yield

$$u(\mathbf{r},t) = \int\int\int d^3\mathbf{r}' \int_{-\infty}^{t} dt'\; g(\mathbf{r},t|\mathbf{r}',t')S(\mathbf{r}',t'). \tag{18}$$

Substituting (17) into (18) and integrating with respect to t' then gives

$$u(\mathbf{r},t) = \int\int\int d^3\mathbf{r}' \frac{S(\mathbf{r}',t-|\mathbf{r}-\mathbf{r}'|/c)}{|\mathbf{r}-\mathbf{r}'|}. \tag{19}$$

We now compute the mutual coherence function of the received signals $u(\mathbf{r}_1,t_1)$ and $u(\mathbf{r}_2,t_2)$ at the two geophone locations $\mathbf{r}_1$ and $\mathbf{r}_2$:

$$\Gamma_{uu}(\mathbf{r}_1,\mathbf{r}_2;t_1,t_2) \equiv \langle u(\mathbf{r}_1,t_1)u(\mathbf{r}_2,t_2)^*\rangle. \tag{20}$$

Substituting (19) into (20), interchanging the orders of correlation and integration, and using (14), we obtain

$$\Gamma_{uu}(\mathbf{r}_1,\mathbf{r}_2;\tau) = \int\int\int \frac{\sigma_s^2(\mathbf{r})}{|\mathbf{r}_1-\mathbf{r}||\mathbf{r}_2-\mathbf{r}|} \times C(\tau-|\mathbf{r}_1-\mathbf{r}|/c+|\mathbf{r}_2-\mathbf{r}|/c)d^3\mathbf{r}, \tag{21}$$

where $\tau \equiv t_1 - t_2$.

This is a key equation. If the bandwidth of the source is broad, then the correlation function, $C(\tau)$, will be narrow. If we momentarily replace $C(\tau)$ with a delta function, i.e., let $C(\tau)\approx\delta(\tau)$ in (21), then $\Gamma_{uu}(\mathbf{r}_1,\mathbf{r}_2;\tau)$ becomes a (weighted) surface integral through the function $\sigma_s^2(\mathbf{r})$ over a hyperboloid whose foci are located at $\mathbf{r}_1$ and $\mathbf{r}_2$. In practice, $C(\tau)$ will have a finite width roughly equal to $1/\omega_c$. This implies a spatial width of approximately the speed of sound divided by the source bandwidth. That is, the "thickness" of the hyperboloid is roughly $\Delta r = 2\pi c/\omega_c$. This is an approximate theoretical upperbound on the image resolution.

As motivation for the reconstruction algorithm, we Fourier transform (21) with respect to τ, giving

$$\tilde{\Gamma}_{uu}(\mathbf{r}_1,\mathbf{r}_2;\omega)=\tilde{C}(\omega)\int\int\int\frac{\sigma_s^2(\mathbf{r})}{|\mathbf{r}_1-\mathbf{r}||\mathbf{r}_2-\mathbf{r}|}\times\exp[i\omega(|\mathbf{r}_1-\mathbf{r}|-|\mathbf{r}_2-\mathbf{r}|)/c]d^3\mathbf{r}, \quad (22)$$

where $\tilde{C}(\omega)$ is the Fourier transform of $C(\tau)$. The image is then obtained by multiplying (22) by $\tilde{b}(\omega)|\mathbf{r}'-\mathbf{r}_1||\mathbf{r}'-\mathbf{r}_2|\times\exp[-i\omega(|\mathbf{r}_1-\mathbf{r}'|-|\mathbf{r}_2-\mathbf{r}'|)/c]$, where $\mathbf{r}'$ is the image point, and integrating over the signal bandwidth and aperture. This gives the following formula for the image (after dropping the prime on $\mathbf{r}'$):

$$\hat{\sigma}_s^2(\mathbf{r})=\int\int_A d^2\mathbf{r}_1\,d^2\mathbf{r}_2\int_{-\omega_c}^{\omega_c}d\omega\,\tilde{b}(\omega)F_\omega(\mathbf{r}_1,\mathbf{r}_2;\mathbf{r})\times\exp[-i\omega(|\mathbf{r}_1-\mathbf{r}|-|\mathbf{r}_2-\mathbf{r}|)/c]. \quad (23)$$

where

$$F_\omega(\mathbf{r}_1,\mathbf{r}_2;\mathbf{r})\equiv|\mathbf{r}-\mathbf{r}_1||\mathbf{r}-\mathbf{r}_2|\tilde{\Gamma}_{uu}(\mathbf{r}_1,\mathbf{r}_2;\omega). \quad (24)$$

Here A denotes the aperture (or receiving array), and $\tilde{b}(\omega)$ is a tomographic filter; in two dimensions, $b(\omega)=|\omega|$[14] and in three dimensions, $b(\omega)=\omega^2$.[15]

The justification for (23) is carried out by substituting (22) into (23) and interchanging orders of integration to obtain an expression of the form

$$\hat{\sigma}_s^2(\mathbf{r})=\int\int\int\sigma_s^2(\mathbf{r}')P(\mathbf{r},\mathbf{r}')d^3\mathbf{r}', \quad (25)$$

where $P(\mathbf{r},\mathbf{r}')$ is the image point-spread function. One can show that, in the limit of an infinite bandwidth and aperture, $P(\mathbf{r},\mathbf{r}')$ becomes delta like for $\mathbf{r}=\mathbf{r}'$, as desired. An analytical derivation of $P(\mathbf{r},\mathbf{r}')$ was derived in Ref. 8 using this formula for the special case of a 2-D circular geometry. In the latter geometry, the receiving points, $\mathbf{r}_1$ and $\mathbf{r}_2$, lie on the circumference of a circle enclosing the region to be imaged. It was shown in Ref. 8 that $P(\mathbf{r},\mathbf{r}')$ tends toward a 2-D Dirac delta function in the limit of an infinite bandwidth (i.e., as $\omega_c\to\infty$).

Equation (23) can be transformed into a backprojection formula by substituting

$$\tilde{\Gamma}_{uu}(\mathbf{r}_1,\mathbf{r}_2;\omega)=\int\Gamma_{uu}(\mathbf{r}_1,\mathbf{r}_2;t)e^{i\omega t}\,dt \quad (26)$$

into (24) and (23), which gives

$$\hat{\sigma}_s^2(\mathbf{r})=\int\int_A d^2\mathbf{r}_1\,d^2\mathbf{r}_2|\mathbf{r}-\mathbf{r}_1||\mathbf{r}-\mathbf{r}_2|\bar{\Gamma}_{uu}[\mathbf{r}_1,\mathbf{r}_2;(|\mathbf{r}_1-\mathbf{r}|-|\mathbf{r}_2-\mathbf{r}|)/c]. \quad (27)$$

In this formula, $\bar{\Gamma}_{uu}(\mathbf{r}_1,\mathbf{r}_2;t)$ is a filtered version of $\Gamma_{uu}(\mathbf{r}_1,\mathbf{r}_2;t)$, that is, $\bar{\Gamma}_{uu}(\mathbf{r}_1,\mathbf{r}_2;t)=b(t)*\Gamma_{uu}(\mathbf{r}_1,\mathbf{r}_2;t)$, where $*$ denotes convolution and $b(t)$ is the inverse Fourier transform of $\tilde{b}(\omega)$.

Equation (27) represents a filtered-backprojection algorithm along hyperbolic paths in two dimensions and over surfaces (hyperboloids) in three dimensions. The discrete version of (27) is given as follows. Suppose we have an array of N geophones on the surface at coordinates $\mathbf{r}_n$, $n=1,2,\ldots,N$. Then (27) reduces to

$$\hat{\sigma}_s^2(\mathbf{r})=\sum_{n=1}^{N}\sum_{\substack{m=1\\n\neq m}}^{N}|\mathbf{r}-\mathbf{r}_n||\mathbf{r}-\mathbf{r}_m|\bar{\Gamma}_{uu}(\mathbf{r}_n,\mathbf{r}_m;\tau_{nm}), \quad (28)$$

where $\tau_{nm}\equiv|\mathbf{r}_n-\mathbf{r}|/c-|\mathbf{r}_m-\mathbf{r}|/c$.

Note that (28) is identical in form to (13). The only difference is that, in (13), $\Gamma_{\bar{u}\bar{u}}$ is backprojected, whereas in (28), $\bar{\Gamma}_{uu}$ is backprojected. That is, in the former case, the cross-correlation is performed on the filtered signals, $\bar{u}$, whereas in the latter case, the filtering is performed after the cross-correlation. Simulations have shown that the distinction between these two cases is not particularly important in affecting image quality or resolution unless the emitted signals are extremely broadband (i.e., have a very large fractional bandwidth). Typically, for artificial sources (e.g., emissions from an underground facility), the fractional bandwidths are not large. In such cases, as simulations demonstrate, the application of an optimal "tomographic filter function" of the form $\tilde{b}(\omega)=|\omega|$ (for two dimensions) or $b(\omega)=\omega^2$ (for three dimensions) prior to backprojection does not significantly affect image quality.

IV. SIMULATED RECONSTRUCTIONS

To convey some idea of the quality and resolution of images that can be obtained using the reconstruction formula (28), we applied this equation to simulated data. We assumed three isolated point sources at the locations indicated in Fig. 4(a), each emitting continuous random noise over a bandwidth of 50 to 200 Hz. The signals were assumed recorded for a duration of one second at a sampling rate of 1 kHz using a geophone array with 21 elements spaced at 4 m intervals. A sound velocity of 500 m/s was assumed. The received signals were cross-correlated between all geophone pairs with a 12 m separation or greater. The cross-correlated signals were then filtered with the tomographic filter $|\omega|$ and backprojected, as prescribed by (28). The resultant image is shown in Fig. 4(b).

Note that the source images are somewhat elongated vertically. That is, the lateral resolution appears somewhat better than the longitudinal (depth) resolution. This is not surprising since lateral resolution is determined by the aperture size (array length) and the bandwidth of the noise source, whereas longitudinal resolution in a passive system is determined primarily by the system's ability to detect the curvature of the wave front over the aperture length. When the source depth is large compared to the aperture, the wave front curvature becomes less pronounced and a loss of longitudinal resolution is expected.

The images in Fig. 4(b) were computed under the assumption of a known sound velocity. It is interesting to investigate the effect of an incorrect velocity estimate on image quality. If the velocity is in error by no more than about 40% or 50% percent, the effect on the image is primarily a vertical shift in the placement of the source images with a relatively minor image distortion. Severe image degradation

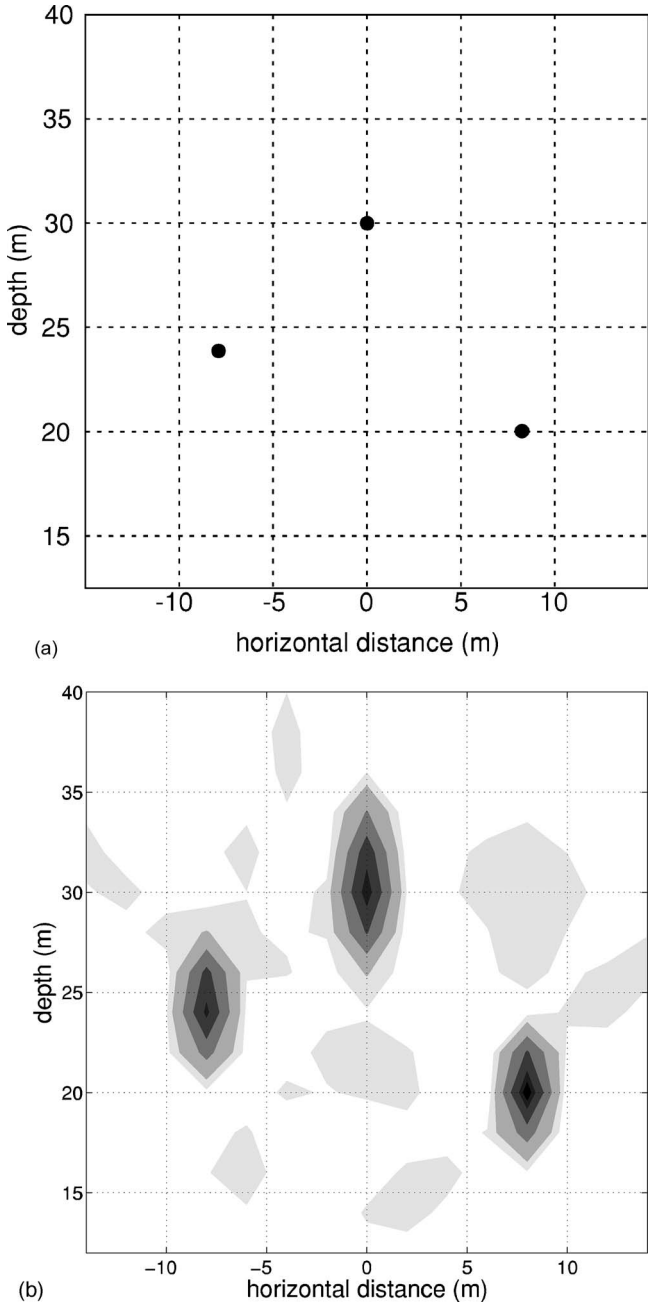

FIG. 4. (a) Three source locations assumed to emit continuous random noise with a bandwidth between 50 and 200 Hz. Depth is measured upward. The array consists of 21 elements on the surface with a 4 m spacing. The array runs along the lower boundary of the imaged region. (b) Image of the three sources using the imaging formula (28).

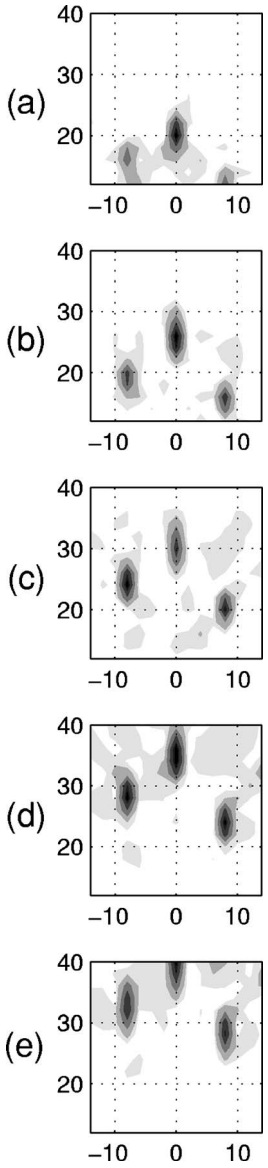

FIG. 5. Figure (a)–(e) are simulated images using an assumed velocity 80%, 90%, 100%, 110%, and 120% of the true velocity, respectively. We see that an underestimation of the velocity, for example, results in a displacement of the image closer to the array.

begins to occur as the velocity error exceeds about 50%. Figures 5(a)–5(e) show images reconstructed under the assumption of a velocity 80%, 90%, 100%, 110%, and 120% of the true velocity, respectively. Thus, an overestimation of the velocity, for example, tends to shift the placement of the sources vertically (i.e., to overestimate the source depth).

V. FIELD DATA

In this section, the two algorithms were compared using a set of field data generated by a hammer blow. The data were acquired with a geophone array that recorded surface waves generated by the hammer source at one location on the ground. The received signal bandwidth was determined to extend from about 5 to 50 Hz by spectral analysis. The resultant images are two dimensional and derived from surface waves only. Surface waves are dispersive and thus, in principle, not optimal for imaging since the algorithms are not designed to account for wave dispersion. Subsurface body waves in three dimensional are not dispersive and should, in theory, provide better images. Nevertheless, as shown below, quite good images of the point source were obtained using this data set.

The data were acquired using a seismograph connected to a 13 element array in the shape of an "L," as illustrated in Fig. 6, with a geophone spacing of 15 ft. In the figure, the area enclosed by the dotted square denotes the imaged region. In this experiment, signals were generated by striking a metal plate on the ground with a hammer at the point labeled "source" in Fig. 6. Data were continually recorded over a

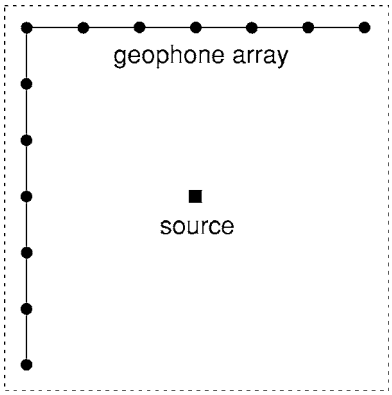

FIG. 6. Geophone array used to acquire field data. The dotted area is the imaged region shown in Figs. 7 and 8.

30 s interval while the ground was struck 12 times; no triggering of the seismograph was used. Figures 7(a) and 7(b) show the reconstructed image using the time-domain migration algorithm shown in both contour and pixel formats, where the latter is a 15 by 15 pixel image. A surface-wave speed of 600 ft/s placed the source in the correct location. Using the same data, the image obtained using the cross-correlation algorithm is shown in Figs. 8(a) and 8(b). These images were reconstructed without an "optimal" tomographic filter, since such filtering was found to make little difference in image quality. The images show that both algorithms perform similarly, as anticipated.

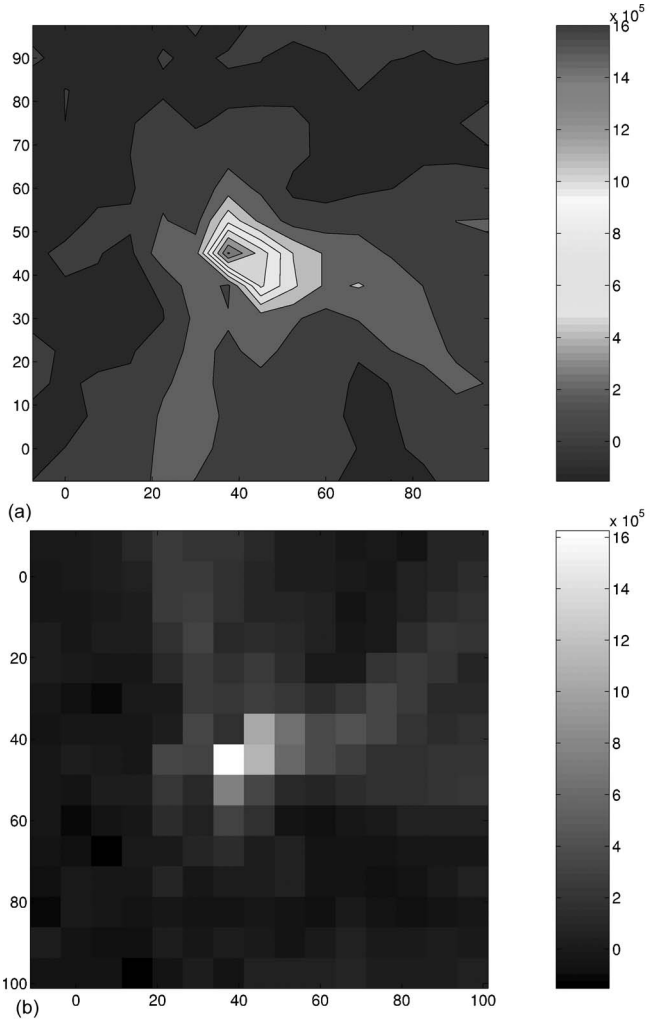

FIG. 7. Image obtained from field data using the time-domain migration algorithm. (a) Contour format; (b) pixel format. Units are in feet.

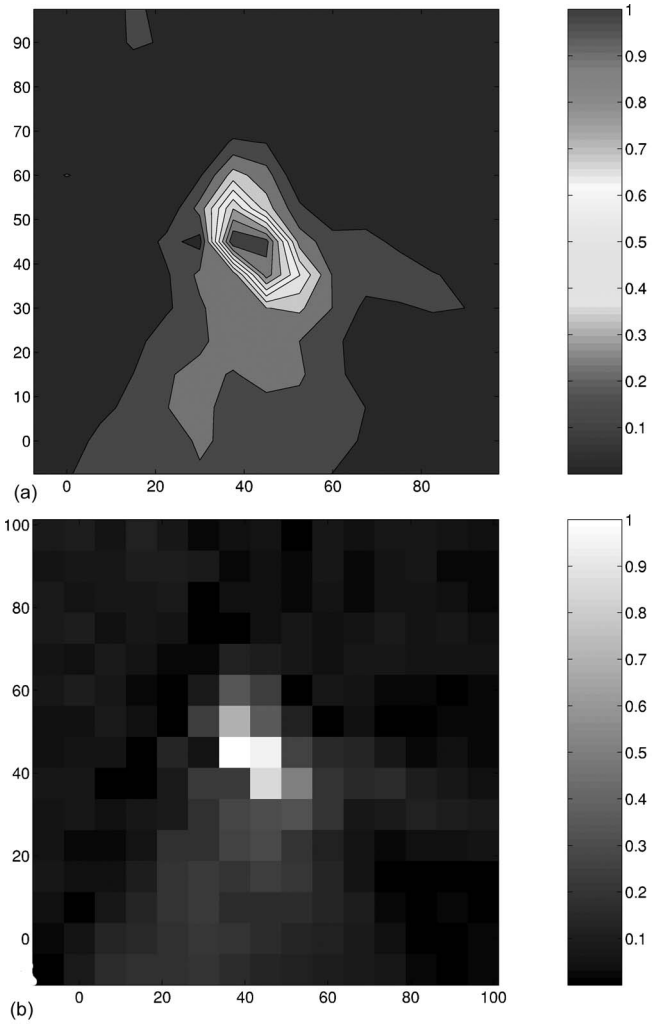

FIG. 8. Image obtained from field data using the cross-correlation algorithm. (a) Contour format; (b) pixel format. Units are in feet.

VI. CONCLUSION

Two passive imaging algorithms were examined, one based on time-domain migration[7] and the other on cross-correlation.[8] A key difference between active and passive imaging is that, in the latter case, no time origin exists with which to reference propagation delays. In the first algorithm examined, an image is obtained by averaging with respect to this time origin. The averaging must be done on an intensity basis, since the "amplitude image" has zero mean. After removal of the dc component of the intensity image, this averaging process was shown to reduce to a form essentially equivalent to the cross-correlation algorithm. The latter algorithm was developed for imaging acoustic emission sources in materials, but could also find applications in the imaging of underground sources. Such sources may arise due to scattering of ambient noise or from emissions generated by machinery inside a manmade facility. In either case, im-

age resolution is ultimately limited by the temporal correlation distance of the source, that is, the speed of sound divided by the source bandwidth.

We conclude by noting again that the algorithms and simulations described here have been idealized for simplicity. Two key idealizations are the assumption of a constant sound velocity and the neglect of mode conversion effects at the surface. For example, the algorithms do not account for the partial mode conversion of the source-generated body waves into surface waves at the air-earth interface. Surface waves can be treated in several ways: (1) by filtering using an optimally designed 2-D surface array, (2) by treating mode conversion as an incoherent noise source, which may tend to average out over time, or, finally, (3) by attempting to incorporate mode conversion into the propagation model. The latter approach could, in principle, be achieved by replacing the acoustic Green's function with an elastic-wave half-space Green's function. This would vastly increase the computational cost of any imaging algorithm but, as computer power continues to advance, may one day become feasible.

[9]We note that the assumption of a spatially incoherent source may appear to fail if the "sources" are scatterers illuminated, for example, by an incident plane wave. However, if the direction of incidence is variable, then spatial incoherence should effectively hold when averaging over a time on the order of the reciprocal of the source bandwidth or greater.

[10]For generality, we allow the fields to be complex, because we may choose $u(\mathbf{r},t)$ to represent either a real quantity or its analytic signal, which is complex.

[11]This hyperbola is not to be confused with the hyperbola shown in Fig. 2, which is a hyperbolic path (or hyperboloid in three dimensions) in data space, that is, in $(\mathbf{r}_n,t)$ space. The hyperbola (or hyperboloid in three dimensions) of Fig. 3 resides in image space.

[12]Strictly speaking, the form of (14) implies a statistically stationary process, at least over the observation interval. In practice, this is a reasonable approximation when the observation interval is long compared to the reciprocal of the source bandwidth.

Middle ear ossicles motion at hearing thresholds with air conduction and bone conduction stimulation

Stefan Stenfelt[a)]
Department of Signals and Systems, Chalmers University of Technology, Göteborg, Sweden

(Received 20 October 2005; revised 9 February 2006; accepted 9 February 2006)

Hearing threshold data with bone conduction and air conduction stimulation are combined with physiological and mechanical measurements of the middle ear ossicles vibration to compute the vibration level of the ossicles at threshold stimulation. By comparing the displacements of the stapes footplate with the two stimulation modalities and assuming the vibration of the stapes footplate to be the input to the cochlea when stimulation is by air conduction, the importance of middle ear ossicles inertia with bone conduction stimulation is evaluated. Given the limitations of the analysis, the results indicate that the inertia of the middle ear is not an important contribution to the perception of BC sound for frequencies below 1.5 kHz; it seems to contribute to perception of bone conducted sound between the frequencies 1.5 and 3.5 kHz. At frequencies above 4 kHz, the analysis failed since the input to the cochlea is probably not through the oval window with bone conduction stimulation. Comparison of basilar membrane vibration data verified the calculations for frequencies between 0.8 and 3.5 kHz. It was also found that the fluid flow at the round window, rather than at the oval window, reflects the stimulation of the basilar membrane with bone conduction stimulation. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184225]

I. BACKGROUND

Behavioral hearing thresholds are the stimulation level where a person starts to perceive a sound. The hearing thresholds for young healthy persons have been measured and their average was used to derive a standard for normal persons hearing ability. This was done for air conduction (AC) stimulation as well as for bone conduction (BC) stimulation (ISO 226, 2003; ISO 389-3, 1994).

It is normally assumed that an AC sound and a BC sound stimulates the basilar membrane and the hearing receptors similarly. This assumption comes from the ability to cancel a pure AC tone with a BC tone (von Békésy, 1932; Khanna *et al.*, 1976), the ability to produce distortion product otoacoustic emissions using AC and BC stimulation (Purcell *et al.*, 1998), and the similarity of resonance frequencies on the basilar membrane with AC and BC excitation (Stenfelt *et al.*, 2003a). Hence, it can be assumed that the basilar membrane motion at threshold levels is equal whether the stimulation is by AC or BC.

The major difference between AC and BC stimulation is that AC stimulation is basically a sound pressure in the ear canal that is transmitted to a sound pressure in the vestibule of the cochlea by the TM and middle ear ossicles, whereas BC stimulation involves several pathways. The most important physical phenomena involved in BC stimulation are believed to be (1) sound radiation into the ear canal, (2) inertial motion of the middle ear ossicles, (3) inertial motion of the fluid in the cochlea, and (4) compression and expansion of the bone encapsulating the cochlea (Stenfelt and Good, 2005a). The first two effects would stimulate the cochlea via the oval window and stapes footplate. Hence, this stimulation is, from the cochlea point of view, similar to AC stimulation.

It has previously been shown that the outer ear component (sound radiation into the ear canal) does not normally contribute to hearing by BC (Stenfelt *et al.*, 2003b). However, the inertial effects of the middle ear ossicles may contribute to the hearing perception when the stimulation is by BC. It has further been shown that the fluid flow at the oval window and round window is unequal for BC stimulation while the fluid flow for AC stimulation at the two windows is similar and with opposite phases (Stenfelt *et al.*, 2004). This indicates that the stimulation of the cochlea is more complicated when the stimulation is by BC than AC. The aim of this paper is to compare the displacement of the malleus umbo, stapes footplate, round window, and basilar membrane at human behavioral hearing thresholds for AC and BC stimulation. Such comparison can give insight to different contributing parts for BC stimulation.

II. METHODS

The data used in this paper are mainly taken from previously published results. The methods for each measurement are therefore not given in detail; the interested reader is encouraged to read those articles for a detailed description of the different methods used. However, a brief overview of the methods is given here for the reader to grasp some of the limitations of the current analysis.

The behavioral thresholds are taken from the standard (BC, ISO 389-3, 1994; AC, ISO 226, 2003). The other data are either taken from isolated human temporal bone specimens (middle ear ossicle, oval window, round window, and

[a)]Present address: Dept of Neuroscience and Locomotion, Division of Technical Audiology. Linköping University Hospital, Linköping, Sweden. Electronic mail: stefan.stenfelt@inr.liu.se

basilar membrane motion) using both AC and BC stimulation, or live humans and human cadaver heads for vibration transmission measurements in the skull (BC). It is only for the skull impedance measurement at the skin (Flottorp and Solberg, 1976) that live human data are used. It should be noted that all data are for the human and that the results are not necessarily applicable for animals. Also, the data derived for BC using isolated temporal bones are primarily stimulated in a single direction (same as the low-frequency piston-like motion of the stapes) while measurement of the cochlear promontory in whole heads with BC stimulation has shown vibration pattern with motions in all three space dimensions (Stenfelt and Good, 2005b). Further, the simplification by using isolated temporal bone specimens with BC stimulation may introduce artifacts in the results since the stimulation of the petrous part of the temporal bone encapsulating the cochlea can differ between isolated temporal bone specimen measurement and whole head measurements.

With AC stimulation, the vibrations of the middle ear ossicles, the round window, and the basilar membrane is measured with a laser Doppler vibrometer (LDV) (HLV 1000, Polytec, Waldbronn, Germany), while the sound pressure in-front of the TM is measured with a probe-tube microphone (ER-7C, Etymotic Research, Elk Grove Village, IL). When the stimulation is by BC, the input impedance at the stimulation position is measured with an impedance head (B&K type 8001, Brüel and Kjær, Nærum, Denmark), the vibration of the whole head is measured with either a three-axial (3D) accelerometer (Endevco model 7253C-10, Endevco, San Juan Capistrano, CA) or with the LDV while the vibrations of the middle ear ossicles, temporal bone, round window, and basilar membrane are measured with the LDV when the isolated temporal bone is rigidly attached to a shaker (B&K type 4810 mini-shaker).

III. AIR CONDUCTION STIMULATION

The minimum audible field (MAF) is defined as the lowest pressure of a sound field where a normal hearing human perceives a sound. The MAF is measured as the sound field pressure at the center of the head when the head is absent in the sound field. The sound pressure at the TM differs from the sound pressure at the center of the head: diffractions of the head as well as resonances of the ear canal alter the sound pressure. Figure 1 shows the MAF according to the standard ISO 226 (2003) as well the sound pressure at the TM at MAF with corrections for the head and ear canal according to Shaw (1974). The MAF is given for binaural hearing and the threshold sound pressure at the TM must be compensated accordingly. Killion (1978) estimated the monaural threshold sound pressure at the TM which is also shown in Fig. 1. The sound pressure thresholds from Killion (1978) are used in this study as reference for air conduction (AC) stimulation and are referred to as the minimum audible pressure (MAP).

The sound energy from the ear canal sound pressure is transmitted to the cochlea and the basilar membrane by the middle ear ossicles. This transmission is affected by several factors. Figure 2(a) shows the displacement of the malleus

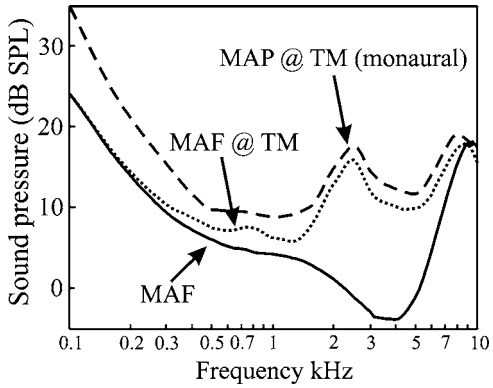

FIG. 1. The minimum audible field according to ISO 226 (2003) (solid line), the minimum audible field at the TM (dotted line), and the minimum audible pressure (dashed line, from Killion, 1978). The curves are interpolated between the frequencies given in the standard ISO 226 and in Killion (1978).

umbo and stapes footplate when the stimulation is a sound pressure of 80 dB SPL at the TM (ossicle displacement at 80 dB SPL, OD_{AC_80}). The magnitude data in Fig. 2(a) are taken from isolated temporal bone preparations (Hato *et al.*, 2003) and mathematically compensated for the artificial expansion of the middle ear cavity. When the ossicles motion was measured in Hato *et al.* (2003), post-mortem isolated temporal bone specimens were used. In order to execute the measurements, a hole was made through the mastoid air cell system and into the antrum where an enlarged opening of the facial recess into the middle ear cavity was made. This opening into the antrum was sealed airtight with a glass cover. However, instead of the natural approximately 0.5 cc tympanic cavity with adjacent antrum and air cells, the total volume of the large, artificially opened and sealed, middle ear cavity is approximately three to four times that of the original (1.5 to 2 cc).

Such alteration of the middle ear cavity affects the motion of the middle ear ossicles. Since subjective hearing thresholds are obtained with an intact middle ear and the vibration measurements of the ossicles in Hato *et al.* (2003) is conducted with an altered middle ear cavity, the results cannot be directly linked. In order to combine these two data sets, the effect from the alteration of the middle ear cavity is estimated using the middle ear model by Zwislocki (1962). Figure 2(b) shows the modeled ossicles motion with an intact middle ear cavity and antrum related to the modeled ossicles motion when the middle ear cavity is altered as in Hato *et al.* (2003). More details of the calculations deriving the correction curve in Fig. 2(b) are found in the appendix. It should be noted that the data in Fig. 2(a) is already corrected according to the curve in Fig. 2(b) meaning that Fig. 2(a) shows the ossicle displacement at 80 dB SPL input with an intact middle ear cavity.

The displacement of the stapes footplate and malleus umbo at hearing thresholds can be calculated by combining Figs. 1 and 2(a). The data used in Fig. 1 is the MAP and the threshold displacements in Fig. 3 is calculated as

$$OD_{MAP} = OD_{AC\_80} \times 10^{(MAP-80)/20}, \quad (1)$$

where OD means ossicle displacement.

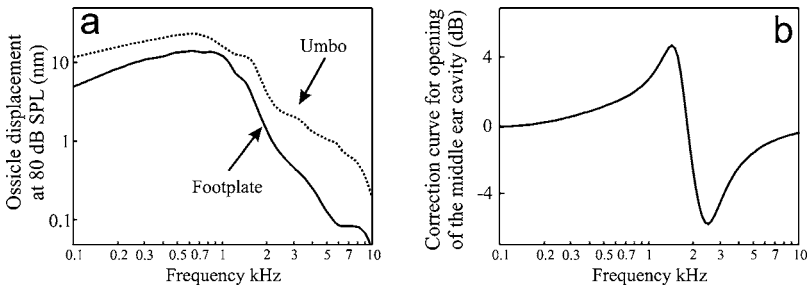

FIG. 2. (a) Displacement of the stapes footplate (solid line) and malleus umbo (dotted line) when the stimulation is a sound pressure of 80 dB SPL at the TM (OD_{AC_80}). The data is taken form Hato *et al.* (2003) and compensated for the effect of altering the space of the middle ear cavity. (b) The correction for the ossicle vibration caused by altering the middle ear volume. Using the middle ear model of Zwislocki (1962) the curve estimates the ratio of ossicle motion between an intact middle ear cavity and an open and resealed cavity as in the temporal bone experiments used to derive the ossicle vibration data (Hato *et al.*, 2003). A more thorough explanation for the calculations deriving the correction curve is given in the text and the Appendix .

IV. BONE CONDUCTION STIMULATION

When bone conduction (BC) threshold testing is conducted, a BC transducer with a circular surface area of 175 mm^2 is pressed against the skin covered mastoid with a static force of approximately 5.4 Newtons. With this setup, the dynamic force produced by the transducer at threshold levels is used as the reference for BC hearing. The reference equivalent threshold force levels (RETFL) given in the standard ISO 389-3 (1994) are shown in Fig. 4. Actually, the RETFL given in ISO 389-3 (1994) for BC audiometry are equal to the dynamic force levels produced by a BC transducer (Radioear B71) on a mechanical coupler (B & K type 4930 artificial mastoid) at electrical input levels directly corresponding to subjectively measured BC thresholds of young otologically normal listeners.

Although the transducer presses the skin onto the skull bone beneath it, the skin together with the skull act as a mass-spring system affecting the force transmission from the transducer to the skull bone. A lumped element impedance model of the vibration transmission through the skin and subcutaneous tissue to the skull bone is shown in Fig. 5(a). The parameters for the skin model (M_{SKIN}, C_{SKIN}, and R_{SKIN}) are taken from the skin covered mastoid impedance measurements made by Flottorp and Solberg (1976) and the skull impedance (Z_{SKULL}) is taken from mechanical point impedance measurements reported in Stenfelt and Good (2005b). Since

$$|Z_{SKULL}| \gg \left| \frac{1}{j\omega C_{SKIN}} + R_{SKIN} \right|$$

the force attenuation through the skin can be approximated with

$$\mathrm{Att}_{SKIN} = \frac{(1 - \omega^2 M_{SKIN} C_{SKIN}) + j\omega R_{SKIN} C_{SKIN}}{1 + j\omega R_{SKIN} C_{SKIN}}, \qquad (2)$$

where ω is the angular frequency and j is the imaginary constant.

The attenuation level of the force through the skin according to the model is shown in Fig. 5(b). The model in Fig. 5 predicts the force at the skull bone to be equal or better than at the skin position for frequencies up to about 4 kHz. At higher frequencies, the force attenuation caused by the skin increases with frequency and becomes approximately 8 dB at 10 kHz. The model prediction in Fig. 5 is in fair agreement with psychoacoustic measurements of the skin attenuation by Stenfelt and Håkansson (1999). However, the data in that study cannot be compared directly with the model predictions; the threshold data at the skin are obtained with the transducer placed at the mastoid behind the pinna whereas the BC thresholds for the skull bone attachment are obtained at the position of the bone-anchored hearing aid (www.entific.com), some 55 mm behind the ear canal opening. This difference in positions can affect the outcome. In an investigation of the human mechanical point impedance at the mastoid with both covering skin and direct skull bone

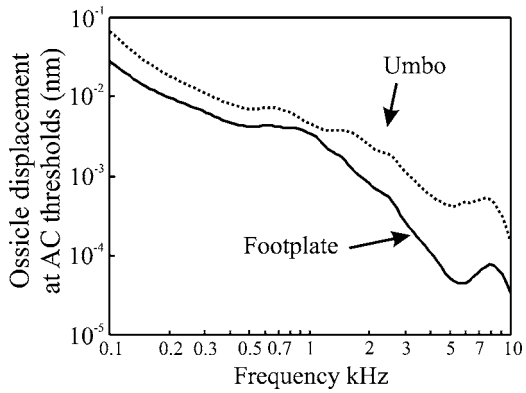

FIG. 3. Displacement of the stapes footplate (solid line) and malleus umbo (dotted line) when the stimulation is at AC behavior thresholds (OD_{MAP}). The result is derived from the ossicle displacement data in Fig. 2 and the minimum audible sound pressure (MAP) presented in Fig. 1.

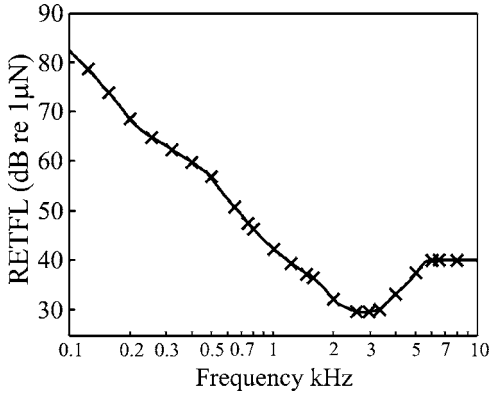

FIG. 4. Reference equivalent force threshold levels (RETFL) according to the standard ISO 389-3 (1994). The crosses indicate the frequencies and values stated in the standard. The solid line is the interpolated values used for the calculations.

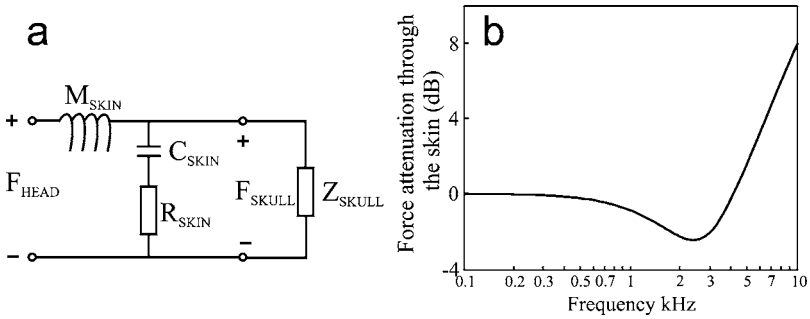

FIG. 5. (a) Lumped element impedance model of vibration transmission from a BC transducer through the skin to the skull bone. F_{HEAD} represents the dynamic force from the BC transducer and F_{SKULL} is the resulting force acting on the skull bone beneath the BC transducer. The impedance of the skull bone is modeled by Z_{SKULL} whereas M_{SKIN}, C_{SKIN}, and R_{SKIN} is the mass, compliance, and dissipation of the skin, respectively. (b) The resulting attenuation from F_{HEAD} to F_{SKULL} according to the model in (a) with skin parameters from Flottorp and Solberg (1976) and measured skull impedance from Stenfelt and Good (2005b).

attachment, Håkansson *et al.* (1986) derived a mathematical model for the impedance. Although Håkansson *et al.* (1986) used a slightly smaller contact area and greater static force between the transducer and skin than prescribed in the standard for BC threshold measurements, their computed model for the skin attenuation produces similar results as in Fig. 5(b). Further, the impedance data for direct skull attachment were, for corresponding positions, similar in Håkansson *et al.* (1986) using live humans with Stenfelt and Good (2005b) study using isolated cadaver heads; this indicates that, at least for the vibration input, isolated cadaver heads is a good substitute for live human heads conducting BC experiments.

The transmission of vibration between the skull bone surface at the mastoid and the cochlea was measured with a vibration transducer attached to the skull bone at the mastoid by means of a screw. With the stimulation at the mastoid, the vibration of the cochlear promontory was obtained with a three-axial accelerometer rigidly glued to the cochlear promontory in isolated cadaveric whole heads (Stenfelt and Good, 2005b). The excitation position is the same as the position applying the bone transducer for the RETFL data. To obtain the displacement of the cochlear promontory (PD) with BC stimulation at threshold, the data from Figs. 4 and 5 is combined with the skull vibration transmission from Stenfelt and Good (2005b) according to

$$PD_{RETFL} = \frac{PD_{1NEWTON} \times 10^{(RETFL-120)/20}}{Att_{SKIN}}, \quad (3)$$

where $PD_{1NEWTON}$ is the displacement of the cochlear promontory with 1 Newton stimulation according to Stenfelt and Good (2005b). PD_{RETFL} is shown in Fig. 6(b).

Although the cochlear promontory vibrates in all three directions of space, only the vibration in the direction in line with the low-frequency pistonlike stapes motion is used for the analysis here. This simplification of only using results from one direction introduces uncertainties that may produce errors in the analysis. However, the vibration of the cochlear promontory is some 5 dB greater in this measurement direction relative to the perpendicular directions when the stimulation is at the ipsilateral mastoid and, also, the relative middle ear ossicle motion is around 5 to 10 dB greater with the stimulation in this direction than with the stimulation in the perpendicular plane (Stenfelt and Good, 2005b; Stenfelt *et al.*, 2002). This means that the vibration of the middle ear ossicles is greatest in the low-frequency pistonlike stapes motion direction when the excitation is at the ipsilateral mastoid; vibrations of the ossicles in the other directions is assumed to only have a minor influence.

The relative motion of the middle ear ossicles with BC vibration was obtained by stimulation of isolated temporal bone specimens in the direction of the low-frequency pistonlike motion of the stapes while measuring the velocity of the ossicles and surrounding bone. The relative motion is then calculated as the velocity difference between the ossicle and bone divided by the stimulation velocity (Stenfelt *et al.*, 2002). This relative motion is shown in Fig. 6(a) (OD_{BC_REL}). Using the knowledge of the promontory displacement at BC thresholds [Eq. (3)] shown in Fig. 6(b), the ossicles displacement at BC threshold stimulation can be calculated as

$$OD_{RETFL} = OD_{BC\_REL} \cdot PD_{RETFL}. \quad (4)$$

The ossicles displacement at BC threshold stimulation is shown in Fig. 6(b).

The ossicle displacement at BC thresholds shown in Fig. 6(b) is derived from measurements in isolated cadaver heads and temporal bone specimens. It may be argued that isolated temporal bones are not a good model for BC stimulation of

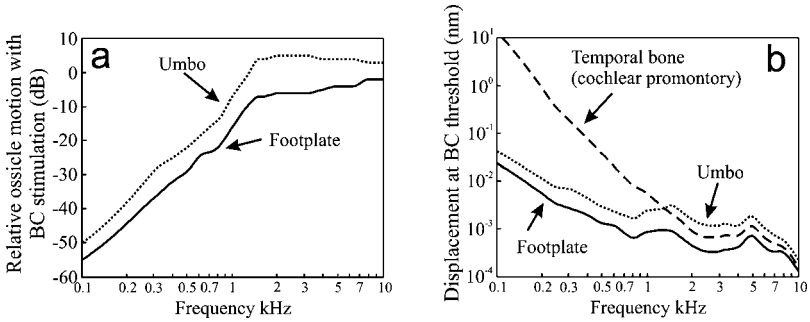

FIG. 6. (a) The relative motion between the stapes and cochlear promontory (solid line) and the relative motion between the umbo and surrounding bone (dotted line) when the stimulation is by BC in the direction of the low-frequency piston-like motion of the stapes. The data are taken from Stenfelt *et al.* (2002). (b) The dashed line shows the cochlear promontory bone displacement in the direction of the low-frequency pistonlike motion of the stapes when the stimulation is at behavioral thresholds at the ipsilateral mastoid (PD_{RETFL}). By combining the promontory displacement at threshold stimulation data (dashed line) with the relative ossicle displacements in (a) the stapes footplate (solid line) and malleus umbo (dotted line) displacements at behavioral BC threshold stimulation is estimated (OD_{RETFL}).

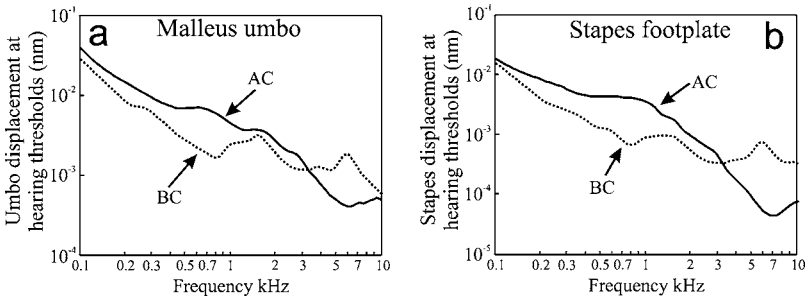

FIG. 7. The ossicle displacement at hearing threshold stimulation (OD_{MAP} and OD_{RETFL}). (a) Malleus umbo displacement and (b) stapes footplate displacement. The displacements using AC stimulation are shown with solid lines and the displacements using BC stimulation are shown with dotted lines.

compression or some other stimulation mode unaccounted for. However, stapes footplate as well as round window membrane motion has been measured in limited whole cadaver heads using BC stimulation producing vibration results similar to average results from isolated temporal bone specimens (Stenfelt *et al.*, 2002, 2004). Further, unpublished results of cochlear promontory vibration data obtained with a LDV aimed through an enlarged ear canal and open middle ear from two patients in our laboratory showed similar results as the cadaver head vibration data in Stenfelt and Good (2005b).[1] Although more experiments are required to verify these cadaver and temporal bone models for BC studies, they seem to be valid for first order effects. However, some caution is recommended interpreting the results in the coming sections.

V. RESULTS AND DISCUSSION

A. Middle ear ossicle motion

Using the analysis in the preceding sections, the displacement of the stapes and umbo can be compared for the two stimulation modalities, AC sound and BC vibration. For the comparison to be interesting, the absolute displacement of the ossicles at AC thresholds (Fig. 3, OD_{MAP}) and the relative displacement between the ossicles and the surrounding bone at BC thresholds [Fig. 6(b), OD_{RETFL}] are compared. This comparison for the stapes and umbo displacements are shown in Fig. 7. The overall displacements at threshold stimulation are similar, whereas AC or BC excitation is used. This similarity can be found in both umbo and stapes data. Although overall similar, a slight difference between the displacements with the two different stimulations is seen. This difference is similar for both the umbo and stapes data: at frequencies below 1.5 kHz the displacement of the ossicles is greater with AC stimulation than with BC stimulation, at frequencies between 1.5 and 3.1 kHz the displacements with AC and BC stimulation are close (the ossicle displacement with AC stimulation is still slightly greater), and at 3.1 kHz and above, the ossicles displacement with BC stimulation is greater than with AC stimulation.

In what follows the assumption is made that, with AC stimulation, the motion of the ossicles at threshold level is the lowest required motion of the middle ear ossicles to produce a hearing sensation. Consequently, if the motion of the ossicles at threshold stimulation is less than this, the hearing sensation cannot be caused by, or transmitted by, the middle ear ossicles. To rephrase this, if, at a specific frequency or frequency range, the motion of the ossicles at BC threshold stimulation is less than the ossicles motion at AC threshold stimulation ($OD_{MAP} > OD_{RETFL}$), the hearing sensation produced at BC thresholds is not primarily caused by the inertial motion of the middle ear ossicles or by sound in the external ear canal that is transmitted to the inner ear via the middle ear ossicles. One limitation with this approach is that it requires the BC stimulation to be generated by inertial forces. If the BC hearing is dominated by other phenomena, for example compression and expansion of the cochlear space, the stapes footplate is not necessarily related to the hearing threshold and the assumption fails. This limits the analysis primarily at higher frequencies. It should also be noted that the ossicle displacement data with BC stimulation are extracted from isolated temporal bone specimens that may not be a good model for compressional or some yet unaccounted for response with BC stimulation; this adds to the uncertainties in the analysis.

The results in Fig. 7 are rearranged to displacement at threshold with BC stimulation relative to AC stimulation (OD_{RETFL}/OD_{MAP}). Viewing the result in this way, Fig. 8(a) shows the relative stapes footplate displacement with a solid line and the relative umbo displacement as a dotted line. Displayed like this, the results found in Fig. 7 are even more evident: at frequencies below 1.5 kHz the ossicles threshold

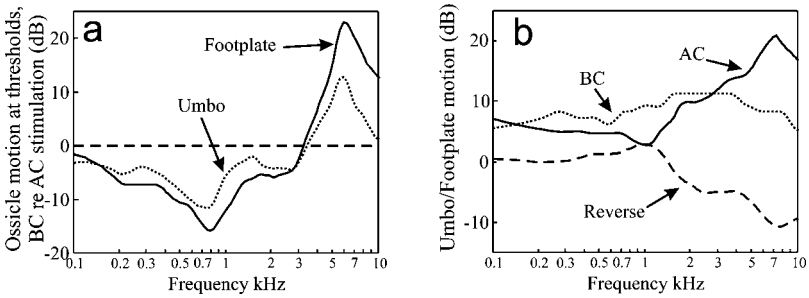

FIG. 8. (a) The ossicle motion at threshold stimulation displayed as the displacement with BC stimulation divided by the displacement with AC stimulation (OD_{RETFL}/OD_{MAP}). The relative stapes footplate motion is shown with a solid line, the relative umbo motion with a dotted line, and the 0 dB level is indicated with a dashed line. The data is taken from Fig. 7. (b) The umbo motion divided by the stapes footplate motion at hearing threshold stimulation. Results using AC stimulation are shown with a solid line and using BC stimulation with dotted line. Also included is the umbo divided with the footplate motion when the ossicles are driven from the vestibule in the cochlea (dashed line). More details about the latter are given in the text.

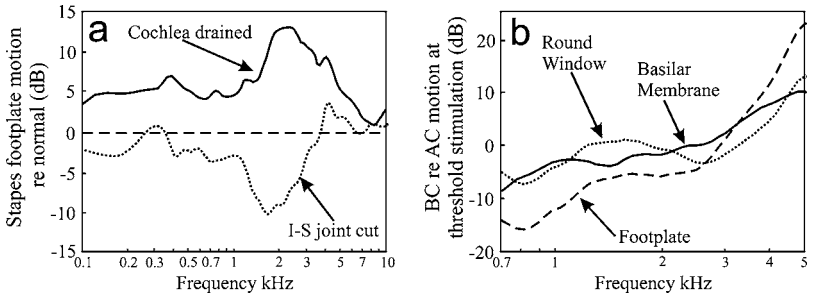

FIG. 9. (a) Alteration of the stapes footplate motion with BC stimulation after artificial lesion of the middle and inner ear. Changes of the motion after the cochlea was drained are shown with a solid line and after the incudo-stapedial joint was severed are shown with a dotted line. (b) The relative motion of the basilar membrane (solid line), round window (dotted line), and stapes footplate (dashed line) at BC threshold stimulation compared with AC threshold stimulation. The footplate data is the same as shown in Fig. 8(a); the frequency range is different.

vibration with BC stimulation is some 5 to 15 dB lower than with AC stimulation, at frequencies between 1.5 and 3.1 kHz the vibration of the ossicles is within 5 dB at AC or BC threshold stimulation, and at frequencies above 3.1 kHz, the stapes footplate vibration is up to 20 dB and the malleus umbo vibration is up to 10 dB greater with BC than AC stimulation at threshold levels.

An interpretation of the results is as follows. At frequencies below 1.5 kHz, the motion of the ossicles with BC stimulation (OD_{RETFL}) is below that of AC stimulation (OD_{MAP}) meaning that at these frequencies, the outer and middle ear is not the dominant contributor to BC sound perception. At the frequencies between approximately 1.5 and 3.1 kHz, the ossicles motion at AC and BC thresholds are within 5 dB, indicating that the middle ear ossicles can contribute to the BC perception in this frequency range. At frequencies above 3.1 kHz, the ossicles displacement at BC thresholds (OD_{RETFL}) are up to 20 dB greater (stapes footplate) or 10 dB greater (umbo) than at AC thresholds (OD_{MAP}). At these high frequencies, wave propagation at a wavelength that can cause alteration of the cochlear space is present (Stenfelt and Good, 2005b). As stated previously, with that type of BC excitation of the inner ear, the footplate vibration does not represent the input to the cochlea and the current analysis is no longer valid.

It is not obvious, given the many uncertainties in the analysis and extraction of the data, the significance of the differences found in Fig. 8(a). The limit for a change or difference to be considered a true change or difference is set to ±5 dB. The reason for the 5 dB significance level is primarily due to the results of basilar membrane motion in Sec. V B. However, as stated previously, the results from the present analysis should be interpreted with some caution.

Another way to present the data in Fig. 7 is to plot the relation between umbo and footplate motion for AC and BC stimulation. This is done in Fig. 8(b) where the AC umbo to footplate motion is shown with a solid line, and the BC umbo to footplate motion is shown with a dotted line. This plot represents the attenuation of motion between the umbo and footplate. Normally, when the ossicles are driven by a sound pressure in the ear canal (AC stimulation), the low-frequency motion of the stapes is slightly lower than the motion of the umbo. The ossicles have a resonance frequency around 1 kHz and above this frequency, the umbo to stapes motion increases at around 20 dB/decade [Fig. 8(b), solid line].

Although not exactly equal, the BC data in Fig. 8(b) (dotted line) shows a trend similar to the AC data (solid line) up to 1.7 kHz. Between this frequency and 4 kHz, the ratio between umbo and stapes motion with BC stimulation is almost constant; above 4 kHz the ratio between the umbo and stapes motion decreases. Since the BC data in Fig. 8(b) is derived from isolated temporal bone models, no sound radiated into the outer ear canal contributes to the result. This means that middle ear ossicles inertia, inner ear fluid inertia, and alteration of the cochlear space are the only components expected to cause the motion of the stapes and umbo. For comparison, the umbo-stapes ratio with the stimulation reversed is also plotted in Fig. 8(b) (dashed line). This data is taken from Stenfelt *et al.* (2003b) where the cochlea in the temporal bones were opened from the internal acusticus meatus, a piston coupled to a minitransducer was attached to the stapes footplate on the vestibular side, and the velocity of the umbo and stapes was measured with a laser Doppler vibrometer. The umbo-stapes ratio shown as the dashed line is expected when the ossicles are purely driven from the cochlea, whereas the solid line (AC) is the umbo-stapes ratio expected when the ossicles are driven purely from a sound pressure in the ear canal. Since the inertial forces of the ossicles also influence the umbo-stapes ratio, the BC curve (dotted line) is neither purely driven from the ear canal sound pressure (solid line) nor purely driven from the cochlea (dashed line). As stated previously, for frequencies up to 1.7 kHz, the trend of the umbo-stapes ratio with BC stimulation is similar to the AC stimulation whereas above this frequency, the trend of the ossicles ratio with BC stimulation is more similar to the driven in reverse curve (dashed line). Although no conclusive evidence can be found by investigating the umbo-stapes ratio using different stimulation modalities, some trends and indications are seen.

Next, the stapes footplate motion with BC stimulation is investigated after the incudo-stapedial (I-S) joint was artificially severed and after the cochlea was drained [Fig. 9(a)]. The results displayed are the stapes motion in temporal bone models with artificially lesions compared with the stapes motion in temporal bones with normal intact middle and inner ear (Stenfelt *et al.*, 2002). The dotted line in Fig. 9(a) shows the stapes motion change after the I-S joint was severed; the solid line shows the stapes motion change after the cochlea was drained.[2] These data were obtained during BC stimulation (the temporal bones were vibrated in the direction of the low-frequency in-and-out motion of the stapes). According to Fig. 9(a), the stapes motion was lowered 5 to 10 dB between the frequencies 1.2 and 2.7 kHz after the I-S joint was severed. After the cochlea was drained, an increase of stapes vibration of around 5 dB was seen up to frequencies of

1.5 kHz. Between 1.5 and 5.0 kHz, the increase is between 5 and 13 dB, and for frequencies above 5.0 kHz, the increase stays between 1 and 5 dB.

The loss in the mid-frequency range with a severed ossicular chain is attributed to the change in resonance frequency of the ossicular chain. With an intact ossicular chain the resonance frequency of the ossicles vibration with BC stimulation is close to 1.5 kHz, but with a disrupted chain (at the I-S joint) the resonance frequency of the stapes vibration is closer to 4 kHz. This resonance frequency change is primarily due to the mass reduction when the malleus and incus no longer is coupled to the stapes. Removing some of the inertial force by severing the ossicular chain results in a decrease of the stapes motion around 2 kHz. This data indicates that the inertia of the ossicles can, with an intact ossicular chain, contribute to the perception of BC sound around this frequency.

The increase of the stapes motion seen after the cochlea was drained is probably due to the removal of the cochlear fluid interaction. The total mass of the middle ear ossicles is 50 to 60 mg whereas the mass of the fluid within the cochlea and vestibule is around twice that, approximately 100 mg (Wever and Lawrence, 1954). The mass of the ossicles is centered to the head of the malleus and body of incus; the ossicles center of rotation goes through these masses. This results in a lower effective mass of the ossicular chain producing the inertial force during BC stimulation than the total sum of the three ossicles masses. However, it is scarcely likely that, during BC stimulation, the total mass of the inner ear fluid contributes to the inertial forces of the inner ear fluid. Although the effective mass of the inner ear fluid and corresponding inertial force is less than the total mass of the inner ear fluid, the inertial force of the inner ear fluid is probably greater than the inertial force of the ossicles. The increase of stapes motion with removal of the cochlear fluid seen in Fig. 9(a) is therefore believed to rather be the removal of fluid motion than the impedance reduction for the stapes motion at the stapes-vestibuli interface.

B. Basilar membrane and round window motion

A last analysis is made with measured basilar membrane and round window motion using both AC and BC stimulation (Stenfelt *et al.*, 2003a; Stenfelt *et al.*, 2004). If the assumptions and calculations here are correct, one can expect equal vibration magnitude of the basilar membrane at threshold stimulation independent if the excitation is by AC or BC. The basilar membrane vibration at BC thresholds compared with the vibration at AC thresholds is displayed in Fig. 9(b) (solid line). This comparison is computed similar as the stapes footplate and malleus umbo data previously. Since the BC data of basilar membrane motion was uncertain at low and high frequencies, only results for frequencies between 0.7 and 5 kHz are included here. For comparison, the stapes footplate relative displacement (dashed line) and the round window relative volume displacement (dotted line) at thresholds are also included in Fig. 9(b). The footplate data are the same as displayed in Fig. 8(a); the frequency range of the plots differ. According to the calculations deriving the results presented in this study, the basilar membrane vibration differ less than 5 dB between BC and AC threshold stimulation in the frequency range 0.8 to 3.5 kHz. Beyond these frequencies, the difference is greater.

The basilar membrane motion is calculated using almost the same data, assumptions, and simplifications as for deriving the stapes footplate and the malleus umbo motion. As a consequence, the results of the basilar membrane motion can be used as a verification of the results presented previously. As stated above, the basilar membrane motion should be equal at AC threshold and BC threshold stimulation. Within the frequency range 0.8 to 3.5 kHz the basilar membrane motion differ less than 5 dB and within the frequency range 0.7 kHz and 5 kHz it differ less than 10 dB between AC and BC threshold stimulation using the calculations presented here. Therefore, in the comparisons, changes and differences less than 5 dB is not considered as significant and differences in the 5 to 10 dB range should be interpreted with care in the frequency range 0.7 to 5 kHz; no validation data is applicable at frequencies outside this range. Since individual AC and BC hearing thresholds may differ more than 5 dB among normal hearing subjects, the basilar membrane data provides a strong indication of the validity of the current analysis, at least in the frequency range 0.8 to 3.5 kHz.

One interesting finding seen in Fig. 9(b) is that the relative round window volume displacement at threshold stimulation is similar to the relative basilar membrane motion. This could implicate that the round window volume displacement, correctly measured, is a good estimate of the hearing excitation, whereas the stimulation is by AC or BC. It should be noted that only one or a couple positions measured on the round window membrane does not give a good estimate of the round window volume displacement; the round window membrane motion depends on the stimulation itself (Stenfelt *et al.*, 2004). It should also be remembered that the basilar membrane data were obtained in cadaver temporal bone specimens; no active mechanism enhancing the basilar membrane motion was present. Although the active mechanism is expected to influence AC and BC stimulation of the basilar membrane similarly, no direct measurement of the basilar membrane motion in the human with AC and BC stimulation has been conducted. As explained in the introduction, the anticipated similarity of the basilar membrane motion with AC and BC stimulation is based on the ability to produce distortion product otoacoustic emissions with both stimulations as well as cancellation of pure tones and similarities of resonance frequencies on the basilar membrane with the two stimulation modalities.

VI. CLINICAL FINDINGS

It would be interesting to compare the results from this analysis to reported clinical findings. Therefore, the computed estimates are compared with findings of superior semicircular dehiscence, mass-loading of the ossicles, otosclerosis of the stapes footplate, and removal of middle ear ossicles.

A. Superior semicircular dehiscence

In rare occasions, an opening can occur between the cranial space and the superior semicircular canal enabling a fluid pathway between the cerebrospinal fluid and fluid in the vestibule. The audiological findings in these patients are, beside sound induced vertigo, worse low-frequency AC thresholds and improved low-frequency BC thresholds (Minor *et al.*, 2003; Mikulec *et al.*, 2004). The worse AC thresholds can be explained by the shunt effect of the dehiscence on the vestibular side reducing the fluid flow from the scala vestibuli to scala tympani and stimulation of the basilar membrane. The sensitivity increase at low frequencies with BC stimulation can be explained by the impedance decrease for fluid flow on the scala vestibule side (paralleling the oval window) that would increase the effect of the fluid inertia. Another explanation for the improved low-frequency BC sensitivity could be a pressure transmission from the CSF to the cochlea that is improved due to the patent fluid connection. Regardless whether the first or second explanation is correct, the improvement of low-frequency hearing thresholds with BC stimulation indicates that hearing of BC sound is not dominated by sound in the outer ear canal or inertia of the middle ear ossicles at these frequencies. However, a dehiscence does not normally alter the hearing thresholds at the frequency range where middle ear inertia is identified as a potential contributor to BC sound (approximately 1.5 to 3 kHz).

B. Mass-loading of the ossicles

Several investigators have increased the mass of the ossicles to manipulate the BC sensitivity (Bárány, 1938; Kirikae, 1959; Brinkman *et al.*, 1965). An increase of the ossicles mass lowers the resonance frequency of the mechanical system and improves the relative low-frequency (below the resonance frequency of the normal ossicular chain) vibration between the ossicles and surrounding bone during BC stimulation. Huizing (1960) used water and mercury on the eardrum to increase the mass of the middle ear ossicles and alter the effect from inertia on BC thresholds. He reported that the BC hearing thresholds below 1 kHz improved with increasing mass for masses up to approximately 250 mg. A further increase of the mass over 250 mg did not change the BC hearing thresholds. In his study, an increase of 100 mg produced a threshold shift of around 10 dB for frequencies below 1 kHz. That result can be compared with the results in Stenfelt *et al.* (2002), where 100 mg was added to the malleus and produced around 20 dB greater relative vibration levels of the stapes for frequencies below 0.7 kHz. Consequently, with BC stimulation an improvement in stapes vibration level of 20 dB corresponds to a threshold shift of 10 dB at low frequencies. This can be interpreted as follows: the vibration of the ossicles with BC excitation due to inertia at frequencies below 1 kHz causes a hearing stimulation that is around 10 dB lower than other phenomena contributing to sound perception via BC stimulation. This also agrees well with the results presented in Fig. 7(a) where the stapes vibration at BC threshold is 5 to 15 dB below the vibration level of the stapes at AC thresholds for frequencies below 1 kHz. Once again, no evidence supporting or refuting the BC middle ear ossicles inertial effect between 1.5 and 3 kHz can be found from these investigations.

C. Otosclerosis of the stapes footplate

Results of the BC thresholds in patients with otosclerosis of the stapes footplate have been reported extensively in the literature. Carhart (1962) drew attention to the typical BC threshold alteration caused by stapes otosclerosis: a loss of approximately 20 dB at 2 kHz, with lesser losses at frequencies below and above this frequency, now known as the Carhart notch. One explanation for the typical BC threshold change with otosclerosis was given by Tonndorf (1966) who suggest that this loss is the lack of excitation from the inertial component of the ossicles. Although this explanation has some support from the result in Stenfelt *et al.* (2002), the threshold elevation can originate from the impedance change at the oval window seen from the inside of the cochlea. For example, fluid flow caused either by fluid inertia or by alterations of the cochlear space can be impeded by increased impedance at the oval window.

The elevation of BC thresholds with otosclerosis is found at, and also slightly below and above, the frequency range identified as the area of possible ossicles inertia contribution to BC sound. The otosclerosis removes effectively any contribution from the ossicles and also from the outer ear with BC stimulation. However, since the otosclerosis also blocks the fluid flow at the oval window, it is difficult to separate the middle ear and inner ear parts of the contribution to the BC sound. Moreover, Everberg (1968) reported that patients without oval windows due to malformations had BC thresholds close to normal. This suggests that even though middle ear ossicle inertia contributes to the hearing of BC sound in the frequency range 1.5 to 3 kHz, other phenomena is nearly as effective producing a hearing sensation with BC stimulation.

D. Middle ear discontinuity

As stated previously, resection of the incudo-stapedial joint increases the resonance frequency for vibration of the stapes when driven by inertial effects during BC stimulation. This can be understood by the decrease of mass (malleus and incus) while maintaining the compliance attaching the stapes (annular ligament). This is not the whole story since some ligaments of the malleus and incus together with the TM influences the stiffness of the middle ear ossicles as well; these are removed from the stapes when severing the I-S joint. However, seen from the stapes, the reduced mass-effect is greater than the alteration of the stiffness. Severing the I-S joint increased the resonance frequency of the stapes with slightly more than one octave while driven by BC. For simplicity, let us assume that the increase is precise one octave. Below the resonance frequency, the relative motion between the stapes and cochlear promontory rises at 12 dB/octave [Fig. 6(a)]. This means that, by severing the I-S joint and causing a resonance frequency shift of one octave, the stimulation at the oval window is reduced by 12 dB for frequencies below the original resonance frequency (approximately

1.5 kHz), between the original and the new resonance frequency the reduction decreases (improves) from 12 dB to 0 dB as a function of frequency. Above the new resonance frequency no alteration of the stimulation is found.

It has been reported that discontinuity of the middle ear ossicles, e.g., lesion of the incudo-stapedial joint, has a small effect on the BC thresholds at frequencies below 2 kHz (Møller, 2000). This agrees well with temporal bone experiments displayed in Fig. 9(a); the change in stapes motion after I-S joint resection is within 5 dB up to 1 kHz where it decreases to below −10 dB at 1.5 kHz. Above this frequency the decrease of the stapes motion recovers and is close to zero for frequencies of 3.5 kHz and above. An interpretation of this result from the model above is as follows: at frequencies below 1 kHz, the middle ear does not contribute to perception of BC sound. At frequencies between 1.5 and 3 kHz the middle ear inertia contributes to the perception of BC sound, and above 3 kHz no conclusions can be made since no alteration is expected from the model. Hence, results with middle ear discontinuity indicate that the inertial forces of the ossicular chain do contribute to the perception of BC sound in the frequency range close to the resonance frequency of the ossicles. It should be noted that the alteration of BC thresholds depend on the position and type of middle ear discontinuity; e.g., if the discontinuity is between the malleus and umbo, less change of BC hearing thresholds is expected.

VII. HIGH-FREQUENCY RESULTS

From Fig. 8 it is clear that, according to the present analysis and at frequencies above 5 kHz, the stapes footplate and umbo vibrates 10 to 20 dB more at BC thresholds than at AC thresholds. Since, according to the previously stated hypothesis, the vibration of the stapes at AC thresholds is considered the lowest required vibration level to cause a hearing sensation, the high-frequency stapes motion at BC thresholds produces cochlear stimulation that are some 20 dB above thresholds. Consequently, the assumptions made are incorrect at these high frequencies. The reason is most probably that for BC stimulation at these high frequencies, the stapes footplate vibration does not reflect the fluid flow in the cochlea causing the basilar membrane vibration.

One explanation is that there are compliant fluid pathways in the cochlea paralleling the oval window allowing fluid flow in the cochlea without involving the oval window and attached stapes. Another plausible explanation is that the dominant excitation mode at these high frequencies is expansion and compression of the cochlear space caused by wave propagation in the skull bone. In such cases, the fluid flow at the oval window is expected to be greater than the fluid flow over the basilar membrane causing a hearing stimulation. A third explanation is that with BC stimulation at high frequencies, the stimulation of the basilar membrane is caused locally, e.g., by the inertial forces of the osseus spiral lamina (Stenfelt *et al.*, 2003a), not involving the fluid flow at the oval window and vibration of the stapes. A fourth explanation for the result is that isolated temporal bone specimen is not a good model of BC stimulation at the high frequencies; threshold data are obtained in live humans while ossicle motions are estimated from temporal bone models and the BC stimulation of the cochlea and middle ear differ between the two.

When examining Fig. 9(b) and comparing threshold motion of the stapes footplate, basilar membrane, and round window, the third explanation appears less plausible. The relative round window and basilar membrane vibration level is similar at threshold stimulation for both stimulation modalities (AC and BC), indicating that the round window fluid flow reflects the stimulation of the basilar membrane. Figure 9(b) only shows results up to frequencies of 5 kHz, and at frequencies above 4 kHz the results begins to deviate, once again indicating that the present analysis may not be valid at those high frequencies. However, according to clinical findings reported in the literature (Martin *et al.*, 2002; Groen and Hoogland, 1958), obstructing the round window affects BC hearing thresholds more than obstructing the oval window. This is another indication that a fluid flow at the round window is essential for hearing by BC and it reflects the stimulation of the basilar membrane when the stimulation is by BC.

VIII. CONCLUSIONS

The analysis presented is based on human behavioral threshold data with AC and BC stimulation together with physiological and mechanical vibration data of the middle ear ossicles, round window, and basilar membrane. With the assumption that the stapes footplate vibration at AC threshold stimulation represents the lowest cochlear excitation required to elicit a neural response and hearing perception, the contribution to BC hearing perception from the middle ear ossicles was investigated. According to that approach, the vibration of the middle ear ossicles with BC stimulation is approximately 10 dB too low to contribute to the BC hearing perception at frequencies below 1.5 kHz. For frequencies above 4 kHz, the assumptions made for this analysis is no longer valid, and no conclusive evidence for the importance of the middle ear ossicles to BC hearing can be given. In the frequency range between 1.5 and 3.1 kHz, the stapes footplate and umbo vibrations were similar at AC and BC threshold stimulation. This frequency range includes the resonance frequencies for the middle ear ossicles vibration with BC stimulation. Although, given the uncertainties of using isolated temporal bone specimens and cadaver heads for the results with BC stimulation, it is proposed that in the frequency range between 1.5 and 3.1 kHz the inertial effect of the middle ear ossicles contributes to hearing by BC stimulation. However, according to clinical findings, as long as there is an opening allowing fluid flow in the scala vestibule side of the cochlea (similar to the oval window), effects within the cochlea produces almost similar excitation of the basilar membrane as the inertial effects of the middle ear ossicles in the frequency range 1.5 to 3.1 kHz.

ACKNOWLEDGMENT

This work was supported by a grant from the Swedish Research Council (Grant No. 621-2002-5624).

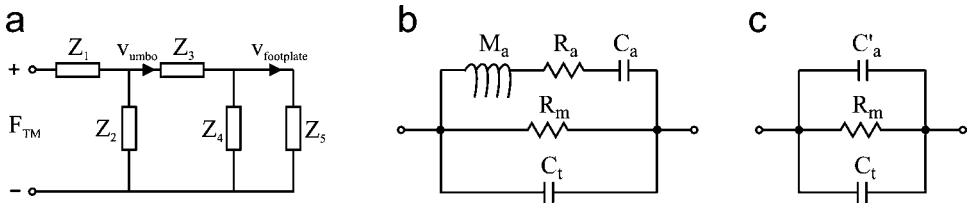

FIG. 10. (a) The impedance model of the middle ear according to Zwislocki (1962). The physical interpretation of the five impedance branches is given in the text. (b) The lumped parameters of impedance Z_1 for the intact middle ear. (c) The lumped parameters of impedance Z_1 for the artificially altered middle ear space.

APPENDIX: EFFECT OF THE MIDDLE EAR CAVITY

Zwislocki (1962) describes the sound (vibration) transmission through the middle ear with a lumped impedance network according to Fig. 10(a). According to this model the input at the left-hand side is the sound pressure in front of the eardrum multiplied with the eardrum area, depicted as F_{TM} ($F_{\mathrm{TM}}=P_{\mathrm{TM}}\cdot A_{\mathrm{TM}}$). The general impedance network and the five impedance branches in Fig. 10(a) were primarily derived considering the anatomy and using acoustic impedance measurements. All five impedances (Z_1–Z_5) can be related to physical structures. The effects of the middle ear cavity are described by Z_1 while Z_2 represents the part of the eardrum that moves differently from the malleus. The part of the eardrum together with the malleus and incus that vibrates nearly as a unit is represented by Z_3 and Z_4 describes primarily the stiffness of the incudo-stapedial joint. Last, Z_5 is the impedance of the stapes and the annular ligament attaching it to the oval window, the input impedance of the cochlea, and the RW membrane. A more detailed description of the impedance model and corresponding parameters is found in Zwislocki (1962).

The details of the impedance branch representing the middle ear cavity, Z_1, are shown for the intact middle ear in Fig. 10(b); this is taken from Zwislocki (1962). The air compliance within the tympanic cavity is modeled by C_t and R_m is the absorption in the tympanic cavity and Eustatian tube. The branch comprising M_a, R_a, and C_a is the resonance from the antrum and mastoid air cells where M_a is the mass behavior of the narrow passage between the tympanic cavity and antrum, R_a models the losses of the same passage, whereas C_a describes the compliance of the air in the antrum and mastoid air cells.

The measurements of ossicle displacement with AC stimulation were conducted in cored temporal bone specimens where part of the mastoid air cells and occasionally part of the antrum are missing (Hato *et al.*, 2003). In these specimens, a hole was drilled into the antrum and tympanic cavity enlarging the small passage between the antrum and tympanic cavity. Before the measurements are executed the isolated temporal bone specimen is enclosed with a latex cover and the opening into the middle ear cavity is sealed with a glass plate. This means that in these manipulated specimens, the resulting middle ear space is best described as a single large air volume and the corresponding impedance model is the one depicted in Fig. 10(c). In this model, R_m and C_t are the losses and compliance of the tympanic cavity as in Fig. 10(b). The difference is that the rest is modeled by C'_a which is basically the rest of the air enclosed in the altered middle ear space, i.e., C'_a+C_t represent the total air volume enclosed in the altered middle ear cavity. The normal tympanic cavity is in the order of 0.5 cc and the artificially opened space is 1.0 to 1.5 cc. This means that C'_a represents an air volume two to three times that of C_t. For the calculations estimating the difference of malleus umbo and stapes footplate displacement between the intact and artificially manipulated middle ear, the relation $C'_a=2C_t$ was used (corresponds to a total middle ear space volume of approximately 1.5 cc).

In the model in Fig. 10(a) the velocities of the umbo (v_{umbo}) and footplate ($v_{\mathrm{footplate}}$) are indicated with arrows. The displacements of the ossicles can be computed by integrating these velocities. Using the parameters given by Zwislocki (1962) and using the model in Fig. 10(b) for an intact middle ear and the model in Fig. 10(c) for an altered middle ear cavity, the change of the umbo and footplate displacements can be estimated. The estimated ratio between the ossicle displacement with an intact middle ear and the artificially altered middle ear space is shown in Fig. 2(b).

[1]The unpublished data were obtained in two patients equipped with a titanium implant anchoring bone conduction hearing aids. This enabled direct BC stimulation of the skull bone behind the pinnae. These two patients had enlarged ear canals and had their eardrums, malleus and incus removed. This allowed for the LDV beam to reach the cochlear promontory and the displacement of the cochlear promontory could be measured when the BC stimulation was applied at the mastoid, similar to the setup in Stenfelt and Good (2005b).

[2]These data with the drained cochlea were never shown in Stenfelt *et al.* (2002). The data shown in that study were with the cochlea drained and the I-S joint severed. The data presented here in Fig. 9(a) were obtained during that same study, using the same setup and measurement method as all other data presented in that study.

Current finite-element (FE) models of the eardrum are limited to low pressures because of the assumption of linearity. Our objective is to investigate the effects of geometric nonlinearity in FE models of the cat eardrum with an approximately immobile malleus for pressures up to ±2.2 kPa, which are within the range of pressures used in clinical tympanometry. Displacements computed with nonlinear models increased less than in proportion to applied pressure, similar to what is seen in measured data. In both simulations and experiments, there is a shift inferiorly in the location of maximum displacement in response to increasingly negative middle-ear pressures. Displacement patterns computed for small pressures and for large positive pressures differed from measured patterns in the position of the maximum pars-tensa displacement. Increasing the thickness of the postero-superior pars tensa in the models shifted the location of the computed maximum toward the measured location. The largest computed pars-tensa strains were mostly less than 2%, implying that a linearized material model is a reasonable approximation. Geometric nonlinearity must be considered when simulating eardrum response to high pressures because purely linear models cannot take into account the effects of changing geometry. At higher pressures, material nonlinearity may become more important. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2188370]

I. INTRODUCTION

Existing finite-element (FE) models of the eardrum (e.g., Funnell and Decraemer, 1996; Beer *et al.*, 1999; Bornitz *et al.*, 1999; Eiber 1999; Ferris and Prendergast, 2000; Koike *et al.*, 2002; Gan *et al.*, 2004) are limited to low pressure levels because of the simplifying modeling assumption that the relationship between applied pressure and the resulting displacements is linear (i.e., that an increase in pressure results in a proportional increase in displacement). However, modeling the response to high pressures would be useful in understanding the mechanics of impedance tympanometry in which the static pressures that are used are so high that the responses become nonlinear.

As one step toward our goal of developing and evaluating an FE model of the eardrum that is valid for high pressures, we measured the shape and displacement patterns of the cat eardrum in response to static pressures (Ladak *et al.*, 2004) by using phase-shift shadow-moiré topography, a noncontacting optical technique that was originally adapted for measurements on the eardrum by Dirckx *et al.* (1988). Our experiments involved cyclically pressurizing the middle ear up to ±2.2 kPa after immobilizing the malleus. The immobile-malleus condition allows us to investigate the behavior of the eardrum in isolation from any possible nonlinearities of the cochlea and middle-ear structures. The immobile-malleus data indicate that the eardrum response itself is nonlinear at the pressures used in the study. In other words, eardrum displacements do not increase in proportion to the applied pressure; specifically, the displacements grow less than in proportion to applied pressure, like that of a stiffening structure.

In order to model the measured data, nonlinearities must be added to current models. Two basic types of nonlinearities must be considered in modeling the eardrum or any other structure: material nonlinearity and geometric nonlinearity. Material nonlinearity manifests itself as a nonlinear relationship between stress and strain. Experimental measurements on the pars tensa indicate that the relationship between stress and strain is indeed nonlinear, with the material becoming stiffer as it undergoes large stretches (Decraemer *et al.*, 1980). For small changes in strain from an equilibrium state, however, materials can often be approximated as linear.

[a)]Electronic mail: hladak@uwo.ca

Geometric nonlinearity is related to changes in the shape of the structure while the structure is being loaded. Large displacements can significantly alter the shape and therefore the stiffness of a structure as well as the line of action of applied loads. For small displacements, geometric nonlinearity can be neglected. However, for thin-shell structures such as the eardrum, geometric nonlinearity starts to become important when the displacements are as large as the thickness of the structure (Timoshenko and Woinowsky-Krieger, 1959; Fung, 1965). At the highest pressures in our experimental study (±2.2 kPa), eardrum displacements measured with an immobile malleus are many times larger than the thickness of the pars tensa (Ladak *et al.*, 2004), implying that geometric nonlinearity must be included in eardrum models when simulating the response to such high pressures.

For soft tissues, both geometric and material nonlinearities often occur together. We hypothesize that for our experiments on the eardrum with an immobile malleus and for pressures up to ±2.2 kPa, geometric nonlinearity must be taken into account because the displacements are larger than the thickness of the pars tensa. However, the relative importance of material nonlinearity is not clear. Although the measured displacements are large relative to the thickness of the pars tensa, they are small relative to the overall dimensions of the eardrum, and the resulting strains may also be small. If the strains are indeed small, then linearizing the relationship between stress and strain under these specific experimental conditions may be a reasonable approximation.

The objective of this work is to investigate the effects of geometric nonlinearity alone on the behavior of the eardrum with an immobile malleus measured for pressure levels up to ±2.2 kPa, by incorporating such nonlinearity into our FE models of the cat eardrum and by comparing computed displacements with measured ones. To investigate the eardrum in isolation from the loading effects of the middle-ear structures and cochlea, we confined our simulations to the case of an immobile malleus as in the experimental study.

II. FINITE-ELEMENT MODELS

A. Mesh geometry

The response of the eardrum depends significantly on its shape (Funnell and Laszlo, 1978; Funnell and Decraemer, 1996), which can vary from subject to subject; hence, individualized FE meshes were constructed from *resting-shape* data measured in our previous experimental study (Ladak *et al.*, 2004); the resting shape is taken to be the shape measured at the beginning of an experiment, with no pressure applied to the eardrum. Meshes were defined for three cats from the previous study (MY1216L, MY1630L, and MY0923R) in which experiments were done with an immobile malleus. A sample image of the resting shape for cat MY1612L is shown in Fig. 1. The grey levels in the image vary from black (points furthest from reader) to white (points closest to reader). A vertical profile through the pars tensa just inferior to the manubrium is shown to the left of the image, and a horizontal profile through the posterior pars tensa is shown below the image. The locations of the profiles in relation to the original image are shown by the dashed lines. The figure also shows a lateral view of the corresponding eardrum mesh along with vertical and horizontal profiles through the mesh corresponding to the profiles shown through the moiré shape image. The procedure for constructing an FE mesh from a moiré shape image has previously been described in detail (Funnell and Decraemer, 1996). The mesh shown has a *nominal resolution* of 25 elements/diameter (Funnell, 1983). Each element of the mesh represents an S3R general-purpose shell element of the ABAQUS commercial FE software package (Hibbit, Karlsson, and Sorensen Inc., Pawtucket, RI). This element is accurate for both thin and thick shells. No elements are generated for the manubrium, as it is assumed to be completely immobile along its entire length in order to model our previously reported immobile-malleus data. In some areas, the mesh only appears to overlap the bony part of the ear canal; however, here the eardrum is actually concealed by overhanging bone. In such cases, the location of the periphery of the eardrum was estimated by extrapolation as described by Funnell and Decraemer (1996).

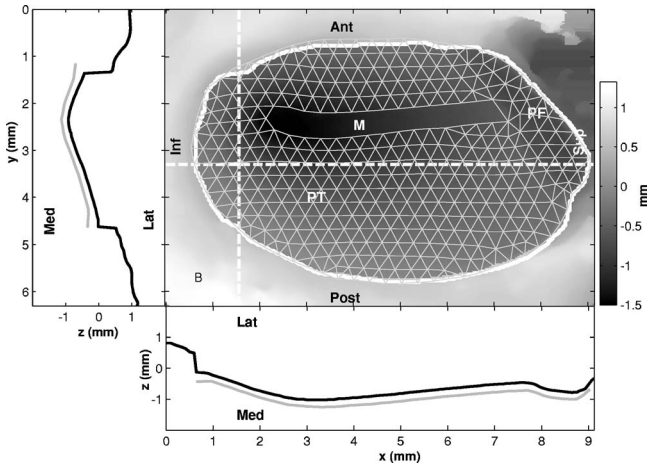

FIG. 1. Grey-level image of the resting shape of the eardrum of cat MY1216L with corresponding FE mesh superimposed. The thick white line encloses the visible portion of the eardrum. The grey levels in the image vary from black (point furthest away from reader) to white (point closest to reader), whereas the mesh is shown in a uniform light grey. The regions of the mesh corresponding to the pars tensa (PT), pars flaccida (PF), and manubrium (M) are labeled. The anterior (Ant), posterior (Post), inferior (Inf), and superior (Sup) directions are approximate because the cat eardrum is actually tilted, and therefore the pars flaccida is both posterior and superior (dorsal) and the manubrium runs in the antero-inferior to postero-superior direction. The bottom panel shows horizontal profiles through the image (black profile) and through the mesh (grey), taken just posterior to the manubrium as indicated by the horizontal dashed line in the image. The left panel shows vertical profiles through the image (black profile) and through the mesh (grey), taken through the pars tensa just inferior to the manubrium as indicated by the vertical dashed line in the image. Mesh profiles are offset so as not to overlap with image profiles.

B. Mechanical properties

As in previous simulations (e.g., Funnell and Decraemer, 1996), both the pars tensa and the pars flaccida are assumed to be elastic, that is, the eardrum is assumed to return to its resting shape upon the removal of applied pressure. Because the purpose of this study was to investigate the effects of geometric nonlinearity, the material of the eardrum

was assumed here to be linear, as in our previous simulations. That is, the relationship between stress and strain is assumed to be linear. Furthermore, again as in previous reports, the pars tensa and the pars flaccida are assumed to be isotropic and homogeneous. The pars tensa is characterized by a single Young's modulus or stiffness of 20 MPa, a thickness of 40 μm and a Poisson's ratio of 0.3; the pars flaccida is assumed to have a Young's modulus of 1 MPa, a thickness of 80 μm and a Poisson's ratio of 0.3 (Funnell and Decraemer, 1996).

The periphery of the eardrum is assumed to be fully clamped to the ear canal, so that nodes on the boundary of the model do not undergo translation or rotation. The boundary of the manubrium is also assumed to be fully clamped in order to simulate an immobile manubrium.

C. Solution procedure

For each model, static-displacement patterns were computed in response to uniform static middle-ear pressures from 0 to +2.2 kPa in steps of 0.1 kPa and from 0 to −2.2 kPa in steps of −0.1 kPa. The static pressure is applied to the medial (middle-ear) surface of the tympanic membrane, such that positive pressures cause laterally directed motions (into the external ear), while negative pressures produced medially directed motions (into the middle ear).

The FE method results in a system of equations of the form

$$\mathbf{Ku} = \mathbf{f}, \tag{1}$$

where $\mathbf{K}$ is a global stiffness matrix that is assembled from the known geometry and material properties of each element, $\mathbf{f}$ is a vector of applied nodal forces that is assembled from the known applied pressure and geometry, and $\mathbf{u}$ is an unknown vector of nodal displacements and rotations that needs to be computed. In *linear* problems, both $\mathbf{K}$ and $\mathbf{f}$ are constants and approximated as being independent of $\mathbf{u}$; thus, $\mathbf{u}$ can easily be computed as $\mathbf{u} = \mathbf{K}^{-1}\mathbf{f}$.

In geometrically nonlinear problems, however, the displacements and rotations are large, and the dependence of $\mathbf{K}$ and $\mathbf{f}$ on $\mathbf{u}$ cannot be ignored: Changes in the shape of the structure as it is being loaded can significantly alter $\mathbf{K}$ and $\mathbf{f}$. Because $\mathbf{K}$ and $\mathbf{f}$ depend on $\mathbf{u}$, simple matrix inversion cannot be used to compute the unknown vector $\mathbf{u}$. Instead, in ABAQUS, an incremental-iterative solution procedure is used to compute $\mathbf{u}$ at each pressure step. The nonlinear solution procedure used in this work is well described in the literature (e.g., Bathe, 1982). Basically, each pressure step of size ±0.1 kPa is automatically broken into smaller increments, the sum of which equals the applied step size. Applying the total pressure step in small increments allows displacements to be accurately computed as the pressure is increased to its final level. At the beginning of each increment, an initial stiffness matrix $\mathbf{K}_0$ is computed from the current geometry of the mesh and its mechanical properties. Based on this stiffness, a linear solution is computed and the geometry of the mesh is updated. Generally, force equilibrium will not be satisfied within the deformed mesh, and the residual vector defined by $\mathbf{r} = \mathbf{f} - \mathbf{K}^{-1}\mathbf{u}$ will be nonzero. ABAQUS uses Newton's method to find a deformed configuration that satisfies force equilibrium and results in an approximately zero residual vector. Note that we calculate the solution in steps of 0.1 kPa instead of the larger step sizes used in the experiments (see Sec. III A). The smaller step size used with the numerical solution procedure ensures convergence to an equilibrium solution at each step.

III. RESULTS

A. Full-field displacement and strain patterns

Displacement patterns computed at a pressure of +2.2 kPa from FE models for cats MY1216L, MY1630L, and MY0923R, are shown by iso-amplitude contours in the left-hand column of Fig. 2. In all plots, we present the component of displacement perpendicular to the plane of the tympanic ring. The difference in amplitude between adjacent contours is 25 μm. As a guide, some of the contours are labeled. Simulated eardrum displacements are maximal in the postero-superior portion of the pars tensa, close to the pars flaccida. Patterns for smaller positive pressures are similar to that for a pressure of +2.2 kPa. (The exact variations in displacement as a function of pressure are described in Sec. III B.)

For comparison, the right-hand column of Fig. 2 shows our previously published displacement patterns measured with the moiré method (Ladak *et al.*, 2004). In those experiments, three cycles of pressure were applied to the middle-ear cavity. Each cycle started from rest (i.e., zero pressure in the cavities) and involved loading the eardrum by applying positive middle-ear pressures in the order 0.1, 0.2, 0.4, 0.7, 1.1, 1.6, and 2.2 kPa, then unloading back to 0 Pa in the reverse order. The eardrum was then loaded by applying negative pressures to the cavities in the same order and unloaded in the reverse order. A moiré measurement is made 5 s after the pressure is adjusted to the new level, and requires approximately 45 s. The figure shows the displacements measured at a pressure of +2.2 kPa during the first cycle; patterns for other positive pressures, including other cycles, are qualitatively similar but with differences in size as described in Sec. III B. Some of the iso-amplitude displacement contours appear to end abruptly because the periphery of the eardrum is obscured by overhanging tissue. The measured patterns are not smooth because they contain small systematic errors associated with the moiré apparatus (Ladak *et al.*, 2000). Nevertheless, a notable difference between the two sets of patterns (simulated and measured) is that the maximal pars-tensa displacement in the simulated patterns is located more superiorly than that in the measured data. The sizes of the simulated and experimental maximal pars-tensa displacements also differ. In cat MY1216L, the maximum value based on the simulation is twice as large as the measured value, and for cat MY1630L, the simulation-based value is 1.5 times as large as the measured value. For cat MY0923R, the simulation result is smaller than the measured value. The measured displacement pattern for cat MY0923R exhibits local maxima in both the anterior and the posterior pars tensa.

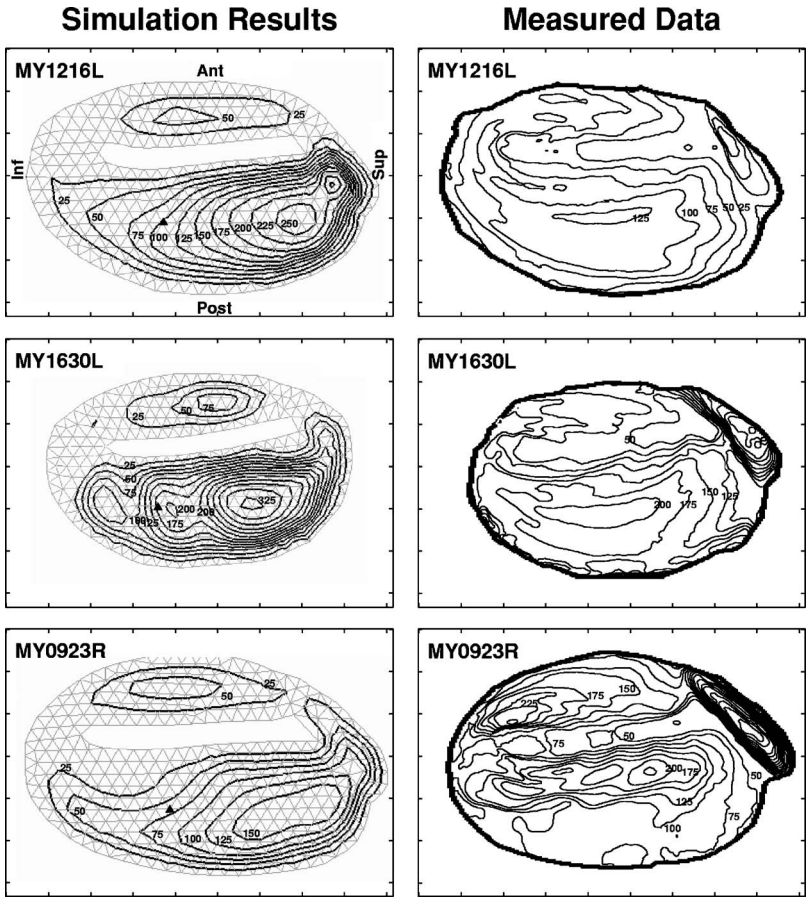

FIG. 2. Simulated and measured iso-amplitude displacement contours for a pressure of +2.2 kPa with an immobile malleus. Computed patterns are shown on the left, and corresponding measured data from Ladak *et al.* (2004) are shown on the right. The measured data are for the first cycle of pressurization. Displacements are in microns and adjacent contours are 25 μm apart. In cat MY0923R, measurements were made on the right ear instead of on the left ear as in the other two cats. In order to facilitate comparison of MY0923R with the other cats, the image of the eardrum was mirrored to look like the others. The triangles indicate points for which results are plotted in Fig. 5.

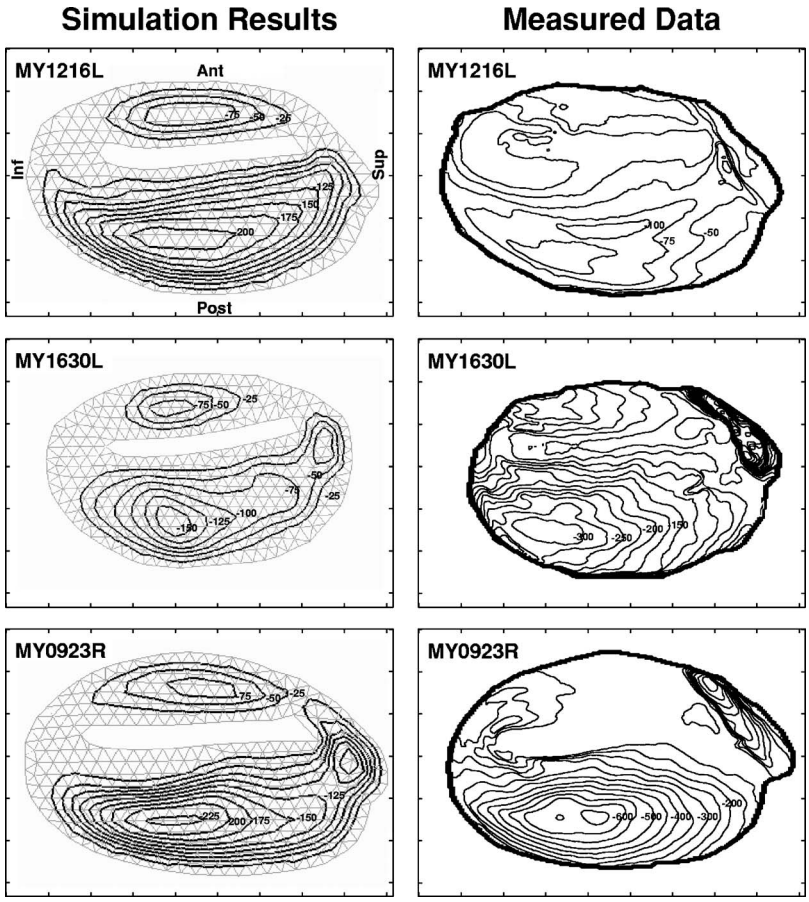

FIG. 3. Simulated and measured iso-amplitude displacement contours for a pressure of −2.2 kPa with an immobile malleus, displayed as in Fig. 2. The negative signs indicate that the displacements are directed medially.

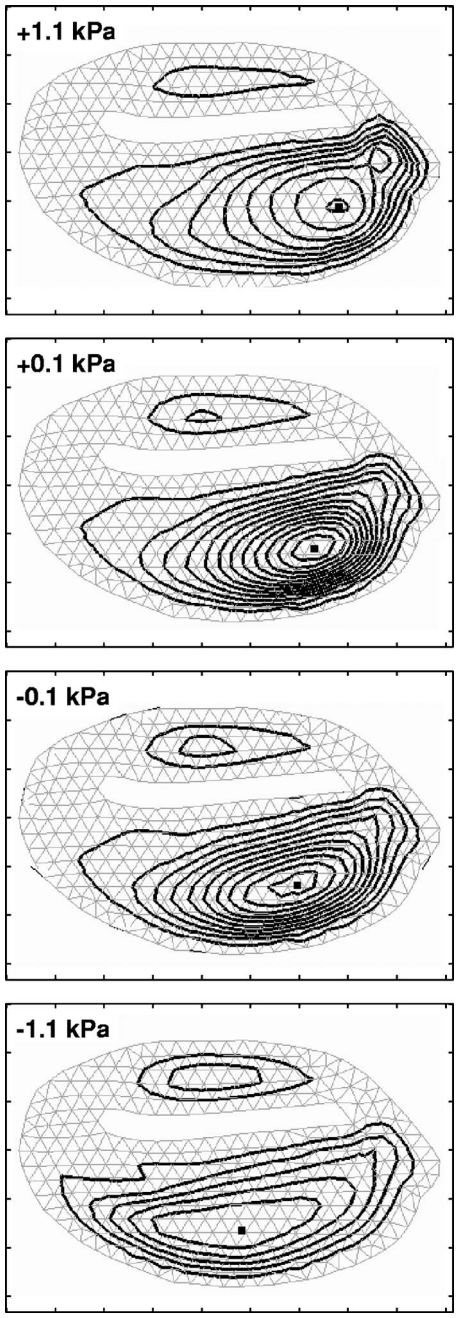

FIG. 4. Simulated iso-amplitude displacement contours for cat MY1216L for pressures of +1.1, +0.1, −0.1, and −1.1 kPa. Displacements are in microns. For pressures of +1.1 and −1.1 kPa, adjacent contours are 25 μm apart, whereas for pressures of +0.1 and −0.1 kPa, adjacent contours are 2.5 μm apart. The square indicates the location of maximal pars-tensa displacement.

Figure 3 shows displacement patterns, both simulated and measured, for a pressure of −2.2 kPa. For large negative pressures, the point of maximum pars-tensa displacement in the simulated patterns is shifted inferiorly compared with that for positive pressures. A shift in the inferior direction can also be seen in the experimental data shown in the right-hand column of the same figure; however, the degree of shift is larger in the simulations than in the measured data. In both the simulations and the experiments, the shift in the location of maximum displacement occurs gradually with pressure. This is illustrated in Fig. 4 which shows computed displacement patterns for +1.1, +0.1, −0.1, and −1.1 kPa for cat MY1216L; the patterns for pressures of +2.2 and −2.2 kPa are shown in Figs. 2 and 3, respectively. For negative pressures close to zero (e.g., −0.1 to −0.2 kPa), patterns are similar to those for positive pressures, with the location of maximum displacement occurring in the postero-superior region of the pars tensa. As the eardrum is further loaded toward −2.2 kPa, the location of the maximum moves inferiorly. Trends in the experimental data are consistent with the computed displacement patterns, but artifacts in the measurements make it difficult to discern the shift.

For negative pressures, there are also differences in maximal pars-tensa displacement magnitudes between the simulations and the experimental data. Specifically, for −2.2 kPa, the displacement magnitude in the simulation for cat MY1216L is twice as large as the measured value. For cat MY1630L the simulation result is half the size of the measured value, and for cat MY0923R the simulation gives a result that is about one third the size of the measured value.

The FE models presented here are not truly subject specific because only the shapes of the models are individualized to match each cat's eardrum; the thickness and Young's modulus are not subject specific because these data were not available. Nevertheless, subject-specific comparisons between simulations and measured data are made because individual eardrum shape significantly affects displacement patterns.

Figure 5 shows the calculated maximum principal nominal strains at the two highest pressures used in this study. The nominal strain is defined as

$$\boldsymbol{\varepsilon}^N = \mathbf{V} - \mathbf{I}, \tag{2}$$

where $\mathbf{I}$ is the identity matrix, $\mathbf{V} = \sqrt{\mathbf{F}\mathbf{F}^{\mathbf{T}}}$ and $\mathbf{F} = \partial\mathbf{x}/\partial\mathbf{X}$ is the deformation gradient tensor which is computed from knowledge of the initial location of a material particle at some three-dimensional position in space specified by the vector $\mathbf{X}$ and its new position $\mathbf{x}$ after deformation. The nominal strain is computed with respect to the initial unpressurized state. *Maximum principal* strains represent the largest possible strains in the tissue. The largest strains in the pars tensa are generally less than 2%. In cats MY1216L and MY1630L, however, strains of 3 to 5% occur in a very small strip along the periphery of the postero-superior pars tensa. Strains in the pars flaccida are generally less than 5% with a few localized areas of higher strain. Although the calculated strains are small, displacements are large because the eardrum has a relatively large diameter and is very thin.

B. Pressure-displacement curves

Figure 6 shows pressure-displacement curves for the locations indicated by triangles in the left-hand column of Fig. 2. Simulated pressure-displacement curves are shown in black, whereas all cycles of measured data are shown in grey. The measured curves are for the same locations indicated by the triangles in Fig. 2. The measured curves vary from one cycle of pressurization to the next and exhibit hysteresis. All three measured cycles are presented for cats MY1216L and MY1630L; however, only the second and third cycles are

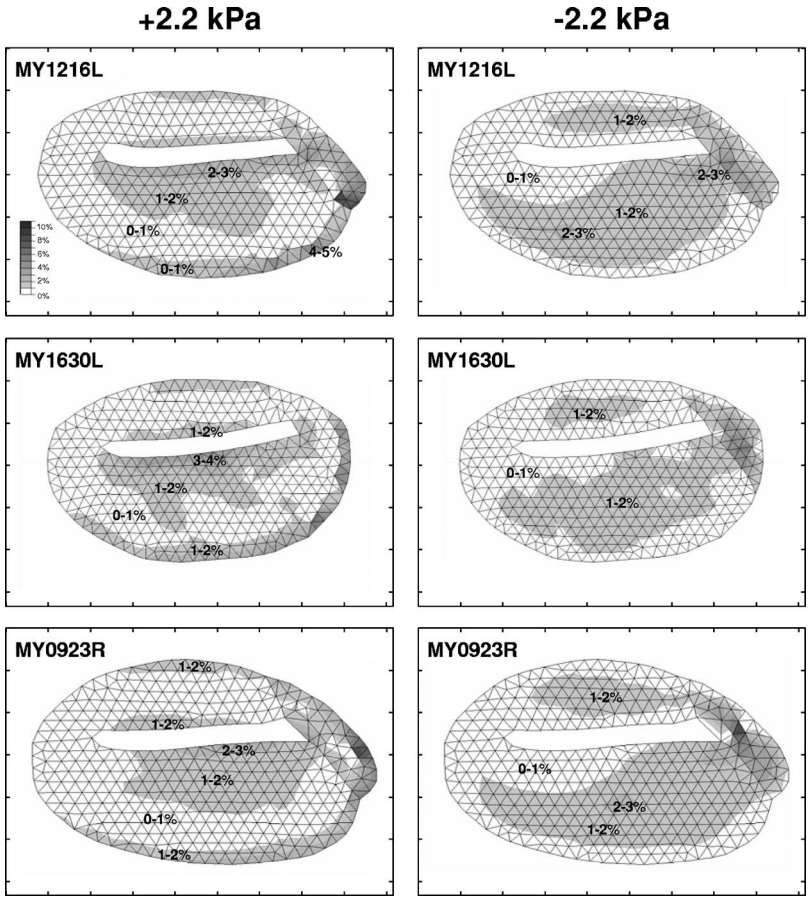

FIG. 5. Calculated maximum principal nominal strains for pressures of ±2.2 kPa with an immobile malleus.

presented for cat MY0923R. As previously noted (Ladak *et al.*, 2004), for cat MY0923R, the first cycle is considerably different from the second and third cycles. After the first cycle (not shown), the response appears to stabilize. Hysteresis is pronounced in this cat as indicated by the large nonzero displacement from the resting shape when the pressure is increased from 0 to +2.2 kPa and brought back to 0 kPa. There is only one simulated curve in the figure because the material is assumed to be elastic, with no hysteresis. For positive pressures, the simulated pressure-displacement curves agree reasonably well with the measured data. For negative pressures, displacements calculated from the nonlinear model for cat MY1216L are larger in magnitude than measured values. In cats MY1630L and MY0923R, there is substantial variation in measured displacements from one cycle to the next, especially for negative pressures. The variation for negative pressures may be due to mechanical instability (Ladak *et al.*, 2004). In any case, for both cats, simulated displacements fall within the range of measured displacements.

Both simulated and measured displacements grow less than in proportion to the applied pressure. For example, at a pressure of +1.1 kPa, the displacement calculated from the model for cat MY1216L is 73 μm; when the pressure is doubled to +2.2 kPa, however, the displacement does not double but increases by a factor of only 1.6, to 120 μm. Similarly, the measured displacement increases by a factor of 1.6, from 84 to 136 μm.

Displacements were also computed from purely linear models. The pressure-displacement curves in these cases are straight lines passing through the origin. Displacements calculated from linear and geometrically nonlinear models agree well with each other for low pressure levels. For instance, at a pressure of 0.1 kPa the displacements calculated from linear models are only 5 to 7% larger than those calculated from geometrically nonlinear models. For very high pressures, however, the linear models predict much larger displacement magnitudes than do the geometrically nonlinear models. For instance, when a linear model is used, the displacement magnitude computed for the point indicated by the triangle in Fig. 2 for cat MY1216L is twice as large as the value computed when a geometrically nonlinear model is used.

For all cats, the discrepancy between simulated (linear or nonlinear) and measured pressure-displacement curves is greatest for points in the superior portion of the posterior pars tensa. Simulation results here are larger in magnitude than measured values, which is consistent with the observation that for positive pressures the point of maximum pars-tensa displacement is located more superiorly in the simulations.

C. Effect of nonuniformity

The location of the displacement maximum can be shifted inferiorly in the simulations, to better match the measured patterns, by including nonuniformity in the models. Since the mechanical behavior of the eardrum is sensitive to both its thickness and its Young's modulus (Funnell and Laszlo, 1978), stiffening the superior region of the posterior pars

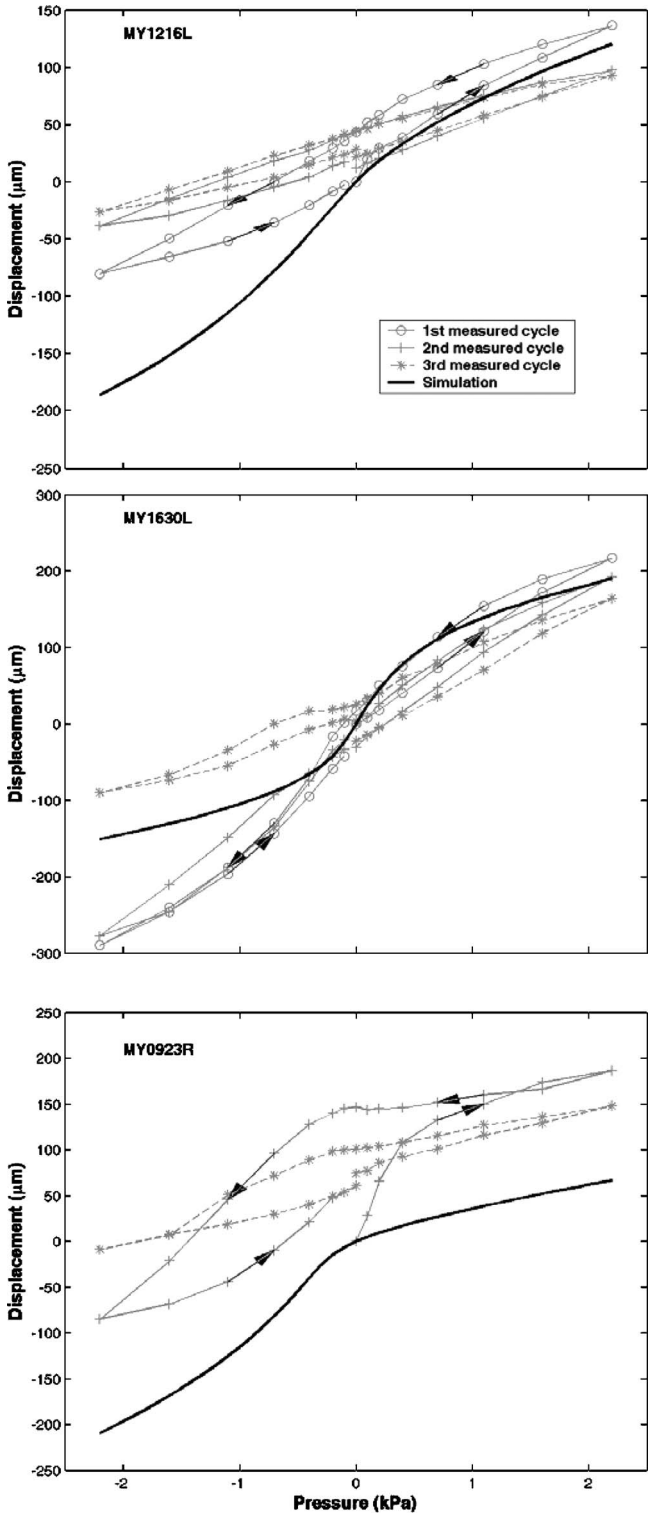

FIG. 6. Computed (black) and measured (grey) pressure-displacement curves for cats MY1216L, MY1630L, and MY0923R after mallear fixation, for locations indicated by triangles in the left-hand column of Fig. 2. The three cycles of measured data are from Ladak *et al.* (2004). The arrows on the measured curves indicate the temporal order of the measurements. Lateral displacements are positive, whereas medial displacements are negative.

tensa by increasing either the Young's modulus or the thickness can potentially shift the location of the maximum inferiorly. To demonstrate this, in the model for cat MY1216L, we arbitrarily increased the thickness of the superior third of the posterior pars tensa from 40 to 80 μm. Figure 7 shows

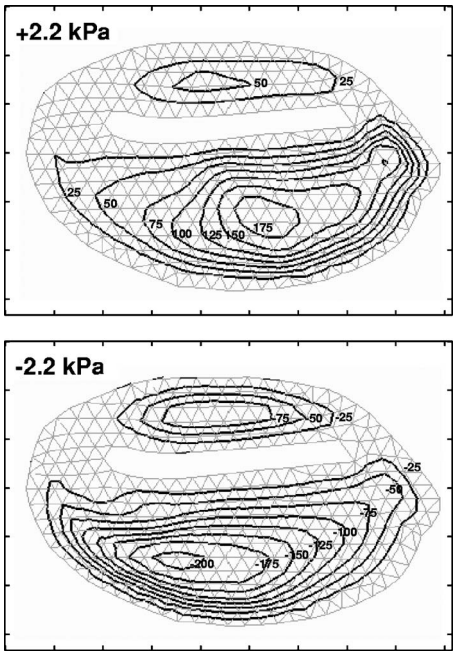

FIG. 7. Computed iso-amplitude displacement patterns for cat MY1216L for pressures of +2.2 and −2.2 kPa after increasing the thickness of the superior third of the posterior pars tensa from 40 to 80 μm. Adjacent iso-displacement contour lines (black) are 25 μm apart and are superimposed on the FE mesh (grey).

displacement patterns computed for pressures of +2.2 and −2.2 kPa. Increasing the thickness in this region has the effect of shifting the pars-tensa maximum inferiorly for positive pressures by decreasing the size of displacements in the postero-superior pars tensa; however, displacements in the inferior region are not significantly altered. Although displacements in the postero-superior region are smaller after the increase in thickness, they remain larger than measured values; no attempt was made to exactly match the simulated and measured displacements by adjusting the thickness of the pars tensa. The location of the maximum for negative pressures does not shift as much and remains in the inferior portion of the pars tensa.

IV. CONCLUSIONS AND DISCUSSION

When geometric nonlinearity is incorporated into FE models, the calculated displacements increase less than in proportion to the applied pressure for high pressures, i.e., those greater than about ±0.1 kPa. Such a lack of proportionality was also observed in the experimental data. By contrast, in *linear* simulations, computed displacements increase in proportion to the applied pressure because the effects of changing geometry on the stiffness matrix and on the direction of applied pressure are ignored.

For small pressures (both positive and negative) and for large positive pressures, the position of the maximum pars-tensa displacement is located more superiorly for the simulation results than it is for the experimental results if uniform mechanical properties are assumed for the model pars tensa. This difference between experiment and theory is also present in linear models (Funnell and Decraemer, 1996) and is not specific to the present addition of geometric nonlinear-

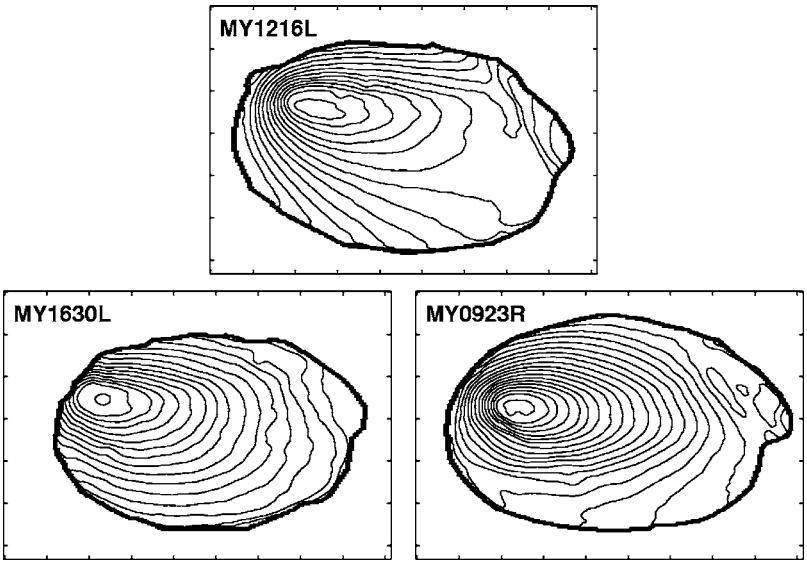

FIG. 8. Iso-depth shape contours. Adjacent contours are 0.1 mm apart. Ticks along the horizontal and vertical axes are 1 mm apart. For each cat, the thick black line encloses the visible portion of the eardrum. For cats MY1216L and MY1630L, measurements were made on the left eardrum, whereas the right eardrum was used for cat MY0923R. To facilitate comparison of cat MY0923R with the other cats, the image of the eardrum was mirrored to look like the others.

ity. By including nonuniformity in the models (e.g., by increasing the thickness of the superior portion of the posterior pars tensa), it is possible to shift the location of the maximum in the simulations toward the experimentally observed location. Such a thickness increase is consistent with recent experimental point-by-point thickness measurements (Kuypers *et al.*, 2005). Differences between simulated and measured displacement patterns and magnitudes can also be reduced by varying the Young's modulus of the pars tensa across its surface. The value used here for the pars-tensa thickness, adopted from our previous models and originally based on a value reported by Lim (1968), is considerably larger than the values found by Kuypers *et al.* (2005). Any adjustment downward of this model parameter could be counterbalanced by an increase in the value of the Young's modulus, as done by Fay *et al.* (2005). The Young's modulus used here, also adopted from our previous models, was originally based on a value reported by Békésy (1949) for a human-cadaver eardrum. The current work underscores the need for detailed quantitative measurement of eardrum properties across its surface.

The similarity in displacement patterns and magnitudes computed from the nonlinear models for *small* negative and positive pressures is expected since for small pressures, between 0 and ±0.1 kPa, the behavior of the nonlinear models is approximately linear, and a linearized model would predict the same displacements (apart from sign) for both positive and negative pressures. At higher negative pressures, the inclusion of geometric nonlinearity in the models accounts for the change in location of the maximum displacement. The same trends are observed in the measurements, where patterns for small negative pressures are found to be similar to patterns for small positive pressures, but the maximum is found to shift inferiorly for higher negative pressures.

As already noted, eardrum displacement magnitudes are significantly affected by the thickness, Young's modulus, and shape of the eardrum (Funnell and Laszlo, 1978), all of which can vary from one subject to the next. Furthermore, as discussed above, displacement patterns are affected by variations in the thickness and Young's modulus across the surface of an individual eardrum. Although we have taken into account individual eardrum shape in our FE models, we have not taken into account inter- and intra-individual differences in eardrum thickness and Young's modulus because of the unavailability of such data. The discrepancies between corresponding simulated and measured displacement patterns seen in Figs. 2 and 3 presumably arise in part because inter- and intra-individual variations in thickness and Young's modulus were not taken into account. As discussed below, the degree of malleus fixation may also affect eardrum displacement magnitudes, but to a smaller degree.

Inspecting the left-hand column of Figs. 2 and 3 shows that simulated displacement patterns vary between cats. In constructing the models, only the shapes of the models were individualized to the particular cat; the thickness and Young's modulus were assumed to be the same. Hence, any variations in simulated displacement patterns between individual models arise only from variations in the shapes. Figure 8 shows iso-depth contours for the measured resting shapes of the three cats; the difference in depth between adjacent contours is 0.1 mm. The depth of the eardrum is approximately 1.5 mm for the three cats used in the present study. However, there are subtle local variations in curvature between the eardrums as indicated by local variations in spacing between adjacent iso-depth contours. Simulated displacement magnitudes have previously been shown to be sensitive to both global (Funnell and Laszlo, 1978) and local (Funnell and Decraemer, 1996) variations in curvature. There is a noticeable difference in the lengths of the major and minor axes of the tympanic ring. The sensitivity study of Funnell *et al.* (1993) indicates that expansion or contraction of the tympanic ring does affect displacement magnitude.

In our models, the eardrum was assumed to be isotropic. This simplification is consistent with our previous models of the cat eardrum (e.g., Funnell and Laszlo, 1978; Funnell and Decraemer, 1996). Funnell and Laszlo (1978) found that the inclusion of anisotropy did not change the basic shape of the displacement patterns as compared to an isotropic model,

although the maximal pars-tensa displacement did increase. The actual nature and degree of anisotropy in the eardrum are not known.

The present study is limited to the case of an immobile-malleus condition. However, measurements indicate that the lack of proportionality between pressure and eardrum displacements is more pronounced with a normal mobile malleus (Ladak *et al.*, 2004). Under normal conditions, eardrum response would be affected by the mechanical load exerted on it by the rest of the middle ear and cochlea. One source of nonlinearity in middle-ear response may be due to an asymmetry in ossicular displacements at high static pressures caused by slippage in the joints between the malleus and the incus (Cancura, 1980; Hüttenbrink, 1988) and between the incus and the stapes (Hüttenbrink, 1988). Another source of nonlinearity in middle-ear response is thought to be due to the annular ligament connecting the stapes to the cochlea, which limits the displacement of the stapes (Price, 1974; Price and Kalb, 1986). Indeed, Price and Kalb (1991) feel that this is the main source of nonlinearity in middle-ear response at high pressures.

In the simulations, the manubrium is assumed to be completely immobile along its length. This only approximately simulates the experimental condition. In the experiments, an attempt was made to immobilize the malleus by gluing a point on the mallear head to the middle-ear wall. Although this does substantially reduce manubrial displacements relative to the case where the malleus is not fixed in this manner, it does not ensure that all points on the manubrium will be immobile (Ladak *et al.*, 2004). Indeed, the experimental data in Figs. 2 and 3 indicate that the manubrium deforms. Specifically, the ratio of umbo displacement after mallear fixation to the displacement without fixation was 21% for MY1216L, 30% for MY1630L, and 31% for MY0923R at a pressure of +2.2 kPa during the first cycle (Ladak *et al.*, 2004). The ratio of the displacement of the superior end of the manubrium after fixation to the displacement before fixation was 7% for cat MY1216L, 17% for cat MY1630L, and 22% for cat MY0923R (Ladak *et al.*, 2004). As the focus of this study was to investigate the effects of geometric nonlinearity on eardrum displacements, we have for simplicity assumed the manubrium to be immobile along its entire length. Although it would be more realistic to explicitly model the malleus with only its head constrained, any resulting small displacements of the manubrium would probably have only a very small effect on the displacements of the eardrum. For example, Funnell and Laszlo (1978) showed that doubling the ossicular-hinge stiffness in their middle-ear model decreased the maximal pars-tensa displacement by only 11%, with little change in the form of the displacement pattern. The effects in the present case would presumably be even smaller.

Material nonlinearity has been ignored in this work in order to investigate the effects of geometric nonlinearity alone. Uniaxial tension tests by Decraemer *et al.* (1980) on strips of pars tensa cut out from the eardrum suggest that the relationship between stress and strain is nonlinear for small strains and approximately linear for high strain levels. Data in their paper are presented as graphs of stress versus specimen length instead of stress versus strain since the resting length of the specimen could not be accurately determined in order to compute strain. It is difficult to determine the resting length of eardrum strips as they tend to wrinkle when no stress is applied. *A priori* it is not clear in which portion of the stress-strain curve (linear or nonlinear) the eardrum is functioning because quantitative experimental data on eardrum prestress are not available; existing data based on perforation tests are of a qualitative nature (Békésy, 1949; Kirikae, 1960) and their validity is questionable (Funnell and Laszlo, 1982). In any case, for small variations in strain with pressure, the stress-strain curve may be linearized. The largest pars-tensa strains computed from each of the models are generally less than 2%, which implies that a linearized material model is a reasonable approximation for most of the pars tensa for pressures up to ±2.2 kPa, at least under the condition of an approximately immobile malleus. For the pars flaccida, material nonlinearity may be more important since the strain variations are larger.

As our focus is to investigate the effects of including geometric nonlinearity, we have not modeled the hysteresis observed experimentally in the pressure-displacement curves during cyclical loading, which would require the inclusion of viscoelastic effects. This should then permit the quantitative modeling of eardrum behavior during impedance tympanometry, including the fact that differences in measurement protocols cause pronounced differences in tympanometric results (Osguthorpe and Lam, 1981).

(Received 26 October 2005; revised 6 March 2006; accepted 10 March 2006)

The purpose of this research was to simultaneously estimate processing delays in the cochlea and brainstem using the same acoustic stimuli. Apparent latencies were estimated from ear canal measurements of $2f_1$-f_2 distortion product otoacoustic emissions (DPOAEs), and scalp recordings of the f_2-f_1 envelope following response (EFR). The stimuli were equal level tone pairs (65 dB SPL) with the upper tone f_2 set at either 900 or 1800 Hz to fix the initiation site of the DPOAE and EFR. The frequency of f_1 was swept continuously between frequency limits chosen to keep the EFR response between 150 and 170 Hz. The average DPOAE latencies were 9.6 and 6.2 ms for f_2 =900 and 1800 Hz, and the corresponding EFR latencies were 12.4 and 8.8 ms. In a control condition, a third (suppressor) tone was added near the DPOAE response frequency to evaluate whether the potential source at f_{dp} was contributing significantly to the measured emission. DPOAE latency is the sum of both inward and outward cochlear delays. The EFR apparent latency is the sum of inward cochlear delay and neural processing delay. Neural delay was estimated as approximately 5.3 ms for both frequencies of stimulation.

I. INTRODUCTION

Acoustic stimuli in the ear canal propagate through the middle ear, travel as a wave to the appropriate place in the cochlea where neural encoding begins, and ascend to higher auditory centers before being perceived as sound. The goal of this research was to estimate processing delays in the cochlea, using acoustic responses from the hair cells, and in the brainstem, using electrical responses from the auditory nervous system. A tone pair with higher frequency f_2 and lower frequency f_1 elicited both responses simultaneously. The acoustic response from the cochlea was the distortion product otoacoustic emission (DPOAE) occurring at the frequency $2f_1$-f_2. The electrical signal was the envelope following response (EFR) occurring at the frequency f_2-f_1.

Processing delays were estimated using the phase versus frequency relationship to calculate apparent latency (Regan, 1966, 1989) or group delay (Goldstein *et al.*, 1971; O Mahoney and Kemp, 1995). Both DPOAEs (Talmadge *et al.*, 1999; Shera and Guinan, 1999; Knight and Kemp, 2000) and EFRs (Dolphin, 1997; Schoonhoven *et al.*, 2001) are initiated at the f_2 characteristic place on the basilar membrane where the stimulus tones overlap most prevalently. The upper tone f_2 was therefore fixed in frequency to maintain the initiation site at a fixed characteristic place (O Mahoney and Kemp, 1995; Moulin and Kemp, 1996a). The f_1 tone was swept slowly but continuously over a small range to obtain phase measurements for the calculation of apparent latency. There is some debate about whether to hold f_1 or f_2 fixed during sweep measurements (Moulin and Kemp, 1996a, b; Bowman *et al.*, 1997). An "f_1-sweep" was chosen to limit the DPOAE and EFR initiation sites to the two f_2 frequencies employed (900 and 1800 Hz).

Latency of the DPOAE measured in the ear canal is the sum of both inward cochlear delay (50% to 82% of the total) and outward cochlear delay (Moulin and Kemp, 1996a, b; Schoonhoven *et al.*, 2001). Propagation delays in the ear canal and middle ear are very short (Gardner and Hawley, 1972; Lutman and Martin, 1979; Giguere and Woodland, 1992, 1994; Kimberley *et al.*, 1993) and will be implicitly combined with the basilar membrane travel times in the treatment of inward and outward cochlear delays. Inward propagation delay is at least 50% of the total DPOAE latency because the response frequency f_{dp} is lower than stimulus f_2. Inward and outward delays are more likely near equal when the response is at the same frequency as the stimulus, such as for the stimulus frequency or transiently evoked otoacoustic emissions. Assuming a single DPOAE source at the f_2 characteristic place, the phase accumulation of the inward f_2 traveling wave will be greater than that of the outward response f_{dp} (O Mahoney and Kemp, 1995; Moulin and Kemp, 1996a, b; Shera and Guinan, 1999). As a traveling wave approaches its characteristic place, wavelength decreases and more phase accumulates for a given distance on the basilar membrane. Since the characteristic place of f_{dp} is more apical than f_2, an outward DPOAE launched from the characteristic place f_2 would experience fewer cycles.

Interpreting DPOAE latency is complicated when a source at the f_{dp} characteristic place contributes significantly to the measured response in the ear canal. In this study, the stimulus ratio f_2/f_1 was chosen to minimize the influence of

[a)]Part of these results were presented at the 19th International Evoked Response Audiometry Study Group meeting in Havana, Cuba, June 2005.

any source at f_{dp}. Ratios significantly smaller than 1.1 can elicit DPOAEs with a dominant source at f_{dp} (Shera and Guinan, 1999; Knight and Kemp, 2000, 2001; Dhar *et al.*, 2005). The smallest ratios were for f_2=1800 Hz and varied with swept f_1 from 1.091 to 1.104. To evaluate whether a significant source existed at f_{dp}, a third tone was added in a control condition at frequency f_{dp}+25 Hz. The purpose of this tone was to suppress any potential source at f_{dp} (Gaskill and Brown, 1996; Heitmann *et al.*, 1998; Talmadge *et al.*, 1999; Konrad-Martin *et al.*, 2001). If a significant f_{dp} source existed, significant changes in the response would occur.

Whereas DPOAE latency is the sum of inward and outward delays, EFR apparent latency is the sum of inward stimulus propagation delay and neural processing delay. These latencies and constituent delays are as follows: w is the DPOAE latency, l is the EFR latency, t is the inward stimulus delay of f_2 to the characteristic place of f_2, d is the outward DPOAE delay and n is the neural response delay.

It would be interesting theoretically and useful clinically to derive the last three delays. However, separating latencies measured for the DPOAE (w) and the EFR (l) into inward and outward cochlear traveling wave propagation, and neural processing delays, is problematic since the two latency equations $t+d=w$ and $t+n=l$ contain three unknown components. These equations can be solved if additional constraints are applied. A useful additional constraint is that the phase accumulated in the traveling wave of a tone to its characteristic place on the basilar membrane is independent of its frequency (Shera and Guinan, 1999). This constraint, together with recordings from different f_2 frequencies and the assumption that n is independent of f_2 frequency, can effectively provide a third equation to allow the estimation of separate cochlear (t,d) and neural delays (n).

II. METHODS

A. Subjects

Twenty-four adults (13 female) varying in age from 19 to 37 years took part in the experiment. All participants had normal hearing thresholds (≤20 dB HL) measured at 500, 750, 1000, 1500, 2000, 3000, and 4000 Hz. During measurements, participants were encouraged to sleep in a comfortable reclining chair located in an Industrial Acoustics Company (IAC) sound-insulated room. The experiment, including the audiogram, was generally completed in less than 90 min.

B. Auditory stimuli

A modified version of the MASTER research system (John and Picton, 2000b, see www.mastersystem.ca) was used to generate stimuli and extract the DPOAE and EFR responses. The stimuli were two different tone pairs. The higher frequency tone of each pair (f_2) was held constant at 900 or 1800 Hz. The lower tone (f_1) was swept slowly over a frequency range of approximately 20 Hz. This stimulus "sweep" lasted 15.36 s. Frequency f_1 was linearly ramped up 20 Hz for the first half of each sweep and ramped down for the second half. The stimuli were designed such that sweeps could be presented sequentially without any discontinuity and 60 sweeps were recorded in each block.

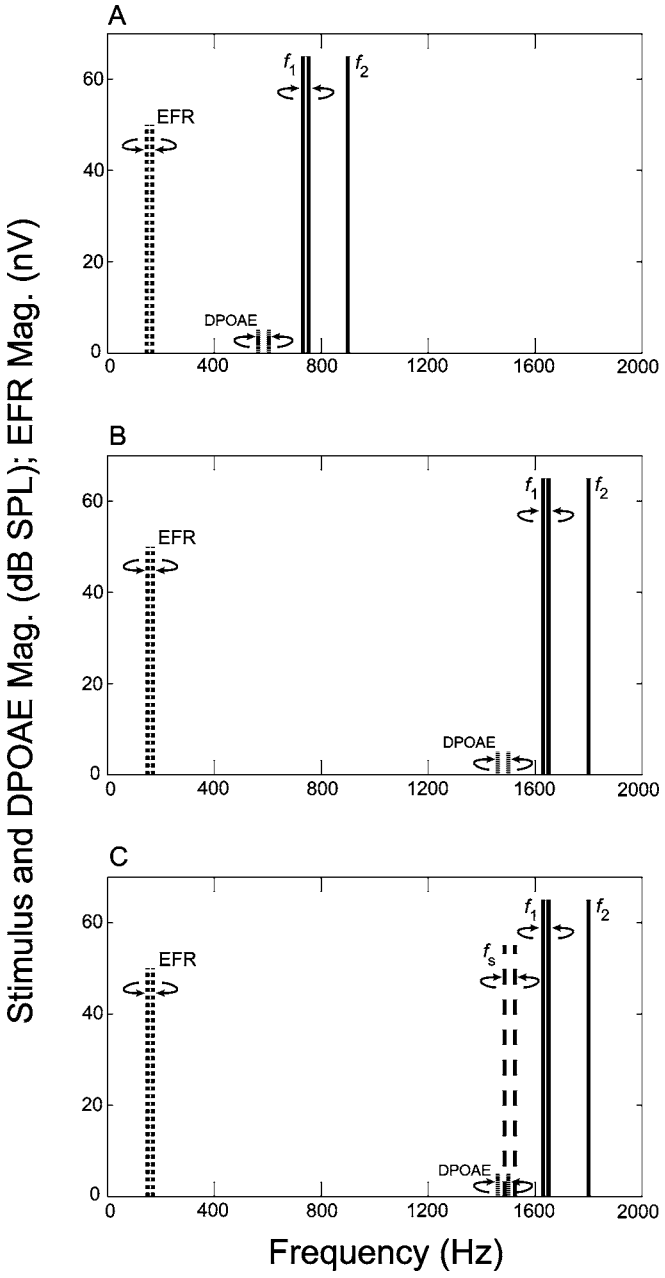

FIG. 1. The three stimulus conditions used in the study are represented in the frequency domain. The horizontal axes show frequency (Hz), and the vertical axes show the acoustic signal levels (dB SPL) and EFR response level (nV). Panel (a) displays the 65 dB SPL stimulus tone pair (solid lines) with f_2=900 Hz, and the bounds of f_1 that were swept from 732 to 752 Hz. An example robust 5 dB SPL DPOAE response is shown at 564 and 604 Hz (short dash lines) for the extremes of f_1. Similarly, a robust 50 nV EFR response is shown (dot lines) at 148 and 168 Hz for the extremes of f_1. Panel (b) displays the 65 dB SPL stimulus tone pair (solid lines) with f_2 =1800 Hz, and the bounds of f_1 swept from 1630 to 1650 Hz. A DPOAE response is displayed (short dash lines) at 1460 and 1500 Hz for the extremes of f_1. Similarly, the EFR is shown (dot lines) at 150 and 170 Hz, in response to the extremes of f_1. Panel (c) is identical to (b), but 55 dB SPL suppressor tones have been added (dash lines). These are 25 Hz above the instantaneous DPOAE frequency and are shown at 1485 and 1525 Hz.

For f_2=900 Hz, stimulus tone f_1 was swept from 732 to 752 Hz [Fig. 1(a)]. The EFR response frequency varied with f_2-f_1 between 148 and 168 Hz, and the DPOAE response frequency varied with $2f_1$-f_2 between 564 and 604 Hz. For f_2=1800 Hz, stimulus tone f_1 was swept from 1630 to

1650 Hz [Fig. 1(b)]. The EFR response frequency varied between 150 and 170 Hz, whereas the DPOAE response frequency varied between 1460 and 1500 Hz. As f_1 increased, the DPOAE increased in frequency, whereas the EFR decreased. Stimulus presentation order was randomized across subjects, and each f_2 condition was presented for two recording blocks in a balanced design for a total of 120 sweeps. The individual tones were presented at 65 dB SPL.

In addition to the two f_2 conditions described above, responses were also recorded for $f_2=1800$ Hz with an additional swept tone 25 Hz higher than the instantaneous DPOAE frequency, f_{dp} (Heitmann *et al.*, 1998). The purpose of this third tone was to act as a suppressor of any potential OAE source at the f_{dp} characteristic place. This suppressor tone (f_s) was presented on the f_1 channel at a level 10 dB below the level of the main stimulus tones f_2 and f_1 [Fig. 1(c)]. Only a single block of 60 sweeps was collected for this condition, and it was always recorded as the third data block (e.g., ABCBA). A single block was sufficient because it is easier to obtain an acceptable signal-to-noise ratio (SNR) with less averaging for the DPOAE. Since the purpose of this condition was to evaluate DPOAE sources, the EFR was not analyzed.

A National Instruments 6052E input/output board was used to perform digital-to-analog conversion at 32 kHz with 16-bit precision. Electrical stimulus amplitude was controlled using a Grason-Stadler Model 16 audiometer, and a pair of Etymotic ER-2 transducers generated the acoustic stimulus. These have a flat frequency response at the eardrum up to 10 kHz and were coupled to an Etymotic ER -10B+OAE probe with a rubber tip selected for fitting each subject's ear canal. To avoid equipment-generated distortion products, the f_2 and f_1 tones were produced on separate channels. Stimulus tones were calibrated using a Knowles DB-100 Zwislocki coupler and Brüel & Kjaer sound level meter (Siegel, 1994; Whitehead *et al.*, 1995).

C. Recordings

The ear receiving the stimulus was randomized across subjects. Microphones in the acoustic probe were used to measure the ear canal sound pressure. This signal was amplified using the +40 dB setting of the Etymotic ER-10B+ battery-powered amplifier and was band-pass filtered 40–4000 Hz with a Krohn-Hite Model 3322 filter with 24 dB/oct slope.

The EEG was measured using gold-plated Grass electrodes located at the vertex (Cz) and just below the hairline at the posterior midline of the neck (reference), with a ground on the collarbone. Electrode impedances were measured at 10 Hz as less than 8 kOhm using a FEZM-5D Grass electrode impedance meter. A Grass P50 battery-powered amplifier applied a gain of 10 000 and band-pass filtered the signal 1–1000 Hz. A further gain of 5 was applied by the acquisition board that sampled the acoustic and EEG signals at a rate of 16 kHz with 16-bit resolution. The EEG signal was down-sampled after acquisition to 2 kHz for analysis.

D. DPOAE and EFR analysis

Although the experimenter was provided with online response feedback, data analysis was performed offline so that noise-reduction techniques could be employed (Purcell *et al.*, 2004). For a given stimulus condition, acoustic and EEG data recorded in response to each stimulus sweep were synchronously averaged in the time domain. Each sweep was divided into 15 epochs of 1.024 s. The noise rejection method excluded epochs of data that exceeded a threshold noise level estimated from a broad frequency band containing the response frequency. This threshold noise level was obtained by first determining the mean and standard deviation (SD) of the noise level in all epochs of the acoustic and EEG data from a given measurement block. The threshold was then set as the mean noise level plus 3 SD for the DPOAE and plus 1.5 SD for the EFR. These values have been previously found by the authors to be a good compromise between producing good quality data without rejecting too many epochs. This rejection method led to a different number of epochs included in the average for each epoch of the 15-epoch sweep, but in practice fewer than ten (out of 160) were typically rejected.

A software implemented Fourier analyzer (FA) extracted the DPOAE from the average acoustic microphone record and the EFR from the average background EEG signal (Regan, 1989; Purcell *et al.*, 2004). Orthogonal reference sinusoids were matched in frequency to the desired signal to be extracted from the averaged response sweeps. For the EFR, the response frequency was f_2-f_1. For the DPOAE, the response frequency was $2f_1$-f_2. The level and phase of the stimulus tones in the ear canal were also obtained using "response" references of f_2 (fixed) and f_1. Two 1.024-s rectangular window filters were applied in series to each of the complex outputs of the FA. Since the stimuli were designed with symmetrical increasing and decreasing response frequencies in each half of the sweep, the second half of the FA sweep output was folded and vector averaged with the first. Physiological delays (up to a maximum of about 30 ms) were neglected during this fold and average because of the broad filter windows and the slow change in frequency over the sweep.

An F ratio (John and Picton, 2000b) determined whether the instantaneous response amplitude at a given frequency was statistically different from the background noise (acoustic for the DPOAE, and EEG for the EFR). A discrete Fourier transform (DFT) estimated the background noise of the average sweeps folded in the time domain. Specifically, the mean noise levels in $-/+20$ DFT frequency bins ($-/+1.3$ Hz) surrounding the instantaneous response frequencies were calculated and subsequently multiplied by a scaling factor of 2.38 (determined using simulated noise) to reconcile the narrower effective bandwidth of the DFT with that of the FA. The signal was judged to be significantly different from noise at $p<0.05$ when the SNR reached approximately 5 dB ($F=3$; df=2,80).

Apparent latency was estimated from the response phase (measured as cosine onset phase) versus frequency data. Stimulus delays from the transducers to the ear canal were

TABLE I. Arithmetic average response magnitudes and apparent latencies across participants (with SD shown in brackets) where $L_1=L_2=65$ dB SPL. Only individuals with valid apparent latencies are included in these summary statistics. Values are not reported for the EFR when the suppressor tone was added because only 60 sweeps were collected instead of the normal 120. For this final row, only individuals who had valid apparent latencies both with and without the suppressor are reported.

	DPOAE			EFR		
f_2(Hz)	Magnitude (dB SPL)	Apparent latency (ms)	N subjects in mean (out of 24)	Magnitude (nV)	Apparent latency (ms)	N subjects in mean (out of 24)
900	2.0 (7.2)	9.6 (2.0)	22	49.8 (15.2)	12.4 (5.1)	15
1800	0.3 (8.2)	6.2 (3.3)	21	45.8 (17.3)	8.8 (2.0)	21
1800 with suppressor	2.9 (12.5)	6.0 (5.1)	20	⋯	⋯	⋯

removed by correcting the response phases with the stimulus phases (denoted ϕ_2 and ϕ_1 for tones f_2 and f_1, respectively). For the EFR, ϕ_2-ϕ_1 was subtracted from the response phase, whereas for the DPOAE, $2\phi_1$-ϕ_2 was subtracted (O Mahoney and Kemp, 1995). Measurement system phase shifts were evaluated, but were not subtracted because they were very small. The estimation of apparent latency assumes that a single source with frequency-independent delay dominates the measured phase response and that phase therefore changes linearly with frequency. It was calculated as the slope of phase (measured in degrees) versus frequency:

$$L = -\delta\phi/(360\delta f). \tag{1}$$

Since noise can corrupt the estimated EFR and DPOAE phase responses, a weighted least squares linear regression was employed to estimate the phase versus frequency slope ($\delta\phi/\delta f$). The weighting varied with the SNR at each measurement frequency. For SNR $\leqslant$3 dB (i.e., when the response power was less than twice that of the noise power) a weight of 0 was assigned, whereas for SNR $\geqslant$15 dB the weight was 1. In between, the weight was scaled linearly between 0 and 1 with SNR (as expressed in dB). The points at the start and end of the phase versus frequency data were not employed due to end-effects associated with the filters of the FA.

Even with the weighted least squares approach, some subjects did not have phase versus frequency responses that could be adequately described by a linear fit, or that led to rational latency estimates. This could have been due to noise (if the noise estimates were inaccurate) or to the superposition of several response sources with different phases and similar magnitudes. Subjects were removed from the apparent latency analysis for a given response type (DPOAE or EFR) if (*i*) more than 75% of their response sweep had zero weighting, (*ii*) the weighted phase versus frequency slope was positive (indicating a negative latency), or (*iii*) the correlation between the phase data and the residual phase error (the *difference* between the data and model) had a Pearson coefficient that was greater than 0.80 (an indication that the linear regression was not adequately modeling the data). These procedures eliminated about 10% of the DPOAE measurements and about a third of the EFR measurements (see "*N*" columns in Table I).

E. Separation of delay constituents

In order to separate the apparent latencies into their constituent parts, the assumption was made that the EFR neural processing delay was independent of stimulus frequency f_2 (900 and 1800 Hz). The neural conduction delays from the 900- and 1800-Hz characteristic places might be slightly different due to their different positions along the modiolus of the cochlea, but the rest of the pathway to the response generator in the brainstem (Herdman *et al.*, 2002) is basically the same and the neural differences within the cochlea are probably not significant. Assuming that neural delay is independent of frequency, the difference in EFR apparent latency between the two values of f_2 is due only to the change of inward f_2 stimulus delay,

$$l_{900} - l_{1800} = t_{900} - t_{1800}, \tag{2}$$

where l is the latency of the EFR and t is the inward stimulus delay.

In DPOAE measurements, the stimulus delay is limited by the time for the f_2 tone to build up at its characteristic place (O Mahoney and Kemp, 1995; Moulin and Kemp, 1996a, b). The time required for the f_2 tone to reach its characteristic place is

$$t = \theta/(2\pi f_2), \tag{3}$$

where θ is the phase accumulated by the f_2 traveling wave to the characteristic place of f_2. Both delay t and θ are unknown for a given measurement.

To solve this equation it is necessary to employ the theory that the phase accumulated in the traveling wave from the oval window to a particular characteristic place is almost frequency independent (Shera and Guinan, 1999). Substituting Eq. (3) in Eq. (2),

$$l_{900} - l_{1800} = \theta(1/(2\pi 900) - 1/(2\pi 1800)). \tag{4}$$

After solving for θ, the inward stimulus delays for both values of f_2 can be calculated with Eq. (3). Outward DPOAE delays can then be evaluated with

$$d = w - t, \tag{5}$$

where d is the outward DPOAE delay and w is the measured DPOAE apparent latency. Finally, the neural portion of the EFR apparent latency can be determined as

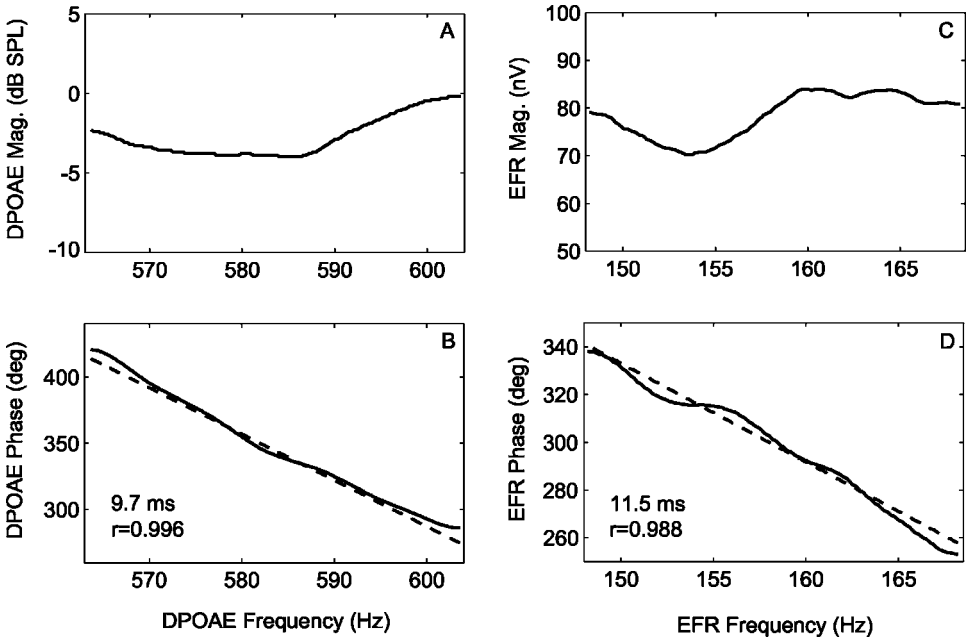

FIG. 2. Responses from a single individual for 120 averaged sweeps are presented for f_2=900 Hz at 65 dB SPL. Panel (a) shows the DPOAE response in dB SPL across frequency as f_1 was swept in frequency. Panel (c) shows the EFR magnitude response that was obtained simultaneously in nV. Phase responses for the DPOAE and EFR are displayed in panels (b) and (d), respectively (solid lines). Weighted linear regressions are shown with dash lines. Apparent latencies and correlation coefficients are reported in the lower left corner of the phase versus frequency plots.

$$n = l - t, \tag{6}$$

where n is the estimated neural processing delay.

The variability of the latency estimates was such that we could not make rational estimates of the constituent delays from an individual subject's data. We therefore combined data across subjects using the arithmetic mean value of the measured apparent latencies.

III. RESULTS

A. Magnitude and apparent latency

The magnitudes and apparent latencies, arithmetically averaged across participants, are given in Table I. A two-way analysis of variance (ANOVA) was performed using Greenhouse-Geisser corrections for apparent latency with factors of response type (DPOAE or EFR) and f_2 frequency (900 or 1800 Hz). The only significant effect was f_2 frequency (F=12.8; df=1,10; $p<0.01$) and there was no interaction. DPOAE and EFR latencies were significantly longer for 900 Hz than for 1800 Hz. Two-tailed separate variance t tests also showed that there was no significant effect of f_2 on the magnitude of the elicited DPOAE or EFR (DPOAE t =0.72; df=40; p=0.48;EFR t=0.74; df=33;p=0.46). The DPOAE measures of magnitude and apparent latency were not significantly affected by the suppressor tone, as assessed using two-tailed separate variance t tests (magnitude t= −0.80; df=33;p=0.43; latency t=0.24; df=35;p=0.81; similar results for paired t tests).

Figure 2 shows example data from a single participant where f_2=900 Hz. For this individual both the DPOAE and EFR had a high SNR (not shown) across the entire measurement band. The DPOAE magnitude varied by about 4 dB across frequency, and the EFR varied by about 14 nV. The DPOAE phase plot shows an apparent latency of 9.7 ms, and linear regression provided a good model of the response (r =0.996). The correlation between the residual phase and the data was only r=0.08. From the EFR phase plot an apparent latency of 11.5 ms was calculated. The phase versus frequency curve shows more deviation from a straight line, but the corresponding linear regression was adequate (r=0.988) albeit less ideal than for the case of the DPOAE. For the EFR, the correlation between the residual phase and the data was r=0.16.

Figure 3 shows f_2=1800 Hz data from a second individual who had a less ideal response. This participant's responses were significant for most of the frequency ranges, but the SNR tended to decrease from low to high frequency. The range of DPOAE magnitudes was about 6 dB, and the weight of points in the phase versus frequency plot decreased from 1.0 to about 0.2 at higher frequencies (not shown). The DPOAE apparent latency was 6.0 ms with a less ideal correlation between modeled and measured data (r=0.946). The correlation between residual phase and the DPOAE data was r=0.35. The EFR decreased about 40 nV from low to high frequency. The corresponding SNR led to weights from about 0.8 to 0.0 as frequency increased. The calculated EFR apparent latency was 9.4 ms with r=0.936. The correlation between residual phase and EFR data was r=0.61.

B. Separation of delay constituents

Apparent latencies separated into estimates of inward stimulus delay and response delays are given in Table II. Using the measured EFR apparent latencies, parameter θ was first calculated using Eq. (4) in the fourth row of Table II. This phase accumulated in the traveling wave was then used to determine the inward stimulus delays for both f_2 frequencies with Eq. (3) in rows 5 and 6. With the estimates of inward stimulus delays and the measured EFR apparent latencies, the neural response delay was evaluated using Eq. (6) in row 7. This delay is considered independent of stimulus frequency f_2. Again with the inward stimulus delays and the measured DPOAE apparent latencies, the outward DPOAE response delays were estimated using Eq. (5) in

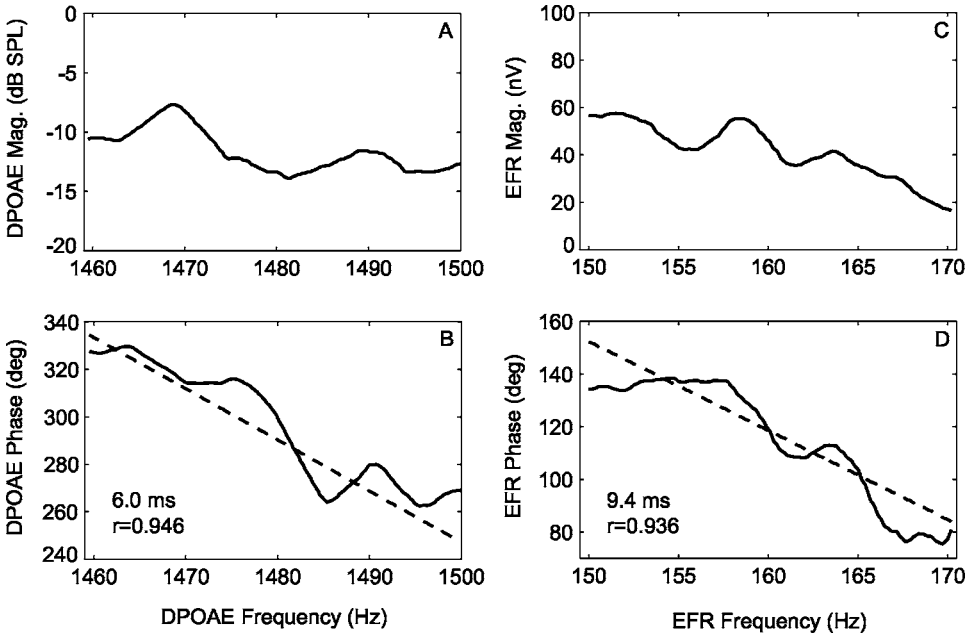

FIG. 3. Responses from a second single individual for 120 averaged sweeps with f_2=1800 Hz at 65 dB SPL. Panels display magnitude and phase data for the DPOAE and EFR as in Fig. 2.

rows 10 and 11. The inward stimulus delays were also represented as percentages of the total DPOAE latencies in rows 12 and 13.

IV. DISCUSSION

The experiment reported here measured DPOAE and EFR responses simultaneously using the same stimuli. While concurrent measurements have been reported previously for transient (e.g., Hoth and Lochmann, 1999) and steady-state responses (Purcell *et al.*, 2003; Rosner *et al.*, 2005), the stimulus here has been optimized for the estimation of apparent latency by employing a continuous sweep of the response frequency. DPOAE apparent latency or group delay has generally been reported using tone pairs of fixed frequency, where f_1 or f_2 is incremented in small steps between measurements (e.g., O Mahoney and Kemp, 1995; Bowman *et al.*, 1996). When f_2 is changed, it is termed an f_2 sweep and, correspondingly, when f_1 is changed, it is referred to as an f_1 sweep. Usually there are relatively few step measurements available for the estimation of latency, whereas continuous sweeps allow for many phase/frequency points (albeit not independent due to the analyzer filters). Continuous stimulus sweeps have been used extensively in EEG studies (e.g., Regan, 1989). An f_1 sweep was chosen here to fix the initiation site of the DPOAE at the characteristic place of f_2 during the estimation of apparent latency.

TABLE II. Estimates of component delays derived from measured DPOAE and EFR apparent latencies. Average measured apparent latencies are from Table I. Values are presented with extra precision to avoid rounding error when making illustrative calculations with values in this table. In the text, values are presented to one decimal place.

Description	Parameter	Equation	Value
Measured EFR latency for f_2=900 Hz	l_{900} (ms)	measured	12.4
Measured EFR latency for f_2=1800 Hz	l_{1800} (ms)	measured	8.8
Traveling wave accumulated phase	θ (rad)	(4)	39.85
Stimulus f_2=900 Hz inward delay	t_{900} (ms)	(3)	7.05
Stimulus f_2=1800 Hz inward delay	t_{1800} (ms)	(3)	3.52
Neural response delay of EFR	n (ms)	(6)	5.32
Measured DPOAE latency for f_2=900 Hz	w_{900} (ms)	measured	9.6
Measured DPOAE latency for f_2=1800 Hz	w_{1800} (ms)	measured	6.2
Outward DPOAE delay for f_2=900 Hz	d_{900} (ms)	(5)	2.54
Outward DPOAE delay for f_2=1800 Hz	d_{1800} (ms)	(5)	2.64
Inward delay as % of total for f_2=900 Hz	$\%t_{900}$(%)	100 t_{900}/w_{900}	73.5
Inward delay as % of total for f_2=1800 Hz	$\%t_{1800}$(%)	100 t_{1800}/w_{1800}	57.2

A. Variability of apparent latency measurements

Apparent latency varies considerably across subjects as reflected by the SD values in Table I. This is in stark contrast to ABR latencies, which are very tightly distributed in the normal-hearing population [e.g., reviewed on p. 265 in Regan (1989)]. The small variance in ABR latencies suggests that the forward stimulus latencies applicable to responses elicited with transient stimuli are not so variable between individuals (Hoth and Weber, 2001). The apparent latency observed from a single delay has a linear relationship between phase and frequency in the sufficiently broad frequency range of interest. Accordingly, any significant filtering introduced by the measurement equipment must be removed from the phase response prior to the calculation. Unfortunately, the auditory system itself may apply significant filtering that cannot be characterized, both in the generation and transmission of DPOAEs, or in neural processing (Bijl and Veringa, 1985; Regan, 1989). In some measure-

ments, a physiological filter can be inferred from the magnitude versus frequency plot, and the phase response can be corrected accordingly (Regan, 1989). Indeed, the EFR magnitude response of Fig. 3 looks low-pass filtered, which would increase the (unweighted) apparent latency estimate. Without weighting, the EFR latency estimate for this participant was 10.6 ms. If the effects of a hypothetical low-pass filter were included in the analysis, the latency estimate would be decreased. These corrections were not, however, attempted in the analysis here because subjects showed different patterns of amplitude fluctuations.

In addition, the physiological signals that are measured tend to have poor SNR, and thus the phase response is distorted by noise. This can be attenuated but never completely removed through signal processing and averaging. Efforts were made to prevent extraneous noise from influencing the estimation of apparent latency, but the intersubject SDs were still from 2 to 5 ms. There are large individual differences in DPOAEs (Probst *et al.*, 1991), and apparent latency can be affected by spontaneous emissions (O Mahoney and Kemp, 1995). Substantial intersubject variability has been reported previously for DPOAE latency, possibly due to individual acoustic and mechanical differences between middle ears and cochleas (Moulin and Kemp, 1996a). The EFR is a small signal relative to the background noise, and across subjects the mean SNR was about 9 dB for $f_2=900$ Hz. Noise in the signal could have played a role in the variance of the EFR apparent latency. This might be improved by averaging more sweeps and/or using a higher stimulus level.

Finally, the presence of multiple generators with different delays leads to a calculated apparent latency of a "virtual" source that can be quite different from the contributors. If the sources happen to sum constructively due to a fortuitous relative delay between them, then the estimated apparent latency can be roughly approximated by the magnitude weighted mean of the two contributors. If they sum destructively, however, the estimate of apparent latency can vary widely and become irrational. The measured DPOAE and EFR can both be generated by multiple sources with distinctly different delays if the stimulus parameters are chosen unfavorably. As discussed in the next section, the second long-latency DPOAE source at f_{dp} did not contribute significantly to the measured emission of individuals who passed the linear regression criteria outlined in the Methods (end of Sec. II D). The scalp-recorded 150–170-Hz EFR may be generated at several brainstem sites, and in different proportions across subjects, but the relatively high response frequency should have prevented the contribution of cortical sources (Herdman *et al.*, 2002; Purcell *et al.*, 2004).

Although the use of apparent latency is fraught with caveats, it is worth exploring as an estimate of true delay since there are few alternatives for use with steady-state responses in humans (Regan, 1989). Despite the constraints imposed by simultaneous recording of DPOAE and EFR responses (Purcell *et al.*, 2003), and despite the variability and uncertainty associated with apparent latency, the delays estimated here are similar to those reported by others studying one response type at a time with various methods.

B. DPOAE latencies

Measured DPOAEs in the ear canal can come from two main sources within the cochlea (Brown *et al.*, 1996; Gaskill and Brown, 1996; Heitmann *et al.*, 1998; Talmadge *et al.*, 1999). The initial initiation site of the DPOAE is at the f_2 characteristic place where the two stimulus tones interact most prevalently. For stimulus frequency ratios of about $f_2/f_1 \leqslant 1.1$, a second source at the characteristic place of the DPOAE f_{dp} can dominate the measured response (Shera and Guinan, 1999; Knight and Kemp, 2000, 2001; Dhar *et al.*, 2005). The apparent latency of a DPOAE dominated by an f_{dp} source is longer than that from an f_2 source because of additional traveling wave times within the cochlea (Knight and Kemp, 2000).

Since interpreting apparent latencies from multiple sources is difficult, the present experiment included a condition with a suppressor tone 25 Hz above f_{dp}. This was to evaluate whether a source at f_{dp} might be contributing significantly to the measurement when the stimulus frequency ratio was close to the transition between source types (i.e., for $f_2=1800$ Hz). The magnitude and apparent latency of individuals who passed the linear regression criteria (which implicitly required a single source) were not statistically affected by the suppressor tone. Thus the dominant DPOAE source was probably at the f_2 characteristic place for the included measurements. The DPOAE apparent latency was therefore simply divided into two components: inward stimulus and outward response delays (O Mahoney and Kemp, 1995; Moulin and Kemp, 1996a).

Stimulus frequency f_2 had a significant effect on the apparent latency of the DPOAEs. The longer latencies for $f_2=900$ Hz were expected since the inward stimulus traveling wave delay would be longer at lower frequencies. DPOAE latencies have been found to decrease monotonically with increasing f_2 (e.g., Bowman *et al.*, 1997; Schoonhoven *et al.*, 2001). There was, however, no effect of frequency f_2 on the DPOAE magnitude. There might have been an effect if the stimulus frequency ratio f_2/f_1 had changed enough between $f_2=900$ and 1800 Hz. DPOAE magnitude varies nonmonotonically with stimulus frequency ratio (Abdala, 1996). For $f_2=1800$ Hz, the ratio was about 1.10, whereas it was about 1.21 for $f_2=900$ Hz. On average these ratios elicited DPOAEs with similar response magnitude.

Table III summarizes some latency values from the literature that can be compared to those obtained here. Using concurrent measurement of DPOAEs and EFRs with multiple tone pairs of fixed frequency, Purcell *et al.* (2003) previously reported DPOAE apparent latencies that were a few milliseconds longer than those found here. The table gives latency values for $f_2=900$ Hz with $f_2/f_1=1.26$ (closest ratio to the 1.21 used here) and for $f_2=1800$ Hz with $f_2/f_1=1.12$ (compared to 1.10 used here). The longer latencies may in part be due to the 25 dB lower stimulus levels. For lower stimulus levels, the f_2 traveling wave should experience sharper tuning at its characteristic place, and corresponding

TABLE III. Summary of delay estimates from OAE and evoked potential (EP) studies. DPOAE studies used f_1 sweeps. Some entries are derived from functions or average values in the specified report, and the delay equations described here. Stimulus levels are in dB SPL unless otherwise noted. Click level is given for derived-band ABRs rather than masking noise level. Tabulated responses were those elicited with stimulus frequencies closest to the f_2 values employed here; actual stimulus frequencies are given in the fourth column.

Study	Technique	Stimulus level (dB SPL)		Actual stimulus frequency (Hz)	Emission latency (ms)		Evoked potential latency (ms)		Inward stimulus delay (ms)		Neural delay (ms)		Outward DPOAE delay (ms)

[b]0.8 ms added to reported value for synaptic delay.

larger phase accumulation (larger θ) and delay (Ruggero, 1992; Giguere and Woodland, 1992, 1994; Bowman *et al.*, 1997).

Transient evoked emissions reported by Neely *et al.* (1988) had longer latencies than the DPOAEs here, but a direct comparison is difficult because they did not use a phase gradient technique. Other DPOAE latencies are reported in the literature using f_1-sweep paradigms. Whitehead *et al.* (1996) have found shorter DPOAE latencies using higher-level stimuli ($L_1=L_2$), although one ear had a latency of about 8.5 ms for a stimulus near 1000 Hz. For unequal level stimuli, Kimberley *et al.* (1993) and Schoonhoven *et al.* (2001) reported shorter latencies. Bowman *et al.* (1997) report a shorter latency for unequal level stimuli spanning the 65 dB SPL value used here for an f_2 between 900 and 1800 Hz. Moulin and Kemp (1996a, b) also found shorter latencies using an f_1 sweep and similar, albeit unequal, stimulus levels. The majority of these studies used unequal level stimuli to optimize DPOAE response magnitude, whereas stimulus levels here were identical to maximize the modulation depth of the EFR stimulus and hence the response. This may have affected the apparent latencies, but the reported values are generally similar (albeit shorter) to those found here, given the intersubject variability.

C. EFR latencies

Stimulus frequency f_2 had a significant effect on EFR latency, which was shorter for $f_2=1800$ Hz. As for the DPOAE, this was anticipated due to the longer inward stimulus traveling wave delay at lower frequencies. There was no significant effect of f_2 on the magnitude of the elicited EFR. This was not unexpected since f_1 was chosen such that the range of response frequencies was essentially the same for both values of f_2. Envelope frequency f_2-f_1 determines that the EFR source was in the brainstem, since high EFR response frequencies are entirely brainstem whereas lower frequencies are both brainstem and cortex (Herdman *et al.*, 2002). The brainstem location of the generator should therefore not change significantly with f_2.

Again referring to Table III, Purcell *et al.* (2003) report longer EFR latencies than those found here for lower level stimuli with f_2-f_1 in the range of 180 Hz. John and Picton (2000a) report EFR latencies for sinusoidal amplitude modu-

lated (SAM) tones with carrier frequencies of 750 and 1500 Hz and modulation frequencies between 150 and 190 Hz. Their latencies are longer than found here, probably due to the lower carrier frequencies. Purcell *et al.* (2004) used SAM noise to elicit the EFR from 100 to 600 Hz. The average apparent latency was shorter than found here and probably reflects responses from areas of the cochlea with characteristic frequencies >1800 Hz, which would therefore experience shorter cochlear travel times than reported here.

Latencies from the peak of ABR wave V measured in frequency-specific paradigms are generally shorter than those reported here for frequencies similar to f_2=900 and 1800 Hz. For these frequencies, shorter delays are reported for derived band ABRs by Schoonhoven *et al.* (2001, their Fig. 3D plus corrections). Using tone-burst stimuli, Neely *et al.* (1988) provide a function where peak wave V latencies can be calculated. The 900-Hz value is shorter than here, but the 1800-Hz latency is very similar. In response to clicks plus noise, Don and Eggermont (1978) and Eggermont and Don (1980) report derived-band wave V latencies that are shorter than the EFR latencies here, but Donaldson and Ruth (1993) found a derived ABR latency quite similar for stimuli near 1800 Hz. Eggermont (1979) also found shorter latencies for narrow-band action potentials (APs) at higher stimulus levels, but these measurements would mostly represent cochlear delays. Shorter wave V latencies may occur because (*i*) the steady-state response is produced by a different generator, (*ii*) neural band-pass filtering causes additional delay in apparent latency calculations (Langner and Schreiner, 1988; Regan, 1989), (*iii*) the transient ABR stimuli with noise have not been adequately matched to the level of pure-tones, and/or (*iv*) responses to transient stimuli occur before the peak of the basilar membrane filter build-up required for steady-state responses (John and Picton, 2000a; Eggermont, 1979; Eggermont *et al.*, 1996; Purcell *et al.*, 2003).

D. Separation of delay constituents

Two assumptions were necessary to separate DPOAE and EFR apparent latencies into inward stimulus and response delays. The first assumption is that neural response delays are independent of the place on the basilar membrane that the EFR is initiated. The neural component of the tone burst auditory brainstem response (ABR) was assumed 5 ms for wave V independently of frequency and level in a study by Neely *et al.* (1988). Shirane and Harrison (1991) found that inferior colliculus neurons in the chinchilla responded with a latency of approximately 8 ms and that this latency was essentially independent of the characteristic frequency of cochlear fibers stimulated using supra-threshold current pulses. Derived responses obtained by Don and Eggermont (1978; Eggermont and Don, 1980) have shown that the latencies of ABR waves I–V are constant across intensity and frequency. Schoonhoven *et al.* (2001) used these findings to estimate cochlear delays from ABR peak V latencies.

The second assumption is that the phase accumulated in the f_2 traveling wave is independent of stimulus frequency f_2. This assumption (Shera and Guinan, 1999) should be reasonable for f_2 values away from the extremes of the cochlear frequency to place map (Greenwood, 1990). This assumption implicitly requires that the stimulus levels are similar for different f_2 so that the sharpness of the cochlear filter does not change (Ruggero, 1992). The stimuli in the present experiment were calibrated for an average ear with the Zwislocki coupler, but it is possible that the relative stimulus levels for f_2=900 and 1800 Hz could be different in the cochlea due to characteristics of the individual ear, especially the transfer function of the middle ear. However, the stimulus calibration was likely adequate to ensure similar signal levels in the cochlea for both values of f_2. The stimuli and DPOAEs could also experience different phase shifts across the ear canal and middle ear for each f_2. Although the relationship between inward stimulus delays for different values of f_2 was determined using θ, other cochlear models could be applied to estimate the relationship.

E. Inward stimulus delay

It was estimated that the inward f_2 stimulus would accumulate a frequency-independent 39.85 rad (6.34 cycles) to the characteristic place of f_2 where both response types were initiated. The higher frequency delay is half that of the lower because the two values of f_2 were an octave apart (which is not a requirement of the technique). The f_2=900 Hz delay here is shorter than that obtained previously using values from a cochlear model at a lower stimulus level (Purcell *et al.*, 2003). As above, shorter cochlear delays are expected at higher stimulus levels.

Cochlear travel times determined by Eggermont (1979) with click-evoked narrow-band action potentials were shorter than found here. The same is true for derived band ABR studies by Don and Eggermont (1978) and Eggermont and Don (1980). The stimulus levels here were different (note dB SL versus SPL in Table III), and responses to transient stimuli occur before the full build-up of the basilar membrane filter (Eggermont, 1979; Eggermont *et al.*, 1996). For the slow sweep of f_1 used here, the EFR responses are essentially steady state and therefore probably experience the full build-up of the basilar membrane filter and associated longer delay (John and Picton, 2000a).

Forward or inward stimulus latency can be estimated from an empirical function provided by Neely *et al.* (1988) from measurements of transient evoked otoacoustic emissions and tone burst ABRs. Their value was shorter for f_2 =900 Hz, but very similar at 1800 Hz. Neely *et al.* (1988) point out that the ABR is generated by the onset of the stimulus. Kimberley *et al.* (1993) halved their DPOAE latencies to obtain shorter inward travel times than those found here. They noted that this was a considerable simplification.

Schoonhoven *et al.* (2001) found that f_1-sweep latency was about twice the corrected delay from electrophysiological measurements and concluded that inward stimulus delay was about 50% of the total DPOAE latency. Their inward delay values from ABR measurements were shorter than those found here. They pointed out, however, that their results may not allow predictions at stimulus levels other than $L1$=65 dB SPL, $L2$=55 dB SPL, and clicks of 70 dB nHL. Indeed, different stimuli (pure tones and clicks with noise)

were used to elicit the various responses in the study, unlike the identical stimuli and simultaneous measurements made here. As discussed above, transient electrophysiological measurements may underestimate cochlear traveling wave delays for steady-state responses, and this would result in the underestimation of the inward stimulus delay as a percentage of total latency when transient measurements are used. Other researchers (O Mahoney and Kemp, 1995; Moulin and Kemp, 1996a, b) have reported larger percentages for inward stimulus delay. This was thought reasonable (e.g., Whitehead *et al.*, 1996) because the low-frequency outward emission from a single source at the f_2 place would be expected to accumulate fewer cycles in the reverse traveling wave than the stimulus (since the DPOAE characteristic place would be more apical). Previously reported values from f_1 sweeps have ranged from 69% evaluated using older electrophysiological data (Moulin and Kemp, 1996a) to 82% found by comparing the latencies of $2f_1$-f_2 and $3f_1$-$2f_2$ DPOAEs generated at the same f_2 place (Moulin and Kemp, 1996b). These percentages were used to estimate the inward stimulus delay ranges for Moulin and Kemp listed in Table III. The values are shorter than reported here at f_2=900 Hz and longer than for 1800 Hz. Using a cochlear model, Purcell *et al.* (2003) reported an inward delay of 79% for a single source DPOAE with f_2=900 Hz at 40 dB SPL. The percentages found here (Table II) of 74% (f_2=900 Hz) and 57% (f_2=1800 Hz) are within the (rather wide) range reported in the literature.

F. Outward DPOAE response delay

For otoacoustic emissions evoked with transient stimuli, the inward stimulus and outward response delays are very similar since they occur at the same frequency (although the reverse transfer function is not identical to the forward one). By halving the transient evoked emission latencies given by a function in Neely *et al.* (1988), the obtained results are several milliseconds longer than those estimated here for the outward DPOAE shown in Table III. However, their given function only accounts for 69% of the variance in their data. Schoonhoven *et al.* (2001) suggest outward DPOAE delay is half the total latency, leading to values that are slightly longer than here for f_2=900 Hz and slightly shorter when f_2=1800 Hz. An estimate of single source DPOAE outward delay at f_2=900 Hz and 40 dB SPL can be derived from Table I in Purcell *et al.* (2003). The outward delay is estimated by taking 21% of the experimental DPOAE latency of 11.5 ms. The result is very similar to the 900-Hz value reported here. Using the percentage of outward DPOAE delay with respect to total latency values of 18% (Moulin and Kemp, 1996b) and 31% (Moulin and Kemp, 1996a) and their total DPOAE latencies, outward delays can be estimated. The upper limit of outward delay estimates derived from their data and relations for f_2=900 Hz is similar to the value reported here, whereas the 1800-Hz value is shorter.

The outward DPOAE delay estimate should have been about 1 to 1.5 ms longer for f_2=900 Hz compared to 1800 Hz if the latencies were derived from a cochlear model (Giguere and Woodland, 1992, 1994). Instead, the calculated values were similar (Table II). The delay of the higher frequency DPOAE is likely increased (in part) by the fact that f_2/f_1 was smaller for f_2=1800 Hz. This pushes the f_{dp} characteristic place closer to the f_2 place, and thus increases the cycles accumulated in the outward f_{dp} signal from the f_2 place. The similarity of the two outward delay estimates is responsible for the change in the inward delay as a percentage of total latency from 74% to 57% for f_2=900 and 1800 Hz, respectively.

G. Neural processing delay

Neural processing delay above the cochlea was assumed to be independent of stimulus frequency f_2 and independent of small changes in envelope frequency f_2-f_1, such as between 150 and 170 Hz used here. Neural delay would be expected to change if f_2-f_1 were sufficiently altered to elicit responses from two different generator regions (e.g., cortical 40 Hz versus brainstem 100 Hz). The neural delay here was estimated as 5.3 ms, which is similar to the neural 5-ms delay (including synaptic delay) employed for tone burst wave V ABRs by Neely *et al.* (1988). Wave V–I delay estimates of 3.8 ms (Don and Eggermont, 1978) and 3.9 ms (Eggermont and Don, 1980) can be adjusted to the full neural delay estimated here and in Neely *et al.* (1988) by adding about 0.8 ms for the synaptic delay between the inner hair cells and auditory nerve (Eggermont, 1979), bringing the total neural delay to about 4.7 ms. Similarly, the wave V-I delays of Schoonhoven *et al.* (2001) can be compared to total neural delay reported here by adding 0.8 ms for the synaptic delay to give a total average neural delay of 4.85 ms. Despite reasonable agreement with the 5.3 ms reported here, it is possible that the multi-synaptic envelope-following circuit between the cochlea and the EFR generators may be to some extent distinct from the circuit subserving the transient ABR (Purcell *et al.*, 2003).

V. CONCLUDING REMARKS

The purpose of this study was to simultaneously measure acoustic latencies from the cochlea and electrical latencies from the auditory brainstem. A technique has been proposed to separate these latencies into stimulus and response delays. The analysis is complicated by the fact that the DPOAE response frequency is different from the pure tones that evoke it. In this regard it might be simpler to use stimulus frequency or transient evoked otoacoustic emissions where the stimulus and response share the same frequencies. Both stimulus frequency emissions and EFRs might be elicited by a SAM tone, for example (Rosner *et al.*, 2005). However, stimulus-frequency emissions are susceptible to electroacoustic artifacts whereas the DPOAE is robust and easy to measure. When DPOAEs and EFRs are simultaneously elicited by the same stimulus, the two responses have the same inward stimulus delay. Concurrent measurements may be helpful to understand the effects of stimulus parameters (overall intensity, frequency ratios, intensity ratios, etc.) on the different delays. Improved methods will be needed to reduce the variability of the measurements before the present technique can be used for individual subjects.

Signal to noise ratio analysis of maximum length sequence deconvolution of overlapping evoked potentials

Jorge Bohórquez
Department of Biomedical Engineering, College of Engineering, University of Miami, Coral Gables, Florida 33124

Özcan Özdamar

(Received 5 December 2005; revised 7 March 2006; accepted 9 March 2006)

In this study a general formula for the signal to noise ratio (SNR) of the maximum length sequence (MLS) deconvolution averaging is developed using the frequency domain framework of the generalized continuous loop averaging deconvolution procedure [Özdamar and Bohórquez, J. Acoust. Soc. Am. **119**, 429–438 (2006)]. This formulation takes advantage of the well known equivalency of energies in the time and frequency domains (Parseval's theorem) to show that in MLS deconvolution, SNR increases with the square root of half of the number of stimuli in the sweep. This increase is less than that of conventional averaging which is the square root of the number of sweeps averaged. Unlike arbitrary stimulus sequences that can attenuate or amplify phase unlocked noise depending on the frequency characteristics, the MLS deconvolution attenuates noise in all frequencies consistently. Furthermore, MLS and its zero-padded variations present optimal attenuation of noise at all frequencies yet they present a highly jittered stimulus sequence. In real recordings of evoked potentials, the time advantage gained by noise attenuation could be lost by the signal amplitude attenuation due to neural adaptation at high stimulus rates. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2191609]

I. INTRODUCTION

Transient evoked potentials (EP) are generally obtained with repetitive stimuli using synchronous signal averaging. The rate of stimuli is adjusted such that the response to each stimulus is complete prior to the presentation of the next stimulus. If this condition is not satisfied, overlapping of responses occurs and steady-state responses (SSR) are generated. SSRs generally display a complex set of time features which are generally analyzed using spectral analysis. Under these conditions, the transient EP, thought to be generating these responses cannot be recovered. In 1982, Eysholdt and Schreiner introduced a novel method to recover individual transient responses from overlapping responses obtained at high stimulus rates. This method uses a specially designed stimulus sequence called maximum length sequences (MLS) and since then has found many applications in basic and clinical research on evoked potential (e.g., Bell *et al.*, 2001, 2002; Burkard *et al.*, 1990, 1996a, 1996b; Chan *et al.*, 1992; Jirsa, 2001; Jiang *et al.*, 2003; Lasky, 1992; Leung *et al.*, 1998) and otoacoustic emission (Thornton, 1993a, b) studies.

MLS is part of a bigger family of sequences called pseudorandom binary sequences (PBS) which are cyclic sequences with flat frequency spectra and impulse circular autocorrelation functions. Because of their special properties, they are used in many diverse fields such as communications, cryptanalysis, systems theory, acoustics, and biomedicine. Other lesser known classes in the same family are Legendre sequences (LGS) and quadratic residue codes (QRC). Maximum length sequences are comprised of two elements, 1 and −1, and generated using well-known algorithms (Davies, 1966; De Graauw and Veltman, 1970). They are characterized by their generator base (b), number of ones (N), and sequence length (L). These parameters are interrelated by the simple rules $N=2^b$ and $L=2^*N-1$. MLS can be generated for all base integers of which the first five are listed in Table I.

For evoked response studies, a binary form (1, 0) of MLS is used with −1 substituted for 0 (Eysholdt and Schreiner, 1982). In this formulation, a "1" represents a stimulus and a "0" represents the lack of a stimulus. As a consequence, the autocorrelation does not produce a perfect impulse function. This difficulty, however, is remedied by using a recovery function with negative and positive elements. As a consequence the autocorrelation function of the binary form of the MLS with length L (MLS_L) results in

$$\mathrm{MLS}_L(t) \copyright \mathrm{MLS}_L(t) = \frac{N}{2}[\delta(t) + 1], \tag{1}$$

where t is the time index, $\delta(t)$ is the impulse function, and © designates auto or cross correlation function. The recovery sequence MLSR_L for the binary MLS_L incorporates the factor N so the following autocorrelation equation can be written as described by Eysholdt and Schreiner (1982) and Burkard *et al.* (1990).

$$\mathrm{MLS}_L(\mathrm{t}) \copyright \mathrm{MLSR}_L(\mathrm{t}) = \delta(t). \tag{2}$$

The left column of Fig. 1 shows the time diagram of the MLS_{31} function with $L=31$ and its recovery function

TABLE I. The listing of the first five maximum length sequences. Other sequences exist for lengths 7, 15, and 63.

Maximum length sequences	
Code	Sequence
MLS_3	1 1 0
MLS_7	1 1 1 0 0 1 0 1
MLS_{15}	1 1 1 1 0 1 0 1 1 0 0 1 0 0 0
MLS_{31}	1 1 1 0 1 1 0 0 0 0 1 1 1 1 1 0 0 1 1 0 1 0 0 1 0 0 0 0 1 0 1 0
MLS_{63}	1 1 1 1 1 0 0 0 0 0 1 0 0 0 0 1 1 0 0 0 1 0 1 0 0 1 1 1 1 0 1 0 1 0 0 0 0 1 1 1 0 0

$MLSR_{31}$. As seen, the recovery function $MLSR_{31}$ has essentially the same form as the MLS function with amplitudes attenuated by the number of ones (or stimuli) which is 16 in this case and zeros replaced by negative pulses with the same magnitude as the positive pulses. Corresponding frequency diagrams are shown on the right column. The flat spectrum of the MLS_{31} stimulus function is displayed on the right top with the dc value showing 16, the number of stimuli. The dc value of the deconvolution filter function is 0.0625 (inverse of 16) which is shown on the right bottom figure.

In auditory applications the interstimulus interval (ISI) or rate has a strong influence on the adaptation of the evoked response components. In conventional evoked potential (EP) studies, stimuli are presented at a fixed rate (constant ISI). For MLS responses, however, a mean rate or minimum ISI is used since the ISI is not constant and shows a wide distribution as a function of L (see Fig. 2). The ratio of the maximum to the minimum ISI can be defined as the stimulus jitter ratio and this ratio increases as a function of *L* as listed in Table II.

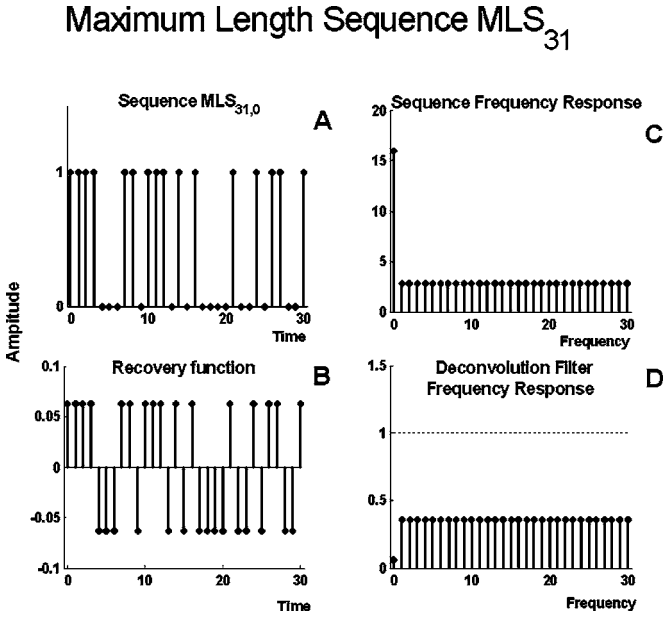

FIG. 1. (a) Time diagram of the MLS_{31} function with $L=31$. (b) Recovery function $MLSR_{31}$. (c) Stimulus frequency response function $S(f)$. (d) Deconvolution filter frequency response function $G(f)$ of the same stimulus sequence. The dotted line in (d) separates the noise amplification (above one) and attenuation (below one) regions.

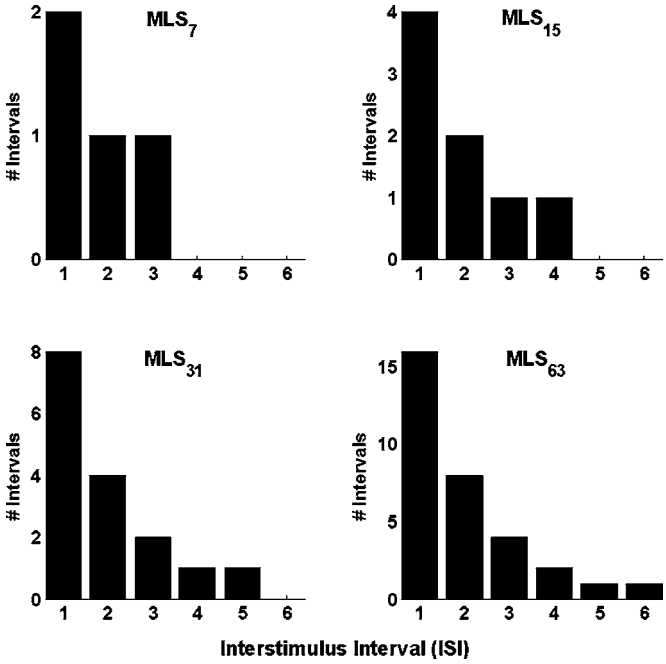

FIG. 2. Interstimulus interval (ISI) distribution histograms for the four MLS functions with lengths 7, 15, 31, and 63 listed in Table I.

Maximum length sequences have a very specific interstimulus interval (ISI) distribution, having a total of *N* components (Fig. 2). The highest component has $2^{(N-2)}$ intervals and each component's frequency decreases by a factor of 2 until reaching the *N*th component, which will have one occurrence (Picton *et al.*, 1992). Even for $N=7$, for which two distinct MLS were derived, the interpulse periods had identical patterns as shown in Fig. 2.

In order to expand the MLS deconvolution of overlapping responses to arbitrary stimulus sequences, Van Veen and Lasky (1994) presented a general matrix-based framework working in the time domain. This approach identified an infinite number of recovery sequences for any given stimulus sequences. A similar matrix-based approach was employed by Gutschalk *et al.* (1999) to deconvolve a specially prepared stimulus pattern compiled by a concatenation of click trains for the investigation of human magnetic steady state fields. Recently a similar time domain generalized procedure called continuous loop averaging deconvolution (CLAD) was presented to deconvolve overlapping responses elicited by arbitrary sequences (Özdamar *et al.*, 2003; Delgado and Özdamar, 2004).

A similar deconvolution procedure in the frequency domain was later presented by Jewett *et al.* (2004). Very re-

TABLE II. The characteristic of the first five maximum length sequences.

Code	Base *b*	Number stimuli *N*	Length *L*	Jitter ratio
MLS_3	1	2	3	2:1
MLS_7	2	4	7	3:1
MLS_{15}	3	8	15	4:1
MLS_{31}	4	16	31	5:1
MLS_{63}	5	32	63	6:1

cently we expanded the CLAD procedure to the frequency domain for fast implementation and better understanding of its noise attenuation/amplification and SNR characteristics (Özdamar and Bohórquez, 2006). This latest study presented a general formulation for the signal-to-noise ratio (SNR) of the deconvolution procedure using the frequency domain analysis. Such analyses showed that unlike conventional averaging, deconvolution averaging can attenuate or amplify phase unlocked noise depending on the frequency characteristics of the arbitrary stimulus sequence (Özdamar and Bohórquez, 2006).

In this study frequency analysis of the CLAD procedure will be used to analyze the SNR characteristics of the MLS deconvolution. Quantitative evaluation of the noise attenuation with MLS deconvolution has been difficult and controversial due to the lack of a basic theory and the interpretation of the real recordings due to the involvement of adaptation and muscle artifacts (Picton *et al.*, 1992; Marsh, 1992; Bell *et al.*, 2001, 2002). A simple formula for SNR for MLS deconvolution is derived and evaluated using sample recordings. MLS and its zero-padded variations are shown to present the optimal attenuation for noise yet it is not as effective as the conventional averaging.

II. THEORY AND MATHEMATICAL ANALYSIS

Using CLAD notation (Özdamar and Bohórquez, 2006), let $\{t_n\}$ be a L length sequence of N stimulus positions in a sweep length T acquisition buffer ($T=L$).

$$0 \leqslant t_n \leqslant T-1, \quad n=1,\ldots,N. \tag{3}$$

Let MLS_L (t) be a MLS sequence of N stimuli with length L as related

$$L = 2^{*}N - 1. \tag{4}$$

The sequence itself is the impulse response of a system triggered with the stimuli as expressed below (Özdamar and Bohórquez, 2006)

$$s(t) = \sum_{n=1}^{N} \delta_{t,t_n}. \tag{5}$$

The recorded signal $v(t)$ in response to the stimulus sequence $s(t)$ can be defined using the convolution formula as follows:

$$v(t) = a(t)^{*}s(t), \tag{6}$$

where $a(t)$ is the transient evoked response to a single stimulus and $v(t)$ is the convolved signal.

The response to a single stimulus can be computed in the frequency domain as

$$A(f) = V(f)/S(f) = V(f)G(f), \tag{7}$$

where $G(f)$ is the deconvolution filter frequency response (Özdamar and Bohórquez, 2006) and is the inverse of $S(f)$. The right portion of Fig. 1 shows the typical frequency response in the special case of MLS_{31} sequence ($L=31$). As observed the dc component has a specific value while all the other frequencies show a constant value with a flat response. As described in Özdamar and Bohórquez (2006) values below one in $G(f)$ shows attenuation while values above one shows amplification of noise at the designated frequency.

A. SNR computation of MLS sequences

MLS sequences can be treated as special cases of CLAD sequences. Spectral characteristics of MLSs are well known. The Fourier transform of a MLS sequence impulse response is flat for all the frequencies except the dc component. The value of the frequency response in the general case can be computed with the aid of the Parseval's energy conservation theorem as follows:

The frequency response $S(f)$ of the stimulus function expressed in Eq. (5) is computed using the Fourier transform definition

$$S(f) = \sum_{t=0}^{L-1} s(t)e^{-2\pi jtf/L}. \tag{8}$$

The dc component $S(0)$ can be computed as

$$S(0) = \sum_{t=0}^{L-1} s(t)e^{-2\pi jt0/L} = N. \tag{9}$$

Since the signal energies are the same in the time and frequency domains, the following equation can be written using the well-known Parseval's theorem:

$$\sum_{t=0}^{L-1} s^2(t) = \frac{1}{L}\sum_{f=0}^{L-1} |S(f)|^2 = \frac{1}{L}[S^2(0) + (L-1)S_{\mathrm{ac}}^2(f)]. \tag{10}$$

The term $S_{\mathrm{ac}}(f)$ is the value of the transfer function for all the nonzero (alternating) frequencies (ac). Since the number of ones in the sequence is known, Eq. (10) can be written as

$$\sum_{t=0}^{L-1} s^2(t) = N = \frac{1}{(2N-1)}[N^2 + (2N-2)S_{\mathrm{ac}}^2]. \tag{11}$$

Equation (11) can be reduced to

$$S_{\mathrm{ac}}^2 = \frac{N^2 - N}{2(N-1)}.$$

This can be solved to obtain

$$S_{\mathrm{ac}} = \sqrt{\frac{N}{2}} = \frac{1}{2}\sqrt{L+1}. \tag{12}$$

For the MLS deconvolution filter without conventional averaging the noise is then attenuated by the inverse of Eq. (12). Using the SNR analysis of Özdamar and Bohórquez (2006), the resulting SNR for the MLS with a given N can be expressed as follows:

$$\mathrm{SNR}_{\mathrm{MLS}} = \frac{\sigma_s}{c_{\mathrm{dec}}\sigma_n} = \sqrt{\frac{N}{2}}\frac{\sigma_s}{\sigma_n} = 2\sqrt{L+1}\frac{\sigma_s}{\sigma_n}. \tag{13}$$

The average noise gain factor c_{dec} of the MLS deconvolution filter is

$$c_{\mathrm{dec\ MLS}} = \sqrt{\frac{2}{N}} = 2\sqrt{\frac{1}{L+1}}. \tag{14}$$

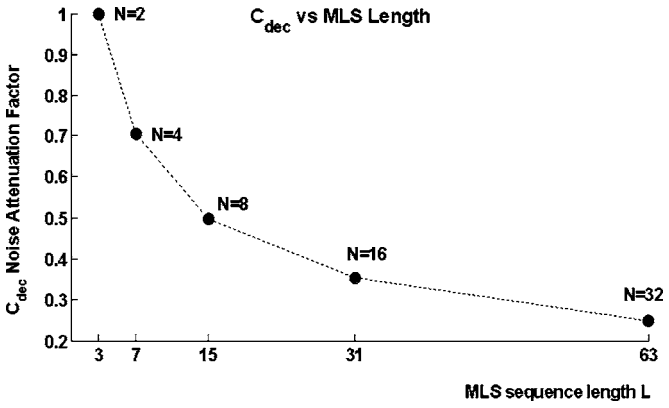

FIG. 3. Change of the noise attenuation factor c_{dec} as a function of the MLS sequence length.

Figure 3 shows the noise attenuation factor of MLS sequences as functions of the sequence length L or the number of stimuli N.

B. Noise attenuation optimality of MLS sequences

The above analysis shows that MLS stimuli have c_{dec} values below one in all frequencies making sure that noise is always attenuated and never amplified. In this section we show that there are no other sequences with the same length and stimulus number that has lower c_{dec} values; that is any arbitrary CLAD sequence with $L=2^{*}N-1$ has a deconvolution average SNR lower than or equal to a MLS sequence.

Let us start with an arbitrary sequence having the same length and stimulus number ($L=2^{*}N-1$). The c_{dec} factor for such a sequence follows the equation (Özdamar and Bohórquez, 2006):

$$c_{\mathrm{dec}}^2 = \frac{1}{L-1}\sum_{f=1}^{L-1}\frac{1}{|S(f)|^2}. \tag{15}$$

We compute the difference of c_{dec}^2 factors between the arbitrary sequence and the MLS sequence (14) to obtain

$$c_{\mathrm{dec}}^2 - c_{\mathrm{dec\ MLS}}^2 = \frac{1}{L-1}\sum_{f=1}^{L-1}\frac{1}{|S(f)|^2} - \frac{2}{N}. \tag{16}$$

Using Eqs. (10) and (11) it can be shown that

$$\frac{1}{L-1}\sum_{f=1}^{L-1}|S(f)|^2 = \frac{N}{2}. \tag{17}$$

If we substitute Eq. (17) in Eq. (16) we obtain

$$c_{\mathrm{dec}}^2 - c_{\mathrm{dec\ MLS}}^2 = \frac{1}{L-1}\sum_{f=1}^{L-1}\frac{1}{|S(f)|^2} - \frac{L-1}{\sum_{f=1}^{L-1}|S(f)|^2}. \tag{18}$$

The right side of Eq. (18) can be interpreted as the difference between the harmonic mean and the inverse of the arithmetic mean of $|S(f)|^2$. Using the arithmetic-harmonic mean inequality we can conclude that

$$c_{\mathrm{dec}}^2 - c_{\mathrm{dec\ MLS}}^2 \geqslant 0 \Rightarrow c_{\mathrm{dec}} \geqslant c_{\mathrm{dec\ MLS}}. \tag{19}$$

Equation (19) means that any other sequence with ($L=2^{*}N-1$) will have a larger or equal c_{dec} than the MLS sequence.

C. Zero padding of MLS sequences

In order to increase the time resolution of the deconvolution, zeros can be padded to the MLS sequences as shown for the MLS_7 example in Table III below. To the sequence $\mathrm{MLS}_{7,0}$, ($N=4$, $L=7$, and $T=7$), when one zero is padded (sequence $\mathrm{MLS}_{7,1}$), N and L stay the same but T increases to 14. The corresponding recovery sequences are shown which have similar patterns.

The effects of zero padding can be ascertained from Fig. 4 where convolution and deconvolution frequency responses are plotted for the MLS sequences listed in Table II. As easily observed, adding a zero adds another frequency cycle to the transfer function. Based on this property, the general formula for the noise attenuation factor of the MLS sequence with length L, N stimulus, and P padded zeros c_{dec} can be expressed as follows:

$$c_{\mathrm{dec}}(\mathrm{MLS}_{N,P}) = \frac{1}{N}\sqrt{\frac{4N^2(P+1)-4N(P+1)+P}{2N(P+1)-(P+2)}}. \tag{20}$$

When $P=0$ this equation reduces to Eq. (14) as expected.

In Fig. 5 noise attenuation factor as a function of P and N are plotted. As seen, the number of padded zeros is important only for small N and P. As the P gets larger ($P \gg 3$) it can be ignored since it does not influence the noise attenuation factor appreciably. For $N=2$ or $N=4$ noise attenuation value falls off significantly when one or two zeros are pad-

TABLE III. MLS_7 and their recovery sequences with increasing zero padding.

Code $L=7$	$N=4$	T	Stimulus sequence
$\mathrm{MLS}_{7,0}$	No 0 padded	7	1100101
$\mathrm{MLS}_{7,1}$	One 0 padded	14	10100000010010
$\mathrm{MLS}_{7,2}$	Two 0 padded	21	100100000000100000100
$\mathrm{MLS}_{7,3}$	Three 0 padded	28	1000100000000000100000001000
MLS Recovery			Recovery sequence
$\mathrm{MLSR}_{7,0}$	No 0 padded	7	1/4 1/4 −1/4 −1/4 1/4 −1/4 1/4
$\mathrm{MLSR}_{7,1}$	One 0 padded	14	1/4 0 1/4 0 −1/4 0 −1/4 0 1/4 0 −1/4 0 1/4 0
$\mathrm{MLSR}_{7,2}$	Two 0 padded	21	1/4 0 0 1/4 0 0 −1/4 0 0 −1/4 0 0 1/4 0 0 −1/4 0 0 1/4 0 0
$\mathrm{MLSR}_{7,3}$	Three 0 padded	28	1/4 0 0 0 1/4 0 0 0 −1/4 0 0 0 −1/4 0 0 0 1/4 0 0 0 −1/4 0 0 0 1/4 0 0 0

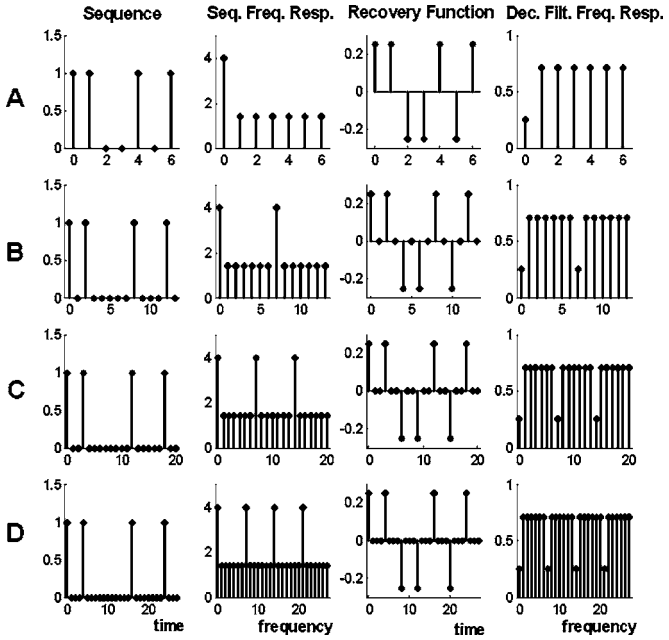

FIG. 4. Time and frequency domain plots of the MLS_7 function with increasing zero padding (a) $P=0$; (b) $P=1$; (c) $P=2$; (d) $P=3$. For each zero padding, first column shows time plots of the stimulus sequence, second column shows the stimulus frequency response, third column shows the recovery sequence, and the fourth column shows the deconvolution filter frequency response.

ded. This, however, become negligible for higher numbers of zero padding. Figure 5 also shows that the number of stimuli is a more important factor in determining the final value of noise attenuation than the number of zeros padded.

The dc value of the deconvolution filter frequency response is $(1/N)$; it is always smaller than c_{dec}. When (P) zeros are padded in time domain, this dc value will appear as notch frequencies in the deconvolution filter frequency response (P) times in equally separated frequencies (Fig. 4). It can be shown that the first notch frequency is

$$f_{nP} = \frac{f_s}{P+1}, \tag{21}$$

where f_s is the sampling frequency. The remaining notches occur at the harmonics of this frequency. This multiple notch filter creation, valid for any MLS or CLAD sequence, can be used to achieve higher noise attenuation factors at specific frequencies.

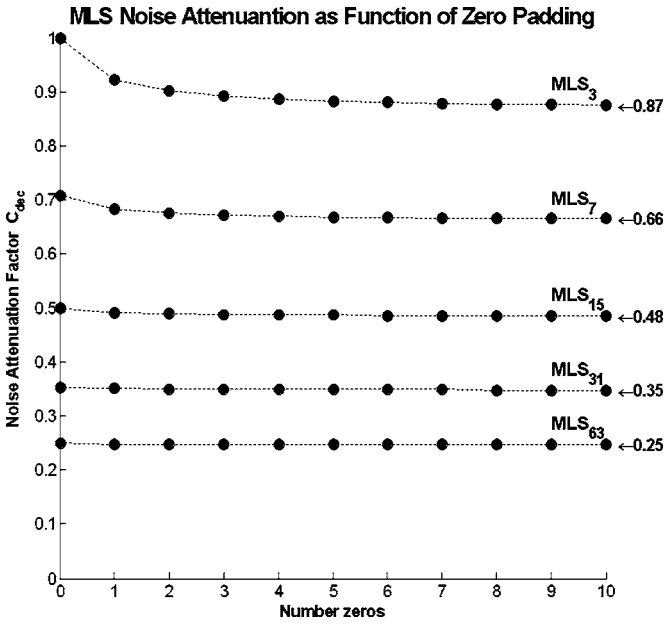

FIG. 5. Noise attenuation factor c_{dec} as a function of the number of padded zeros for the first five MLS sequences listed in Table I. Asymptotic values for infinite zeros padded are marked by arrows on the right.

III. EXPERIMENTAL METHODS

In this study human recordings were obtained to verify the validity of the theory and the equations developed in the previous section. The goal was to demonstrate the characteristics of the noise as a function of the sweeps averaged and deconvoluted. This required the recording of the data in a single sweep mode and performing averaging and deconvolution operations off line. For comparisons with the theoretical results, rms values were computed for estimating noise and signal amplitudes.

Recording parameters were chosen such that auditory brainstem responses (ABRs), middle latency responses (MLRs), and early portions of the late latency responses (LLRs) were simultaneously recorded using monaural stimulation. Scalp continuous electroencephalogram (EEG) recordings were obtained by saving individual sweeps in a digital computer. Recordings were done with 100 000 amplification at 1–1000 Hz (12 dB/oct), sampling frequency was at 20 kHz, and 1500 sweeps were recorded. Scalp differential recordings (noninverting: forehead; inverting: ipsilateral mastoid; common: contralateral mastoid) were stored digitally for later processing and analysis. Four young normal adults with normal hearing and no history of neurological or otological problems served as subjects.

MLS_{15} sequence was used in all the recordings. This sequence had a length of 15 and was padded with 255 or 267 zeros to increase the overall sweep length to $L=3840$ or $L=4020$, respectively. With 50 μs sampling time, sweep times of 192 or 201 ms were obtained. Since each sweep had eight clicks this acquisition format resulted in about 40 Hz average stimulus rate.

Acoustic stimulation was achieved by using a laptop computer which generated the sounds delivered to the subject's ear. The trigger points were recorded in one of the acquisition channels of the recording system. Tone pip stimuli (1 kHz tone pips Blackman, 5 ms duration) were exclusively used as stimuli. They were delivered monaurally to the subject's ear at 92 dB sound pressure level (SPL) using ER-3A insert phones (Etymotic Research, Elk Grove Village, IL). Acoustic calibration was done in a 2cc acoustic coupler using a precision sound level meter (Quest Model 1800) to measure peak dB SPL levels.

IV. RESULTS

An example of single sweep recordings made from a subject using the MLS_{15} sequence is shown in Fig. 6. The time pattern of the pip stimuli and a sample of the raw EEG

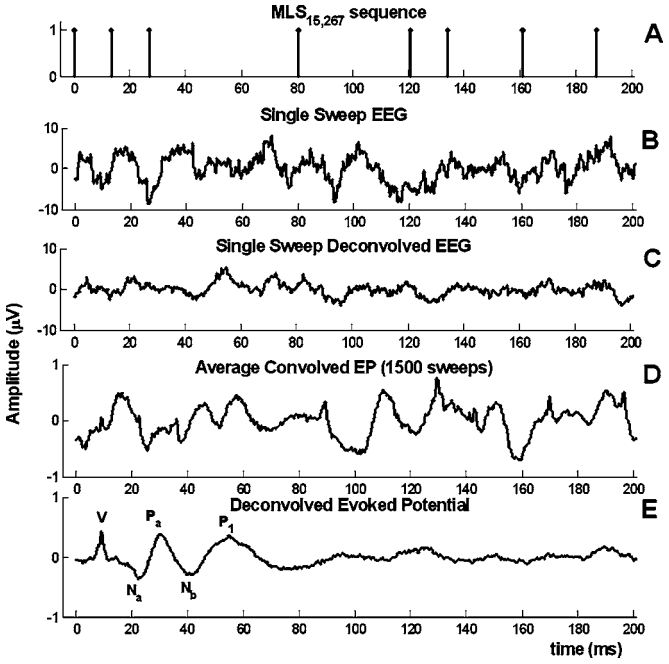

FIG. 6. Results from a recording made in an adult subject using MLS_{15} sequence with 267 zeros (see text for details). (a) Time diagram of the MLS_{15} stimulus sequence, (b) a single sweep EEG sample, (c) single sweep deconvolved EEG of the above trace, (d) averaged convolved EP, and (e) corresponding deconvolved EP. Major peaks (Wave V of ABR, N_a, P_a, N_b of MLR, and P_1 of LLR) are marked as shown.

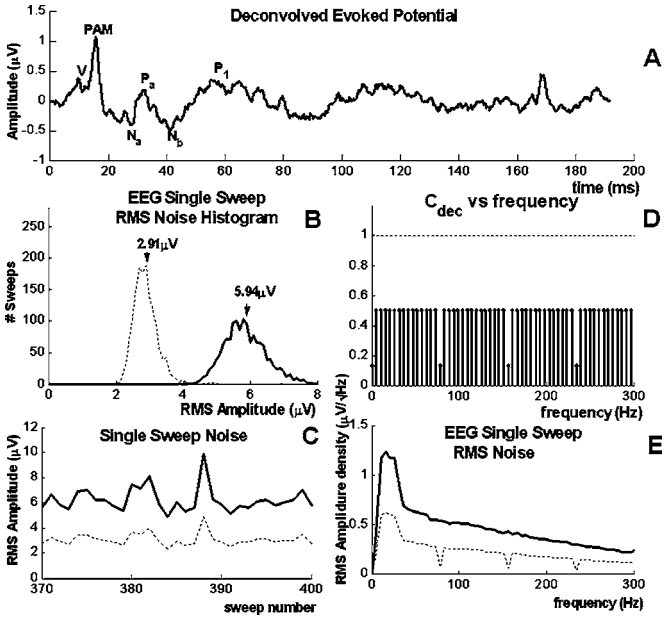

FIG. 7. Statistical and frequency results from another recording from another subject made with another MLS_{15} sequence with 255 zeros (see text for details). (a) Deconvolved EP showing major peaks [Wave V of ABR, post auricular muscle (PAM) response, N_a, P_a, N_b of MLR and P_1 of LLR], (b) RMS single sweep EEG amplitude distribution histograms for raw (solid) and deconvolved EEG (dotted), (c) RMS amplitude of single sweep recordings (370–400) raw EEG (solid) and deconvolved EEG (dotted), (d) deconvolution filter frequency plot for the MLS sequence for the dc-300 Hz region, and (e) RMS densities for each frequency bin of the corresponding frequency region.

are shown in the first two rows [Figs. 6(a) and 6(b)]. The third row shows the corresponding deconvolved EEG according to the stimulus pattern shown at the top. Reduced amplitude of the EEG [Fig. 6(c)] compared to the raw EEG [Fig. 6(b)] can readily be observed in this trace.

In the last two rows average convolved and deconvolved recordings are shown. As expected none of the (AEP) components can be readily recognized in the convolved recording [Fig. 6(d)]. Close scrutiny, however, reveals sharp positive waves corresponding to wave V of the ABR at around 6–7 ms after clicks. The remaining MLR and LLR components cannot be recognized because of heavy overlapping due to short time intervals between clicks. The last trace [Fig. 6(e)] shows a very clean easily recognized AEP recording with all components, wave V of ABR, N_a, P_a, N_b of MLR, and P_1 of LLR. A very small N_1 around 80 ms can also be detected. However, none of the other remaining LLRs (P_2 or N_2) can be observed possibly due to high stimulus rate.

In Fig. 7(a) another sample deconvolved AEP recording from another subject is shown. In this particular recording post auricular muscle (PAM) activity was present as observed in the high amplitude sharp component around 13 ms. As expected, this EP is noisier than the previous recording due to the PAM activity. A rms amplitude histogram of the single sweep convolved and deconvolved EEGs are shown in Fig. 7(b). As expected both distributions have a Gaussian shape with the means (convolved 5.94 μV and deconvolved 2.91 μV) separated by about 3.03 μV. A sample of single sweep rms EEG amplitudes are shown in Fig. 7(c) with a similar reduction between convolved and deconvolved EEG amplitudes.

In Fig. 7(d) the deconvolution filter response function of the MLS_{15} for the low frequency region is plotted. The average noise reduction is about 0.48 and constant for all frequencies other than the repetitive dips with $c_{\mathrm{dec}}=0.125$ at dc, 78.125 Hz and above harmonics due to the padded zeros. RMS EEG amplitudes corresponding to frequency bins are plotted in Fig. 7(e). As expected, EEG amplitudes are higher in low frequencies and monotonically decrease at about 35 Hz. Again the deconvolved EEGs show lower amplitudes than the raw EEG (convolved). The noise attenuation dips seen in the deconvolution filter of Fig. 7(d) are clearly reflected in the deconvolved EEG noise trace.

The recordings from all subjects showed the same results and are depicted in Figs. 6 and 7. EEG noise attenuation was the same as predicted by the theory in averaged as well as single sweep recordings. The results were the same whether the recording contained little or no EMG noise as in Fig. 6 or high PAM or EMG noise as in Fig. 7.

V. DISCUSSIONS

In conventional averaging, SNR is improved with the square root of the number of stimuli averaged. When the MLS method was developed, it was hoped that a similar improvement would be achieved since higher stimulation rates can be achieved. It was suggested that it might be possible to reduce the recording time of EPs such as ABRs by using MLS averaging at high rates (Thornton and Slaven, 1993). The experimental recordings, however, did not show much improvement and noise reduction was less than what is

achieved by conventional averaging (Marsh, 1992). The problem was further complicated by the adaptation effects that come into play with high stimulation rates. In general the SNR improving property of the MLS method is opposed by the signal attenuating property of the physiological adaptation effect.

An early formula to the SNR improvement due to MLS averaging was provided by Thornton (1993a,b) for the acquisition of otoacoustic emissions (OAEs). OAE recording with MLS has the advantage of little adaptation and no peak delay at higher rates; thus, produces more dramatic results. Thornton's proposed formula based on signal and noise improvement expectations is remarkable since it is derived without the use of basic signal and noise equations. If no adaptation is assumed ($k=1$) and percentage of stimuli per sweep ($c=N/L$) is approximated by half, this approach predicts a SNR improvement $1/\sqrt{2}=0.707$ as much as shown in this study. Since little theoretical reasoning for the proposed formula or few quantitative measurements at single sweep level are presented, no assessment of this difference can be offered. These equations are later used to show the feasibility of reducing OAE recording time as tested experimentally under controlled conditions (Thornton, 1993a,b; Hine *et al.*, 2001). In other evoked potential studies recording time of MLR was shown to improve fourfold at a MLS rate of 89/s (Bell *et al.*, 2001).

Another approach to SNR improvement for MLS averaging was provided by Van Veen and Lasky (1994) who presented a general framework for the general arbitrary sequence stimulation. The general framework was then used to develop analytical expressions for relative efficiencies of conventional and MLS averaging. It was concluded that an infinite number of recovery sequences can be identified for a given sequence. The minimization of noise with the recovery functions was analyzed and optimized. The authors' formulation of the problem precluded the use of the frequency domain and interpreting the process as an equivalent filter. Thus, arriving to a simple general solution in the time domain proved difficult to achieve. Such a time domain generalized approach will undoubtedly provide great insight to the analysis of nonlinear effects (Lasky *et al.*, 1998). Linear effects, however, are better analyzed and interpreted in the frequency domain as shown in the present study.

In this study we derived a general formula for the noise attenuation effect of the MLS method based on our frequency domain formulation of the general deconvolution method (Özdamar and Bohórquez, 2006). This analytical approach shows that with the MLS deconvolution the SNR improves with the square root of half of the stimuli [Eq. (13)]. This improvement is less than what is achieved with the conventional averaging but definitely an advantage that can be achieved in addition to the SNR increase due to the sweep averaging. SNR improvement is also influenced by the number of zeros padded when the number of stimuli is small ($N<8$). This improvement, however, becomes negligible as the number of stimuli increase as shown in Fig. 5.

Noise attenuation factors computed by Eq. (20) are consistent with the SNR percentage measured by Marsh (1992) in controlled experimental recordings. For large number of zero paddings, attenuation factors of 0.87, 0.66, and 0.48 are obtained for 2, 4, and 8 stimuli, respectively (see Fig. 5). In experimental recordings Marsh (1992) obtained 0.87, 0.69, and 0.48 for the same number of stimuli which compares very favorably with the theoretical predictions.

Our experimental recordings also confirm this prediction. In Fig. 7 the noise attenuation percentage is 0.49 as computed by dividing the rms value of the raw EEG with that of the deconvolved EEG. This percentage compares very favorably with the calculated value of 0.48 for MLS_{15} sequence with several zeros as shown in Fig. 5.

As shown in our earlier paper, the deconvolution of overlapping responses can be achieved by arbitrarily selected stimulus sequences (Özdamar and Bohórquez, 2006). Depending on their characteristics, deconvolution by such sequences can result in attenuation or amplification of noise in different frequencies. Several sequences can be found that attenuate noise. As proven in Sec. II B, the MLS sequences, however, are unique in their noise elimination since they provide the maximum attenuation possible for a given number of stimuli.

The noise attenuation formulas of the MLS deconvolution show that this method is not as efficient as the conventional averaging method. With large number of zeros padded, only about 70% noise reduction can be achieved with the same number of stimuli used as in conventional averaging. This performance, however, can be degraded with adaptation which depends highly on the rate characteristics of the EP component (Picton *et al.*, 1992; Bell *et al.*, 2001).

MLS deconvolution averaging of AEPs may offer several advantages of decreased data acquisition time and increased test sensitivity to temporal stress on the auditory system at high rates. An additional advantage of the MLS deconvolution is the ability to analyze the nonlinear behavior of the human auditory system and other nonlinear systems, as shown by Shi and Hecox (1991). In prior studies, effective design of stimuli and acquisition paradigms using MLS were hampered by the lack of frequency domain SNR formulation. With the present formulation such studies can be designed quantitatively for a better understanding of the physiological properties of the auditory system considering the differential adaptation effects of different ISIs. In addition to shortening testing time, stress testing and separation of components (especially of event related potentials) at high rates will be important applications in the future.

(Received 1 September 2005; revised 20 December 2005; accepted 7 January 2006)

The time-course of the human medial olivocochlear reflex (MOCR) was measured via its suppression of stimulus-frequency otoacoustic emissions (SFOAEs) in nine ears. MOCR effects were elicited by contralateral, ipsilateral or bilateral wideband acoustic stimulation. As a first approximation, MOCR effects increased like a saturating exponential with a time constant of 277 ± 62 ms, and decayed exponentially with a time constant of 159 ± 54 ms. However, in ears with the highest signal-to-noise ratios (4/9), onset time constants could be separated into "fast," $\tau = \sim 70$ ms, "medium," $\tau = \sim 330$ ms, and "slow," $\tau = \sim 25$ s components, and there was an overshoot in the decay like an under-damped sinusoid. Both the buildup and decay could be modeled as a second order differential equation and the differences between the buildup and decay could be accounted for by decreasing one coefficient by a factor of 2. The reflex onset and offset delays were both ~25 ms. Although changing elicitor level over a 20 dB SPL range produced a consistent systematic change in response amplitude, the time course did not show a consistent dependence on elictor level, nor did the time-courses of ipsilaterally, contralaterally, and bilaterally activated MOCR responses differ significantly. Given the MOCR's time-course, it is best suited to operate on acoustic changes that persist for 100's of milliseconds.

I. INTRODUCTION

The medial olivocochlear reflex (MOCR) is one of several sound-activated feedback circuits that control the input to the mammalian hearing system (for a review see Guinan, 1996). Activating medial olivocochlear (MOC) fibers reduces the amplitude of basilar membrane motion in response to low-level sound by 10–20 dB at the characteristic frequency (CF) (Murugasu and Russell, 1996, Dolan *et al.*, 1997, Cooper and Guinan, 2003). Despite general knowledge about how the MOCR changes cochlear and neural responses to sound, a fundamental question remains, "What use is the MOCR?" Understanding how fast the MOCR produces its effects can suggest auditory processing that is affected by the MOCR; and quantification of the time constants that describe the MOCR time-course can help determine which cellular processes are involved by focusing attention on those processes with similar time constants.

The discovery that otoacoustic emissions (OAEs) (Kemp, 1978) are modulated by MOC activation (Mountain, 1980, Siegel and Kim, 1982) has led to the investigation of the MOCR in humans via its effects on OAEs. Several investigations have used OAE-based measurements to pursue the MOCR time-course (Kim *et al.*, 2001, Maison *et al.*, 2001a, Bassim *et al.*, 2003). However, interpreting the very different results from these transient and distortion-product otoacoustic emission (TEOAE and DPOAE) studies is complicated by intra-cochlear interactions such as two-tone suppression and by efferent activation by the test stimuli.

One way to avoid these complications is to use stimulus-frequency otoacoustic emissions (SFOAEs). SFOAE-based methods require only one low-level probe-tone thereby avoiding multiple frequency interactions, providing the most frequency-specific measure, and reducing the likelihood that the probe itself will elicit efferent activity (Guinan *et al.*, 2003).

We used an SFOAE-based method to quantitatively answer five questions: (1) How rapidly does the MOCR produce its effects in the cochlea? (2) How rapidly do those effects decay? (3) Is there a relationship between the buildup and decay? (4) Is there any difference in the time-course when more intense elicitor stimuli are used? (5) Is there any difference in the time-course between the ipsilaterally, contralaterally, and bilaterally elicited reflexes?

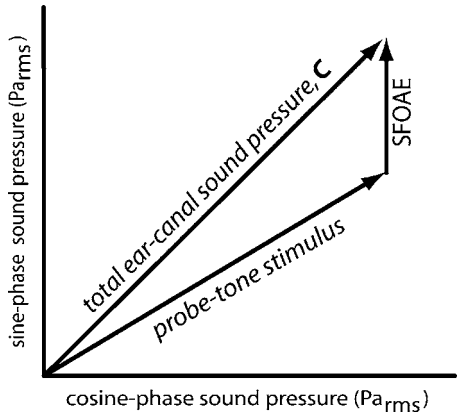

FIG. 1. Vector diagram representing the summation in the ear canal (EC) of two tonal components that differ in magnitude (length of arrows) and phase (direction of arrows). A tone stimulus (probe-tone) and the SFOAE it generates add to produce a compound-tone, **C**, that is measured as the EC sound pressure at the probe-tone frequency. If the probe-tone component and middle-ear transmission are invariant, any change in the measured EC sound pressure reflects a change in the SFOAE magnitude and/or phase.

II. METHODS

A. Overview

A "probe-tone" was played into the ear canal in order to generate an SFOAE from within the cochlea. This SFOAE combined with the probe-tone in the ear canal to produce a complex-valued compound-tone, $\mathbf{C}(t)$, that is the ear canal sound pressure at the probe-tone frequency (Fig. 1). If the acoustic probe-tone and middle-ear transmissions are invariant, e.g., if there are no middle-ear-muscle (MEM) contractions, changes in the compound-tone can be wholly attributed to changes in the SFOAE. Since activation of medial-olivocochlear (MOC) fibers reduces the sound-induced motion of the basilar membrane (BM) (Murugasu and Russell, 1996, Dolan *et al.*, 1997, Cooper and Guinan, 2003) it is likely that part or all of the MOCR inhibition of SFOAEs is caused by the reduction of BM motion.

We used a continuous (40 dB SPL) bilateral probe-tone[1] near 1 kHz (within 12%) to produce an SFOAE and to thereby create a compound-tone. A heterodyne technique (Kim *et al.*, 2001, Guinan *et al.*, 2003) was used to extract the magnitude and phase of the compound-tone across time, $\mathbf{C}(t)$, while a second acoustic stimulus, the elicitor, was introduced to activate the MOCR and thereby alter the SFOAE and the measured $\mathbf{C}(t)$. Changes in the compound tone, $\Delta\mathbf{C}(t)$, were calculated by vector subtracting the average pre-elicitor $\mathbf{C}(t)$—the average in a time window from 450 to 50 ms prior to elicitor onset—from each time point in $\mathbf{C}(t)$. The result, $\Delta\mathbf{C}(t)$, quantifies changes from the no-elicitor condition (for details see Guinan *et al.*, 2003).

We strove to keep the probe-tone stimulus invariant by using elicitor levels below middle-ear-muscle reflex (MEMR) thresholds and by asking subjects to be as still as possible during measurements. To test whether our elicitor levels ($\leqslant$60 dB SPL) were below MEMR thresholds, we performed "phase-slope MEMR tests" in which we calculated the phase-slope of $\Delta\mathbf{C}$'s produced by a 60 dB SPL wide-band noise elicitor (for details see Guinan *et al.*, 2003). No ears had measurable MEMR effects at elicitor levels of 60 dB SPL.

Since SFOAE amplitudes vary widely across frequencies and ears, our measurements of MOCR effects are reported in units relative to an estimate of the SFOAE amplitude. In other words, our MOCR measurements are *normalized* and are reported as "Δ**SFOAE**(t)" with normalized units of $\%|\mathbf{SFOAE}|$ (for detail see Appendix A). Without normalization one cannot compare the magnitude of MOCR effects on SFOAEs across ears and/or frequencies as the widely varying SFOAE amplitudes will be reflected in the responses.

B. MOCR elicitor stimuli

Two and a half second 60 dB SPL wide-band (100 Hz–10 kHz) noise bursts repeated every 5 s were used to activate the MOCR. Because wide-band noise induces two-tone suppression effects when presented into the measurement ear, we only used contralateral wide-band noise elicitors in the first set of experiments. When ipsilateral and bilateral activation of the MOCR was required (for looking at the ipsilateral and bilateral MOCR time-course) we used notched-noise elicitors. For these, a 2.1 octave spectral notch centered at the probe-tone frequency was used to remove energy from the wide-band noise elicitor at frequencies that produced measurable two-tone suppression effects (details in Appendix D).

C. Subjects and screening

Of 28 subjects screened for the study, nine young adult subjects, 19–30 years of age, were chosen to participate (8 female, 1 male). Participation was contingent on passing four tests: (1) A two-interval forced choice audiogram using 1/3 octave band noise bursts centered at 250 Hz, 500 Hz, 1 kHz, 2 kHz, and 4 kHz was used to insure subjects had normal hearing in both ears (within 20 dB re: ANSI pure tone thresholds); (2) measurements of spontaneous emissions in quiet were used to insure that the probe-tone was at least 50 Hz from any spontaneous emission[2] greater than −5 dB SPL; (3) a MEMR phase-slope test was used to insure that MOCR effects dominated the measured changes in the compound-tone; and (4) a signal to noise ratio (SNR) test[3] was applied to the results and was used to select those subjects for whom turning on the elicitor noise produced a clear, strong and consistent $\Delta\mathbf{C}(t)$ signal.

D. Choosing a probe-tone frequency

Selecting ear/probe-tone-frequency combinations that produced large SFOAEs and thereby high SNR measurements was important for looking at details of the MOCR time-course. For this reason, each subject was initially measured at 11 or 12 probe-frequencies (20 Hz steps from 900 to 1100 Hz or from 900 to 1120 Hz); and then the ear/probe-tone-frequency combination that yielded the largest $\Delta\mathbf{C}(t)$ response was selected for further measurements. Initial measurements used 40 dB SPL continuous bilateral probe-tones and 60 dB SPL bilateral wideband noise elicitors

TABLE I. Stimulus types (top panels) and stimulus presentation timings (bottom panel) for all measurements. To form a measurement, an even number (44-816 depending on SNR and subject availablity) of presentations were made and the acoustic responses were averaged.

*** With raised cosine ramps (5 ms rise/fall) and alternating polarity on successive trails.

(2500 ms in duration). The response was taken to be the average $|\Delta \mathbf{C}(t)|$ in a post elicitor window, 50 to 150 ms after elicitor cessation.

E. Measurement procedure

Subjects were comfortably seated in a sound-dampening chamber during 30 min measuring sessions that were interleaved with 15 min breaks. Some subjects took several hours to measure and were measured over multiple days.

In every session, two earphones (Etymotic Research ER10c) each containing two sound sources and one microphone were fitted in the subject's ear canals, one in each ear. To eliminate potential distortion, one source from each ER10c was allocated exclusively to the continuous probe-tone stimulus while the second source was used for the elicitor (or suppressor) stimulus. Calibrations were done at the beginning, during, and at the end of every measuring session to insure proper sound pressure levels for all stimuli. Stimuli were created digitally (sampling rate of 20 kHz) and stimulus levels were set by attenuators (0.1 dB accuracy). A raised cosine ramp (5 ms rise and fall) reduced spectral splatter for the pulsed stimuli. Microphone signals were digitized using the same 20 kHz sample timer used for stimulus generation.

Elicitor and suppressor stimuli were adjusted to suit each measurement type (see Table I). For instance, because MOCR effects develop slowly compared to two-tone suppression effects, the stimulus durations for noise elicitors used in MOCR measurements (and also in the MEMR test) were 2500 ms while the stimulus durations for suppressor-tone stimuli used for SFOAE estimation were either 500 ms or 200 ms. MOCR elicitors were 60 dB SPL wideband (100 Hz–10 kHz) noise except during (a) level-dependence experiments where 40, 45, 50, 55, and 60 dB SPL elicitors were used and (b) laterality-dependence experiments where the elicitor was a 60 dB SPL wideband noise with a 2.1 octave spectral notch centered at the probe-tone frequency. Suppressor-tone stimuli were 60 dB SPL tones placed −110 Hz below the probe-tone frequency (except during suppression bandwidth measurements for which the suppressor-tone frequency was varied).

Every measurement consisted of an average of an even number of presentations. Elicitor (or suppressor) polarities

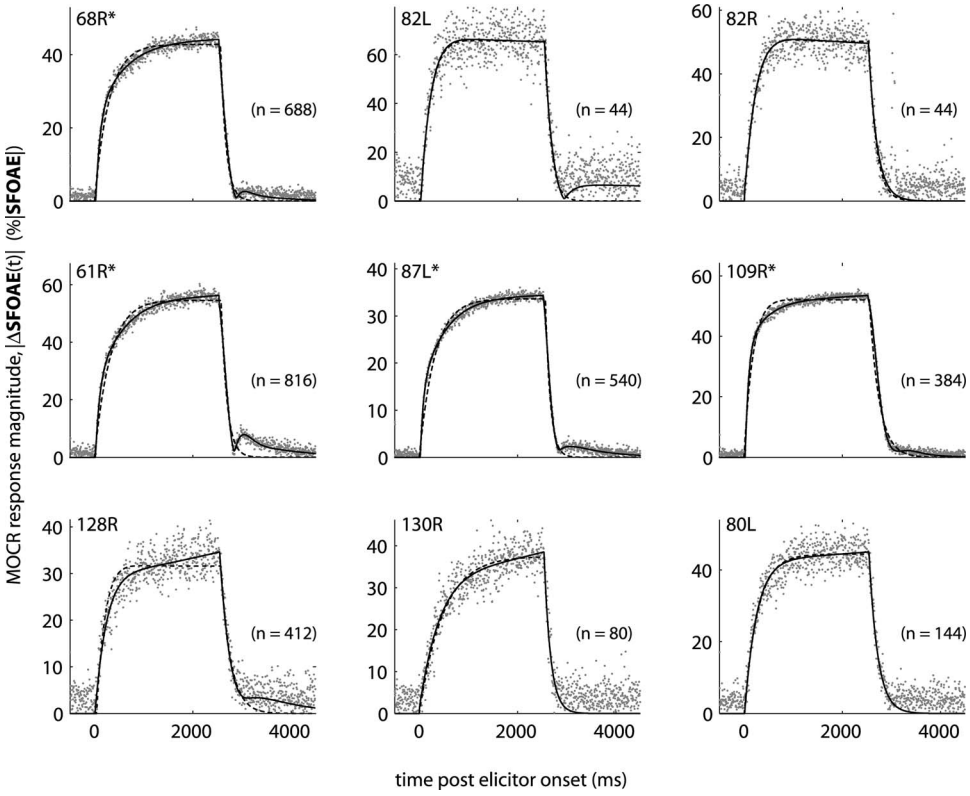

FIG. 2. MOCR time-courses for 9 ears (no special order). Responses were evoked by contralateral wideband noise (60 dB SPL). Repetition interval was 5 s and n is the number of responses that were averaged for each measurement. Points are data samples (5 ms resolution), dashed curves are single exponential characterizations, and solid curves are sum of exponentials characterizations of the data. The four subjects with *'s are those with the four highest SNRs.

were alternated on successive presentations to cancel their acoustic contributions to the averaged EC sound pressure. This manipulation did not appear to have any effect on the emission.

F. Mathematical characterizations of the responses

Each MOCR response waveform, $\Delta\mathbf{SFOAE}(t)$, was characterized mathematically to quantify its time-course. We sought to characterize each waveform's rising curvature, decaying curvature, onset delay, and offset delay (for equations and details see Appendix B).

1. "Single complex exponential" characterization

Our first characterization used a single complex saturating exponential term to represent the rising curvature, a single complex decaying exponential term to represent the decaying curvature, and included onset and offset delay parameters (the amount of time between elicitor onset or offset and a change in the response). This "single complex exponential" characterization provided reasonable approximations to the curvatures and was useful for the purpose of assigning an *overall onset time constant* and an *overall decay time constant* to the rising and decaying portions of the waveforms, respectively.

2. "Sum of complex exponentials" characterization

Although the single complex exponential characterizations captured the basic curvatures of the waveforms, subjects with high SNR measurements produced curvatures that differed visibly from their single complex exponential characterization (e.g., a bounce in the decay of subject 61R in Fig. 2). To describe these waveforms better, a more complicated mathematical characterization, using a sum of complex exponential terms, was made (for details see Appendix B). These "sum of exponentials" characterizations better approximate the waveforms and they were used to quantify the onset and offset delays; and when the SNR was large enough, they were used to extract and quantify multiple time constants.

III. RESULTS

A. The contralateral MOCR time-course

Both the amplitude and phase of SFOAEs were affected by MOCR activation; however, since most important aspects of the time-course can by shown by the amplitude alone, this paper focuses on amplitude changes. The MOCR manifested its effects on the amplitude of SFOAEs over 100's of milliseconds and produced onset rises and offset decays that looked roughly like saturating and decaying exponentials (Fig. 2).

1. MOCR overall onset and decay time constants

We assigned a single overall time constant to the rising and falling portion of each MOCR response (associated curves have dashed lines in Fig. 2). Estimates of overall onset and decay time constants varied from ear to ear, spanning 178–400 ms for the onset and 104–259 ms for the decay. For 7 of 9 ears the decay was more rapid than its buildup (Fig. 3). Only ear 109R showed the opposite trend significantly with an overall onset time constant of 178±3.2 ms, 35 ms faster than its overall decay time constant (213±3.0 ms). There was an apparent but not statistically

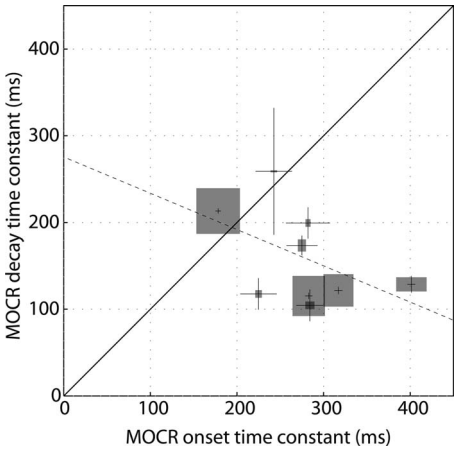

FIG. 3. MOCR overall onset vs. decay time constants for 9 ears show that MOCR effects generally buildup more slowly than they decay. Error bars =1 SD (for details see Appendix B3). To emphasize more accurate data points, i.e., those with small error bars, rectangles, whose areas represent relative accuracy, are centered on each data point (bigger area means more accurate).There was an apparent inverse relationship between the speed of the buildup of MOCR effects and the speed of the decay of those effects (dashed line, $R=-0.48$, $P=0.15$).

significant inverse relationship between the speed of the MOCR's onset and decay (as shown by the dashed line in Fig. 3, $R=-0.48$, $P=0.15$).

2. MOCR effects can decay with an overshoot

While the rising phase of each response was monotonic and appeared to approach a steady state like a saturating exponential, the decaying portion in 6 of 9 ears exhibited a "bounce" that defied exponential decay (see Fig. 2). This bounce led us to pursue a more complicated sum of complex exponentials characterization.

With a 3 term sum of complex exponentials we were able to mathematically characterize the bounce. The decay curvatures of the 4 highest SNR subjects (61R, 87L, 68R, and 109R) were well approximated by the combination of an under-damped sinusoid and a "long"[4] decay time constant (see Appendix C) indicating that the observed bounces were in fact an overshoot. In other words, as the SFOAE re-equilibrates to its pre-MOCR activation level (upon elicitor cessation), it can overshoot that level. Phase data (not shown) corroborates the overshoot.

3. The MOCR overall onset time constant is primarily a combination of "fast" and "medium" underlying time constants

The sum of exponentials characterization was also a better approximation of the MOCR's onset response, as evidenced by higher goodness-of-fit values, R^2. For the four highest SNR ears, the MOCR onset time constants (Table II) were found to be composed of a mixture of fast, ~70 ms, medium, ~330 ms, and slow, ~25 s, time constants with the bulk (88%–93%) of the curvatures determined by the fast and medium time constants. As shown in Table II, ears 61R and 109R differed widely in their overall onset time constants (317±4.59 ms versus 179±3.2 ms), yet their fast and medium underlying onset time constants were similar (69±31 ms versus 65±10 ms and 331±106 ms versus 294±68 ms). For these subjects, it was a different mix of fast and medium underlying onset time constants that produced their different overall onset time constants. Subjects 61R, 68R, 87L, and 109R all had sufficient SNR to allow the extraction of fast, medium, and slow onset time constants. All generated qualitatively consistent slow onset time constants (10s of seconds) and quantitatively similar fast (~70 ms) and medium (~330 ms) onset time constants (Table II).

Slow onset time constants could be extracted even though the measurements recorded only 2.5 s of onset and thus were not geared to detecting slow onset time constants. Values for the slow onset time constant ranged from 11 to 39 s. It was not possible to put an upper bound on all these estimates because the relatively brief MOCR elicitor,

TABLE II. Onset and decay time constants and their % contributions to contralateral MOCR time courses for 9 ears. Subjects 61R, 68R, 87L, and 109R had sufficiently large SNR to extract multiple time constants for the rising curvature. Numbers on the left are time constants in ms and the numbers on the right in parenthesis are their relative % contribution to the time course. Low SNR subjects (80L, 82L, 82R, 128R, and 130R) could not distinguish "fast" time constants from "medium" ones. MOCR decay time constants could not be well approximated by a mixture of underlying time constants, but did include a "long" decay time constant. "±" are the estimated standard deviations (see Appendix B).

Ear	Fast onset time constant (ms) and (%)	Medium onset time constant (ms) and (%)	Slow onset time constant (s) and (%)	Overall onset time constant (ms)	Overall decay time constant (ms)	Long decay time constant (ms) and (%)
61R*	69±31 (27%±12%)	331±106 (61%±11%)	~18 (12%±4%)	317±5	122±5	918±97 (14%±1%)

130R	404±50 (79%±5%)		~11 (21%±5%)	401±5	129±10	unmeasureable

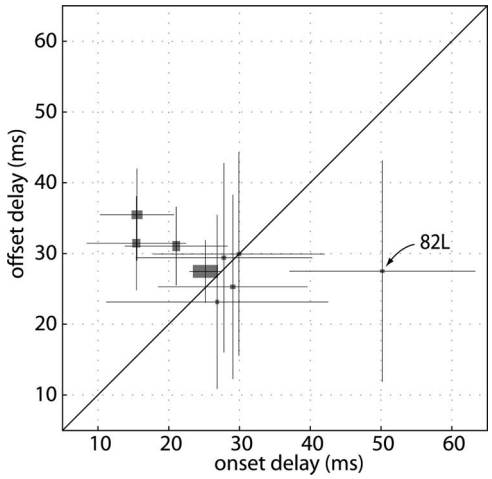

FIG. 4. MOCR onset vs offset delays for 9 ears show that both are near 25 ms. Error bars=1 SD. To emphasize more accurate data points, i.e., those with small error bars, rectangles, whose areas represent relative accuracy, are centered on each data point (bigger area means more accurate). Subject 82L's large onset delay value is probably a result of this subject's response not completely decaying to zero between presentation intervals, see Fig. 2.

2.5 s, did not allow us to sample enough of the curvatures. It was possible, however, to put a lower bound on the estimates.[5] Ear 130R produced a slow time constant >5.9 s (with 95% confidence) and all other ears produced ones >10.0 s. The average slow onset time constant estimate across ears was 24 s.

4. MOCR onset and offset delays are both near 25 ms

Onset and offset delays were calculated from the sum of complex exponentials characterizations (see Appendix B) and were generally between 15 and 40 ms (Fig. 4). Ear 82L produced a 50 ms onset delay but this subject had a very low SNR and was the only subject for which the response did not entirely decay to zero, which complicated detecting the response onset. In summary, the MOCR began to respond to an acoustic stimulus within 10's of milliseconds, and began to shut off just as quickly. Both the onset and offset delay were near 25 ms.

5. A second-order model can describe the MOCR time-course

By comparing the parameters from the sum of complex exponentials characterization with similar parameters from a simple second order system, it was found that a simple second-order model could largely account for the rising and decaying time-courses of the responses. Furthermore, the difference between the rising and decaying time-courses could be re-produced by changing the "damping factor" (i.e., the coefficient of the first derivative term in the model) by a factor of 2 while keeping all other model elements constant (see Appendix C).

B. MOCR time-course, elicitor level dependence

1. No consistent systematic dependence of MOCR time-course on elicitor level was observed

To investigate whether the MOCR time-course is affected by elicitor sound level, a second experiment was carried out on 4 of the original 9 ears using contralateral wideband noise elicitors at sound levels of 40, 45, 50, 55, and 60 dB SPL. Ears, 80L and 68R did not initially produce a measurable response at 40 dB SPL and further attempts to measure this level on those ears were abandoned.

Waveform curvatures were similar for the elicitor levels tested; and there was no obvious consistent and systematic effect of elictor level on the time course across subjects (Fig. 5). Ear 61R's overshoot was larger for larger elicitor levels both in absolute value and as a percentage of the maximum magnitude. In contrast, subject 68R had a constant percentage overshoot (8.6%). Neither the delays nor the MOCR time constants showed statistically significant systematic dependence on elicitor level (Fig. 6).

2. MOCR growth function

MOCR response amplitude increased in proportion to elicitor level almost linearly at $\sim 2\%$ per dB SPL (Fig. 7), over the elicitor range we sampled. Correlation coefficients (R values in Fig. 7) from linear least squares regression for 3 of the 4 ears strongly suggested a linear relationship. Ear 61R had a slightly lower correlation coefficient. At the highest level, 61R produced the largest response of the group, one that departed from the linear trend. This could be an early sign of reflex saturation; perhaps for this ear the 60 dB SPL elicitor was beginning to maximally stimulate the reflex or perhaps at 60 dB SPL that particular SFOAE was becoming suppressed as much as could be measured. Using higher level elicitors to determine the saturation point was not possible because of confounding middle-ear-muscle activation.

C. Time-courses of the ipsilaterally, contralaterally, and bilaterally activated MOCR

To investigate the differences between ipsilaterally, contralaterally, and bilaterally activated MOCR time-courses, a third experiment was carried out on 3 of the original 9 ears. For this experiment, elicitors were presented ipsilaterally (re: the measurement ear), contralaterally, or bilaterally. Since activating the MOCR ipsilaterally or bilaterally requires that the elicitor be presented together with the probe-tone, we developed a stimulus that would minimize interactions (e.g., two-tone suppression) that caused non-MOCR mediated changes in the SFOAE. A "notched-noise" elicitor was chosen. The notch, a 2.1 octave spectral notch centered at the probe-tone frequency, was designed to remove all energy at those frequencies that produced measurable two-tone suppression effects (Appendix D).

1. No systematic dependence of MOCR time-course on elicitor laterality

Ipsilaterally, contralaterally, and bilaterally activated MOCR responses produced waveform curvatures (Fig. 8) for which neither the delays nor the single time constants

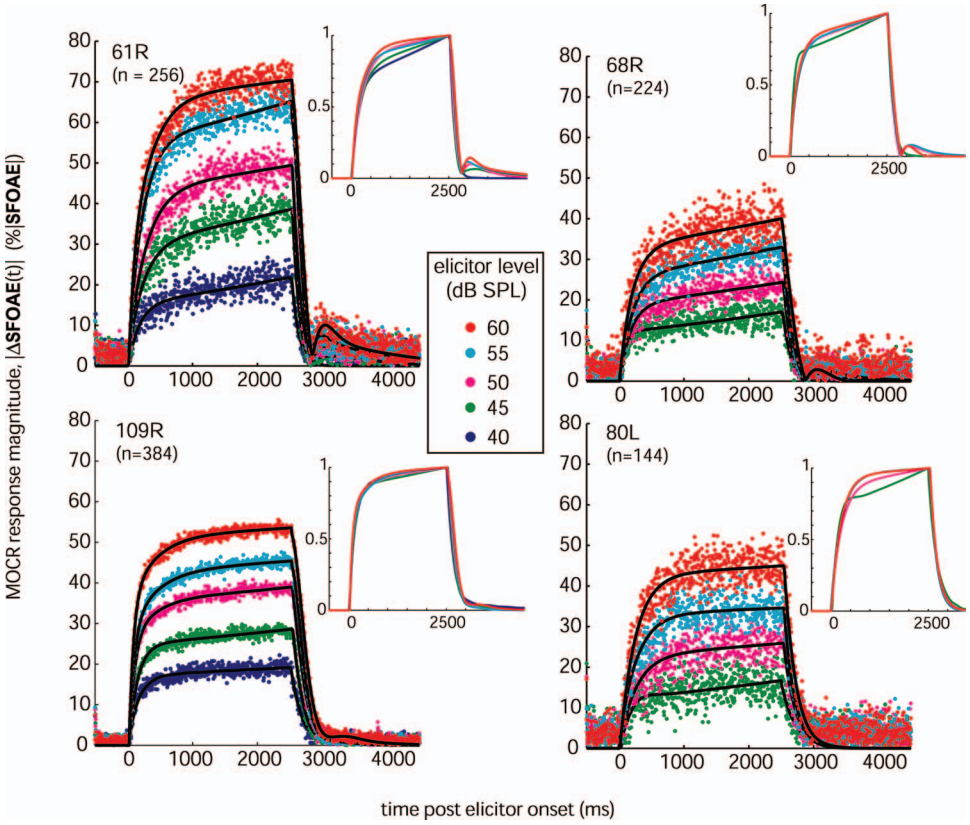

FIG. 5. MOCR responses for wideband contralateral elicitors at various elicitor levels show that while response amplitudes changed in a consistent and systematic way with elicitor level the time courses were qualitatively similar across levels (four subjects). Repetition interval was 5 s and n is the number of responses that were averaged for each measurement. Elicitor was on at 0 ms and off at 2500 ms. Solid lines are sum of complex exponentials characterizations of the waveforms. Insets show the characterizations normalized and overlaid to allow a comparison of time course vs. elicitor level (coded by color).

showed any systematic dependence on elicitor laterality (Fig. 9). Subjects 68R and 109R produced greater responses during contralateral activation than during ipsilateral activation; the opposite was true for subject 82L.

2. MOCR can exhibit binaural interaction

How do the ipsilateral and contralateral limbs of the MOCR combine when activated together? One hypothesis is that the two effects add. To test this, we added the three-term characterizations of the ipsilaterally and contralaterally elicited responses (complex addition at each time point) and compared the result with bilaterally elicited responses. Two of three ears (68R and 82L) agreed with the addition hypothesis. Ear 109R, however, departed significantly from the hypothesis producing a lower bilateral response (by a factor of 0.8) and a greater phase (+20 degrees, not shown) than would be predicted by simple addition. Although the magnitude of 109R's response was not predicted by the simple addition hypothesis, the "shape" of this response on the complex plane was predicted by the simple addition hypothesis, and this was true for all three subjects.

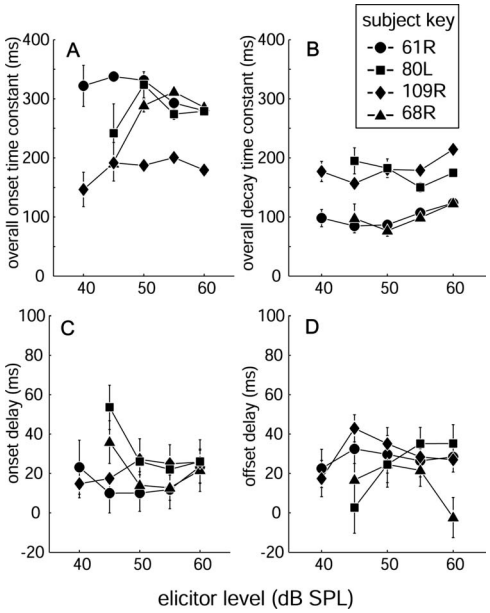

FIG. 6. MOCR overall onset and decay time constants (panels A and B) and onset and offset delays (panels C and D) vs contralateral elicitor level for four subjects show no consistent systematic dependence on elicitor level. Error bars=1 SD.

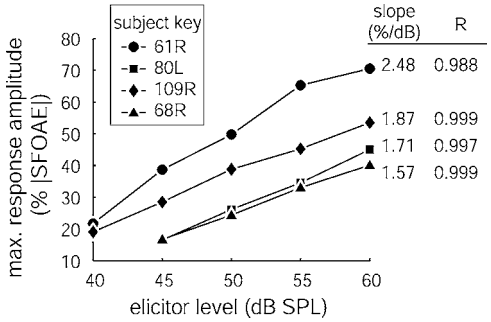

FIG. 7. Growth of MOCR, response amplitude vs. contralateral elicitor level shows an almost linear growth (correlation coefficient, R, from linear least squares regression, is close to 1). Standard deviations are smaller than the symbols.

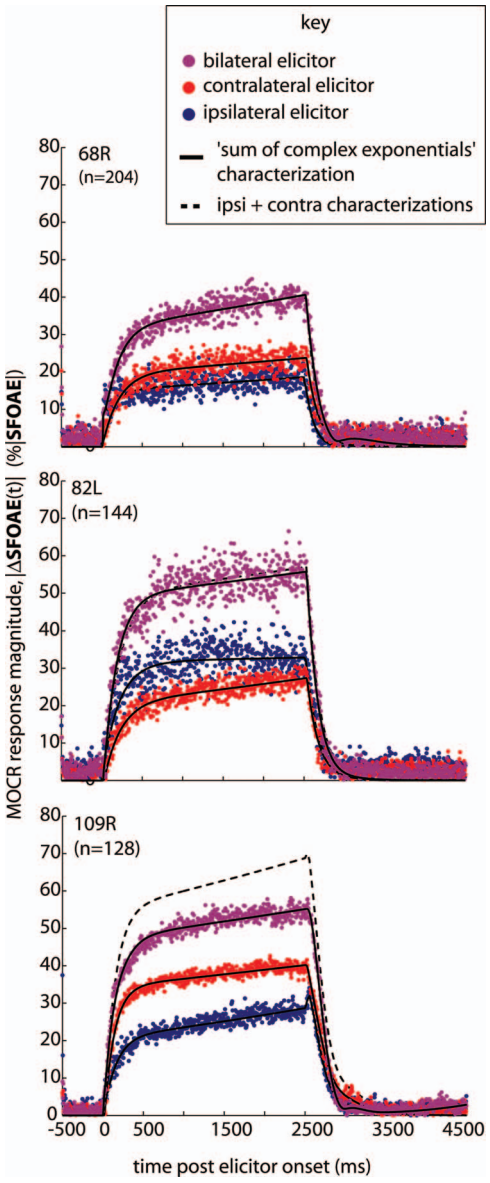

FIG. 8. MOCR response waveforms for notched-noise elicitors presented ipsilaterally, contralaterally, and bilaterally in three subjects show that the waveforms were similar across laterality. Complex addition of the ipsilaterally and contralaterally activated responses (dashed lines) predicted the bilaterally activated response for subjects 68R and 82L, but not for subject 109R. Elicitor was on between 0 and 2500 ms, repetition interval was 5 s and n is the number of responses that were averaged for each measurement.

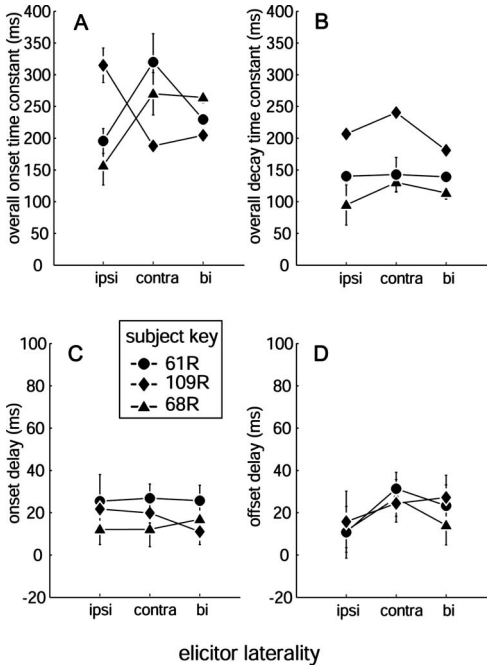

FIG. 9. MOCR overall onset and decay time constants (panels A and B) and onset and offset delays (panels C and D) vs elicitor laterality for three subjects show no systematic dependence on elicitor laterality.

IV. DISCUSSION

A. MOCR time constants

1. Onset time constants compared with previous work

We observed similar MOCR time-courses across all ears including similar, but not identical, overall onset (277±62) and decay (159±54 ms) time constants. The subset of ears that provided high SNR (4 of 9 ears) enabled us to probe the details of their time-courses which revealed (a) the existence of 3 underlying onset time constants, τ_{fast}=60–80 ms, τ_{medium}=290–350 ms, and τ_{slow}=10s of seconds, and (b) that the responses decayed like under-damped sinusoids with an overshoot—the under-damped sinusoid accounted for >70% of the curvatures—and also included an exponentially decaying component with a long time constant, τ_{long} =400–900 ms.

Previous data on the human MOCR time-course come from a variety of OAE measurements. Early data are accessible from a study investigating changes in spontaneous otoacoustic emissions (SOAEs) due to contralateral acoustic stimulation (CAS) (Mott *et al.*, 1989). Here CAS-induced SOAE frequency shifts (which were more salient than concurrent amplitude changes) required 40–200 ms to reach 25% of their final value, corresponding to onset time constants of 139–695 ms, and consistent with our overall onset time constant values (Table II).

Another MOCR time-course measure comes from the effects of CAS (30 dB SL, 80 or 244 ms duration wideband noise) on transiently evoked otoacoustic emissions (TEOAEs) (Maison *et al.*, 2001b). In this study, MOCR effects appeared to grow roughly linearly from 0 to 60 ms post CAS onset and then remain almost constant thereafter. This time-course is different from that found by other studies. The discrepancy may be due to limitations of the experimental method and the fact that the 60 dB SPL click stimulus used has been shown to also be an effective MOCR elicitor (Guinan *et al.*, 2003).

The most extensive previous studies of the human MOCR time-course used distortion product otoacoustic emissions (DPOAEs). These studies measured changes in DPOAEs due to CAS or adaptation (Kim *et al.*, 2001, Bassim *et al.*, 2003). DPOAE adaptation time-courses were fit with 2 exponentials: One with a fast time constant, 10 ms$<\tau_{fast}<$350 ms (median ~70 ms), and another with a slow time constant, 350 ms$<\tau_{slow}<$5.5 s (medians 1.5 and 2.1 s from two studies). While the 70 ms time constant[6] matches our fast onset time constant (Table II), the 1.5–2 s

time constant is notably absent from our data. One explanation comes from a DPOAE adaptation study in cat where a ~1 s onset time constant was observed and persisted after complete OCB section showing that it was mediated by intrinsic cochlear processes, not the MOCR (Liberman *et al.*, 1996). Counter to this explanation, Bassim *et al.* (2003) reports roughly similar ~1 s time constant for changes in DPOAEs due to either CAS or adaptation.

Another difference between our data and the DPOAE data is that onset time constants of ~300 ms and ~10s of s are present in our data but were not noted in the DPOAE studies. Kim *et al.*, did observe a peak in their time constant histogram at the maximum obtained value of 5.5 s, and suggested that longer stimuli and recording durations would be necessary to determine these time constants accurately. A similar comment can be made about our slowest onset time constants, $\tau_{slow} \sim 10$s of s. Our fitting procedures showed that there were such slow time constants. We were able to put a lower bound, $\tau_{slow} > 5.9$ s, on the slow time constant so it cannot correspond to the 1 to 2 s time constant reported in the DPOAE data (Liberman *et al.*, 1996, Kim *et al.*, 2001, Bassim *et al.*, 2003). Histograms of the time constants obtained via DPOAEs give hints of more peaks than the 2 time constants put forward by Kim *et al.* (2001) and Bassim *et al.* (2003). It seems likely that higher SNR DPOAE measurements would have revealed more details of the time-course, including more than two onset time constants. However, pursuing the MOCR time-course using DPOAE adaptation is complicated because (1) DPOAEs are composed of two underlying OAE sources with different properties that may behave differently under MOCR activation and (2) DPOAE adaptation can be mediated by intrinsic cochlear effects in addition to the MOCR activation. Presumably it is these complexities that cause MOCR activation to sometimes increase DPOAE levels;[7] furthermore these complexities may explain the wide scatter in DPOAE-based measures of MOCR time constants. Until these complexities are understood, it is difficult to appreciate the MOCR time-course via a DPOAE method.

SFOAE-based methods are better suited to MOCR time-course investigation. They are able to measure the time-course in individual subjects, and are easier to interpret than those considered above because they require only a single low-level (40 dB SPL) probe-tone in the measurement ear, one that does not appear to activate the MOCR itself (Guinan *et al.*, 2003). While a suppressor was used to normalize the data, and could be considered a complication, normalization does not affect the time-courses of the measurements.

There are limits to the present study. Specifically, the MOCR time-course reported here applies only to our measurement conditions, i.e., bilateral 40 dB SPL probe tones near 1 kHz, wide-band noise elicitors (flat spectrum and notched), and subjects that were awake but with unmonitored arousal states. It is possible that other conditions, for example other elicitors, e.g., narrow-band noise elicitors, tones, clicks, etc., would produce different results. Another limitation is that we used only noise elicitors of moderate to low levels. At high-levels, where the MOCR appears to afford protection from acoustic trauma (Rajan, 1988, Maison and Liberman, 2000, Rajan, 2000), the time-course of efferent effects might be different. Finally, our study involved only 9 ears.

2. Onset time constants compared with cellular processes in outer hair cells (OHCs)

The fast (~70 ms) onset time constant we report was also found in many other cochlear measurements in animals involving MOC activation: Basilar membrane motion, otoacoustic emissions, cochlear microphonic, endolymphatic potentials, compound action potentials, and single auditory nerve fiber recordings (Fex, 1962, Desmedt *et al.*, 1971, Warren and Liberman, 1989, Cooper and Guinan, 2003). Such universal presence indicates that the 70 ms time constant is a fundamental time constant of the MOCR.

Evidence for one possible cellular correlate for the ~70 ms time constant comes from measurements of the calcium (Ca^{2+})-mediated potassium (K^+) current found in OHCs (Housley and Ashmore, 1991, Fuchs and Murrow, 1992, Sridhar *et al.*, 1997). Animal work on guinea pig isolated outer hair cells (OHCs) has shown that upon application of acetylcholine (ACh), an outward K^+ current develops with a time constant of 70 ± 14 ms (Evans *et al.*, 2000) but these measurements were done at room temperature and the actual K^+ current time constant at body temperature is likely to be faster. The K^+ current is a result of the change in intracellular calcium concentrations due to an influx of Ca^{2+} through MOC synapses. Could this be what gives rise to the universal ~70 ms time constant?

Ca^{2+} concentrations in the basal end of OHCs following the application of ACh have also been seen to increase on a ~300 ms time scale (Evans *et al.*, 2000) presumably through a different mechanism. It is possible that the ~330 ms time constant we report is related to Ca^{2+} release from local subsynaptic cisternae involving ryanodine receptors (Sridhar *et al.*, 1997).

Evidence of a slow (10s of s) onset time constant (Table II) has been previously reported in guinea pig ($\tau_{slow} = 34 \pm 9$ s) (Sridhar *et al.*, 1995, Sridhar *et al.*, 1997). In addition, a study on guinea pig basilar-membrane (BM) motion found that BM motion is inhibited by MOC activation on fast (10–100 ms) and slow (10–100 s) time scales and these data indicate that the slow effect has a different mechanical origin (Cooper and Guinan, 2003) than the fast effect.

A possible OHC cellular correlate for τ_{slow} comes from the observations that (1) application of ACh to isolated OHCs results in a decrease of OHC axial stiffness on a slow time scale (~20 s), and (2) increases in intracellular Ca^{2+} cause the OHC cell body to elongate on the slow time scale (Sziklai *et al.*, 1996, Dallos *et al.*, 1997, Frolenkov *et al.*, 2003). The decrease in OHC stiffness appears to involve OHC regions far from MOC-OHC synapses. Perhaps the slow time constant is due to the time it takes for Ca^{2+} to migrate up the OHC[8] and affect the cytoskeleton (Evans *et al.*, 2000).

Whether, the above postulated origins for these onset time constants are correct or not, the rough correspondence between the fast, medium, and slow time constants we measured and those found in OHCs suggest that OHC cellular

processes could account for the majority of the MOCR time-course. Other possibilities do not look as promising. Post stimulus time histograms (PSTH) from recordings of single MOC neurons responding to tone bursts showed that MOC firing rate decreased over time (i.e., MOC neurons adapted) with a time constant of ~68 ms (Brown, 2001). The MOCR effects we measured *increased* monotonically with continued stimulation, thus we did not see any effect of adaptation in our MOCR time-courses. The MOCR time-course we observed could conceivably be caused by recruiting more and more efferent fibers as the stimulus persists. However, since OHCs have been shown to have processes that evolve with time-courses similar to the MOCR time-course, a more likely explanation is that a majority of the time-course is generated downstream of MOC neurons.

B. Onset and offset delays

Our best estimates of onset and offset delays (i.e., the time between elicitor onset or offset and a change in the observed response) put these values at ~25 ms for both. Previous studies found a large range of contralateral reflex latencies (Mott *et al.*, 1989, Lind, 1994, Giraud *et al.*, 1997, Hill *et al.*, 1997, Maison *et al.*, 2001b) though the methods used in these studies varied greatly in their ability to accurately detect the latency.

Our measured reflex delays can be divided into three components: (1) A neural delay,[9] defined as the delay from sound onset (or offset) to the firing (or decrease in firing) of MOC neurons at their OHC synapses; (2) an MOC-OHC synaptic delay, which includes the delays within OHCs; (3) a reverse otoacoustic delay, the delay for the MOC-induced change to appear as a change in the SFOAE in the ear canal. One theory puts the reverse otoacoustic delay at approximately half of the overall SFOAE delay (Zweig and Shera, 1995) or ~5 ms, another theory puts it close to 0 (Siegel *et al.*, 2005). The minimum neural delay in experimental animals is approximately 5 ms (reviewed by Brown *et al.*, 2003) but the latency of most neurons varies with sound level and is typically ~20 ms at 10 dB above the neuron's threshold. Thus, there is between 0 and 20 ms left for the MOC-OHC synaptic delay although the true synaptic delay is probably much less than 20 ms. There could be as little as only a few ms synaptic delay for MOC activity to begin to increase the flow of calcium into the OHC postsynaptic region and produce a measurable MOC effect.

The accuracy of our latency measures (SDs=15 ms) combined with the small range of levels tested (20 dB range) prevented us from determining whether MOCR latencies were level dependant as has been reported for individual MOC fibers (Brown, 1989). However, a strong systematic (e.g., slope=30 ms/10 dB) level dependence is unlikely.

C. MOCR decay and onset time-courses appear to be governed by a single second-order system

Both the onset and decay of MOCR responses can be fit to a second-order system and only one system parameter needs to be changed to account for the elicitor-on/elicitor-off difference (Appendix C). The onset time-course, by itself, can be produced by separate, single-time-constant processes. The decay time-course, on the other hand, shows an overshoot like a decaying sinusoid that cannot be produced by separate, single-time-constant processes. The finding that a second-order system can account for 70%–90% of both time-courses (Table II and Appendix C) by allowing one parameter to change by a factor of 2 is evidence that the MOCR's onset and decay are governed by the same second-order system. In short, one system can account for the bulk of the time-course, giving rise to the two faster onset time constants as well as the decay overshoot. Considering the similarity of the MOCR time constants with those from various OHC measurements, this "one system" seems likely to be in OHCs.

D. Time-course evidence for binaural interaction

Two of three subjects produced bilaterally activated MOCR responses that were well approximated by the sum of the ipsilaterally and contralaterally activated responses, i.e., they showed no binaural interaction of the reflexes (Fig. 8). In contrast, ear 109R produced a lower bilateral response than the sum of the unilateral responses, indicating a binaural inhibition. Possible sources for this binaural inhibition include central reflex inhibition and/or a saturation of the MOC effect in the periphery.

Binaural interactions that were a function of elicitor interaural time difference have been recently reported (Kemp *et al.*, 2005). Our experiments used the same elicitor noise in both ears and, therefore, could not detect binaural interactions that required different signals in the two ears.

E. Implications of the MOCR time-course for the role of the reflex in hearing

The human MOCRs time-course is best suited to operate on acoustic changes that persist for 100's of ms or longer. This conclusion is based upon the fact that overall MOCR effects in the cochlea build up and decay over a time scale of 100's of milliseconds. Time constants of 10s of seconds are also present. Consequently, MOCR is not fast enough to be operating on the information-carrying envelope of speech or to provide any protection from isolated loud impulse noises, such as gunshots (Wagner *et al.*, 2005). The time-course is, however, consistent with other roles that have been postulated for the MOCR: Protection (from long-lasting, >100 ms loud sounds) (Rajan and Johnstone, 1983, Reiter and Liberman, 1995), dynamic range adjustment (Geisler, 1974, Winslow and Sachs, 1988), signal detection in noise (Winslow and Sachs, 1988, Kawase *et al.*, 1993), and aiding selective attention (Hernandez-Peon, 1956, Meric and Collet, 1994).

The MOCR and the MEMR respond differently to increasing acoustic elicitor levels. MEMR response onset latencies and onset time constants decrease with increasing elicitor level (Moller, 1961), but MOCR latencies and time constants appear to depend very little on elicitor level (Fig. 6). In addition, MEMR responses wane in the presence of continuing low-level elicitors, but do not adapt for high-level elicitors (Dallos, 1964). Furthermore, the MEMR has a high threshold. These MEMR time-course properties are useful

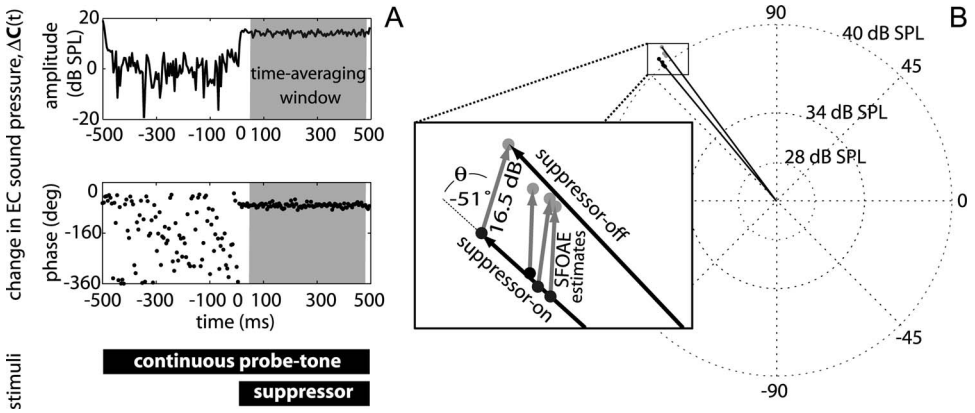

FIG. 10. Panel A shows how the change EC sound pressure (relative to the average pre-suppressor EC pressure across $t=-450$ to -50 ms) during a two-tone suppression measurement is used to estimate an SFOAE amplitude. Vector time-averaging the change in EC sound pressure due to the suppressor-tone (i.e., across shaded region, 50–450 ms) produced an estimate of the native SFOAE. Panel B shows the repeatability of the estimate of SFOAE by plotting four such SFOAE estimates (grey vectors) made at different times for the same subject, ear, and probe-tone frequency. The SFOAE vector labeled 16.5 dB SPL in panel B was obtained from the measurement shown in panel A. The raw suppressor-off and suppressor-on vectors (from time averaging over the same shaded window prior to subtraction, and not shown in panel A) are also shown. Stimulus parameters were: probe-tone frequency=1.04 kHz, probe-tone level =40 dB SPL, suppressor-tone frequency=930 Hz, suppressor-tone level=60 dB SPL, subject 87L.

for a reflex serving a protective role, the primary role of the MEMR. The MOCR time-course, on the other hand, shows little or no dependence on elicitor level (Fig. 5) and has a lower threshold so that it is acting throughout most of the range of hearing. In other words, over the measurable range of elicitor levels for both reflexes, there is a fundamental difference in the way the two reflexes respond to increasing elicitor levels. This difference broaches the possibility of different primary functions for the two reflexes.

The pupillary light reflex is similar to the MOCR in that it operates over 100's of milliseconds. The function of the pupillary light reflex is to adjust the amount of light entering the eye in order to optimize visual acuity (Campbell and Gregory, 1960). Perhaps the MOCR does a similar thing for sound and the ear.

ABBREVIATIONS

BM = basilar membrane
$\mathbf{C}(t)$ = time varying complex compound-tone (measured)
CAS = contralateral acoustic stimulation
CF = characteristic frequency
CM = cochlear microphonic
DPOAE = distortion-product otoacoustic emission
EC = ear-canal
EP = endolymphatic potential
MEM = middle-ear-muscle
MEMR = middle-ear-muscle reflex
MOC = medial olivocochlear
MOCR = medial olivocochlear reflex
OCB = olivocochlear bundle
OHC = outer hair cell
P = significance probability ($P<0.05$ is considered statistically significant)
PSTH = post-stimulus time histogram
R = correlation coefficient
SNR = signal-to-noise ratio
SFOAE = stimulus-frequency otoacoustic emission
$\Delta\mathbf{SFOAE}(t)$ = time varying change in complex stimulus frequency emission (calculated)
SOAE = spontaneous otoacoustic emission
TEOAE = transiently evoked otoacoustic emission
VS = vector strength

APPENDIX A: MEASUREMENT NORMALIZATION

SFOAE-based MOCR measurements produce low-amplitude responses when the SFOAE has a low-amplitude; however, MOCR strength is not necessarily weak in these cases. To compare MOCR strengths across measurements with varying SFOAE amplitudes, we report responses in units relative to an estimate of the amplitude of the SFOAE being monitored

$$|\Delta\mathbf{SFOAE}(t)| = \frac{|\Delta\mathbf{C}(t)|}{|\mathbf{SFOAE}|}. \quad \text{(A1)}$$

To estimate $|\mathbf{SFOAE}|$ we suppressed the SFOAE via two-tone suppression. Ideally, if suppression of the SFOAE is complete, the amplitude of the vector difference in EC sound pressure between the suppressed and nonsuppressed conditions would equal the native SFOAE amplitude (i.e., $|\Delta\mathbf{C}|=|\mathbf{SFOAE}|$). We used a 60 dB SPL ipsilateral suppressor-tone stimulus 110 Hz below the probe-tone to suppress the SFOAE. This tone did not completely suppress the SFOAE (see Appendix D for more details) but gave a good approximation. $|\mathbf{SFOAE}|$ was taken to be the average change in EC sound pressure amplitude caused by the suppressor-tone (the average $|\Delta\mathbf{C}(t)|$, see Fig. 10). The $|\mathbf{SFOAE}|$ estimate was stable and repeatable across sessions and days even though the pre-suppressor baseline wandered.

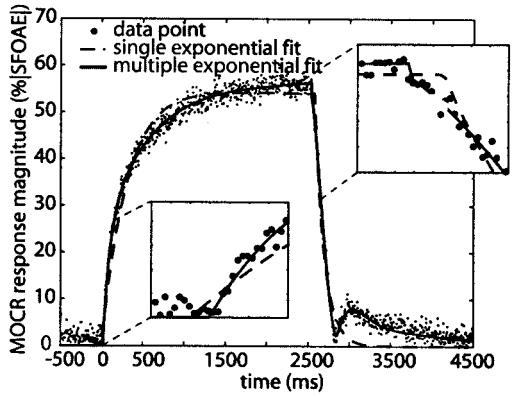

FIG. 11. Two characterizations of the MOCR time course evoked by contralateral sound. Data (points) show MOCR mediated change in the SFOAE induced by a 60 dB SPL contralateral wideband noise elicitor (on at 0 ms and off at 2500 ms). The two curves represent two mathematical characterizations of the data: a fit using a single complex exponential term for the rising and decaying portions (dashed) and one using three such terms for each portion (solid). Exploded views show transition regions. Since the rising and falling portions were fitted separately, "jumps" (less than the measurement noise) could occur (ear S61R, test tone 1.1 kHz, 816 averages).

In other words the SFOAE rode on baseline variations (Fig. 10). One source of these baseline variations is movement of the earphone assembly within the ear canal.

APPENDIX B: MATHEMATICAL CHARACTERIZATIONS OF THE MOCR RESPONSE WAVEFORM

In order to quantify the MOCR responses, two mathematical characterizations were made for each waveform (Fig. 11). First, single complex exponential characterizations were made to quantify MOCR time constants for the rising and decaying portions of each response. Second, sum of complex exponentials characterizations were made to quantify onset and offset delays, extract multiple time constants (when possible), and to describe the rising and decaying curvatures more accurately. Complex exponentials were always used because these produced curvatures similar to the measured responses and because complex terms could fit magnitude and phase data simultaneously.[10]

1. Single complex exponential characterization

For the single complex exponential characterization a piecewise continuous function $\mathbf{y}_1(t)$ [Eq. (B1)] with 5 free parameters (t_r, $\mathbf{Z}_r$, $\mathbf{s}_r$, t_d, and $\mathbf{s}_d$) was used to characterize each response waveform, $\Delta\mathbf{SFOAE}(t)$.

$$\mathbf{y}_1(t) = \begin{cases} t < t_r, & \mathbf{y}_0 = 0 + 0i \\ t_r \leqslant t \leqslant t_d, & \mathbf{y}_r(t) = \mathbf{Z}_r(1 - e^{\mathbf{s}_r(t-t_r)}) \\ t_d < t, & \mathbf{y}_d(t) = \mathbf{Z}_d e^{\mathbf{s}_d(t-t_d)} \\ \textit{with } \mathbf{Z}_d \textit{ set to } \mathbf{y}_r(t_d) & \end{cases} . \tag{B1}$$

Where:

t_r=time when the response onset begins (re: elicitor onset, i.e., the onset delay)

t_d=time when the response offset begins (re: elicitor *onset*)

$\mathbf{s}_r$=complex exponent of the rise[11]

$\mathbf{s}_d$=complex exponent of the decay

$\mathbf{Z}_r$=eventual (saturated) maximum (complex-valued)

$\mathbf{Z}_d$=complex value from which the decay begins (not a free parameter, determined by $\mathbf{Z}_r$, $\mathbf{s}_r$, and t_d)

All parameter values were determined simultaneously using a non-linear parametric least-squares search algorithm that minimized the error between $\mathbf{y}_1(t)$ and a response waveform, $\Delta\mathbf{SFOAE}(t)$. From this "single-complex-exponential" characterization, single onset and offset time constants were calculated [Eqs. (B2) and (B3)]

$$\tau_r = -1/\mathrm{Re}\{\mathbf{s}_r\}, \tag{B2}$$

$$\tau_d = -1/\mathrm{Re}\{\mathbf{s}_d\}. \tag{B3}$$

2. "Sum of complex exponentials" characterization

For the "sum of complex exponentials" characterization, the piecewise function, $\mathbf{y}_2(t)$, [Eq. (B4)] was used to characterize each response waveform, $\Delta\mathbf{SFOAE}(t)$

$$\mathbf{y}_2(t) = \begin{cases} t < t_r, & \mathbf{y}_0(t) = 0 \\ t_r \leqslant t \leqslant t_d, & \mathbf{y}_r(t) = \mathbf{Z}_{DC} + \sum_{n=1}^{2 \text{ or } 3} \mathbf{Z}_{r_n}(1 - e^{\mathbf{s}_{r_n} t}) \\ t_d < t, & \mathbf{y}_d(t) = \sum_{n=1}^{2 \text{ or } 3} \mathbf{Z}_{d_n} e^{\mathbf{s}_{d_n} t} \end{cases} . \tag{B4}$$

The number of terms (and, therefore, parameters) was determined by an algorithm.[12] The roles of the parameters in this characterization are analogous to those in the single complex exponential characterization described above except: (1) The real and imaginary parts of the complex exponents cannot necessarily be separated when being interpreted (e.g., complex conjugate exponents add to form sinusoids[13]); (2) the eventual maximum value of the response is represented by the sum of $\mathbf{Z}_{r_n}$ and a constant, $\mathbf{Z}_{DC}$.

To carry out each characterization, the waveform was split into three regions: (a) Pre-response, in which the response was considered to be zero; (b) rising response (including the plateau); and (c) decaying response. Every data point was ascribed to one of the three regions. Two time-boundaries, t_r, and t_d, were chosen in order to separate the regions (this was re-done for all reasonable t_r, t_d pairs). For each t_r, t_d pair, all remaining parameters in each region were determined by using a matrix pencil method (Hua, 1990, Sarkar, 1995). The parameters of the rising portion were not constrained to make the $\mathbf{y}_2(t)$ curve go though the point 0. Neither were the rising and decaying portions of the characterization constrained to coincide. When discontinuities appeared at these boundaries they were within the measurement noise.

The number of terms to use was determined by a cost/benefit approach. Terms were added, $\mathbf{Z}_{r_n}(1-e^{\mathbf{s}_{r_n}t})$ for the rising region or $\mathbf{Z}_{d_n}e^{\mathbf{s}_{d_n}t}$ for the decaying region, until the additional term failed to improve the goodness of fit (R^2 value) in that region or did so only incrementally.[14] Once the optimal number of terms and the associated parameter values were determined for each region, the three regions (i.e., the rising, falling, and the pre-elicitor region assumed to contain no signal) were conjoined to form a curve. The "fit" between the resulting composite curve, $\mathbf{y}_2(t)$, and the entire response waveform being characterized, $\Delta\mathbf{SFOAE}(t)$, was evaluated using the standard goodness of fit value, R^2, evaluated over all three regions. The process was repeated for all reasonable $[t_r, t_d]$ pairs, and the $\mathbf{y}_2(t)$ curve that gave the highest R^2 value was selected as the winning sum of exponentials characterization (this included the t_r and t_d parameters that segregated the winning curve as well as the associated parameters determined from the matrix pencil method: $\mathbf{Z}_{r_n}, \mathbf{s}_{r_n}, \mathbf{Z}_{d_n}, \mathbf{s}_{d_n}$)

The sum of exponentials characterization was used to extract multiple time constants where possible. Conventional time constants are defined by real-valued exponents but our exponents were complex-valued. Consequently, the calculation of multiple conventional time constants was complicated by interactions between $\mathbf{s}_{r_n}$ or $\mathbf{s}_{d_n}$ terms. However, if the imaginary parts of the parameters were small relative to their real parts (i.e., the exponents were mostly real), multiple onset and decay time constants were approximated, respectively, as

$$\tau_{r_n} = -1/\mathrm{Re}\{\mathbf{s}_{r_n}\}, \tag{B5}$$

$$\tau_{d_n} = -1/\mathrm{Re}\{\mathbf{s}_{d_n}\}. \tag{B6}$$

In order to quantify onset and offset delays with greater time resolution than our sample rate (5 ms/point), onset and offset delays were calculated from the winning sum of exponentials characterization. The response onset time (the time of earliest MOCR response after elicitor inception) was determined by the time of intersection, or the time of nearest miss when there was no intersection,[15] of the rising portion of the characterization and 0 (the origin of the complex plane). The response-offset time was similarly determined by the time of intersection, or the time of nearest miss when there was no intersection, of the rising and decaying portions of the characterization. The onset delay and the offset delay were then calculated by subtracting elicitor onset and offset times from response onset and offset times respectively.

C. Calculating the best estimates of parameters and estimating their errors

To provide the best estimate for each parameter and to quantify the error of those best estimates, two simulations were done for every waveform characterized. The first simulation was used to quantify the error caused by measurement noise; the second simulation was used to quantify biases introduced by the characterization process.

The first simulation calculated means and variances at each time point from individual trials prior to averaging. These statistics were used to define independent Gaussian distributions for the real and imaginary parts at each time point from which new samples could be picked. By sampling from each time point's distribution 500 times, 500 waveforms that were statistically similar to the original waveform were generated. These 500 waveforms were mathematically characterized in the same way as the original response waveform, and they produced 500 estimates for each parameter so that each parameter had a distribution.

The second simulation added noise taken at random with replacement from a subject's pre-elicitor response region (−450 to −50 ms) to a signal with preset parameters. 500 waveforms were made this way; these produced 500 estimates of each known parameter. The known parameter values were then subtracted from the estimates to reveal any bias. This analysis showed that onset and decay time constants were free from significant bias, but that onset and offset delays were underestimated by 0–10 ms depending on the noise level.

The distribution of values of a parameter from the first simulation was convolved with the bias distribution from the second simulation. The resulting distribution was used to obtain the best estimate for that parameter (the distribution mean) and the standard deviation of the best estimate (the distribution standard deviation).[16] These are the values reported in this manuscript.

APPENDIX C: A SIMPLE PHENOMENOLOGICAL MODEL FOR THE MOCR RESPONSE

Although the rising time-course of the MOCR response appears fundamentally different in shape than its decay, a simple model shows how the main features of both time-courses may be due to the same underlying system. To better understand how these time-courses might be connected, we attempted to model both using a simple second-order system, Eq. (C1). Symbols common for a mechanical system were used but the actual underlying system is more likely neurochemical.

$$M\ddot{x}(t) + B\dot{x}(t) + Kx(t) = F_{\mathrm{in}}. \tag{C1}$$

For the system of Eq. (C1), the displacement time waveform, $x(t)$, in response to a step displacement input, F_{in}, can be found by invoking a Laplace transformation and solving which gives Eq. (C2).

$$x(t) = Z_0 + \sum_{n=1}^{2} \mathbf{Z}_n e^{\mathbf{s}_n t}. \tag{C2}$$

The system's behavior is determined by the parameters M, B, and K or equivalently by the loci of the complex-valued "poles" [$\mathbf{s}_1$ and $\mathbf{s}_2$ after solving Eq. (C2) for $\mathbf{s}$ or the roots of Eq. (C1)]. If the poles lie on the real axis, pure exponential curvatures exist; if the poles are complex conjugates, a sinusoidal component exists. The intensity independence of the time-course means that multiplication of Eq. (C1) by any constant will continue to produce the same time-course, therefore, it is the ratios of the parameters that determine the time-course thus the problem can be reduced to two parameters K/M and B/M.

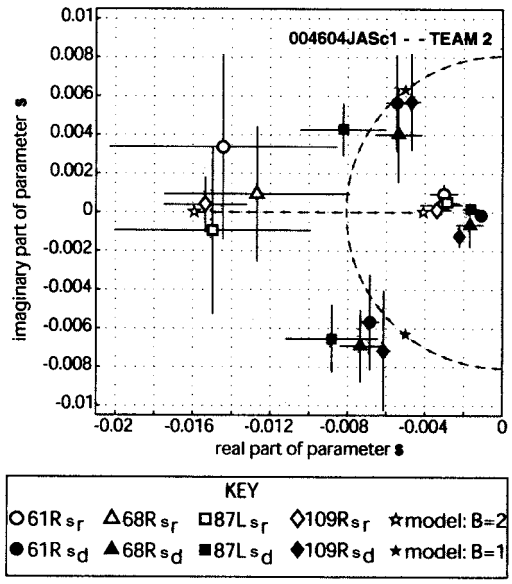

FIG. 12. Exponent parameters or poles for data from four ears that had high SNR compared with the poles of a simple second order model (for an explanation of parameters see Appendix B). The rising portion of the responses (unfilled symbols) were well characterized by two real "poles" with two corresponding time constants. The decaying portion of the responses (filled symbols) were well characterized by 2 complex conjugate poles (accounting for >70% of the decay curvature) plus a single real pole with a long time constant. The dashed lines with arrows show how the two poles of a simple second order system move when the value of the damping element is changed from 0 to 2 (while keeping chosen mass and spring elements constant: $M=100$ kg, $K=0.0065$ N/m). Particular pole locations for two values of the damping element are designated by stars. The bulk of the observed wave-shapes can be accounted for by changing a single parameter, the damping element (or first derivative coefficient) in a simple second order model. Open symbols are onset poles and filled symbols are decay poles and different symbol shapes are used for different ears as shown in the key.

The loci of four sets of $\mathbf{s}_{r_n}$ and $\mathbf{s}_{d_n}$ parameters (see Appendix B) from the sum of exponentials characterizations of our four highest SNR MOCR responses were compared with the loci of $\mathbf{s}_1$ and $\mathbf{s}_2$ poles from the simple second-order model (Fig. 12). With M and K fixed ($M=100$ kg and $K=0.0065$ N/m) we matched the locations of the rising $\mathbf{s}_{r_n}$ parameters with a B value of 2 Ns/m. Keeping M and K at their fixed values, we closely matched two of the three[17] $\mathbf{s}_{d_n}$ parameters solely by reducing B by a factor of two to $B=1$ Ns/m (Fig. 12). Thus, for these subjects, the transition from the rising curvature to the decaying curvature can be largely achieved by changing a single parameter (the first derivative coefficient) in a second-order model. This suggests that a single second order process rather than multiple unconnected processes are largely responsible for the MOCR's time-course.

The agreement between these data and the simple second-order model is not perfect. The "conjugate poles" were not true conjugates in the sense that they did not form a vertical line and in that they did not have equal weighting (generally the term with the lower pole had a larger coefficient magnitude). And the data constellations did not strictly overlay the second-order system's path (dashed line in Fig. 12). Nonetheless, the model provides a good approximation to the measured data and shows that much of the difference between the rising and falling time-courses can be accounted for by a single underlying second-order system.

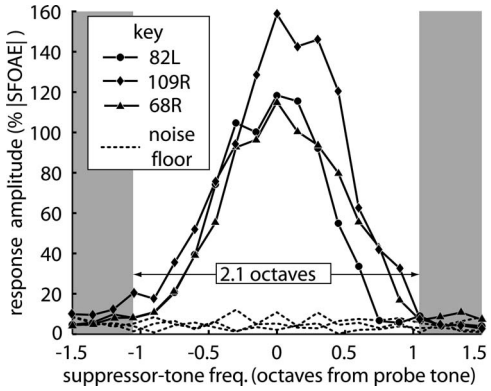

FIG. 13. Bandwidth of two-tone suppression measured via the average change in SFOAE magnitude between suppressor-on and suppressor-off conditions for 60 dB SPL tone suppressors at various frequencies relative to the probe tone. 16 one-second responses were averaged for each point. Ipsilateral suppressor tones (500 ms duration) produced two-tone suppression effects (solid lines), while contralateral "suppressor tones" produced no effects (dashed lines) and were used to asses the noise floor. The edges of the gray bands demark the chosen 2.1 octave span for the spectral notch incorporated into elicitors when comparing ipsilaterally, contralaterally, and bilaterally elicited MOCR responses.

APPENDIX D: TWO-TONE SUPPRESSION BANDWIDTH

Measuring ipsilaterally or bilaterally activated MOCR responses using our SFOAE-based method required a probe-tone and an elicitor-noise be presented simultaneously in the measurement ear. In this situation, two-tone suppression by the elicitor can reduce the SFOAE amplitude, obfuscating MOCR responses. To avoid such contamination of our MOCR responses, we used an elicitor-noise with a spectral notch centered at the probe-tone frequency. The notch width was designed to be wide enough to not produce two-tone suppression effects. To determine the appropriate notch width, we measured the bandwidth of two-tone suppression of the SFOAE (Fig. 13).[18] For these measurements, a 40 dB SPL probe tone was fixed at a subject's probe frequency (near 1 kHz) while a 60 dB SPL suppressor-tone was presented at various frequencies (21 logarithmically spaced frequencies spanning three octaves and centered at the probe tone frequency were used). Since the MOCR does not respond well to pure tone stimuli (Guinan *et al.*, 2003) as demonstrated in Fig. 13 by the lack of any effect of contralateral "suppressor-tones" dashed lines), all resulting changes in the SFOAE from adding ipsilateral tone suppressors were presumed to be to non-MOCR, two-tone suppression effects. The bandwidth of suppression was found to be ~2.1 octaves.

When comparing ipsilaterally, contralaterally, and bilaterally activated MOCR time-courses (Sec. III C), a 2.1 octave spectral notch centered at the probe-tone frequency was used for all noise-elicitors. In retrospect, since subject 109R showed some suppression at −1.05 octaves, perhaps the notch should have been extended for this subject. This oversight, however, is unlikely to have much of an effect. The total level of the notched-noise elicitor was 60 dB SPL,

therefore the elicitor would introduce much less energy at the −1.05 octave place in the cochlea than the 60 dB SPL suppressor-tone used for Fig. 13 that concentrates all its energy there.

[1]Bilateral probe tones were used because our previous work used them. For these experiments, however, bilateral probes do not provide any benefit aside from allowing comparison with our prior work.

[2]Because spontaneous emissions can be entrained (Van Dijk and Wit, 1988), they may shift toward and interact with the probe-tone stimulus confounding SFOAE-based measures (Burns *et al.*, 1984). To resolve this issue, once a potential measurable probe-tone frequency was identified, two buffers (2621 ms each) were acquired from the microphones in quiet and their spectra were averaged. If any spontaneous emission >-5 dB SPL was detected within 50 Hz of the prospective probe-tone frequency, a new probe frequency was chosen.

[3]The criterion for acceptable SNR was 95% phase coherence, defined by a vector strength (VS) >0.95 in a time window during the elicitor (i.e., 1950–2450 ms, see Table I). Phase coherence was used because coherent phase is a strong indicator of signal presence. Vector strength was calculated by adding vectors of unity magnitude but with phase values taken from the data points in the time window (Goldberg and Brown, 1969) (n in the equation below represents indexes to these $\sim$500 consecutive samples). The resultant sum vector was then divided by the total number of vectors included in the sum, and its length had to be >0.95:

$$VS = \frac{1}{N}\sum_{n=1}^{N} e^{i\angle \mathbf{C}(n)} > 0.95.$$

[4]The term "long" was used for this time constant to differentiate it from the three other time constants discussed in this paper, i.e., fast, medium, and slow. All four time constants are numerically distinct.

[5]The idea that allows us to put a lower bound on the slow time constant is, "if the time constant were shorter, we would have seen the curvature produced by it." Since the early rise of an exponential is approximately linear, when the data displayed a very slow (or effectively linear) curvature, we could put a lower bound on the time constant that depended on the SNR of that parameter and the analysis window length. The lower bound was set at 95% confidence.

[6]70 ms was the reported *median*, the average is larger due to significant scatter in the data.

[7]*In the present dataset* the MOCR always decreased the estimated SFOAE.

[8]There is a system of Ca^{2+} stores (sub-surface cisternae) located along OHC lateral cell-membranes that could be involved in migration of Ca^{2+}.

[9]The neural delay contains both forward-otoacoustic and neural delays. One reason these two delays are combined is because it is hard to calculate what the forward-otoacoustic delay should be for a wideband stimulus—delays in the cochlea are different for different frequencies. Time "0" in all figures was when the elicitor stimulus's electrical signal was sent to the sound source, therefore, all otoacoustic delays include acoustic delays of <0.1 ms between the earphone and the tympanic membrane.

[10]This strategy removes the bias that is introduced when fitting the magnitude data alone. When noise exists in a complex-valued measurement (zero mean noise in x and y) the resulting magnitude is always $>$ zero. Therefore, an estimate of the magnitude of the signal based on only magnitude data will be biased and the amount of the bias will increase with increasing noise.

[11]For a single term complex exponential, the complex-valued exponent can be thought of in its component parts. The real part of the exponent is inversely related to a conventional time constant and determines the speed of the magnitude changes over time, while the imaginary part determines the speed with which the phase changes over time.

[12]The number of parameters was increased until the least squares fit failed to improve or did so only incrementally. Higher SNR measurements produced more terms. The maximum number of parameters generated was 14. This happened for the four highest SNR subjects: 87L, 109R, 68R, and 61R, who's rising and decaying response curvatures were described by the sum of 3 complex exponential terms.

[13]No restrictions were placed on the parameters; consequently, the functions may defy interpretation as combinations of familiar functions.

[14]Over-fitting manifested when sinusoidal oscillations appeared in the characterization curves. Such oscillations were obvious in the curves when they occurred, and were not present in the data. These oscillations were excluded to insure smooth curves and their exclusion set an upper bound of 3 on the number of complex exponential terms that could be used in the characterization.

[15]The parameters of the rising portion were not constrained to make the $\mathbf{y}_2(t)$ curve go though the point 0. Neither were the rising and decaying portions of the characterization constrained to coincide. When discontinuities appeared at these boundaries they were within the measurement noise.

[16]This is an over-estimate of the standard deviation because both simulations used measurement noise (albeit different types). Measurement noise only appears once in the actual data.

[17]The third decay parameter $\mathbf{s}_{d_3}$ represented a long exponential time constant that was not captured by this model. It was ignored because it accounted for $<30\%$ of the decay curvature.

[18]Our standard suppression measurement used to estimate $|\mathbf{SFOAE}|$ for normalization of MOCR responses uses a suppressor tone presented 110 Hz below the probe frequency. However, the excellent cancellation afforded by alternating elicitor polarity rendered this offset unnecessary and created a situation where a suppressor tone presented nearer or even at the probe tone frequency yielded a response greater than the nominal 100%.

Asynchrony and the grouping of vowel components: Captor tones revisited

Brian Roberts[a] and Stephen D. Holmes

(Received 27 October 2005; revised 21 February 2006; accepted 4 March 2006)

Asynchrony is an important grouping cue for separating sound mixtures. A harmonic incremented in level makes a reduced contribution to vowel timbre when it begins before the other components. This contribution can be partly restored by adding a captor tone in synchrony with, and one octave above, the leading portion of the incremented harmonic [Darwin and Sutherland, Q. J. Exp. Psychol. A **36**, 193–208 (1984)]. The captor is too remote to evoke adaptation in peripheral channels tuned to the incremented harmonic, and so the restoration effect is usually attributed to the grouping of the leading portion with the captor. However, results are presented that contradict this interpretation. Captor efficacy does not depend on a common onset, or harmonic relations, with the leading component. Rather, captor efficacy is influenced by frequency separation, and extends to about 1.5 oct above the leading component. Below this cutoff, the captor effect is equivalent to attenuating the leading portion of the incremented harmonic by about 6 dB. These results indicate that high-level grouping does not govern the captor effect. Instead, it is proposed that the partial restoration of the contribution of an asynchronous component to vowel timbre depends on broadband inhibition within the central auditory system. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Acoustic elements arising from independent sources are unlikely to begin or end at the same time. Indeed, onset asynchrony is arguably the most powerful cue for the perceptual segregation of concurrent sounds (Bregman, 1990; Darwin and Carlyon, 1995). In general, an onset asynchrony of 30–50 ms greatly reduces the contribution of a single component to judgments of the timbre (e.g., Bregman and Pinker, 1978; Green and Dai, 1992) or location (e.g., Hill and Darwin, 1996) of a complex tone, and causes it to be heard out as a separate sound (e.g., Bregman and Pinker, 1978; Dannenbring and Bregman, 1978). A longer onset asynchrony, of about a few hundred milliseconds, is needed to exclude a component from the computation of global pitch (e.g., Darwin and Ciocca, 1992; Hukin and Darwin, 1995), or to exclude a whole formant from the computation of vowel timbre (Darwin, 1981).

Listeners are highly practiced at categorizing speech sounds, and so judgments of vowel quality provide a convenient way of assessing the contribution of an asynchronous component to the timbre of a complex tone. Darwin (1984a) pioneered this approach by measuring the effects on perceived vowel quality of manipulating the relative onset/offset time and level of individual harmonics in the first-formant (F1) region. These harmonics are resolved, and so the F1 frequency must be abstracted in some way from the individual peaks in this region of the excitation pattern. Darwin (1984a) noted that the perceived F1 frequency of a vowel does not correspond simply to the frequency of the highest local peak in the excitation pattern, but rather corresponds to the weighted mean of the harmonics in this spectral region (Karnickaya *et al.*, 1975; Carlson *et al.*, 1975; Assmann and Nearey, 1987). Darwin (1984a) boosted the level of a single harmonic in the F1 region and found that the extra energy changed the perceived vowel quality in a way consistent with the change in the physical position of the formant peak. However, the contribution of the extra energy was greatly reduced when it began before the other components. Darwin (1984b) demonstrated that this exclusion by asynchrony occurs even when the level of a harmonic is not raised above the vowel's original spectral envelope. Subsequent work has shown that listeners are generally able to subtract from perceived vowel quality the amplitude of that part of a harmonic that begins before vowel onset (Darwin, 1995). This result can be understood in terms of the old-plus-new heuristic, which states that any part of a current sound that can plausibly be interpreted as the continuation of a previous sound should be removed perceptually from the mixture (Bregman, 1990).

What physiological mechanism might mediate the effect of onset asynchrony on judgments of timbre? Darwin (1984a) pointed out that peripheral adaptation provides a possible alternative to an explanation based on a higher-level mechanism for grouping. The response of an auditory nerve fiber to a pure tone of fixed level is greatest at stimulus onset, decreases gradually, and reaches a steady state after a few tens of milliseconds (Kiang *et al.*, 1965; Westerman and Smith, 1984; see Palmer, 1995). Therefore, the neural response to the leading component will have adapted substan-

[a]Electronic mail: b.roberts@aston.ac.uk

tially by the time the vowel begins. This might be equivalent perceptually to reducing the level of the leading component. Darwin's (1984a) demonstration that part of the effect of leading energy persists when a silent gap of 30 ms is introduced between it and vowel onset is consistent with an explanation in terms of peripheral adaptation. However, two lines of evidence suggest that the effect of onset asynchrony depends, at least partly, on a higher-level grouping mechanism. These are considered in turn.

Darwin (1984a) pointed out that perceptual grouping can operate retroactively, whereas adaptation cannot. Therefore, if the contribution of a component to vowel quality can be reduced by making that component end after the vowel, then the effect cannot be explained in terms of peripheral adaptation. The effect of offset asynchrony is greatest for vowels of short duration (Darwin, 1984b; Darwin and Sutherland, 1984; Roberts and Moore, 1991), giving a maximum effect of about half that found for onset asynchrony. Roberts and Moore (1991) considered and rejected the idea that the effect of offset asynchrony on vowel quality is a consequence of backward masking. In particular, they noted that backward masking (*i*) tends to be weak or absent in practiced listeners (Miyazaki and Sasaki, 1984; Oxenham and Moore, 1994); (*ii*) only occurs when the masker is much higher in level than the signal (Elliott, 1971); and (*iii*) largely disappears after about 10 ms (Zwislocki, 1978), whereas the effect of offset asynchrony takes about 80 ms to approach asymptote. Although the evidence is indirect, the influence of offset asynchrony on judgments of vowel quality strongly implies that a substantial part of the effect of onset asynchrony is attributable to perceptual grouping rather than to peripheral adaptation.

Darwin and Sutherland (1984) suggested that a leading component may make a reduced contribution to vowel quality because the leading portion of the component forms, with its continuation into the vowel, a separate perceptual group. If so, they reasoned that it should be possible to restore the contribution of the leading component to vowel quality by weakening the grouping between its leading portion and its continuation into the vowel. Their approach was to introduce an additional tone that was intended to form a perceptual group with the leading portion of the asynchronous component, and thus to free its continuation to integrate into the vowel percept. To encourage this *captor* tone to group with the leading portion, it was set to begin at the same time as the leading component and to end at vowel onset. The frequency of the captor tone was set to be one octave higher than the frequency of the leading component. This value was chosen so that any peripheral adaptation, or two-tone suppression (Houtgast, 1974), caused by the captor tone would be negligible at the frequency of the leading component. Although not explicitly stated, it is implied that the choice of a harmonic relationship between the captor and the leading component was also intended to encourage their perceptual fusion.

Darwin and Sutherland (1984) found that the presence of the captor tone partly reversed the reduction in the contribution of the leading component to vowel quality. This part-reversal cannot be explained in terms of peripheral adaptation. Furthermore, the fact that the extent of the reversal was limited to about one third does not necessarily imply that the rest of the effect of onset asynchrony is attributable to adaptation. This is because the physical continuity of the leading portion of the asynchronous component and its continuation into the vowel is likely to support some perceptual integration of the leading and continuing portions, despite the presence of the captor tone. Darwin and Sutherland's (1984) elegant study has since become a textbook example of how the perceptual effects of onset asynchrony reflect the operation of specific grouping mechanisms (see, e.g., Bregman, 1990; Darwin and Carlyon, 1995; Darwin, 1997; McAdams and Drake, 2002). However, the underlying assumption that the effect of the captor tone arises from its grouping with the leading portion of the asynchronous component, on the basis of their common onset time and their harmonic relationship, was not tested by Darwin and Sutherland and has not been tested since. The experiments reported here test this assumption explicitly and demonstrate that the effect of the captor tone does *not* depend on either of these grouping cues. Instead, it is proposed that the captor effect depends on inhibitory processes acting within the central auditory system.

II. GENERAL METHOD

A. Overview

Darwin has developed a sensitive paradigm for measuring the extent to which a harmonic in the F1 region is perceptually integrated into a vowel (Darwin, 1984a, b; Darwin and Sutherland, 1984). Darwin's paradigm is based on an approach pioneered by Carlson *et al.* (1975), and we have used it in all the experiments reported here. The British English vowels /ɪ/ and /ɛ/ do not differ greatly in their second and higher formants (see, e.g., Henton, 1983). Therefore, it is possible to construct a continuum of vowels, differing only in their F1 frequencies, that spans the /ɪ/-/ɛ/ phoneme boundary. Stimuli from this continuum can be presented to listeners in a forced-choice categorization task to provide an estimate of the position of the phoneme boundary.

The F1 frequency used to synthesize a vowel is defined as its *nominal* F1 value. If the effect of adding energy to a harmonic *raises* the perceived F1 frequency, then the boundary will move to a *lower* nominal F1 value on the continuum. Similarly, a reduction in perceived F1 frequency will cause the boundary to rise. For a given increase in the level of a harmonic in the F1 region, the extent to which a particular factor affects the perceptual integration of the extra energy can be measured by comparing the size of the boundary shifts across conditions.

Darwin (1984a, b) used vowels with an F0 frequency of 125 Hz and manipulated their third (375 Hz) and fourth (500 Hz) harmonics. Darwin (1984a) found that the extent to which the original vowel quality was recovered when the additional energy began before and continued after the vowel was greater when the fourth harmonic was manipulated. This effect was attributed to differences in masking. Specifically, it was argued that boosting the third harmonic masked the fourth harmonic for sounds near the phoneme boundary, and so prevented the fourth harmonic from reemerging as a fac-

tor influencing perceived F1 frequency. Darwin (1984b) used linear predictive coding to estimate perceived F1 frequency for vowels with a range of increments in level applied to the third or fourth harmonic. Discrepancies between these estimates and listeners' judgments indicated that the extra energy was not always fully integrated into the vowel percept, even when it was added in synchrony. This effect was quite marked when the energy was added at 375 Hz, below the F1 frequency at the phoneme boundary, but the 500-Hz component had to be boosted by 12 dB before any of the extra energy was excluded from the vowel percept. Darwin (1984b) argued that this difference may reflect a specific constraint on vocal-tract transfer functions. For these reasons, all the experiments reported here manipulated the level of the fourth harmonic.

B. Stimuli and conditions

The spectrum of each vowel was computed by adding harmonics with the amplitudes and phases given by the equations for the vocal-tract transfer function using cascade formant synthesis (Klatt, 1980). Vowel stimuli in the basic F1 continuum were synthesized with an F0 frequency of 125 Hz, and an F1 bandwidth of 90 Hz. All harmonics were present up to the fortieth (5 kHz). Formants 2–5 were set to frequencies of 2300, 2900, 3800, and 4600 Hz, with bandwidths of 120, 170, 1000, and 1000 Hz, respectively. There were 20 vowels per continuum, with F1 values spaced in equal steps of 10 Hz and ranging either from 350 to 540 Hz (experiments 1–3) or from 360 to 550 Hz (experiments 4 and 5). Vowel stimuli were 56 ms in duration (seven pitch periods), including linear onset and offset ramps of 16 ms each. To ensure roughly constant loudness across the basic continuum, all vowels were normalized to give the same root-mean-square (rms) voltage. The normalized basic continuum constituted the *vowel-alone condition*.

The continuum for the *incremented-fourth condition* was generated by adding in phase a pure tone at the frequency of the fourth harmonic (500 Hz) to each vowel in the normalized basic continuum. The additional tone had the same rise, steady-state, and fall times as the vowel and was added in synchrony. Its level was set to be 6 dB higher than the fourth harmonic, and so the 500-Hz component for each vowel was boosted by 9.5 dB relative to the value specified by the normalized transfer function. The continuum for the *leading-fourth condition* was generated by extending the additional tone so that it began before the vowel. The lead times used ranged from a few tens to a few hundreds of milliseconds across experiments. Figures 1(a) and 1(b) show schematic spectrograms representing stimuli from the incremented-fourth and leading-fourth conditions, respectively.

Captor conditions were generated by accompanying each vowel of the leading-fourth condition with a higher-frequency pure tone that was set to the same level as the additional 500-Hz tone. The onset and offset ramps for the captor were 16 ms each. Captor offset always began at vowel onset, and so its amplitude envelope reached zero at the same moment as the envelope of the vowel reached steady state. The captor tone began in synchrony with the leading fourth harmonic in some cases, but began before or after it in other cases. Captor-control conditions differed only in that the vowels were taken from the incremented-fourth condition, and so the leading portion of the fourth harmonic was absent. These controls were included to measure the extent to which perceived vowel quality is influenced by the captor tones in the absence of asynchronous energy at 500 Hz. Phoneme boundaries for these control conditions should not differ from the incremented-fourth condition if the captor produces no perceptual change in the vowel. Figures 1(c) and 1(d) show schematic spectrograms representing stimuli from the synchronous-captor and captor-control conditions, respectively.

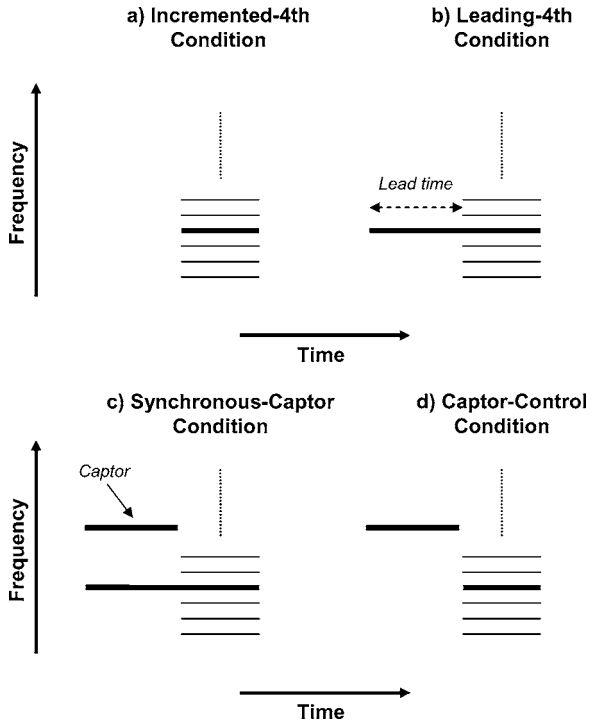

FIG. 1. Schematic spectrograms representing the stimulus arrangements for the following conditions: (a) incremented-fourth; (b) leading-fourth; (c) synchronous captor; (d) captor control. Each part displays harmonics in the F1 region of a vowel (the continuation of the spectrum is shown by a vertical dotted line). In each case, a tone has been added to the vowel to increase the level of its fourth harmonic. The perceptual consequences of this manipulation depend on the context (Darwin and Sutherland, 1984): (a) adding the tone in synchrony with the vowel changes its quality; (b) this change is largely abolished by an onset asynchrony; (c) adding the captor partly reverses the effect of making the tone asynchronous; (d) adding the captor does not alter the phonetic change caused by adding the tone in synchrony with the vowel.

All stimuli were generated using MITSYN software (Henke, 1997). Stimuli were synthesized at a sampling rate of 16 kHz, stored on disk, and played back via a 16-bit digital-to-analog converter (Data Translation DT2823). They were low-pass filtered (Fern Developments EF16X module; corner frequency = 5.2 kHz, roll-off = 100 dB/oct) and presented diotically over Sennheiser HD 480-13II earphones. Stimuli were checked using a spectrum analyzer (Stanford Research Systems SR780). The overall output level was set using a programmable attenuator (0.25-dB steps) and calibrated using a sound-level meter (Brüel and Kjaer, type 2209) coupled to the earphones by an artificial ear (type

4153). The presentation level for vowels from the basic continuum was about 69 dB SPL. The maximum presentation level for a vowel from the incremented-fourth continuum was about 76 dB SPL.

C. Listeners

Twelve listeners took part in each experiment. All volunteers were native speakers of British English who reported no hearing impairment. They were paid for their assistance and had earlier successfully completed a screening procedure. Initial screening was undertaken to ensure that each listener was able to distinguish between the two vowel categories and to produce a monotonic change in the identification function as the F1 value increased across a continuum. Listeners first identified two randomized blocks of the full set of 20 stimuli in the vowel-alone condition to familiarize themselves with the task. These could be repeated if required. Listeners then identified ten randomized blocks of tokens from the vowel-alone and incremented-fourth conditions (400 trials). To pass the screening, listeners also had to reach a criterion shift in phoneme boundary for the incremented-fourth condition compared with the vowel-alone condition. The criterion was a minimum downward shift of 20 Hz, confirming that boosting the 500-Hz component increased the perceived F1 frequency of vowels along the continuum. About 75% of volunteers passed the screening and were free to take part in as many or as few experiments as they wished. An extended screening, including an additional and stricter criterion, was used for listeners who took part in experiments 4 and 5. This is described in Sec. VI A.

D. Procedure

Stimuli were played to the listeners in a double-walled sound-attenuating chamber (Industrial Acoustics 1201A). On each trial, listeners responded using a keyboard to indicate whether the vowel token was perceived as /ɪ/ or /ɛ/. The printed instructions for listeners gave the words "hid" and "head" as examples in "h-d" context of the two phonemic categories. Except for practice blocks, described below, listeners were not allowed to repeat a stimulus before making their identification. The next trial began 0.5 *s* after the return key was pressed to confirm the choice. Listeners were asked to note the trial number, displayed on screen, for any accidental key presses. These were then corrected manually in the data file before analysis. Listeners were asked to focus on the vowel and to try to ignore any additional sounds that might be present. No feedback was provided.

A block of stimuli consisted of all 20 tokens for every condition in that experiment. The number of trials per block varied from 140 to 340 trials, depending on the number of conditions. The stimulus order was randomized anew for each repetition of a block, and ten repetitions were presented to listeners over the course of an experiment. As stimuli from all conditions were intermingled in a block, any difference in the position of the phoneme boundary between conditions cannot be attributed to range effects (Brady and Darwin, 1978). The use of randomized order also precludes the possibility of systematic contrast effects influencing the boundary position.

Each experiment was run as one or more sessions that lasted between 40 and 70 min. Every session began with a practice block that consisted of a subset of the stimuli from the main experiment. The subset included one token of either every second or every fourth F1 step from the full set, depending on the number of conditions in each experiment, and comprised between 70 and 110 randomized trials. A typical session comprised the practice block and about 1800 experimental trials. Listeners typically took breaks after every few hundred trials.

E. Data analysis

The data for each listener comprised the number of /ɪ/ responses out of ten for each nominal F1 value and condition. Following previous practice (e.g., Darwin, 1984a; Roberts and Moore, 1990), each data set was fitted individually by probit analysis (Finney, 1971). The nominal F1 frequency at the /ɪ/-/ɛ/ phoneme boundary was defined as the mean of the probit function (50% point). The effect on vowel timbre of the additional energy at 500 Hz was estimated for each condition by measuring the shift in boundary position relative to the reference condition (vowel alone). The probit function also provided an estimate of the slope of the identification function. In all experiments, these slopes did not change substantially across conditions and so are not considered further.

Occasionally, a misclassification would occur for a stimulus clearly some distance from the crossover region of the identification function, giving a "9-1" or "1-9" pattern of /ɪ/-/ɛ/ responses for that stimulus, rather than a "10-0" or "0-10" pattern. Although this did not greatly affect the probit estimate of boundary position, it could affect the estimate of slope. Therefore, following Roberts and Moore (1990, 1991), these response patterns could be changed to "10-0" or "0-10," as appropriate, before performing the probit analysis. The criterion for making the change was that at least the neighboring two continuum members on both sides gave a "10-0" or "0-10" response pattern. Overall, about 20% of the listeners who completed an experiment were replaced because they obtained, for one or more conditions, either a nonmonotonic identification function or a boundary estimate that fell outside the range of nominal F1 values tested.

Once data collection was completed, a within-subjects analysis of variance (ANOVA) was performed on the boundary estimates. Given the small number of pairwise comparisons required from the large set of possible two-tailed comparisons in each experiment, they were computed using the restricted least-significant-difference (LSD) test (Snedecor and Cochran, 1967). In most cases, the only pairwise comparisons quoted are for the following conditions: vowel-alone versus incremented-fourth, incremented-fourth versus leading-fourth, and vowel-alone versus leading-fourth.

Of central interest in experiments 1–4 is the extent to which the *asynchrony-induced reduction* in the effect of the added 500-Hz tone is reversed by the presence of a captor.

This is called the *restoration effect* and its value, in Hz, is defined as the difference between the boundaries for the captor condition and its control subtracted from the difference between the boundaries for the leading-fourth and incremented-fourth conditions. The computation compares each captor condition with its control (rather than with the incremented-fourth condition) to take account of any effect that the captor may have on perceived vowel quality, other than through its modulating influence on the phonetic effect of the leading fourth harmonic.

To establish whether or not different captor conditions produced different amounts of restoration, a within-subjects ANOVA was performed on the transformed data. As before, any subsequent pairwise comparisons were performed using the restricted LSD test. It was also important to demonstrate that the restoration effects obtained were significantly greater than zero. Unless the ANOVA revealed a significant effect of captor condition on the restoration values, this was achieved by calculating a mean value across conditions for each listener and performing a single one-sample t test (two tailed) to compare the overall mean with zero. Otherwise, a separate one-sample t test was performed for each condition.

III. EXPERIMENT 1

Darwin and Sutherland (1984) demonstrated that accompanying the leading portion of additional energy in the F1 region with a captor tone partly reversed the effect of the asynchrony. They argued that the effect of the captor depends primarily on its common onset with the leading 500-Hz tone. Experiment 1 tested this hypothesis by replicating Darwin and Sutherland's experiment and extending it to include two additional kinds of captor tone, one which began before the leading 500-Hz tone (advanced-onset captor) and one which began after it (delayed-onset captor). In terms of the nominal F1 value along the /ɪ/-/ɛ/ continuum, it was expected that the phoneme boundary would be lower in the incremented-fourth condition than in the vowel-alone condition, that it would shift back towards its original value in the leading-fourth condition, and that (relative to its control) the extent of this upward shift would be reduced in the synchronous-onset captor condition. If the asynchronous-onset captors are found to be as effective as the synchronous-onset captor at restoring the contribution of the leading 500-Hz tone, then captor efficacy must depend on factors other than the grouping of the captor with the leading tone on the basis of common onset.

A. Method

There were nine conditions in total. These were the three standard conditions (vowel alone, incremented fourth, leading fourth), plus three captor conditions and their controls. The lead time on the added 500-Hz tone was 240 ms (cf. Darwin and Sutherland, 1984). The captor conditions were created by adding a pure tone at 1000 Hz to the stimuli from the leading-fourth continuum. For each member of the continuum, the level of the 1-kHz tone was the same as that of the added 500-Hz tone. These parameters are identical to those used by Darwin and Sutherland (1984). The captor either began at the same time as the leading 500-Hz component (synchronous onset), 160 ms before it (advanced onset), or 160 ms after it (delayed onset). Hence, the durations of the captors for these conditions were 240, 400, and 80 ms, respectively. In all cases, captor amplitude was ramped down to zero at the same time as vowel amplitude was ramped up to steady state. Each captor condition had a corresponding control condition, for which the stimuli differed only in that the leading portion of the added 500-Hz tone was absent. The number of trials per block in the main experiment was 180 (9 conditions $\times$ 20 F1 values).

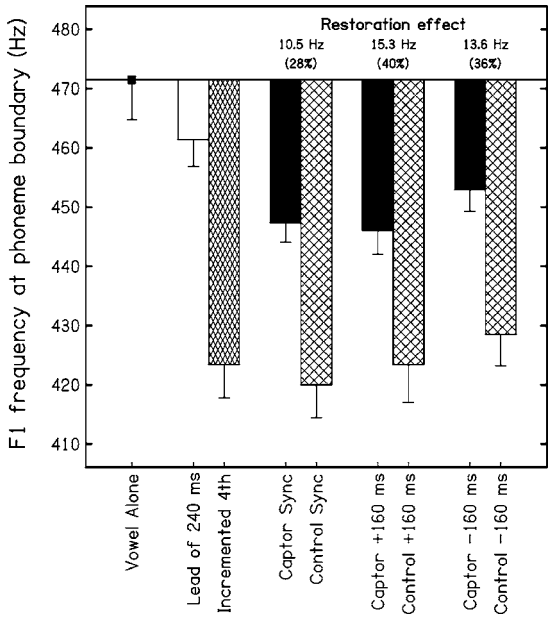

FIG. 2. Results for experiment 1—effect of captor asynchrony for a long lead-time on the fourth harmonic (240 ms). Mean phoneme boundaries are expressed as nominal first-formant frequencies for 12 listeners (with intersubject standard errors). The boundary for the reference condition (vowel alone) is indicated by the horizontal line and the square symbol. The boundaries for the leading-fourth condition and the incremented-fourth condition are shown by the open bar and narrow-hashed bar, respectively. The boundaries for the captor conditions and for their controls are shown by the solid bars and wide-hashed bars, respectively. The extent to which each captor condition restores the effect of the leading fourth on vowel quality, relative to its own control, is shown above each pair of bars. Each restoration effect is quoted as an F1 boundary shift in Hz and as a percentage of the boundary difference between the leading-fourth and incremented-fourth conditions.

B. Results and discussion

Figure 2 displays the mean phoneme boundaries (and intersubject standard errors) across conditions in terms of nominal F1 frequency. Mean restoration effects for the captor conditions are shown above the corresponding histogram bars. Each value is quoted as an F1 boundary shift in Hz and also as a percentage of the boundary difference between the leading-fourth and incremented-fourth conditions. The effect of condition on the position of the phoneme boundary was highly significant $[F(8,88)=27.732,\ p<0.001]$. The boundary for the incremented-fourth condition was lower than the boundary for the vowel-alone condition $[t(11)=13.358,\ p<0.001]$, indicating that perceived F1 frequency was raised when extra energy was added in synchrony to the fourth harmonic. The size of the mean bound-

ary shift was 48 Hz. The boundary for the leading-fourth condition was higher than the boundary for the incremented-fourth condition [$t(11)=6.315$, $p<0.001$], but did not differ from the boundary for the vowel-alone condition [$t(11)=1.511$, $p=0.159$]. This indicates that the extra energy at 500 Hz was excluded from the perceptual computation of F1 frequency when it began 240 ms before the vowel.

For ease of comparison, our preliminary analysis of the effects of the captor conditions followed the approach of Darwin and Sutherland (1984). This analysis showed that all captor conditions gave significantly lower boundaries than the leading-fourth condition [synchronous onset: $t(11)=3.908$, $p=0.002$; advanced onset: $t(11)=3.923$, $p=0.002$; delayed onset: $t(11)=2.941$, $p=0.013$]. There was one captor-control condition for which the boundary position was significantly different from the incremented-fourth condition [delayed-onset: $t(11)=3.122$, $p=0.010$]. This occurrence indicates the importance of including captor-control conditions in the experiment.

The efficacy of the three types of captor was compared using the computed restoration values (see Sec. II E). Restoration values describe the extent of the boundary shift induced by the captor when the effect of the corresponding captor control has been factored out. Analysis of the restoration effects revealed that there was no significant difference between the three captor conditions [$F(2,22)=1.149$, $p=0.335$], and that the overall magnitude of the restoration effect was significantly above zero [$t(11)=4.084$, $p<0.001$]. This suggests that the captors were equally effective in weakening the effect of applying a lead time of 240 ms to the added 500-Hz tone, irrespective of the onset time of the captor. The overall mean restoration effect was about 35%. Note that the failure to find a significant reduction in captor efficacy when the onset of the captor leads or lags the onset of the 500-Hz component cannot be attributed to a lack of statistical power, because the observed magnitude of the restoration effect was actually smallest for the synchronous-captor condition.

The magnitude of the boundary shift induced by boosting the fourth harmonic of the vowel by 9.5 dB, the near-complete return of the boundary when the additional energy begins 240 ms before the vowel, and the extent to which the captor reverses the boundary return are all very similar to the findings of Darwin and Sutherland (1984). However, the absence of an effect of captor onset time does not support their proposal that the restoration induced by the captor depends on a common onset for the captor and the leading 500-Hz component. Note that captor duration covaried with captor onset time, ranging from 400 ms (advanced-onset case) to 80 ms (delayed-onset case). Hence, the comparable restoration values for the three captor types suggests that temporal integration of captor energy is complete by 80 ms.

IV. EXPERIMENT 2

The absence of an effect of relative captor onset time in experiment 1 is consistent with the idea that captor efficacy does not depend on grouping by common onset. However, the use of a long lead time (240 ms) for the added 500-Hz tone leaves open the possibility that the perceptual consequences of a difference in onset time had "worn off" long before the vowel began. If so, the captor may have grouped with the leading portion of the added tone on the basis of their octave relationship. Indeed, if one listens to a harmonic complex for which one component begins before the others, the salient pitch heard for that component within the complex begins to fade as time passes. Therefore, as a precaution, we compared the efficacy of synchronous and asynchronous captors in the context of a short lead time (40 ms) on the added 500-Hz tone. If these captors are similarly effective under these conditions, then we can rule out the alternative proposal and conclude that grouping by common onset does not mediate the captor effect.

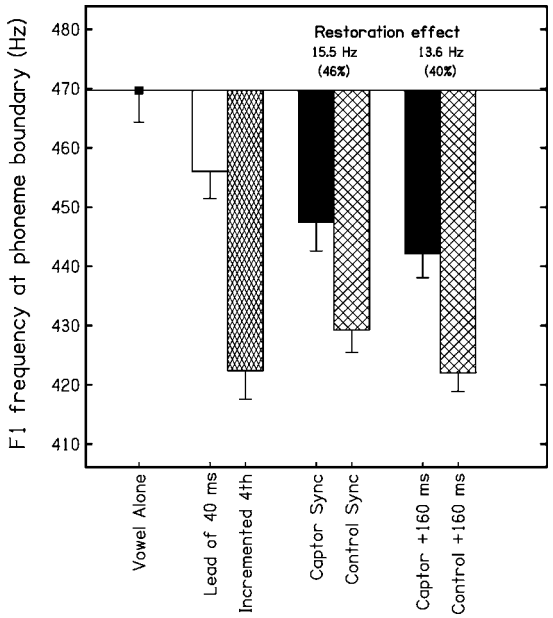

FIG. 3. Results for experiment 2—effect of captor asynchrony for a short lead-time on the fourth harmonic (40 ms). Phoneme boundaries and restoration effects are displayed as for Fig. 2.

A. Method

There were seven conditions—the standard three plus two captor conditions and their controls. The lead time on the added 500-Hz tone was set to 40 ms. The 1-kHz captor either began at the same time as the leading 500-Hz component (synchronous onset), or 160 ms before it (advanced onset). Hence, the durations of these captors were 40 and 200 ms, respectively. The number of trials per block in the main experiment was 140 (7 conditions $\times$ 20 F1 values).

B. Results and discussion

Figure 3 displays the mean phoneme boundaries for each condition, with intersubject standard errors, and restoration effects for each captor condition. The effect of condition on the position of the phoneme boundary was highly significant [$F(6,66)=32.543$, $p<0.001$]. The boundary for the incremented-fourth condition was lower than the boundary for the vowel-alone condition [$t(11)=9.694$, $p<0.001$], indicating that perceived F1 frequency was raised when extra

energy was added in synchrony to the fourth harmonic. The size of the mean boundary shift was 47 Hz. The boundary for the leading-fourth condition was higher than the boundary for the incremented-fourth condition [$t(11)=5.242$, $p<0.001$], but was still lower than the boundary for the vowel-alone condition [$t(11)=2.577$, $p=0.026$]. This indicates that most, but not all, of the extra energy at 500 Hz was excluded from the perceptual computation of F1 frequency when it began 40 ms before the vowel.

Analysis of the restoration effects revealed that there was no significant difference between the two captor conditions [$F(1,11)=0.499$, $p=0.495$], and that the overall magnitude of the restoration effect was significantly above zero [$t(11)=4.672$, $p<0.001$]. This suggests that both the synchronous-onset and the advanced-onset captors were equally effective in weakening the effect of applying a lead time of 40 ms to the added 500-Hz tone. The overall mean restoration effect was about 43%, which is at least as large as the overall mean for experiment 1.

An asynchrony of 40 ms is almost as effective at excluding the additional energy at 500 Hz from the perceptual estimation of F1 frequency as the lead time of 240 ms used in experiment 1. This is consistent with the findings of Roberts and Moore (1991). They added tones to the F1 region, at frequencies other than harmonics of F0, and showed that the reduction in the effect on vowel quality when the extraneous energy began before the vowel approached asymptote around a lead time of 40 ms. Darwin (1984b) and Darwin and Sutherland (1984) found that an onset-time difference of only 32 ms was sufficient largely to abolish the phonetic effects of boosting the fourth harmonic (500 Hz) of a vowel. Furthermore, Rasch (1978) found that a lead time of 30 ms was sufficient for a signal tone to be perceived as continuing through a masking tone. Clearly, the auditory system can utilize small differences in the onset times of acoustic events to segregate them perceptually.

Darwin and Sutherland's (1984) study did not include any short-duration captors. The size of the restoration effect brought about by the synchronous-onset captors (duration =40 ms) was comparable with that brought about by the advanced-onset captors (duration=200 ms) and also by the long captors (duration=up to 400 ms) used in experiment 1. This extends the findings of experiment 1 by suggesting that temporal integration of captor energy is essentially complete by 40 ms. However, the most important outcome is the replication of the finding that relative onset-time does not affect captor efficacy. The later of the two onsets determines the point at which the auditory system can detect an asynchrony between the 500-Hz tone and the captor tone. Only 40 ms elapsed from this point to the onset of the vowel in the current experiment, whereas, in experiment 1, 80 ms elapsed for the delayed-onset captors and 240 ms elapsed for the advanced-onset captors. The short time from captor onset to vowel onset in the current experiment makes it highly unlikely that the effect of the asynchrony had decayed away by the time the vowel began. Therefore, we can conclude that the similar efficacy of synchronous and asynchronous captors is a genuine effect.

V. EXPERIMENT 3

Darwin and Sutherland's (1984) choice of a captor frequency one octave above the leading 500-Hz tone means that their captor tone may have formed a perceptual group with the leading portion of the added tone on the basis of harmonic relations. Experiments 1 and 2 manipulated the relative onset time of the captor and the leading tone, but maintained this octave relationship. Therefore, it is possible that captor efficacy in all of these experiments depended on grouping by harmonic relations rather than on grouping by common onset. Experiment 3 explored this possibility by including some captors that were harmonically related to the leading tone and some that were not. The range of captor frequencies used exceeded two octaves, and so also allowed the effect of frequency separation between the captor and the leading tone to be measured. The lowest-frequency captor used was 900 Hz, which is about four ERBs [equivalent rectangular bandwidths (Glasberg and Moore, 1990)] above the leading tone. This lower limit was set to ensure that any spread of excitation from the captor would not produce any significant adaptation in auditory nerve fibers tuned to 500 Hz.

A. Method

There were 17 conditions—the standard three plus seven captor conditions and their controls. The lead time on the added 500-Hz tone was set to 240 ms, and the captor always began at the same time as the leading 500-Hz component (synchronous onset). Captor frequencies were set to be multiples of either 450 Hz or 500 Hz, only the latter of which are harmonically related to the leading fourth harmonic. The set of values used was 900, 1000, 1350, 1500, 1800, 2000, and 2250 Hz. The range of frequencies used ensured that each harmonic value tested was bracketed by inharmonic values. The 1-kHz captor case is identical to the synchronous-onset captor case in experiment 1. The number of trials per block in the main experiment was 340 (17 conditions $\times$ 20 F1 values).

B. Results

Figure 4(a) displays the mean phoneme boundaries for each condition, with intersubject standard errors. The "H" symbols indicate cases where the captor frequency was harmonically related to the leading 500-Hz component. The effect of condition on the position of the phoneme boundary was highly significant [$F(16,176)=23.058$, $p<0.001$]. The boundary for the incremented-fourth condition was lower than that for the vowel-alone condition [$t(11)=10.144$, $p<0.001$], indicating that perceived F1 frequency was raised when extra energy was added in synchrony with the fourth harmonic. The size of the mean boundary shift was 50 Hz. The boundary for the leading-fourth condition was higher than that for the incremented-fourth condition [$t(11)=5.501$, $p<0.001$], but did not differ from the boundary for the vowel-alone condition [$t(11)=0.308$, $p=0.764$]. As for experiment 1, this indicates that the extra energy at 500 Hz was excluded from the perceptual computation of F1 frequency when it began 240 ms before the vowel.

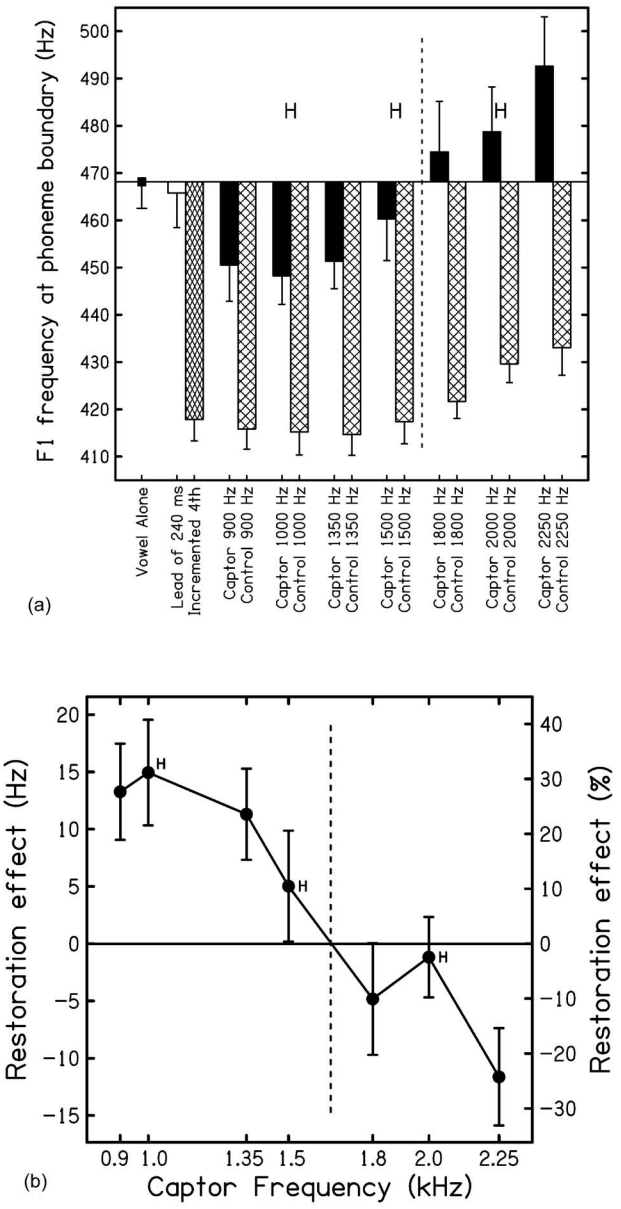

FIG. 4. Results for experiment 3—effect of captor frequency and harmonic relations with respect to the leading fourth harmonic. Part (a) displays the phoneme boundaries as for Fig. 2. The H symbols indicate captor conditions for which the captor frequency was harmonically related to the leading fourth harmonic. The vertical dotted line divides the captor conditions for which the control boundaries are close to the incremented-fourth boundary (on the left) from those for which the control boundaries drift towards higher F1 values (on the right). See text for a full discussion of the underlying basis for this distinction. Part (b) displays the restoration effects across captor frequency as F1 boundary shifts in Hz (left axis) and as a percentage of the boundary difference between the leading-fourth and incremented-fourth conditions (right axis). The H symbols and the vertical dotted line correspond to their counterparts in part (a).

The boundaries for the captor controls were very similar to the boundary for the incremented-fourth condition for frequencies up to 1500 Hz, but drifted upwards for frequencies of 1800 Hz and above. This distinction is indicated by the vertical dotted line in Fig. 4(a). The upward drift in boundary for the captor controls was significant for the highest two frequencies tested [2000 Hz: $t(11)=2.770$, $p=0.018$; 2250 Hz: $t(11)=2.444$, $p=0.033$]. Furthermore, in contrast with the usual pattern, the boundary shifts for the corresponding captor conditions were *negative* (i.e., upward) for frequencies of 1800 Hz and above.

Figure 4(b) displays the mean restoration effects for each captor condition, with intersubject standard errors. The "H" symbols and the vertical dotted line correspond to their counterparts in Fig. 4(a). Analysis of the restoration values revealed a highly significant effect of captor frequency [$F(6,66)=8.285$, $p<0.001$]. Restoration values were significantly above zero for captor frequencies below 1500 Hz [900 Hz: $t(11)=3.161$, $p=0.009$; 1000 Hz: $t(11)=3.244$, $p=0.008$; 1350 Hz: $t(11)=2.842$, $p=0.016$]. This indicates that the ability of the captor partly to reverse the effect of starting the added 500-Hz tone before the vowel is frequency dependent. The restoration effect was about 25%–30% for captor frequencies up to 1350 Hz, but declined to zero as the captor frequency was increased to about 1500–1800 Hz. Pairwise comparisons showed that the restoration values for the lower-frequency captors (900, 1000, and 1350 Hz) did not differ from one another, but they all differed ($p<0.05$) from the restoration values for the higher-frequency captors (1800, 2000, and 2250 Hz). The restoration effect for the highest-frequency captor (2250 Hz) was the only value to fall significantly below zero [$t(11)=-2.735$, $p=0.019$]. Captor efficacy does not appear to depend on a harmonic relationship between the captor and the added tone.

C. Discussion

First, we consider the effects of captor frequencies in the range 900–1500 Hz, for which the boundaries for the corresponding captor controls were very close to the boundary for the incremented-fourth condition. Next, we consider the effects of captor frequencies in the range 1800–2250 Hz, for which the corresponding control boundaries are shifted upwards relative to the incremented-fourth condition. Finally, we consider the extent to which harmonic relations between the captor and the leading fourth harmonic may influence captor efficacy.

The findings for the lower-frequency captors indicate that frequency separation is a key factor governing the magnitude of the restoration effect. The effect of the captor appears to be broadband with an upper cutoff frequency of about 1500 Hz. This indicates that the response to the captor extends up to about one-and-a-half octaves above the frequency of the leading fourth harmonic. Note that this estimate of the bandwidth of the captor response is not affected by the atypical boundary shifts observed for the higher-frequency captors, because captor efficacy clearly declines in the 1350–1500-Hz region, before the control boundaries show any clear sign of upward drift with respect to the incremented-fourth condition. The significance of the observed bandwidth effect is considered further in Sec. VIII.

The findings for the higher-frequency captors illustrate the importance of including captor controls in the experiment. The upward drift in the boundaries of the captor controls for frequencies of 1800 Hz and above indicates that the influence of these captors on perceived vowel quality was not solely through modulating the effect of asynchrony on the contribution of the boosted fourth harmonic. How else

might these captors have affected vowel quality? The test range used was chosen to avoid the spread of adaptation to frequencies close to F1, but the higher-frequency captors used will have adapted the lower skirt of the second formant, which began around 1800 Hz for our stimuli. The degree of adaptation may have been considerable, given that the captors were set to be 6 dB above the original level of the fourth harmonic, and that the intensity of F2 was below that of F1.

We used a fixed F2 frequency of 2300 Hz for all our stimuli, but spoken examples of /ɛ/ typically have a lower F2 frequency than spoken examples of /ɪ/ (see, e.g., Henton, 1983). Therefore, the rise in perceived F2 frequency resulting from adapting the lower skirt of F2 may have made our stimuli sound more /ɪ/-like, leading to a rise in phoneme boundary. The finding that the highest-frequency captor (2250 Hz) was associated with the greatest upward shift in the control boundary seems to challenge this idea, because here the perceptual effect of the adaptation would have been to flatten the F2 peak rather than to raise the F2 frequency. However, the cluster of higher formants in front vowels is typically integrated perceptually into a single energy peak called F2-prime (Chistovich *et al.*, 1979; Chistovich, 1985). The center-of-gravity of this cluster would be raised by flattening the F2 peak. The finding of a negative restoration effect for the highest-frequency captor indicates that the inclusion of captor controls is not always entirely successful in partialling out unwanted effects. Perhaps the influence of the captor on perceived F1 (via modulation of the effect of asynchrony) and its influence on perceived F2-prime (via adaptation) are not strictly additive effects.

Darwin and Sutherland's (1984) choice of an octave relationship between the captor and the leading portion of the added tone in principle may have provided another cue for grouping them together. However, the results of the current experiment do not support this hypothesis. Not only is it clear that the captor does not need to be harmonically related to the leading component to produce a restoration effect, but there is also little or no evidence that captor efficacy is increased by this kind of harmonic relationship. Rather, the influence of frequency on captor efficacy appears to depend only on spectral separation. Nonetheless, it should be acknowledged that the use of pure-tone captors does not provide a very strong test of the effect of harmonic relations. Bregman (1990) has argued that at least three components must be present before their simultaneous grouping can be influenced by harmonic relations. In support of this idea, he noted that Bregman and Doehring (1984) had shown that a partial could be captured from a three-component complex into a sequential stream more easily when it was mistuned relative to the others, whereas Bregman and Pinker (1978) had not found such an effect for two-tone complexes. A more rigorous test of whether or not harmonic relations can influence captor efficacy would require the use of multicomponent captors. This idea is considered further in Sec. VIII.

VI. EXPERIMENT 4

Experiments 1–3 have shown that captor efficacy does not depend on the formation of a perceptual group between the captor and the leading portion of the 500-Hz tone on the basis of either common onset or harmonic relations. However, in all of these experiments, one or other of these grouping factors was left undisrupted. Therefore, to rule out the possibility that the remaining factor favoring the grouping of the captor and the leading tone was sufficient to maintain captor efficacy, we included a condition in which the captor had neither a common onset nor harmonic relations with the leading tone.

A. Method

There were 11 conditions—the standard three plus four captor conditions and their controls. The lead time on the added 500-Hz tone was set to 160 ms. The four captor conditions were derived from a combination of two binary-state variables: (a) captor began at the same time as the leading 500-Hz component (synchronous onset, captor duration $=160$ ms) or 80 ms earlier (advanced onset, captor duration $=240$ ms) and (b) captor frequency was set to 1000 Hz (harmonic case) or 900 Hz (inharmonic case). The number of trials per block in the main experiment was 220 (11 conditions $\times$ 20 F1 values).

The procedure used to screen for listeners to take part in experiments 4 and 5 was more stringent than that used in the earlier experiments. The original screening used only the vowel-alone and incremented-fourth continua. Experiments 1–3 established that asynchrony can produce a clear reduction in the effect of added energy at 500 Hz, and that the effect of the extra energy can be partly restored by accompanying the leading portion with a captor tone. Therefore, the screening and training was extended to include a leading-fourth condition (lead time$=240$ ms), a captor condition (1 kHz, synchronous onset), and its control. Listeners identified ten randomized blocks of tokens from these five conditions (1000 trials). The additional criterion was that a minimum restoration effect of 5 Hz was required for listeners to proceed to the main experiment. This criterion further excluded about 10% of those volunteers who would have passed the original screening. However, it largely eliminated the subsequent exclusion of data from the main experiment based on obtaining a nonmonotonic identification function, or a boundary estimate that fell outside the test range, for one or more of the conditions.

B. Results and discussion

Figure 5 displays the mean phoneme boundaries for each condition, with intersubject standard errors, and restoration effects for each captor condition. The effect of condition on the position of the phoneme boundary was highly significant [$F(10,110)=49.971$, $p<0.001$]. The boundary for the incremented-fourth condition was lower than the boundary for the vowel-alone condition [$t(11)=15.031$, $p<0.001$], indicating that perceived F1 frequency was raised when extra energy was added in synchrony to the fourth harmonic. The size of the mean boundary shift was 51 Hz. The boundary for the leading-fourth condition was higher than the boundary for the incremented-fourth condition [$t(11)=8.4000$, $p<0.001$], but did not differ from the boundary for the vowel-

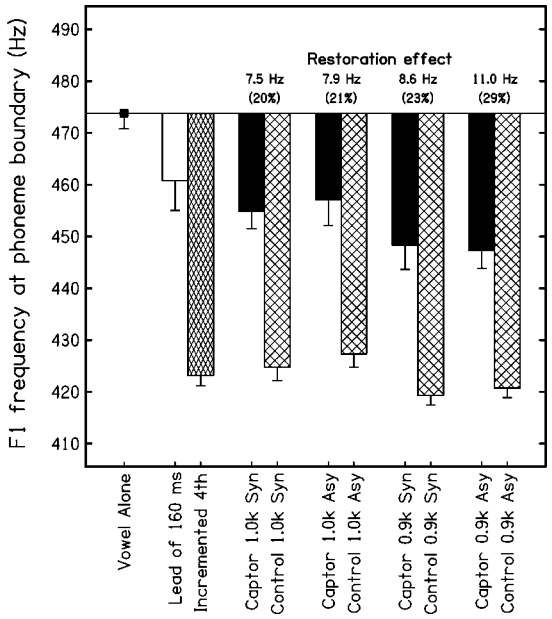

FIG. 5. Results for experiment 4—effect of captor asynchrony and inharmonicity. Phoneme boundaries and restoration effects are displayed as for Fig. 2.

alone condition [$t(11)=2.027$, $p=0.068$]. This indicates that the extra energy at 500 Hz was excluded from the perceptual computation of F1 frequency when it began 160 ms before the vowel.

Analysis of the restoration effects revealed that there was no significant difference between the four captor conditions [$F(3,33)=0.470$, $p=0.706$]. The overall magnitude of the restoration effect (about 8.7 Hz, or 23%) was smaller than that observed in experiments 1 and 2 and was not quite significantly greater than zero [$t(11)=2.003$, $p=0.071$]. However, an inspection of the individual data identified one listener who obtained negative restoration values for all four captor conditions, owing to an unusually small boundary return for the leading-fourth condition. For the other 11 listeners, the overall magnitude of the restoration effect was significantly greater than zero [$t(10)=3.034$, $p=0.013$].

The results suggest that the four types of captor were equally effective in weakening the effect of applying a lead time of 160 ms to the added 500-Hz tone. Note that the failure to find a significant reduction in efficacy when the captor is both asynchronous and inharmonic cannot be attributed to a lack of statistical power, because the observed magnitude of the restoration effect was actually greatest for this condition. Therefore, we can rule out the possibility that captor efficacy was maintained in the earlier experiments because the captors used retained *at least* either a common onset or a harmonic relationship with the leading 500-Hz tone. It is clear that captor efficacy, both in our study and in the study of Darwin and Sutherland (1984), does *not* depend on the grouping of the captor with the leading 500-Hz tone on the basis of common onset or harmonicity.

VII. EXPERIMENT 5

Whatever the basis of the restoration effect, it is clear that asynchrony is less effective at excluding an added 500-Hz tone from perceived vowel quality when the leading portion is accompanied by a captor tone. Darwin (1995) has shown that asynchrony is also less effective at perceptually excluding the added tone when its leading portion is reduced in level. The greater the attenuation, the greater the downward shift in boundary towards the value for the incremented-fourth condition. The extent of this *boundary return* provides a measure of the effect of the attenuation that is closely analogous to the magnitude of the restoration effect as a measure of captor efficacy. Hence, finding the attenuation required to produce a boundary return of similar size to a typical restoration effect (about a third) allows the effect of the captor to be expressed as equivalent to applying that level of attenuation to the leading portion of the fourth harmonic. Darwin's (1995) stimuli were similar to ours and included instances equivalent to attenuating the leading portion of the fourth harmonic by 6 dB and by 15 dB. Interpolating between these values suggests that the effect of the captors that we used in experiments 1–4 was equivalent to attenuating the leading portion of the fourth harmonic by about 9 dB. Our informal observations were generally consistent with Darwin's, but suggested that the boundary return produced by a given level of attenuation may have been greater than was apparent in his data. Therefore, we tested a full set of listeners using parameters for the vowel stimuli that were identical to those used in experiment 4.

A. Method

There were seven conditions—the standard three plus four conditions in which the level of the *leading portion* of the added 500-Hz tone was attenuated by 6, 12, 18, or 24 dB, with respect to the leading-fourth condition. The linear increase in amplitude at the end of the leading portion of the added tone, to reach its steady-state value, was simultaneous with the onset ramp for the vowel. No captor tones were present in any of the conditions. The lead time on the added 500-Hz tone was set to 160 ms. The number of trials per block in the main experiment was 140 (7 conditions conditions $\times$ 20 F1 values).

B. Results and discussion

Figure 6 displays the mean phoneme boundaries for each condition, with intersubject standard errors. It can be seen that attenuating the leading portion of the added 500-Hz tone causes the boundary to shift downwards from its value for the leading-fourth condition towards its value for the incremented-fourth condition. Mean boundary returns are displayed for each level of attenuation above the corresponding histogram bars. Each value is quoted as an F1 boundary shift in Hz and also as a percentage of the boundary difference between the leading-fourth and incremented-fourth conditions.

The effect of condition on the position of the phoneme boundary was highly significant [$F(6,66)=48.136$, $p<0.001$]. The boundary for the incremented-fourth condition was lower than the boundary for the vowel-alone condition [$t(11)=16.837$, $p<0.001$, indicating that perceived F1 frequency was raised when extra energy was added in syn-

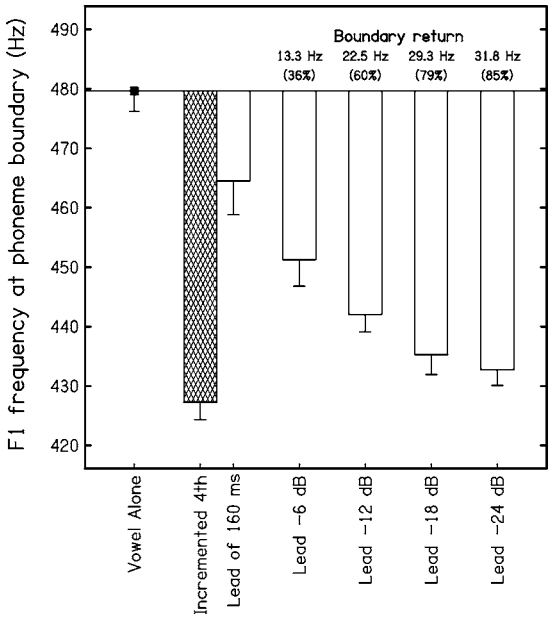

FIG. 6. Results for experiment 5—effect of attenuating the leading portion of the fourth harmonic. Phoneme boundaries for the reference condition (vowel alone) and for the incremented-fourth condition are displayed as for Fig. 2. From left to right, the open bars show the boundaries for the leading-fourth conditions as the attenuation of the leading portion is increased from 0 to 24 dB in 6-dB steps. The extent to which attenuating the leading portion returns the boundary to that for the incremented-fourth condition is quoted as an F1 boundary shift in Hz and as a percentage of the boundary difference between the leading-fourth (0 dB) and incremented-fourth conditions.

chrony to the fourth harmonic. The size of the mean boundary shift was 52 Hz. The boundary for the leading-fourth condition was higher than the boundary for the incremented-fourth condition [$t(11)=7.005$, $p<0.001$], but was still lower than the boundary for the vowel-alone condition [$t(11)=2.354$, $p=0.038$]. This indicates that most, but not all, of the extra energy at 500 Hz was excluded from the perceptual computation of F1 frequency when it began 160 ms before the vowel.

To assess the effect of attenuation on the extent of the boundary return, a within-subjects ANOVA was performed on the transformed data. Analysis of the boundary returns revealed a highly significant effect of level of attenuation [$F(3,33)=22.488$, $p<0.001$]. Pairwise comparisons with the leading-fourth condition indicated that even the smallest attenuation used (6 dB) caused a significant shift in the boundary back towards its position for the incremented-fourth condition [$t(11)=3.977$, $p=0.002$]. Pairwise comparisons with the incremented-fourth condition indicated that the boundary return, though substantial, was incomplete even for the largest attenuation used (24 dB) [$t(11)=3.771$, $p=0.003$]. These findings indicate that reducing the level of the leading portion of the added 500-Hz tone progressively weakens the effect of the asynchrony, but that a small effect remains even when the leading portion has been attenuated to far below the level of any harmonic in the F1 region of the vowel. Darwin (1995) found a similar relationship, except that the boundary return for a given level of attenuation was about 10% greater in our study than in his. Nonetheless, it should be noted that this difference is small enough for our data to be compatible with Darwin's conclusion that listeners are generally able to subtract perceptually the amplitude of the leading portion of the added 500-Hz tone from the overall amplitude at that frequency during the vowel.

The extent of restoration brought about by the captors used in the earlier experiments averaged about a third. Therefore, the boundary returns observed in the current experiment suggest that accompanying the leading portion of the fourth harmonic with a captor tone of equal level is equivalent to reducing its physical level by about 6 dB. This is a little less than the reduction of 9 dB suggested by Darwin's (1995) data. It seems plausible that this degree of "gain reduction" in the neural response might arise from an inhibitory process in the central auditory system. Note that this does not necessarily imply that the captor decreases the perceived level of the leading portion of the fourth harmonic.

VIII. FINAL DISCUSSION

Darwin and Sutherland (1984) proposed that the partial restoration of the contribution of the asynchronous fourth harmonic to vowel quality depends on the perceptual grouping of the captor tone with the leading portion of that component. They envisaged the common onset time for the captor and the leading portion as the primary factor governing their grouping. Harmonic relations between them may have provided an additional basis for their grouping. However, our results indicate that the restoration effect produced by a pure-tone captor does not depend either on a common onset, or harmonic relations between the captor and the leading component. In the absence of any other obvious factors encouraging their grouping, a different kind of explanation is required. Given the results of experiment 5, we propose that the effect of the captor is mediated by a reduction in the *effective* level of the leading portion of the fourth harmonic that arises from an inhibitory interaction between the two components. Before this proposal is discussed in more detail, it is important to consider the implications of using single- (rather than multi-) component captors, in relation to assessing the possible contribution to the restoration effect of grouping by harmonicity.

A. Captor efficacy and harmonic relations

Darwin and Ciocca (1992) showed that a slightly mistuned component made a smaller contribution to the global pitch of an otherwise harmonic complex tone when it began 160 ms or more before the other components. Ciocca and Darwin (1993) found that this effect of onset asynchrony could be reduced by accompanying the leading portion of the mistuned harmonic with a simultaneous multi-component captor. The target complex had an F0 of 155 Hz and the leading fourth component was set to either 640 or 600 Hz, corresponding to a mistuning of about +3% or −3%, respectively. The captor comprised harmonics 1–2 and 4–5 of either an F0 of 200 Hz or of 213.3 Hz. These values were chosen so that the leading component either corresponded to the third harmonic of the captor F0 or was mistuned from it by about 6%. Ciocca and Darwin (1993) found that the captor was effective at restoring the contribution of the leading

component to global pitch only when it was harmonically related to that component and when the onset asynchrony on the leading component was 160 ms or more. This result suggests that grouping by harmonicity primarily determines captor efficacy in this context, such that an inharmonic relationship between the leading component and the captor prevents grouping by common onset.

Bregman (1990) has argued that a minimum of two components is needed to define a harmonic frame with which another component may fuse perceptually on the basis of sharing a common F0. This requirement was not met by Darwin and Sutherland (1984), or in our experiments, because pure-tone captors were used. However, there are potential difficulties in using captors comprising more than one component when judgments of vowel quality are required. To avoid significant adaptation in the region of F1 and F2, the captor components would need to be restricted to fall in the spectral trough between these two formants. To ensure that the captor components and the leading fourth component (500 Hz) also form a set of consecutive harmonics, the only option would be to use a two-component captor with frequencies of 1000 and 1500 Hz. The efficacy of this captor could be compared with that of others whose partials did not form a harmonic series with the leading fourth component. However, it should be noted that pitch and timbre are distinct perceptual properties of a complex tone (cf. Hukin and Darwin, 1995), and so the factors that govern the ability of a captor to reduce the effects of onset asynchrony on judgments of these different attributes are not necessarily the same. Whatever the outcome of the proposed experiment, we can be confident that the significant restoration effect produced by pure-tone captors, in the context of judgments of vowel quality, cannot be explained in terms of harmonic relations.

B. How might the restoration effect arise from inhibitory interactions in the central auditory system?

Our proposal that the restoration effect arises from inhibitory interactions between the captor and the leading portion of the fourth harmonic poses the question of how and where this happens in the auditory system. Inhibitory interactions between cells occur at many levels in the central auditory system, and so the psychophysical restoration effect may arise at one of several (or even multiple) locations along the auditory pathway. Given this, our approach has been to propose a neural processing scheme that is simple, based on known physiology, and located as early in the auditory pathway as is plausible. On this basis, a cochlear-nucleus circuit is presented that has the right kind of response properties to account for the restoration effect, but which also serves a more general illustrative purpose. Even if the restoration effect is eventually shown to arise from inhibitory interactions elsewhere in the auditory system, these interactions are very likely to produce responses with the same general form as those described here.

The key to the circuit is broadband inhibition in the ventral cochlear nucleus (Palombi and Caspary, 1992) applied by onset chopper (OC) cells to transient chopper (CT) cells, as shown schematically in Fig. 7. Each CT cell receives excitation from auditory nerve fibers arising from the same place along the cochlea, and so has a narrow-band receptive field. CT cells are known to receive inhibitory inputs from OC cells (Ferragamo *et al.*, 1998), and these connections are assumed to occur between cells sharing a common "best frequency" or BF (e.g., Pressnitzer *et al.*, 2001). Each OC cell receives excitation from auditory nerve fibers arising from different places along the cochlea, and so has a wideband receptive field. The receptive field of an OC cell extends on average from about two octaves below the cell's BF to about one octave above (Palmer *et al.*, 1996). Note that the effect of frequency separation on captor efficacy that was observed in experiment 3 is broadly consistent with the expected upper cutoff frequency for OC cells with a BF equal to the frequency of the leading fourth harmonic (500 Hz). The output of the circuit is transmitted via the excitatory projections from the CT cells to the dorsal cochlear nucleus and inferior colliculus (e.g., Adams, 1983).

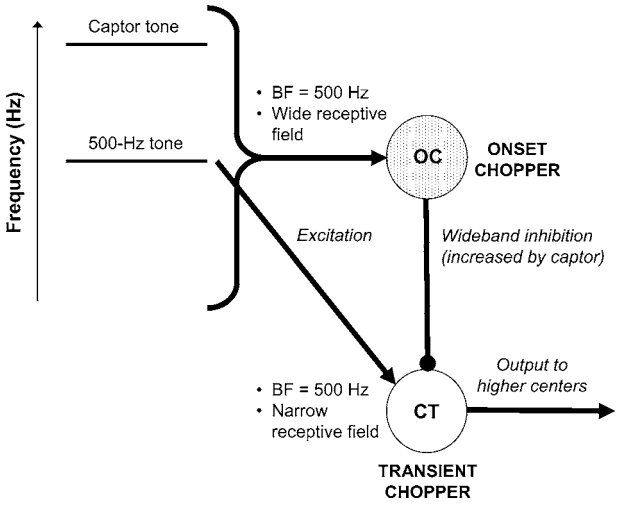

FIG. 7. Schematic of a hypothetical neural circuit in the cochlear nucleus to account for the restoration effect. BF refers to the best frequency of a cell. It is proposed that the captor tone reduces the excitatory response of transient choppers (CTs) tuned to the leading portion of the 500-Hz tone by increasing the wideband inhibitory input to these cells from onset choppers (OCs) with the same BF. This is equivalent to reducing the level of the leading portion, which has been shown to reduce the effect of asynchrony on the contribution of the 500-Hz tone to perceived vowel quality (experiment 5). See text for a full discussion.

Consider the response of CT and OC cells with a BF of 500 Hz to the leading portion of the fourth harmonic in our stimuli. Both types of cell will receive excitation from auditory nerve fibers tuned to 500 Hz, but the response of the CT cells will depend on the balance of this excitation and the weaker inhibition received via the OC cells. Now consider how the output of these CT cells will change when the leading portion of the 500-Hz component is accompanied by a 1-kHz captor tone. The captor tone falls outside the narrow receptive field of the CT cells, but falls within the wide receptive field of the OC cells. Hence, the direct excitatory input to these CT cells will not change, but the indirect inhibitory input will increase, leading to a reduced response to the 500-Hz component. This net inhibition may be regarded as reducing the *effective* level of the leading portion of the

fourth harmonic, such that the presence of the captor has a similar effect to that of reducing its *physical* level, as observed in experiment 5. However, there is another means by which the increased inhibition evoked by the captor tone might lead to a restoration effect. Both we and Darwin and Sutherland (1984) have used captor tones that ended at the same moment as the components of the vowel began. The release from inhibition at captor offset may have produced a transient rebound in the excitatory response of CT cells tuned to 500 Hz, and hence an increased response to the fourth harmonic at vowel onset.

Bleeck *et al.* (2005) have recently observed responses in the ventral cochlear nucleus of the guinea pig that are consistent with the two aspects of the proposed mechanism. They used a two-component complex tone in which the higher component ended first. The lower component was chosen to match the BF of the unit being recorded and the higher component was set to be spectrally remote. This arrangement is analogous to that of our fourth harmonic (which continues through the vowel) and captor tone (which ends at vowel onset). A number of units, some of which were classified as CT cells, showed both a reduced response to the lower tone when the upper tone was present (sustained inhibition) and a rebound burst when the upper tone terminated (release from inhibition). Of course, the response to stimuli like those used in our psychophysical studies is complicated by the onset of all the other components of the vowel when the captor ends, many of which may act to inhibit the response to the continuing 500-Hz component. However, two points are worth noting. First, the fourth harmonic is the most intense component of the vowel, because it is both close to the F1 frequency and incremented by 9.5 dB relative to the spectral envelope. Second, the key comparison is between the response to the fourth harmonic at vowel onset in the presence or absence of the captor. Compared to the no-captor case, the termination of the captor would still have produced a *relatively* greater response to the fourth harmonic at vowel onset, even if the other components of the vowel acted to reduce the absolute magnitude of the response.

In conclusion, our proposed processing scheme provides a good qualitative account of our psychophysical findings. Although there is insufficient evidence to conclude that the restoration effect arises specifically in the cochlear nucleus, it seems very probable that it arises somewhere in the central auditory system from broadband inhibition of a similar form.

C. Implications for asynchrony as a cue for auditory grouping and concluding remarks

Our findings contradict Darwin and Sutherland's (1984) proposal that the restoration effect depends on the perceptual integration of the captor and the leading portion of the four harmonic. However, this outcome does *not* undermine the idea that the reduced contribution to vowel quality made by a component that begins before the others depends on asynchrony acting as a perceptual grouping cue for its exclusion. It was noted earlier that an offset asynchrony, produced by extending a component beyond the end of a vowel, can reduce its contribution to vowel quality (Darwin and Sutherland, 1984; Darwin, 1984b; Roberts and Moore, 1991). Peripheral adaptation cannot account for this perceptual effect. What remains for conjecture is the functional significance of the restoration effect and the reason for its insensitivity to the established grouping cues of common onset-time and harmonic relations.

We suggest that the restoration effect produced by a captor arises as a by-product of a mechanism that has evolved to enhance the representation of spectral features in broadband stimuli. The simple neural circuit that we have proposed to account for our data provides the basis for a network of lateral inhibition in which the more intense components will be more effective than the less intense ones at reducing the excitation evoked by the other components. For our stimuli, only two elements preceded the vowel (the captor and the leading portion of the fourth harmonic) and these were equally intense, most probably leading to a comparable degree of mutual inhibition. Hence, the idea that accompanying the leading portion of the fourth harmonic with a captor tone reduces the effective level of the leading portion seems a reasonable one. Furthermore, it seems plausible that a mechanism designed to enhance spectral features in a stimulus is fundamental enough to operate *before* grouping cues are used to decide whether the stimulus represents one or more acoustic events in the environment.

Further research is required to assess how well our proposed neural circuit in the cochlear nucleus can explain why onset asynchrony is less effective at excluding an added 500-Hz tone from perceived vowel quality when it is accompanied by a captor. However, it can be concluded from our psychophysical results that the *modulating* influence of a pure-tone captor on the consequences of onset asynchrony for timbre perception does not depend on grouping cues. Whatever the details of the underlying neural processes eventually prove to be, it seems very likely that the restoration effect arises from some kind of inhibitory interaction between the captor and the leading portion of the asynchronous component of the vowel. More generally, researchers should be aware of the potential for the presence of broadband inhibitory effects to produce patterns of behavior confusable with those produced by more cognitive mechanisms of auditory grouping.

ACKNOWLEDGMENTS

This research was supported by Research Grant No. 6/S17805 from the Biotechnology and Biological Sciences Research Council (UK) to the first author. We are grateful to Ian Winter, Stefan Bleeck, Jesko Verhey, and Neil Ingham for their collaborative research on the neural mechanisms in auditory brainstem that may mediate the perceptual effects reported here. Our thanks go to Al Bregman for stimulating discussion about the possible functional significance of the restoration effect produced by the captor tones. We are also grateful to the reviewers, Chris Darwin and Christophe Micheyl, for their helpful comments on an earlier version of this manuscript.

Spectral loudness summation for short and long signals as a function of level

Anne-Kristin Anweiler and Jesko L. Verhey[a)]

(Received 15 June 2005; revised 8 February 2006; accepted 9 February 2006)

The equal-loudness-ratio hypothesis (ELRH) assumes that the loudness ratio between equal-level long and short signals with the same spectrum is independent of level and spectrum. Thus, it predicts the same amount of spectral loudness summation for equal-level short and long signals. To investigate how duration and level affect spectral loudness summation, loudness functions for 10- and 1000-ms bandpass-filtered noise centered at 2 kHz were obtained for normal-hearing listeners using categorical loudness scaling. The bandwidth was varied from 200 to 6400 Hz. From the loudness functions the level difference between the 3200-Hz-wide reference signal and the equally loud test signals was determined for reference levels in the range from 25 to 105 dB SPL. In addition, for two reference levels (45 and 65 dB SPL), this level difference was measured using a loudness-matching procedure. Both procedures showed similar results for the two reference levels. Over a wide level range spectral loudness summation is larger for the short than for the equal-level long signals. This is in contrast to the predictions of the ELRH. However, the data at moderate levels are consistent with the expectations of a modified ELRH which assumes a smaller loudness ratio for broadband than for narrow-band signals.

I. INTRODUCTION

Many studies have shown that loudness depends on the spectrum of a sound. The loudness of a sound with constant intensity significantly increases with bandwidth when a critical bandwidth is exceeded (e.g., Fletcher and Munson, 1933; Zwicker and Feldtkeller, 1955; Zwicker *et al.*, 1957; Scharf, 1959; Cacace and Margolis, 1985; Schneider, 1988). Thus, the level of a narrow-band signal is greater than that of a broadband signal at the same loudness. This effect is commonly referred to as spectral loudness summation. It is believed to be a consequence of two properties of the auditory system: spectral filtering and compression (e.g., Zwicker and Fastl, 1999). In each frequency band, loudness is determined separately. Then total loudness is determined by summing partial loudnesses across frequency bands. Due to the compressive relation between intensity of the signal components falling within the passband of each frequency band and partial loudness, the sum of partial loudnesses for a broadband signal stretching across several frequency bands is larger than the loudness of an equal-SPL narrow-band signal processed within one frequency band.

Loudness depends not only on the spectral content but also on the duration of a sound. Many studies examining the effect of signal duration on loudness have shown that loudness increases with signal duration (Port, 1963; Ekman *et al.*, 1966; Zwicker, 1966; Poulsen, 1981; Takeshima *et al.*, 1988). This effect is commonly referred to as temporal integration of loudness. Temporal integration is usually quantified as the level difference between equally loud short and long signals with the same spectrum (e.g., Poulsen, 1981; Florentine *et al.*, 1996; Buus *et al.*, 1997). Two recent studies investigating the level dependence of temporal integration of loudness (Florentine *et al.*, 1996; Buus *et al.*, 1997) found that the temporal integration of loudness varied nonmonotonically with level. They concluded that the loudness function must have a different slope for short and long stimuli at the same loudness. Based on these findings, Florentine *et al.* (1996) proposed the equal-loudness-ratio hypothesis (ELRH), which assumes that the loudness ratio between equal-SPL long and short signals is independent of level. This hypothesis is in good agreement with the data of Epstein and Florentine (2005) who measured loudness functions for short (5 ms) and long (200 ms) 1-kHz tones using cross-modality matching. They obtained an approximately constant loudness ratio except for a slight increase at low levels (below 40 dB SPL). In addition, Buus *et al.* (1997) assumed that this ratio is also independent of the spectral content of the signal, i.e., the ratio between the loudnesses of two stimuli with different durations, but the same spectrum, is independent of stimulus level and spectrum. Therefore, the loudness versus intensity curves of short and long sounds are vertical transposes of one another, provided they have the same spectrum and loudness is expressed in sones on a logarithmic scale. The ELRH predicts the same magnitudes of spectral loudness summation for different signal durations when compared at the same reference level (Verhey and Kollmeier, 2002) (see also Fig. 2, right panel). However, recent loudness matching data with a broadband reference at medium levels (Verhey and Kollmeier, 2002) indicate that the magnitude of spectral loudness summation (i.e., the level difference between equally loud narrow- and broadband sig-

[a)]Electronic mail: jesko.verhey@uni-oldenburg.de

nals) at the same reference level is larger for short signals (10 ms) than for long signals (1000 ms). Verhey and Kollmeier (2002) argued that a modified version of the ELRH may account for the data if it is assumed that the loudness ratio is smaller for broadband signals than for narrow-band signals.

The effect of duration on the magnitude of spectral loudness summation has hitherto only been investigated over a limited level range and only using a loudness matching procedure (Verhey and Kollmeier, 2002; Fruhmann *et al.*, 2003). The present study investigates whether a similar effect of duration on the magnitude of spectral loudness summation can be found using a different procedure and whether it is only limited to the intermediate level range used in the previous studies. Another aim of the study is to investigate if a modified ELRH with a spectrum-dependent loudness ratio can predict the loudness data. The present study uses the adaptive categorical loudness scaling procedure to investigate spectral loudness summation as a function of duration over a wide level range. In addition, for two intermediate levels, data are obtained using a loudness matching procedure, so that results can be compared across methods.

II. METHOD

A. Procedure

1. Loudness scaling

Loudness functions for short and long bandpass noise signals with different bandwidths were measured using the adaptive categorical loudness scaling procedure (Brand and Hohmann, 2002). Presentation levels were chosen adaptively across the entire auditory dynamic range of the subject and presented in random order. Subjects were asked to rate the loudness of each signal on a response scale consisting of 11 response alternatives. Named loudness categories were "sehr leise" ("very soft"), "leise" ("soft"), "mittel" ("medium"), "laut" ("loud"), and "sehr laut" ("very loud"). Four unnamed intermediate response alternatives were represented by horizontal bars. In addition, the two extreme categories "unhörbar" ("inaudible") and "zu laut" ("too loud") could be selected.

Preliminary measurements showed that for most subjects judging the loudness of the short signals was very difficult when tracks of different bandwidth were interleaved. In order to reduce scattering, bandwidths were therefore presented sequentially. In addition, the shorter signals were presented twice with a silent interstimulus interval of 700-ms duration during each trial.

All subjects performed three repetitions of loudness scaling for each signal duration. The sequence of presentation of durations was randomized between subjects.

Loudness scaling can be biased by several factors including the inaccurate estimation of the limits of the auditory dynamic range and an uneven distribution of the levels within those limits. Brand and Hohmann (2002) showed that the adaptive procedure better covers the dynamic range than a nonadaptive loudness scaling procedure that roughly determined the auditory dynamic range in a premeasurement phase. The accuracy of the categorical scaling procedure is limited by the number of response alternatives. Brand and Hohmann (2002) reported that, because of the restriction to 11 response alternatives, the subjects were forced to respond less accurately than they could, especially at soft levels. Thus, in the present study only levels above 25 dB were further analyzed. At higher levels this effect is reduced. This is probably due to the different slopes of the loudness functions at high and low levels. Brand and Hohmann (2001, 2002) reported that loudness functions tend to be steeper at high than at low levels.

2. Loudness matching

Test stimuli with different bandwidths were matched in loudness to a reference signal with fixed bandwidth and level using a two-interval, two-alternative forced choice procedure with interleaved tracks (Verhey and Kollmeier, 2002). In each trial, test and reference signal were presented in random order separated by a silent interval of 500-ms duration. Subjects indicated which signal was louder by pressing the corresponding key on a keyboard. The level of the test signal was varied according to a one-up one-down procedure. Starting level was either +10 or −10 dB relative to the level of the reference signal. If the subject indicated that the test signal was louder, its level was decreased in the next trial, otherwise it was increased. Step size started at 8 dB. At each upper reversal of the level tracking procedure it was decreased by a factor of 2 until a minimum step size of 2 dB was reached. At this step size the track continued for four reversals and then stopped. The level difference between test and reference signal needed to obtain equal loudness was determined as the mean value of the levels at these last four reversals.

Matching was performed for the two signal durations separately, i.e., signals of different duration were not compared directly. Each subject completed four runs of the experiment for each combination of duration and reference level. The sequence of presentation of reference level and duration was randomized between subjects. Tracks of the five different bandwidths of the same duration were interleaved. The five starting levels of the first and third experimental run were selected randomly from the values 10 and −10 dB relative to the reference level. For the second and fourth runs the respective opposite starting levels were used. This choice of starting levels differs from Buus *et al.* (1997) and Verhey and Kollmeier (2002). However, Verhey (1999) showed that the starting level has a negligible effect on spectral loudness summation for bandpass-noise signals when using an adaptive procedure with interleaved tracks.

B. Data analysis

For analysis of loudness scaling, loudness categories were linearly transformed to numerical values (categorical units, cu) from 0 (inaudible) to 50 (too loud). A model loudness function similar to the one used in Brand and Hohmann (2002) was fitted to all responses of one track. The function consists of two linear parts with independent slope values. The transition region between these linear parts is smoothed using a Bezier fit. The exact equations are given in Appendix

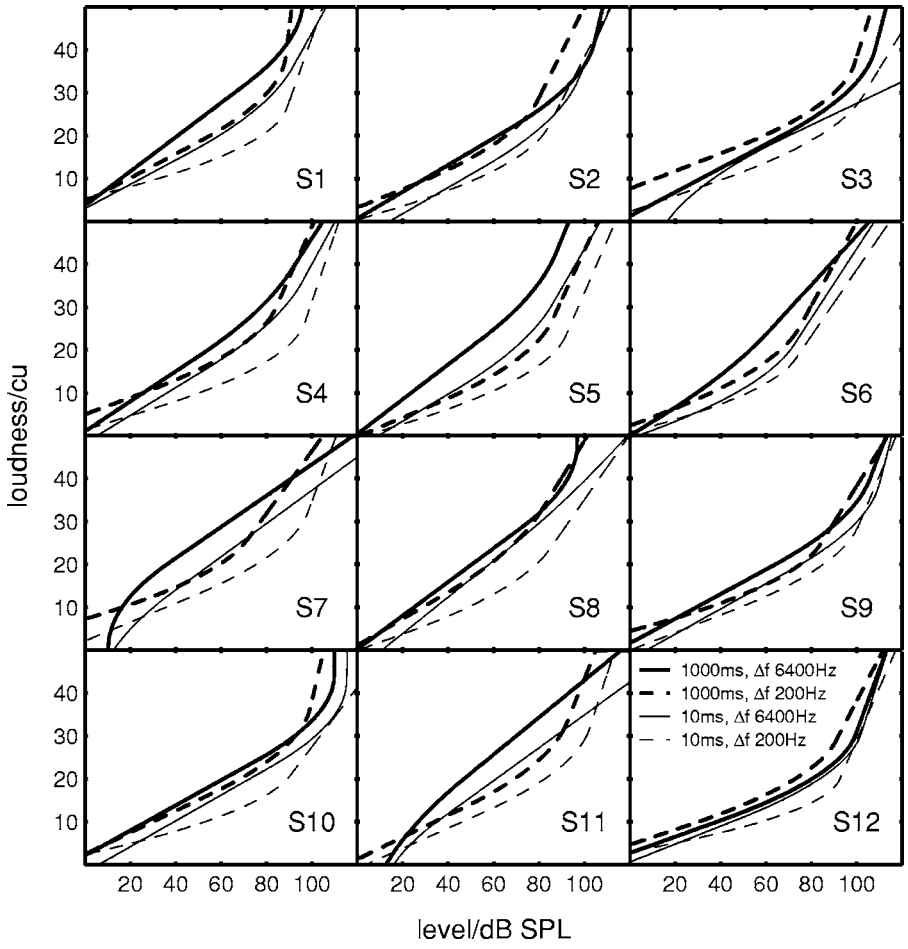

FIG. 1. Individual loudness functions in categorical units as a function of signal level in dB SPL for 12 normal-hearing listeners. Thick lines represent long signals (1000 ms) and thin lines short signals (10 ms). Data are shown for the widest (6400 Hz, solid lines) and narrowest (200 Hz, dashed lines) bandwidth used in the present study. Functions were averaged across three repetitions of the experiment.

A. In contrast to the function used by Brand and Hohmann (2002), the loudness of the intersection point of the linear parts is not fixed at 25 cu but is an additional parameter. A fixed loudness of the intersection point would only allow a horizontal shift along the axis of the physical level between the loudness functions of the short and long signals with the same spectral content. However, Florentine *et al.* (1996) argue that the loudness function for the short signal is a vertically shifted version (towards lower loudness values) of that for the long signal. Therefore the loudness of the intersection point was introduced as a parameter. The loudness function was fitted to the data for each run individually by minimizing the standard deviation. From the loudness functions, the level differences needed to produce the sensation of equal loudness were calculated individually using the inverse loudness function (see Appendix A).

For loudness scaling and matching the mean level difference of all repetitions of the experiment was calculated for each combination of bandwidth, duration, and reference level. To examine the statistical significance of the effects of the stimulus variables a four-way ANOVA for repeated measures was performed (SPSS Release 12.0). The dependent variable was the level difference between test and reference signals at equal loudness. Fixed factors were bandwidth, level, and duration. For loudness scaling five reference levels were chosen: 25, 45, 65, 85, and 105 dB SPL. Subject was a random factor. To investigate sources of significance *posthoc* Scheffé tests were performed.

Levels below 25 dB SPL were not analyzed because of the limited number of response alternatives at soft levels (see above). In addition, Blum *et al.* (2002) reported that the fitted loudness functions tend to underestimate quiet threshold.

C. Stimuli and apparatus

Stimuli for both procedures were bandpass noise signals centered geometrically around 2 kHz. In order to reduce envelope fluctuations, single-iterated low-noise noise was used, i.e., signals were divided by their Hilbert envelope and then restricted to their original bandwidth (Kohlrausch *et al.*, 1997; Verhey and Kollmeier, 2002). Signal durations were 10 and 1000 ms including 5-ms cosine-square ramps at signal on- and offset.

For the loudness scaling experiments signal bandwidths were 200, 400, 800, 1600, 3200, and 6400 Hz. For loudness matching the bandwidth of the reference signal was 3200 Hz. Test signal bandwidths were the remaining band-

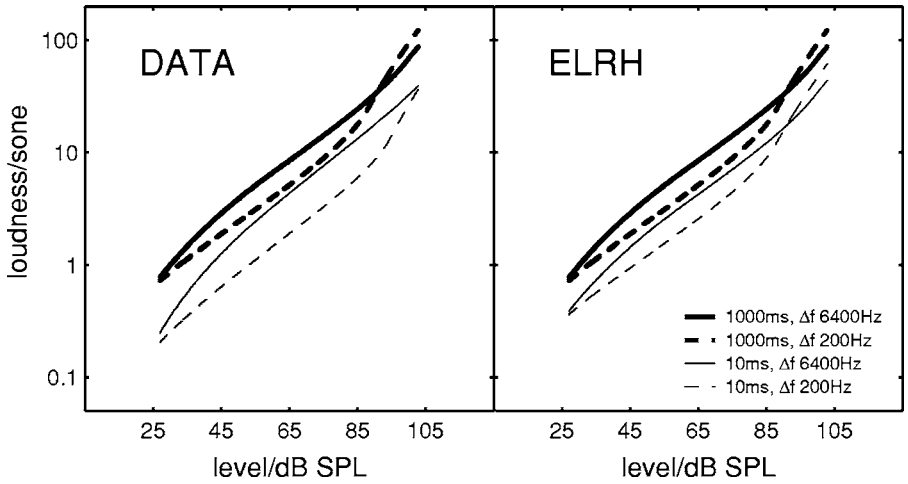

FIG. 2. Loudness functions in sones plotted as a function of signal level in dB SPL for two different bandwidths and two durations. Solid lines represent broadband signals (6400 Hz), dashed lines narrow-band signals (200 Hz). The left panel shows average loudness functions across 12 normal-hearing listeners calculated from loudness scaling data for long signals (1000 ms, thick lines) and short signals (10 ms, thin lines). The right panel shows the same functions as the left panel for long signals, whereas for short signals loudness functions are shifted by a constant factor of 2 relative to those for long signals independent of level and bandwidth as assumed by the equal-loudness-ratio hypothesis (ELRH). In contrast to the predicted loudness functions for the short tones (right panel), the data (left panel) show that the loudness ratio between short and long signals depends on the spectrum and may not be constant for very low and high levels.

widths used in the scaling experiment. Test and reference signal always had the same duration. Reference levels were 45 and 65 dB SPL.

Stimuli were generated digitally at a sampling rate of 44.1 kHz. A standard personal computer controlled stimulus generation and presentation and recorded results using a software package developed at the University of Oldenburg. Stimuli were D/A converted (RME TDIF-1), amplified (Tucker-Davis HB7), and presented monaurally via a Sennheiser HDA 200 headphone with free-field equalization. Subjects were seated in a sound-insulated booth. Responses were given by touching the corresponding button on a touch screen.

D. Subjects

Twelve normal-hearing subjects (ten male, two female; aged 21–29 years) participated in both the loudness scaling and loudness matching experiments. Two subjects were members of the research group, the others were paid volunteers. None of them had previous experience in loudness judgment experiments. Subjects were given no training on the task, but four subjects (S1, S7, S8, and S11) participated in preliminary loudness scaling experiments of half an hour each. All subjects had normal audiograms with hearing thresholds lower than or equal to 15 dB HL at the standard audiometric frequencies from 125 Hz to 8 kHz.

III. RESULTS

A. Loudness scaling

Figure 1 shows individual loudness functions averaged across three repetitions of the experiment for the narrowest and widest bandwidth used in the present study (200 Hz represented by dashed lines and 6400 Hz represented by solid lines). Long and short signals (1000 and 10 ms) are indicated by thick and thin lines, respectively. In general, loudness functions for all subjects show a similar behavior. Long signals are perceived as louder than short signals at the same level and, except for subjects S3 and S12, loudness functions for narrow-band signals curved more than those for broadband signals, i.e., for intermediate levels broadband signals are perceived as louder than narrow-band signals at the same level. However, there are large interindividual differences in the amount of spectral loudness summation, i.e., the horizontal distance between the solid and dashed lines with the same line width. It ranges from a few dB (e.g., subjects S8 and S10) up to 30 dB (subject S5) for the long signals. In general, the level difference between equally loud narrow- and broadband signals tends to be smaller for the long signals than for the short signals at the same level of the broadband signal.

The left panel of Fig. 2 shows average loudness functions across 12 normal-hearing listeners calculated from the individual data shown in Fig. 1. In contrast to Fig. 1, loudness is expressed in sones. To determine the average loudness functions, for each category from "very soft" to "very loud" the corresponding level was calculated for each subject from the individual loudness functions. Then the model loudness function was fitted to the mean of these levels and the loudness in categorical units was transformed to loudness in sones using the equation in Appendix B.

The loudness functions are shallower at moderate levels than at low and high levels. The vertical distance between loudness functions of the same bandwidth but different duration is approximately constant which supports the assumption of a level-independent loudness ratio. However, in qualitative agreement with Epstein and Florentine (2005) the ratio increases for levels below 40 dB SPL. In contrast to the assumptions of the equal-loudness-ratio hypothesis as proposed in Buus *et al.* (1997), the vertical distance between loudness functions of long and short duration is not independent of the spectrum of the sound. For the broadband signals,

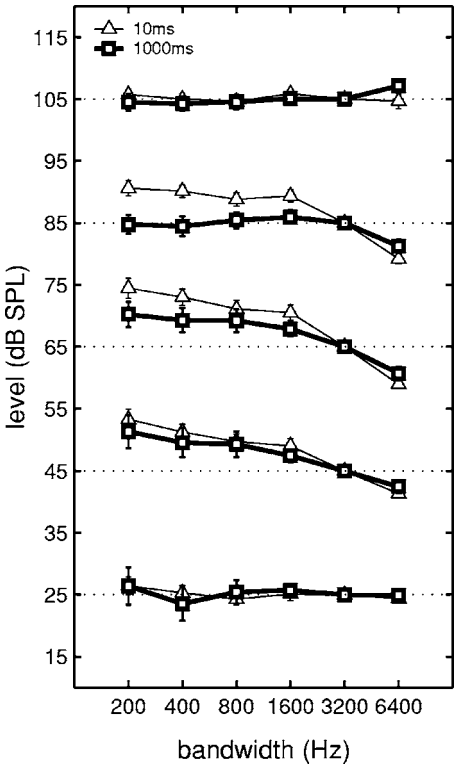

FIG. 3. Average spectral loudness summation as a function of signal bandwidth obtained from loudness scaling data of bandpass noise signals for 12 normal-hearing subjects. The level difference between the signal and the 3200-Hz-wide reference at equal loudness is plotted as a function of the signal bandwidth. Lines connect points of equal loudness for different reference levels (dotted horizontal lines): 25, 45, 65, 85, and 105 dB SPL. Signal durations were 1000 ms (squares, thick lines) and 10 ms (triangles, thin lines). Vertical bars show plus and minus one standard error across 12 listeners.

the vertical distance is smaller than for the narrow-band signals. This indicates that for signals with different spectra different level-independent loudness ratios between short and long signals exist.

To allow for a direct comparison with the predictions of the equal-loudness-ratio hypothesis, the right panel shows the same loudness scaling data as the left panel for long signals, whereas for short signals loudness functions are shifted by a constant factor of 2 relative to those for long signals independent of level and bandwidth. A factor of 2 was found by Zwicker and Fastl (1999) as the loudness reduction in sones between 2-kHz sinusoids with durations of 10 and 1000 ms at a SPL of 57 dB. In the present study, the average ratios between long and short signals of equal SPL are 3.0 ± 0.4 for 200-Hz-wide signals and 2.0 ± 0.2 for 6400-Hz-wide signals in the range from 45 to 105 dB SPL.

Figure 3 shows equal loudness contours and standard errors derived from the scaling data for 12 normal-hearing subjects. Lines connect signal levels for different bandwidths that were perceived as equally loud as the 3200-Hz-wide reference. Reference levels were 25, 45, 65, 85, and 105 dB SPL. Thick and thin lines indicate data for 1000 ms (squares) and 10 ms (triangles), respectively.

On average, a level dependence in the amount of spectral loudness summation can be observed. For the long signals, spectral loudness summation is largest for medium levels with a maximum level difference of 7 dB between equally loud 200- and 3200-Hz-wide stimuli at a level of the 3200-Hz-wide stimulus of 45 dB SPL. For the short signals, spectral loudness summation is also largest for medium levels but the maximum is now about 10 dB at a reference level of 65 dB. For very low and very high reference levels (25 and 105 dB SPL, respectively), no spectral loudness summation can be found for the long signal (<2 dB).

For medium to high levels (45 and 85 dB SPL), the level difference between the equally loud 200- and 3200-Hz-wide stimuli is up to 6 dB larger for the 10-ms than for the 1000-ms signals. At the lowest reference level, no duration dependence can be found. The effect of duration increases with increasing level up to a maximum difference in the amount of spectral loudness summation between short and long signals at 85 dB SPL and then decreases towards the highest level.

These effects are supported by a four-way ANOVA for repeated measures (see Table I). The stimulus variables bandwidth and reference level have significant effects on the level difference between the test and the reference signal ($p<0.001$). A Scheffé *posthoc* test for bandwidth shows no significant effect between 200 and 400 and between 400, 800, and 1600 Hz ($p>0.05$). For all other bandwidth pairs the level difference is significantly larger for the signal with the smaller bandwidth, i.e., there is a significant effect of spectral loudness summation. The significant interactions between bandwidth and subject and between duration and subject ($p<0.01$) indicate that the effects of the stimulus parameters on loudness depend on the subject. The significant interaction of bandwidth and duration ($p<0.05$) shows that the amount of spectral loudness summation depends on the duration. The significant interaction of bandwidth, duration,

TABLE I. Four-way analysis of variance for repeated measures of loudness scaling for normal-hearing subjects. The dependent variable is the level difference at equal loudness between the reference signal with 3200-Hz bandwidth and signals of all other bandwidths measured. Bandwidth (bw; five steps: 200, 400, 800, 1600, and 6400 Hz), signal duration (dur; two steps: 10 and 1000 ms), and level of the reference signal (lev; five steps: 25, 45, 65, 85, and 105 dB SPL) are fixed factors. Subject (sub; 12 steps: S1–S12) is a random factor.

The level difference between the signal and the 3200-Hz-wide reference at equal loudness is plotted as a function of the signal bandwidth. Lines connect points of equal loudness for two different reference levels (dotted horizontal lines): 45 and 65 dB SPL. Signal durations were 1000 ms (squares, thick lines) and 10 ms (triangles, thin lines). Vertical bars show plus and minus one standard error across 12 listeners.

and subject ($p<0.001$) indicates that the effect of duration on the amount of spectral loudness summation depends on the subject. A Scheffé *posthoc* test for level shows no significant effect between 25, 85, and 105 dB SPL and between 45 and 65 dB SPL ($p>0.05$). For all other level pairs the level difference is significantly larger for medium levels than for very high and very low levels. As indicated by the significant interactions between bandwidth and level ($p<0.001$) and bandwidth, level, and subject ($p<0.01$), spectral loudness summation depends on the reference level and this interaction in turn depends on the subject. The interaction of duration, bandwidth, and reference level is significant ($p<0.01$). This indicates that within the investigated level range, the effect of duration on spectral loudness summation depends on the reference level. The significant interactions of duration and level ($p<0.05$) and duration, level, and subject ($p<0.001$) indicate that the duration effects depend on the level and that this interaction in turn depends on the subject.

Figure 4 shows the average level differences and standard errors for 12 normal-hearing listeners between a 200-Hz-wide signal and the 3200-Hz-wide reference as a function of level of the broadband signal. Data for the 10-ms signals are indicated by triangles. Squares denote the data for the 1000-ms signals. In addition to the measured data (solid line) model predictions are shown which will be discussed in Sec. IV. The figure gives a more detailed overview of the data already presented in Fig. 3 for the 200-Hz bandwidth. At low levels, the same amount of spectral loudness summation is found for short and long signals. At medium to high levels (>40 dB SPL), however, spectral loudness summation is larger for short than for long signals with a maximum difference of 7 dB at 80 dB SPL.

B. Loudness matching

Figure 5 shows average loudness matching data and standard errors for 12 normal-hearing subjects. Test signal levels that were perceived equally loud as the reference signal are plotted as a function of the bandwidth of the test signal. Lines connect points of equal loudness. Reference levels were 45 and 65 dB SPL and reference bandwidth was 3200 Hz. Signal durations were 1000 ms (squares, thick lines) and 10 ms (triangles, thin lines).

The average data show spectral loudness summation for both signal durations and both reference levels. The average level differences found for 1000-ms signals quantitatively agree with the data in Verhey and Kollmeier (2002): ΔL between equally loud signals with the smallest bandwidth (200 Hz) and the largest bandwidth (6400 Hz) is 17 dB for a reference level of 65 dB SPL [compared to 15 dB in Verhey and Kollmeier (2002)] and 18 dB for a reference level of 45 dB SPL [compared to 16 dB in Verhey and Kollmeier (2002)]. Spectral loudness summation is slightly larger for the lower reference level. The amount of spectral loudness summation depends on duration. For both reference levels, a 4-dB larger level difference for short than for long signals can be observed between the 200-Hz-wide test signal and the reference.

These effects are supported by a four-way ANOVA for repeated measures (see Table II). All stimulus variables (bandwidth, signal duration, and reference level) have significant effects on the level difference between the test and the reference signal ($p<0.001$ for bandwidth and reference level, $p<0.05$ for signal duration). A Scheffé *posthoc* test shows no significant effect between 200 and 400 Hz ($p>0.05$). For all other bandwidth pairs the level difference is significantly larger for the signal with the smaller bandwidth, i.e., there is a significant effect of spectral loudness summation. The significant interaction of bandwidth and subject ($p<0.05$) indicates that spectral loudness summation depends on the subject. The significant interactions and of bandwidth, duration, and subject ($p<0.01$) show that the amount of spectral loudness summation depends on the duration of the signal and that this interaction in turn depends on the subject. As indicated by the significant interaction between bandwidth and level ($p<0.001$), spectral loudness summation also depends on the reference level. The interaction of duration, bandwidth, and reference level is not significant ($p>0.05$). This indicates that within the investigated

TABLE II. Four-way analysis of variance for repeated measures of loudness matching for normal-hearing subjects. The dependent variable is the level difference between test and reference signal at equal loudness. Bandwidth of the test signal (bw; five steps: 200, 400, 800, 1600, and 6400 Hz), signal duration (dur; two steps: 10 and 1000 ms), and level of the reference signal (lev; two steps: 45 and 65 dB SPL) are fixed factors. Subject (sub; 12 steps: S1–S12) is a random factor.

level range, the effect of duration on spectral loudness summation does not depend on the reference level. The significant interactions of duration and subject ($p<0.05$) and of duration, subject, and level ($p<0.001$) show that duration effects depend on the subject and that those effects in turn depend on the level.

IV. DISCUSSION

On average, the amount of spectral loudness summation in normal-hearing listeners was found to depend both on level and signal duration. Similar results were obtained by both measuring procedures.

A. Comparison between loudness matching and loudness scaling

At a reference level of 65 dB SPL, the average level differences between equally loud 1000-ms signals are almost the same as those measured by loudness matching (except for a test signal bandwidth of 6400 Hz, which will be discussed later). The average ΔL between the 200-Hz-wide test signal and the reference is 5 dB for both procedures. In addition, both procedures exhibit a similar duration dependence of spectral loudness summation at this reference level.

At a reference level of 45 dB SPL, however, there are considerable differences between the average results of loudness matching and loudness scaling. For a duration of 1000 ms, the average ΔL between the 200-Hz-wide test signal and the reference is only 6 dB for loudness scaling compared to 12 dB for loudness matching. In addition, loudness scaling data show only a small difference between long and short signals at this level while a clear duration dependence of spectral loudness summation can be observed for the loudness matching data. The standard error of the loudness summation derived from loudness scaling data (Fig. 3) is considerably larger than that for the matching data (Fig. 5). Thus, the differences may be due to the greater standard error for loudness scaling which is a result of the large level range investigated and the limited number of loudness categories. In addition, at levels below about 40 dB the slope of the loudness function is very shallow and the number of loudness categories in this level range may be not sufficient (Brand and Hohmann, 2002), which would further increase the inaccuracy of the measurement.

A comparison between loudness matching and loudness scaling data shows large differences in the amount of spectral loudness summation between the 3200-Hz-wide and the 6400-Hz-wide signal. For loudness matching the amount of spectral loudness summation between these bandwidths is 11 dB at a level of 65 dB SPL compared to 4 dB for loudness scaling. This is in agreement with the results in Fruhmann *et al.* (2003) who used a 400-Hz-wide reference signal and found a spectral loudness summation between the 3200-Hz-wide and 6400-Hz-wide test signals of 5 dB at a reference level of 65 dB SPL. Thus, in contrast to Verhey (1999), the present data for the broadest test-signal bandwdith and a level of 65 dB SPL of the 3200-Hz-wide reference indicate that the loudness matching procedure may be slightly biased by the choice of the reference signal.

B. Comparison with data in the literature

Interindividual differences in the amount of spectral loudness summation such as those shown in Fig. 1 were already observed in previous loudness studies using categorical loudness scaling (Blum *et al.*, 2000; Brand and Hohmann, 2001). They were also found using other methods such as absolute magnitude estimation (e.g., Blum *et al.*, 2000) or loudness matching (e.g., Verhey and Kollmeier, 2002).

The average data resulting from the loudness scaling measurements show a level dependence in the amount of spectral loudness summation for the 1000-ms signals. A similar level dependence of spectral loudness summation for long signals is reported in the literature (e.g., Zwicker *et al.*, 1957; Wagner *et al.*, 2004). In qualitative agreement with the present loudness scaling data, Zwicker *et al.* (1957) and Wagner *et al.* (2004) found the largest spectral loudness summation for a level of the broadband signal of about 50 dB SPL and no spectral loudness summation for very high and very low levels (above 90 and below 30 dB SPL). For both procedures, the present data show a spectral loudness summation for the 1000-ms signals that was slightly larger for a reference level of 45 dB SPL than for a reference level of 65 dB SPL which qualitatively agrees with the data in Verhey and Kollmeier (2002).

Verhey and Kollmeier (2002) measured a 6 to 8 dB larger level difference between the 3200-Hz-wide reference and the 200-Hz-wide test signal for 10-ms signals than for 1000-ms signals at a reference level of 65 dB SPL. At the

same level, Fruhmann *et al.* (2003) measured a 5 dB larger level difference between the 400-Hz-wide reference and the 3200-Hz-wide test signal for the short signal. The effect of duration on the amount of spectral loudness summation in those two studies agrees well with the present data. In the present study, the difference in spectral loudness summation for short and long signals was 4 dB at a reference level of 65 dB SPL for both procedures.

C. Proposed modification of the equal-loudness-ratio hypothesis

The duration dependence of the amount of spectral loudness summation at the same reference level is at odds with the predictions of the equal-loudness-ratio hypothesis. In contrast to the data, it predicts the same amount of spectral loudness summation at the same reference level. The reason for the latter behavior is the assumption of a loudness ratio that is independent of the spectrum of the signal (see Fig. 2, right panel). In order to account for the duration dependence of spectral loudness summation found in the present study, a possible modification of the equal-loudness-ratio model might be the assumption that different level-independent loudness ratios exist for signals with different spectra (ratio increasing with decreasing bandwidth; see Fig. 2, left panel).

The dashed lines in Fig. 4 show model predictions assuming a bandwidth-dependent constant loudness ratio between long and short signals (thick and thin lines, respectively). Loudness functions for long signals were calculated from loudness scaling data averaged across 12 subjects. To obtain the loudness functions for short signals, those for long signals were shifted by a level-independent value. This value was derived from the data by averaging the ratio across levels between 45 and 105 dB SPL. Levels below 45 dB SPL were omitted because for these levels loudness ratios have been shown to increase [Epstein and Florentine (2005); see also Fig. 2, left panel]. The ratio between long and short signals was 3.0 ± 0.4 for a bandwidth of 200 Hz and 2.4 ± 0.2 for 3200-Hz signals. From the resulting loudness functions, level differences between narrow-band (200 Hz) and broadband (3200 Hz) stimuli needed to produce the sensation of equal loudness were calculated for both signal durations. Predictions and data for long signals slightly differ since the predictions are derived from average loudness functions. For both durations, model predictions are in reasonable agreement with the data for intermediate levels. For levels of the broadband stimulus $\geqslant$85 dB SPL a bandwidth-dependent loudness ratio cannot account for the data. This may indicate that for high levels the loudness ratio between long and short signals is not independent of level. Such a deviation of the constant loudness ratio above 85 dB seems to be inconsistent with the average data in Epstein and Florentine (2005). They found a nearly constant average ratio from 40 to 95 dB SL, although individual data show some deviation from this trend. However, they used a 1-kHz tone instead of a broadband noise. It is possible that the loudness ratio for narrowband signals is constant up to higher levels than for broadband signals. In general, a varying loudness ratio of only one of the stimuli considered in Fig. 3 will result in a mismatch between predictions and data in the present study.

V. SUMMARY AND CONCLUSION

The effect of duration on spectral loudness summation in normal-hearing listeners was investigated over a wide level range using categorical loudness scaling. In addition, loudness matching was used for two intermediate levels. In general, both procedures yielded similar results for these levels. Categorical loudness scaling is an effective method to investigate loudness over a large level range but is less accurate than loudness matching.

As already known from the literature, the amount of spectral loudness summation was found to be level dependent with a maximum effect at intermediate levels. On average, spectral loudness summation was larger for short signals (10 ms) than for long signals (1000 ms) at the same reference level. The duration dependence at the same level cannot be explained by the equal-loudness-ratio hypothesis.

The loudness ratio between long and short signals with the same bandwidth was found to be almost independent of level for levels greater than about 45 dB SPL. However, in contrast to the assumptions of the equal-loudness-ratio hypothesis, this loudness ratio was not found to be independent of the spectral content of the signal. For moderate levels, a corresponding modification of the equal-loudness-ratio hypothesis could in principle account for the duration dependence of spectral loudness summation in normal-hearing listeners.

APPENDIX A: MODEL FUNCTION FOR LOUDNESS SCALING DATA

The two linear parts with slopes m_l and m_h intersect at the point (L_c, c), where L_c denotes the level and c the categorical loudness value of the intersection point. The model function fitted to the data is then given by

$$f(L) = \begin{cases} \max[(c + abs(m_l)(L - L_c)), 0], & L \leqslant L_l, \\ (c - 10) + 20t(L), & L_{lo} < L < L_h, \\ \min[(c + abs(m_h)(L - L_c)), 50], & L \geqslant L_h, \end{cases} \tag{A1}$$

with

$$t(L)=\begin{cases}-\dfrac{x_1}{2x_2}-\sqrt{\dfrac{L-L_l}{x_2}+\dfrac{x_1^2}{4x_2^2}}, & \dfrac{L_c-(c-10)}{L_c-L_l}<\dfrac{c-(c+10)}{L_c+L_h},\\ -\dfrac{x_1}{2x_2}+\sqrt{\dfrac{L-L_l}{x_2}+\dfrac{x_1^2}{4x_2^2}}, & \dfrac{L_c-(c-10)}{L_c-L_l}>\dfrac{c-(c+10)}{L_c+L_h},\end{cases} \tag{A2}$$

and

$$x_1=2L_c-2L_l,$$

$$x_2=L_l-2L_c+L_h.$$

The equations for the linear parts ensure that slopes are always positive and that the loudness function has no values higher than 50 (corresponding to "too loud") or lower than 0 (corresponding to "inaudible").

Levels L_l and L_h at the beginning and end of the Bezier smoothing in the transition region between upper and lower linear part are given by

$$L_l=L_c-\frac{10}{m_l},$$

$$L_h=L_c+\frac{10}{m_h},$$

i.e., the Bezier interpolation stretches across an interval of 20 on the categorical unit axis centered around c. In Brand and Hohmann (2002) the parameter c was fixed at 25 cu.

To calculate level differences for a given loudness l the inverse of Eq. (A1) is needed:

$$f^{-1}(L)=\begin{cases}\dfrac{l-c}{abs(m_l)}+L_c, & 0\leqslant l\leqslant f(L_l),\\ x_2\left(t(l)+\dfrac{x_1}{2x_2}\right)^2-\dfrac{x_1^2}{4x_2^2}+L_l, & f(L_l)<l<f(L_h),\\ \dfrac{l-c}{abs(m_h)}+L_c, & f(L_h)\leqslant l\leqslant 50,\end{cases} \tag{A3}$$

with

$$t(l)=\frac{l}{20}-\frac{c-10}{20} \tag{A4}$$

and x_1, x_2 defined as above.

APPENDIX B: TRANSFORMATION OF CATEGORICAL UNITS INTO SONES

The present study uses the following transformations between sones and categorical units (cu) as suggested by Apell (2002):

$$cu'=0.3942\,\mathrm{lg}(\mathrm{sone})^3+3.2018\,\mathrm{lg}(\mathrm{sone})^2+9.7334\,\mathrm{lg}(\mathrm{sone})+11.2097, \tag{B1}$$

$$\mathrm{cu}=\max(0,\mathrm{cu}'). \tag{B2}$$

The equation assumes a cubic relation between the logarithmic sone scale and the categorical scale. It is a modified version of the transformation proposed in Blum *et al.* (2002). They assumed a quadratic relation between the logarithm of the sone values and the categorical units. Appell (2002) showed that the cubic transformation is a better approximation of the relation between categorical units and sones than the quadratic transformation [see Figure on p. 78 in Appell (2002)].

Discrimination of nonlinear frequency glides

Nick Thyer
School of Healthcare, University of Leeds, United Kingdom

Doug Mahar
School of Psychology and Counseling, Queensland University of Technology, Australia

(Received 26 May 2005; revised 6 March 2006; accepted 7 March 2006)

Discrimination thresholds for short duration nonlinear tone glides that differed in glide rate were measured in order to determine whether cues related to rate of frequency change alone were sufficient for discrimination. Thresholds for rising and falling nonlinear glides of 50-ms and 400-ms duration, spanning three frequency excursions (0.5, 1, and 2 ERBs) at three center frequencies (0.5, 2.0, and 6.0 kHz) were measured. Results showed that glide discrimination was possible when duration and initial and final frequencies were identical. Thresholds were of a different order to those found in previous studies using linear frequency glides where endpoint frequency or duration information is available as added cues. The pattern of results was suggestive of a mechanism sensitive to spectral changes in time. Thresholds increased as the rate of transition span increased, particularly above spans of 1 ERB. The Weber fraction associated with these changes was 0.6–0.7. Overall, the results were consistent with an excitation pattern model of nonlinear glide detection that has difficulty in tracking signals with rapid frequency changes that exceed the width of an auditory filter and are of short duration. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2191587]

I. INTRODUCTION

The discrete frequency and duration cues that define rate of change of frequency in linear frequency glides are confounded. This makes it difficult to differentiate between mechanisms responsible for glide discrimination that are sensitive to change *per se* and those related to simply duration or frequency coding. Research has generally concentrated on discrimination of either unidirectional frequency glides (Dooley and Moore, 1988a, b; Madden and Fire, 1996, 1997; Moore and Sek, 1998; Nabelek and Hirsch, 1969; Tsumura and Nimura, 1972) or periodic frequency modulated (FM) signals (Carlyon, 2000; Gardener and Wilson, 1979; Gockel, Moore, and Carlyon, 2001; Kay and Matthews, 1972; Moore and Sek, 1994; Moore and Sek, 1995b, 1996; Plack and Carlyon, 1994, 1995; Sek and Moore, 2000; Tansley and Suffield, 1983). Discrimination of both forms of signal might well require the detection of frequency rate change, but it does not follow that there is a common underlying mechanism for frequency glide and FM perception. In this paper we measured discrimination thresholds for nonlinear tone glides with identical end-point frequencies and duration where only rate of frequency change information was available so that participants' performance should reflect sensitivity to rate of change of frequency.

The perception of FM involves monitoring a continuous and cyclic modulation of frequency which, given sufficient periods of the modulating frequency, affords continuous rate of change information. Place coding theories (e.g., Zwicker, 1970) predict that FM discrimination is achieved by monitoring changes in the distribution of rate-place related activity on the basilar membrane and other structures in the auditory system where differences in the excitation patterns that arise from stimulation relate to perceived frequency changes. In this case threshold values would be linked to the more steeply sloping low frequency side of the excitation pattern where changes in level are greatest (Zwicker, 1970), or to multiple points from both sides of the excitation pattern (Moore and Sek, 1994). In either case the slopes of the excitation patterns for a particular center frequency are associated with the width of the auditory filter at that center frequency. Thus FM difference limens should be a constant proportion of the equivalent rectangular bandwidth (ERB) of the auditory filter at that carrier frequency (Glasberg and Moore, 1990). Thresholds at modulation rates of 10 Hz and above do show such a pattern (Moore and Sek, 1995b, 1996). At modulation rates below 5 Hz, and in particular where the carrier or center frequency is below 5 kHz, they do not and results are similar to those obtained from steady frequency difference limens (FDL). These results are more easily explained by a mechanism that utilizes information contained in temporal patterns of the auditory nerve (Moore and Sek, 1995b, 1996; Sek and Moore, 2000). This phase locking typically fails above 4–5 kHz and is unlikely to be involved over the entire frequency range of hearing which accounts for the elevated FDLs found at and above 6 kHz.

In contrast, unidirectional glide discrimination involves comparing two or more signals which only afford the listener discrete frequency change information over the signal duration. A possible mechanism underlying linear glide discrimination is one that allows a listener to perform a simple frequency or duration discrimination. Dooley and Moore (1988b) measured thresholds for static frequency discrimination and linear frequency glide detection where the rate of change of frequency changed as a function of *either* frequency *or* duration and thus either endpoint frequency or duration was available as a cue. Glide detection thresholds followed the general pattern expected for static FDLs and

were observed both as a function of frequency and duration at least up to 4 kHz. These results are more consistent with a temporal process related primarily to available static end-point frequency information and not differences in excitation pattern level or rate of change of frequency.

If excitation pattern monitoring was used in glide detection then a pattern of results like Zwicker's FM DL data would be expected. In order to test this, Madden and Fire (1996, 1997) used a roving design where the center frequencies of standard and target linear glides were uniformly varied to limit the use of end-point frequencies and the likelihood of invoking a simple frequency discrimination mechanism. They found that thresholds expressed as a constant proportion of the ERB varied little with center frequency and that duration had little effect on discrimination (the duration of their stimuli was 50 and 400 ms, frequency spans were 0.5, 1, and 2 ERBs, and their center frequencies were 0.5, 1.0, 2.0, 4.0, and 6.0 kHz). These data were taken as evidence for a rate of change processing mechanism that monitors excitation pattern changes. Thresholds were similar for the 0.5 and 1 ERB spans but worsened markedly for the 2 ERB spans. Performance more or less adhered to Weber's Law above transitions of 1 ERB.

Moore and Sek (1998) replicated and extended the Madden and Fire studies. Their data was not entirely consistent with an excitation pattern model nor was it sufficient to implicate the use of phase locking. To make it difficult to use cues based on monitoring changes in excitation levels, Moore and Sek added random glides in level to the glides in frequency and predicted that in these conditions glide discrimination thresholds would be raised. Small and moderate glides in level did not greatly affect performance. However, performance where large glides in level were present was actually better than theoretical limits would predict assuming an excitation-pattern model (Glasberg and Moore, 1990). They argued that phase locking might play a part in glide discrimination, particularly for slower transitions with lower center frequencies, but an excitation-pattern model could account for glide discrimination for larger frequency spans of 2 ERBs since the change in excitation pattern due to frequency change was large in comparison with changes they introduced in level.

In a further study Sek and Moore (1999) measured frequency DLs for pairs of different frequency tone bursts with center frequencies of 0.5, 1, 2, 4, and 6 kHz that were separated by either 5 ms of silence or were joined by glides of different durations between 0 and 500 ms. In one condition the center frequency was fixed in each trial and in another the center frequency was roved over trials with a range of ±2 ERBs. In a third condition cues based on changes of excitation level were disrupted by introducing random linear glides in level. Thresholds were similar across all center frequencies. Performance was poorer when the center frequency was roved. Sek and Moore interpreted this finding in two ways. First, that a fixed center frequency allowed listeners to monitor the start and end frequencies. Second, randomization of center frequencies was simply distracting or made the generation of an internal representation of the signals difficult. In either case thresholds in the roved condition were lower than the theoretical limit using only end-point information. Glide detection was also impaired by glides in level but was also better than would be predicted if listeners were simply using excitation pattern information. Importantly, when the 5 ms of silence were replaced with a 5-ms glide, thresholds improved significantly. They concluded that this was evidence for the additional involvement of a glide detection mechanism that was distinct from excitation pattern or end-point frequency monitoring.

Sek and Moore (1999) suggested that below 4 kHz there are two mechanisms available for glide discrimination and detection; a temporal mechanism that samples the end points combined with a glide detection mechanism based on excitation patterns. Since, in their study the glide duration lengthened at the cost of the steady state plateau duration, the prediction would be that the longer the glide the less end-point information would be available. Thresholds were poorer for long glides and better for short glides where both kinds of information were available. Nevertheless, linear glides that do not have start and finish plateaus such as the Sek and Moore 500-ms stimuli still have end-point cues available (Pollack, 1968, Dooley and Moore, 1988a, b; Madden and Fire, 1996, 1997) which makes it difficult to interpret their data in terms of how absolute rate of change of frequency is detected without the influence of end-point cues.

In the present study, glide discrimination was tested using pairs of stimuli that had identical end-point frequencies and durations. This allowed the direct measurement of listener's sensitivity to different glide rates over a range of frequency spans, durations, and center frequencies without the confounding availability of end-point cues. Previous studies have not convincingly done this and their conclusions regarding underlying mechanisms involved in glide detection are therefore questionable. It was hypothesized that participants would be able to detect differences in rate of change of frequency even though duration and end-point values were identical between and within trials. Further, it was predicted that nonlinear glide performance would be poorer than that reported by studies using linear glides because of the complete unavailability of end-point cues to augment performance. Finally, it was predicted that if an excitation pattern model is involved in processing rate of change of frequency then thresholds would generally be a constant proportion of the ERB irrespective of center frequency.

II. METHOD

A. Participants

All participants (9 females and 11 males) had hearing thresholds better than 20 dBHL for octave frequencies between 250 and 8000 Hz. The group mean age was 21 years [standard deviation (SD)=4.3].

B. Stimuli

The stimuli used in this study were nonlinear frequency glides. The common stimulus parameters are shown in Table I. Duration (t) refers to the duration of the gliding portion of the stimulus. The center frequency (fc) is defined as the frequency midway between start frequency (sf) and the end

TABLE I. Common stimulus parameters of center frequency *fc* and frequency transition span *ft* expressed in ERB and hertz for nine conditions. Four sets of stimuli were synthesized using these nine core values making 36 conditions in all. These were (1) gliding up in 50 ms, (2) gliding down in 50 ms, (3) gliding up in 400 ms, and (4) gliding down in 400 ms. The center frequency *fc* is midway between start and end frequencies at $t/2$.

Condition	*fc* (kHz)	Transition span *(ft)* in ERBs	Transition span *(ft)* in hertz
1	0.5	0.5	39
2	2.0	0.5	120
3	6.0	0.5	336
4	0.5	1.0	79
5	2.0	1.0	241
6	6.0	1.0	672
7	0.5	2.0	157
8	2.0	2.0	481
9	6.0	2.0	1345

frequency (*ef*) at $t/2$. All stimuli had 25-ms onsets and offsets during which frequency remained steady at either *sf* or *ef*. Stimulus amplitudes rose from zero to maximum values in a half hanning function. The gliding portion of the frequency glides in each condition is described by the general form

$$\int \sin[2\pi(aft^3 + bft^2 + cft + d)]dt.$$

The nonlinear glide tracks were generated by evaluating the roots of the equation that defined a frequency glide between *sf* and *ef* which at, $t/2$, passed through either $fc+S$ Hz for the upper stimulus (shown by the dashed line in Fig. 1) or $fc-S$ Hz for the lower stimulus (shown by the thin solid line in Fig. 1). Coefficients were then calculated that defined frequency tracks that passed through center frequencies at intervals of $S=fc\pm1\%$ of the frequency span. When

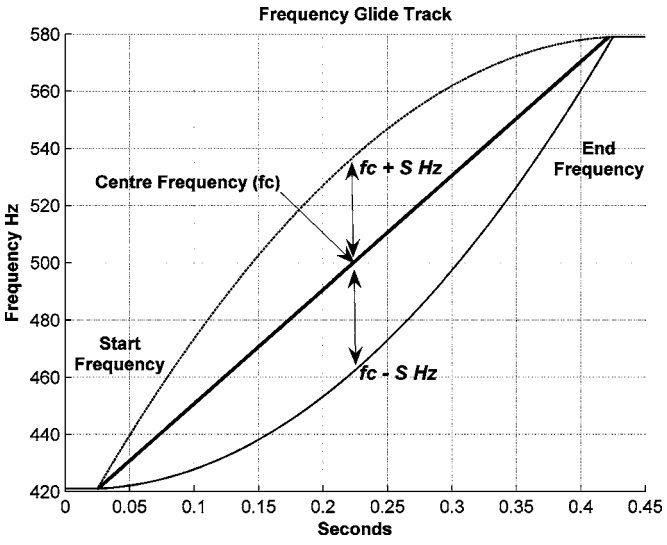

FIG. 1. Schematic view of frequency changes associated with the nonlinear glide stimuli: *fc* is the stimulus center frequency. The distance in hertz between the midpoint frequencies of stimuli in the standard and signal intervals of a trial is given by $(fc+S)-(fc-S)$ and is the raw value used to express threshold in ERBs.

$S=0$ the function is linear and both upper and lower glides are identical and pass through *fc* as shown by the thick solid line in Fig. 1. Threshold was defined in terms of the smallest discriminable difference between an upper and a lower glide expressed as the difference in their center frequencies. A step size for *S* which was a constant percentage of the transition span was chosen since preliminary data indicated that thresholds were greater for larger transition spans. The index *S* ranged from 0 to 90 % of the transition span.

The complete set of tone glides for each of the 36 conditions is described in Table I. Frequency span ERB values were calculated using the formula $\text{ERB}=24.7(4.37fc+1)$ from Glasberg and Moore (1990). Stimuli were digitally synthesized and stored on disk and output using an AWE 16-bit D/A converter controlled by a proprietary PC computer. Sampling rate was 20 kHz with 16 bit resolution. Participants listened individually to the stimuli over Sennheiser 490D headphones, presented binaurally at 68 dB sound pressure level (SPL).

C. Procedure

Stimuli from each of the 36 conditions were presented by computer in a same-different paradigm. Participants practiced for at least 2 h in all 36 conditions before data collection. The experiment was self-paced with the order of condition presentation sequentially balanced. Participants started each trial by clicking a single "present sounds" button displayed on a computer screen before hearing the first trial's stimulus pair. Following the presentation of each trial, a second screen comprising two buttons marked "same" or "different" was displayed and participants indicated their decision by clicking a mouse pointer on the appropriate button. The computer recorded the response, calculated the next stimulus level, and loaded two stimuli from disk for the next trial. When ready to proceed, participants clicked a further button and the next stimulus pair was presented.

On 50% of trials, the upper frequency glide was presented in the first of two intervals and its lower opposite presented in the second. The reverse was true for the remainder of the trials. Difference limen were expressed in terms of *S* as ERBs and were determined using an up-down-transformed-rule (UDTR) procedure to estimate the 70.7% correct point on the psychometric function (Levitt, 1971). An initial step size of $2S$ Hz was used and the procedure was terminated when a step size of *S* was called for. The geometric mean value of *S* over the last four reversals with a step size of *S* Hz was taken as threshold. Thresholds were calculated from the average of two repetitions of this procedure. The interstimulus interval was 500 ms. Duration, center frequency, transition span, and direction were fixed within a block of trials.

III. RESULTS

A. Glide discrimination

Figure 2 shows mean thresholds, expressed in ERBs, with bars representing transition span plotted as a function of center frequency. In general, thresholds increased as the frequency transition span increased from 0.5 to 2 ERBs. This

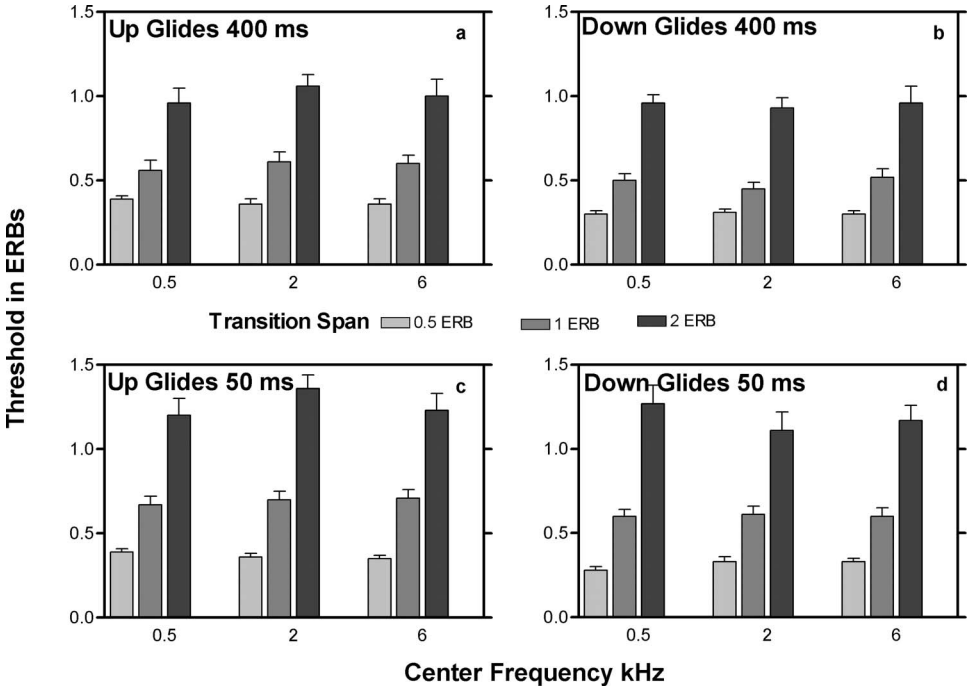

FIG. 2. Mean thresholds for discriminating nonlinear frequency glides expressed in ERBs plotted as a function of center frequency for three transition spans: 0.5, 1.0, and 2.0 ERBs. Error bars are ±2 standard errors of the mean.

pattern was present irrespective of center frequency but was more pronounced for shorter duration glides and for up glides. Figure 3 shows mean thresholds expressed in ERBs, plotted as a function of transition span with duration and direction as parameters, respectively. For 50-ms glides, thresholds became poorer in comparison to those for 400-ms glides as frequency span increased from 0.5 to 2 ERBS irrespective of direction, and thresholds for up glides were marginally better than those for down glides. To statistically test these observations a repeated measures analysis of variance (ANOVA) was performed with two levels of direction and duration and three levels of center frequency and frequency transition span as factors. Thresholds are expressed as a proportion of the equivalent rectangular bandwidth (ERB). As initial inspection suggested, the results revealed significant main effects of transition span, glide direction, and glide duration. Overall mean thresholds increased significantly as the transition span increased ($F_{2,17}=168.39$, $p<0.001$), thresholds were significantly better for down glides than up glides ($F_{1,18}=5.45$, $p<0.05$) and were better by 0.12 ERBs for the 400-ms glides compared to the 50-ms glides ($F_{1,18}=6.36$, $p<0.05$). Since the variation in thresholds was independent of center frequency, the data was collapsed across center frequency for further analysis.

There was a significant interaction between frequency

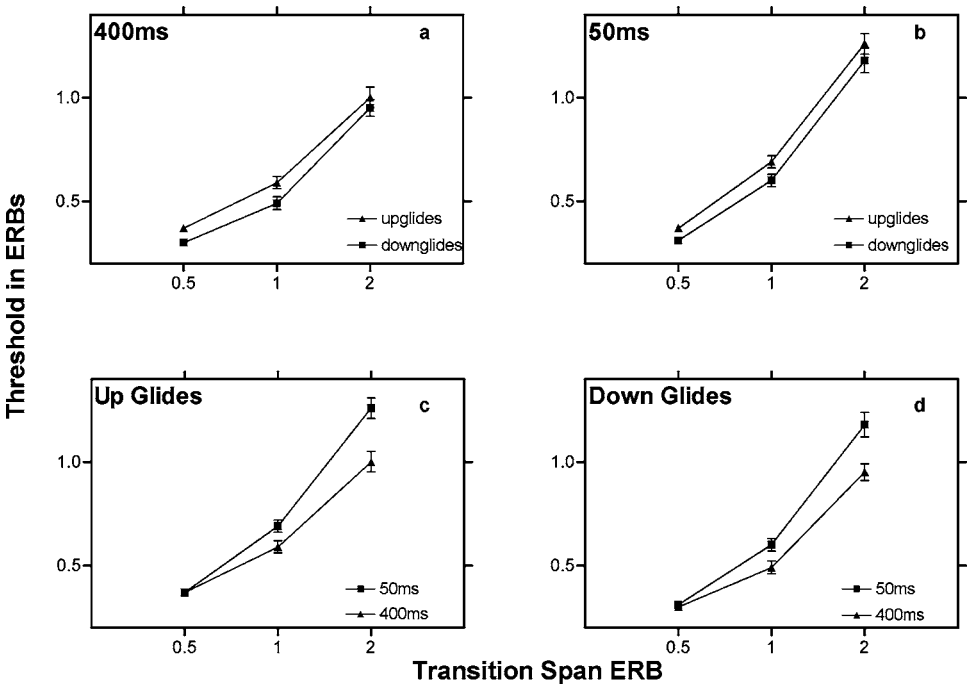

FIG. 3. Panels (a) and (b) results comparing mean thresholds expressed in ERBs for 400- and 50-ms glides as a function of transition span. Panels (c) and (d) results comparing mean thresholds expressed in ERBs for down glides and up glides as a function of transition span. Data is collapsed across center frequency and error bars are ±2 standard errors of the mean.

transition span and glide duration ($F_{2,17}=5.67$, $p<0.05$). To determine the source of the simple effects, pairwise comparisons of the duration marginal mean thresholds for each transition span were made using a bonferroni protected alpha level of $p=0.05$. Inspection of Fig. 3 [panels (a) and (b)] shows mean threshold differences between 0.5, 1, and 2 ERB frequency transition spans that were all significantly different from each other in both the 400-ms glides ($F_{2,17}=71.45$, $p<0.001$) and the 50-ms glides ($F_{2,17}=111.81$, $p<0.001$).

Figure 3 [panels (c) and (d)] shows that for down glides, 400-ms thresholds were significantly better for 1 ERB ($F_{1,18}=4.50$, $p<0.05$) and 2 ERB ($F_{1,18}=4.79$, $p<0.05$) spans than 50-ms glide thresholds (mean difference 0.12 and 0.23 ERB, respectively). For up glides, 400-ms glide thresholds were again better at 1 and 2 ERB spans in comparison to 50-ms glide thresholds, but were only significantly so at the 2 ERB transitions ($F_{1,18}=9.23$, $p<0.01$: mean difference 0.262 ERB). For all transition spans, thresholds for down glides were on average, worse by a factor of 0.07 ERBs. These differences were only significant for the 400-ms 0.5 ERB span ($F_{1,18}=17.51$, $p<0.001$: mean difference=0.07 ERBs) and the 50-ms 1 and 2 ERB spans ($F_{1,18}=8.81$, $p<0.05$, mean difference=0.059 ERBs and $F_{1,18}=4.86$, $p<0.05$, mean difference=0.09 ERBs, respectively).

B. Excitation level

Time-frequency modeling (O'Donovan and Furlong, 2005; Patterson and Allerhand, 2005) indicated a clear difference in the level of excitation elicited by each of the upper and lower glides when stimulus differences were at threshold values. This is most clearly seen in the analysis of 2 kHz glides with a 2 ERB transition shown in Fig. 4. Panels (a) and (b) indicate the patterns evoked by the upper and lower glides, respectively, presented in the standard and signal intervals of a threshold trial. Maximal differences between the excitation patterns produced by the standard and signal stimuli at threshold and for all conditions, were calculated using the method described in Moore and Glasberg (1987), Glasberg and Moore (1990), and Moore, Glasberg, and Baer (1997). The maximum differences in decibel excitation level on the low and high sides of the excitation patterns were not significantly different across center frequency for low frequency and high frequency sides at 400 ms ($F_{1,12}=3.59$, $p>0.05$; $F_{1,2}=0.03$, $p>0.05$, respectively) or for low frequency and high frequency sides at 50 ms ($F_{1,2}=3.63$, $p>0.05$; $F_{1,2}=1.16$, $p>0.05$, respectively). Therefore the data was collapsed across frequency and the maximum difference level on each side of the excitation pattern calculated for the three transition spans, two durations, and directions. These are shown in Fig. 5. The data show differences that are predominantly larger on the low frequency side and increase as transition spans increase.

IV. DISCUSSION

A. General discussion

This study showed that glide discrimination is possible when differences in end-point frequency are unavailable as physical cues. Performance was relatively unaffected by glide center frequency and seemed to depend on the frequency transition span with thresholds becoming poorer as frequency excursion increased. Thresholds for 2 ERB transitions were almost twice as large as those for 1 ERB transitions and three times as large as those for 0.5 ERB transitions. This trend was reduced in the longer duration signals and seemed to be more marked for upward glides than downward glides.

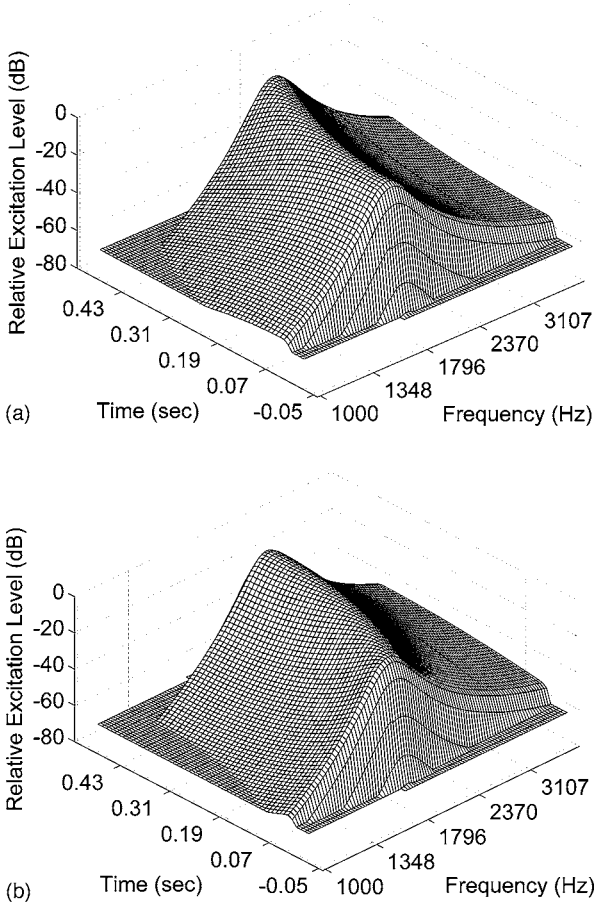

FIG. 4. A model of the excitation pattern elicited by an upper glide (panel a) and a lower glide (panel b) which glide upward with *fc* of 2 kHz and a transition span of 2 ERBs. The stimuli represent a pair of glides at threshold values. The time frequency analysis method used is described by O'Donovan and Furlong (2005).

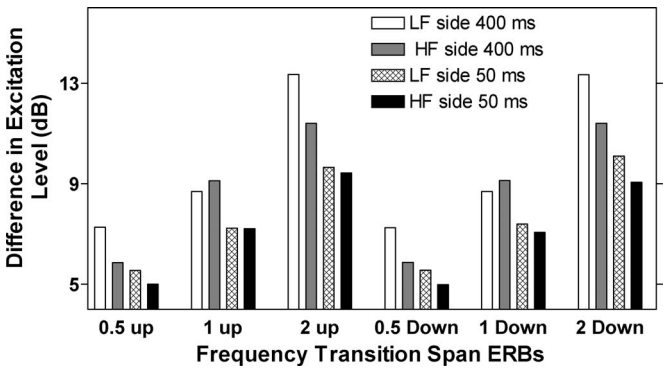

FIG. 5. Maximum difference in level (decibels) between excitation patterns elicited by the upper and lower nonlinear frequency glides that correspond to threshold. Data is given for the low and high frequency sides of the excitation pattern for 50- and 400-ms glides.

In the present study, listeners had no alternative but to use glide information whereas in previous studies (e.g., Moore and Sek, 1998; Madden and Fire, 1996, 1997; Dooley and Moore, 1988a, b) thresholds may have been determined by differences in end-point frequency as well as rate of change information. Limited contrasts with previous work can be drawn. Moore and Sek (1998) used a roving technique to limit listener's use of end-point information in glide discrimination. Their threshold data in comparable conditions were generally of the same order as those reported in this study, indicating that their strategy was successful. The Madden and Fire (1997) threshold data from comparable conditions were also generally similar. But, their absolute thresholds were substantially better than the current data and to a lesser extent the Moore and Sek (1998) data. Madden and Fire roved their stimuli over a much smaller range than Moore and Sek which may have afforded their listeners a greater opportunity to supplement their performance by using end-point cues. One possibility in the present study is that listeners were able to focus on center frequency differences at the midpoint of the stimuli and make a simple frequency discrimination. If this strategy was adopted we would expect to see a pattern of results in the data that reflect frequency DLs that typically vary with center frequency (Moore and Glasberg, 1989; Palmer, 1995) and this was not the case.

B. Modeling perception of nonlinear glides

Evidently listeners can discriminate nonlinear glides using rate of frequency change information, but how do they do this? Place models assume that glide or FM discrimination is performed by monitoring one or both sides of the excitation patterns evoked by the glide stimuli. The task of discriminating an upward linear glide in frequency for example, could be achieved by selecting the signal interval that has the larger decrease in the time-averaged excitation level (Moore and Sek, 1998). The time-averaged frequency content of the upper nonlinear glide stimulus is identical to the lower nonlinear glide stimulus. These stimuli, however, evoke a difference in the rate at which the excitation develops along the basilar membrane. Figure 4 shows that at any instant during upward glide stimulation the developing excitation pattern of the upper glide will always be advanced in terms of the place of maximum excitation on the basilar membrane in comparison with that of the lower glide. This leads to a greater decrease in excitation level on the low frequency side and a greater increase in excitation level on the high frequency side. Since thresholds reported in the present study did not vary significantly with center frequency and are therefore not consistent with a temporal model and we can interpret the data as evidence for a pattern excitation model for glide discrimination. This is consistent with the findings of Madden and Fire (1996, 1997) and of Moore and Sek (1998) suggesting that performance may primarily be based on place information derived from level changes in the excitation pattern.

However, for an upward glide over 0.5 ERBs a difference of at least 7.3 dB in the low frequency side of the excitation pattern is needed to detect a difference between the upper and lower glides. In contrast, for stimuli of the same duration and center frequency which glide over 2 ERBs, 13.3 dB is needed in the low frequency sides of the excitation pattern at threshold. If one only needed to monitor differences in the excitation pattern elicited by each stimulus pair then it would be expected that thresholds for discriminating glides would be similar irrespective of transition span. Similarly thresholds for larger spans would be expected to be better by at least a factor of two than the data indicate since detecting changes of at least 1 dB in the excitation pattern is usually possible (Zwicker, 1970). Differences of less than 13 dB should have been easily detected in 2 ERB transitions suggesting that monitoring excitation patterns might not have been the optimum strategy. It might be that information about differences in the developing excitation pattern is unavailable when the glide rate is too fast. With constant duration, larger transition spans mean a faster rate of change of frequency (and place related excitation level) and if these cues are involved in glide discrimination this might explain increases in threshold with increased transition span and therefore rate, found in the present study and others (Madden and Fire, 1997; Moore and Sek, 1998).

Part of the function of a glide discrimination mechanism must be to integrate activity over time. If we consider our nonlinear glides to be equivalent to the rising (or falling) portion of a frequency modulated tone with a carrier frequency of fc, length 1/4 of the modulating period, and with a modulation depth equivalent to the frequency transition span, then a comparison of rates of change can be made. The 400-ms glides in all conditions are roughly equivalent to the rate of change in frequency that would be produced by a modulation rate of about 0.63 Hz and the 50-ms glides to a modulation rate of about 5 Hz. It has been argued that for low frequency modulation rates (below 2 Hz) a mechanism based on phase locking operates but above modulation rates of 10 Hz a place mechanism operates (Moore and Sek, 1995a, 1996). It is therefore possible that, like low rates of FM, the temporal information contained in the low center frequency 400-ms glides with small transition spans could facilitate monitoring of changes in the instantaneous neural phase-locking pattern which signals frequency change. At modulation rates above 5 Hz the temporal mechanism is less responsive and at 10 Hz a place mechanism takes over since the rate of frequency change is too quick for a temporal mechanism to monitor. It could be argued that if a temporal mechanism based on phase locking is involved in glide discrimination, then at fast rates of change equivalent to 5 Hz modulation it is starting to flag but place information is starting to become available and supplements performance. We could further speculate that when the glide rate becomes even faster, comparison of excitation pattern level becomes difficult and it is this that is reflected in the 1 and 2 ERB threshold data. There is some support for this notion in the present data in that mean thresholds for the 50-ms glides were poorer than those for the 400-ms glides and for the larger transitions.

Our data indicates that glide discrimination is more difficult with increasing rates of spectral change. Thresholds for

all center frequencies are generally greater when the rate of change is fastest. Plack and Carlyon (1994) found that discrimination of modulation depth of 5 Hz FM became poorer as depth and consequently rate of change increased. In this study duration was kept constant within trial blocks such that any resultant changes in rate between the 50-ms and 400-ms conditions were unrelated to overall stimulus duration or frequency span on a given discrimination trial. If an underlying mechanism was based on rate of frequency change it should adhere to Weber's law as suggested by Dooley and Moore (1988a, 1988b) and the Weber fraction for rate[1] should be constant. In our study, while performance was poorer for the 50 ms compared to the 400-ms glide for the longer transition spans of 1 and 2 ERBs, the Weber fraction was fairly constant across the ERB transitions ranging from 0.6–0.7 for 50-ms glides and 0.7 for the 400-ms glides. These findings could be interpreted as being consistent with a mechanism that monitors the rate of spectral change.

Finally, thresholds for rising glides in the present study are generally better than for falling glides particularly for the 50-ms 1 and 2 ERB transitions, although the maximum differences in excitation patterns calculated at threshold for these are of a similar order (between 3 and 12 dB and increase with transition span). Madden and Fire (1997) found higher thresholds for 50-ms down glides (but only for glide detection not for glide discrimination) and Moore and Sek (1998) found no clear evidence of direction effects. The excitation patterns calculated from rising glides and their mirror image falling glides are more or less identical providing few place cues when of the same duration, center frequency, or transition span. An explanation for this finding might be that in gliding from high to low frequencies the traveling wave on the basilar membrane masks decreases in excitation level whereas for glides from low to high frequencies it does not.

V. CONCLUSIONS

The study presented here investigated glide discrimination where duration and end-point cues were unavailable. Our results have shown that nonlinear pairs of glides with identical end-point frequencies and duration are discriminable by their frequency change characteristics. We have shown that thresholds expressed as a proportion of ERB do not alter as a function of center frequency which is commensurate with a place model of processing rather than one related to simple frequency discrimination. We found that thresholds increased with change in glide rate, whether engineered by the manipulation of duration or by frequency transition span, although the increase was mainly associated with transition span. Threshold increase was most marked for the 2 ERB transition but Weber fractions for all transitions were fairly similar, being between 0.6 and 0.7. In consideration of previous studies' findings (Madden and Fire, 1997; Moore and Sek, 1998; Sek and Moore, 1999) our results could be interpreted as a reflection of a glide discrimination mechanism that monitors differences in the integrated excitation pattern level where these differences become less available as glide rate increases and the ability to successfully integrate excitation level information related to frequency change becomes limited.

(Received 22 March 2005; revised 15 February 2006; accepted 28 February 2006)

The mechanisms underlying the detection of second-order amplitude modulation (AM) were explored. The detectability of second-order AM (fixed depth for each subject) was measured for first- and second-order modulation rates of 16 and 2 Hz, respectively (slow-rate pair), and 50 and 10 Hz, respectively (fast-rate pair), with no masker, a low-band modulation masker (centered at 2 or 10 Hz), and a high-band modulation masker (centered at 16 or 50 Hz). This was done in the absence and presence of an audio-frequency notched noise centered at the carrier frequency of 4000 Hz. Both modulation maskers were "low-noise" noises, to prevent overmodulation. In the absence of notched noise, both modulation maskers impaired performance for the slow-rate pair, but only the low-band masker impaired performance for the fast-rate pair. When notched noise was present, the low-band masker had no significant effect for either rate pair and the high-band masker had an effect only for the slow-rate pair. These results suggest that second-order AM detection is mediated both by an envelope distortion component at the second-order rate and by slow fluctuations in the output of a modulation filter tuned to the first-order rate. When notched noise is present, the distortion component plays little role. © *2006 Acoustical Society of America.*

I. INTRODUCTION

The perception of amplitude modulation (AM) in sounds has often been modeled using an array of bandpass filters simulating the auditory filters, or a single broad filter, each followed by a nonlinearity and a "smoothing" device implemented as a low-pass filter (Viemeister, 1979) or a sliding temporal integrator (Festen amd Plomp, 1981; Moore *et al.*, 1988; Plack and Moore, 1990). An alternative approach is based on the idea that the envelopes of the outputs of the auditory filters are fed to a second array of overlapping bandpass filters tuned to different envelope modulation rates (Kay, 1982; Dau *et al.*, 1997a, 1997b; Ewert and Dau, 2000; Ewert *et al.*, 2002; Verhey *et al.*, 2003). This set of filters is usually called a "modulation filter bank" (MFB). The concept of the MFB implies that the auditory system performs a spectral analysis of the envelope at the output of each auditory filter. Evidence broadly consistent with such a view has come from experiments on "modulation masking," in which listeners are required to detect "probe" modulation in the presence of masker modulation; such experiments show selectivity in the modulation domain analogous to that observed for audio frequencies, but with relatively poor resolution or selectivity (Bacon and Grantham, 1989; Houtgast, 1989; Dau *et al.*, 1997a, 1997b, 1999; Ewert and Dau, 2000; Lorenzi *et al.*, 2001a; Ewert *et al.*, 2002; Sek and Moore, 2003).

A challenge for the MFB approach comes from studies using "second-order" AM (Lorenzi *et al.*, 2001a, 2001b; Verhey *et al.*, 2003). To produce second-order AM, the audio-frequency carrier is first sinusoidally amplitude modulated with a first-order modulator of rate f_m. Then, the depth of modulation of the first-order modulator is itself sinusoidally modulated with a second-order modulator of rate f'_m. The "envelope of the envelope," which corresponds to the second-order modulator, has been called the "venelope" (Ewert *et al.*, 2002; Verhey *et al.*, 2003). Usually, the task of the subject is to detect the second-order modulation, i.e., to distinguish a stimulus with second-order modulation from a stimulus with first-order modulation only. The modulation spectrum of a stimulus with second-order AM does not contain a component at f'_m. For example, if f_m is 50 Hz and f'_m is 10 Hz, the modulation spectrum contains components at 40, 50, and 60 Hz, but not at 10 Hz. However, subjects are able to detect second-order AM (Lorenzi *et al.*, 2001a, 2001b). Furthermore, when second-order AM is presented, subjects report hearing a slow fluctuation at a rate which corresponds to f'_m. The problem for the MFB approach is to explain how second-order AM is detected, since, for a linear MFB, the modulation filter tuned to f'_m would often have a negligible output. Two mechanisms have been suggested. The first is that nonlinearities in the auditory system distort the internal

a)Author to whom correspondence should be addressed. Electronic mail: ruchanski@wustl.edu

representation of the envelope, introducing a component with rate f'_m; detection of the second-order AM might then be mediated by detection of this distortion component (e.g., Moore *et al.*, 1999; Lorenzi *et al.*, 2001a). Various nonlinearities may contribute to the generation of an envelope distortion component, such as basilar-membrane compression (Moore *et al.*, 1999), "thresholding" (Verhey *et al.*, 2003), and adaptation (Shofner *et al.*, 1996). The second possible mechanism is based on the fact that the output of the modulation filter tuned to f_m would show fluctuations at rate f'_m. Subjects may be sensitive to these fluctuations. Thus, relatively slow-rate second-order AM may be detected via temporal fluctuations at the output of a modulation filter tuned to a faster rate (Ewert *et al.*, 2002; Millman *et al.*, 2003; Verhey *et al.*, 2003).

There is reasonably strong evidence supporting the idea that the auditory system introduces a distortion component in the "internal" modulation spectrum at the venelope rate in response to sounds with complex envelopes, and this evidence suggests that the magnitude of the distortion component is small. For example, Moore *et al.* (1999) and Sek and Moore (2004) estimated that, for moderately large modulation depths of the primary components (modulation depth, $m \approx 0.3$ per component), the magnitude of the distortion component was equivalent to that produced by a first-order modulator with $m \approx 0.03$ ($20 \log m = -30$). This corresponds to a barely detectable modulation depth for a sinusoidal carrier (Riesz, 1928; Zwicker, 1952; Sek and Moore, 1994; Kohlrausch *et al.*, 2000; Moore and Glasberg, 2001). The magnitude of the venelope component implied by the results of other studies (Ewert *et al.*, 2002; Verhey *et al.*, 2003; Füllgrabe *et al.*, 2005) is about a factor of two to four greater, but still relatively small. It is not clear whether the magnitude of the distortion component is sufficient to account for the detection of second-order AM, especially when the second-order modulation depth is relatively small. However, the distortion component is usually well separated in frequency from the primary modulation components, so it would be masked little, if at all, by the primary components.

To test the role of envelope distortion in the perception of second-order AM, Lorenzi *et al.* (2001b) measured second-order temporal modulation transfer functions (TMTFs) using a 5000-Hz sinusoidal audio-frequency carrier and a 2-Hz-wide narrow-band noise carrier centered at 5000 Hz. The envelope of the noise carrier had inherent slow fluctuations, which were intended to mask envelope distortion components at slow second-order modulation rates. For the sinusoidal carrier, the second-order TMTFs were nearly low pass in shape and the overall sensitivity and cut-off frequency increased when f_m increased from 16 to 256 Hz. For the narrow-band-noise carrier, the second-order TMTFs were nearly flat in shape for $f_m = 16$ and 64 Hz, and they showed a high-pass segment for $f_m = 256$ Hz. For slow second-order modulation rates (i.e., low values of f'_m), thresholds were much poorer (by about 6–8 dB) for the noise carrier than for the sinusoidal carrier. Lorenzi *et al.* (2001b) concluded that a distortion component at the second-order rate probably contributed to the detection of second-order modulation.

As a further test of this idea, Millman *et al.* (2003) measured thresholds for detecting second-order AM of a 5000-Hz sinusoidal carrier in the presence of two types of modulation masker, each of which was a band of noise applied to the same carrier. One noise masker was centered on the second-order modulation rate ($f'_m = 2$ Hz) and the other was centered on the first-order modulation rate ($f_m = 16$ Hz). Increasing the depth of the masker centered on 2 Hz had little effect on detection thresholds for second-order AM (thresholds increased by about 3 dB), but increased detection thresholds for 2-Hz first-order AM by a factor of six (thresholds increased by about 15 dB). Increasing the depth of the masker centered on 16 Hz increased detection thresholds for both first- and second-order AM by a factor of three (about 10 dB). Millman *et al.* concluded that the detection of second-order AM, when f'_m is 2 Hz, is not dependent on the detection of a distortion component at f'_m but is dependent on the detection of fluctuations at the output of modulation filters centered close to f_m. This conclusion is not entirely consistent with that of Lorenzi *et al.* (2001b), who state that detection of spectral energy at the second-order rate contributes to the detection of second-order modulation. However, Millman *et al.* pointed out that the interpretation made by Lorenzi *et al.* was based on the assumption that the inherent amplitude fluctuations in the narrow-band noise carrier would only mask AM at the second-order rate, and not at the first-order rate. This assumption may not have been correct.

One limitation of the study of Millman *et al.* (2003) is that they used relatively small modulation depths. The first-order modulation depth was 0.25 and the second-order depth at threshold ranged from about 0.06 to 0.14. These small modulation depths were used to avoid overmodulation when the noise modulation maskers were added. The magnitude of a putative envelope distortion component at the second-order rate would increase with increasing first- and second-order modulation depths (Moore and Sek, 2000; Sek and Moore, 2003). Thus, for larger first- and second-order modulation depths, a distortion component at the second-order rate might play a greater role in the detection of second-order AM. In the present study, we tested this idea by performing an experiment similar to that of Millman *et al.* (2003), but using larger modulation depths for the first- and second-order modulators. To avoid the problem of overmodulation when the noise modulation maskers were added, we used "low-noise noise" maskers with minimal amplitude fluctuations (Pumplin, 1985; Kohlrausch *et al.*, 1997).

A second limitation of the study of Millman *et al.* (2003) is that the first- and second-order frequencies were both relatively low, 16 and 2 Hz, respectively. It may be that part of the nonlinearity that introduces an envelope distortion component at the second-order rate is time varying. If so, the effective magnitude of the distortion component may vary with first- and second-order modulation rate. In the present study, we extended the work of Millman *et al.* by using first- and second-order modulation rates of 50 and 10 Hz, respectively, in addition to the modulation rates of 16 and 2 Hz used by them.

A factor not considered in most studies of the perception of second-order AM is that the detection of AM of a sinu-

soidal carrier probably depends strongly on the use of information from the high-frequency side of the excitation pattern evoked by the carrier (Zwicker, 1956; Florentine and Buus, 1981; Moore and Sek, 1994; Kohlrausch *et al.*, 2000). This part of the excitation pattern appears to be processed almost linearly on the basilar membrane, at least for medium to high frequencies (Rhode and Robles, 1974; Sellick *et al.*, 1982; Ruggero, 1992; Nelson and Schroder, 1997). If listeners use information mainly from the high-frequency side of the excitation pattern ("off-frequency listening") when detecting second-order modulation, it seems unlikely that envelope distortion produced by basilar membrane compression would play any role. However, the amount of envelope distortion produced at some later stage in the auditory system might be influenced by the amount of amplitude fluctuation at its input. The amount of fluctuation would be greater for an audio-frequency channel centered above the carrier frequency than for a channel centered close to the carrier frequency. Hence, the amount of envelope distortion generated at the later stage might be greater for an "off-frequency" channel than for an on-frequency channel. We return to this point later.

Füllgrabe *et al.* (2005) explored the influence of off-frequency listening by examining the effect of a notched noise centered at the audio-carrier frequency. They measured the detectability of 5-Hz probe modulation of a 5000-Hz carrier in the presence of 5-Hz second-order masker modulation, as a function of the relative phase $\Delta\varphi$ between the probe modulation and the venelope of the masker. In the absence of the notched noise, the value of $\Delta\varphi$ leading to poorest detectability of 5-Hz second-order modulation varied with the first-order modulation rate. If the results are interpreted in terms of an envelope distortion component at the second-order modulation rate, this pattern of results suggests one or more of the following: (1) several nonlinearities contribute to the generation of the distortion component, and the relative contribution of those nonlinearities varies with first-order rate; (2) at least one component of the nonlinearity that generates the distortion component is time varying; (3) some other factor (e.g., the extent of off-frequency listening) is affected by the first-order rate. In the presence of the notched noise, the value of $\Delta\varphi$ giving poorest detectability hardly varied with first-order modulation rate, but it did vary across subjects, from about 45° to 135°. These results suggest that more than one nonlinear mechanism may contribute to the generation of an envelope distortion component. In the present study, the effect of modulation maskers on the detectability of second-order AM was examined both in the presence and absence of a notched noise centered at the audio-carrier frequency; the noise was intended to restrict off-frequency listening. The comparison between the conditions with and without notched noise was intended to allow us to assess the contribution, if any, of basilar-membrane mechanisms to the generation of a distortion component in the modulation domain.

In summary, to explore further the possibility of second-order modulations being detected via a distortion component in the modulation domain, we examined the effect of modulation maskers (low-noise noise maskers), centered at different modulation frequencies, on second-order modulation detection. Also, to assess the contribution of basilar-membrane mechanisms to the generation of a distortion component, the second-order modulation detection experiment was performed both with and without notched noise in the audio-frequency domain. In addition to the experiment on second-order modulation detection, first- and second-order modulation detection thresholds were measured for the same subjects, both with and without notched noise.

II. GENERAL METHOD

A. Subjects

Six subjects with normal hearing were tested. Five of the subjects were recruited from the local community and were paid for their services. One subject was one of the authors, and was unpaid. The ages of the subjects ranged from 20 to 45 years. All had audiometric thresholds less than 20 dB HL (ANSI, 2004) at frequencies between 250 and 8000 Hz. All subjects were similarly inexperienced with modulation detection tasks. Hence, they were given practice runs, for both the first- and second-order modulation detection tasks, until their thresholds were stable, i.e., the standard deviation of the last three thresholds was less than 2.5 dB. This took roughly 9–12 runs per condition, yielding about 9 h total of practice per subject for the two detection tasks.

B. Signal generation

The modulated carrier was digitally generated using a Tucker-Davis Technologies (TDT) System II, controlled by a PC. The sampling rate was 51 200 Hz. The stimuli were presented monaurally over Sennheiser HD580 headphones, at a level of 75 dB SPL (this is the estimated level at the eardrum, taking into account the diffuse-field response of the headphones; the equivalent diffuse-field level was 66 dB SPL). For all modulated stimuli, the carrier was a sinusoid with frequency f_c equal to 4000 Hz.

A noise with a spectral notch at the carrier frequency was used to restrict off-frequency listening and to prevent the detection of distortion components in the audio-frequency domain. This noise, whose characteristics were based on calculation of excitation patterns as described by Glasberg and Moore (1990), consisted of three bands: Band 1 extended from 50 to 1500 Hz and had a spectrum level of 10 dB (re 20 μPa); Band 2 extended from 1600 to 2400 Hz and had a spectrum level of 18 dB; Band 3 extended from 6000 to 13 000 Hz and had a spectrum level of 18 dB (see also, Alcántara *et al.*, 2003). All spectrum levels here are equivalent diffuse-field levels; levels at the eardrum would have been higher, especially for frequencies in the range 1500 to 6000 Hz. Together, these bands produced: (a) negligible excitation at the carrier frequency; (b) relatively high excitation for frequencies near the carrier frequency ($f_c \pm 0.3 f_c$) so as to restrict off-frequency listening; and (c) moderate excitation at frequencies well below the carrier frequency (to mask audio-frequency distortion components at the first- or second-order modulation rate). The noise was digitally generated, by summing sinusoidal components spaced at 0.1-Hz intervals, and the 10-s noise sample was repeated seamlessly and recorded onto a compact disc. For the notched-noise

conditions, this noise was played continuously from a compact-disc player and was added to the modulated signals via a TDT SM3 mixer.

III. EXPERIMENT 1. MODULATION DETECTION WITH AND WITHOUT NOTCHED NOISE

A. Conditions and stimuli

To allow comparisons across first- and second-order modulation conditions, as well as comparisons with data from previous studies, first-order modulation detection thresholds were measured for four first-order modulation rates: f_m=2, 10, 16, and 50 Hz. For these conditions, the subject's task was to detect the presence of sinusoidal amplitude modulation (SAM) applied to the 4000-Hz carrier (the "target"). The "standard" was the unmodulated carrier. Modulation detection thresholds were determined for the four modulation rates in both the absence and presence of notched noise.

To examine second-order modulation perception at both slow and fast rates, second-order modulation detection thresholds were measured using two different pairs of modulation rates: "slow" with f_m=16 Hz and f'_m=2 Hz; "fast" with f_m=50 Hz and f'_m=10 Hz. For these conditions, the subject's task was to detect the presence of sinusoidal modulation applied to the modulation depth of the first-order SAM (the "target"). The "standard," in this case, was the carrier modulated at the first-order modulation rate f_m with a fixed modulation depth m. Second-order modulation detection thresholds were determined in both the absence and presence of the same notched noise as before.

Equations for the first- and second-order modulation "targets" $T(t)$ and $T'(t)$, respectively, are given below

$$T(t) = c\{1 + m\sin(2\pi f_m t + \varphi_m)\}\sin(2\pi f_c t + \varphi_c) \quad (1)$$

$$T'(t) = c\{1 + m[1 + m'_B\sin(2\pi f'_m t + \varphi'_m)] \times \sin(2\pi f_m t + \varphi_m)\}\sin(2\pi f_c t + \varphi_c), \quad (2)$$

where f_m and m are the modulation rate and depth, respectively, of the first-order modulation, and f'_m and m'_B are the second-order modulation rate and depth, respectively, of the second-order modulation. The multiplicative scalar c was used to adjust levels such that all stimuli had a constant overall power. Starting phases, φ_c, φ_m, and φ'_m, were chosen randomly for each trial. For detection of second-order AM, the first-order modulation depth m was 0.5 for both the "target" and the "standard" stimuli. To avoid overmodulation in the second-order modulation conditions, the second-order modulation depth m'_B was constrained to be $\leqslant(1/m)-1$. Stimuli were 1 s in duration with 20-ms raised-cosine on/off ramps.

In recent publications, two different equations have been used to describe second-order modulation signals. Hence, comparisons of second-order threshold values across studies must be made carefully, as the definition of second-order modulation depth differs depending on the equation used. For example, Lorenzi *et al.* (2001a; b) and Füllgrabe *et al.* (2005) describe the second-order "target" signal by the following equation (ignoring initial phases):

$$T'(t) = c\{1 + [m + m'\sin(2\pi f'_m t)] \times \sin(2\pi f_m t)\}\sin(2\pi f_c t), \quad (3)$$

while in this study the second-order modulation "target" signal is described by Eq. (2) above and in Millman *et al.* (2003) an equation of the same form as Eq. (2) is used. In Eq. (2), the second-order modulation depth is defined as m'_B while in Eq. (3), the second-order modulation depth is defined as m' (the first-order modulation depth is m in both equations). Mathematically, the second-order modulation depth m'_B in Eq. (2) is equivalent to m'/m of Lorenzi *et al.* (2001a; b) and Füllgrabe *et al.* (2005).

B. Procedure

First- and second-order modulation detection thresholds were measured using an adaptive three-interval, three-alternative forced-choice procedure, using a three-down one-up stepping rule that estimates the 79.4% correct point on the psychometric function (Levitt, 1971). The "target" signal was presented in one of the three intervals, selected at random, and the stimuli were separated by 400-ms interstimulus intervals. Each stimulus was accompanied by a separate light on the response box; the response buttons were positioned below the lights. Visual feedback, using the lights, was provided after each trial.

For the measurement of first-order AM detection thresholds, the modulation depth m was initially set to 0.4 (−8 dB), while for the measurement of second-order AM detection thresholds, the modulation depth m'_B was initially set to 0.5(−6 dB). For both first- and second-order modulation detection, the initial step size was 5 dB in units of 20 log m or 20 log m'_B. After four reversals the step size was reduced to 2 dB. Twelve reversals were obtained and threshold, for each adaptive run, was defined as the mean of the values of 20 log m or 20 log m'_B at the last eight reversals. For each condition and each subject, modulation detection threshold was estimated from the average of three adaptive runs.

C. Results and discussion

Individual-subject data and group-mean data are shown in Fig. 1 for both first- and second-order modulation detection. The lowest thresholds were obtained for first-order modulation detection in the absence of notched noise (open triangles). There is some variability across subjects and across the range of modulation rates examined (2 to 50 Hz), with first-order modulation thresholds ranging from −19 to −28 dB. These thresholds are higher than typically reported by others for similar carrier frequencies and modulation rates. For example, Lorenzi *et al.* (2001b) reported thresholds of about −33 dB, and Kohlrausch *et al.* (2000) reported thresholds of about −28 dB. Millman *et al.* (2003) reported first-order modulation thresholds of roughly −37 dB for f_m =2 Hz, and roughly −27 dB for f_m=16 Hz, using a 5000-Hz carrier. However, in all these studies the adaptive procedure converged on the modulation depth required for 70.7% correct detection, using a two-interval forced-choice task, which corresponds to a sensitivity index d' of about 0.76. This contrasts with the procedure used in this study which tracks the

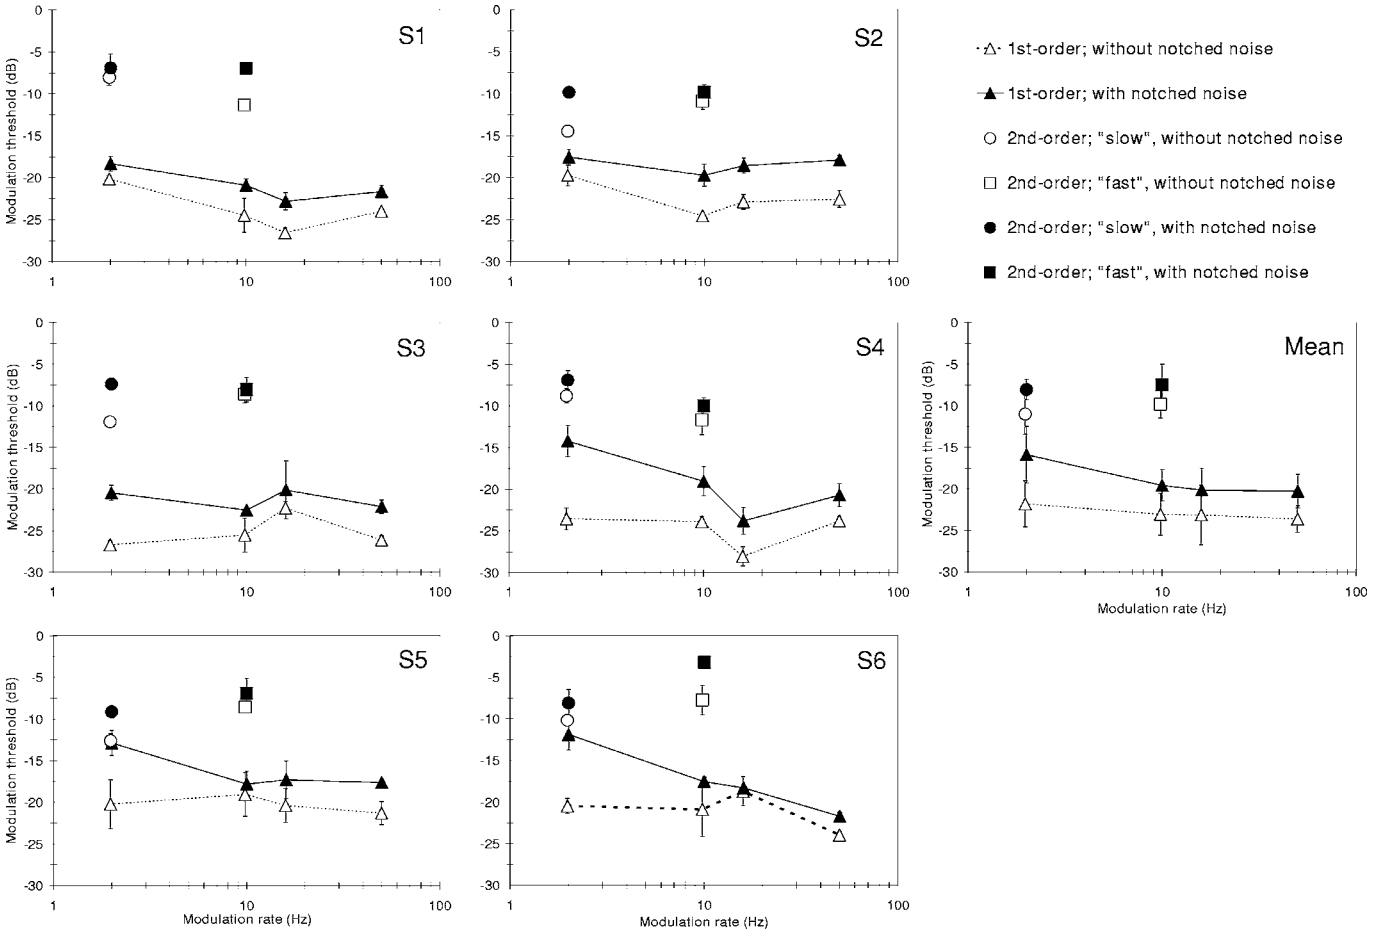

FIG. 1. Individual and mean first- and second-order modulation detection thresholds. Each panel shows the modulation depth at threshold, in decibels, on the ordinate: $20 \log m$ for first-order detection and $20 \log m'_B$ for second-order detection. The abscissa represents the modulation rate: f_m for first-order detection and f'_m for second-order detection. Data for first-order modulation detection are represented by triangles, and are drawn with lines connecting the symbols. Data for second-order modulation detection are represented by circles for the slow-rate pair and by squares for the fast-rate pair. Open and filled symbols represent data from conditions without and with notched noise, respectively. First-order modulation depth m was fixed at 0.5 for all second-order modulation detection conditions. The symbols (triangles, circles, and squares) represent the mean and error bars represent ±1 standard deviation from the mean (note: data from the conditions without notched noise are offset slightly along the abscissa for readability).

79.4% correct point using a three-interval forced-choice task; this corresponds to a d' value of about 1.62. Moore and Glasberg (2001) used the same procedure as here and reported similar thresholds for a 5000-Hz carrier. In addition, the stimuli in the studies of Lorenzi *et al.* (2001b) and Millman *et al.* (2003) were twice as long as the stimuli in this study (2 s versus 1 s), which may have made modulation detection somewhat easier in their studies, especially for the lowest modulation rates.

The presence of the notched noise increased thresholds for first-order modulation detection by about 3–6 dB (compare the filled to the open triangles). Again, there is some variability across subjects and across modulation rates. Threshold increases produced by the notched noise ranged from 2.9 to 5.4 dB across the six subjects, and ranged from 0.4 to 9.3 dB across subjects and modulation rate. Overall, the effect of the notched noise is similar in magnitude to that reported by Strickland and Viemeister (1997) for slow modulation rates (2–50 Hz), although Strickland and Viemeister (1997) used an 800-Hz-wide noise carrier rather than a sinusoidal carrier. Consistent with the results of others (Zwicker, 1956; Füllgrabe *et al.*, 2005), this result indicates that off-frequency listening contributes to first-order modulation detection, for these moderately slow modulation rates.

Individual and mean second-order modulation detection thresholds are also shown in Fig. 1 (see open and filled squares and circles). In quiet, second-order thresholds for the slow-rate pair varied across listeners from −8 to −15 dB (open circles). For the fast-rate pair, thresholds varied from about −8 to −12 dB (open squares). These thresholds are substantially higher than those reported by Lorenzi *et al.* (2001b) and Millman *et al.* (2003) using a carrier frequency of 5000 Hz. For the rates similar to those for our slow-rate pair, Lorenzi *et al.* (2001b), using a first-order depth of 0.5, reported thresholds that correspond to $m'_B = 0.08$ (or −22 dB; Note: $m' = 0.04 \rightarrow m'_B = m'/m = 0.04/0.5 = 0.08$), as compared to the average m'_B value here of about 0.28 (−11 dB). Millman *et al.* also reported m'_B values of about −22 dB, even though the first-order modulation depth was much smaller ($m = 0.25$). Again, the higher thresholds obtained in our study are probably due to the higher d' value tracked by our procedure, and by the shorter stimulus duration used here.

The addition of notched noise elevated thresholds for detecting second-order modulation (filled circles and

squares). On average, thresholds were elevated by 3 dB for the slow-rate pair and by 2.3 dB for the fast-rate pair. Again, this effect varied somewhat across subjects and across rates. For some subjects (S2, S3, S5), the effect of the notched noise was greater for the slow-rate pair than for the fast-rate pair, while for others (S1, S6) the opposite occurred. Overall, the effect of the notched noise suggests that second-order modulation detection also depends to some extent on off-frequency listening in the audio-frequency domain, regardless of the subsequent mechanism for detecting the second-order modulation (generation and detection of a distortion component in the modulation-frequency domain, or detection of temporal fluctuations at the outputs of the modulation filters tuned to the first-order rate).

IV. EXPERIMENT 2. DETECTABILITY OF SECOND-ORDER AM IN THE PRESENCE OF MODULATION MASKERS

In this experiment, the effects of different noise modulation maskers on the ability to detect second-order modulation were measured. A noise modulation masker was centered either at the first- or second-order modulation rate. If the detection of second-order modulation depends on the detection of an envelope distortion component generated by the auditory system at the second-order rate, then a narrow-band noise modulation masker should have a more deleterious effect on second-order modulation detection when it is centered at the second-order rate than when it is centered at the first-order rate. If, on the other hand, second-order modulation detection depends on the detection of fluctuations at the second-order rate in the output of the modulation filter tuned at, or close to, the first-order rate, then a modulation masker centered at the first-order rate should have the more deleterious effect, since this modulation masker would interfere directly with such fluctuations and since the modulation masker centered at the second-order rate would have little effect on such fluctuations (i.e., it would not be passed, or would be significantly attenuated, by the modulation filter tuned to the first-order rate).

A. Conditions and stimuli

For each rate pair, second-order AM-detection performance was measured for three masker conditions: (i) no-masker—no modulation masker; (ii) low-band—modulation masker centered at the second-order modulation rate (f'_m); and (iii) high-band—modulation masker centered at the first-order modulation rate (f_m). Each condition was tested in the absence and presence of the notched noise described in Sec. II B.

As in Experiment 1, the carrier frequency was 4000 Hz for all modulated stimuli. For the no-masker conditions, the "target" stimulus is described by Eq. (2) of Sec. III A. For the low-band and high-band conditions, the equation for the second-order modulated "target" stimulus, $T'_N(t)$, is given below:

$$T'_N(t) = c\{1 + an(t) + m[1 + m'_B \sin(2\pi f'_m t + \varphi'_m)] \times \sin(2\pi f_m t + \varphi_m)\}\sin(2\pi f_c t + \varphi_c), \quad (4)$$

where all variables are the same as in Eq. (2), but with the addition of a modulation masker $n(t)$, which is scaled by the coefficient a. When a was equal to 1, the root-mean-square amplitude of the modulation masker was equal to 1. For the slow-rate pair, the low-band masker was a 2-Hz-wide noise centered at 2 Hz (f'_m) while the high-band masker was an 8-Hz-wide noise centered at 16 Hz (f_m). For the fast-rate pair, the low-band masker was a 5-Hz-wide noise centered at 10 Hz (f'_m) while the high-band masker was a 25-Hz-wide noise centered at 50 Hz (f_m). The bandwidths of the low- and high-band maskers for the slow-rate pair were chosen to match those used by Millman *et al.* (2003). The bandwidths for the fast-rate pair were chosen to be comparable to or less than the bandwidths of the modulation filters at their respective center frequencies; the bandwidth of each modulation filter has been estimated to be approximately equal to its center frequency (Dau *et al.*, 1997a, 1997b; Sek and Moore, 2003). Long samples of these low-band and high-band maskers were generated in advance using an algorithm that generates noise with a very low peak factor, called low-noise noise (Pumplin, 1985; Kohlrausch *et al.*, 1997). The algorithm used here was the one described by Kohlrausch *et al.* Selections from the long samples were chosen randomly for each interval. In all conditions, the first-order modulation depth was fixed at $m=0.5$. The second-order modulation depth m'_B and the masker coefficient a were chosen separately for each subject (see below). As in Experiment 1, stimuli were 1 s in duration with 20-ms raised-cosine on/off ramps.

B. Procedure

The subject's task, as before, was to detect the presence of sinusoidal modulation applied to the modulation depth of the 4000-Hz carrier—but, in this case, in the presence of an additional modulation masker $n(t)$ in the low-band and high-band conditions. The "standard" signal was the 4000-Hz carrier modulated at rate f_m, with a fixed modulation depth ($m=0.5$). For the low-band and high-band conditions, the "standard" signal also had the appropriate modulation masker.

The effects of masker modulation on second-order modulation detection were evaluated using the method of constant stimuli, and a three-interval, three-alternative forced-choice procedure. The method of constant stimuli was chosen because it is easier to prevent overmodulation with this method than with an adaptive procedure. For each subject, the second-order modulation depth was chosen (on the basis of data from a preliminary experiment) so as to give roughly 80%–85% correct in the absence of a modulation masker. Since the second-order modulation depths at threshold found in Experiment 1 were dependent on the rate pair and on the presence or absence of notched noise, the supra threshold values of m'_B used in this experiment also depended on the rate pair and on whether notched noise was present or absent. Table I lists the second-order modulation depth m'_B

TABLE I. Values of second-order modulation depth m'_B and of modulation masker coefficient a used in Experiment 2, for both the low-band and high-band modulation masker conditions. The first-order modulation depth was 0.5 for all conditions and all subjects.

	Slow (f_m=16 Hz, f'_m=2 Hz)				Fast (f_m=50 Hz, f'_m=10 Hz)			
	Without notched noise		With notched noise		Without notched noise		With notched noise

and the modulation masker coefficient a used for each subject for each rate-pair and notched-noise condition. To avoid overmodulation, the masker coefficient a was not allowed to exceed $1-m(m'_B+1)$, but otherwise was as large as possible. The order of conditions was randomized. For each subject and each condition, six blocks of 50 trials each were run, and average percent-correct detection scores across the six blocks are reported.

C. Results and discussion

Individual and group mean results are shown in Fig. 2. Each panel shows percent correct detection scores for one of the four rate-pair × notched-noise conditions. Within each panel detection performance is shown, for each subject and for the mean across subjects, by bars from left to right representing the no-masker, low-band masker, and high-band masker conditions, respectively. The upper-left panel shows scores for the slow-rate pair for the condition without notched noise. The upper-right panel shows scores for the slow-rate pair for the condition with notched noise. The bottom two panels show corresponding data for the fast-rate pair.

Four separate within-subject analyses of variance were performed on the arcsine-transformed data, with factor modulation masker condition (no-masker, low-band, or high-band). For both the slow- and fast-rate pairs, and both with

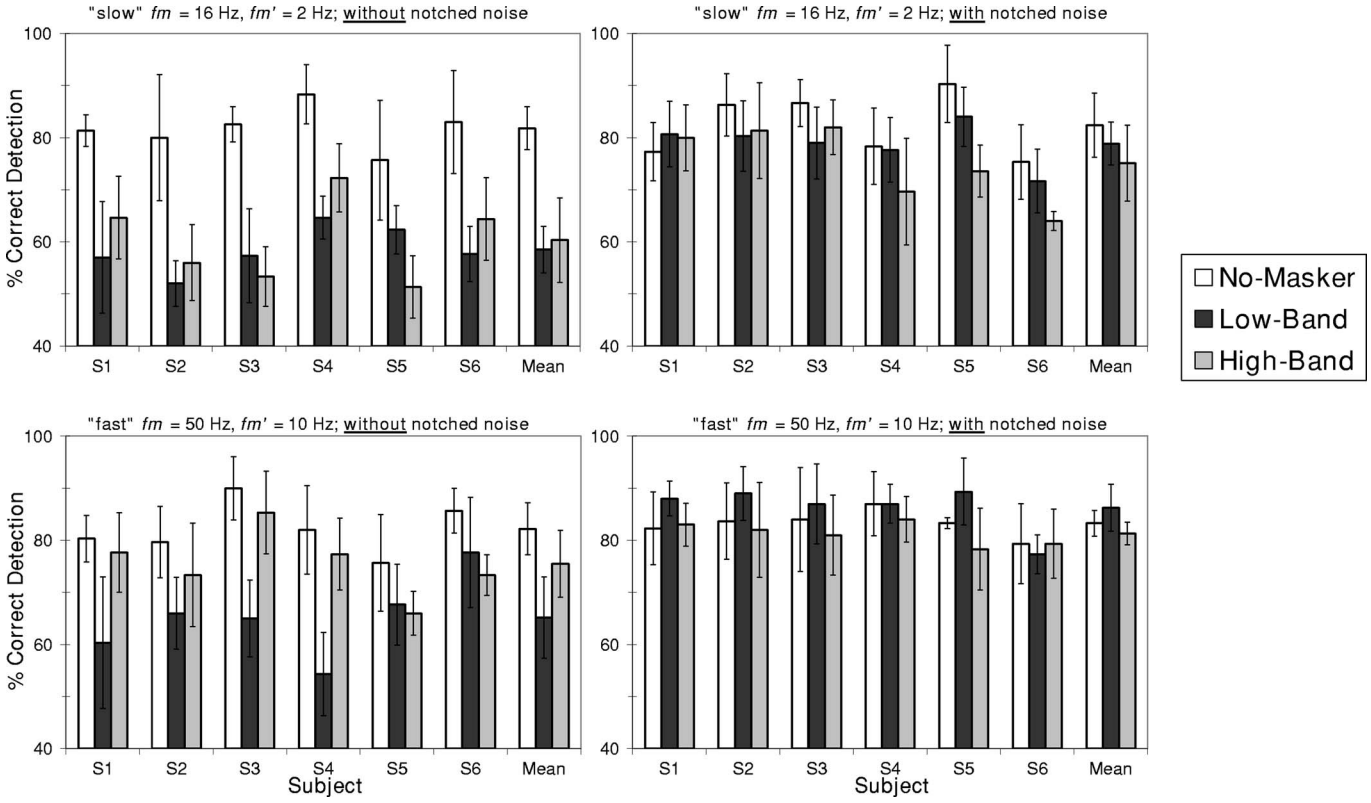

FIG. 2. Individual and mean scores for detection of second-order modulation with and without a notched-noise masker. The top and bottom panels represent data for the slow- and fast-rate pairs, respectively. Left and right panels show data from the conditions without and with notched noise, respectively. Within each panel, the data for each subject are shown as the mean ±1 standard deviation for the conditions with no-masker (unfilled bars), the low-band masker (dark gray filled bars), and the high-band masker (light gray filled bars), from left to right. First-order modulation depth was 0.5 for all subjects and conditions. Other parameters are specified in Table I.

and without notched noise, modulation masker condition had a significant effect on second-order modulation detection performance [$F(2,10) > 5.33, p \leq 0.027$]. The significance of the differences between specific pairs of maskers was determined using Fisher's least-significant differences (LSD) test.

For the slow-rate pair without notched noise (upper-left panel), there was a significant difference between the no-masker condition and the low-band ($p < 0.001$) and high-band ($p < 0.001$) conditions. Thus, both the low- and high-band maskers degraded performance, and by a similar amount (there was no significant difference between scores for the low- and high-band conditions). For the slow-rate pair with notched noise (upper-right panel), scores for the no-masker and low-band conditions did not differ significantly and scores for the low-band and high-band conditions did not differ significantly. However, the mean score was significantly lower for the high-band condition than for the no-masker condition ($p < 0.01$). Thus, the high-band masker degraded performance.

For the fast-rate pair without notched noise (bottom-left panel), there was no significant difference between the no-masker condition and the high-band condition. However, there was a significant difference between the no-masker condition and the low-band condition ($p < 0.01$) and between the low-band and high-band conditions ($p < 0.02$). Thus, the low-band masker significantly degraded performance, while the high-band masker did not. For the fast-rate pair with notched noise (bottom-right panel), there was no significant difference between the no-masker condition and the low-band condition and no significant difference between the no-masker condition and the high-band condition. However, there was a significant difference between the low-band and high-band conditions ($p < 0.01$).

In summary, in the absence of notched noise, both modulation maskers tended to degrade performance relative to the no-masker condition, although the effect of the high-band masker was not significant for the fast-rate pair. The low-band masker had a significant deleterious effect for both rate pairs. In the presence of notched noise, the effects of the modulation maskers differed. For the slow-rate pair, only the high-band masker had a significant deleterious effect on performance, while for the fast-rate pair, neither the low- nor high-band masker significantly affected performance compared to that for the no-masker condition. However, there was some individual variability in the effects obtained when notched-noise was present. For example, for the slow-rate pair, three subjects (S4, S5, S6) showed a larger negative effect for the high- than for the low-band masker, while the other three subjects (S1, S2, S3) showed similar effects for the two maskers.

Our results obtained in the absence of notched noise differ from those reported by Millman *et al.* (2003) for similar stimuli. Using modulation rates the same as for our slow-rate pair, they found that a modulation masker centered at 2 Hz had only a small negative effect on the detectability of second-order AM, while a modulation masker centered at 16 Hz had an effect that was 2–3 times greater for the larger masker modulation depths. For this slow-rate pair, we found a substantial effect of both the low-band and the high-band modulation maskers. The difference may have occurred because of the small modulation depths used by Millman *et al.* It is likely that, when the first- and second-order modulation depths are small, the magnitude of the distortion component at the second-order rate is very small, and therefore that component hardly contributes to the detection of second-order modulation. Our results suggest that, when the first- and second-order modulation depths are larger, and in the absence of a notched noise that restricts off-frequency listening, the detection of second-order modulation is partly mediated by a distortion component at the second-order rate in the internal representation of the envelope. It is not known why the effect of the high-band masker differs for the fast-rate pair (no significant effect) and for the slow-rate pair (significant deleterious effect).

As described in the Introduction, the effective magnitude of the distortion component at the second-order rate is likely to be small, even when the modulation depths of the first- and second-order modulators are large. As a result, even a moderate level of a modulation masker centered at the second-order rate should be sufficient to mask completely the distortion component. The fact that the low-band modulation masker did not abolish the ability to detect second-order modulation, but only partially impaired that ability, suggests that second-order modulation detection can be mediated via a mechanism other than the detection of a distortion component at the second-order rate. An alternative, as mentioned earlier and as proposed by Ewert *et al.* (2002), is that second-order modulation can be detected using fluctuations at the second-order rate at the output of the modulation filter(s) tuned at, or close to, the first-order rate. This alternative was supported by a recent experiment of Füllgrabe and Lorenzi (2005), which involved matching the perceived "beat" rate in a complex modulator with inharmonic components.

Generally, the effects of the modulation maskers were smaller when notched noise was present than when it was absent. This may be partly attributed to the fact that the magnitude of the modulation noise, determined by coefficient a, was somewhat smaller when the notched noise was present than when it was absent (see Table I). For example, for the slow-rate pair, the mean value of a was 0.34 when the notched noise was absent, and 0.29 when the notched noise was present. Also, the depth of the second-order modulator m'_B needed to achieve about 85% correct in the no-masker condition was usually somewhat greater when the notched noise was present (mean m'_B of 0.41) than when it was absent (mean m'_B of 0.31). However, not all of the individual results can be explained in this way. For example, for the slow-rate pair, the values of m'_B and a for subject S4 were almost the same for the conditions with and without notched noise, but for S4 the low-band modulation masker had a large effect on the detectability of second-order AM when the notched noise was absent, and had no effect when the notched noise was present.

In the absence of notched noise, subjects could use information from the high-frequency side of the excitation pattern of the carrier, where the effects of basilar-membrane compression are small or absent, and where the effective

amount of modulation is greater than around the central part of the pattern (Zwicker, 1956; Florentine and Buus, 1981; Moore and Sek, 1994; Kohlrausch *et al.*, 2000). As described in the Introduction, there is evidence that such off-frequency listening is beneficial for the detection of first-order modulation, and the results of Experiment 1 indicate that it is also beneficial for the detection of second-order modulation, in agreement with the results of Füllgrabe *et al.* (2005). Moore *et al.* (1999) suggested that basilar-membrane compression could be partly responsible for the introduction of a distortion component at the second-order rate. However, later work (Verhey *et al.*, 2003; Sek and Moore, 2004; Füllgrabe *et al.*, 2005) showed that the phase of the distortion component was not what would be predicted from basilar-membrane compression. In addition, recent results indicate that listeners who presumably experience little or no basilar membrane compression, such as those with impaired hearing or cochlear implants, have second-order AM-detection thresholds that are similar to or only slightly higher than those for normal-hearing listeners (Tandetnik *et al.*, 2001; Füllgrabe *et al.*, 2003; Lorenzi *et al.*, 2004). These results suggest that there is a nonlinearity other than basilar-membrane compression which is the primary generator of the distortion component at the second-order rate. Whatever this nonlinearity is, it seems plausible that: (a) it occurs later in the auditory system than basilar-membrane compression, and (b) the effective magnitude of the distortion component increases as the amount of amplitude fluctuation on the basilar membrane increases.

This line of reasoning leads to the conclusion that the effective magnitude of the distortion component at the second-order rate may be markedly reduced when off-frequency listening is restricted by notched noise, simply because of the reduction in the effective amount of modulation at the input to the nonlinearity that generates the distortion component. This could account for our finding that the low-band modulation masker had no significant effect when notched noise was present. However, for some subjects, the notched noise had only a small effect on second-order modulation detection thresholds (e.g., for S1, S4, and S6, the presence of notched noise resulted in threshold increases for the slow-rate pair of 1.1, 1.9, and 2.1 dB, respectively; see Fig. 1). For some of these subjects, the lack of an effect due to the low-band modulation masker in the presence of notched noise may be a result of the different values of second-order modulation depth m_B' and modulation masker scalar a in the absence and presence of notched noise.

For the slow-rate pair, the high-band modulation masker impaired the detection of second-order modulation when notched noise was present, but the effect was smaller than when the notched noise was absent. The smaller effect in the presence of notched noise can probably be explained in terms of the relative magnitude of m_B' and a. When the notched noise was absent, m_B' and a were typically about equal in magnitude, although the relative values differed from one subject to another. When the notched noise was present, m_B' was typically larger than a, so one would expect the effect of the high-band modulation masker to be smaller.

According to the argument given above, second-order detection by normally hearing subjects may be improved by off-frequency listening (when no notched noise is present) because the lack of basilar-membrane compression on the high-frequency side of the excitation pattern leads to a greater amount of fluctuation at the input to the nonlinearity generating the envelope distortion product, and hence to a larger magnitude of the distortion product. If this argument is correct, then one might expect that subjects with reduced basilar-membrane compression (those with cochlear hearing impairment or cochlear implants) would show comparable second-order AM detection thresholds to those for normally hearing subjects. As noted earlier, this has been found to be the case (Tandetnik *et al.*, 2001; Füllgrabe *et al.*, 2003; Lorenzi *et al.*, 2004).

V. CONCLUSIONS

(1) Detection thresholds for both first-order and second-order amplitude modulation were increased by the addition of noise with a spectral notch at the carrier frequency, to restrict off-frequency listening. This effect may occur because, in the absence of notched noise, subjects use information from the high-frequency side of the excitation pattern, where the effective amount of modulation is greater because of more linear (less compressive) basilar-membrane processing.

(2) In the absence of notched noise, the detectability of second-order modulation was reduced both by the addition of a modulation masker centered at the first-order rate (high-band masker), and by the addition of a modulation masker centered at the second-order rate (low-band masker), although the deleterious effect of the high-band masker for the fast-rate pair was not significant; for the fast-rate pair (f_m=50 Hz, f_m'=10 Hz), the effect of the low-band masker was greater than the effect of the high-band masker, although performance remained above chance in the presence of the low-band masker. These results suggest that the detectability of second-order modulation when off-frequency listening is not restricted can be mediated by two mechanisms: (a) detection of a distortion component at the second-order rate in the internal representation of the envelope and (b) detection of fluctuations at the second-order rate at the output of modulation filters tuned at, or close to, the first-order rate.

(3) In the presence of notched noise, the detectability of second-order modulation was not significantly affected by the addition of the low-band modulation masker. This suggests that, when off-frequency listening is restricted, detection of second-order modulation is not mediated by detection of a distortion component at the second-order rate, possibly because the amplitude of this component is too small.

(4) In the presence of notched noise, the detectability of second-order modulation was impaired by the addition of the high-band modulation masker for the slow-rate pair but not for the fast-rate pair. At least for slower modulation rates, this result is consistent with the idea that detection of second-order modulation can be medi-

ated via detection of fluctuations at the second-order rate at the output of modulation filters tuned at, or close to, the first-order rate.

ACKNOWLEDGMENTS

The authors thank our subjects for participating in these experiments. The first author thanks all members of the Auditory Perception Group at the University of Cambridge for the intellectual and incredibly congenial work environment. The authors also thank Christian Füllgrabe and an anonymous reviewer for helpful comments on this manuscript. This work was funded by the MRC (UK).

(Received 25 July 2005; revised 7 February 2006; accepted 13 February 2006)

The effect of sound incidence angle on loudness was investigated using real sound sources positioned in an anechoic chamber. Eight normal-hearing listeners produced loudness matches between a frontal reference location and seven sources placed at other directions, both in the horizontal and median planes. Matches were obtained via a two-interval, adaptive forced-choice (2AFC) procedure for three center frequencies (0.4, 1, and 5 kHz) and two overall levels (45 and 65 dB SPL). The results showed that loudness is not constant over sound incidence angles, with directional sensitivity varying over a range of up to 10 dB, exhibiting considerable frequency dependence, but only minor effects of overall level. The pattern of results varied substantially between subjects, but was largely accounted for by variations in individual head-related transfer functions. Modeling of binaural loudness based on the at-ear signals favored a sound-power summation model, according to which the maximum binaural gain is only 3 dB, over competing models based on larger gains, or on the summation of monaural loudness indices. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2184268]

I. INTRODUCTION

There is growing awareness in psychoacoustics that, for a thorough understanding of loudness perception, its binaural nature has to be taken into account. That is true for basic research, namely the construction of general loudness models (e.g., Moore *et al.*, 1997), as well as for applications to audio reproduction systems (Zacharov *et al.*, 2001) or to perceived sound quality (Bodden, 1997). Especially for instrumental loudness predictions based on Zwicker's modeling, as standardized in ISO 532 (1975), the fact that it is essentially monophonic has been regarded as a major drawback. Nevertheless, the adjustments recently made to loudness modeling rest on a fairly narrow empirical data base, which the present study hopes to extend.

To clarify the issues, it may be helpful to distinguish two stages of processing involved when the loudness of a real sound source in space is perceived: (1) the physical transformation of the "distal" stimulus emitted by the source to "proximal" stimuli arriving at the listener's ears, and (2) the neural, psychological, and cognitive process of integrating the two at-ear stimuli into a single percept.

A. Physical (HRTF) filtering

The first stage can be described in purely acoustical terms, namely by applying head-related transfer functions (HRTFs, Shaw, 1974; Wightman and Kistler, 1989a; Møller *et al.*, 1995; Blauert, 1997, Chap. 5). These account for the filtering of the source due to the physical effects of the human torso, head, and pinnae, depending on the incidence angle of the sound. Further along, through the ear canal, the physical sound transmission has been shown to be independent of the direction of the sound source (see, e.g., Hammershøi and Møller, 1996). Thus, the direction-dependent part of an HRTF can be measured at the entrance to the blocked ear canal, and described by (adopted from Møller *et al.*, 1995)

$$\mathrm{HRTF}_{\text{dir-dep}}(\phi,\theta)=\frac{P_2}{P_1}(\phi,\theta), \tag{1}$$

where ϕ is azimuth, θ is elevation, P_1 is sound pressure at the center position of head, and P_2 is sound pressure at the entrance to the blocked ear canal.

In the median plane, the HRTFs of the two ears are fairly similar due to the physical symmetry of the human body in this plane. However, level differences between HRTFs for different directions can approach 10 dB or more over a fairly wide frequency range. By contrast, large interaural time and level differences (ITDs and ILDs, respectively) between the two ears emerge in the horizontal plane, where the ILDs can reach up to 30 dB at high frequencies. HRTFs have been a major research topic during the past

[a)]Portions of the data were presented at the 147th Meeting of the Acoustical Society of America, New York, May, 2004, and at Internoise, Prague, August, 2004.

15 years, but the focus of this research has been on adequate "auralization" or sound localization (Wightman and Kistler, 1989a,b; Bronkhorst, 1995; Møller *et al.*, 1996), not on loudness.

B. Binaural loudness summation

The second stage of processing has been termed binaural loudness summation. It describes how the acoustic inputs to the left and right ear are integrated to yield a single, binaural loudness. Starting from the observation that a sound appears louder when listened to with both ears (i.e., binaurally) than with only one (i.e., monaurally), a number of investigators conducted experiments using headphones, through which different combinations of left- and right-ear sound-pressure levels were presented in order to quantify this effect. The results are often summarized as providing evidence for a binaural-to-monaural loudness ratio of 2:1, or perfect loudness summation, corresponding to a binaural gain of approximately 10 decibels (e.g., Levelt *et al.*, 1972; Marks, 1978; Schneider and Cohen, 1997), in accordance with the sone scale of loudness. The evidence is far from unequivocal, however, with many studies finding less-than-perfect summation (e.g., loudness ratios of approximately 1.5:1; Zwicker and Zwicker, 1991), and a level dependence of the binaural gain, which appears to increase from approximately 3 dB near threshold to 6–10 dB at high sound-pressure levels (Shaw *et al.*, 1947; Reynolds and Stevens, 1960; Hellman and Zwislocki, 1963).

Interestingly, binaural loudness summation, as conceptualized in this paradigm, has not been investigated with sounds that are likely to reach the eardrums when emitted from a real source in space, i.e., with products of the first (HRTF) filtering stage. Rather, artificial sounds such as tones, or broadband noise, lacking all spatial or directional information have been used, often at interaural level differences (e.g., in monotic-to-diotic comparisons) far exceeding what would naturally occur. Such conditions of stimulation do not yield an externalized sound image, but rather more or less lateralized inside-the-head percepts. Generally, it appears that the considerable literature on binaural loudness summation has contributed more to the development of scaling methodologies than to the auditory issues involved.

C. Loudness of free and diffuse sound fields

For practical purposes, in an attempt to relate the monophonic measurement of a sound field to perceived loudness, two specific types of sound fields have been considered: The free field, where the sound incidence angle is frontal to the listener, and the diffuse field, where the sound is reaching the listener's ears with equal intensity from all directions.

In order to account for the fundamental difference in sound incidence, the standardized loudness model (ISO 532, 1975) has different computation procedures for the two sound fields. The two procedures are based on both objective and subjective data (Kuhl and Westphal, 1959; Robinson *et al.*, 1961; ISO 389-7, 1996): The objective data represent the differences in the at-ear sound pressures between the two sound fields, i.e., investigating only the effect of the first (HRTF) filtering stage; the subjective data represent the differences in perceived loudness, including effects of both the first and the second stage. Even though the agreement between the objective and subjective data is fair, these investigations do not specify how the two signals at the ears of a listener are summed into a single loudness percept, due to the fact that the stimulation of the auditory system in both sound fields is essentially diotic.

The increasing use of dummy heads for acoustical recordings and measurements, often resulting in dichotic at-ear signals, has led to growing interest in how dichotic at-ear signals should be summed to correspond to the diotic stimulation of the conventional free- and diffuse-field loudness paradigms.

D. Directional loudness

Thus, while studies of HRTF filtering have not explicitly been concerned with the loudness of dichotic sounds, the work on binaural loudness summation appears to lack ecological validity to predict the perception of real sources positioned in space. What remains, then, is less than a handful of studies that have actually investigated directional loudness of real sources in space, taking into account both stages delineated: the physical filtering due to HRTFs, and the ensuing "psychological" summation.

Sivian and White (1933) investigated the effect of direction on hearing thresholds, reporting that at absolute threshold, the binaural minimum audible field is not significantly different from the monaural one. This implies no or a very small binaural advantage, the ear receiving the higher sound pressure determining the binaural hearing threshold. While the directional HRTF effects are the same at higher sound-pressure levels, extrapolating from a detection task to suprathreshold binaural loudness and to its summation across the two ears may be unjustified.

By far, the most pertinent and complete study investigating directional loudness was published by Robinson and Whittle (1960) more than 45 years ago. The authors used a circular array of 12 equally spaced loudspeakers positioned around the listener seated in an anechoic room to obtain loudness matches between a reference and each test position. Using narrow-band sounds having six center frequencies between 1.6 and 10 kHz, and rotating their apparatus when required, they investigated the horizontal, median, and frontal planes in a sample of 16 to 20 listeners. Using probe-tube microphones they also measured sound-pressure levels at the ears of their subjects, as produced by the same stimuli, thus obtaining crude magnitudes of "HRTFs" for the six test frequencies.

As expected, the average loudness matches showed a strong frequency dependence, with the greatest directional effects (of up to 15 dB; see their Fig. 2) observed at higher frequencies (4–10 kHz). Relating the mean loudness matches to the average at-ear sound-pressure measurements, Robinson and Whittle (1960; see their Fig. 5) found the former to be reasonably well predicted by a "6-dB summation rule,"

$$L_{\text{mon}} = 6 \times \log_2(2^{L_{\text{left}}/6} + 2^{L_{\text{right}}/6}), \quad (2)$$

where L_{mon} is the equivalent sound pressure needed for monotic stimulation to match any binaural (diotic: $L_{\text{left}} = L_{\text{right}}$, or dichotic: $L_{\text{left}} \neq L_{\text{right}}$) combination of left-ear (L_{left}) and right-ear (L_{right}) input levels. If, for example, both ears are exposed to 70 dB SPL, the equivalent monotic SPL turns out to be 76 dB SPL (i.e., a 6-dB binaural gain). Note, however, that there is not sufficient information on the fit of this heuristic (other than what can be judged from visual inspection of their Fig. 5) in Robinson and Whittle's report, or on its feasibility to predict individual subjects' data.

Two more recent studies picked up the issue, though using considerably fewer experimental conditions and subjects, and not including HRTF measurements. Both studies (Remmers and Prante, 1991; Jørgensen, 2002) used wideband noise to obtain loudness matches, thus potentially obscuring a frequency dependence, and obtained much smaller effects than Robinson and Whittle (1960), with directional loudness matches varying by less than 3 dB across incidence angles.

E. Rationale for the present study

It thus appears worthwhile to take up the issue of directional loudness once more. This will be done paying special attention to five methodological issues, which are elaborated in turn:

(1) Well-defined narrow-band stimuli are needed to investigate the effects of HRTFs and binaural loudness summation. Note that, in Robinson and Whittle's (1960) report, the sounds used were not sufficiently specified beyond stating that they were "below a critical band" (p. 75), and the later studies used wideband noise which might wash out some of the directional effects.
(2) Given the evidence from earlier headphone experiments showing the binaural gain to increase from approximately 3 dB near threshold to up to 10 dB at high sound-pressure levels, level effects will be taken into account by making measurements at two overall sound-pressure levels.
(3) With the exception of Jørgensen's (2002) study, classical "method(s) of adjustment" have been used to collect the subjective data. By their transparency, and the explicit control they give listeners over the outcome, these methods are prone to subject-induced biases, such as "correcting" an adjustment due to some expectation. Forced-choice procedures (Levitt, 1971; Jesteadt, 1980), especially when interleaving adaptive tracks for different experimental conditions, are much less susceptible to such biases.
(4) Advances in the methodology to HRTFs will be brought to the study of directional loudness. Note that Robinson and Whittle's (1960) pioneering study was done before the term HRTF was coined, and that their at-ear measurements of the stimuli actually used merely provide six points along the frequency scale, and thus do not constitute HRTFs as we conceive of them today.
(5) Since HRTF filtering is known to be highly idiosyncratic, it is likely that with averaged data frequency-dependent directional effects might partially cancel each other, thus underestimating the true effect size. Therefore, a greater emphasis than in earlier studies will be on individual results and analyses.

To sum up, the present investigation will be conducted by having subjects assess loudness in a directional sound field in an anechoic room, and by relating the listening test data both to the distal stimulus given by the sound-pressure level emitted by the active loudspeaker, and to the proximal stimuli given by the participants' at-ear exposure levels as obtained via state-of-the-art HRTF measurements.

II. METHOD

A. Subjects

Eight normal-hearing listeners (between the age of 22 and 46 years; five male, three female), including the second author, participated in the experiment. The subjects' hearing thresholds were determined using standard pure-tone audiometry in the frequency range between 0.25 and 8 kHz with the requirement that none of the thresholds exceed 15 dB hearing level *re*: ISO 389-1 (1998). The five subjects who were not staff members were paid an hourly wage for their participation.

B. Apparatus

1. Loudspeaker setup in the anechoic chamber

The experiment was carried out in an anechoic chamber, which is anechoic above approximately 200 Hz, and has background noise at an inaudible level.

The loudspeaker setup for the experiment consisted of eight identical speakers (Vifa M10MD-39) mounted in hard plastic balls with a diameter of 15.5 cm. A typical frequency response of the loudspeaker can be found in Møller *et al.* (1995).

The loudspeakers were positioned both in the horizontal and median planes. In the horizontal plane, the incidence angles were 30°, 60°, 90°, and 135° of azimuth, and in the median plane the angles were 45° and 90° of elevation. Loudspeakers were also placed ahead and behind the listening position (at 0° and 180° of azimuth with 0° of elevation), where the horizontal and the median planes coincide. Due to assumed symmetry, the loudspeakers were placed only on the left-hand side in the horizontal plane. The distances from the diaphragms of the loudspeakers to the listening position at the center of the setup were 206±4 cm.

The subjects were seated in a chair, the height of which could be adjusted. The chair had a small headrest to restrict head movements of the subjects during the experiment. The subjects' heads and ears were carefully aligned with the center position of the setup by making adjustments to chair height and headrest position using a laser and two video cameras. A photograph of the setup in the anechoic chamber is shown in Fig. 1. The loudspeakers ahead, at 30° and 60° in the horizontal plane, and at 45° and 90° in the median plane are visible in the photograph. The structure suspending the

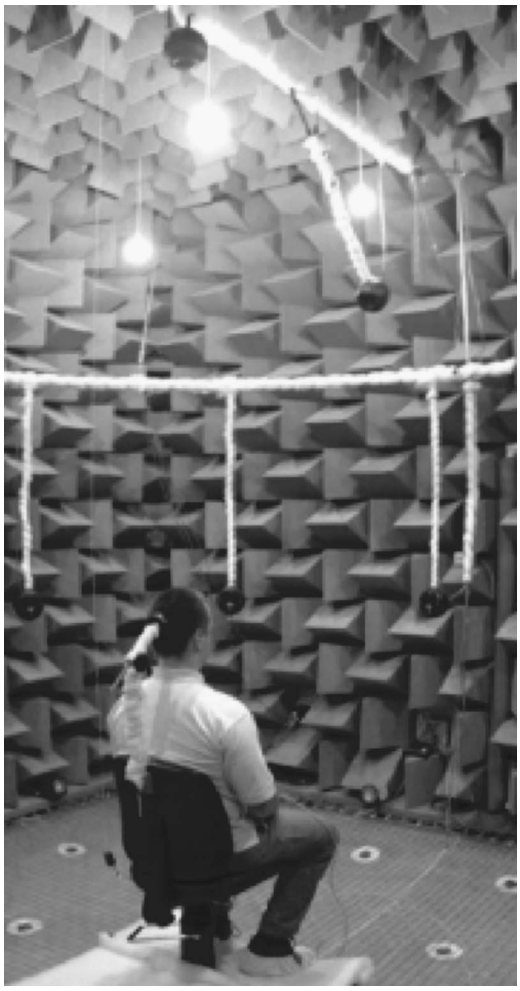

FIG. 1. The experimental setup in the anechoic chamber.

loudspeakers and the platform (an open metal grid) under the chair were covered with sound-absorbing material.

The subjective responses were collected with a two-button response box. The response box had small lights above the buttons to indicate observation intervals. An enlarged copy of the indicator lights was placed behind and slightly above the frontal loudspeaker to avoid subjects tilting their heads downwards to the response box in their hands.

2. Signal generation and control

All other equipment was placed in a control room next to the anechoic chamber. A personal computer (PC) was used for controlling the experiment and carrying out objective measurements. The PC was equipped with a digital sound card (RME DIGI96/8 PST) with eight audio channels, connected to an external AD/DA-converter (RME ADI-DS8). A custom-made eight-channel attenuator with a 128-dB dynamic range and 0.5-dB step size was used to individually control the level of the eight loudspeakers. The signals from the attenuator were amplified by power amplifiers (Rotel RB-976 Mark II), and then fed to the loudspeakers in the anechoic chamber.

The experiment was run using a program developed in LABVIEW. The program took care of reading session files, playing back appropriate stimuli, collecting subjects' responses, adapting the attenuator gains according to the responses, and writing the data into result files.

C. Measurements

Acoustical measurements were carried out using the maximum-length-sequence (MLS) system as specified by Olesen *et al.* (2000), with an MLS order of 12, preaveraging of 16, and a sampling rate of 48 kHz. The length of the acquired impulse responses was 4095 samples, which, due to the scarcity of reflections inside the anechoic chamber, was long enough to avoid time aliasing. The measurements were carried out at a level of approximately 70 dB SPL (at 1 kHz), measured in the absence of a listener at the center position of the setup.

First, responses of each loudspeaker [P_1 pressures, see Eq. (1)] were measured at the center position using a 1/4-in. pressure field microphone (Brüel & Kjær type 4136) with 90° incidence to the loudspeaker under measurement. Then, responses of each loudspeaker at each listener's ears [individual P_2 pressures, see Eq. (1)] were measured at the blocked entrance to the ear canal using two miniature microphones (Sennheiser KE 4-211-2), one microphone specifically for each ear. The miniature microphones were fitted inside foam earplugs (E·A·R Classic, halved in length), and mounted flush with the ear-canal entrance. All microphone signals were bandpass filtered between 22.5 Hz and 22.5 kHz by the measurement amplifier used (Brüel & Kjær type 2607 or type 2690 Nexus).

The above measurements were carried out three times: in the beginning, halfway through, and at the end of the experiment. The loudspeaker responses were used to equalize the stimuli for the listening experiment and to obtain reference pressures (P_1) for the HRTF calculations. The responses at each listener's ears were used to obtain individual HRTFs. The HRTF measurement procedure was as described by Møller (1995) with the following exceptions: The subjects were sitting in a chair instead of standing, the anechoic chamber was smaller, and the MLS measurement system was different.

Computation of the HRTFs involved 1024 samples from P_1 and P_2 pressures. First, individual head-related impulse responses (HRIRs) were calculated from P_1 and P_2 including a correction for the differences in the frequency responses of the two types of microphones used in the measurements. These HRIRs included reflections from the loudspeaker setup; therefore, only 140 samples from the HRIRs were used for calculating the final HRTFs. The resulting samples included all reflections from the subjects themselves (and from the chair), but excluded reflections from the other loudspeakers, the loudspeaker suspension, and any other objects inside the anechoic chamber. Note, however, that the excluded reflections were very small compared to the magnitude of the pure HRTFs.

D. Stimuli

The stimuli used for the listening experiment were third-octave noise bands centered at 0.4, 1, and 5 kHz. The length of each stimulus was 1 s.

For generating the stimuli, a 1-s white-noise signal was created, and subsequently filtered using third-octave-band filters at each center frequency. The relative differences in the frequency responses of the loudspeakers were equalized by applying minimum-phase inverse filters based on the direct sound coming from the loudspeakers. Each narrow-band signal was convolved with each of the inverse filters characterizing the individual loudspeakers, resulting in 24 stimuli for each (center frequency $\times$ loudspeaker) combination. Finally, raised-cosine rise and decay ramps of 20-ms duration were applied. The sound files thus corrected were played back at a sampling rate of 44.1 kHz, and with 16-bit resolution in the experiment proper.

The third-octave-band levels of the stimuli were aligned to 64.7 ± 0.1 dB SPL at 0.4 kHz, 64.7 ± 0.2 dB SPL at 1 kHz, and 63.9 ± 0.1 dB SPL at 5 kHz. At the highest possible playback level (75 dB SPL) the levels of the second- and third-order harmonics were more than 37 and 43 dB below the level of the center frequencies of the narrow-band noises, respectively. The distortion was measured to be highest at the lowest center frequency, but it was inaudible for all stimuli. Furthermore, the spectral envelope of the equalized stimuli was verified to be very similar between different loudspeakers.

In the experiment proper, the stimuli were played back at two overall levels as measured at the listener's position; a "low" overall level of around 45 dB SPL and a "high" overall level of around 65 dB SPL. Even though the actual measured sound-pressure levels deviated slightly from these values, note that the misalignment between the loudspeakers was less than ± 0.2 dB at each center frequency.

E. Procedure

The aim of the experiment was to determine how loudness is affected by the sound incidence angle at three center frequencies and two overall levels. This was accomplished by matching the loudness of test sounds emanating from each of the loudspeakers in the setup to the loudness of the same sound coming from the reference loudspeaker positioned in front of the subject at 0° of azimuth and elevation.

1. Adaptive matching procedure

Matches were obtained using a two-interval, adaptive forced-choice (2AFC) procedure (Levitt, 1971) converging on the point of subjective equality (PSE) by following a simple 1-up, 1-down rule. On each trial, the (variable) test sound, and the (fixed) frontal reference were presented in random order, with a 500-ms pause in between. Synchronized with the sounds, two light-emitting diodes were successively lit both on the hand-held response box, and on its larger model in order to mark the observation intervals to be compared. The subject's task was to judge which of the two noises sounded louder by pressing one of the two buttons aligned with the observation-interval lights. The participants were instructed to judge the loudness of the sounds only, and to disregard any other differences (due to direction, or timbre, for example) they might perceive.

For each adaptive track, the overall level of the frontal reference was fixed to either 45 or 65 dB SPL, as was the center frequency of the sounds to be played, and the test loudspeaker to be matched. The level of the test loudspeaker, however, was controlled by the adaptive procedure: Whenever the subject judged the test sound to be louder than the (frontal) reference, its sound-pressure level was lowered by a given amount; whenever the subject judged the reference to be louder, the level of the test loudspeaker was increased by that same amount. The initial step size was 4 dB; after two reversals (i.e., changes in the direction of the adaptive track) it was decreased to 1 dB. A total of eight reversals was collected in each adaptive track; the arithmetic mean of the last six of them was used to estimate the PSE. Two different starting levels were employed for the adaptive tracks, one 10 dB above, one 10 dB below the level of the reference loudspeaker, thus providing clearly discriminable loudness differences at the outset of each track.

2. Experimental design

For a given overall level, the experimental design required loudness matches to be determined in 44 different experimental conditions. These resulted from the factorial combination of 7(test loudspeakers) $\times$ 3(center frequencies) $\times$ 2(adaptive starting levels), and additional two conditions of the reference loudspeaker being matched to itself for the 1-kHz center frequency only (using both starting levels) to obtain a measure of the baseline variability of the matches.

Collection of these data was organized as follows: In order to allow subjects to adapt to a given loudness range, "high-SPL" (65 dB; "*A*"), and "low-SPL" (45 dB; "*B*") measurements were strictly separated in different sessions, which were counterbalanced following a succession of *ABBA* (respectively, *BAAB*) schemes. The order of the 44 experimental conditions to be investigated at each level was randomized, and subsequently divided into blocks of eight (the remaining four being assigned to the next block, i.e., the following replication of the measurements). Thus, within a given block of trials, eight adaptive tracks were randomly interleaved on a trial-by-trial basis, providing some random sampling of loudspeaker locations, center frequencies, and starting levels. Consequently, it was impossible for the subjects to track the immediate "adaptive" consequences of their judgments, and from their perspective the task was just a succession of unrelated paired comparisons with respect to loudness.

Each listening session consisted of four such blocks (containing eight adaptive tracks each). Completing a block of trials took approximately 10 min. While it lasted, the subjects were instructed to sit as still as possible in order to maintain the alignment with the loudspeaker setup. A short break was taken after each first and third block in a session, and participants were allowed to move their heads and upper body during those breaks, but not to leave the chair. After each second block they had a longer break during which they

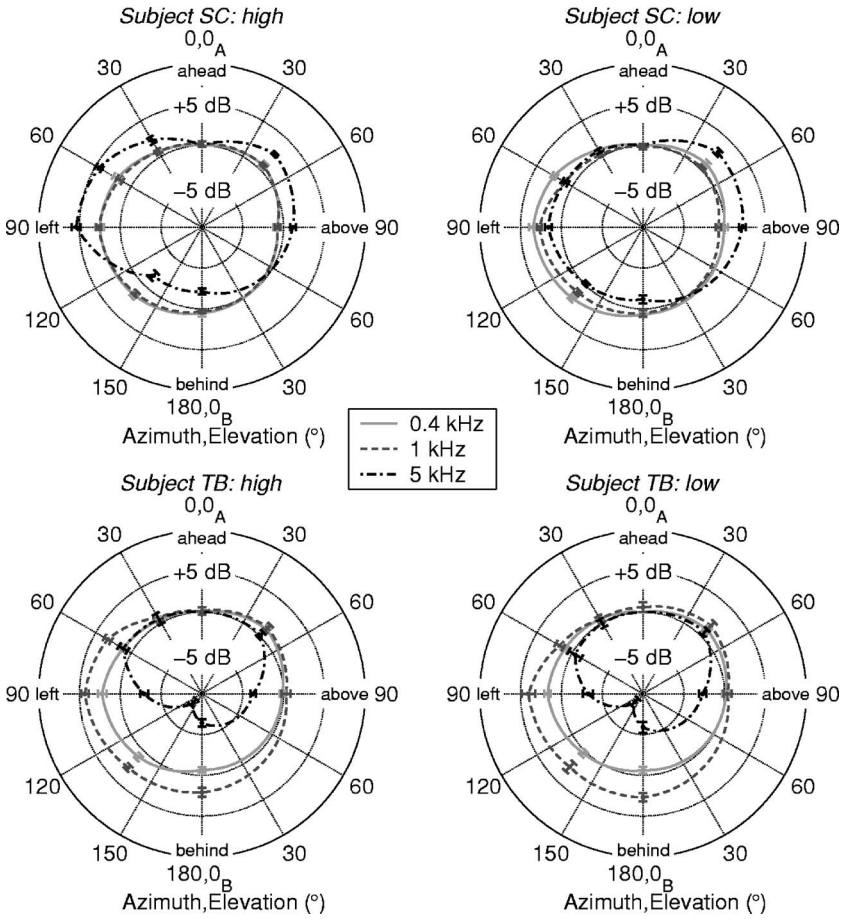

FIG. 2. Directional loudness sensitivities at the two overall levels for subjects SC and TB with 95% confidence intervals of 16 replications. The graphs on the left show the results for the high overall level (65 dB SPL), the graphs on the right for the low overall level (45 dB SPL). Elevations 0°_{A} and 0°_{B} are ahead and behind the listener, respectively.

left the anechoic chamber, thus requiring them to realign the seating position upon return. An entire session lasted approximately 1 h.

Since 16 replications of the matches (eight with each of the two adaptive starting levels) were collected per experimental condition, all subjects had to participate in 22 listening sessions. The participants completed a maximum of two sessions per day with a minimum of 1 h between sessions. With three additional sessions reserved for audiometry, HRTF measurements, and practice (one block in each of the high-SPL and low-SPL conditions), the total number of hours amounted to 25 per subject.

III. RESULTS

A. Directional loudness sensitivities

The adaptive procedure matched the loudness of a sound of a given center frequency coming from one of the loudspeakers in the horizontal or the median plane to the loudness of the same sound with frontal incidence. Thus, the raw data from the experiment were the sound-pressure levels (in dB SPL) the loudspeakers would have to be set to, in order to be perceived equally loud as the frontal reference. These raw data were averaged across the 16 repetitions that each participant accumulated in each condition, and normalized by subtracting the result from the fixed level of the respective frontal reference (65 or 45 dB SPL). That way, (relative) directional loudness sensitivities[1] were obtained, positive values of which indicate loudness enhancement, i.e., a lower sound-pressure level required for that direction to achieve a match with the frontal reference.

1. Individual data

Individual directional loudness-sensitivity curves are depicted for two subjects, SC (upper panels) and TB (lower panels), representing extremes of performance, in Fig. 2. The data are rendered in polar coordinates, though in a particular, asymmetrical way: The left-hand side of each polar graph shows the data for the horizontal plane as the loudspeakers were physically positioned in the setup. On the right-hand side of each polar graph the data are shown for the median plane where the loudspeakers were actually above the subjects. Note that these two planes coincide ahead of and behind the subjects.

For subject SC, loudness matches at 0.4 and 1 kHz vary as a function of sound incidence angle over a range of approximately 3 dB, the subject being most sensitive to loudness for sounds coming from the side, i.e., from 90° to the left in Fig. 2. That holds for both overall levels used. At 5 kHz, by contrast, this pattern is observed at the high overall level only, whereas at the low level the loudness pattern is fairly omnidirectional in the horizontal plane. In the median plane the directional patterns are similar across overall levels.

For subject TB, loudness matches vary over a range of less than 3 dB at 0.4 kHz. At 1 kHz the direction has a larger

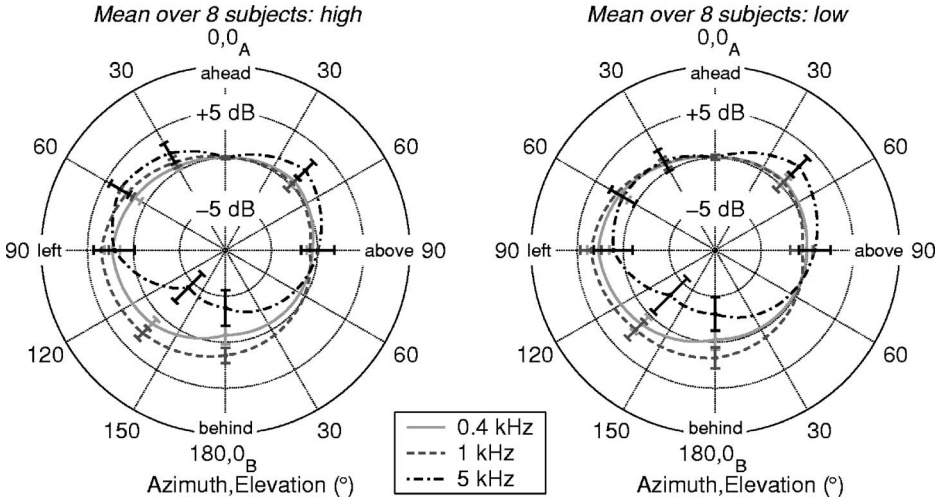

FIG. 3. Directional loudness sensitivities at the two overall levels for means across all eight subjects with 95% confidence intervals of the means. The graph on the left shows the results for the high overall level (65 dB SPL), the graph on the right for the low overall level (45 dB SPL). Elevations 0°_{A} and 0°_{B} are ahead and behind the listener, respectively.

effect on loudness, the sensitivity being up to 4 dB higher on the left-hand side than straight ahead. At 5 kHz the directional effect is even more pronounced, the minimum sensitivity at 135° in the horizontal plane being approximately 8 dB below and the maximum being close to the frontal sensitivity. The directional sensitivity patterns for this subject do not appear to be level dependent.

The confidence intervals for the matches of subjects SC and TB in Fig. 2 are small. Average individual standard deviations of the loudness matches across all subjects were 1.0 and 1.2 dB at the high and low overall levels, respectively. All participants adjusted the (identical) 1-kHz frontal test sound to a sound-pressure level close to the (fixed) reference, indicating that there was no systematic bias in the matches. The standard deviation of the identical-direction matches (0.9 dB) was only marginally lower than that of the across-direction matches, suggesting that these were of no greater difficulty.

2. Group data

Figure 3 shows mean loudness sensitivities when data are aggregated across all of the eight subjects. When the listener-specific idiosyncrasies are thus removed, directional loudness sensitivity still varies over some 3 dB at the two lowest center frequencies, whereas at 5 kHz the directional effect is approximately twice as large. Also, the error bars are larger at the highest center frequency due to a wider spread in the individual data. The overall level does not seem to have a marked effect on the patterns when considering the average data: the left and the right panels of Fig. 3 are hardly distinguishable.

The data and the subsequent analyses show that loudness is not constant over sound incidence angles, and the directional loudness-sensitivity patterns change considerably with center frequency, and to a lesser extent, with overall sound-pressure level.

3. Statistical analysis

The significance of the effects observed in the averaged data was confirmed by a $7\times3\times2$ (directions $\times$ center frequencies $\times$ levels) repeated-measures analysis of variance (ANOVA) on the means obtained from each subject in each of the experimental conditions.

In addition to a significant main effect of direction, $F(6,42)=28.35$, $p<0.001$, indicating that directional loudness-sensitivity differences persist, even when collapsing across levels and frequencies, all its interactions were highly significant:

(1) As expected, the direction $\times$ frequency interaction produced the highest F value, $F(12,84)=31.29$, $p<0.001$, confirming that the way in which directional loudness varies is strongly frequency dependent (see Fig. 3). It should be noted that this interaction is also highly significant for each of the eight subjects when statistical analyses are done individually.
(2) Furthermore, there is a significant direction $\times$ level interaction in the pooled data, $F(6,42)=7.29$, $p<0.001$. Inspecting the average directional loudness sensitivities in Fig. 3, it appears that—ignoring center frequency—the directional effects on loudness are slightly more pronounced at the higher overall level (65 dB SPL).
(3) More importantly, there is a three-way (direction $\times$ frequency $\times$ level) interaction, indicating that the frequency-dependent directional effects show a different pattern for the two overall levels, $F(12,84)=7.42$, $p<0.001$. This appears to be largely due to the 5-kHz data showing a slightly larger gain in sensitivity in front of the listener, and a slightly larger loss behind when comparing the high with the low overall level (see Fig. 3). Again, this interaction is significant for all of the eight subjects, even though the patterns show strong individual differences (see Fig. 2).

B. Head-related transfer functions

Individual head-related transfer functions were measured to investigate how sound is being filtered from a free field to the subjects' ears, depending on the angle of incidence. As an example, the HRTF magnitude spectra for subject IA from all eight directions are plotted in Fig. 4. Each panel depicts curves for the three separate sets of measurements made at different stages of the experiment. These mea-

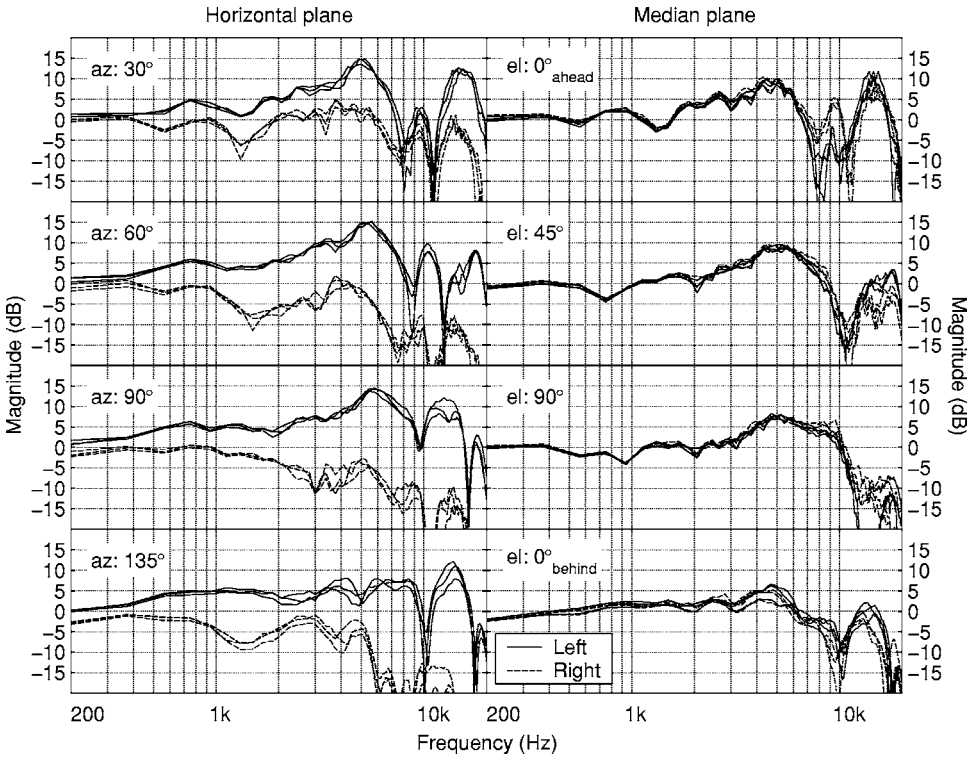

FIG. 4. Three HRTF measurements, performed at different stages of the experiment. The figure shows data for the left and right ears of a single subject (IA), for stimulation from all eight directions. The left panel depicts measurements obtained in the horizontal plane (azimuths of 30°, 60°, 90°, and 135°), the right panel those obtained in the median plane (elevations of 0°_{ahead}, 45°, 90°, and $0^{\circ}_{\text{behind}}$). 0°_{ahead} incidence is the frontal (reference) direction.

surements include individual fitting and positioning of the microphones, aligning of the subjects to the listening position, calibration, and acoustic measurements. As seen in Fig. 4, the measurements are highly repeatable, the variation below 1 kHz on average being within ±0.4 to ±0.6 dB (comparable to e.g., Møller *et al.*, 1995).

Figure 4 also shows that the interaural level differences in the median-plane HRTFs are very small up to around 7 kHz. In the horizontal plane, however, HRTFs of the left and right ears differ considerably due to a pressure buildup at the ipsilateral ear and head shadowing at the contralateral ear, especially at high frequencies. For the fairly representative subject whose HRTFs are depicted in Fig. 4, the maximum magnitudes of the ipsilateral (left) ear in the horizontal plane are around 15 dB for azimuths from 30° to 90° (front-left side), while the magnitudes at the contralateral (right) ear are typically below 0 dB.

C. HRTFs and directional loudness

1. Calculating normalized at-ear exposure

In order to investigate the effects of the physical HRTF filtering on the directional loudness matches on an individual basis, the objective HRTF measurements and the subjective loudness data were combined. This was done in order to obtain the actual frequency-specific at-ear exposure, and to evaluate whether the peculiarities of individual HRTFs might account for some of the interindividual variation seen in the directional loudness matches. Note that this analysis was based on the magnitude spectra of the HRTFs, and that the effect of the interaural time difference was disregarded.

The individual HRTFs were averaged across the three repetitions by calculating the mean of the linear magnitude spectra. These means were then converted to the corresponding third-octave-band levels in decibels. Finally, the left- and right-ear SPLs were normalized, for each incidence angle and at each center frequency, by subtracting the respective frontal left- and right-ear levels from them, since the loudness matches were always made to the frontal reference.

2. Relating loudness matches to HTRFs

For each of the eight participants, the normalized at-ear levels and directional loudness matches are combined in Fig. 5 and Fig. 6.

a. Horizontal plane. The combined data for the horizontal plane are plotted in Fig. 5. As seen in Fig. 5, in this plane the individual ILDs reach a maximum of 5 dB at 0.4 kHz, of 12 dB at 1 kHz, and of up to 30 dB at 5 kHz for the calculated third-octave-band at-ear SPLs.

For all subjects, except for subject IA at 0.4 kHz, the subjective directional loudness sensitivities at the high and low overall levels largely fall between the objective at-ear sound-pressure levels. It thus seems that the agreement between the two types of data is fair: For example, by considering the 5-kHz data for subjects TB and WE in Fig. 5, the idiosyncrasies in their at-ear SPLs are reflected in equally individual directional loudness sensitivities. However, the picture is not as clear when considering the two overall levels ("high" at 65 dB SPL and "low" at 45 dB SPL): Generally, the subjective data at the two overall levels are fairly congruous. In some cases, however, the most extreme case being subject SC at 5 kHz in Fig. 5, a clear overall level dependence can be observed.

If loudness were perceived as being constant over sound incidence angles, the subjective directional sensitivity data would follow the 0-dB horizontal in Fig. 5 or, equivalently, the 0-dB circles in Figs. 2 and 3. That would imply loudness

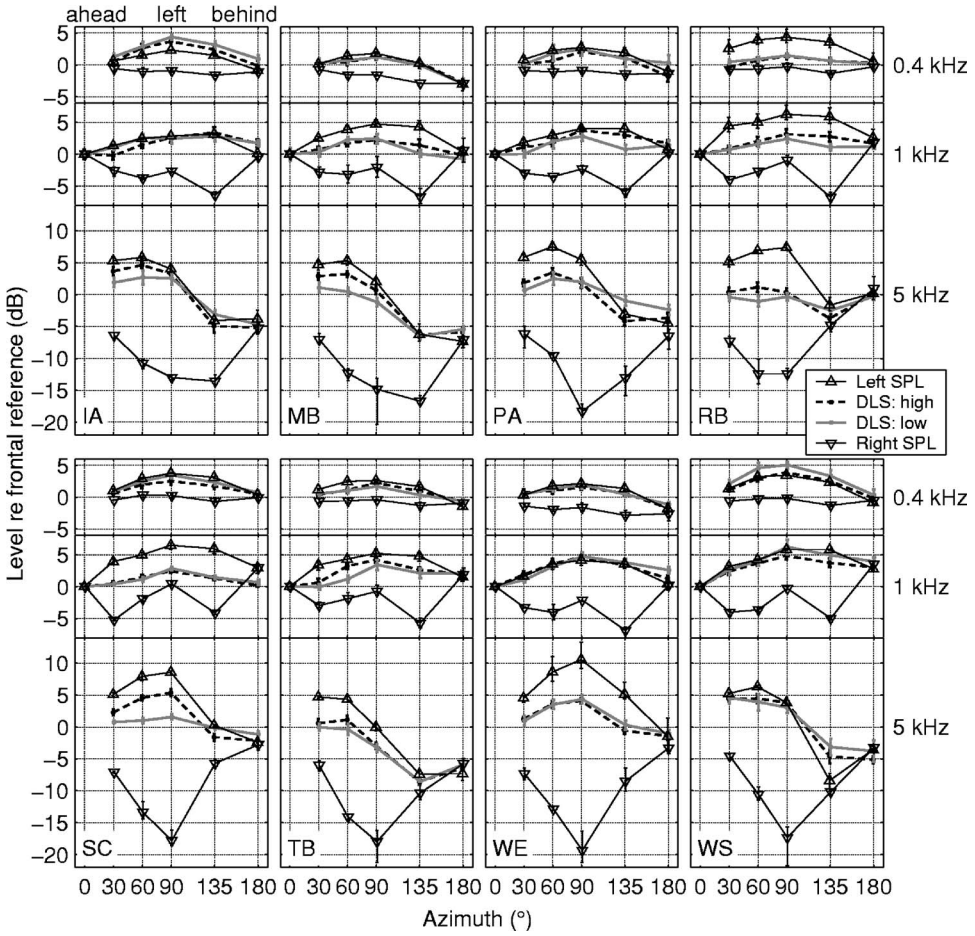

FIG. 5. Horizontal plane: Directional loudness sensitivities (DLS) at the high and low overalls level (DLS high: 65 dB SPL and DLS low: 45 dB SPL) with 95% confidence intervals, along with left- and right-ear sound-pressure levels, plotted relative to the frontal reference (see the text).

to be governed solely by the sound-pressure level of the source measured in the absence of a listener, irrespective of the changes in the at-ear sound-pressure levels as a function of sound incidence angle. This does not seem to be the case for any of the data sets.

If, on the other hand, the subjective loudness data always followed the ear with the higher SPL, this would imply *no* binaural loudness summation, i.e., loudness would be determined by the ear getting the higher input alone. Evidence for this kind of behavior may be seen in the data of IA, WS, and to some extent in those of WE and PA, though not at 5 kHz.

b. Median plane. In the median plane the ILDs are small, and the two ears are getting approximately the same

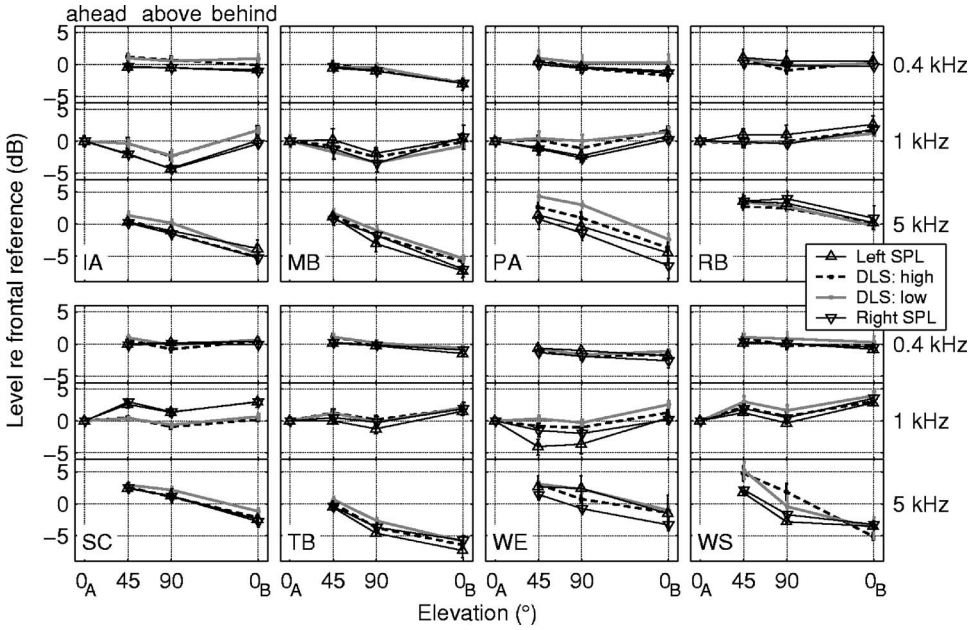

FIG. 6. Median plane: Directional loudness sensitivities (DLS) at the high and low overall levels (DLS high: 65 dB SPL and DLS low: 45 dB SPL) with 95% confidence intervals, along with left- and right-ear sound-pressure levels, plotted relative to the frontal reference (see the text). Elevations 0°_{A} and 0°_{B} are ahead and behind the listener, respectively.

input at all sound incidence angles; see Fig. 6. The differences between the ears are largest for subject WE, producing ILDs as large as 3 dB.

The normalized at-ear levels as a function of direction vary over less than 3 dB at 0.4 kHz, by up to 5 dB at 1 kHz, and over a range of almost 10 dB at 5 kHz. In this plane a change in the at-ear SPLs with incidence angle should presumably be reflected in a similar change in directional loudness sensitivity, which is true for most of the subjects. Occasional exceptions from this rule can be seen, however, for example for subjects SC and IA at 1 kHz, and for subject WS at 5 kHz.

c. Summary. Both in the horizontal and median planes, the patterns of the individual directional loudness sensitivities can largely be explained by directional effects the individual HRTFs have on at-ear sound-pressure levels. The way the subjects combine their left- and right-ear SPLs to a single loudness percept is further explored in the next section concerned with modeling binaural loudness.

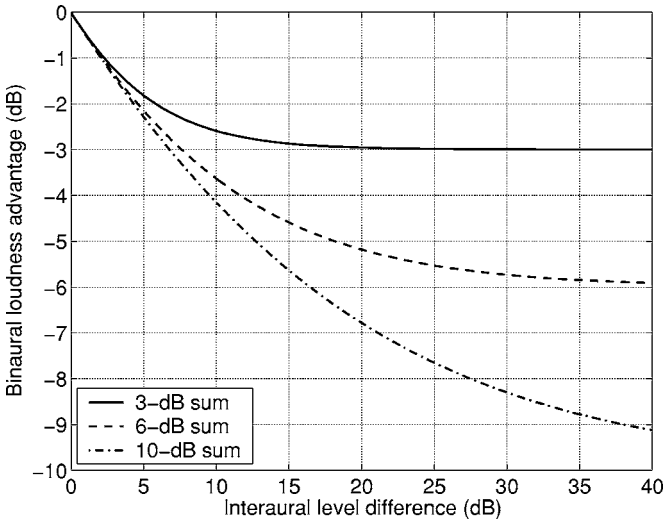

FIG. 7. Binaural loudness advantage as a function of interaural level difference; solid: 3-dB, dashed: 6-dB, and dash-dotted line: 10-dB summation rule.

IV. MODELING OF BINAURAL LOUDNESS

Large interindividual variation was found in subjects' directional loudness sensitivities. As seen in the previous section, these sensitivities exhibit systematic dependencies on the directional variations in individual HRTFs. Thus, a straightforward strategy in modeling binaural loudness is to take the HRTF effects into account, and to relate the physical changes in the at-ear signals—independent of direction—to the corresponding changes in loudness as perceived in a real sound field.

In the median plane, where the loudspeakers were positioned symmetrically with respect to the subjects' left and right ears, the listening situation was close to diotic. In this plane, the sound-pressure levels at the two ears were similar at the elevations under investigation (0°_{A}, 45°, 90°, and 0°_{B}); see Fig. 6. In such a situation, the actual amount of summation across the two ears has no effect on binaural modeling. This is due to the fact that the same binaural listening advantage takes effect both for the reference and the comparison to be matched. Note that the same applies for the traditional free- and diffuse-field loudness paradigms.

Dichotic stimulation, with different at-ear levels, thus constitutes the most interesting case for the modeling of binaural loudness. Dichotic at-ear SPLs were observed for the azimuths of 30°, 60°, 90°, and 135° in the horizontal plane (see Fig. 5). At these azimuths subjects typically had to match a dichotic sound to the diotic frontal reference.

Narrow-band stimuli were used in the listening experiment in order to simplify the modeling of binaural loudness, by being able to ignore spectral summation of loudness across critical bands. Also, assuming that perceived loudness is doubled when the listening is binaural (diotic) instead of monaural, a relationship between the psychophysical dimension of loudness (as measured in sones) and its physical correlate, the sound-pressure level (in dB SPL) can be established. By definition, a loudness of 1 sone is produced by a 40-dB SPL, 1-kHz tone, and doubling or halving loudness (in sones) corresponds to a 10-dB increment or decrement in sound-pressure level, respectively. Due to the shape of the equal-loudness contours (ISO 226, 2003), the increments within the range of sound-pressure levels used in the present experiment are approximately 10.5 and 9.5 dB SPL at 0.4 and 5 kHz, respectively, for a doubling of loudness. Thus, at all three center frequencies (0.4, 1, and 5 kHz) used in the present study, doubling in sones corresponds fairly closely to a 10-dB gain in sound-pressure level.

In order to illustrate how binaural loudness is affected by various interaural level differences, theoretical curves can be obtained utilizing Eq. (2), taken from Robinson and Whittle (1960). It is reasonable to assume that the summation of sound-pressure levels across the two ears is nonlinear, as suggested by Eq. (2): At large ILDs, the ear receiving the lower sound-pressure level presumably has little effect on overall binaural loudness, and the stimulation is effectively monaural. When approaching a diotic situation, however, the signals at the two ears tend to be weighted equally in contributing to overall loudness.

Theoretical curves for three hypothetical binaural loudness-summation rules are plotted as a function of the interaural level difference in Fig. 7. In addition to the 6-dB summation rule adopted from Robinson and Whittle (1960), two other curves were derived by changing the binaural gain factor in Eq. (2): A 3-dB summation rule corresponding to the "power summation" of the linear at-ear magnitude spectra, and a 10-dB summation rule, which for the stimuli used in the present study roughly corresponds to perfect binaural summation in sones.

The different curves in Fig. 7 are normalized so that they all coincide in the origin of the graph: it represents the diotic case with an ILD of zero. As the ILD increases, loudness decreases by different amounts, depending on the summation rule with the "loss" to be read from the ordinate corresponding to the "binaural loudness advantage" achievable by switching from dichotic to diotic stimulation. The 3-dB summation rule fairly quickly converges to the −3-dB level in the graph: when the ILD increases beyond 15 dB, binaural loud-

TABLE I. Least-squares estimates for the amount of binaural loudness summation [x in Eq. (3), in dB], at the three center frequencies (f_c: 0.4, 1, and 5 kHz) at high (65 dB SPL) and low (45 dB SPL) overall levels. The two right-most columns show the best fits when pooling center frequencies, and the best fits across center frequencies when the data are averaged across subjects (bottom row). Extreme values are marked with stars (see the text for details).

	f_c							
	0.4 kHz		1 kHz		5 kHz		Best fit across f_c	
Subject	High	Low	High	Low	High	Low	High	Low
IA	0.1	0.1	0.1	0.1	0.7	1.5	0.1	0.1
MB	0.3	0.4	3.3	3.5	2.2	4.8	2.4	4.6
PA	1.0	0.4	0.7	1.3	3.1	3.0	2.1	2.4
RB	99.9*	99.9*	4.0	9.3	10.0	18.4*	9.1	17.6*
SC	1.6	0.3	13.1	29.7*	3.1	8.2	3.8	8.5
TB	1.1	2.8	2.1	3.0	3.7	5.0	3.3	4.6
WE	0.1	0.1	0.1	0.3	4.9	4.5	2.8	2.6
WS	0.1	0.1	1.7	0.5	0.1	0.1	0.7	0.1
Median	0.7	0.4	1.9	2.2	3.1	4.7	2.6	3.6
Averaged data							2.6	3.9

ness is no longer affected. At these ILDs loudness is determined by the ear with the higher sound-pressure level alone, and dichotic loudness is 3 dB lower than the corresponding diotic one. With the 6- or 10-dB summation rules, much larger ILDs are required until the curve asymptotes at −6 and −10 dB, respectively. For the 10-dB summation rule, at an ILD of 40 dB (far exceeding the ILDs observed in the present study) binaural loudness still continues to decrease.

A. Individual data

The third-octave-band at-ear sound-pressure levels computed from the HRTFs were used in the modeling, in order to find the best-fitting binaural summation rule to predict the directional loudness-sensitivity data. Robinson and Whittle (1960) reported their average data to support a 6-dB loudness summation across their listeners' ears [see Eq. (2)]. This type of modeling was explored for the present data, but on an individual basis. The modeling was carried out by relaxing the factor 6 in Eq. (2).

To that effect, the optimal amount of binaural loudness summation (x)—assumed to be fixed at 6 dB in Eq. (2)—was *estimated* by minimizing the sum-of-squares of the errors (SSE) between the actual directional loudness sensitivity (DLS) and the sensitivity predicted (L_{mon}) from the changes in at-ear sound-pressure levels using Eq. (3). All 16 (j) repetitions of each condition, and the mean at-ear sound-pressure levels for each of the four horizontal-plane angles of incidence (i; 30°, 60°, 90°, and 135°) were included in the modeling, which was performed individually for each subject, and separately for the three center frequencies and the two overall levels.

$$\mathrm{SSE} = \sum_{i=1}^{4} \sum_{j=1}^{16} \{\mathrm{DLS}_{\mathrm{high/low}_{i,j}} - [L_{\mathrm{mon,comp}_i}(x) - L_{\mathrm{mon,ref}}(x)]\}^2, \quad (3)$$

where

$$L_{\mathrm{mon,comp}_i}(x) = x \times \log_2(2^{L_{\mathrm{left,comp}_i}/x} + 2^{L_{\mathrm{right,comp}_i}/x}), \quad (4)$$

and

$$L_{\mathrm{mon,ref}}(x) = x \times \log_2(2^{L_{\mathrm{left,ref}}/x} + 2^{L_{\mathrm{right,ref}}/x}). \quad (5)$$

In these equations, $L_{\mathrm{left,comp}}$ and $L_{\mathrm{right,comp}}$ refer to the third-octave-band levels for the comparison incidence calculated from the individual left- and right-ear HRTFs, respectively. Likewise, $L_{\mathrm{left,ref}}$ and $L_{\mathrm{right,ref}}$ refer to the corresponding levels for the frontal reference at the left and right ears, respectively.

The subjective directional loudness sensitivities had been normalized to the frontal reference (see Figs. 2 and 5). Therefore, the predictions were normalized as well by subtracting Eq. (5) from Eq. (4) in the minimization of the sum of squares of the errors. Due to this normalization, the overall level (65 vs 45 dB SPL) does not have an influence on the predictions. The possible dependence of binaural loudness summation may nevertheless show up in the subjective directional loudness sensitivities at the high and low overall levels, and may thus influence the estimate of the variable x, the binaural gain estimated from the data. Forty-eight such estimates (for eight subjects, three center frequencies, and two overall levels) for the amount of binaural loudness summation are listed in Table I. The minimization algorithm was limited to a summation value between 0.1 and 99.9 dB.

As was already seen in Fig. 5, the amount of binaural loudness summation varies greatly across subjects, and also within subjects across the three center frequencies. The best-fitting binaural gain estimates roughly fall into three categories: The summation is minor (less than 1 dB) for 19, moderate (from 1 to 10 dB) for 24, and extreme (greater than 10 dB) for 5 out of the 48 cases analyzed. There is a tendency for the summation values to increase with center frequency, but due to the fact that the center frequencies are confounded with variations in ILDs, the comparison may not be fair.

The smaller the amount of binaural loudness summation, the more binaural loudness is determined by the ear getting a higher input. By contrast, the higher the summation value, the more influence the ear receiving the lower sound-pressure level has on binaural loudness. Some extreme values marked with stars in Table I, e.g., subject RB at 0.4 kHz, seem to imply the latter behavior. Closer inspection of Fig. 5, however, reveals that for this subject the directional loudness sensitivity remains close to the 0-dB line, even if the at-ear sound-pressure levels vary over a fairly wide range. As Robinson and Whittle (1960) pointed out, the actual value of the summation parameter (at the natural ILDs in question) does not have a great effect on the directional loudness sensitivities predicted from the at-ear SPLs. For these reasons the minimization algorithm can reach very high summation values (up to the limit of 99.9 dB) when searching for the best fit. However, it is unrealistic that the binaural gain (i.e., the loudness match between monotic and diotic stimulation) for a normal-hearing subject is much larger than 10 dB.

To get a more stable estimate, the amount of binaural summation was also determined by pooling across the three center frequencies; see the two right-most columns in Table I. This was achieved by aggregating the data across center frequencies, and finding the best-fitting summation rule to the aggregated data set. The individual differences are still retained, and the summation values again fall into the three categories defined above.

In order to deal with the variance inherent in the subjective data, a partial F-test (Bates and Watts, 1988, Chap. 3) was performed to investigate whether the subjects summed their at-ear levels in significantly different ways. In a "restricted" model *one* least-squares fit of binaural loudness summation [x in Eq. (3)] common to all subjects was estimated, whereas in a "full" model the summation value was relaxed to estimate *different* parameters for the eight subjects. The data were aggregated across incidence angles, overall levels and center frequencies. The partial F-test showed that the error sum of squares between the subjective data and the estimate was significantly larger for the restricted model having a common parameter for all subjects [$F(7,3064)=211.58$; $p<0.001$]. Therefore, the full model allowing for individually different binaural-gain parameters predicted the data better, and hence, the differences in the way the subjects summed the at-ear levels appear to be significant.

B. Group data

The individual third-octave-band HRTFs and directional loudness sensitivities were averaged across subjects, to make an estimate for the mean data thus obtained. Aggregating over center frequencies, as before, the best fits for the averaged data came fairly close to suggesting a 3-dB summation rule both at the high and the low overall level (see the bottom row of Table I).

Thus far the prediction was entirely based on the at-ear sound-pressure levels at the center frequency of the narrow-band noises used. However, by using a loudness model, the possible spread of excitation to neighboring critical bands can be taken into account in the modeling. Furthermore, given a relatively large dynamic range, the shape of the loudness function may be better accounted for when using a loudness model.

Therefore, the most widely accepted loudness model by Moore *et al.* (1997) was tested in predicting the present data. This model facilitates the use of eardrum pressures for loudness computations, i.e., using at-ear signals as a product of the HRTF-filtering stage. The model also predicts monaural loudness, by assuming perfect loudness summation in sones between the two ears, and calculating monaural loudness simply as being one half of the binaural, diotic loudness. Dichotic loudness can then be computed as a sum of the two monaural loudness values in sones.

Since the HRTFs of the present study had been measured at the entrance to the blocked ear canal, a direction-independent transfer from the measurement point to the eardrum (mean P_4/P_2) was adopted from Fig. 13 in Hammershøi and Møller (1996). In contrast to the summation rule explored in the previous section, here absolute binaural loudness values were computed. The effects of the HRTFs were taken into account, as before, but now the entire at-ear spectra were included (instead of only using the level at the center frequency). The input data to the loudness model thus were third-octave-band spectra based on the measured stimulus spectrum in the absence of a listener (P_1), combined with the left- and right-ear HRTFs (P_2/P_1), and corrected by the eardrum-to-the-measurement-point transfer function (P_4/P_2).

Monaural loudness values were computed for (dichotic) left- and right-ear signals, subsequently summed, and compared to the loudness produced by the (close to) diotic frontal reference. First, binaural loudness values for each of the frontal reference stimuli were computed, as described above. Then, sone values for the comparison directions were computed by varying the level of the P_1 pressures, within the range of ±10 dB from the frontal reference level, in steps of 0.5 dB. The P_1 sound-pressure levels yielding the binaural loudness values closest to that of the frontal reference were selected. In this way the loudness model was used to find equal-loudness sound-pressure levels for each incidence angle, including the effects of the HRTFs. The inverses of these sound-pressure levels relative to the frontal reference were taken as the directional loudness sensitivities predicted by the model.[2]

Figure 8 contrasts the predictions made by the loudness model (Moore *et al.*, 1997) with the 3-dB power summation, which fared best in the earlier analysis. Since the effect of overall sound-pressure level on directional loudness was minor for the averaged data (see Fig. 3), only the high-level (65 dB SPL) directional sensitivities are plotted.

For all dichotic situations (horizontal plane, left column in Fig. 8), the 3-dB summation rule predicts the obtained mean loudness-sensitivity data quite well. At each center frequency, the patterns of the 3-dB prediction and the actual matches made are congruous, and only in two instances (at 0.4 kHz, azimuths of 90° and 135° in Fig. 8) do the 95% confidence intervals of the subjective data not include the 3-dB prediction. By contrast, the prediction of the loudness

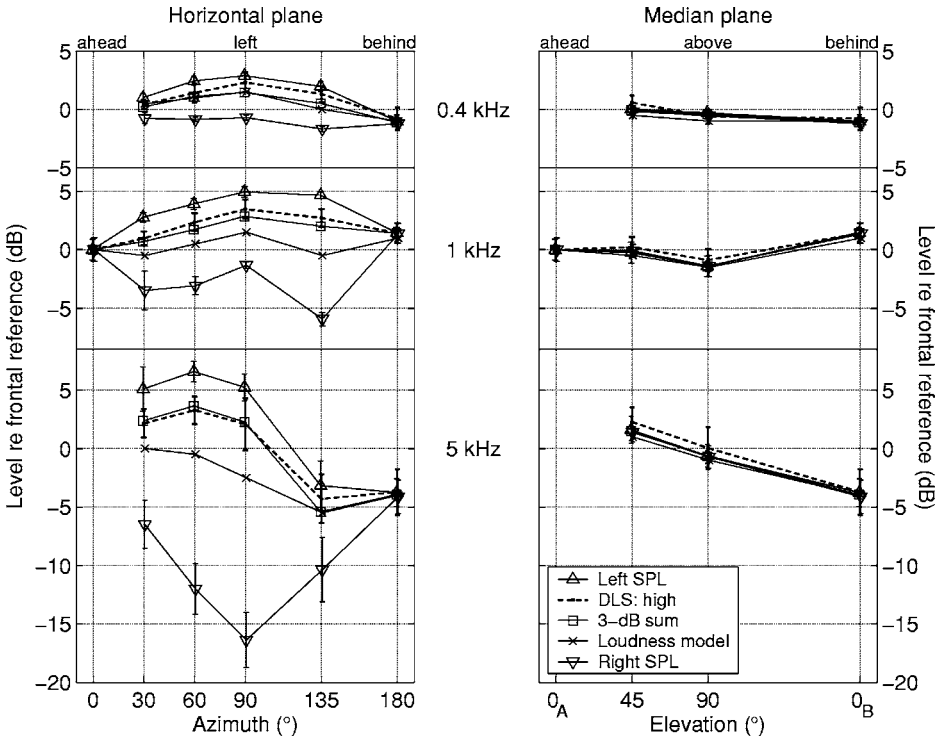

FIG. 8. Average left- and right-ear sound-pressure levels, a 3-dB summation rule, loudness summation in sones, and obtained average DLS at the high overall level (65 dB SPL). The error bars denote the 95% confidence intervals of the means across the eight subjects. The left panel depicts data and predictions for the horizontal plane, the right panel for the median plane. Elevations 0°_{A} and 0°_{B} are ahead and behind the listener, respectively.

model markedly deviates from the obtained directional loudness sensitivities, particularly at the two higher center frequencies (1 and 5 kHz). These are the situations in which the interaural level differences range from 6 to over 20 dB. For these ILDs, the prediction is not bracketed by the confidence intervals of the data for seven out of the eight dichotic conditions, the difference between data and predictions reaching up to 5 dB (5 kHz, azimuth 90° in Fig. 8). It thus seems that the 3-dB summation rule of at-ear sound-pressure levels predicts the directional loudness of dichotic sounds considerably better than the assumption of perfect binaural loudness summation in sones.

In the median plane, all five curves (at-ear levels, directional loudness sensitivities, and model predictions) are nearly indistinguishable; see the right panels in Fig. 8. The 95% confidence intervals of the subjective data include both the physical changes in left- and right-ear sound-pressure levels, and the predicions of 3-dB sum and loudness summation in sones. Obviously, the diotic stimulation condition does not provide a critical test for these models.

V. DISCUSSION

A. Comparison with previous work

When comparing the present results to the work of Robinson and Whittle (1960), it may be observed that the average directional effect sizes they obtained are comparable to those measured in the present study: For the incidence angles presented here, the average directional loudness sensitivities Robinson and Whittle (1960) obtained at center frequencies below 6.4 kHz varied from −6.5 to +5.0 dB (see their Fig. 2) relative to the frontal reference level. The corresponding range for the average data in the present study is −4.3 to +3.5 dB (see Fig. 3), although the actual stimulus center frequencies used differed somewhat between the two investigations.

In both investigations, direction had a smaller effect on loudness at lower center frequencies, and the effect increased with stimulus center frequency. Qualitatively, this can be explained by the fact that with increasing frequency the physical dimensions of a listener start to obstruct the sound field. The obstruction also becomes more direction dependent at higher frequencies (as can be seen in the sample HRTFs plotted in Fig. 4), and this is reflected in its increasing effect on the directional loudness sensitivities.

The present empirical data collection, however, goes beyond previous work by reporting individual analyses. Consequently, and as expected from research on HRTFs, idiosyncratic directional loudness-sensitivity patterns were found. The individual data also showed that all participants were highly consistent in their judgments, even though the loudness of two sounds coming from different directions, and typically having different timbres, had to be compared.

The consistency in the participants' directional loudness matches provided considerable statistical power. On the one hand, that means that the significance of the major frequency-dependent effects of the direction of incidence on perceived loudness may be ascertained with great confidence. On the other hand, that entails that even small effects on the range of 1–2 dB level will emerge as statistically significant, and thus require further interpretation. That is the case for the effects of overall presentation level, [3] and its interaction with the directional and frequency-specific effects.

Comparison of both individual data (e.g., Fig. 2, top row) and of the group averages (Fig. 3) shows a tendency for the frequency-dependent directional effects to become more

pronounced with increasing level. Likewise, small but systematic level effects are found when trying to estimate the amount of binaural gain from the data (Table I). Contrary to what is reported in the literature (Shaw *et al.*, 1947; Reynolds and Stevens, 1960; Hellman and Zwislocki, 1963; Scharf and Fishken, 1970), this gain appears to be smaller at the higher overall level. That may be due to the low-level directional sensitivities being less affected by the ear receiving the greater input than the high-level directional sensitivities (see Fig. 5). Due to the small magnitudes of the overall-level effects, the present authors consider them to be negligible for most practical purposes, at least in the midlevel range investigated here (45–65 dB SPL).

Furthermore, the relatively low binaural-gain parameter derived from the present data is in conflict with the outcome of most of the classical studies (such as Reynolds and Stevens, 1960; Hellman and Zwislocki, 1963; Marks, 1978; Zwicker and Zwicker, 1991, among others) employing headphones, and largely focusing on monotic-to-diotic comparisons. But, note that—apart from other methodological distinctions—a key feature of these earlier studies is that signals may have been generated that would never reach the two ears when being emitted by a real source positioned in space, and fail to produce an externalized auditory event. It is unclear whether the results of the two paradigms (binaural loudness summation versus directional loudness) can be compared directly, since the auditory events produced are so drastically different. The directional loudness paradigm, however, is not only closer to "real-world" stimulation, but also to the application of measuring sound fields using a dummy head, where the signals at the ears of the dummy are due to the physical obstruction in the sound field.

B. Individual differences

Even though tentative general conclusions on the computation of binaural loudness may be drawn from the present data, it is striking how large the interindividual differences in loudness matches (see Figs. 2 and 5), and hence, in directional loudness sensitivity are when comparing the eight listeners participating. The original hope, that *all* of this interindividual variance might be accounted for by the equally large differences in individual HRTFs (e.g., Fig. 4) does not seem to be warranted, as is evident from our analysis of individual "summation rules" displayed in Table I. Obviously, using the actual at-ear sound-pressure levels rather than the levels emitted by the loudspeakers in the analysis still leaves us with considerable residual individual variance.

Several potential reasons for that variance might be explored: An obvious reason may be that the third-octave-band levels derived from the HRTF measurements do not reflect the actual at-ear stimulation well enough. However, the quality of the HRTFs may be examined by contrasting the present results with data obtained in individual binaural synthesis where the directional sound sources are recreated via virtual acoustics, the crucial difference being that the at-ear levels are precisely known in that situation. Performing such an experiment with six listeners from the original sample of eight (Sivonen *et al.*, 2005), we found no appreciable, or statistically significant, differences between the two sets of data (real vs virtual sound field). Rather, the individual differences remained, leading us to look for factors other than differences in the physical shape of pinnae, heads, and torsos.

A more speculative explanation for the individual differences found might be that the participants exhibited different degrees of "loudness constancy" in our experimental setup. The notion of "perceptual constancy" refers to situations in which a percept remains constant despite profound changes in the physical stimulation affecting the sensory receptors (Zahorik and Wightman, 2001). Typically, loudness constancy is observed when the loudness of a source (e.g., a musical instrument, a human voice) is judged to remain constant, even though its distance to the observer is varied. Stretching this notion somewhat, we might also speak of loudness constancy when listeners judge sounds to be equally loud, despite variations in their angle of incidence (which greatly affects the at-ear stimulation). It might be speculated that observers have learned to deconvolve the signals with their HRTFs in order to infer the loudness at the source.
