In order to characterize the sonic boom response in the interiors of buildings in urban settings, first the loading forces impinging on such buildings must be understood. To do this in an urban setting, many factors must be taken into account including the shape and surface structure of the building of interest, the kind of boom being propagated, and the scale of the propagation space. Nearby buildings and their features also require consideration. In addition, the importance of specular reflection versus diffuse reflections should be addressed. In this study, these factors are discussed and evaluated relative to the impact on the overall sound field. Preliminary results on a simple case are presented. [Work supported by NASA.]

2aSA7. Wideband fast multipole accelerated boundary element methods for the three-dimensional Helmholtz equation. Nail A. Gumerov and Ramani Duraiswami (Perceptual Interfaces and Reality Lab., UMIACS & Comput. Sci. Univ. of Maryland, College Park, MD 20742)

The development of a fast multipole method (FMM) accelerated iterative solution of the boundary element method (BEM) for the Helmholtz equations in three dimensions is described. The FMM for the Helmholtz equation is significantly different for problems with low and high kD, where k is the wave number and D the domain size, and for large problems, the method must be switched between levels of the hierarchy. The BEM requires several approximate computations: numerical quadrature and approximations of the boundary shapes using elements. These errors must be balanced against approximations introduced by the FMM and the convergence criterion for an iterative solution. These different errors must all be chosen in a way that, on the one hand, excess work is not done and, on the other, that the error achieved by the overall computation is acceptable. Details of translation operators for low and high kD choice of representations and BEM quadrature schemes, all consistent with these approximations, are described. A novel preconditioner using a low accuracy FMM accelerated solver as a right preconditioner is also described. Results of the developed solvers for large boundary value problems with $0.0001 \leqslant kD \leqslant 500$ are presented and shown to perform close to theoretical expectations.

2aSA8. Energy flux streamlines vs the alternatives for the visualization of energy coupling at and inside the surface of an ensonified fluid loaded elastic cylindrical shell with vacuum interior: Preliminary results. Cleon E. Dean (Phys. Dept., P.O.B. 8031, Georgia Southern Univ., Statesboro, GA 30460-8031, cdean @GeorgiaSouthern.edu) and James P. Braselton (Georgia Southern Univ., Statesboro, GA 30460-8093)

Energy flux streamlines are compared with alternative presentations of the energy flux vector field to visualize energy coupling at the surface and inside an ensonified fluid loaded elastic cylindrical shell with vacuum interior for both forward and retrograde guided propagating waves. The present work uses a method adapted from a simpler technique due to Kaduchak and Marston [Gregory Kaduchak and Philip L. Marston, "Traveling-wave decomposition of surface displacements associated with scattering by a cylindrical shell: Numerical evaluation displaying guided forward and backward wave properties," J. Acoust. Soc. Am. **98**, 3501–3507 (1995)] to isolate unidirectional energy flows.

2aSA9. Locating arbitrary noise sources in three-dimensional space in real time. Na Zhu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202 dv6930@wayne.edu) and Sean Wu (Wayne State Univ., Detroit, MI 48202)

A portable, easy to use and effective device using four microphones only is developed for locating arbitrary noise sources in 3-D space in real time. The microphones can be placed anywhere in space so long as they are not on the same plane. This provides application flexibilities. Using cross-correlations, the differences in arrival times of these four microphone channels can be specified. This information together with a spherical spreading assumption of acoustic wave traveling in a free field enables one to determine the (x, y, z) coordinates of target sources. Error analyses are conducted and the impacts of signal noise ratios, microphone spacing, source distances, and frequencies on the accuracy of localization are examined. In particular, an empirical formulation for estimating the errors in locating a target source is developed. Using this empirical formulation, one can locate a target source for any given signal noise ratio, microphone spacing, source distance, and frequency range. Numerical simulations and experimental validations are conducted to check the effectiveness of this device to locate a variety of real world sounds, including truck pass-by noise, thundering, human voices, etc. Satisfactory results are obtained in most cases, even when the sources are behind the measurement microphones.

2aSA10. Low frequency radiation from a (compact) structure with and without sound holes. Kyle Martini (84 Sherman St., Cambridge, MA 02140, kmartini@alionscience.com)

At long wavelengths, a force driven, closed elastic structure radiates as a dipole. However, this may or may not be the case in the presence of a sound hole. Radiation remains dipole-like when the interior volume behaves as an acoustic fluid coupled to the structure. This is commonly referred to as the sound hole sum rule in musical acoustics [Weinreich (1985)]. However, should the interior acoustic volume be uncoupled, or simply ignored, the radiated field is dominated by a monopole contribution. For example, this may occur with mechanically isolated, piping systems exposed to the exterior medium. In this situation, the monopole or dipole nature of the radiation depends on the effective number of sound holes, for example, whether the driven system is well connected to the exterior along both the inlet and outlet. Finite element structural-acoustic models are developed and exercised to investigate these systems and issues. In addition, a substructuring technique is utilized to account for the potential influences of interior structural complexity.

TUESDAY MORNING, 19 MAY 2009 GRAND BALLROOM I, 8:00 A.M. TO 12:00 NOON

Session 2aSC

Speech Communication: Phonetics and Phonology (Poster Session)

Ratree Wayland, Chair
Program in Linguistics, Univ. of Florida, Gainesville, FL 32611-5454

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon

2aSC1. The perception of word-final nasals in Southern Min and Mandarin Chinese. Ying Chen and Susan G. Guion (Dept. of Linguist., 1290 Univ. of Oregon, Eugene, OR 97403, ychen12@uoregon.edu)

There is a historical pattern of word-final nasal merger in Chinese languages. Some languages preserve the old Chinese final nasals /m, n, ŋ/, others preserve only /n, ŋ/, while others preserve only /ŋ/. The pattern of merger and loss, /m/ > /n/ > /ŋ/, may be due to a hierarchy of confusability among the nasals. Here, relative confusability of nasals was examined in identification tasks. Effects of vowel quality and lexical tone were also considered. First, perception of final nasals in the Quanzhou dialect of Southern Min, which preserves /m, n, ŋ/, found that /m/ was most often confused, while /n/ was least often confused. High vowel /i/ conditioned more mishearing than mid vowel /ə/ and low vowel /a/; low-level tone conditioned more mishearing than high-level, midlevel, midlow-rising and midhigh-falling tones. Second, perception of final nasals in Mandarin, which preserves /n, ŋ/, found that /n/ was more often confused than /ŋ/. High vowel /i/ again conditioned more mishearing than /ə/ and /a/; low-dipping tone conditioned more mishearing than high-level, midrising, and high-falling tones. The results do not strongly support the hierarchy of confusability among the nasals but suggest that high vowels and low tones condition more misidentifications.

2aSC2. Velarization of word-initial /l/ in African American English. Janneke Van Hofwegen and Erik R. Thomas (Dept. of English, North Carolina State Univ., Box 8105, Raleigh, NC 27695-8105, ethomas@social.chass.ncsu.edu)

Word-initial /l/ was examined in African American English in North Carolina, with comparisons with European American English, archival interviews with ex-slave African Americans and Spanish. The degree of velarization was measured using the F2-F1 difference in Bark. Interactions with formant values of the following vowel and the duration of /l/ were examined. Past research has produced conflicting results. First, initial /l/ in English is regarded as relatively unvelarized, but some research has found it to be velar. Second, there is disagreement about whether velar or nonvelar /l/ shows greater duration. Third, there has been controversy over whether velarization of /l/ is categorical or scalar. Results showed that English speakers exhibited significantly more velarization than Spanish speakers. Moreover, the degree of velarization increased across generations of African Americans. Less velarized /l/ proved to show greater duration than more velarized /l/. Velarization was quite scalar: there was no discernable division between more and less velarized tokens. /l/ tended to be more velar before a back vowel than before a front vowel, but this correlation showed no interaction with the observed generational and individual differences in velarization. [Work supported by NSF.]

2aSC3. An acoustic study of /w/ in Korean. Sun-Ah Jun and Jason B. Bishop (Dept. of Linguist., UCLA, Los Angeles, CA 90095-1543)

This study examines acoustic characteristics of Korean /w/. Modern Korean is claimed to have four /w/ diphthongs: /w/ before two front vowels (/wi, we/) and two back vowels (/wa, wʌ/). The two front diphthongs are a product of a more recent sound change from front rounded monophthongs, high /y/ and mid /ø/. However, a pilot study shows that the phonetic real-

izations of /w/ before front vowels differ from those before back vowels, and also differ whether /w/ comes after a consonant (CwV) or not (wV). It was found that /w/ before front vowels is similar to a labial-palatal approximant, especially after a consonant, showing a trace of front rounded monophthongs. To confirm this finding, a large set of data was collected from six Korean speakers and the acoustic realizations of Korean /w/ were compared with those of French labial-palatal and labial-velar approximants produced by six French speakers. The implication of the results in the phonological system will be discussed.

2aSC4. Sound change and perceptual weight of acoustic correlates to Korean stops. Kyoung-Ho Kang and Susan Guion (Dept. of Linguist., Univ. of Oregon, 1290 Univ. of Oregon, Eugene, OR 97403)

The Korean stop system is experiencing a sound change. Younger Korean speakers born in the 1970s or after produce aspirated and lenis stops differently from older speakers. Results from clear speech production experiments revealed differences in clear speech enhancement patterns. Older speakers enhanced voice onset time (VOT) difference, whereas younger speakers primarily enhanced F0 difference [K.-H. Kang and S. G. Guion, J. Acoust. Soc. Am. **124**, 3909–3917 (2008)]. These results indicate that older and younger speakers have different phonetic targets for the production of stops. The primary goal of the current study was to examine any perceptual differences related to the production differences. In order to assess the extent to which acoustic correlates to the stops contribute to the identification of the Korean stops, a perception experiment using resynthesized stimuli was conducted. Younger ($n=$ 10, mean of 20.2 years old) and older listeners ($n=$ 10, mean of 48.5 years old) participated in a stop identification task. The results suggested that F0 is a more weighted correlate than VOT for younger listeners for the distinction of the aspirated and lenis stops.

2aSC5. Phonation categories in Cajonos Zapotec. Laura Tejada (Dept. of Linguist., Univ. of So. California, GFS 301, Los Angeles, CA 90089, ltejada @usc.edu)

Phonation categories such as breathy, modal, and creaky have been described using the acoustic measurements (H1–H2) and (H1–A1). The measure (H1–H2) is the difference in dB between the first and second harmonics and is used to approximate the proportion of a glottal cycle in which the glottis is open (the open quotient). (H1–A1) is the difference in dB between the first harmonic and the most prominent harmonic in the F1 region. (H1–A1) is used as a measure of F1 bandwidth that is related to degree of glottal opening. These measures were applied to an undocumented variety of Villa Alta Zapotec spoken in San Miguel Cajonos. Acoustic data from four speakers were analyzed. Measures were taken at four evenly spaced points in time for /i/, /e/, /a/, and /o/. Results show that (H1–H2) and (H1–A1) discriminated correctly between the categories breathy, modal, and creaky with varying percentages of accuracy at different time points. (H1–H2) had a (58%) accuracy rate at time point three, compared with (63%) for (H1–A1). Combining the two measures showed that the accuracy rates rose from point one (50%) through points two (61%) and three (65%), and fell slightly at point four (58%).

2aSC6. The phonetics of contrastive phonation in Gujarati. Sameer ud Dowla Khan (Pitzer College, 1050 N. Mills Ave., Claremont, CA 91711, and Dept. of Linguist., 3125 Campbell Hall, UCLA, Los Angeles, CA 90095) and Victoria Thatte (UCLA, Los Angeles, CA 90095)

Gujarati is known for distinguishing breathy and modal phonation in both consonants and vowels [(Cardona and Suthar, 2003)], e.g., /ba:r/ "twelve" versus /Ba:r/ "burden" versus /bA:r/ "outside," where uppercase represents breathiness. The current study investigates acoustic and glottographic properties of this three-way contrast. [Fischer-Jørgensen (1967)] and [Bickley (1982)] showed that the H1-H2 measure can reliably distinguish breathy and modal vowels, and [Esposito (2006)] further found that Gujarati listeners exclusively attend to H1-H2 to categorize audio samples from other languages, even when H1-H2 did not reliably distinguish contrastive voice quality in those languages. However, do other acoustic properties also distinguish breathiness in Gujarati? In addition what physiological differences underlie the acoustic differences? The current study tests the reliability of several phonetic measures (e.g., H1-H2, H1-A1, CPP, CQ, etc.) to distinguish 33 (near-) minimal sets contrasting breathy and modal segments in audio and electroglottographic data produced by both male and female Gujarati speakers. [Work supported by NSF].

2aSC7. The effect of boundary recoverability on geminate length in English. Grace E. Oh and Melissa A. Redford (Dept. of Linguist., 1290 Univ. of Oregon, 1451 Onyx St., Eugene, OR 97403)

[Payne (2005)] argues that fake geminates are longer than true geminates, and [Ridouane (2007)] shows that their preceding vowel duration is also significantly longer. These effects are likely due to the boundary that distinguishes fake from true geminates. If this is correct, then we might expect that boundary strength will also affect geminate realization. We investigated this possibility by comparing the absolute and relative durations of assimilated and concatenated word-internal and cross-word boundary fake geminates in English (e.g., immoral versus unnamed versus fun name). Eight speakers produced five repetitions of 32 stimuli (four types: three geminate, one singleton) in two speech styles. The results showed that although cross-boundary geminates were longer than word-internal concatenated and assimilated geminates in absolute terms, both types of concatenated geminates were shorter than assimilated geminates in relative terms. A follow up experiment, comparing geminates in compound words to those emerging across words showed no differences in relative duration between the two. These results suggest that boundary strength may be less important than boundary recoverability in production. Overall, we argue that boundary recoverability impacts the phonetic implementation of geminates and likely does so whether these are true or fake.

2aSC8. Articulatory comparison of Tamil liquids and stops using real-time magnetic resonance imaging. Michael Proctor (Yale Univ., New Haven, CT 06520), Louis Goldstein, Dani Byrd, Erik Bresch, and Shri Narayanan (Univ. of Southern California, Los Angeles, CA 90089)

It has been hypothesized that liquid consonants differ from stops in that they exhibit more global control over tongue shapes. This has been demonstrated by ongoing work showing greater vowel context effects in the production of stops than liquids in Spanish and Russian. Languages with rich inventories of coronal consonants, like Tamil, provide an interesting challenge for this view, as the presence of retroflex-dental contrasts among the stops may require substantial global tongue control, and therefore inhibit context effects. To test this, dynamic magnetic resonance imaging (MRI) was used to investigate the midsagittal production of Tamil liquids in intervocalic environments. MRI sequences were acquired at a frame rate of 22.4 Hz. The five liquids of Brahmin Tamil were elicited from three speakers in three different vowel contexts. Nasal stop consonants were also elicited at the same places of articulation to compare the influence of vocalic coarticulation on liquids and stops. Greater coarticulatory influences were observed during the production of nasals than during the production of liquids in the same vowel contexts, suggesting that the production of liquids involves a more active control of dorsal articulation than that used in the production of stops. [Work supported by NIH.]

2aSC9. A study of articulatory kinematics of American English diphthongs. Sungbok Lee and Dani Byrd (Dept. of Linguist., Univ. of Southern California, 3601 Watt Way, GFS-301, Los Angeles, CA 90089)

Diphthongs are acoustically characterized by formant movements between initial and final vocalic segments [cf, Holbook and Fairbanks, J. Speech Hear. Res., (1962); Thomas Gay, J. Acoust. Soc. Am., (1968)]. It has been observed that the initial (onset) and final (offset) portions may not correspond to typical monophthongal vowels and that there exists more acoustic variability in the offset portions than in the onset portions. Spectral transition rates have been found to be different from diphthong to diphthong. In the current study, the articulatory properties of American English diphthongs are investigated in tandem with their acoustic properties. We collected both acoustic and articulatory data of five diphthongs and seven monophthongs in [b-t] context embedded in a carrier sentence using electromagnetic articulography. The data were recorded from two male and one female subjects, and each diphthong was repeated five times. The main analysis focus is on the kinematic characteristics of the three different tongue sensors

(tongue tip, tongue dorsum, and tongue rear) in each diphthong production and the comparisons to monophthongs that are close to either the onset portion or the offset portion of the given diphthong. [Work supported by NIH.]

2aSC10. Revisiting the role of the sublingual cavity in the /s/-/ʃ/ distinction. Christine H. Shadle, Michael I. Proctor, Khalil Iskarous (Haskins Labs., 300 George St., New Haven, CT 06511, shadle@haskins.yale.edu), and Maria A. Berezina (MIT-SHBT, Cambridge, MA 02139)

The sublingual cavity (SC) has been shown to play an important role in shaping the spectra of consonants, potentially distinguishing /s/ from /ʃ/. This work reports on acoustic-articulatory experiments using MRI and mechanical modeling designed to investigate the details of how the SC acts as an acoustic filter and whether it also affects the aeroacoustic source in fricative production. Five American English subjects were imaged while producing fricatives in various vowel contexts. Two subjects that show opposite patterns were studied in detail. In M1, the /s/-/ʃ/ distinction is mainly carried by SC presence and lip protrusion in /ʃ/ versus absence in /s/, resulting in marked spectral differences. M2 exhibits significant variability in SC shape and size, and tongue and lip position, in both fricatives; the acoustic spectra likewise vary. Mechanical model experiments show that the noise generation changes as the sublingual cavity is filled in. The main resonance frequency does not necessarily change. It seems thus that the sublingual cavity is just one of many articulatory variables available to the speaker and may not be the principal cause of observed acoustic differences in all subjects. [Work supported by NIH NIDCD DC 006705 to Haskins, NIH NIDCD T32 DC00038 to MIT-SHBT.]

2aSC11. End-state comfort governs kinematic variation in English flap/tap sequences. Donald Derrick and Bryan Gick (Dept. of Linguist., Univ. of British Columbia, Totem Field Studios, 2613 W. Mall, Vancouver, BC, V6T 1Z4, Canada)

Derrick & Gick [Can. Acoust. **36**(3), 162 (2008)] found that North American English flap/tap singletons are produced using up to four phonetically conditioned kinematic variants (up-flaps, down-flaps, postalveolar taps, and alveolar taps), dependent on the position of the tongue tip in neighboring rhotic and nonrhotic vowels. Our pilot work has shown that sequences of multiple flap/tap variants are highly mechanically interdependent (e.g., subjects never produce two up-flaps or two down-flaps in adjacent syllables). The present study tests flap/tap sequences for compliance with "end-state comfort" [Rosenbaum *et al.*, Acta Psychologica **94**, 59 (1996)], as evidence for look-ahead planning. Twelve subjects' tongue positions were measured during production of English words and word pairs with one- and two-flap sequences. Results show that sequences of flaps end with a preferred tongue tip position. For example, for 11 subjects, the /d/ of "edit" is realized as an alveolar tap or down-flap in "edit the," but an up-flap in "edit a," both facilitating ending the sequence with a low tongue position. A general avoidance of a sequence-final up-flap was also observed, such that /d/ of "edify" is an alveolar-tap or down-flap, while, for eight subjects, "editor" shows an up-flap, postalevolar tap sequence. [Work supported by NSERC.]

2aSC12. An articulatory study of lexicalized and epenthetic schwa using real time magnetic resonance imaging. Adam Lammert (Dept. of Comp. Sci., Univ. Southern California, 941 W. 37th Pl. Los Angeles, CA 90089), Erik Bresch, (Univ. Southern California, Los Angeles, CA 90089), Dani Byrd, Louis Goldstein, (Univ. Southern California, Los Angeles, CA 90089), and Shrikanth Narayanan (Univ. Southern California, Los Angeles, CA 90089)

Debate exists about the nature of schwa in terms of articulatory planning and execution. It is commonly believed that schwa lacks a specific constriction target. Another view is that the constriction target for schwa is the mean of the language's targeted vowels. Some have argued that both lines of thinking are correct [I. Smorodinsky, J. Acoust. Soc. Am. **109**, 2446 (2001)]. Specifically, epenthetic schwas (e.g., needed) may indeed be targetless, while lexical schwas (e.g., panda) have a target. To investigate this, we collected midsagittal realtime l MR images [S. Narayanan et al., J. Acoust. Soc. Am. **115**, 1771 (2004)] from two native English speakers. The speakers read sentences aloud which contained, variously, lexical or epenthetic schwas in multiple contexts. Images of the various schwas were extracted from the MR data and a profile of the vocal tract was fit to the image. If both targeted and targetless schwas exist, then they should be evident by examining the vocal tract shape in these images. Lexical schwas, if they are targeted, should have relatively low variability as compared to epenthetic schwas. Conversely, the vocal tract shape during epenthetic schwas should be highly correlated with the surrounding vowel context. [Work supported by NIH.]

2aSC13. Evidence of an articulatory saturation effect in the production of /s/ in American English. Joseph S. Perkell, Melanie L. Matthies, and Mark Tiede (Speech Commun. Group, Res. Lab. of Electronis, MIT, Rm. 36-591, 50 Vassar St., Cambridge, MA 02139.)

Previous work [JSLHR, *47*, 1259–1269 (2004)] demonstrated that speakers of American English who consistently activated a contact sensor on the lower alveolar ridge with the tongue tip during /s/ but not /sh/ tended to produce greater sibilant contrast than speakers who did not consistently show this contact difference. This result is compatible with the existence of a sublingual cavity during /sh/ that is eliminated by the tongue-ridge contact for /s/, which creates an abrupt decrease in volume and resulting rapid increase in resonant frequency of the cavity anterior to the sibilant constriction. This study uses data from articulatory movements (EMMA), contact of the tongue tip with the alveolar ridge, and analysis of the acoustic signal to investigate a hypothesized articulatory saturation effect: abrupt articulatory and acoustic changes result from continuous forward movement of the tongue, which does not have to be controlled precisely in stopping at /s/ onset. In tentative support of this hypothesis, preliminary observations from productions of continuous /sh/-to-/s/ transitions show movements of tongue-blade points, which slow but do not stop immediately following articulatory contact and/or a rapid rise in sibilant spectral mean. Additional tests of the hypothesis and corresponding results will be reported. [Work supported by NIDCD.]

2aSC14. Relation of vocal tract constriction location to identification of voiced stop consonants. Brad H. Story and Kate Bunton (Dept of Speech, & Lang., Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721)

Consonant identification experiments are typically based on stimuli produced with a formant synthesizer where a particular acoustic characteristic is varied along some continuum of values (e.g., onset frequency of F2). In this experiment, however, vowel-consonant-vowel (VCV) stimuli were generated with a synthesizer based on a kinematic model of the vocal tract shape [B. H. Story, JASA, 117(5), 3231–3254 (2005)] where the acoustic characteristics result from the time-varying tract configuration. Each VCV was produced by superimposing a constriction at a particular location within the vocal tract on an underlying vowel-vowel sequence. Five different vowel-vowel sequences were produced, and for each, a constriction was imposed at 20 consecutive locations extending from the lips to approximately the velum. VCVs were presented in random order, ten times each, to ten listeners, using a forced choice paradigm where only the voiced English consonants /b, d, g/ were available. Listener responses indicated that the relation of formant frequencies near the consonant, to those of the preceding or succeeding vowel can provide reasonably accurate predictions of regions within the vocal tract that correspond to specific consonants. It was also revealed that the location and length of each region is dependent on the vowel. [Research supported by NIH R01-DC04789.]

2aSC15. Phonetic properties of syllabic consonants in Slovak. Marianne Pouplier (Inst. of Phonet. , Ludwig Maximilians Univ., Munich, Schellingstr 3/ii, 80799 Munich, Germany, pouplier@phonetik.uni-muenchen.de) and Štefan Beňuš (Constantine the Philosopher Univ., 94974 Nitra, Slovakia)

Studies on the articulatory correlates of syllable structure have shown that onset and coda consonants differ systematically in the timing and amplitude of their movements, and their temporal coordination with the vocalic syllable nucleus. Little is known, however, about consonants functioning as syllable nuclei. We present EMA data on Slovak, a language that allows the liquids /l/ and /r/ to be syllabic nuclei of CCC syllables. Phonologically, syllabic consonants behave like vocalic nuclei. We investigate the kinematic properties of syllabic consonants, and potential differences between vocalic and consonantal nuclei in their patterns of coordination with onsets and codas. Our data indicate that liquids in onset clusters are shorter than singletons (e.g., /r/ in "mrak" < "rak"), yet syllabic consonants (/r/ in "mrk") pattern durationally with singletons. Generally, Slovak onset clusters show little

or no overlap, which may result in an open transition schwa. For C1C2C3 syllables, C1-C2 show more overlap compared to an onset cluster, yet open transition schwas can still be observed ("mˆrk"). C2-C3 overlap less than C1-C2 in terms of movement onset, yet C1-C2 show a bigger plateau lag. These data contribute to our knowledge about the phonetic nature of syllabic consonants and articulatory correlates of syllable structure.

2aSC16. Rate conditioned variability in Western Andalusian Spanish aspiration. Benjamin Parrell (Dept. of Linguist., Univ. of Southern California, Grace Ford Salvatori 301, Los Angeles, CA 90089, parrell@usc.edu)

Western Andalusian Spanish normally shows aspiration of /s/ in coda position, but post-, rather than pre-, closure aspiration in /s/ + /p,t,k/ sequences. This has been hypothesized to be the result of gestural reorganization, with pre-closure aspiration the result of anti-phase coordination and post-closure the result of in-phase [Torreira, 9th HLS, 2007]. This experiment explores this hypothesis by leveraging the fact that fast speech can lead to instability in gestural organization and even a spontaneous switch from anti- to in-phase coordination [Turvey, Am. Psych., 1990]. Subjects produced words with the target /s/+/p,t,k/ sequences in time with an acoustic metronome that steadily increased in rate. Results show three patterns of production: consistent preaspiration, consistent postaspiration, and a transition from pre- to post-aspiration as rate increased, corresponding to anti-phase, in-phase, and an anti- to in-phase transition, respectively. Excluding the trials with consistent postaspiration, which would not be expected to transition given their stable in-phase coordination, postaspiration increases as rate increases. If there were no change in gestural coupling, we would expect the opposite pattern: as rate increases, VOT should decrease. The result thus supports the original hypothesis that postaspiration in these sequences is the result of gestural re-phasing.

2aSC17. A production study on phonologization of /u/-fronting in alveolar context. Reiko Kataoka (Dept. of Linguist., Univ. of California, Berkeley, 1203 Dwinelle Hall, Berkeley, CA 94720-2650)

Recently many researchers modeled sound change as the result of phonologization [Hyman (1976)], a process whereby coarticulatory perturbation of a speech sound becomes intended properties of the sound. Although phonologization is a useful concept, diagnostic criteria have yet to be proposed. By using /u/-fronting in alveolar context in American English as a case study, this paper demonstrates how production data of various speech rates may be used to differentiate phonologized speech variations from mechanically caused variations. English speakers produced /CuC/ forms where the place of both Cs was either alveolar (text context) or other (control context), in fast, medium, and slow speech rates. [Lindblom (1963)] demonstrated that the magnitude of coarticulatory influence on the vowel reduces as the vowel's duration increases. Thus, if the fronting of the vowel in alveolar context persists regardless of its duration, then this would constitute as evidence for phonologization. The results from a study with 30 speakers show that the vowels had significantly higher mean F2 values in alveolar contexts than in bilabial or zero contexts even in slow speech rate, suggesting that speakers have distinct production goals for /u/s in different contexts, or /u/-fronting has been phonologized.

2aSC18. Acoustic cues to stop coda voicing contrasts in 1 to 2-year-olds' American English. Katherine Demuth (Dept. of Cognit. and Linguistic Sci., Brown Univ., 190 Thayer St., Providence, RI 02912), Stefanie Shattuck-Hufnagel (Massachusetts Inst. of Technol., Cambridge, MA 12139), Jae Yung Song (Brown Univ., Providence, RI 02912 and MIT, Cambridge, MA 12139), Karen Evans, Jeremy Kuhn, and Miranda Sinnott-Armstrong (Brown Univ., Providence, RI 02912)

One limitation in understanding the mechanisms underlying children's variable productions has been the reliance on perception-based segmental transcription. This raises the possibility that children may make covert, acoustic distinctions that are not perceived by the transcriber. Shattuck-Hufnagel *et al.* [S. Shattuck-Hufnagel, K. Demuth, H. Hanson & S. Stevens, submitted] investigated this issue employing Stevens' [K. N. Stevens, J. Acoust. Soc. Am. **111**, 1872–1891 (2002)] feature-based acoustic model of perception/production. They found that 2,6–3,6-year-olds exhibited systematic acoustic cues to coda voicing contrasts (e.g., dog versus duck): voice-bar was more likely to precede voiced codas, whereas vowel glottalization was more likely to precede voiceless codas. The present study extended this investigation to velar codas in three 1,6–2,6-year-olds and their mothers, showing similar results: both exhibited more use of voice-bar before voiced compared to voiceless codas. For mothers, the duration of voice-bar was also longer for voiced codas, and children showed a trend in this direction. However, only mothers showed a significantly higher use of vowel glottalization before voiceless codas. Thus, although younger children also produce some acoustic cues to voicing distinctions, others take time to become adultlike. Physiological and environmental factors are discussed to explain these results. [Work supported by R01 HD057606.]

2aSC19. Segmentation of speech based on perceptual equivalence: Case of alveolar trill. Diana Stojanovic (Dept. of Linguist., Univ. of Hawaii, 1890 East-west Rd., Moore Hall 569, Honolulu, HI 96822)

Turk et al. (2006) proposed a set of rules for segmentation in durational studies. R-sounds were not included in the recommended class due to their variable realizations. The authors suggested segmentation of tap variants was straightforward but that of approximants prohibitively difficult. In this paper, we discuss the issue of segmentation of the alveolar trill in Serbian. Three native speakers read a set of minimal pair phrases in which consonants /d/, /n/, and /r/ occurred intervocalically. Phrases were matched for the position and type of pitch-accent. The four-syllable phrases produced by each speaker were judged by the native listeners as being rhythmically equivalent. When /r/ is segmented to include only the closure, vowels matched for quality, position, and accent type are significantly longer before /r/ than before /d/ or /n/. The three consonants are all voiced thus compensatory lengthening is not likely to affect the length of the preceding vowel. Based on perceived rhythmic equivalence of the examined phrases, we formulate a segmentation rule that places the start of /r/ during the vocalic portion preceding the closure. This strategy equalizes measured durations of the preceding vowels and additionally enables us to treat /r/ equivalently in all environments.

2aSC20. Non-native listener's linguistic background and use of contextual cues. Lu-Feng Shi (Dept. of Commun. Sci. and Disord., Long Island Univ.–Brooklyn Campus, One Univ. Plaza, Brooklyn, NY 11201, lu.shi@liu.edu)

Non-native listeners have more difficulty perceiving acoustically degraded English speech than native listeners. In addition, performance in non-native listeners varies greatly depending on many linguistic factors. Recognizing the importance of these factors, the current study assessed how 30 non-native listeners utilized contextual information on the reverberant speech-perception-in-noise test [Sandridge et al., AAS (2005)] based on their linguistic profiles, obtained through the Language Experience and Profile Questionnaire [V. Marian et al., JSLHR **50**, 940–967 (2007)]. Specifically, these SPIN sentences (high versus low context) were processed in two levels of multi-talker babble (signal-to-noise ratio $=+6$ versus 0 dB) and two levels of reverberation (reverberation time $=1.2$ vs 3.6 s). Significant factors in language dominance, proficiency, learning, and use were identified using correlation and multiple regression procedures. Most strikingly, factors related to reading in English (age of acquisition, age of fluency, and preference) emerged as the strongest predictors of performance regardless of the main effect (noise, reverberation, or context). Most variance in performance could be accounted for by these reading factors and two additional factors related to speaking in English (proficiency and accent).

2aSC21. Acoustic analysis of the tones and tone sandhi in Hakka Chinese. Eric Zee and Wai-Sum Lee (Dept. of CTL, City Univ. of Hong Kong, 83 Tat Chee Aven., Kowloon, Hong Kong, eric.zee@cityu.edu.hk)

This paper analyzes F0 contours of (i) the six citations tones of Hakka Chinese which consist of four long tones that occur on open syllables and closed syllables with a nasal and two short tones on checked syllables and (ii) tone contours on 36 bisyllabic compounds, representing possible permutations of the six citation tones, and 120 commonly used trisyllabic compounds. Based on the F0 data, (i) tone values are assigned to the citation tones and (ii) tone patterns on the bisyllabic and trisyllabic compounds are defined. Tone sandhi rules are formulated, summing up the phonological changes in the citation tones when juxtaposed. Phonetic tonal coarticulations are also examined. The F0 data show that the citation tones may be represented in terms of tone letter as [53 31 33 11] (long) and [5 32] (short). Major tone sandhis include [33] becoming [35] and [53] becoming

[55] before [11], [31], or [53]; and before another [31], [31] becomes [33]. Process such as [53 53 53 53] becoming [5 5 5 53] illustrates simultaneous application of tone sandhi to only tones on the non-compound-final syllables, and [5 33 11 53 31] do not undergo tone sandhi before [5] or [33].

2aSC22. Effect of tone on consonant + vowel interaction. Augustine Agwuele (Dept. of Anthropology, Texas State Univ. San Marcos, 601 University Dr., San Marcos, TX 78666)

Examining consonant + vowel coarticulation for American English [Agwuele *et al.*, 16th ICPhS, **1**, 617–620 (2007) and Lindblom *et al.*, J. Acoust. Soc. Am. **121**, 3802–3813 (2007)], the effect of speech tempo and emphatic stress on F2onset and F2mid of the following vowel were quantified and dissociated from the underlying traditional coupling of consonant and vowel. Thus, these two prosodic factors were shown to pose additional confound to CV coarticulation. Adopting the approach of these works, this present study examines VCV sequences in Yoruba, a tonal language, in order to determine whether lexical tone produces as additional confounding effect to the interaction between consonant and tone bearing vowel that could be shown to be separate from the traditionally expected CV bonding. The study shows that the changing pattern of tone configuration in VCV sequences, e.g., from VMCVM [M=midtone] to VLCVL [L=low tone] produces differing consonant + vowel interaction. The study provides acoustic evidence for a possible independence of the "source" from the "filter," i.e., the resonances of the vocal tract [Fant, G. Acoustic Theory of Speech Production (1960)].

2aSC23. The production and perception of Mon voice registers. Arthur S. Abramson, Gordon Ramsay (Haskins Labs., 300 George St., Ste. 900, New Haven, CT 06511, arthur.abramson@uconn.edu), and Theraphan Luangthongkum (Chulalongkorn Univ., Bangkok 10330, Thailand)

As a continuation of our work on voice registers [Abramson *et al.*, Phonetica **61**, 147–171 (2004); Abramson *et al.*, Phonetica **64**, 80–104 (2007)], another language, Mon, has been examined. A voice register on a syllable is a bundle of phonetic properties among which one, usually phonation type, is paramount. Fieldwork, with support from acoustics [Thongkum, in Bamroongraks *et al.*, (eds.), International Symposium on Language and Linguistics, pp. 22–50 (1998)], has yielded primarily modal voice and higher pitch for one register and breathy voice and lower pitch for the other. Our acoustic analysis has confirmed the significance of F0 height as well as that of the intensity ratios of higher harmonics and the first harmonic. The greater attenuation of the higher spectrum for breathy voice is taken as a consequence of a larger open quotient of the glottal cycle. For validation, electroglottography of the native speakers used for our acoustic analysis has been done. A control test of the robustness of the distinction in natural speech has been run along with one with synthetic speech for the efficacy of incremental changes along three dimensions, F0, spectral slope, and turbulence mixed with glottal pulsing. Final data will be shown.

2aSC24. Tone space reduction in Mandarin Chinese. Jeffrey Berry (Dept. of Linguist., Univ. of Arizona, Douglass Bldg., Rm. 200E, Tucson, AZ 85721)

Work on clear versus conversational speech has shown that speakers expand the vowel space in clear speech, which maximizes the perceptual contrast, making it easier for listeners to parse the speech signal. This study investigates how the realization of lexical tones changes for different speech tasks, and whether it is sensitive to the number of repetitions of the same word in a conversation. Native Mandarin speakers participated in a map task in which they were instructed to explain the route on the map to a partner. The first and last tokens of each target word were extracted from the dialogues and compared to the same word read from a list. Pitch and duration were normalized and quadratic curve fitting was performed on the test items. Results of statistical analyses show that contour tones from later occurrences of the target words have a smaller slope, are more linear, and tend to have pitch values closer to the overall average pitch of the speaker. In other words, all tones are realized closer to a midlevel tone when they have been previously mentioned in the conversation. In this sense, there is a contraction of the tone space for later tokens.

2aSC25. Contextual tonal variation in level tone languages. Kristine M. Yu (Dept. of Linguist., Univ. of California, Los Angeles, 3125 Campbell Hall, Los Angeles, CA 90095, krisyu@humnet.ucla.edu)

While contextual tonal variation in languages with contour tones has been well studied [Han and Kim (1974); Gandour (1992); Xu (1994)], contextual tonal variation has been less well-studied in level tone languages [Meyers (1976)]. The acoustic variation of tones due to different tonal contexts in Hausa, Bole (with two tones H and L) and Yoruba (with three tones H, M, and L) will be investigated. The description of cross-linguistic contextual tonal variation is essential for understanding the task that infants are undertaking in acquiring tonal categories in the face of variance in tonal realization. The focus of the investigation will be how the acoustic variation compares to that in languages with contour tones and if there are general patterns across languages or language-specific differences in variation.

2aSC26. Perception of Mandarin Chinese tone 2/tone 3 and the role of creaky voice. Rui Cao and Ratree Wayland (Linguist., Univ. of Florida, 4131 Turlington Hall, PO Box 115454, Gainesville, FL 32611-5454, ruicao@ufl.edu)

Previous research has established that among the four tones of Mandarin Chinese, tone 2 and tone 3 are very similar in their pitch contour shapes and are, thus, difficult to distinguish by native and nonnative listeners. On the other hand, creaky voice has been reported to be associated with tone 3 production among native speakers. However, the role of creaky voice in the perception of tone 3 has yet to be studied systematically. This study aims to investigate (1) the extent to which creaky voice is present in tone 3 production by native speakers; (2) the perceptual boundary between tone 2 and tone 3 among native and non-native speakers; and (3) the effect of creaky phonation on this perceptual boundary. Thirty native Chinese speakers and 30 native speakers of American English who are learning Chinese will participate in this study. Tone stimuli with and without creaky voice will be presented auditorily for tonal identification. The data obtained will be analyzed to examine the effect of creaky voice in the identification of tone 3 among these two groups of speakers. In addition, the native production of tone 3 will be examined for the presence of creaky voice.

2aSC27. Perceptional experiment on Mandarin tones by Mandarin, Spanish, and Cantonese speakers. Yi-Chu Ke (Dept. of Foreign Lang. and Linguist., Natl. Chiao Tung Univ., 1001 Univ. Rd., Hsinchu, Taiwan 300, ROC), Mu-Ling Teng, Chu-ting Chen, Lai-Iok Ip, Bo-hong Lu (Natl. Chiao Tung Univ., Taiwan 300, ROC), Shih-wen Chen (Natl. Tsing Hua Univ., Hsinchu, Taiwan 30013, ROC), Hsiu-Min Yu (Chung Hua Univ., Hsinchu, Taiwan 300, ROC), and Ho-hsien Pan (Natl. Chiao Tung Univ., Taiwan 300, ROC)

This paper discussed perception of three contrastive Mandarin tones: high tone (Tone1), rising tone (Tone2), and falling tone (Tone4). Based on the previous study by Hallé (2004), in which tone (Mandarin) and non-tone (French) speakers joined, our perceptional experiment employed both identification and discrimination paradigm, and categorical result of tones was expected. We recorded two Mandarin words "tu" and "wa" in those three contrastive tones, and these six words were manipulated into same duration. We then synthesized the F0 of Tone1 to Tone2, Tone1 to Tone4, and Tone2 to Tone4 in seven steps. Subjects were separated in accordance to their mother tongues, namely Mandarin, Spanish, and Cantonese. Categorical perception is obvious in Mandarin group. Cantonese speakers revealed a similar categorical pattern to Mandarin speakers, while Spanish speakers showed no categorical pattern. On the whole, Mandarin speakers had an earlier drop-down on second or third step over each pair of tone stimuli.

2aSC28. Fundamental frequency in English and Mandarin. Patricia Keating (Phonet. Lab., Dept. of Linguist., Univ. of California at Los Angeles, Los Angeles, CA 90095-1543, keating@humnet.ucla.edu)

It has been suggested that Mandarin, as a tone language, uses a larger F0 range than English. This study addresses two questions: (1) Do English and Mandarin F0 profiles differ? (2) How does the type of voice sample which is measured affect this F0 characterization and language comparison? Native speakers of English or Mandarin produced a variety of speech samples intended to elicit a wide range of F0s. Maximum phonation frequency range was measured from pitch sweeps, and speaking F0 was measured from readings of the Rainbow passage, isolated words with various intonations, and a dramatic story. Cepstral pitchtracking was used to log the entire F0 contour for each utterance, and various measures were computed. Preliminary results suggest, first, that the maximum phonation frequency ranges are the same

for the two languages; second, that in reading Mandarin speakers use a higher mean F0, but at the same time English speakers use higher maximum F0 and wider range of F0; and third, that these differences do not depend on the speech samples being compared. [Work supported by NSF.]

2aSC29. Breathing behavior in relation to prosody and linguistic structure in spontaneous speech. Peter J. Watson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr. SE, Minneapolis, MN 55455)

Hird and Kirsner [K. Hird and K. Kirsner, Brain Lang., **80**, 536–555 (2002)] reported that F0 is reset at higher values at the beginning of grammatically complete sentences during spontaneous speech. Hird and Kirsner reported that inspirations taken at the beginning of complete sentences "appeared" to be deep, but they did not make physiological measures of breathing behavior. [Watson, *et al.* J. Acoust. Soc. Am., **113**, 2812–2819 (2003)] found that when sentences were read aloud at higher values within the vital capacity they were initiated at higher F0s; however, these measures were not made during spontaneous speech and grammatical structure was not varied. For this study, we measured breathing behavior using Respitrace while three women and one man were interviewed. Posthoc, breath groups were grammatically organized according to the method used by Hird and Kirsner. On average, breath groups that comprised complete sentences were initiated from higher lung volumes and F0 was reset at higher levels at the beginning of these breath groups. Results will be discussed in relation to the interaction of linguistic structure and breathing behavior.

2aSC30. How do ordinary listeners perceive prosodic prominence? Syntagmatic versus paradigmatic comparison. Yoonsook Mo, Jennifer Cole (Dept. of Linguist., Univ. of Illinois, Urbana–Champaign, 405 N. Mathews Ave., Urbana, IL 61801), and Mark Hasegawa-Johnson (Univ. of Illinois, Urbana-Illinois, Urbana, IL 61801)

In comprehending speech, listeners are sensitive to the acoustic variation encoding the prosodic structures that mark phrasing and prominence. The present study, based on prosody transcriptions of untrained listeners (74 monolingual American English speakers), tests which acoustic feature or feature combinations cue prosodic prominence, and specifically, whether ordinary listeners perceive prosodic prominence based on changes in acoustic measures in the local context (syntagmatic comparison) or based on the value of an acoustic measure relative to the distribution of that measure across all instances of the specific phoneme in the listener's experience (paradigmatic comparison). Subjects listened to 36 short excerpts (11–25 s) of spontaneous speech from the Buckeye Corpus, and marked prominent words on a transcript. After evaluating intertranscriber agreement rates, acoustic measures (duration, intensity, subband intensities, F0 max, and formants) were extracted from stressed vowels and normalized within two domains (syntagmatic/paradigmatic). The results show that all the acoustic measures are correlated with perceived prominence and combinations of the acoustic measures account for the variability in listeners' perception of prominence. Moreover, syntagmatically normalized acoustic measures explain more of the variability, indicating that ordinary listeners perceive prosodic prominence based on local changes in acoustic measures and especially in changes in overall intensity.

2aSC31. Computational modeling of juncture strength using articulatory synthesis of prosodic gestures. Sungbok Lee, Benjamin Parrell, and Dani Byrd (Dept. of Linguist., Univ. of Southern California, 3601 Watt Way, GFS-301, Los Angeles, CA 90089)

Prosodic boundary gestures or "pi-gestures" (Byrd and Saltzman, J. Phonetics, 2003) have been introduced to model the local slowing or lengthening of articulatory gestures in the vicinity of phrase boundaries. Computational modeling of articulatory dynamics is an important tool in assessing the predicted effects of pi-gestures of varying boundary strength on constriction gestures in varying contexts. We simulate pi-gestures within the TaDA task dynamics computational model [Nam and Kim, JASA, **116**, 172–185 (2004)] and examine how functional data analysis can provide a tool for connecting articulatory lengthening with underlying pi-gesture activation strength. Specifically, the model is applied to the articulatory synthesis of two sequences: [CV#CV] and [CVC#CV], where C is bilabial or alveolar. The pi-gesture's midpoint is coordinated synchronously with the midpoint of following consonant's constriction gesture, and pi-gesture activation strength and duration are manipulated. Results indicate that pi-gesture activation strength has a much stronger effect on slowing than its duration. The slowing effect is asymmetrical, skewed earlier than the midpoint in the pi-gesture interval. After removing linear-time slowing effect (i.e., after length normalization), the slowing effect is slightly stronger in [CV#CV] than in [CVC#CV]. The strength of pi-gesture also affects spatial articulatory characteristics depending on constriction location and sequential context. [Work supported by NIH.]

2aSC32. Comparing contrastively focused and clear speech productions of color terms. Melissa A. Redford (Dept. of Linguist., Univ. of Oregon, 1451 Onyx St., Eugene, OR 97403-1290, redford@uoregon.edu), Adriano Vilela Barbosa, and Eric Vatikiotis-Bateson (Univ. of British Columbia, Vancouver, BC V6T 1Z4, Canada)

Words that are prosodically marked as focused in English are phonetically similar to clear speech words. Just as clear speech words are longer and better articulated (hyperarticulated) compared with matched casual speech words, prosodically focused words are longer and hyperarticulated compared to matched, unemphasized words. These similarities suggest that the implementational difference between prosodic focus and clear speech is merely one of scope: the same parameters are adjusted to either highlight a single element in an utterance (focus marking) or all the elements in an utterance (clear speech). To explore this idea we investigated the acoustics and jaw kinematics of producing color terms in either a casual style, a clear speech style, or with contrastive focus. Preliminary acoustic results indicate that clear speech lengthening is greater than focus-marking lengthening in some speakers. These same speakers also vary f0 more when contrastively focusing color terms than when producing them clearly, though this effect interacts with phrase position. Focused and clearly produced color terms are similarly hyperarticulated relative to casually produced terms. The results suggest that most speakers have different parameter settings for prosodic highlighting than for clear speech.

2aSC33. Acoustic correlates of rhythm in Western Cham. Kaori Ueki (Dept. of Linguist., Univ. of Hawaii, 1890 East-West Rd., Honolulu, HI 96822, kueki@hawaii.edu)

Chamic languages, which are part of the Austronesian language family, are generally known to bear lexical stress on final syllables [Thurgood, (2005)] but no instrumental studies of its prosodic features have been carried out. The current study seeks quantitative results to back up these impressionistic descriptions, and to examine how this language compares against the prosodic typology in June 2005. Syllable rimes of Western Cham, an understudied Chamic language, were measured for duration with respect to position of syllable within a phrase (initial, medial, final). The study shows that durations for final syllables were significantly longer, and that unstressed syllables are reduced in all positions. Preliminary results show that durations and pitch excursions of syllable rimes do not differ markedly with respect to phrasal position. Interactions of pitch and duration at lexical and postlexical levels will also be discussed.

2aSC34. Boundary- and prominence-related lengthening and their interaction. Argyro Katsika (Dept. of Linguist., Yale Univ., 370 Temple St., New Haven, CT 06520, argyro.katsika@yale.edu)

The durational effects of prosodic boundaries and prosodic prominence are well known, but their interaction is less well-understood. Recent studies in English [Turk and Shattuck-Hufnagel (2007); Byrd and Riggs (2008)] indicate that the two effects might be interdependent. Two acoustic experiments are presented, examining the role of boundary- and prominence-related lengthening and their interaction in Greek. The first experiment explores the effects of boundary-adjacent lengthening (conditions: no boundary, intermediate phrase, intonational phrase) and prominence (on the first, second, and third syllable away from the boundary). The second experiment examines these same effects, but post-boundary. Data from eight speakers were collected. The results from five speakers are presented. Results show that pre-boundary, both prominence and boundary have an effect on segment duration. Two prosodic levels (the level of word and one higher level) are distinguished. Furthermore, for two speakers, there is an interaction effect, such that three prosodic levels are distinguished when the prominent syllable is boundary-adjacent. The post-boundary condition shows less systematic results, with different speakers exhibiting different patterns.

These results suggest that prosodic effects are speaker dependent, more stable pre-boundary, and that prominence and boundaries interact, increasing prosodic boundary marking. Implications for models of prosodic structure are discussed.

2aSC35. Real-time MRI tracking of articulation during grammatical and ungrammatical pauses in speech. Vikram Ramanarayanan (Speech Anal. and Interpretation Lab., Dept. of Elec. Eng., RTH 320, 3710 McClintock St., Univ. of Southern California, Los Angeles, CA 90089, vramanar@usc.edu), Erik Bresch, Dani Byrd, Louis Goldstein, and Shrikanth S. Narayanan (Univ. of Southern California, Los Angeles, CA 90089)

Grammatical pauses in speech generally occur at a clause boundary, presumably due to parsing and planning; however, pausing can occur at grammatically inappropriate locations when planning, production, and/or lexical access processes are disrupted. Real-time MRI of spontaneous speech production (responses to queries like "tell me about your family," etc.) was used for seven subjects to examine the articulatory manifestations of grammatical and ungrammatical pauses (manually classified as such by two experimenters depending on the presence/absence of a clausal juncture). Measures quantifying the speed of articulators were developed and applied during these pauses as well as their immediate neighborhoods. Results indicate a consistently higher articulatory speed and spatial range for grammatical compared to ungrammatical pauses, and an appreciable drop in speed for grammatical pauses relative to their neighborhoods, suggesting that higher-level cognitive mechanisms are at work in planning grammatical pauses. On the other hand, ungrammatical pauses show only a slight decrease in articulator speed at the pause but are followed by a spurt in speed immediately after, suggesting that the planning mechanism has been reengaged only at that point, giving an indication of how much time it takes to "recover" from the perturbation of the linguistic structural integrity of the utterance. [Work supported by NIH.]

2aSC36. A corpus search methodology for focus realization. Jonathan Howell and Mats Rooth (Dept. of Linguist., Cornell Univ., 203 Morrill Hall, Ithaca, NY 14853-4701, jah238@cornell.edu)

We describe a methodology for investigating the semantic-grammatical conditioning and phonetic realization of contrastive intonation using a web harvest of particular word strings followed by grammatical and acoustic analysis. A commercial audio web search engine using speech recognition retrieved 179 MP3 files purportedly containing a token of the string "than I did." In this comparative clause fragment, contrastive focus commonly falls on the subject (she did more than I_F did), on "did" (I wish I had done more than I did_F), or following (I said more now than I did $before_F$). The 96 true tokens of "than I did" were classified into the categories "subject," "did," and "following" by grammatical and semantic criteria. For each token, 5 segment intervals were hand-annotated and more than 300 acoustic parameters extracted using a Praat script. SVM machine learning classifiers were trained that identify focus classes by acoustic criteria. On a 10-fold cross-validation test, the classifier achieves 90.2% accuracy in discriminating the dominant "subject" and "following" classes. In a listening task, human subjects achieved comparable accuracy of 90.3‘ given only the acoustic target "than I did." Stepwise logistic regression revealed measures of duration, *f*0, intensity, formants, and formant bandwidths among the significant factors.

2aSC37. Prosodic planning: Local and distant effects of phrase length on pause duration. Jelena Krivokapic (Dept. of Linguist., Yale Univ., 370 Temple St., Rm. 302, New Haven, CT 06511, jelena.krivokapic@yale.edu)

Prosodic boundaries, as manifested in pause duration, are known to be influenced by structural properties of the phrases immediately preceding and following the boundary, such as their syntactic structure, prosodic structure, and phonological length. Little is known, however, about how phrases at a distance from a boundary, i.e., not immediately preceding or following it, may affect the durational characteristics of pausing at that boundary. An experiment is presented that investigates the effects on pause duration of prosodic phrases of different length, both immediately at the boundary and farther away from it. The goal is to (a) examine local and distant effects of prosodic phrase length on pause duration and (b) to examine incrementality in production of prosodic structure, i.e., to examine how far ahead speakers plan an utterance, and how prosodic structure affects the planning process. Subjects read 24 English sentences varying along the following parameters: (a) length in syllables (two or four syllables) of the intonational phrase immediately following a target pause and (b) length in syllables of the second, distant, intonational phrase following the pause (10 or 16 syllables long). The synchronous speech paradigm [F. Cummins (2002); E. Zvonik, F. Cummins (2002)] was used to minimize variability in production.

2aSC38. Duration and fundamental frequency patterns in Brazilian Portuguese polysyllabic words. Pablo Arantes and Plinio Barbosa (Dept. of Linguist., Campinas St. Univ., PO Box 6045, Campinas, SP, Brazil 13083-970, parantes@fastmail.fm)

Brazilian Portuguese polysyllabic words are said to have secondary stress (SS). There is no clear consensus, though, on how SSs are assigned and what the acoustic correlates for SSs are. We analyzed a corpus of read speech in order to gain some insight on those two issues. The corpus' target words have 2 to 4 pre-stressed syllables with primary lexical stress falling either on the last or penultimate syllable. Target words appeared in initial, medial, or final position on carrier sentences. Previous works showed that duration and F0 are the main correlates of stress marking in BP with a marginal contribution of vowel quality and spectral emphasis. Statistical analysis of normalized (*z*-scored) syllable and vowel-to-vowel duration show no evidence of binary alternation. Duration increases exponentially up to the stressed syllable. A Praat script was used to determine global and local F0 maxima and minima. Lexically stressed syllables have F0 peaks associated with them. There is at most one F0 peak on the pre-stressed syllable chain. Peaks tend to be higher in 4-pre-stressed-syllable words and be absent in 2-pre-stressed-syllable words. Target word position do not have a significant effect on duration contour shape and on F0 peak placement.

2aSC39. Rhythmic structures in content word untterances. Joo-Kyeong Lee (Dept. of English Lang. and Lit., Univ. of Seoul, 90 Jeonnong-dong, Dongdaemun-gu, Seoul, 130-743, Korea) and Sunmi Kang (Korea Univ., Seoul, 136-701, Korea)

This study investigates rhythmic structures in the utterances composed of only content words. Content words are potentially accentable in utterance, and English necessitates a rhythmic alternation between strong and weak beats. What will happen if only content words are sequenced and they are all one-syllable words? A phonetic experiment was conducted to see if a rhythmic pattern is still produced in content word utterances and how it is manifested along the intonational contours. Results showed that merely 7% of the utterances were produced with every content word accented. Most utterances were rhythmically produced with every two (38%) or three (26%) words accented, and the other patterns such as a H^* and L^* alternation, two H^*'s intervened with L-, and consecutive downstepped H^*'s were interpreted as conforming the tonal rhythm [J.-K. Lee and S. Kang, Korean J. Speech Sci., **10**(2), 303–317 (2003)]. In two-syllable content word utterances, the patterns where two words were unaccented suggest that strong and weak rhythmic beats should be counted with the number of words rather than syllables at the level of utterance. It is proposed that it is an accentual foot as opposed to a lexical foot at the level of lexical word.

2aSC40. The production of English lexical stress by Thai speakers. Jirapat Jangjamras and Ratree Wayland (Program in Linguist., Univ. of Florida, Box 115454, Gainesville, FL 32611-5454, jirapat@ufl.edu)

The major goal of this work is to report acoustic correlates of English lexical stress produced by native and second language learners of American English. Fifteen native Thai speakers and fifteen native English speakers were asked to concatenate two English monosyllabic nonwards into one disyllabic word and to produce stress on either the first or the second of the resulting disyllables. Disyllabic English nonwords were constructed by pairing CVO, CVVO, CVV, CVS, and CVVS monosyllables. It is predicted that Thai speakers' production of English lexical stress will be influenced by Thai prosodic system including Thai tonal distribution rules which are constrained by syllabic structure, the presence of fixed final-stress placement, and the use of duration as the primary cue in L2 English lexical stress production. The acoustic parameters measured included vowel duration, intensity, fundamental frequency, and formant frequencies (F1, F2, F3). The ratio values of these measurements between stressed and unstressed syl-

lables will be correlated with stress identification scores obtained from native English listener judges to examine the amount of acoustic information required for accurate perception of stress location by native listeners.

2aSC41. Formant frequency development and gender differences in Mandarin-learning children before 5 years of age: A longitudinal analysis. Li-mei Chen (Dept. of Foreign Lang. and Lit., Natl. Cheng Kung Univ., 1 University Rd., Tainan City, Taiwan, leemay@mail.ncku.edu.tw)

This study is designed to investigate the longitudinal developmental process of vocalic production in Mandarin-learning children from birth. This current study focuses on the fifth year and the continuity in the process. Major findings are: (1) From three years and six months, the boy subject showed lower vowel formant values, reflecting gender differences in the development of vocal tract. In addition to three years and six months, there was another stage of decrease of frequency at four years and six months in the boy subject. The trend was especially evident in F2 values. (2) The girl subject used more high front rounded vowels /y/, which is the only late-acquired single vowel. (3) Corner vowels /i, u/ were used more often by the girl subject. (4) Diphthongs continued to show high frequency of occurrence at this stage. (5) The frequency of vowels with nasal endings showed prominent increase at this stage in both genders. However, the girl subject showed more preference in using this vowel category as was found in a previous stage. Gender differences in vowel development found in this stage can be traced in the following longitudinal observation. [This investigation was supported through funds from National Science Council in Taiwan, Republic of China (NSC 96-2411-H-006 -023).]

2aSC42. Effects of speaker gender on voice onset time in Korean stops. Eunjin Oh (Dept. of English Lang. and Lit., Ewha Womans Univ., 11-1 Daehyun-dong, Seodaemun-gu, Seoul 120-750, South Korea, ejoh@ewha.ac.kr)

Several studies have shown that the voice onset time (VOT) of English stops varies as a function of speaker sex. The overall trend indicates that females exhibit longer VOT values than males for voiceless stops. The suggested explanations have mainly attributed this difference to physiological or stylistic differences between the sexes. If this is so, we would expect to find identical sex differences in the VOTs of stops in other languages. This study tested 38 native speakers of Korean (19 males and 19 females), who produced fortis, lenis, and aspirated stops in /CVn/ words. The males tended to exhibit longer VOTs than females for most of the syllables, the greatest differences occurring in aspirated stops. The males also exhibited more distinctive distributions in VOT values than the females in Korean. These results indicate that the physiological or stylistic explanations previously suggested are not tenable since there is no automatic reason why VOT values for voiceless stops are, in general, longer for females in English, but longer for males in Korean. Sociophonetic factors may explain why languages can exhibit opposing trends in gender differences in temporal acoustic properties such as VOTs.

2aSC43. Variation in the phonetic realization of Thai lexical tones across speaking styles. Donruethai Laphasradakul and Ratree Wayland (Program in Linguist., Univ. of Florida, Gainesville, FL 32603)

Thai is a tonal language with five contrastive tones: mid-falling, low-falling, high-falling, high-rising, and low falling-rising. Previous literature has shown that the acoustic realization of Thai lexical tones, namely their fundamental frequency or F0, is affected by the phonetic contexts in which they are produced. For example, in connected, conversational speech, Zsiga [(2006)] found that F0 contours of Thai tones produced in phrase-final position are different from those produced in non-phrase-final position. Context-dependent variation in F0 contours among lexical tones in Thai was also noted in Luksaneeyanavin [(1983)]. The main aim of this research was to further investigate F0 variations across the five lexical tones in Thai. Ten native Thai speakers (5 males and 5 female) were asked to produce Thai words in two speaking styles: slow, careful reading style; and fast, conversational style. Preliminary analyses revealed that: (1) the high-falling tone exhibited the highest degree of variation; (2) a greater amount of variation was observed among female speakers than among male speakers; and finally (3) a greater amount of variation was observed in open syllables than in closed syllables.

2aSC44. Quantifying the time-varying coordination between performer and audience. Adriano Barbosa (Linguist., Univ. of British Columbia, 2613 West Mall, Vancouver, BC, Canada, V6T 1Z4, adriano.vilela@gmail.com), Kevin G. Munhall (Queen's Univ., Kingston, ON, Canada, K7L 3N6), Hani C. Yehia (CEFALA, UFMG, Belo Horizonte, MG 31270-901, Brazil), and Eric Vatikiotis-Bateson (Univ. of British Columbia, 2613 West Mall, Vancouver, BC, Canada, V6T 1Z4)

This study examines the coordination that occurs ubiquitously during behavioral interaction (e.g., linguistic, social, musical). Coordination, however, does not imply strict synchronization. Musicians in a quartet, for example, will deviate slightly from the measured beat, alternately playing slightly ahead or behind. This paper showcases a new algorithm for computing the continuous, instantaneous correlation between two signals, at ANY temporal offset, resulting in a two-dimensional mapping of correlation and temporal offset that makes it possible to visualize and assess the time-varying nature of the coordination. The algorithm is demonstrated through analysis of the extraordinary performer-audience coordination evoked by Freddie Mercury during the rock group, Queen's, Live Aid Concert at Wembley Stadium in 1985.

2aSC45. Perception of intonation as a function of sex. Yu-Wen Chen and Peter J. Watson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr. SE, Shevlin 115, Minneapolis, MN 55455)

Fitzsimons *et al.* [M. Fitzsimons, N. Sheahan, and H. Staunton, Brain Lang. **78**, 94–108 (2001)] reported differences in the production of intonation between men and women during speech production. A relationship between the production and perception of segmental variables has been recognized [J. Perkell *et al.*, Speech Commun. **22**, 227–250 (1997)]; however, little information is available about the relationship of prosodic perception and production. Five men and five women listened to sentences produced by one man and one woman. The fundamental frequency (F0) of each sentence was resynthesized with 22 levels of F0 variation ranging from no variation to F0 variation that was 3.5 times greater than the typical variation of a sentence. For each sentence, a listener was randomly presented one of the levels of F0 variation and asked to adjust variation up and down until they were satisfied that the variation of that sentence sounded the most "natural." Additionally, each subject read a set of sentences aloud, and the F0 variation of these productions was analyzed. Results will be discussed in relation to the production and perception of intonation within and between the men's and women's groups.

2aSC46. Perceived sexual orientation and speech style: A perceptual and acoustic analysis of intentionally clear and conversational speech. Benjamin Munson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr., Minneapolis, MN 55455, munso005@umn.edu), Sarah Hargus Ferguson, and Catherine L. Connealy (Univ. of Kansas, Lawrence, KS 66045)

Munson *et al.* [Journal of Phonetics (2006)], found a correlation between perceived speech clarity and perceived sexual orientation (PSO) of male talkers: those who had been rated to sound gay were rated by an independent group to produce speech clearly. A smaller, opposite influence was found for women talkers. Munson *et al.* hypothesized that gay male speech styles might be based, in part, on clear speech styles. One weakness of Munson *et al.*'s study was that none of the speech examined was intentionally clear. This study follows up on this finding. A new group of 29 listeners rated the PSO of four men and four women producing conversational and intentionally clear speech, recorded as part of a larger study on interspeaker differences in talker intelligibility. PSO was rated using a five-point scale. Speech style had a moderate, statistically significant influence on PSO. In contrast with previous research, both men and women were rated as gayer-sounding when producing clear styles than when producing conversational ones. The differences in mean ratings were small. This investigation, thus, partly sup-

ports Munson *et al.*'s findings. The relatively small influence of speech style on PSO likely reflects the complex, content-dependent nature of gay speech styles and PSO.

2aSC47. Sexuality and personality: The effect of pitch height and contour width on perception in Japanese. Margaret Camp (Dept. of East Asian Stud., Learning Services Bldg., Rm. 102, Univ. of Arizona, 1512 First St., P.O. Box 210105, Tucson, AZ, 85721-0105, mcamp@arizona.edu)

This work investigates how Japanese listeners judge a speaker's personality characteristics and sexual orientation. Base sentences, produced in Japanese by a male and a female native Japanese speaker, were resynthesized to manipulate specific acoustic characteristics believed to influence perceived sexual orientation or personality. Overall, the higher the fundamental frequency (f0) of the female voice, the less likely it was to be perceived as lesbian. Similarly, the flatter the intonation pattern of the female voice, the more likely it was to be viewed as lesbian. For male voices, the higher the f0, the more likely the voice would be perceived as gay. Pitch variability did not play a significant role in this perception. Finally, out of the four personality scales investigated, two showed a significant correlation to lesbian voices: masculinity and calmness. Male voices showed the same pattern, with gay voices correlating with femininity and emotionality. The influence of the sex of the listener was also investigated, but male and female listeners appear to make similar judgments about most, but not all, characteristics.

2aSC48. An acoustic analysis of /æ/ variation and its relationship to perceived sexual orientation in American English. Benjamin Munson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr., Minneapolis, MN 55455, Munso005@umn.edu), Kathleen Currie Hall, and E. Allyn Smith (Ohio State Univ., Columbus, OH 43210)

Munson *et al.* [J. Phonetics (2006)] found that 11 self-identified gay and 11 heterosexual men produced different variants of the vowel /æ/, with gay men producing lower, more retracted variants and heterosexual men producing higher, more tense variants. Listeners' performance in a perception task in which they rated these talkers' sexual orientation was correlated with these measures: talkers with higher, more-tense /æ/ were rated as sounding more heterosexual than talkers with lower, more retracted /æ/. However, Smith *et al.* [New Ways of Analyzing Variation (2008)] found the opposite pattern in an experiment in which listeners rated the sexual orientation of productions by 10 trained talkers of sentences containing either tense or retracted /æ/ variants. A different group of listeners showed the same pattern when rating the /æ/ words excised from these sentences, though these listeners replicated Munson *et al.*'s original finding when presented with the /æ/ words from the original 22 talkers. An attempt to reconcile these findings is made through detailed acoustic analysis of the /æ/ productions in the two experiments. Results underscore the importance of doing careful acoustic analyses in concert with careful phonetic transcription when conducting experiments on perception of social variables and speaker attributes.

2aSC49. Parametrization of *f*0 characteristics of register ("Shiki") in mid-western Japanese dialects. Kenji Yoshida (Dept. of Linguist., Indiana Univ., 1021 E. 3rd St, Bloomington, 47405, keyoshid@umail.iu.edu)

Although the ToBI framework has achieved great success in modeling intonation in various languages, it may not capture the nature of certain aspects of f0 movements. This study models dynamic aspects of *f*0 movement in "pitch register" contrasts observed in mid-western Japanese dialects, called "Shiki" by Japanese dialectologists. An exponential function [f0 = intercept + $b \times$ time $\times \exp(-c \times \text{time})$] was fitted to the observed f0 movement of speakers of two Japanese dialects with Shiki contrasts (Kan'onji and Kishiwada). The results show that the two contrastive Shiki types are clearly discriminated in the 3-D parameter space [intercept = baseline, b = magnitude of f0-excursion, c = inverse of peak timing]. Further analysis revealed that the two contrastive Shiki types are not reliably differentiated by the baseline. The more reliable predictors of Shiki types are the other two parameters that determine f0 movement within a word. The results are more congenial to a "dynamic" definition of Shiki system by Japanese dialectologists [e.g., Uwano, (1988)] and suggests that the analysis of Shiki as an initial f0 target [(High vs. Low, Pierrehumbert Beckman, 1988 for Osaka dialect] should be reconsidered.

2aSC50. Dialect distribution of North American English /r/. Suzanne Boyce (Dept. of Commun. Sci. and Disord., Univ. of Cincinnati, Cincinnati, OH 45267, boycese@email.uc.edu), Mark Tiede (Haskins Lab., New Haven, CT 06510), Kathy Groves-Wright (Cincinnati Veterans Affairs Medical Ctr., Cincinnati, OH 45220), Carol Espy-Wilson (Univ. of Maryland, College Park, MD 20742), Christy Holland, and Kyuran Choe (Univ. of Cincinnati, Cincinnati, OH, 45267)

It is well-known that North American English /r/ may be produced by a number of different tongue shapes. This was first reported in detail by Delattre and Freeman (1968), who examined x-ray data from 46 speakers from various regions of the United States and identified six basic tongue shapes used by speakers of "rhotic" dialects to produce /r/. It is unclear, however, whether different shapes are characteristic of particular dialects or geographic regions, or a matter of individual variation based on anatomy, developmental history, etc. In this study, we review findings from a number of published x-ray and MRI studies of tongue shapes for /r/ using speakers from various dialect regions. In addition, we characterize the variability of tongue shapes used for /r/ in an unpublished x-ray database of elderly men with normal speech from the area of Cincinnati, OH. Results show that distinct tongue shape patterns in /r/ production occur both within and across dialect regions, suggesting the primacy of subject-specific factors over dialectal effects. [Work supported by NIH.]

2aSC51. Pitch accommodation in synchronous speech. Miran Kim (Dept. of Linguist., SUNY at Stony Brook, S201 SBS Bldg., Stony Brook, NY 11720, mrkim@ic.sunysb.edu) and Hosung Nam (Haskins Labs., New Haven, CT 06511)

Synchronously read speech, in which a pair of speakers reads a text together, has been shown to reduce variability in speech tempo and unveil underlying properties of speech competence. Our study question is whether a synchronous speech condition also influences a pitch domain as well as a temporal one, which has been the main focus in studies of synchrony. We investigated how tones are modulated in the synchronous speech condition. Eight speakers of Mandarin Chinese were instructed to read a story text alone and together in pairs. Speakers also read the text together with recorded speech. Each trial was repeated five times. We measured F0 at onset, center, and offset of a resonant period for each syllable and compared read-alone to read-together speeches. Results show that (1) speakers in the synchronous speech condition tend to tune their pitch to each other such that F0 difference in pairs decreases overall; (2) they exhibit less variability in F0 across their own repetitions; (3) tonal targets in the read-together condition are achieved more stably in time. The pitch accommodation found in our study implies that speakers attend to F0 manifestation as well as tempo when F0 changes are phonologically contrastive in their language.

2aSC52. Effects of semantic context and regional dialect variation on speech intelligibility in noise. Cynthia G. Clopper (Dept. of Linguist., Ohio State Univ., 1712 Neil Ave., Columbus, OH 43210, clopper.1@osu.edu)

Speech intelligibility in noise is affected by the semantic content of the utterance; semantically predictable utterances are more intelligible than semantically unpredictable or anomalous utterances. However, dialect variation interacts with semantic predictability in production; talkers produce more dialect-specific variants in semantically predictable contexts and more standard variants in semantically unpredictable contexts. The goal of the current study was to explore the interaction between dialect variation and semantic context in perception. Participants were asked to transcribe the final word of semantically predictable, unpredictable, and anomalous sentences produced by talkers from four regional dialects of American English and mixed with speech-shaped noise. The listeners exhibited an intelligibility benefit in the predictable context relative to the other two semantic contexts, regardless of talker dialect. However, differences in intelligibility between the dialects were reduced in the unpredictable and anomalous contexts relative to the predictable context, suggesting greater online adaptation to dialect variation in the unpredictable and anomalous contexts than the predictable context. These results are consistent with the finding that dia-

lect differences may be attenuated in production in low predictability contexts, and suggest that perceptual dialect adaptation is affected by fine-grained intratalker acoustic variation.

2aSC53. Investigating perceptual measures of speech alignment: Do matching tasks make the grade? Rachel M. Miller, Kauyumari Sanchez, and Lawrence D. Rosenblum (Dept. of Psych., Univ. of California, Riverside, 900 University Ave., Riverside, CA 92521)

Speech alignment is the tendency to produce speech which sounds similar to that of a person with whom one is speaking. It is often measured perceptually using an AXB-matching task [e.g., S. D. Goldinger, Psychol. Rev. **105**, 251 (1998)]. In this procedure, naïve raters determine which of two utterances of a talker, produced prior (baseline) and after interaction with a model (e.g., shadowed), sounds more similar to that model. However, utilizing this type of perceptual measure has come under scrutiny due to its reliance on baseline utterances produced by talkers reading text. It has been suggested that AXB matching results reveal more about inherent differences between read and produced (shadowed) speech, than actual alignment. The present research addressed this concern. Experiment 1 involved a modified AXB task for which raters judged whether a subject sounded more like the model they had shadowed or another model. In Experiment 2, raters judged whether a subject sounded more similar to the model they had shadowed or to another subject who shadowed a different model. In both cases, results revealed that subjects sounded more similar to the model they shadowed. This suggests that alignment is perceivable by raters even when removing the comparison to read text. [Work supported by NIDCD Grant R01DC008957.]

2aSC54. Identification of synthetic vowels based on time-varying vocal tract area functions. Kate Bunton and Brad H. Story (Dept. of Speech, Lang., & Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721)

Identification accuracy for synthetic vowel stimuli generated with static vocal tract area functions from eight speakers was recently reported (K. Bunton and B. H. Story, JASA, in press). Although vowels were identified with reasonably high accuracy, in many cases neighboring vowels were confused. In the present study, new stimuli were generated based, again, on area functions from the same eight speakers. This time, however, the temporal variation of the vocal tract shape during natural production of isolated vowels was incorporated by developing a formant-to-area mapping for each speaker based on principal components analysis. This allowed formant contours extracted from recorded vowels to be mapped onto time-varying area functions. These were coupled to a voice source model and acoustic waves were propagated with a wave-reflection vocal tract model to generate vowels. Vowels were identified by listeners using a forced choice paradigm. Results indicated that including variation in vowel tract shapes, and hence formant frequencies, along with natural vowel durations improved identification accuracy relative to the previously tested static versions. It is concluded that these eight sets of area functions generate good renditions of target vowels when changes in vocal tract shape and duration were included. [Research supported by NIH R01-DC04789.]

2aSP1. Passive detection in deep water using the reliable acoustic path. Lisa M. Zurk (Elec. & Comp. Eng. Dept., Portland State Univ., PO Box ECE 751, Portland, OR 97201, zurkl@pdx.edu)

The detection of quiet targets in deep water environments is of increasing interest for Navy applications, and detection performance depends critically on efficiently exploiting the frequency-dependent signal and noise structure. Previous measurements in the deep ocean environment of the northeast pacific has demonstrated the significant depth and frequency dependence of the noise, which can also vary with local wind conditions [Gaul *et al.*, IEEE JOE (2007)]. The signal structure depends both on the spectrum of the target itself, but also on the propagation characteristics of the channel. In the concept of a reliable acoustic path (RAP), a receiver placed at or below the critical depth can detect shallow sources out to moderate ranges independent of near-surface water conditions or bottom interaction (hence, the identification as a "reliable" path). In this presentation, we present analysis of noise and signal structure for deep water channels from historic data, propagation modeling, and more recent experimentation. This structure is then used to compute signal excess to quantify detection performance as a function of receiver array placement and topology. Implications of the results on future Navy systems is discussed.

8:50

2aSP2. Enhancing passive automation performance using an acoustic propagation simulation. Ashley J. Llorens, Trudy L. Philip, Iman W. Schurman, and Cory R. Lorenz (Natl. Security Technol. Dept., JHU/APL, 11100 Johns Hopkins Rd., Laurel, MD 20723, ashley.llorens@jhuapl.edu)

During an at-sea encounter, signatures of interest can exhibit characteristics that differ from those observed in previously recorded data. These differences can occur due to variations in a number of factors including encounter geometry, propagation channel, and receiving sensor configuration. This paper presents a simulation technique that imposes low-frequency propagation effects on a time-domain signal using a normal mode method. High-quality, time-varying recorded signatures are used as inputs into the algorithm, which outputs band-limited time-series data for a selected geometry and environment. The output time-series are phased to simulate the time-varying pressure amplitudes that would be received by a towed array or any multielement passive sensor configuration operating in a realistic multipath environment. These capabilities enable the simulation of signatures of interest as captured under a broad range of littoral conditions by various passive sensors. These simulated data are used to augment scarce signature collections for training and assessing the performance of passive sonar automation.

9:10

2aSP3. Underwater target detection and classification using high resolution sensors and wide band sonar. Yvan Petillot, Yan Pailhas, Chris Capus, and Keith Brown (Oceans Systems Lab., Heriot-Watt Univ., UK)

In this presentation, our work on integrated target detection and identification using sonar systems is presented. Standard high-resolution imaging sonar such as side scan and synthetic aperture are used for detection. Existing methods focus on statistical techniques using Markov models and machine learning-based techniques. Results on both synthetic and real data acquired in a large variety of terrains are presented. Identification can be based on either the shape of the target or its internal structure. Techniques-based active contours for shape analysis have been developed but these techniques only work well on very high-resolution data such as SAS and can be difficult to use on cluttered terrain. We propose to use the wide-band bio-sonar we developed to perform this task. In that case, the analysis focuses on the resonances induced by the internal structure of the target and the material used. Simulation confirmed by theoretical analysis on simple targets and experimental results demonstrate the effectiveness of this approach. These techniques are integrated on real vehicles in a collaborative vehicle framework to perform detection, classification, and identification of targets. [This work was supported by Thales, The Ministry of Defence, and the European Union under contract MRTN/CT/2006/036186.]

9:30

2aSP4. What do cognitive models and human judgments suggest about the desired structure of automatic classifiers? Jason E. Summers (SAIC, 10401 Fernwood Rd., Ste. 120, Bethesda, MD 20817-1133), Charles F. Gaumond, Colin W. Jemmott, and Derek Brock (Naval Res. Lab., Washington, DC 20375-5320)

Past studies probed human listeners' efficacy at classification of impulsive sonar echoes by using paired-comparison ratings to measure perceptual dissimilarity. Interpreting these ratings requires a cognitive model comprising both a representation of the stimuli and a process operating on that representation. Initially, perceived dissimilarities were represented as distances in Euclidean space via multidimensional scaling. This assumed a continuous and spatial cognitive representation and proved difficult to relate to a linear vector space of features. Later work by the authors suggested a discrete (categorical) cognitive representation may better reflect perception of these stimuli. While similarity-based classifiers can bypasses feature extraction [S. Philips and J. Pitton, J. Acoust. Soc. Am. **123**, 3344 (2008) (A)], the form of the similarity measure reflects the assumed cognitive representation [L. Cazzanti and M. R. Gupta, Proc. IEEE Intl. Symposium Info. Theory, pp. 1836–1849 (2006)]. Here, findings based on paired-comparison ratings and verbal descriptions of stimuli are discussed in terms of the cognitive models they reflect and implications for classifier architecture: the form of similarity measures, whether features are continuous or discrete, and whether features are common to all classes. [Work supported by the Office of Naval Research.]

2aSP5. A generalized linear filtering approach for sonar receivers. Nabin S. Sharma and John R. Buck (Dept. of ECE, Univ. of Massachusetts Dartmouth, 285 Old Westport Rd., North Dartmouth, MA 02747, nsharma2@umassd.edu)

Active sonar systems operating in realistic environments face the challenge of simultaneously detecting and resolving multiple targets. Receiver signal-to-noise ratio gain and main-lobe width of the receiver response to the transmitted signal limit the detection and resolution capability of an active sonar receiver, respectively. A matched filter is commonly used for target detection to exploit its optimal detection property. Theoretically, an inverse filter achieves optimal resolution and can be used to resolve targets. In practice, the inverse filter is difficult to implement and requires unrealistically high signal-to-noise ratio to perform well. For an active sonar receiver operating in a cluttered environment with closely spaced targets, a matched filter might not resolve some targets and an inverse filter could not detect some targets. For such environments, a generalized linear filtering approach is proposed. This new approach combines the matched and inverse filter properties in a controlled manner to achieve smooth trade off between detection and resolution. In simulation, the generalized linear filter output is compared with the matched and inverse filter outputs to demonstrate the advantages of the proposed filter. In addition, receiver operating characteristics of the filters confirm the improved performance of the generalized linear filter. [Work funded by ONR Code 321US.]

10:25

2aSP6. Pulse propagation and classification in time/frequency and position/wave number phase space. Patrick Loughlin (Depts. of Bioengineering and ECE, Univ. of Pittsburgh, 745 Benedum Hall, Pittsburgh, PA 15261, loughlin@pitt.edu)

In dispersive pulse propagation, different frequencies travel at different velocities, and, hence, the pulse is nonstationary in that it changes over time and distance. Joint phase space representations, such as the Wigner distribution and the spectrogram, are often employed to study nonstationary signals, and, hence, it is natural to consider their application to dispersive propagation. We consider position/wave number and time/frequency representations of a pulse propagating with dispersion and damping. We give the

Wigner distribution of the pulse at a particular time/position in terms of the Wigner distribution of the initial pulse. Approximations of this result are derived, which are accurate and remarkably simple to apply, as compared to the stationary phase approximation. The approximations provide insights as well, in that they show how each point in phase space propagates at the group velocity, and lead to new features for classification, based on local phase space moments, that are invariant to the propagation effects of dispersion and damping. Examples relevant to sound propagation and classification in shallow water are presented. [Work supported by ONR Grant No. N00014-06-1-0009.]

10:40

2aSP7. Krylov methods in time-reversal imaging by multiple-signal-classification. Paul E. Barbone (Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, barbone@bu.edu), Assad A. Oberai (Rensselaer Polytech. Inst., Troy, NY 12180), and Gonzalo R. Feijóo (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Multiple signal classification (MUSIC) has been used to form images and identify sound sources since 1986 [R. O. Schmidt, "Multiple emitter location and signal parameter estimation," IEEE Trans. Antennas Propag., **AP-34**, 276–280 (1986)]. In active sonar imaging of point targets, the MUSIC method can be used to estimate the range of the time-reversal operator. In this context, the method is related to the decomposition of the time-reversal operator method. Typical implementations of these methods utilize measurements of the entire time-reversal operator, and require computations of its eigenvalues and eigenvectors. By contrast, we show that Krylov iterative methods can be used to perform MUSIC imaging with relatively few acoustic excitations. Furthermore, by using the Lanczos technique, no eigenvalues or eigenvectors need be computed. Rather, an orthonormal basis for the range space of the time-reversal operator can be constructed directly from the received data. Most of the necessary computing is performed by the array itself, performing as a kind of "analog computer." Finally, we show that useful images can be formed from one iteration to the next, while the data are being collected.

10:55

2aSP8. Automatic classification of underwater targets using fuzzy-cluster-based wavelet signatures. Hui Ou (Dept. of Elec. Engr., Univ. of Hawaii at Manoa, 2540 Dole St., Honolulu, HI 96822, ou@hawaii.edu), John S. Allen, III, and Vassilis L. Syrmos (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

A novel active acoustic underwater target recognition approach is applied to simulated mine-like targets. A feature extraction and integration method is introduced based on the continuous wavelet transform (CWT) and the Gustafson-Kessel (GK) clustering algorithm. CWT projects the acoustic signals onto the time-scale space, and the time-scale signatures are represented by a number of clusters. A modified GK clustering algorithm allows for specific enhancements: (i) autoadjustment of the shape of the clusters according to the time-scale patterns and (ii) autovalidation of the optimum number of clusters. The feature integration encompasses the application of the clustering analysis N times. The resulting cluster centers are combined and overlaps are eliminated. Using this method, the target of interest is characterized by an integrated clustering distribution, or a feature template. A classification scheme is developed by matching the clustering distributions of the echoes received from an unknown target with the existing feature templates. White Gaussian noise has been added to the signals to simulate the interface of an ocean floor. The recognition rate varies from 72–98% for a SNR between 5–15 dB.

11:10

2aSP9. Distributed detection and estimation based on the turbo approach. Michael Roan and Elizabeth Hoppe (Mech. Eng., Virginia Tech., 141 Durham Hall, Blacksburg VA 24060)

We develop a centralized information fusion architecture from basic principles of information theory and Bayesian statistics. It is well known that any clustering, quantizing, or thresholding of data causes loss of information unless a sufficient statistic is computed in the processing. For the case of wideband active ranging systems, the coherent output of an optimum beamformer and a matched filter is a sufficient statistic that can be transmitted to the fusion center. For unknown target velocity, range, and bearing, the wideband space-time matched filter output can be interpreted as a multidimensional wavelet transform or a delay-scale-bearing map. In this paper, an iterative, Bayesian, joint estimation-detection approach is used for computation of sufficient statistics and multisensor information fusion. An approach borrowed from sequential Bayesian processing is used to compute prior densities for joint Bayesian estimation-detection. In this approach *a posteriori* densities become priors after a coordinate transformation that transforms the outputs of each sensor to a common reference frame for all sensors. In this paper, receiver operating characteristics and Cramer–Rao lower bounds are given for several undersea signal processing cases of interest.

11:25

2aSP10. Variational Bayesian particle filtering for underwater target localization and tracking. T. Scott Brandes, Nilanjan Dasgupta, and Lawrence Carin (Signal Innovations Group, Inc., 1009 Slater Rd., Ste. 200, Res. Triangle Park, NC 27703)

Kalman filtering methods used in target tracking applications fail to perform satisfactorily when the true underlying posterior density of a target's location is non-Gaussian. These circumstances arise often in highly noisy environments dominated by strong scattering returns from clutter. Advanced tracking approaches, such as particle filters (PFs), that do not have the linear and Gaussian requirements of Kalman filtering are needed for target tracking in those complex environments. We used a variational Bayesian (VB) particle filter in our research to accurately track underwater targets simulated for such regimes. Particle filters rely on a Monte Carlo method of approximating the posterior distribution of an underwater moving target's location by a weighted set of sample points (particles) that evolve in time with the target. Variational Bayesian inference uses a Monte Carlo approach to estimate a distribution of the parameters of the posterior through a series of converging approximations. Our VB approach is shown to outperform the standard PF in both an active system (target tracking) and a passive system (source localization) in simulations.

Session 2aUW

Underwater Acoustics and Acoustical Oceanography: Mid- to High-Frequency Propagation and Scattering with Application to Underwater Communications

Mohsen Badiey, Cochair
College of Marine and Earth Sciences, Univ. of Delaware, Newark, DE 19716-3501

Daniel Rouseff, Cochair
Applied Physics Lab., Univ. of Washington, Seattle, WA 98105-6698

Chair's Introduction—8:00

Invited Papers

8:05

2aUW1. The dependence of the intensity of surface scattered signals on surface wave characteristics. James Preisig (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, jpreisig@whoi.edu), Grant Deane (Univ. of California, La Jolla, CA 92093), and Chris Tindle (Univ. of Auckland, Auckland, New Zealand)

The compensation for the fluctuations in surface scattered signals remains one of the challenges for reliable and high rate underwater acoustic communications systems. Communication using phase coherent signals relies on the ability of the receiver to track the fluctuations in the impulse response of the channel between the transmitter and receiver. Techniques that can exploit *a priori* statistical characterizations of the fluctuations of the arrivals in the channel impulse response (fading statistics) will generally outperform systems that do not have access to such information. While fading statistics in radio communications is generally assumed to be Rayleigh or Rician, prior work [J. C. Preisig and G. B. Deane, J. Acoust. Soc. Am. **116**, 2067–2080 (2004)] has shown that surface wave focusing can significantly change channel fading statistics. The physical basis for the intensity of surface scattered signals for both isolated specular scattering points and caustics developed in [C. T. Tindle and G. B. Deane, J. Acoust. Soc. Am. **117**, 2783–2794 (2005)] relates intensity to ray geometry parameters. In this work, surface wave characteristics are related to both the source to receiver ranges at which normal focused specular scattering and caustics will occur and to the intensities of the surface scattered arrivals in each case. Experimental data are presented comparing theoretically predicted and measured intensities.

8:25

2aUW2. Channel simulation for predicting acoustic modem performance. Michael B. Porter, Paul Hursky (HLS Res., 3366 N. Torrey Pines Ct., Ste. 310, La Jolla, CA 92037, mikeporter@hlsresearch.com), and Martin Siderius (Portland State Univ., Portland, OR 97207)

Acoustic modems usually provide the link in modern Distributed Netted Systems. However, their performance is strongly affected by the ocean weather as both the propagation medium and the source of background noise. Understanding these effects is important in pre-experiment planning, real-time adaptation, and retrospection (to ensure appropriate lessons are learned for future deployments). To this end, we have developed a channel simulator called VirTEX (Virtual Timeseries Experiment) that includes Doppler effects due to platform and ocean surface dynamics. VirTEX, in turn, is a component of the AComms Advisor, which provides links to ocean forecasts and other environmental information and uses HIL (Hardware in the Loop) testing to include a faithful modem simulation. This talk will discuss the process, as well as progress, in the algorithms.

8:45

2aUW3. Synthetic aperture communications exploiting fluctuations of the ocean environment. H. C. Song, W. S. Hodgkiss, W. A. Kuperman, T. Akal (Marine Physical Lab., Scripps Inst. of Oceanogr., UC San Diego, La Jolla, CA 92093-0238), and M. Stevenson (Spawar Systems Ctr., San Diego, CA 92152-5001)

Typically, fluctuations of the ocean environment pose difficulties for high-rate underwater acoustic communications. On the other hand, these fluctuations can be exploited in synthetic aperture communications (SAC) that take advantage of the relative motion between a transmitter and a receiver to create the equivalent of an array aperture. SAC requires that the channel impulse responses are sufficiently different from each other between transmissions for diversity combining to be effective. Rapid channel variations facilitate a shorter interval between transmissions resulting in a shorter integration time to achieve the desired diversity. This paper demonstrates high-rate SAC in shallow water exploiting fluctuations of the ocean environment.

9:05

2aUW4. Coherent communications performance in environments with strong multi-pathing: Model/data comparison. Daniel Rouseff (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105)

Coherent underwater communications is hampered by the time spread caused by multi-pathing and the Doppler spread caused by the rapidly changing shallow water environment. In practice, a time-varying impulse response model will retain only a finite number of paths as useful signal and will be updated to compensate for the changing environment at a finite rate. In the present study, communications performance is examined as a function of the number of retained paths and the model-update interval. Results are quantified in terms of the mean squared error in the soft demodulation output. A physics-based performance model is developed. The model uses as input acoustic quantities like the Rayleigh parameter and environmental quantities like the significant wave height and the dominant period for surface waves. Model predictions for performance are compared to experimental results for data collected near the Hawaiian Island of Kauai. [Work supported by ONR.]

9:20

2aUW5. Ocean variability effects on high-frequency coherent acoustic communications. Aijun Song, Mohsen Badiey (Robinson Hall 114C, College of Marine and Earth Studies, Univ. of Delaware, Newark, DE 19716,), H. C. Song, and William Hodgkiss (Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238)

The variability of the ocean environment can cause fluctuations of acoustic channels and these fluctuations often pose serious difficulties for high rate digital communications. During a series of recent acoustic communications experiments conducted around Kauai Island, Hawaii (KauaiEx'03, MakaiEx'05, and KAM'08), coherent communication data with concurrent environmental measurements were collected under different experimental settings. The variability of the ocean parameters, mainly the water temperature profiles and the sea surface condition, has been studied in order to understand their impact on the performance of acoustic communications at high frequencies (greater than 10 kHz). It is shown that both the long-term (in hours) changes in the ocean volume and the fast fluctuations (in seconds) of the sea surface have impact on the receiver design and on the receiver performance. Using time reversal combining followed by a single channel decision feedback equalizer, the ocean variability effects on the performance of coherent acoustic communications are shown as a function of receiver depth, source depth, and communication range.

9:35

2aUW6. Sonar simulation toolset modeling for underwater acoustic communications and networking. Julia B. Hsieh (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, julia@apl.washington.edu), Daniel Rouseff (Univ. of Washington, Seattle, WA 98105-6698), Aijun Song, and Mohsen Badiey (Univ. of Delaware, Newark, DE 19716)

The sonar simulation toolset (SST) is a ray-based propagation model capable of generating time series realizations with stochastic spreading of acoustic sequences. The model supports varying environments and geometries including moving sources and/or receivers. The simulated data were compared with experimental data collected at the Pacific Missile Range Facility, Kauai, Hawaii in 2003 (KauaiEx2003) and 2008 (KAM08). Models generated with appropriate sound speed profiles and wind speeds are shown to have similar channel impulse response functions to those observed during the experiments. The high-frequency communications sequences simulated from those models have been demodulated to demonstrate analogous results. These results suggest that underwater acoustic communications and networking can be effectively simulated with sonar simulation toolset to aid in experiment planning and data analysis. [Work supported by the Office of Naval Research.]

9:50

2aUW7. Basic research on time-reversal communication with a moving source-receiver. Takuya Shimura, Yoshitaka Watanabe, Hiroshi Ochi (Adv. Marine Tech. R&D Program, JAMSTEC, 2-15 Natsushima-cho, Yokosuka 237-0061, Japan, shimurat@jamstec.go.jp), and Takehito Hattori (Nippon Marine Enterprises, Ltd., Yokosuka 238-0004, Japan)

A basic research on time reversal, to be used for communication with a long cruising AUV, has been researched by our research group. In such application, it is preferred to maintain its cruising speed. However, time reversal does not compensate the effect of moving source-receiver in principle. So in this study, simulations with a normal mode method considering the effect of source-receiver movement are executed in which the carrier frequency is 500 Hz and symbol rate is 100 bps. The method of combining time reversal and adaptive decision feedback equalizer is applied. In both cases of shallow water and the deep ocean, demodulation cannot be realized with only time reversal as expected, while the proposed method achieves communication at the moving speed up to 1.0 m/s.

10:05—10:20 Break

10:20

2aUW8. Impact of bottom type on orthogonal frequency division multiplexing in underwater communications. Nathan Parrish, Sumit Roy (Dept. of Elec. Eng., Univ. of Washington, Seattle, WA 98195-2500, nparrish@u.washington.edu), and Payman Arabshahi (Univ. of Washington, Seattle, WA 98105-6698)

The impact of bottom sediment type in relation to acoustic communications via orthogonal frequency division multiplexing (OFDM) is shown via experimental results and simulation. Experimental data from Lake Washington, Seattle with a "silty clay" bottom show that the multipath delay spread is longer at 250 m than at 4 km. This results in better OFDM performance at the longer range. Similar results are shown via simulation using a channel model developed from Bellhop, a Gaussian Ray tracing tool [M. Porter, "Bellhop Gaussian beam/finite element beam code," Available: http://oalib.hlsresearch.com/Rays/index.html (2007)]. Through simulation, results are also shown under similar conditions to the experiment but with varying bottom type. The results show that the performance of OFDM signaling is dependent on the bottom type as well as specific source/receiver geometry. [Work supported by NASA ESTO.]

10:35

2aUW9. Capacity of orthogonal frequency division multiplexing systems over fading underwater acoustic channels. Chantri Polprasert, James A. Ritcey (Dept. of Elect. Eng., Univ. of Washington, Seattle, WA 98195-2500, ritcey@ee.washington.edu), and Milica Stojanovic (Northeastern Univ., Boston, MA 02115)

The channel capacity bounds of orthogonal frequency division multiplexing (OFDM) systems over the underwater (UW) acoustic fading channel as a function of the distance between the transmitter and receiver are investigated. The upper bound is obtained under perfect channel state information (CSI) assumption at the receiver. The lower bound is obtained under imperfect CSI at the receiver. The reduction from the upper bound is due to the linear minimum mean square prediction error. The UW channel deviates from the wide sense stationary and uncorrelated scattering (WSSUS) model commonly used for small bandwidths. Frequency-selectivity is incorporated due to the acoustic propagation into each arrival path between the transmitter and receiver. This leads the UW channel to be modeled as a frequency-dependent doubly spread fading channel characterized by the wide sense stationary and correlated scattering (WSS-non-US) fading assumption. Both Rayleigh and Ricean fading assumptions are investigated in the model. Results from the model show a gap between the upper and lower bounds that depends not only on the ranges and shape of the scattering function of the UW channel but also the distance between the transmitter and receiver. The model for the scattering function was confirmed from experimental data.

10:50

2aUW10. Multichannel combination investigations for differential frequency hopping transmissions in shallow water. Dianne E. Egnor, Geoffrey S. Edelson (BAE Systems, Advvaned Systems & Technol., P.O. Box 868, Nashua, NH 03061-0868), Luca Cazzanti, and Julia Hsieh (Univ. of Washington, Seattle, WA 98105)

Underwater acoustic communication requires waveforms that are robust to the signal distortions caused by the acoustic channel. Many waveforms used for this purpose require the transmission of training symbols that span the intersymbol interference to "learn" and compensate for these channel effects. These waveforms also require exacting coordination between the transmitters to avoid multiple access interference. Differential frequency hopping (DFH) is a fast frequency hopping, digital signaling technology that requires minimal information at the transmitter to communicate in the underwater channel. DFH has the desirable performance features of noninterfering spread spectrum operation, spectral reuse, and fading and interference resistance. This presentation describes the baseline autosynchronizing, single-user DFH decoder for a multiple hydrophone receiver and investigates two processing techniques incorporated for shallow-water multiuser applications: fading mitigation and multiuser interference mitigation, as implemented in conjunction with array processing. We present the performance of the baseline DFH decoder in terms of bit error rate with and without these enhancements on single- and multiuser data collected at sea during the 2008 Surface Processes and Acoustic Communications Experiment (SPACE08).

11:05

2aUW11. Modeling differential frequency hopping communication in the underwater acoustic channel. Luca Cazzanti, Julia Hsieh (Appl. Phys. Lab., Univ. of Washington, Box 355640, Seattle, WA 98105), Dianne Egnor, and Geoffry S. Edelson (BAE Systems, Nashua, NH 03061)

Differential frequency hopping (DFH) is a fast frequency hopping digital modulation scheme with proven multiple-access and jamming robustness properties in typical wireless channels. Characterizing the capabilities of DFH modulation in the more challenging underwater acoustic channel requires careful analyses that rely on both computer simulations and data collected at sea. The Sonar Simulation Toolkit (SST) is used to model challenging underwater environments and simulate the propagation of DFH waveforms in the corresponding underwater acoustic channels. Our simulations provide baseline performance results that can be used to assess the capabilities of DFH modulation and guide future algorithmic improvements to the receiver. In particular, our simulations show that incorporating equalization techniques into the DFH baseline receiver leads to improved decoding performance in challenging environments characterized by long channel impulse responses, which are known to cause inter-symbol interference in the received acoustic bit stream. To ensure their relevance to practical applications, our computer-based SST models are calibrated to the environmental parameters measured during recent at-sea experiments, including the Rescheduled Acoustic Communications Experiment (RACE08), and the corresponding performance is analyzed.

11:20

2aUW12. Achieving maximum space-time-frequency diversity in shallow water acoustic channels: System design and experimental results. Costas Pelekanakis and Arthur B. Baggeroer (5-206, Ctr. for Ocean Eng., Dept. of Mech. Eng., Massachusetts Inst. of Technol., 77 Massachusetts Ave., Cambridge, MA 02139, gas@mit.edu)

This work sheds light on the individual impact of coded modulation and diversity in achieving reliable underwater acoustic (UWA) communications. Two systems with the same bit-rate and complexity but different diversity order are designed and compared. The "conventional" system combines trellis coded modulation (TCM), symbol interleaving and an 8PSK signal set. The "alternative" or bit-interleaved coded modulation (BICM) system combines a convolutional code, bit interleaving, and a 16QAM signal set. Both systems are coupled with orthogonal frequency division multiplexing (OFDM) to cope with the intersymbol interference (ISI). When two or three projectors are used, the above coding schemes are concatenated with space-time block codes (STBC). Bit-error rates using data recorded during the RACE'08 off the coast of Narragansett, USA are computed demonstrating the superiority of BICM schemes relative to their TCM counterparts over an extensive collection of shallow water channels, thus proving that BICM is a promising technique towards achieving reliable UWA communications. In particular, by using BICM and 4 kHz of bandwidth, we have successfully accomplished a 7150 b/s transmission rate over 1 km range.

11:35

2aUW13. Improving underwater vehicle communication in the littoral zone through adaptive vehicle motion. Toby E. Schneider and Henrik Schmidt (Ctr. for Ocean Eng., Dept. of Mech. Eng., MIT, 77 Massachusetts Ave., Cambridge, MA 02139, tes@mit.edu)

Autonomous underwater vehicles (AUVs) are increasingly being used in clusters to perform detecting and sensing tasks in the littoral zone. These tasks require substantial data throughput between underwater and surface nodes. Acoustic modems provide the only practical means of sending these data, but sound in the littoral waveguide is heavily refracted downward and multiply reflected by the shallow bottom. These effects lead to shadow zones where messages are lost and convergence zones that allow for longer range receipt of high bitrate messages. During the GLINT08 sea trials, messages were sent using a multiple rate 25-kHz acoustic modem (the WHOI "MicroModem") between several undersea and surface nodes. The message quality (mean square error) was analyzed and compared to dynamic ray tracing models of the transmission loss, using environmental data measured by the AUVs and the research vessel. Significant correlation was found between the data and the modeled acoustic field, suggesting that such models could be run on-board the AUVs to predict regions of low transmission loss. This would give the AUVs predictive ability to choose when to send messages to maximize the probability of receipt and the choice adaptively move to improve chances of successful message reception.

Meeting of Standards Committee Plenary Group

to be held jointly with the meetings of the
ANSI-Accredited U.S. Technical Advisory Groups (TAGs) for:
ISO/TC 43, Acoustics,
ISO/TC 43/SC 1, Noise,
ISO/TC 108, Mechanical vibration, shock and condition monitoring,
ISO/TC 108/SC 2, Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures,
ISO/TC 108/SC 3, Use and calibration of vibration and shock measuring instruments,
ISO/TC 108/SC 4, Human exposure to mechanical vibration and shock,
ISO/TC 108/SC 5, Condition monitoring and diagnostics of machines,
ISO/TC 108/SC 6, Vibration and shock generating systems,
and
IEC/TC 29, Electroacoustics

P. D. Schomer, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 43 Acoustics and ISO/TC 43/SC 1 Noise
2117 Robert Dr., Champaign. IL 61821

D. J. Evans, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108 Mechanical vibration shock and condition monitoring, and ISO/TC 108/SC 3 Use and calibration of vibration and shock measuring devices
National Inst. of Standards and Technology, 100 Bureau Dr., Stop 8220, Gaithersburg, MD 20899

W. C. Foiles, Co-Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 2 Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures
BP America, 501 Westlake Park Blvd., Houston, TX 77079

R. Taddeo, Co-Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 2 Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures
NAVSEA, 1333 Isaac Hull Avenue, SE, Washington Navy Yard, Washington, DC 20376

D. D. Reynolds, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 4 Human exposure to mechanical vibration and shock
3939 Briar Crest Ct., Las Vegas, NV 89120

D. J. Vendittis, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 5 Condition monitoring and diagnostics of machines
701 Northeast Harbour Ter., Boca Raton, FL 33431

R. Taddeo, Vice Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 5 Condition monitoring and diagnostics of machines
NAVSEA, 1333 Isaac Hull Avenue, SE, Washington Navy Yard, Washington, DC 20376

C. Peterson, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 6 Vibration and shock generating systems
200 Dixie Ave., Kalamazoo, MI 49001

V. Nedzelnitsky
U.S. Technical Advisor (TA) for IEC/TC 29 Electroacoustics
National Inst. of Standards and Technology, 100 Bureau Dr., Gaithersburg, MD 20899–8221

The reports of the Chairs of these TAGs will not be presented at any other S Committee meetings.

The meeting of the Standards Committee Plenary Group will precede the meetings of the Accredited Standards Committees S1, S3, S3/SC 1, and S12 which are scheduled to take place in the following sequence:

ASC S3, Bioacoustics	**Tuesday, May 19**	**10:30 a.m. - 11:30 a.m.**
ASC S3/SC 1, Animal Bioacoustics	**Tuesday, May 19**	**11:45 a.m. - 1:00 p.m.**
ASC S1, Acoustics	**Tuesday, May 19**	**2:45 p.m. - 3:45 p.m.**
ASC S12, Noise	**Tuesday, May 19**	**4:00 p.m. - 5:00 p.m.**

Please note that ASC S2, Mechanical Vibration and Shock will meet in advance of the Plenary meeting, on Monday, May 18 at 4:30 p.m.

Discussion at the Standards Committee Plenary Group meeting will consist of national items relevant to all S Committees and U.S. TAGs.

The U.S. Technical Advisory Group (TAG) Chairs for the various international Technical Committees and Subcommittees under ISO and IEC, which are parallel to S1, S2, S3, and S12 are as follows:

U.S. TAG Chair/Vice Chair	TC or SC	U.S. Parallel Committee
ISO		
P. D. Schomer, Chair	**ISO/TC 43** Acoustics	S1/S3
P. D. Schomer, Chair	**ISO/TC 43/SC1** Noise	S12
D. J. Evans, Chair	**ISO/TC 108** Mechanical vibration, shock and condition monitoring	S2
W. C. Foiles, Co-Chair R. Taddeo, Co-Chair	**ISO/TC 108/SC2** Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures	S2
D. J. Evans, Chair	**ISO/TC 108/SC3** Use and calibration of vibration and shock measuring instruments	S2
D. D. Reynolds, Chair	**ISO/TC 108/SC4** Human exposure to mechanical vibration and shock	S2/S3
D. J. Vendittis, Chair R. Taddeo, Vice Chair	**ISO/TC 108/SC5** Condition monitoring and diagnostics of machines	S2
C. Peterson, Chair	**ISO/TC 108/SC6** Vibration and shock generating systems	S2
IEC		
V. Nedzelnitsky, U.S. TA	**IEC/TC 29** Electroacoustics	S1/S3

Meeting of Accredited Standards Committee (ASC) S3 Bioacoustics

C. A. Champlin, Chair S3
Univ. of Texas, Dept. of Communication Sciences & Disorders, CMA 2–200, Austin, TX 78712

D. A. Preves, Vice Chair S3
Starkey Laboratories, Inc., 6600 Washington Ave., S. Eden Prairie, MN 55344

Accredited Standards Committee S3 on Bioacoustics. Working group chairs will report on the status of standards under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note — those meetings will be held in conjunction with the Standards Plenary meeting at 9:00 a.m. on Tuesday, 19 May 2009.

Scope of S3: Standards, specifications, methods of measurement and test, and terminology in the fields of psychological and physiological acoustics, including aspects of general acoustics which pertain to biological safety, tolerance and comfort.

Meeting of Accredited Standards Committee (ASC) S3/SC 1 Animal Bioacoustics

D. K. Delaney, Chair S3/SC 1
USA CERL, 2092 Farber Dr., Champaign, IL 61822

M. C. Hastings, Vice Chair S3
6422 Crosswoods Dr., Falls Church, VA 22044 12144

Accredited Standards Committee S3/SC 1 on Animal Bioacoustics. Working group chairs will report on the status of standards under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

Scope of S3/SC 1: Standards, specifications, methods of measurement and test, instrumentation and terminology in the field of psychological and physiological acoustics, including aspects of general acoustics which pertain to biological safety, tolerance and comfort of non-human animals, including both risk to individual animals and to the long-term viability of populations. Animals to be covered may potentially include commercially-grown food animals; animals harvested for food in the wild; pets; laboratory animals; exotic species in zoos, oceanaria or aquariums; or free-ranging wild animals.

Session 2pAA

Architectural Acoustics: Computer Auralization

Robert C. Coffeen, Chair
School of Architecture and Urban Design, Univ. of Kansas, Lawrence, KS 66045

Chair's Introduction—1:00

Invited Papers

1:05

2pAA1. Auralization–audibility of changing scattering coefficients for audience areas in different size venues. Sarah Rollins (Sparling, Inc., 720 Olive Way, Ste. 1400, Seattle, WA 98101, srollins@sparling.com)

Auralizations in computer modeling are affected by many different variables, such as absorption coefficients, scattering coefficients, and the complexity of the model. However, scattering coefficients are often determined by the best guess of the consultant. In order to isolate the changes due to the scattering coefficient for comparison with measured data, a simple rectilinear room was measured and modeled. This paper will show how changing the architectural surface and audience scattering coefficients affects the auralizations for this room. For comparison, the effects of changing these same coefficients in a larger venue will also be presented.

1:25

2pAA2. Comparison of modeled versus measured room acoustic parameters in the recently completed Shaghoian Concert Hall in Clovis, California. Bill Dohn (Dohn and Assoc., Inc., 630 Quintana Rd. 312, Morro Bay, CA 93442, bill.dohn@gte.net) and Richard H. Campbell (Bang-Campbell Assoc., Falmouth, MA 02536)

The Shaghoian Concert Hall in Clovis, CA is a popular new variable acoustic music venue in the greater Fresno, CA area. The design process for this hall included CATT-Acoustic (TM) modeling for analysis and verification of essential room acoustic parameters based upon the settings of the variable acoustic devices. The model of the final design produced parameters that were closely in line with ideal values for a hall of this size and use. Model results will be compared to measured parameters in the completed hall.

1:45

2pAA3. From toy to tool—advanced auralization procedure in daily design work. Wolfgang Ahnert and Stefan Feistel (AFMG, Arkonastr. 45-49, 13189 Berlin, Germany)

Since more than 20 years simulation procedures are more and more common, but the auralization procedure is considered mainly as a toy. The reason for this relates partially to the efforts needed to get real auralized sound files. In a previous paper the authors reported about a method to produce high end auralization files. This method allows to use normal head phones to get the right spatial impression without in-head localization. The main reason not to use an auralized sound impression in the daily design work is the time-consuming procedure to calculate true impulse responses (IR) especially in large halls. In this paper new algorithms are reported to calculate IRs in multithread mode with one computer or better via a network with a set of CPUs working in parallel. So calculations in large halls maybe be reduced from 8–10 h with one CPU to 10–20 min with multicore computers. The paper explains the way from the model to high-end auralized files. Some examples demonstrate the quality of these derived binaural files.

2:05

2pAA4. The spatial perception of a large pipe organ in various locations in a church computer model is investigated using multiple sources properly spaced within an organ chamber, with each source representing an organ stop. Richard Campbell (Bang-Campbell Assoc., 26 G Chilmartk Dr. East Falmouth, MA 02536)

It is surmized that the auralization of a large pipe organ should use multiple sources properly spaced in the organ chamber with each source representing a stop. But at some point in the acoustic environment of the listener, the advantage of such spatial sourcing disappears. A MIDI sequencer is used to generate audio files of a Buxtahuda fugue in six parts using six different stops. The sources are properly spaced within an organ chamber in a large church. Binaural recordings are evaluated at various locations in the church.

2:25

2pAA5. Comparison of auralized and measured sound in moderately reverberant spaces. Robert C. Coffeen, Jonathan Birney, Stephanie Hoeman, Shane Kanter, Hannah Schultheis (School of Architecture and Urban Planning, Univ. of Kansas, 1465 Jayhawk Blvd., Lawrence, KS 66045, coffeen@ku.edu), Lauren M. Ronsse, and Lily M. Wang (Univ. of Nebraska-Lincoln, Omaha, NE 68182-0681)

This research performs an in-depth comparison of sound from computer auralizations with measured binaural room impulse responses and recordings taken in actual spaces. Binaural measurements and recordings have been gathered in two church naves with midfrequency reverberation times of about 1.5 and 2.5 s. The results from these measurements are compared with auralizations from computer models of the spaces in two different room acoustic modeling programs. The source and receiver positions used for the auralizations are the same as those measured in the real spaces. One of the naves was previously investigated [R.C. Coffeen and G. Caunt, J. Acoust. Soc. Am. **105**, 1174 (1999) (A)] with results from computer auralizations compared to measured binaural recordings in the space. As numerous advancements have been made to computer modeling programs since that time, this project revisits and expands the previous research using updated modeling and measurement techniques. The results of this research not only portray the developments in computer modeling that have occurred over the past decade, but also depict the relationship between current computer auralizations and actual sound in moderately reverberant spaces.

2:55

2pAA6. Using computer auralization to help prevent major problems relating to room acoustics and electroacoustic sound reinforcement. Robert C. Coffeen (Sch. of Archit. and Urban Plan., Univ. of Kansas, 1465 Jayhawk Blvd., Lawrence, KS 66045, coffeen@ku.edu)

Computer modeling and computer auralization will produce comparative listening experiences for architects, building owners, and building users based on selected interior surface shapes, interior finish materials, and electroacoustic sound distribution. Auralization can be a significant tool in helping building designers, owners, and users understand potential acoustical problems and the need for proper acoustic and electroacoustic design.

Contributed Papers

3:15

2pAA7. Diffraction culling for virtual-acoustic simulations. Paul Calamia (Dept. of Comp. Sci., Princeton Univ., 35 Olden St., Princeton, NJ 08540, pcalamia@cs.princeton.edu), Benjamin Markham (Acentech Inc., Cambridge, MA 02138), and U. Peter Svensson (Norwegian Univ. of Sci. and Technol., NO-7491 Trondheim, Norway)

Acoustic simulations of complex virtual environments typically are created with geometrical-acoustics techniques. Such simulations can be augmented with edge diffraction modeling for improved accuracy, but not without a significant increase in processing time due to the additional propagation paths which must be considered and the computational complexity of the diffraction calculations. However, for a given modeling scenario, the contribution of a diffracted path to the overall impulse response can vary over a large range, suggesting that certain diffracted paths can be ignored, or culled, to reduce processing time with a limited effect on the accuracy of the simulation. In this talk, we first analyze the effects of diffraction culling through a precomputed, amplitude-based ranking scheme. We then describe a simple procedure for identifying and culling insignificant diffraction components during a virtual-acoustic simulation which approximates the performance of the precomputed ranking. Through numerical and subjective analysis, we show that a significant percentage of diffracted paths can be ignored if the retained paths are those which lead to the highest-amplitude diffraction components, although the audible effects of such diffraction culling are dependent on the input signal.

3:30

2pAA8. Singers' preferences for acoustical characteristics of performing spaces. Kathleen Stetson (Arup Acoust., 155 Ave. of the Americas, New York, NY 10013, kathleen.stetson@arup.com) and Jonas Braasch (Rensselaer Polytechnic Inst., Troy, NY 12180)

Classical singers, whose instruments' close proximity to their ears makes them unique among musicians, require particular attention from acousticians addressing musician support in performance space design. This study expands upon the few previous analyses of acoustics for singers by exploring what is most basic about solo voice self-perception in halls used for concerts and recitals. A questionnaire was given to a number of professional classical singers and their numerical and narrative responses were analyzed. Five concert halls were measured from the singer's perspective on stage, utilizing a head and torso simulator with a mouth speaker to mimic the proximity of a singer's voice and ears. The resulting impulse responses were utilized in preference tests featuring real-time binaural auralization of singers' vocalizations. The correlations between the subjective results, existing objective parameters, and physical hall characteristics were explored. A strong connection was found between increasing preference and increasing reverberation time. Additionally, test subjects indicated a statistically significant dislike of or preference for a hall, regardless of the singing location on stage or the classical genre being sung. Further developments of this study are discussed in the context of ongoing opera house design utilizing computer model simulations.

3:45

2pAA9. Thirteen findings in ten minutes. Michael Ermann, Nate Crawford, Braden Field, Jessica Green, Sky Kim, Julia Mitchell, Steve Smith, Matthew Van Wagner, John Samuel Victor, and Amanda Massengill (School of Architecture and Design, Virginia Tech, 201 Cowgill Hall, Blacksburg, VA 24061-0205, mermann@vt.edu)

Nine architecture students in an architectural acoustics course studied the influence of design on the acoustic response of spaces. Thirteen of their projects will be presented, rapidly, with time to delve into some of them more deeply in response to questions from attendees. Areas of focus include: room shaping and balcony composition; ceiling and canopy height; canopy design; perception and preference of double sloped decays; side wall angle and orientation; room length; very tall ceilings; room width; side wall diffusion; mapping background noise levels; and frequency content of noise.

Session 2pAB

Animal Bioacoustics and Acoustical Oceanography: Autonomous Remote Monitoring Systems for Marine Animals II

Kathleen C. Stafford, Chair
Applied Physics Lab., Univ. of Washington, Seattle, WA 98105

Invited Papers

1:00

2pAB1. Validating acoustic monitors for marine animals: Field experience with beaked whales and digital acoustic monitors (DMONs). Mark Johnson, Tom Hurst (Woods Hole Oceanograph. Inst., 86 Water St., Woods Hole, MA 02543, majohnson@whoi.edu), Anton Arias, and Natacha Aguilar de Soto (Univ. of La Laguna, Tenerife, Spain)

Passive acoustic monitoring (PAM) is a promising tool for improving the effectiveness of visual surveys for marine animals and for stand-alone persistent monitoring. Nonetheless, significant data gaps make it difficult to predict PAM performance for many species. Detection functions are only beginning to be formed for some vocalizations and detectors. Statistical models for calling rates, as a function of behavior, are needed to translate acoustic detections into abundance estimates, or lack of detections into decisions about absence of animals. Finally, ambient noise levels and spectra are unavailable in most of the world's oceans, complicating the application of results from one area to another. Although some of these gaps are being addressed by a growing group of researchers, there is an urgent need to develop standards for measuring and reporting results, and to foster the interchange of data. To exemplify the form such standards might take, and the potential pitfalls, we present results from a series of field experiments designed to assess the performance of an acoustic monitor for beaked whales. The experiments made use of a freely available reference design for an acoustic detector, called the DMON, which may provide a basis for standardizing and validating real-time implementations.

1:20

2pAB2. Screening large data sets and real-time data streams for bioacoustic signals. Holger Klinck (Cooperative Inst. for Marine Resour. Stud., and NOAA Pacific Marine Environ. Lab., Oregon State Univ., 2030 SE Marine Sci. Dr., Newport, OR 97365, Holger.Klinck@oregonstate.edu), Lars Kindermann (Alfred Wegener Inst. for Polar and Marine Res., 27568 Bremerhaven, Germany), David K. Mellinger (Oregon State Univ., Newport, OR 97365), and Olaf Boebel (Alfred Wegener Inst. for Polar and Marine Res., 27568 Bremerhaven, Germany)

This presentation will discuss a major challenge of passive-acoustic monitoring systems: the analysis of large data sets to identify the occurrence of bioacoustic signals of interest. Triggered by the rapid development of digital audio technology and the increasing capacity of memory devices, it has become easier than ever to produce large, long-term acoustic data sets. However, analyzing these data sets is challenging, as suitable automated detection and classification systems are needed to perform the analysis in a reasonable amount of time. One such large data set is currently produced by the Perennial Acoustic Observatory in the Antarctic Ocean. This passive acoustic observatory has been operated by the Alfred Wegener Institute since January 2006 and has generated more than 10,000 hours of data to date. The observatory features a data link via satellite, which allows analysis of the recorded hydroacoustic data in real time in Germany. However, to be able to run custom algorithms over the entire data set in several times real-time speed, a distributed computing system was developed and applied. Here we provide a detailed description of this system and discuss further possible applications.

1:40

2pAB3. Acoustic sampling for marine mammals in the Beaufort Sea July 2007–March 2008. Kathleen Stafford (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle WA 98105, stafford@apl.washington.edu), Sue Moore (Alaska Fisheries Sci. Ctr., Seattle WA 98115), Catherine Berchok (Natl. Marine Mammal Lab, Seattle WA 98115), and David K. Mellinger (Oregon State Univ., Newport OR 97365)

As climate change is driving rapid, unprecedented warming of the Arctic, there is increasing interest in how such change will impact Arctic marine mammals. Impacts are anticipated from from habitat alteration, including increasing ambient noise levels from shipping, seismic exploration for oil and gas and geophysical research, and (potentially) commercial fishing. In order to monitor natural and anthropogenic sources of noise, four autonomous recorders were deployed along the 100-m isobath between Cape Halkett and Barrow and recorded data from July 2007–March 2008. The instruments sampled at 8192 Hz on a schedule of 10 min on, 20 min off. Marine mammal sounds recorded included pinnipeds (walrus and bearded seals) and cetaceans (bowhead and beluga whales), while anthropogenic sources included shipping and air gun sounds. Seasonal and geographic patterns for these sounds will be presented. These data form part of a broader-scale international, year-round monitoring program in the Arctic that we hope will eventually span the entire Arctic and provide a basin-wide acoustic observatory.

2:00

2pAB4. Integration of automated detection methods into NOAA Southwest Fisheries Science Center (SWFSC) acoustic marine mammal monitoring protocol. Tina M. Yack, Jay Barlow, Shannon Rankin (Natl. Marine Fisheries Svce., Southwest Fisheries Sci. Ctr., 3333 N. Torrey Pines Court, La Jolla, CA 92037, tina.yack@noaa.gov), and Douglas Gillespie (Univ. of St. Andrew, Fife KY16 8LB, Scotland)

Southwest Fisheries Science Center (SWFSC) has used combined visual and acoustic techniques to monitor marine mammal populations for the past 8 yrs. Currently, SWFSC passive acoustic surveys of cetaceans require specially trained personnel to monitor hydrophone signals in real-time. While effective, this method is time-consuming and costly. Automated detection of cetacean vocalizations would be a valuable tool during SWFSC surveys, allowing for detection when experienced technicians are unavailable. This technique is advantageous because it significantly reduces effort and removes sources of human error and bias in detection ability. PAMGUARD 1.0 CORE software was evaluated for use in automated detection of cetacean acoustic signals. Three different detector configurations of PAMGUARD were evaluated. This work shows that the majority of whistle and click events can be detected using PAMGUARD software. All of the PAMGUARD trials were capable of detecting whistles and clicks of cetacean species with varying success. These techniques were field-tested at sea during a recent SWFSC marine mammal survey. Automated detection of beaked whales and Dall's porpoise during this survey will also be discussed. It is our goal to integrate automated detection methods into SWFSC's acoustic marine mammal monitoring protocol and this work is an important step in doing so.

2:15

2pAB5. Tracking fin and blue whales above the Juan de Fuca Ridge with a local seafloor seismic network. William S. D. Wilcock, Dax C. Soule (School of Oceanogr., Univ. of Washington, Box 357940, Seattle, WA 98195, wilcock@u.washington.edu), and Richard E. Thomson (Inst. of Ocean Sci., Sidney, BC, V8L 4B2 Canada)

The Endeavour segment of the Juan de Fuca mid-ocean ridge hosts several high-temperature hydrothermal fields. Previous analysis of bioacoustical data shows that zooplankton are enhanced at all depths above the hydrothermal vent fields compared with sites $\geqslant$10 km away. From 2003–2006, a seafloor seismic network was deployed around the hydrothermal vent fields to monitor earthquakes and it also recorded an extensive data set of fin and blue whale calls. As part of an investigation of a potential correlation between whale tracks, enhanced zooplankton concentrations, and hydrothermal vents above the Juan de Fuca Ridge, an automatic algorithm is being developed to track vocalizing whales that swim near the network. Events are detected by triggering with the ratio of short-term to long-term running RMS averages and whale calls are distinguished from earthquakes based on their spectra. For fin whales each 1-s arrival is identified based on its instantaneous amplitude and frequency and a pick is made at the mid-energy point. A grid search method is used to localize calls using direct and multipath arrivals. The algorithm and preliminary results will be presented. [The Keck Foundation supported the seismic network and the Office of Naval Research is supporting this study.]

2:30

2pAB6. Frequency quantiles and dual harmonic tracking for detection and classification of killer whale calls. Val Veirs (The Whale Museum, Friday Harbor, WA 98250, Colorado College, Colorado Springs, CO, val@beamreach.org)

The Salish Sea Hydrophone Network, www.OrcaSound.net, is operating five streaming hydrophones in the critical habitat of the endangered Southern Resident orcas. Software is being developed that allows each site to sift through the approximately 10 Gbytes of information that are produced each day at each site in order to detect killer whale calls and related sounds. Detection of calls is accomplished via triggering on three time dependent features extracted in real-time from sequential power spectra. One of these three features is derived from the bandwidth between quartiles of the filtered power spectrum. The other two quantify the degree to which the power spectrum has one or two harmonic structures. Features are extracted into feature sets that save the details of each feature: amplitudes; durations; and time variations. A metric has been devised that measures the similarity of different sequences of feature sets. With this metric an unsupervised learning algorithm builds a tree structure that classifies sounds by their similarity. As new calls come in, they either fall into pre-existing groups or create new branches. Automatic reports are made via the Web and e-mail.

2:45

2pAB7. Tracking multiple sperm whales with widely spaced bottom-mounted hydrophones. Eva-Marie Nosal (Dept. of Ocean and Resources Eng., Univ. of Hawaii, 2540 Dole St., Honolulu, HI 96816)

One dataset from the 2nd Int. Workshop on Detection and Localization of Marine Mammals Using Passive Acoustics Data featured multiple clicking sperm whales recorded for 20 min. Data were recorded on five widely spaced bottom-mounted hydrophones at the Atlantic Undersea Test and Evaluation Center. This dataset is used to develop and apply a model-based time difference of arrival (TDOA) method that is capable of simultaneously tracking multiple animals. Clicks on all hydrophones are detected. For every receiver pair, all possible time-differences of arrival (within reasonable time limits) are formed from the detected clicks. A scatterplot of TDOAs versus time, although noisy due to many false TDOAs formed from incorrectly associated clicks, reveals clear "tracks" of slowly varying TDOAs. These tracks are extracted and input to a TDOA tracking algorithm that gives 3-D likelihood surfaces of whale position. Local maxima in the likelihood surfaces are extracted and clustered to give estimated whale tracks.

3:00—3:20 Break

Invited Paper

3:20

2pAB8. The Acousonde: A miniature autonomous wideband recorder. William C. Burgess (Greeneridge Sci. Inc., 6060 Graham Hill Rd., Fl. 2 Stop F, Felton, CA 95018, burgess@greeneridge.com)

The Acousonde™ is a newly designed miniature acoustic/ultrasonic recording tag incorporating several improvements over its predecessor, the Bioacoustic Probe. Design trade-offs for its acoustic data paths targeted acquisition of both near and distant odontocete echolocation clicks with minimal distortion while preserving general-purpose utility and low-power operation. Two acoustic channels are available: a low-power channel for long-term recording of signals up to 9 kHz and a high-frequency channel for signals up to 100 kHz. Each channel has its own dedicated hydrophone. For antialiasing, the low-power channel uses an adjustable switched-capacitor elliptic filter, while the high-frequency channel uses a fixed-frequency linear-phase filter; both filters may be bypassed if raw acquisition is desired. "Ping-pong" alternating sampling may be used to acquire samples from both channels concurrently, possibly to assess time-of-arrival differences between the two hydrophones. The controlling microprocessor, an ARM 9 with vector floating point accelerator, can digitally filter and downsample acoustic data during acquisition to reduce storage requirements. Other sensors include a 3D accelerometer, a 3D compass, a depth transducer, and a temperature monitor. Eight gigabytes of data storage are available, with data offload via a MicroUSB connector. Initial tests with captive animals are planned shortly. [Work supported by ONR.]

3:40

2pAB9. Validated reef fish sound scans of passive acoustic monitors on Hawaiian coral reefs. Timothy C. Tricas and Kelly Boyle (Dept. of Zoology and Hawaii Inst. of Marine Biol., Univ. of Hawaii at Manoa, Honolulu, HI)

Monitoring of fish sounds on coral reefs is a valuable potential technique for fisheries managers to remotely assess local fish populations and their behaviors. However, the species identity of most fish sounds on shallow coral reefs is not known. We have deployed two ecological acoustic recorders (EARs) at 20 m deep on two shallow reefs on the island of Hawaii. In order to validate which fish species produce these acoustic behaviors we used closed circuit rebreather diving, which produces almost no ambient acoustic noise, to record video and sonic behaviors of fish near the recording sites. From the videos we have identified 37 putative acoustic species many of which produce multiple sounds that include behaviors associated with intra- and interspecific aggression, feeding, courtship, and spawning. Cluster analysis was used to identify acoustic clades among and within species. Acoustic waveform average templates were constructed for different species clades and used in XBAT to screen the long-term recordings from the EAR. The use of these species-specific sound templates confirms the potential to detect diel, lunar, and longer-term rhythmicity for several species. This technique also shows promise for characterizing seasonal and annual periods of activity of sounds associated with context-specific behaviors.

3:55

2pAB10. Beaked whale density estimation from single hydrophones by means of propagation modeling. Elizabeth T. Küsel, David Mellinger (NOAA/PMEL, Hatfield Marine Sci. Ctr., Oregon State Univ., Newport, OR 97365, elizabeth.kusel@noaa.gov), Len Thomas, Tiago A. Marques (Univ. of St. Andrews, Scotland), David J. Moretti, and Jessica Ward (Naval Undersea Warfare Ctr., Newport, RI 02841)

Passive acoustic sonar systems offer many advantages to the study of marine mammals. For density estimation studies, it is important to evaluate the probability of detecting an animal as a function of its distance from the receiving sensor. In this work, acoustic propagation modeling is used to estimate the transmission loss as a function of depth and range between a source whale and a single-hydrophone receiver. The computed transmission loss is compared to ambient noise levels and source level distributions to estimate the detection probability as a function of range. Results will be compared to beaked whale data recorded on bottom-mounted sensors in the Atlantic Undersea Test and Evaluation Center (AUTEC) in the Bahamas, where the location of clicks is relative to one hydrophone. Source level and beam pattern extracted from digital acoustic tags (DTags) applied to a sample of animals at the same location will also be used in the detection model, and beaked whale spatial density will be estimated. The detection probability function will provide a relevant comparison to the detection function derived empirically from the DTag data by Marques *et al.* [Marques *et al.*, J. Acoust. Soc. Am. (submitted).]

4:10

2pAB11. Passive acoustic monitoring of fish activity in the Hawaiian Archipelago. Pollyanna Fisher-Pool, Marc O. Lammers (Joint Inst. for Marine and Atmospheric Res., NOAA-CRED, 1125B Ala Moana Blvd., Honolulu, HI 96814, Pollyanna.Fisher-Pool@noaa.gov), Kevin Wong, Russell E. Brainard (NOAA Fisheries, Honolulu, HI 96814), and Whitlow W. L. Au (Univ. of Hawaii, Kailua, HI 96734)

Fish are an important component of coral reef ecosystems and can be valuable indicators of ecological change on reef environments. Many species of fish produce sounds and are therefore well suited for passive acoustic monitoring. Since 2006, NOAA has been using Ecological Acoustic Recorders (EARs) to monitor coral reef habitats in the main and Northwestern Hawaiian Islands in an effort to develop multi-year time series of biological activity at these locations. Sixteen EARs are presently deployed on reef habitats ranging in depth from 2 to 23 meters. Preliminary results reveal that each site is characterized by a unique composition of acoustically active fish . Many sounds are also common at multiple sites. Different species show considerable variability in their diet and seasonal patterns of activity. The results indicate that long-term acoustic monitoring of fish at these sites is likely to yield useful information about changing patterns of fish presence, behavior, and relative abundance. These metrics can be used to gauge the relative stability of ecosystems and be related to physical, oceanographic, and anthropogenic variables affecting them.

4:25

2pAB12. Using moored passive acoustic recorders to assess seasonal occurrence and movements of southern resident killer whales in the coastal waters of Washington State. M. Bradley Hanson, Candice K. Emmons (NOAA/NMFS/Northwest Fisheries Sci. Ctr., 2725 Montlake Blvd. E, Seattle, WA 98112, brad.hanson@noaa.gov), Jeffrey A. Nystuen (Univ. of Washington, Seattle, WA 98105-6698), and Marc O. Lammers (Oceanwide Sci. Inst., Honolulu, HI 96839)

Designating critical habitat is mandated for species listed under the U.S. Endangered Species Act. This task has only been partly accomplished for southern resident killer whales (SRKWs) because winter distribution is poorly understood due to a variety of factors limiting visual sightings within their known central California to northern British Columbia range. To capitalize on the unique vocal behavior of resident killer whales, including pod-specific dialects, two types of acoustic recorders were deployed at strategic locations that span the Washington coast. Between 2005 and 2008 recorders were deployed in early winter for an average of 175.5 days at up to four sites. These functioned for an average of 114.8 days and collected a total of 47 SRKW detections. This exceeds the number of visual sightings during the same time period (15). Additionally, northern resident, transient, and offshore killer whales were recorded as well as Pacific white-sided dolphins, and humpback and sperm whales. SRKW were detected by both types of recorders and in all areas. Detections were made between Jan. and July with the majority of these detections in Mar., Apr., and May. This new information will be of key importance to managers in meeting recovery goals.

Session 2pAO

Acoustical Oceanography and Underwater Acoustics: Environmental Inferences in Inhomogeneous Ocean Environments I

David P. Knobles, Chair
Applied Research Labs., Univ. of Texas at Austin, Austin, TX 78713

Chair's Introduction—1:00

Invited Papers

2pAO1. Environmental influences on low-frequency, shallow-water acoustic propagation and inversion. George V. Frisk (Dept. of Ocean Eng., Florida Atlantic Univ., 101 N. Beach Rd., Dania Beach, FL 33004, gfrisk@seatech.fau.edu)

Historically, the seabed has been considered to play the dominant role in shallow-water acoustic propagation at low frequencies. As a result, propagation models have focused on the incorporation of accurate values of bottom properties, while inversion techniques have concentrated on the determination of geoacoustic properties of the seabed. In recent years, however, the assumption of a benign water column has increasingly come under scrutiny in addressing both the forward and inverse problems. This paper addresses these issues as they relate to a measurement and inversion methodology in which acoustic data are acquired on synthetic radial apertures that are created using a moving source/receiver configuration in concert with precision navigation. These data can be transformed into the horizontal wavenumber domain to obtain an estimate of the propagation characteristics of the waveguide; namely, its modal content. The modal spectra can then be inverted using a variety of techniques to determine estimates of the waveguide parameters, specifically the geoacoustic properties of the seabed. The issues associated with the successful implementation of this modal mapping method in a highly variable shallow-water environment are discussed. [Work supported by ONR.]

1:25

2pAO2. The impact of ocean sound speed variability on the uncertainty of geoacoustic parameter estimates. Ross Chapman and Yongmin Jiang (School of Earth and Ocean Sci. Univ. of Victoria, Victoria, BC V8W 5C2, Canada, chapman@uvic.ca)

This paper investigates the influence of water column variability on the estimates of geoacoustic model parameters obtained from matched field inversions. The acoustic data were collected on the New Jersey continental shelf during the Shallow Water 2006 experiments. The oceanographic variability was evident when the data were recorded. To quantify the uncertainties of the geoacoustic parameter estimates in this environment, Bayesian matched field geoacoustic inversion was applied to multi-tonal continuous wave data. The spatially and temporally varying water column sound speed was parametrized in terms of empirical orthogonal functions and included in the inversion. Its impact on the geometric and geoacoustic parameter estimates was then analyzed by the inter-parameter correlations. Two different approaches were used to obtain information about the variation of the water sound speed. One used only the profiles collected along the experimental track during the experiment, and the other also included observations from a larger area and a greater time period. The geoacoustic estimates from both the large and small sample sets were consistent. However, due to the diversity of the oceanic sound speed, more empirical orthogonal functions were needed in the inversion when more sound speed profile samples are used. [Work supported by ONR.]

1:45

2pAO3. Observed temporal statistics of acoustic travel time and intensity in the South China Sea. Ching-Sang Chiu and Christopher W. Miller, D. Benjamin Reeder, Justin M. Reeves, Steven R. Ramp (Dept. of Oceanography, Naval Postgraduate School, 833 Dyer Rd., Monterey, CA 93943, chiu@nps.edu)

The coupled ocean and acoustic variability in the Northeastern South China Sea basin was monitored using moored oceanographic and acoustic sensors during the 2005-2006 Windy Island Soliton Experiment (WISE). The temperature and current records captured prominent ocean variability at multiple scales, induced by mesoscale eddies, internal tides, and large amplitude internal waves. The latter two were transbasin, propagating from near the Luzon Strait, through the deep basin, onto the northeastern shelf. The concurrent acoustic measurements were attained from the transmission of a 400 Hz, phase-modulated signal along a 166 km path every 15 min. The receptions were processed to give the arrival structure of a pulse and its temporal change over a nine-month period. The observed temporal variability in the statistics of the acoustic travel time and intensity were analyzed using time-series techniques and models with emphasis to elucidate the connection and sensitivity to the observed ocean variability. Results from the analysis are discussed, as they pertain to the ocean processes and those parameters that can potentially be inferred from these types of acoustic transmissions. [The research is sponsored by the Office of Naval Research.]

2:05

2pAO4. Phase front fluctuations due to internal waves in shallow water 2006 experiment. Boris Katsnelson (Voronezh State Univ., Voronezh, Russia), Mohsen Badiey, Jing Luo (Univ. of Delaware, Newark, DE 19716), and James Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Experimental results and theoretical analysis of the sound phase front fluctuations measured by Vertical and Horizontal Line (VHLA) array (or L-shaped array) are presented. Low frequency broadband signals were radiated by the source (Miami Sound Machine) placed at the distance of ~25 km from the VHLA. During the time period 18:00–22:00 GMT on Aug. 17, 2006, a train of internal solitons traveled across the acoustic track and initiated fluctuations of the sound field. In an earlier paper [J. Acoust. Soc. Am. **124**, EL66–EL72 (2008)], it was shown that intensity of these fluctuations results from the horizontal refraction of the sound waves due to internal solitons. Here we show the acoustic phase front fluctuations for separate waveguide modes for the same period. To obtain phase fronts for the individual modes, a special approach using an L-shaped receiver array is used. The vertical part of the array was used to obtain modal amplitudes. Using the measured sound field based on the perturbation theory, modal phases at the HLA can be calculated. Results of data processing are compared with theoretical calculations. [Work supported by ONR, CRDF, and RFBR.]

2:20

2pAO5. Signal intensity fluctuations in Shallow Water 2006 (SW06) experiment during Event 50. Mohsen Badiey, Jing Luo (College of Marine and Earth Stud., Univ. of Delaware, Newark, DE 19716), Boris Katsnelson (Voronezh State Univ., Voronezh, Russia), and James Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

During the Shallow Water 2006 (SW06) experiment, several internal wave (IW) events were recorded by moving and stationary instruments simultaneously with the acoustic propagation tests. More than 50 IW events were recorded using the University of Delaware's R/V Sharp's radar. On this ship, a J15 sound source transmitted various acoustic signals at different bearings and ranges to the Woods Hole Oceanographic Institution's vertical and horizontal hydrophone arrays. During one of the IW events, the acoustic source was kept at a constant water depth while moving in horizontal plane with the advancing internal wave front. This internal wave packet, named Event 50, was also recorded by R/V oceanous radar a few kilometers away. The reason for placing the sound source on the advancing IW front was to examine the effects of azimuthal variability of the waveguide on the acoustic propagation. A detailed transition of the waveguide as the internal wave progressively occupied the acoustic propagation track between the source and receiver is reported. It is shown that the intensity peaks at small angles between the acoustic track and the internal wave front where sound intensity focusing and defocusing occurs. [Work supported by ONR 321OA and CRDF, and RFBR.]

2:35

2pAO6. Intensity measurements and fluctuations of acoustic transmissions from the Research Vessel Sharp during Shallow Water 2006. Georges A. Dossot, James H. Miller, Gopu R. Potty (Dept. of Ocean Eng., Univ. of Rhode Island, Narragansett Bay Campus, Narragansett, RI 02882), James F. Lynch, Aurthur E. Newhall (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), and Mohsen Badiey (Univ. of Delaware, Newark, DE 19716)

During the Shallow Water 2006 (SW06) experiment, the University of Delaware's R/V Sharp transmitted various acoustic signals at several different bearings and ranges to the Woods Hole Oceanographic Institute's vertical and horizontal hydrophone line array. The array was strategically positioned near the shelfbreak front, and in an area where internal waves are known to occur. During several of the R/V Sharp's acoustic transmissions, internal waves passed through the sound field. The internal waves and the shelfbreak front can cause complex multimode and multipath interference patterns which result in intensity variations of received acoustic signals. This presentation provides an overview of the R/V Sharp's transmissions, and the corresponding intensity fluctuations of received signals at the array. These fluctuations are compared to internal wave events that were recorded at both the transmission and reception locations. These internal wave events were also imaged by the R/V Sharp's radar and satellite-based radar. Following the work of Fredricks *et al.* [J. Acoust. Soc. Am. **117**, 1038 (2005)], statistical distributions are fit to the calculated intensities for different transmission directions, distances, and times. These distributions are compared to modeled data with and without the internal wave field. [Work sponsored by the Office of Naval Research.]

2:50

2pAO7. Time-frequency pattern of the sound intensity fluctuations of midfrequency signals in presence of internal waves in Shallow Water 06 experiment. Boris Katsnelson, Valery Grigorev, and James Lynch (Woods Hole Oceanograph. Inst., 98 Water St., Woods Hole, MA 02543, jlynch @whoi.edu)

In given paper fluctuations of intensity of sound signals, radiated by the midfrequency source (R/V Knorr) during ~5 h were studied. Broadband signals (2–8 KHz) were received by four single hydrophones fixed at the bottom (SHRUs) placed at different distances from the source (from 4 to 12 km). These four acoustic tracks have different directions relative direction of propagation of the train of intensive internal waves (the corresponding angles in horizontal plane are from ~5 to ~15 deg). Time-frequency diagrams were constructed using frequency filtering of the spectrum of broadband signals with sliding narrow window. Temporal dependences of intensities of received signals within frequency window were constructed for period 14:00 until 19:00 GMT for experiment carried out on 13 August. During this time train of internal solitons was registered, propagating toward the coast. Mentioned time-frequency diagrams demonstrate specific features of influence of internal waves on the temporal variations of the sound intensities at four SHRUs. More exactly variations of predominating frequency in spectra correspond to variations of positions of the solitons at the acoustic tracks. Results of experimental data are compared with theoretical estimations. [Work was supported by RFBR and CRDF.]

3:05

2pAO8. Acoustic ducting, refracting, and shadowing by curved nonlinear internal waves in shallow water. James F. Lynch, Ying-Tsong Lin, Timothy F. Duda, Arthur E. Newhall, and Glen Gawarkiewicz (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, jlynch@whoi.edu)

Nonlinear internal waves are common on continental shelves and have been shown to have strong effects on acoustic propagation and scattering. Transmissions from previous field work performed in an along-shelf geometry show very strong ducting of low-frequency (50–500 Hz) sound between nonlinear waves. This strong ducting effect is acoustically important. Most all of the acoustic propagation studies of internal waves have used straight line internal wave fronts for individual waves or packets. In our work, we implement a theoretical analysis using the Weinberg-Burridge horizontal rays and vertical modes formalism to study the acoustic ducting, refracting and shadowing of low-frequency sound due to curved internal waves, which seem to dominate in shelf break regions. A three-dimensional parabolic-approximation sound propagation model is also used with consideration of realistic environmental conditions, and the modeling results provide a clear depiction of the underlying physical processes. The oceanographic origin of the internal wave curvature is discussed, as this affects the predictability of the sound speed field. [This work is sponsored by the Office of Naval Research.]

2pBB1. Ultrasonic manipulation in microfluidic chips for accurate bioparticle handling. M. Wiklund, O. Manneberg, J. Svennebring, B. Vanherberghen, B. Onfelt, and H. M. Hertz (Dept. of Appl. Phys., Royal Inst. of Technol., SE-10691 Stockholm, Sweden)

Micro-manipulation of cells or other bioparticles has important applications in biological and biomedical research. Dielectrophoresis and optical tweezers are the classical tools in this field. Ultrasonic standing wave (USW) technology is presently emerging as powerful alternative, especially in microfluidic chips and other miniaturized systems. In this contribution we will review our present activities in USW-based particle manipulation in microfluidic chips. Recent experiments and simulations allow us to tailor the spatial distribution of the USW force field by multi-frequency actuation and appropriate microchannel/transducer resonance design. We introduce the concept of ultrasonic micro-cages for single-cell or single-particle 3-D ultrasonic manipulation. It is shown that these manipulation tools can be combined with high-resolution optical microscopy, thereby allowing state-of-the-art characterization of individual cells. Frequency-modulation is shown to stabilize the manipulation performance as well as allowing flow-free transport of particles and cells. Environmental control inside the channels has been achieved and proliferation and viability studies are promising. Finally, for bio-analysis, we demonstrate potential for femtomolar bio-analytical sensitivity in bead-based assays using USW enrichment.

2pBB2. Acoustofluidics: Theory and simulation of streaming and radiation forces at ultrasound resonances in microfluidic devices. Henrik Bruus (Dept. of Micro- and Nanotechnology, Tech. Univ. of Denmark, DTU Nanotech, Bldg. 345 East, DK-2800 Kongens Lyngby, Denmark, Henrik.Bruus@nanotech.dtu.dk)

During the past few years, there has been an increasing interest in applying ultrasound waves to manipulate biological particles and liquids in microfluidic devices. To obtain optimized designs and functionalities of the acoustofluidic devices, more detailed theoretical studies and numerical simulations are called for. The basic second-order perturbation theory is presented for acoustic fields applied at ultrasound frequencies in silicon/glass systems containing water-filled microfluidic channels and chambers. For various specific device geometries, the resonance frequencies and corresponding modes of the acoustic fields are calculated numerically to first order. At these frequencies, the largest possible acoustic powers are obtained in the microfluidic system. The first order fields are then used as source terms in the equations for the time-averaged second order pressure and velocity fields, which are directly related to the acoustic radiation force on single particles and to the acoustic streaming of the liquid. For the radiation pressure effects, there is good agreement between theory and simulation, while the numeric results for the acoustic streaming effects are more problematic. Possible improvements in the latter case are discussed.

2:00

2pBB3. Transient processes in acoustic resonators. Armen Sarvazyan (Artann Labs., 1753 Linvale-Harbourton Rd., Lambertville, NJ 08530, armen@artannlabs.com) and Lev Ostrovsky (Zel Technologies/Univ. of Colorado, Boulder, CO 80305)

The use of ultrasound in resonators for manipulating particles in various biomedical applications is a relatively well studied topic. These studies were mostly concerned with steady-state processes. However, in certain important applications, such as stirring and mixing fluids in microfluidics and biosensors, the time scale of a process plays a crucial role. In this presentation we consider some of these applications. In particular, the radiation force-induced motion of microparticles and microbubbles in a swept-frequency ultrasonic resonator is considered. The particles are forced to move due to switching the resonance modes in a resonator cell, thus providing effective stirring of the fluid. Another field of medical application of standing waves, where transient processes are of crucial importance, is ultrasonic treatment of tissues. In this new field of ultrasonic therapy, standing waves are used for producing lesions in the tissue with simultaneous monitoring the formation of the lesion by automatic controlling parameters of the standing wave field. The spatial and temporal distribution of ultrasound energy in the resonator containing treated tissue portion is theoretically analyzed. Dynamics of temperature changes in the tissue, which is important for optimizing tissue treatment regimes, is evaluated. Experimental data illustrating theoretical results are presented.

2pBB4. Current applications of ultrasonic resonators to biomolecular studies. Tigran Chalikian (Faculty of Pharmacy, Univ. of Toronto, 144 College St., Toronto, ON M5S 3M2, Canada, chalikan@phm.utoronto.ca)

The most versatile family of instruments providing the highest precision of acoustic measurements in the lowest sample volumes utilizes the method of fixed-path interferometer. The speed of sound in a medium is a simple function of its density and compressibility. Both parameters are determined by and, therefore, reflect the entire spectrum of intra- and intermolecular interactions within the system. In addition, compressibility probes the pressure response of these interactions. Current resonator-based instruments provide reliable measurements in diluted solutions of biological compounds with solute concentrations on the order of 1 mg/mL and solution volumes of 1 mL. They require less than 1 mg of sample, a range acceptable for the majority of biochemical and biophysical investigations. Ultrasonic velocimetric measurements have been employed to study a range of biologically relevant reactions, including the folding /unfolding transitions of proteins and helix-to-coil transitions of nucleic acids, as well as drug-DNA, ligand-protein, protein-protein, and protein-DNA association events. The limiting factor in such investigations is the need to rationalize the measured properties (volume, compressibility, and their derivatives) in terms of microscopic events, such as solute-solvent interactions. This presentation reviews biomolecular applications of acoustic measurements and discusses the development of approaches for microscopic interpretation of macroscopic volumetric observables.

2:40

2pBB5. Cylindrical standing wave resonator for liquid food quality control. Aba Priev (Hebrew Univ.-Hadassah Med. School, Jerusalem 91120; NDT Instruments Ltd., 56 Anilevich St., Jerusalem, Israel, abbap@ekmd.huji.ac.il) and Armen Sarvazyan (ARTANN Labs., Inc., Lambertville, NJ 08530)

In this paper, an innovative technology based on the use of ultrasonic cylindrical standing waves for continuous monitoring of quality of various liquid food products, such as milk, juices, beer, wine, and drinking water is described. A proprietary unique feature of the developed ultrasonic analyzer is that it employs a combined mode of operation using both high-intensity and low-frequency (10 W/cm^2, 1 MHz) waves for separation and concentration of the high-molecular-weight particles (fat globules or cells) and low-intensity and high-frequency (0.5 W/cm^2, 10 MHz) waves for compositional analysis. High accuracy for ultrasound velocity measurements (up to 0.001%) and ultrasound attenuation (of about 1%) and rapid testing time (2–20 s) have been achieved. Comparative analyses of the ultrasonic method with standard reference techniques have produced linear calibration curves for major components with correlation coefficients higher than 0.95. It is thus possible to monitor total protein and fat content, and somatic cell count in raw milk in cowsheds, or salinity, turbidity, specific gravity, and particles (bacteria) in drinking water directly. Advantages of the proposed technology include the reagent-free nature, no need for sample pretreatment, ease-of-use, and low cost.

2pBB6. Movement of liquids and solid particles on multiwall acoustic plates. Jeremy J. Hawkes (School of Chem. Eng. and Analytical Sci., The Univ. of Manchester, MIB 131 Princess St., Manchester, M1 7DN, UK), Rito Mijarez-Castro (Instituto de Investigaciones Elctricas, Morelos, Mexico, rmijarez@iie.org.mx), and Peter R. Fielden (The Univ. of Manchester, Manchester, M1 7DN, UK)

Well-defined vibration modes are used to form acoustic wells on flat plates. Within these dynamic traps, acoustic streaming continually stirs the contents. Traps can be used to hold liquids in separate heaps on a surface or to hold particles in levitated arrays. A protocol for creating trap patterns will be described, where FE modelling is used to select modes and then maneuver the modes to the desired frequency.

2pBB7. Nonlinear ultrasonic standing waves in bubbly liquid: A numerical study. Vanhille Christian (Escet, Univ. Rey Juan Carlos, Tulipán s/n, 28933 Móstoles, Madrid, Spain, christian.vanhille@urjc.es) and Campos-Pozuelo Cleofé (Inst. de Acústica, CSIC, 28006 Madrid, Spain)

This study deals with the behavior of nonlinear ultrasonic standing waves in a bubbly liquid. A water air mixture is considered. The SNOW-BL numerical code gives the solution of a differential system coupling the nonlinear bubble equation with the linear wave equation. Several kinds of high power standing waves which may be useful in biomedical applications are considered here: pulses propagating in water with air bubbles clouds or layers, harmonic waves in a bubbly resonator, non-resonant standing waves in a fluid with bubbles. Conclusions about acoustic pressure distributions, waveforms, and frequency content, as well as mean and rms pressures, are given. Particular acoustical effects induced by the dynamics of the air-bubbles on the pressure standing wave are commented. Comparisons with results in homogeneous fluids are also presented. [Work supported by DPI2008-01429.]

2pBB8. Use of resonator method for body fluids composition assessment. Viktor Klemin (BIOM, 3 Veterinarnaya Str., Nizhny Novgorod, 603098, Russia, klemina@rf.unn.ru)

Ultrasonic resonator method of body fluids composition evaluation is described. The experimental data on assessment of whole blood, blood serum, gastric juice, and saliva are presented. The developed method is based on the assumption of additivity of the contributions of major components of fluids in their acoustic characteristics. The acoustic characteristics measured by the ultrasonic resonator method include the speed and absorption of ultrasound and their frequency and temperature dependences. The device for evaluation of body fluid composition comprises differential ultrasonic resonator cells with the volume of 80 mkl each, operating at about 8 MHz, mounted in a micro-thermostat, and a compact electronic unit. The method allows for simultaneous determination of total protein, $Na+$ and $K+$, in saliva and gastric juice, lipid components (cholesterol total, cholesterol of high and low density, and triglycerides), the total protein and protein fractions in blood serum within a very short period of time, on the order of minutes, in contrast to conventional time consuming tests. Other advantages of the proposed technology include the reagent-free nature, no need for sample pretreatment, ease-of-use, and low cost. The accuracy of ultrasonic method for body fluid composition assessment is comparable to that of conventional time-consuming and expensive assays.

4:15

2pBB9. Ultrasound standing wave fields control the spatial distribution of cells and protein in three-dimensional engineered tissue. Kelley A. Garvin (Dept. of Biomedical Eng., 205 Goergen Hall, Univ. of Rochester, Rochester, NY 14627, garvin@bme.rochester.edu), Denise C. Hocking, and Diane Dalecki (Univ. of Rochester, Rochester, NY 14627)

The application of ultrasound standing wave fields (USWFs) to cell suspensions results in the radiation force-mediated movement of cells to areas of the field separated by half-wavelength intervals. In this study, USWF-induced cellular arrangements were maintained after removal of the sound field by polymerization of a collagen type-I solution around the organized cell bands. Using a water tank setup, cell suspensions of varying concentrations were exposed to a 1-MHz, continuous wave USWF for 15 min, during which time collagen polymerization occurred. An acoustic pressure amplitude of 0.2 MPa was used to achieve the USWF-induced cell organization. Compared to sham samples with a random cell distribution, cell viability was not adversely affected by USWF exposure. The organization of cells into a banded pattern within the collagen gels resulted in a significant two-fold increase in cell-mediated gel contraction, suggesting that USWF-induced cell organization leads to differential extracellular matrix remodeling. Protein organization within the tissue constructs was further controlled by USWF-mediated collocalization of soluble fibronectin to cell bands. These technologies have applications to the fabrication of tissue analogs with desired tissue characteristics for the repair or replacement of diseased or injured tissues and organs in the field of tissue engineering.

4:30

2pBB10. Two-dimensional numerical simulations for the time-averaged acoustic forces acting on a rigid particle of arbitrary shape in a standing wave. Jingtao Wang (Ctr. of Mech., Dept. of Mech. and Process Eng., ETH Zurich, 8092 Zurich, Switzerland, wang@imes.mavt.ethz.ch) and Jurg Dual (ETH Zurich, 8092 Zurich, Switzerland)

The time-averaged acoustic force can be applied to many practical fields such as contactless particle manipulation in biomedicine. It is necessary to accurately predict the mean forces on suspended obstacles to design ultrasonic particle manipulators. Although there have been many analytical solutions on this topic, it is difficult to determine the acoustic forces on obstacles under more complex system conditions such as proximity to the chamber wall, complex viscous function, acoustic streaming, and complicated particle shapes. Therefore, the numerical modeling may become a powerful tool. In this paper, the time-averaged forces, which act on rigid 2-D particles with different shapes in ideal and viscous fluids exerted by a standing sound wave field, are computed by solving the Navier-Stokes equations directly using the finite volume method (FVM) technique. The cylinder results agree well with Haydock's theoretical prediction and his lattice Boltzmann simulations. Then, the force and torque acting on a needle shaped particle in a standing wave are calculated and discussed in detail. Furthermore, the viscous effects of the host medium are also investigated. Our program with the FVM algorithm proves to be quite suitable for calculating the acoustic forces in standing waves.

2pBB11. Time reversal of monochromatic signals in elastic media. Brian E. Anderson, Robert A. Guyer, Timothy J. Ulrich, and Paul A. Johnson (Geophys. Group EES-17, Los Alamos Natl. Lab., Los Alamos, NM 87545)

A set of experiments has been conducted to show that time reversal of steady state monochromatic signals can produce spatial focusing in a reverberant elastic cavity when multiple channels are used. The transient portion of the received signals is not used. A single channel does not produce spatial focusing as it only drives the system according to its modal distribution. The amplitude of the energy at the focal location increases as the square of the number of channels used, while the amplitude elsewhere in the medium increases proportionally with the number of channels used. This work has importance in the field of medical ultrasound where the use of a long duration monochromatic excitation may be used for lithotripsy or other ultrasonic therapy. [This work is supported by Institutional Support (LDRD) at Los Alamos National Laboratory.]

2pEAa1. The piezoelectric thickness mode hydrophone using tonpilz structure for deep-sea application. Min Sung, Haksue Lee, and Wonkyu Moon (Dept. of Mech. Eng., Pohang Univ. of Sci. and Tech., PIRO, Rm. 416, san31 hyja-dong, nam-gu, Pohang-si, kyungsangbuk-do, Korea)

A piezoelectric thickness mode hydrophone for deep-sea application using tonpilz structure was designed, and its macroprototype was made as a preliminary for the micromachined version. Several types of micromachined thin-diaphragm sensors for hydrophone application have been reported. They have two issues in deep-sea applications. One is a sensitivity problem. To enhance the sensitivity, a cone structure for sound pressure amplification was placed between the clamped diaphragm and the piezoelectric square plate. To evaluate the effect of the cone structure on sensitivity, which was motivated by tonpilz structure, an air-backed prototype was made using aluminum and piezoelectric ceramic square plate of 700 μm length and 400 μm thickness. A lumped parameter model was used in the design procedure. The measured sensitivity of the prototype was −249.60 dB ref. One volt per micropascal without a preamplifier, and the measured resonant frequency was 30 kHz, which agreed with the prediction. The other is an endurance problem due to high hydrostatic pressure. To develop the endurance for the high hydrostatic pressure in deep-sea, PZT thickness mode and oil-backing on the diaphragm backside were proposed. The comparison of oil-backing and air-backing is to be presented as an evaluation of the endurance development. [Research supported by MRCnd.]

2pEAa2. Rapid identification of candidate materials for tonpilz head-mass design. Scott P. Porter, Douglas C. Markley, David J. Van Tol, and Richard J. Meyer, Jr (Appl. Res. Lab., The Pennsylvania State Univ., P. O. Box 30, State College, PA 16804, scott.porter@psu.edu)

Optimum performance of a tonpilz transducer head-mass section is often achieved when the mass is minimized and the stiffness is maximized. High stiffness keeps head-mass modes away from the band of interest with minimal material; low mass maximizes the motor section aspect ratio and re-

duces the stored energy in the head-mass, raising the electromechanical coupling coefficient. Therefore, the material selected for the head-mass construction plays an integral role in transducer performance. In the practical design of tonpilz radiating heads, a tool which can rapidly identify the materials best suited for a given design is desirable. The figure of merit, $E\rho^3$, has traditionally been used. This figure of merit, however, is based on thin-plate approximations. Most actual tonpilz head-masses require thick-plate theory for accurate analysis. In this paper, the authors use a numerical routine to rapidly assess the thick-plate behavior of various materials and rank their suitability for a given head-mass geometry. These results are corroborated with finite element modeling. Finally, the thick-plate ranking scheme is compared to the traditional figure of merit. The results of this comparison challenge established assumptions about the best materials for head-mass design and identify ceramic materials as strong candidates for future designs.

2pEAa3. Investigation of single crystals for U.S. Navy standard electro-acoustic transducer applications. Jeffrey A. Szelag and Thomas R. Howarth (Naval Sea Systems Command Div. Newport, Newport, RI)

The Underwater Sound Reference Division (USRD), Naval Sea Systems Division in Newport, RI, is the U.S. Navy's primary source for the provision of standard underwater electro-acoustic reference transducers. USRD has over 40 years of traceable and repeatable historic data for each transducer that is currently available for underwater calibrations and experiments. As such, USRD's primary focus is on the continuous development of new reference transducers incorporating the latest technologies available. Requirements for these standards include repeatability over extended time, traceability, and ease of maintenance. This presentation covers an on-going USRD investigation to feature single crystal PMN-PT as the active substrate in the current F41 program transducer. In addition, lossy rubber substrates are being examined to replace the legacy corprene passive materials in order to extend the operating depths of the transducer. Our presentation will begin with an overview of the fabrication techniques followed by experimental underwater data comparing the new active and passive materials with the traditional F41.

1:45

2pEAa4. A generalized differential effective medium model of piezoelectret foams. Michael R. Haberman (Appl. Res. Labs., The Univ. of Texas at Austin, 10000 Burnet Rd., Austin, TX 78758)

Piezoelectrets are closed-cell foams consisting of a continuous polymer matrix containing preferentially oriented and electrically polarized ellipsoidal voids. These materials display low density, low characteristic impedance, thicknesses on the order of 100 μm, and potential to act as conformal transducers on complex geometries. They therefore provide an intriguing alternative to piezoelectric ceramics and piezopolymers for applications such as air-coupled ultrasonics or underwater receive elements. Unfortunately, some fundamental attributes of piezoelectret behavior, such as their nonmonotonic change in receive sensitivity with increasing ambient pressure, remain unexplained by physical modeling or experiment. To explain this and other behavior, this work develops a fully coupled multiscale microelectromechanical model which captures the void-scale physics and predicts macroscopically observed piezoelectric properties. The model employs volume averaged Green's function solutions of the three-dimensional stress equilibrium equations and Gauss's Law. The resulting model approximates the effective stiffness, dielectric permittivity, and piezoelectric coupling tensors as a function of the constituent material properties, void fraction, shape, and orientation, as well as the deposited charge density. Strain localization tensors of the model are then employed to approximate piezoelectret dependence and external pressure. Model results show good agreement with experimental results and data from the literature.

2:00

2pEAa5. A micromachined piezoelectric flexural mode hydrophone for audible frequency application. Haksue Lee, Sungjoon Choi, and Wonkyu Moon (Dept. of Mech. Eng., Postech, South Korea, wkmoon@postech.ac.kr)

A micromachined hydrophone is designed for audible frequency application (20 Hz–20 kHz). The basic structure is a flexural unimorph consisting of a clamped silicon diaphragm and a piezoelectric film. Two design approaches can enhance its sensitivity. One is a unimorph with unequal radii between the piezoelectric film and the diaphragm, which increases electromechanical coupling. The other is an air-backed chamber, which reduces mechanical impedance in the flexural vibration and, consequently, enhances sensitivity. To predict the effects of these approaches on sensitivity, an equivalent transduction model is composed and used for calculations. In the case of oil backing, compared to air backing, a reduction in sensitivity of about 40 dB is expected. The dimensions of the micromachined diaphragm (piezoelectric film) are 630 μm (400 μm) radius and 15 μm (3 μm) thick. A fabricated microsensor is constructed as a hydrophone by using a rubber housing filled with castor oil. The measured sensitivity is −228.3 dB at 1V /μPa without a preamplifier. A flat frequency response within ±1 dB deviations were measured in the 100 Hz–5 kHz band. Based on the simulation, it can resist the hydrostatic pressure of 100 m depth, without pressure balancing, while decreasing in sensitivity. The results of a larger model having a higher sensitivity of −207.6 dB will also be presented. [Research supported by MRCND and R0A-2007-000-20042-0.]

2:15

2pEAa6. Advantages of piezoelectric microelectromechanical systems (MEMS) microphones. Robert Littrell and Karl Grosh (2250 GG Brown Bldg., 2350 Hayward St., Ann Arbor, MI 48109)

Microphones fabricated using microelectromechanical systems (MEMS) technology are one of the fastest growing applications of MEMS. Capacitive sensing has been the dominant form of transduction in both traditional and recently commercialized MEMS microphones. Models and experiments, however, indicate that the thin layers and fine spatial resolution made possible by MEMS technology lend themselves more appropriately to piezoelectric microphones. Although piezoelectric MEMS microphones have typically been shown to have a relatively high noise floor, this limitation can be overcome with appropriate design and high quality piezoelectric material. Models indicate that piezoelectric MEMS microphones can achieve a comparable noise floor to capacitive MEMS microphones of similar size and bandwidth while achieving 1000 times greater dynamic range. A piezoelectric MEMS microphone utilizing aluminum nitride (AlN) will be presented. Previously experienced film quality issues have been addressed. This microphone is designed to have a noise floor below 40 dB (A), a dynamic range greater than 160 dB SPL, a 10 kHz bandwidth, and a sensing area of less than 1 mm^2.

2:30

2pEAa7. Infrasonic microphone. Timothy Marston and Thomas B. Gabrielson (Grad. Prog. in Acoust., Penn State Univ., PO Box 30, State College, PA 16804, tmm357@psu.edu)

The high cost of many infrasonic transducers can be a setback for universities interested in performing research in the field of infrasound. Reasonably effective infrasonic transducers can be constructed in the laboratory, however, and for a fraction of the cost. A simple, inexpensive infrasonic microphone that operates on the principle of carrier demodulation has been constructed. Noise analysis of the microphone demonstrates its potential usefulness for cost-effective field research and deployment in temporary infrasonic arrays. [Research funded by the Penn State Applied Research Laboratory Educational and Foundational Fund.]

2:45

2pEAa8. Mechanical characterization of capacitor microphones for analysis and study. YuFan Chuang (Master Program of Electroacoustics, Feng Chia Univ., 100 Wenhwa Rd., Seatwen, Taichung, Taiwan 40724, ROC, yufan420@gmail.com), S. J. Pawar, and Jin H Huang (Feng Chia Univ., Taichung, Taiwan 40724, R.O.C.)

An attempt is made to investigate the mechanical properties of the diaphragm of capacitor microphone using MTS Tytron 250 micro-force testing machine. The compliance of the diaphragm is calculated from the force-displacement diagram. The simulation of the microphone is carried out using equivalent circuit method. The mechanical parameters like mass

(measured), compliance (measured and calculated), and resistance (assumed from literature) are being used to formulate mechanical domain of microphone in equivalent circuit model. The sensitivity curve of microphone is being plotted. Simultaneously, the experimental measurement has been carried by PULSE Electroacoustics with the software Sound Check in an anechoic chamber. The simulation and experimental results for sensitivity are found to follow each other within a wide frequency range. The characteristic investigation is carried out using validated equivalent circuit model for parametric study of microphone. [Work supported by Contract Nos. NSC 95-2221-E-035-013-MY3 and 95-2221-E-035-087. The authors would like to thank Leo Liao and Jack Wei of Merry Electronics Co. Taiwan and Listen Inc. for supplying Sound Check measurement.]

2pEAa9. Head related transfer functions for KEMAR. Gunnar Rasmussen (G.R.A.S. Sound & Vib., Skovlytoften 33, 2840 Holte, Denmark, gr@gras.dk)

The head related transfer functions (HRTFs) for KEMAR for a number of ear pinnas of different sizes and hardnesses have been measured. Right and left ear differences on KEMAR as well as change in HRTFs over the last 40 years will be reported along with data for the ITU - Type 3 and the IEC 60959 standardized pinna. The influencing factors on the uncertainty budget will be discussed.

3:15

2pEAa10. A transfer matrix method for estimating the dispersion and attenuation of plane waves in the standing wave tube. Kang Hou and J. Stuart Bolton (Herrick Lab, Purdue Univ., West Lafayette, IN)

In this paper, an iterative method based on the transfer matrix approach is described for evaluating the sound speed and attenuation constant of air in a standing wave tube. The procedure is based on transfer matrix, the four-microphone method for measuring the transmission loss of acoustical materials. In the latter procedure, a sample is placed between two pairs of microphones, where the sample is exposed to an incident plane wave field. In the present case, the air inside the standing wave tube is treated as the sampled material. Since the knowledge of the dispersion characteristics of plane waves within the tube is required to perform this measurement, an iterative method must be applied at the postprocessing step to estimate the complex wave numbers in the sample section. The result from the experiments showed that the air temperature within the tube has a significant impact on the results. The measured results were found to be in good agreement with the Temkin formula for attenuation in tubes. In addition, the approach may be extended to the accurate measurement of viscosity and sound velocity of liquids and gases.

2pEAb1. Bridging the gap between macro- and microdevices for manufacture of piezoelectric energy harvesters. Arthur L. Chait (EoPlex Technologies, Inc., 3698-A Haven Ave., Redwood City, CA 94063, achait@eoplex.com)

In this presentation, materials engineer and entrepreneur, Arthur L. Chait will show why there is a gap at the miniature scale when building complex devices with multiple materials. He will explain why few technologies can handle several materials, with complex geometries, in small parts. Miniature piezoelectric (PZ) energy harvesters are an example of this challenge. Mr. Chait will describe his piezoelectric energy harvester, designed for tire pressure sensor systems. This tiny device uses PZ materials to convert some of the vibration of the tire into electricity. The electric current is stored in a capacitor and used to power the system. Audiences will learn why it is difficult and costly to build a small, rugged system to power a tire sensor. The anatomy of this device includes at many diverse materials and five basic design elements. These are bonded into a strong package about the size of a contact lens. Building this energy harvester would be almost impossible with conventional manufacturing techniques. Mr. Chait will share a relatively new solution; i.e., a print deposition technique that produces thousands of parts simultaneously from many different materials. Active elements like circuits, catalyst beds, mixing chambers, capacitors, and piezoelectric actuators are produced all in one step.

4:00

2pEAb2. Acoustic energy harvesting using an electromechancal Helmholtz resonator. Fei Liu (Dept. of Mech. and Aerosp. Eng., Univ. of Florida, Gainesville, FL 32611-6250), Alex Phipps , Stephen Horowitz, Louis Cattafesta , Toshikazu Nishida , and Mark Sheplak (Univ. of Florida, Gainesville, FL 32611-6250)

This talk presents the development of an acoustic energy harvester using an electromechanical Helmholtz resonator (EMHR). The EMHR consists of an orifice, cavity, and a piezoelectric diaphragm. When the acoustic wave is incident on the EMHR, a portion of acoustic energy is converted to electrical energy via piezoelectric transduction in the diaphragm of the EMHR. Moreover, the diaphragm is coupled with energy reclamation circuitry to increase the efficiency of the energy conversion. Two power converter topologies are

adopted to demonstrate the feasibility of acoustic energy reclamation using an EMHR. The first is comprised of only a rectifier, and the second uses a rectifier connected to a flyback converter to improve load matching. Experimental results indicate that approximately 30 mW of output power is harvested for an incident sound pressure level of 160 dB with a flyback converter. Such power level is sufficient to power a variety of low power electronic devices.

2pEAb3. Theoretical study of thermoacoustic power conversion with a piezoelectric transducer. Carl Jensen and Richard Raspet (Natl. Ctr. for Physical Acoust., Univ. of MS, Univ., MS 38677)

A heat-driven thermoacoustic engine prototype has been designed with a piezoelectric transducer as an electroacoustic transformer. The design under consideration uses a bending, unimorph transducer placed between two identical thermoacoustic engines operating out of phase such that the transducer is driven in a push-pull fashion. The thermoacoustic engine is modeled using a one-dimensional low amplitude simulation. The piezoelectric unimorph is modeled by an electroacoustic equivalent circuit aimed at capturing the first order resonant behavior of the transducer; loss mechanisms from hysteretic behavior of the dielectric or elastic properties are not considered by the model. Issues in optimizing the geometry of the model will be presented as well as comparisons to other forms of waste heat power harvesting such as thermoelectric.

2pMUa1. Evaluation of two control parameters of trumpet players as function of sound features. Rene Causse (Ircam, 1 place Igor Stravinsky, F-75004 Paris, France) and Vincent Freour (McGill Univ., Montréal, PQ Canada.)

Experiments were performed by five trumpet players with the same trumpet and mouthpiece. For each subject, two control parameters are measured: mouth-pressure and force applied by the lips on the mouthpiece. The sound is also recorded. The players are asked to play sustained notes at different pitch and sound levels. We calculate fundamental frequency, sound pressure level, and some spectral features: noisiness, spectral roll-off, etc. Although little mouth-pressure variability as function of pitch and dynamic appears between subjects, clear differences were obtained in terms of the force applied on the mouthpiece. Therefore, we suggest to focus on the link between sound features and the ratio of these two control parameters measured, sort of "gesture estimator." The representation of the ratio as function of the sound features shows a good classification of musicians. Moreover, in some specific cases such as noisiness, the relation seems independent from the players. These observations suggest that these two control parameters could be efficient to characterize players' embouchure and to access some sound characteristics without knowledge of the mechanical characteristics of the lips. These results will be described and discussed, and direction for future works suggested. [Consonnes project, supported by the French Research Agency.]

1:30

2pMUa2. Does a brass-instrument's timbre depend on the alloy from which it is made? Robert W. Pyle, Jr. (11 Holworthy Pl. Cambridge, MA 02138, rpyle@post.harvard.edu)

Most brass players with a few years experience would give an affirmative answer to the question posed in the title. In the past, audible differences have proven elusive when pursued through spectral analysis of sustained tones, perhaps because the right question was not asked. This talk will examine several attributes of trombone spectra. The trombone used has a "modular construction" so that different bells can easily be installed on an otherwise unchanged instrument. A clear difference, consistent with the player's and listener's perception of the tone quality, emerges between yellow brass (70% Cu, 30% Zn) and red brass (90% Cu, 10% Zn). Transient behavior, particularly during the attack, is at least as important to the performer as sustained sounds. Here, too, differences are attributed to the alloy. Yellow brass is characterized by "crisp" attacks, red brass by "rounded" attacks. This talk will also analyze attack transients, even though attacks that are perceived as similar appear quite variable when examined in detail.

2:00

2pMUa3. Comparison of the mechanics of the brass players' lips during slurred note transients. John P. Chick and Shona M. Logie (SEE, Univ. of Edinburgh, Kings Bldgs., Edinburgh EH9 JL, UK, john.chick@ed.ac.uk)

When sounding a note on a brass instrument, a strong coupling is established between the vibrating lips of the player and the air column resonance. In moving between notes as smoothly as possible, or "slurring," there is a transition from one strongly coupled, steady-state, regime of the lip/air column to a different steady-state coupling of the lip/air column. To the listener, there are sometimes subtle differences in the sound of the transition between notes depending on how this transition is achieved: by lip slur, valve slurs, and, in the case of the trombone, slide slurs. This paper uses data collected from high speed video capture of the players' lips, synchronized with microphones in the mouthpiece and the bell of the instrument, to investigate and compare the motion of the brass players' lips for different types of slurred internote transients.

2:30

2pMUa4. Acoustical history of the tuba. Arnold Myers (Univ. of Edinburgh, Reid Concert Hall, Bristo Square, Edinburgh EH8 9AG, U.K.)

Low-pitched valved brass wind instruments are often described generically as tubas. In fact, the term "tuba" covers a broad family of instruments, with sounding lengths ranging from the 8 ft C of the classic French orchestral tuba to the 18 ft Bb of the brass band and orchestral contrabass. The first instrument designated as a tuba was introduced in 1835, and since then a variety of models differing in bore profile as well as in nominal pitch have been used. This paper explores the the historical development of the tuba family from an acoustical perspective, presenting and discussing measurements of bore profile and input impedance for a number of representative instruments from different periods and musical traditions.

2pMUa5. The double bell descant euphonium. Frederick J. Young (Div. of Com. and Arts, Univ. of Pittsburgh, 800 Minard Run Rd., Bradford, PA)

A euphonium is presented that has better intonation and is easier to play in the extreme registers. It is a complete double horn having five double valves in contrast to the incomplete normal double French horn having only three double valves. The valves descend 2, 1, 3, 4, and 5 semitones from the open tones. The large bell is for the B♭ standard part of the instrument. A switch valve activates the smaller alto bell in the key of high E ♮ and sends the air through the five shorter valve slides and out the small bell. The fundamental frequency of the E side is 82.4 Hz or six semitones above the fundamental of the B♭ euphonium. The key of E rather than F or E♭ enables all notes in the complete range (about 29–988 Hz) to be played with a single tunable valve slide. Either of the other keys would introduce a need for one additional valve or compromise the intonation.

3:30

2pMUa6. Optimization of valve tube lengths for brass instruments. Frederick Young (Div. of Com. and Arts, Univ. of Pittsburgh, 800 Minard Run Rd., Bradford, PA 16701, youngfj@youngbros.com)

The intonation deviations from the well-tempered scale are presented for valve brass wind instruments. Compensating and full double instruments are considered. Systems including descending valves and less popular ascending valves are studied. The lengths of the valve tubes are optimized by minimizing the overall root mean squared (rms) intonation error using the method established in 1967 [R. Young, J. Acoust. Soc. Am. **42**, 224–235 (1967)]. Open note detuning is considered in each case and improves the overall intonation. The worst three valve instrument without open note detuning has an rms deviation 24 cents The best of the three and four valve instruments is a three valve compensating euphonium tuned 3 cents sharp on the open notes and flat on valves 2, 1, and 3 by 3, 3, 10 cents, respectively. It exhibits only 2 cents rms deviation on single valves and less than 3 cents on combinations of valves. The comparisons also include several new three, four, and five valve systems. Included is a double horn with only two double valves and a switch valve.

2pMUa7. The input impedance of an alphorn including an Alexander mouthpiece. Frederick J. Young (Div. of Com. and Arts, Univ. of Pittsburgh, 800 Minard Run Rd., Bradford, PA 16701, youngfj@youngbros.com)

The alphorns built and sold by the late Joseph Littleton of Hammondsport, NY are used in this study. His dimensions of bore as a function of position are used in solution of the Webster equation for impedance solved numerically earlier [F. J. Young, Acustica, **10**, 91–97 (1960)]. The musical notation for the frequencies of the impedance peaks are given below. Here the subscripts refer to the harmonic number. The fundamental, rarely used, is 13 cents flat from A at 55 Hz. The intonations errors for. C_1, C_2, G_3, C_4, E_5, G_6, B^{b}_{7}, C_8, D_9, E_{10}, F_{11}, G_{12}, A_{13}, B^{b}_{14}, B_{15}, C_{16}, $C^{\#}_{17}$, and D_{18} are 287, 58, 195, 28, 1.5, 0.83, -28, -0.85, -2.63, 1.5, 40, 14, -49, 1, -3, 16, 24 and 28 cents.

4:15

2pMUb1. Imitating the human voice: The renaissance cornett and sackbut. Murray Campbell (Sch. of Phys. and Astron., Univ. of Edinburgh, Edinburgh EH9 3JZ, U.K., d.m.campbell@ed.ac.uk)

In the 16th century the lip-reed instruments most commonly used in sacred and chamber music were the cornett (Italian "cornetto") and the sackbut (Italian "trombone"). The sound ideal described by contemporary writers for these instruments was clearly distinguished from the ceremonial and often military splendor of the trumpet ensemble: the cornett and the sackbut were expected to produce dynamic levels and timbres comparable to those of human singers. The acoustical features, which make it much easier to approach this ideal on the renaissance instruments than on modern trumpets and trombones are explored through measurements on original instruments and modern reproductions.

Session 2pPA

Physical Acoustics and Biomedical Ultrasound/Bioresponse to Vibration: Numerical Methods for Weak Shock Propagation

Andrew A. Piacsek, Chair
Dept. of Physics, Central Washington Univ., Ellensburg, WA 98926-7422

Invited Papers

1:00

2pPA1. Numerical modeling of weak shock propagation: Past, present, and future. Andrew Piacsek (Dept. of Phys., Central Washington Univ., 400 E. University Way, Ellensburg, WA 98926, piacsek@cwu.edu)

This presentation provides an overview of the subject of numerical modeling of weak shock propagation, with the aim of providing context for subsequent talks in this session. First is a brief history of analytical approaches to the problem of weak shocks in both one and two dimensions, emphasizing the characteristic physical behavior of the solutions. This leads to a discussion of the physical processes that must be modeled, including the Rankine-Hugoniot conditions at the shock interface, nonlinear steepening, and self-refraction, refraction and diffraction due to an inhomogeneous medium, dissipation, relaxation, and heating of the medium. Next is a summary of paraxial numerical methods, specifically the NPE and KZK equations, and their recent applications, followed by a description of efforts to develop "wide-angle" versions of these codes. Computational challenges, and possible approaches, to extending these methods to three dimensions are also presented. Last, a brief introduction to new approaches to 3-D modeling will be given, along with a discussion of the applicability of computational improvements such as adaptive meshing and parallel processing.

1:20

2pPA2. Numerical simulation of acoustical shock waves: Beyond the parabolic approximation. Franck Dagrau, Mathieu Renier, François Coulouvrat, and Regis Marchiano (Univ. Pierre et Marie Curie, Institut Jean Le Rond d'Alembert (UMR CNRS 7107), 4 place Jussieu, 75005 Paris, France)

The KZK equation is the reference equation for the modeling of finite amplitude diffraction effects. It has been applied with success to many applications in various domains. Nevertheless, the parabolic approximation underlying the KZK equation limits the validity of this one to narrow-angle propagation. A new formulation of the Kuznetsov equation enables us to go beyond the parabolic approximation for the diffraction effects in the homogeneous case, the parabolic approximation being now limited only to the heterogeneous perturbation which is one order of magnitude smaller. This method formalizes and generalizes to the weakly heterogeneous case the

previous work of Christopher and Parker [J. Acoust. Soc. Am. **90**, 488–499 (1991)]. Special attention is paid to the implementation of boundary conditions (such as absorbing or perfectly matched layers). Several validation tests will illustrate the potential of the method, such as nonlinear focusing or scattering. Applications to sonic boom propagation in a turbulent atmosphere will finally be discussed.

1:40

2pPA3. Extension of the iterative nonlinear contrast source method to nonlinear media exhibiting tissue-like attenuation. Martin Verweij, Jacob Huijssen (Lab. of Electromagnetic Res., Fac. of Elec. Eng., Mathematics and Comput. Sci., Delft Univ. of Technol., Mekelweg 4, 2628 CD Delft, The Netherlands, m.d.verweij@tudelft.nl), and Nico de Jong (Erasmus Medical Ctr., Rotterdam, The Netherlands)

Recently, the Iterative Nonlinear Contrast Source (INCS) method has been developed to compute the pulsed acoustic pressure field in a nonlinear and lossless medium that extends over a very large, 3-D domain. This method solves the nonlinear wave equation by considering the nonlinear term as a distributed contrast source in a linear background medium. The full nonlinear wave field follows by convolving the background Green's function with successive estimates of the contrast source. It has been shown that by spatiotemporal filtering of the convolution factors, the method yields accurate field predictions even for a discretization approaching two points per smallest wavelength or period. The current paper discusses how attenuation, in particular tissue-like power law losses, may be incorporated into the method through the introduction of a causal compressibility relaxation function. The latter gives the background the desired loss behavior. Fields in nonlinear media with different power law losses are presented, as computed by the extended INCS method. Moreover, the ability of both the lossless and the extended INCS method to evaluate fields at the shock formation distance is shown. Especially the latter results show the significance of using a proper, tissue-like power law. [Work supported by STW and NCF.]

2:00

2pPA4. Weak shock propagation in the ocean and marine sediments. B. Edward McDonald (Acoust. Div. Naval Res. Lab, Washington DC 20375, mcdonald@ccs.nrl.navy.mil)

The nonlinear progressive wave equation (NPE) [B. E. McDonald and W. A. Kuperman, JASA 81, 1406 (1987)] was initially developed to model weak shock waves in a refracting medium (specifically, ocean acoustic convergence zones). It has been refined to include high-angle and two-way propagation. Inclusion of two-way propagation improves agreement with empirical power laws for peak pressure from an explosive as a function of range and explosive charge. The NPE is currently being used to examine weak shock propagation into marine sediments for studies related to mine countermeasures. An intriguing behavior results from the stress-strain relation for Hertzian granular media, in which stress is proportional to the 3/2 power of strain rate. Numerical and analytic solutions with the Hertzian nonlinearity reveal its most nonlinear behavior (shock formation) near zero stress, whereas in a fluid, shock formation results from high stress. Numerical experiments are presented to determine whether shocks resulting from Hertzian nonlinearity can be observed with nominal values of frequency-linear attenuation common to granular media. [Work supported by the Office of Naval Research.]

2:20

2pPA5. Modeling weak shocks produced by high-intensity focused ultrasound. Vera A. Khokhlova (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105/ Moscow State Univ., Moscow 119991, Russia), Olga V. Bessonova (Moscow State Univ., Moscow 119991, Russia), Michael S. Canney, Michael R. Bailey (Univ. of Washington, Seattle, WA 98105), Joshua E. Soneson (Food and Drug Administration, Silver Springs, MD 20993), and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

Shock waves of up to 100 MPa may form at the focus of high-intensity focused ultrasound (HIFU) transducers at clinically reported *in situ* intensities of up to 30,000 W/cm^2. The heating due to shocks is sufficient to boil tissue in milliseconds, which dramatically alters the treatment. Quantification of enhanced heating from shocks is therefore critical to treatment planning. In this work, several approaches and temporal grids of different resolutions were used to simulate HIFU fields. Peak positive pressure, which determines the shock amplitude, and thus the heating rate were found to be the most sensitive to the parameters of the numerical scheme. Heating rates calculated in modeling and estimated using weak shock theory from the measured and modeled waveforms were compared. Time to boil measured in tissue phantoms and tissue was used as a metric of the heating efficiency of shocks. It is shown that the bandwidth limitations in the waveform measurements result in underestimation of the heat rates, although boiling onset predicted in modeling agreed well with the experimental data. An experimentally validated numerical model thus can be an effective tool in both laboratory and clinical HIFU setting. [Work is supported by NIH EB007643 and NSBRI SMST01601.]

2:40

2pPA6. Numerical simulation of the propagation of three-dimensional helical shock waves in a weakly heterogeneous medium. Regis Marchiano, Francois Coulouvrat (Univ. Pierre et Marie Curie, Institut Jean Le Rond d'Alembert (UMR CNRS 7107), 4 place Jussieu, 75005 Paris, France), and Jean-Louis Thomas (Univ. Pierre et Marie Curie, 75005 Paris, France)

A numerical method for the simulation of 3-D acoustical shock wave propagation through a homogeneous or weakly heterogeneous medium is presented. It is based on a generalization of the KZ equation taking into account weak heterogeneities. The algorithm is based on a spectral treatment of the linear diffraction (angular spectrum), coupled with quasianalytical solutions for the heterogeneous part and for the nonlinear one. This last one solves Burgers' equation with the so-called Burgers-Hayes method using the potential instead of the pressure field. The combination of these several algorithms lead to the development of an efficient software, allowing to solve full 3-D problems for standard personal computers. This software is used to study the dynamics of helical shock waves also called acoustical vortices (AVs) which are the acoustical equivalent of optical vortices. The 3-D helical spatiotemporal wave field is characterized by azimuthal shocks. The dynamics of the so-called topological charge, an intrinsic property of AVs, is studied in the nonlinear regime through different focusing lenses.

3:00—3:20 Break

3:20

2pPA7. Numerical methods for weak shock propagation and diffraction around a microphone. Victor W. Sparrow (Penn State, Grad. Program in Acoust., 201 Appl. Sci. Bldg., University Park, PA 16802, vws1@psu.edu)

There are two interrelated goals for this presentation. The first goal is to give an overview of available numerical approaches for weak shock propagation. There are multiple approaches available, including formulations based on the Burgers equation, KZK or NPE equations, the second-order equations of nonlinear acoustics, the Navier-Stokes equations, or the Boltzmann equation. There are also multiple numerical techniques for discretizing each of underlying equations, and while some approaches give special treatment to weak shocks others handle the shocks automatically. The second goal of this presentation is to show recent simulation results for an explosion shock interacting in two dimensions with a microphone. The diffraction of the weak shock around the microphone housing does turn out to be amplitude dependent. It is only a modest effect, increasing for higher amplitudes. This knowledge is important for precise, close-range blast source characterization. In the future, the nonlinear diffraction of weak shocks around transducers also should be investigated for finite amplitude biomedical ultrasound, since the mechanisms for nonlinear diffraction are almost identical for ultrasound and explosion waves. [Work supported by U.S. Army ERDC-CERL.]

3:40

2pPA8. Simulations of converging shocks in water. Veronica Eliasson (Graduate Aerosp. Lab., Caltech, 1200 E. California Blvd., Pasadena, CA 91107, vero@caltech.edu), William D. Henshaw (LLNL, Livermore, CA 94551), and Paul E. Dimotakis (Caltech, Pasadena, CA 91125)

Numerical simulations of weak shocks in water traveling through a convergent geometry were performed. The convergent geometry is surrounded by an elastic solid, which is deformed by the fluid, thereby, generating elastic waves in the solid, which in turn affect the liquid, thus creating a coupled fluid-structure problem. Here, we use the Overture suit, which is a code for solving partial differential equations on curvilinear overlapping grids using adaptive mesh refinement. In particular, we use a multiphysics solver to solve the fluid-structure problem. The Euler equations with a stiffened equation of state are used in the fluid domain and the linear elasticity equations are used in the solid domain. The solutions at the interface between the fluid and the solid are matched using continuity of normal velocities and forces. Preliminary results indicate that the wave speed of the material has a large influence on the behavior of the converging shock. The numerical simulations are also compared to schlieren photographs and pressure measurements obtained from experiments. Results can enhance the design of marine structures with convergent sections subjected to dynamic loading events. [Work supported by ONR.]

3:55

2pPA9. Comparison of time and frequency domain approaches to simulate propagation of weak shocks. M.V. Averiyanov, P.V. Yuldashev (Faculty of Phys., Moscow State Univ., Moscow 119991, Russia, misha@acs366.phys.msu.ru), Ph. Blanc-Benon (LMFA, UMR CNRS 5509, Ecole Centrale de Lyon, 69134 Ecully Cedex, France 5509), and V.A. Khokhlova (Univ. of Washington, Seattle, WA 98105)

Simulations of acoustic fields using finite-difference methods are performed either in time or frequency domains. A method of fractional steps with an operator splitting procedure is frequently applied to solve nonlinear equations of the evolution type. Either time or frequency domain solvers can be used to calculate different terms in the equation over a propagation grid step. In this work, several algorithms that have been used to simulate quadratic nonlinear term in the Burgers or KZK-type evolution equations are applied to model the propagation of weak shocks. Shock capturing schemes of Godunov type, exact analytic solution with further extrapolation of the waveform over a uniform temporal grid, time-domain conservative schemes, direct modeling in the frequency domain, and asymptotic spectral approach are compared. The parameters of the schemes that would provide the results of the same accuracy, an artificial absorption necessary for stability of the schemes, resolution of shocks, and internal viscosity of the algorithms are discussed. It is shown that the Godunov-type algorithm is better suited to model weak shocks with sufficient accuracy achieved with only three temporal grid points per shock. [Work supported by the RFBR and NIH EB007643 grants.]

4:10

2pPA10. A shock-fitting method for general nonlinear progressive waves. Francois Coulouvrat (Univ. Pierre et Marie Curie, Institut Jean Le Rond d'Alembert (UMR CNRS 7107), 4 place Jussieu, 75005 Paris, France)

Many physical phenomena are concerned with the propagation of weak nonlinear waves that can be modeled under the form of a generalized Burgers equation. Physical examples include nonlinearities that can be either quadratic (nonlinear acoustical waves in fluids or longitudinal waves in solids), cubic (nonlinear shear waves in isotropic soft solids), or nonpolynomial (Buckley-Leverett equation for diphasic fluids, models for car traffic, Hertz contact in granular media). A new weak shock formulation of the generalized Burgers equation using an intermediate variable called "potential" is proposed. This formulation is a generalization to nonquadratic nonlinearities of the method originally proposed by Burgers himself in 1954 for his own equation, and later applied to sonic boom applications by Hayes et al. (1969). It is an elegant way to locate the position of a shock. Its numerical implementation is almost exact, except for an interpolation of Poisson's solution that can be performed at any order. It is also numerically efficient. As it is exact, a single iteration is sufficient to propagate the information at any distance. It automatically manages waveform distortion, formation of shock waves, and shock wave evolution and merging. The theoretical formulation and the principle of the algorithm are detailed and illustrated by various examples of applications.

4:25

2pPA11. A nonlinear computational method for the propagation of shock waves in ducts: Application to buzz-saw noise. Rasika Fernando, Yann Druon (Airbus France, Acoust. Environment Dept. Turbomachinery Acoust. (EDEA3), 316 route de Bayonne, 31060 Toulouse Cedex 03), Regis Marchiano, and Francois Coulouvrat (Univ. Pierre et Marie Curie, 75005 Paris, France)

A numerical method to compute shock wave propagation in uniform waveguides in 2-D and 3-D is presented. The solution is searched under the form of a modal solution of the Kuznetsov equation for which the modal amplitudes of the analytical linear modes are supposed to vary along the duct axis due to nonlinear interactions between the different modes and frequencies. This finally yields to a differential system on the mode amplitudes, which is solved numerically using a standard Runge-Kutta algorithm for ordinary differential equations after numerical truncation of the modal series. Examples are presented of the nonlinear evolution of the pressure field for a 2-D waveguide. One important 3-D application is the so-called "buzz-saw" noise occurring for high-bypass-ratio turbofan engines, when fan blade tip relative flows exceed the sound velocity. First results on 3-D simulations for nonlinear propagation of a saw-tooth waveform spiraling inside a hard-walled cylindrical will be presented. Extensions of the model to ducts with uniform flows or with liners (walls with impedance) will finally be discussed.

4:40

2pPA12. Evaluation of a wave vector frequency domain method for nonlinear wave propagation. Yun Jing and Greg Clement (Dept. of Radiology, Harvard Med. School, Brigham and Women's Hospital, Boston, MA 02155)

In this paper, a wave vector frequency domain method is presented to describe both forward and backward nonlinear wave propagations in acoustic media. A frequency domain nonlinear wave equation is first derived based on the Westervelt equation by taking the Fourier transform in the temporal and spatial domains. Since the model works directly in the frequency domain, arbitrary dispersion relations can be elegantly considered. The nonlinearity is further evaluated by multidimensional autoconvolution of the Fourier transform of the sound pressure. An implicit solution of the equation is proposed by employing the Green's function, and is solved numerically. Comparisons between the numerical simulations and the Burger's solution show good agreements within the shock formation distance. Error study is also carried out to test the efficiency of the model. It is found that the error grows as the initial pressure increases and the spatial resolution decreases. Finally, the present model is compared with a time-domain approach for a practical case, where the diameter of the transducer is 100 mm, the fundamental frequency is 1 MHz, and the focus range is 150 mm.

Session 2pSA

Structural Acoustics and Vibration: Emerging Applications of Structural Acoustics

Sean F. Wu, Chair
Dept. of Mechanical Engineering, Wayne State Univ., Detroit, MI 48202

Invited Papers

2:00

2pSA1. Intrinsic damping models and their role in predicting structural response. Allan D. Pierce (Dept. of Mech. Eng., Boston Univ., Boston, MA 02215, adp@bu.edu) and Adnan Akay (Bilkent Univ., Ankara, Turkey)

In many industries, it is often desired to estimate whether a structure can withstand severe broad-band high-frequency loads. Because the structures have many natural frequencies within the band of interest, the response is critically affected by the damping within the structure. One typically performs finite element model computations with the elastic modulus replaced by a complex number, the ratio of imaginary to real parts being the loss factor, this taken as frequency independent. The crudity of such a model invariably leads to designs that are either overly conservative or not inspiring confidence. The present paper revisits the topic of internal damping from a fundamental standpoint and adopts the viewpoints of [J. J. Thomson (1888), Clarence Zener (1948)], in which "all anelastic phenomena are regarded as the superposition of elementary processes in which the stress relaxes exponentially." The resulting general model involves a continuous distribution over relaxation times. Lumped parameter realizations require that the configuration of the structure be described by the positions of all the mass points, and also by those of a large number of "hidden variables" connected to the mass points by Maxwell elements (spring and dashpot is series). General implications of the model are derived and explained.

2:20

2pSA2. Measurement methodologies for the analysis of influence of surface panels and their vibrations on interior cabin noise. Sean Wu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202, aa3199@wayne.edu) and Allan Pierce (Boston Univ., Boston, MA 02215)

In the design of quiet automobile compartments, one analyzes the influence of individual panels and enclosure surface leaks on noise received in a specific region (the location of the driver's ear position). Two recent papers [Hald *et al.*, Internoise (2006); Wolff, Internoise (2007)] suggest the needed measurement process can be shortened using a sound source at the typical listener position, taking measurements over the enclosure surface, and then invoking the principle of reciprocity. The present paper clarifies the analytical discussions of these earlier papers with improved and more nearly rigorous derivations and suggests improved measurement methodologies. One exemplary model considered is that of an arbitrarily shaped cavity with sound absorbing walls that are also moving due to external influences. The boundary condition on the pressure field inside the cavity is shown to be well approximated such that the normal component of the pressure gradient is a superposition of a constant times the pressure itself (locally reacting surface with finite impedance) plus a constant times the portion of the surface velocity that is due to the external sources. The pressure inside the cavity can be solved by Green's function techniques, and the Green's function can be proven to rigorously satisfy reciprocity.

2:40

2pSA3. Using structural acoustics methods to study new materials. J. D. Maynard (Dept. of Phys., The Pennsylvania State Univ., University Park, PA 16802)

In structural acoustics it is usually necessary to know the vibration properties of the structure under study, and this requires knowing the elastic constants of the materials involved. A relatively recent and powerful method for measuring elastic constants is resonant ultrasound spectroscopy (RUS). Very new and exotic materials for structures often require RUS; the reason is that new materials, when first fabricated, are often available only in very small samples (a few hundred micrometers) or as thin films on substrates, and RUS is the best method for handling such samples. On some occasions samples are fragile or chemically reactive so that they cannot be pol-

ished into the shapes required by conventional RUS. Thus, it has been necessary to develop a RUS analysis for arbitrarily shaped samples. This has been accomplished by borrowing a method from structural acoustics: the finite element method (FEM). The discussion of the application of FEM to RUS for arbitrarily shaped samples will include bridging the gap between theory (involving matrices as boldfaced symbols without indices in textbooks on FEM) and actual lines of computer code. Applications of the RUS method for materials will also be discussed.

3:00—3:20 Break

3:20

2pSA4. Spatial maps of modal damping from frequency response measurements. J. Gregory McDaniel, Craig Boucher, and Hande Öztürk (Mech. Eng. Dept., Boston Univ., 110 Cummington St., Boston, MA 02215)

A method is proposed for constructing spatial maps of modal damping for viscously damped structures. These maps are intended to be useful in assessing the effectiveness of spatially distributed damping, particularly in complex structures that are damped by a variety of mechanisms. The method uses frequency response measurements and modal analysis to determine the natural frequencies and mode shapes of the damped structure. The damping matrix is estimated directly from the frequency response measurements and is expressed as a sum over connectivity matrices weighted by dashpot constants. This sum is substituted into the well-known approximation for the modal loss factor that results by neglecting off-diagonal elements of the modally transformed damping matrix. The resulting expression quantifies the contribution of local dashpot properties to the modal loss factor, and may be visually presented as a spatial map of damping. A significant advantage of this approach is its independence from a detailed model of the structure or its damping, allowing it to be used for complex structures. The resolution of the map is directly correlating to the number of measurement locations, as will be illustrated by examples. [Work supported by ONR under Grant No. N000140810531.]

3:40

2pSA5. A three-dimensional Wiener-Hopf technique for general bodies of revolution, Part II: Substructuring and implementation. Rudolph Martinez and Carina Ting (CAA-Alion Corp., 84 Sherman St., Cambridge, MA 02140)

This paper begins with a brief review of Part I's main ideas and conclusions regarding: (a) Operator-induced symmetry and reciprocity leading to compatibility of the halfplanes of analyticity between the integral equation's non-translational kernel and those of the Fourier-transformed displacements and pressures on the surface of a scattering or vibrating body of revolution; and (b) subsequent spectral factorizations in juxtaposition to those of the classical Wiener–Hopf case for the planar geometry. The spatial and spectral domains in question refer to the arclength variable along the body's generator and to its transform wavenumber, respectively. The analysis described in this Part-II paper brings out some of the additional positive consequences of the pre-symmetrization of the integral equation that governs the response of the coupled fluid and structure. It then applies standard substructuring schemes to extend Part I's formulation to include departures from axisymmetry resulting from generic appendages as discontinuities along the shape's circumferential coordinate. The presentation ends with sample applications of its new 3-D Wiener–Hopf technique to canonical shapes of revolution, and with a summary of the physical insights made possible by the new approach relative to numerical results by boundary elements.

4:00

2pSA6. Surface wave testing of pavements. Nils Ryden (Eng. Geology, Faculty of Eng., Lund Univ., Box 118, SE-22100 Lund, Sweden)

Pavements are constructed using several layers of materials, and their durability depends on the quality of all of these strata. It is, therefore, valuable to be able to determine the properties of the layers nondestructively. A method is presented for evaluating the thickness and stiffness of multilayered pavement structures from guided waves measured at the surface. In this type of layered structure, the interaction of leaky Lamb waves in the embedded layers generates surface waves corresponding only to certain portions of the guided wave dispersion curves and branches measurable at the pavement surface. To resolve the different mode branches, the wavefield is measured at the surface by using a light hammer as the source and an accelerometer as receiver, generating a synthetic receiver array. The recorded data are transformed to a phase velocity spectrum, which is then inverted to give the layer properties using a global inversion algorithm. The theoretical background along with experimental results of the application to nondestructive testing of pavements will be presented. Ongoing research on noncontact air-coupled measurements is also demonstrated. This opens up the possibility for faster on-the-fly surface wave testing of pavement layers, since surface contact is no longer required.

4:20

2pSA7. Innovative structural acoustic strategies to reduce sound transmission through lightweight flexible structures. Donald Bliss, Qinxian He, Linda Franzoni, and Cassidy Palas (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708, dbb@duke.edu)

This paper describes research utilizing structural acoustics in novel ways to cancel the transmission of sound and vibration through multielement flexible barriers. Configurations analyzed include panels with different thickness and elastic modulus in different regions and layered structures connected by an elastic suspension. The purpose of the research is to demonstrate that flexibility and controlled resonant behavior can be used to block sound transmission even when structural damping is very low. Strategies are considered to alter vibrating surface wavenumber spectra to reduce coupling between the structure and the acoustic field. Another approach that can be employed is the utilization of structural wave cutoff with multielement multipath (MEMP) structures. Finally, multiple differentially tuned subsidiary elements acting as resonators can be used to greatly reduce the structural response. Examples of acoustic transmission

loss through panel barriers using different strategies are presented, and the potential advantages and possible shortcomings of various approaches are evaluated. Possible configurations for layered sound reduction materials are proposed. The work has particular application to the reduction of vehicle interior noise and addresses the need for good acoustic performance of the lighter weight flexible structures that will be used in the future.

TUESDAY AFTERNOON, 19 MAY 2009 EXECUTIVE SALON I/II/III, 2:00 TO 5:30 P.M.

Session 2pSC

Speech Communication and Psychological and Physiological Acoustics: Exploring the Relationship Between Cognitive Processes and Speech Perception (Lecture/Poster Session)

Amee P. Shah, Chair
Dept. of Speech and Hearing, Cleveland State Univ., Cleveland, OH 44115

Chair's Introduction—2:00

2pSC1. Perceptual learning and expectations: Cognitive mechanisms in speech recognition. Howard Nusbaum (Dept. of Psych., The Univ. of Chicago, 5848 S. University Ave., Chicago, IL 60637, h-nusbaum@uchicago.edu)

There is substantial plasticity in adult perceptual processing of speech that cannot be accounted for by most theories. Even 1 h of training on low-intelligibility synthetic speech can improve recognition by 20 percentage points for novel words. Whether speech perception is based on auditory properties or articulatory properties, few theories acknowledge the role of cognitive processes, and some explicitly exclude these mechanisms. Evidence will be examined suggesting perceptual learning of phonetic information in adult listeners involves processes such as attention and working memory. In addition, evidence will be examined that speech perception can be influenced, if not typically guided, by listeners' expectations about speech. In some cases, expectations may be derived by explicit instruction to listeners, and in others, from contextual information. For example, research on talker normalization and perception of sinewave speech has demonstrated that listeners' expectations about the speech signal change perceptual processing. Evidence will be discussed suggesting mechanisms that mediate this effect of expectations and compare this to mechanisms involved in perceptual learning. Perceptual learning may depend on the same kinds of cognitive mechanisms involved in the top-down guidance of perception by expectations and these mechanisms may be necessary for stable phonetic perception. [Research supported by NIDCD.]

2:25

2pSC2. The role(s) of capacity limitations in speech perception. Alexander L. Francis (Speech, Lang., and Hearing Sci., Purdue Univ., 500 Oval Dr., West Lafayette, IN 47907, francisa@purdue.edu)

This paper reviews some current research exploring the role that capacity limitations play in recognizing speech, particularly in the presence of competing speech. Load theory [Lavie, Trends Cogn Sci **92** (2005)] suggests that perceptual capacity limits the number of objects (or features) that can be processed simultaneously, while cognitive capacity limits rejection of irrelevant information. Functional imaging studies show increased cognitive (working memory) load corresponding to failure of inhibition of (increased activity in) brain regions associated with processing distractor stimuli [de Fockert *et al.*, Science **291** (2001)], whereas increased perceptual load results in decreased activity in distractor-related areas [Rees *et al.*, Science **278** (1997)]. However, all of these studies were carried out in the visual modality, and it is unclear whether the same predictions were obtained in audition or speech perception. A series of experiments in which perceptual and working memory load were varied as listeners identified words produced by one talker while ignoring another provides qualified support for the predictions of load theory and lays the groundwork for subsequent studies of the effects of hearing impairment, cognitive deficits, and perceptual and cognitive training on the perception of speech in competing speech. [Work supported by NIDCD R03DC006811.]

2:45

2pSC3. Hearing the forest despite the trees: Perceptual learning of systematic variation in speech. Lynne C. Nygaard (Dept. of Psych., Emory Univ., Atlanta, GA 30322)

A fundamental problem for the understanding of spoken language processing is listeners' robust perceptual constancy in the face of enormous variability in the instantiation of linguistic form. On the one hand, listeners are sensitive to the fine-grained structure of linguistic segments that signal differences among talkers and speaking styles. On the other hand, listeners tolerate large discontinuities in this same fine structure forming robust, perceptually constant linguistic categories. Data from a perceptual learning paradigm addressing both the limits and flexibility of speech perceptual mechanisms will be presented and discussed in light of evidence for perceptual learning of accented speech. In a series of studies, listeners were exposed to accented English under learning conditions in which

the opportunity to compare across instances varied. At test, generalization and long-term retention of perceptual learning were evaluated. The results suggest that adaptation to lawful variation in speech is fundamentally influenced by the character and structure of the learning experience. These findings suggest cognitive constraints on behavioral and representational plasticity in speech perception and spoken language processing.

3:05

2pSC4. The nature and time course of the relationship between surface variability and linguistic processing. Amee Shah (Dept. of Health Sci., Cleveland State Univ., 2121 Euclid Ave., MC 429, Cleveland, OH 44115) and Conor McLennan (Cleveland State Univ., Cleveland, OH 44115)

It is becoming increasingly prevalent to study and understand the role of surface information in the process of speech perception and to attempt to accommodate these variables in theories of speech perception. Indeed, theories of speech perception increasingly require an account of the precise circumstances under which surface details affect the ease with which listeners access spoken words. To date, the majority of studies have focused on manipulating various components of surface information (e.g., speaking rate, talker differences, dialect difference, and so on) to determine whether these manipulations matter to the processing task. The present set of studies in our laboratory represents the converse component of this relationship in order to determine whether linguistic complexity can affect or modulate listeners' overt subjective impressions of the surface information. Two different methodologies, including semantic priming and repetition priming, were used manipulate ease of lexical access and determine the role on listeners perception of surface details (foreign accent). Additionally, the time course of the effect of linguistic context on accent rating judgments was studied as it manifested itself differently at different points during perceptual processing. Overall, these studies help understand the complex nature of the relationship between surface variability and linguistic processing.

3:25

2pSC5. Influences of auditory object formation on speech perception. Barbara G. Shinn-Cunningham and Dali Wang (Boston Univ. Hearing Res. Ctr., Auditory Neurosci. Lab., 677 Beacon St., Boston, MA 02215)

In common social settings, our ears receive a jumbled mixture of sound coming from different sources in different directions. A normal hearing listener is adept at using the low-level acoustic structure in the sound mixture to organize this cacophony into auditory objects, each corresponding to a distinct talker (i.e., performing auditory scene analysis). Typical listeners are also proficient at focusing on the talker of interest and ignoring distracting objects (i.e., directing selective attention to the desired object). Often, despite the efficacy of object formation and selective attention, portions of an attended object are inaudible, masked by sources that overlap the attended source in time and frequency. In such situations, listeners "fill in" the missing speech and extract a meaningful, whole message from the sound mixture, a process known as "phonemic restoration." This talk will review some recent studies demonstrating that the process of phonemic restoration, which relies on high-level, acquired knowledge about speech structure and meaning, is directly impacted by low-level acoustic attributes that influence auditory grouping. These results demonstrate the inter-connected nature of the high-level processes that allow listeners to communicate in challenging settings.

3:55—4:25 Panel Discussion

4:25—4:30 Break

Contributed Papers

All posters will be on display from 4:30 p.m. to 5:30 p.m. To allow all contributors an opportunity to see other posters, contributors of odd numbered papers will be at their posters from 4:30 p.m. to 5:00 p.m. and contributors of even numbered papers will be at their posters from 5:00 p.m. to 5:30 p.m.

2pSC6. The learning of lexical tones. Sunjing Ji (Dept. of Linguist., Univ. of Arizona, Douglass Bldg., Rm. 200E, Tucson, AZ 85719, sunjing@email.arizona.edu)

Our understanding of speech perception suggests that categorization is an essential task of our cognitive system. Based on previous research on segment perception, this study explores the questions of what mechanism is involved in the acquisition of lexical tones and whether contour tones are decompositional in the process of cognitive learning. An experiment adopting the statistical training method from Maye *et al.* (2002) and Hayes-Harb (2007) was conducted on the learning of lexical tones by adult naive tone learners. The results show that statistical distribution of stimuli along a pitch continuum in training affects naive tone learners' formation of level lexical tone categories. In addition, the perception of level tones behaves more like the perception of vowels rather than consonants. Moreover, exposure to statistical training on a level tone continuum alone affects participants' performance in contour tone discrimination. This indicates that participants were able to apply level tone categories to generate new mental categories of contour tones, providing psychological evidence for the auto-segmental argument that contour tones are composed of a sequence of multiple level tones.

2pSC7. Effects of differences in fundamental frequency on cross-formant grouping in speech perception. Robert J. Summers, Brian Roberts (Psych., Sch. of Life and Health Sci., Aston Univ., Birmingham B4 7ET, UK, r.j.summers@aston.ac.uk), and Peter J. Bailey (Dept. of Psych., Univ. of York, Heslington, York YO10 5DD, UK)

In isolated syllables cross-formant perceptual grouping can be promoted by a common fundamental frequency (F0), but this effect is relatively weak [Darwin, Q., J. Exp. Psychol. **33A**, 185–207 (1981)]. Few studies have explored the role of F0 in cross-formant grouping using sentences. Three-formant (F1+F2+F3) analog of almost continuously voiced natural utterances were synthesized using a monotonous glottal source (F0=150 Hz). Perceptual organization was probed by presenting stimuli dichotically (F1+F2C+F3; F2), where F2C is a competitor for F2 that listeners must resist to optimize recognition. Competitors were created using time-reversed

amplitude and frequency contours of F2, and F0 was manipulated ($\Delta F0 = \pm 8, \pm 2$, or 0 semitones relative to the other formants). Adding F2C reduced intelligibility for most utterances, and this reduction was greatest overall when $\Delta F0 = 0$. However, as for isolated syllables, the effect of $\Delta F0$ was quite small. Competitor efficacy was also somewhat dependent on absolute F0. Manipulation of relative F2C level indicated that competitor efficacy was not due primarily to energetic masking. The modest effect of $\Delta F0$, both for sentences and isolated syllables, suggests that cross-formant grouping depends more on other factors, for example common patterns of modulation. [Supported by EPSRC]

2pSC8. The perceptual organization of sine-wave speech under competitive conditions. Brian Roberts, Robert J. Summers (Psych., Sch. of Life and Health Sci., Aston Univ., Birmingham B4 7ET, UK, b.roberts@aston.ac.uk), and Peter J. Bailey (Univ. of York, Heslington, York YO10 5DD, UK)

Speech comprises dynamic and heterogeneous acoustic elements yet is heard as a single perceptual stream, even when accompanied by other sounds. The relative contributions of grouping primitives and of speech-specific factors, for example modulation patterns, to the perceptual coherence of speech are unclear, and the critical acoustical correlates of the latter remain unknown. The parametric manipulations possible with simplified speech, such as sine-wave analogs, make them attractive experimental stimuli to explore this issue. Given that the factors governing perceptual organization are generally revealed only where competition operates, the second-formant competitor (F2C) paradigm was used, in which the listener must resist competition to optimize recognition [Remez et al., Psychol. Rev. 101, 129–156 (1994)]. Three-formant (F1+F2+F3) sine-wave analogs were derived from natural utterances and presented in a dichotic configuration (one ear = F1+F2C+F3; opposite ear = F2). Different versions of F2C derived from F2 by manipulating its amplitude and frequency contours were effective at reducing intelligibility except when the frequency contour was constant. Manipulation of relative F2C level indicated that competitor efficacy was not due primarily to energetic masking. The findings suggest that modulation of the frequency, but not the amplitude, contour is critical for cross-formant grouping. [Work supported by EPSRC.]

2pSC9. Developing audio-visual associations in infancy. Francisco Lacerda, Eeva Klitfors, and Ellen Marklund (Dept. of Linguist., Stockholm Univ., SE-106 91 Stockholm, Sweden, frasse@ling.su.se)

To investigate how possible biases in matching of object sizes with sound intensities may be influenced by the ecological relevance of the potential associations, three groups of Swedish infants (4, 6, and 8 months of age) are being tested in their preferences to match speech or nonspeech sounds of different intensities with visual stimuli showing faces or unanimated objects of different sizes. The infants' audio-visual matching preferences are measured by the cumulative time that the infants' gaze vector was directed to each of the faces and objects simultaneously displayed on the screen, in response to the presentation of an acoustic stimulus (either a speech sound or a nonspeech sound). The results appear to suggest a general trend towards matching of visual prominence with sound intensity, when the ecological relevance of the audio-visual associations was high (i.e., matching speech sounds with faces and nonspeech sounds with unanimated objects) but the pattern seems to be disturbed when only nonecologically relevant matches are possible. [Work carried out within grants from The Bank of Sweden Tercentenary Foundation, Grant No. K2003:0867, MILLE, from EU-NEST Project No. 5010, CONTACT, and from the Knut and Alice Wallenberg Foundation, Grant No. KAW 2005.0115.]

2pSC10. Voice familiarity helps infants tackle variability in the speech signal. Marieke van Heugten and Elizabeth Johnson (Dept. of Psych., Univ. of Toronto Mississauga, 3359 Mississauga Rd. N., Mississauga, ON, Canada, L5L 1C6, marieke.vanheugten@utoronto.ca)

The acoustic realization of lexical items produced by different speakers can vary greatly. Current research suggests that infants, unlike adults, struggle to cope with this lack of invariance in the realization of words. Although 7.5-month olds are able to recognize words across different utterances when produced by speakers of the same gender with similar voices, they fail to do so when target words produced in a female voice are subsequently produced in a male voice [Houston and Jusczyk (2000)]. Note that all work in this area has used disembodied unfamiliar voices to test infants. In the current study, we ask whether infants might perform better under more ecologically valid conditions, i.e., when tested on familiar rather than unfamiliar voices. Using the headturn preference procedure, infants were familiarized with passages spoken by their mother. During the test phase, they were presented with their father's voice producing isolated repetitions of familiarized target words. Preliminary results suggest that infants may recognize words across different utterances produced by speakers of different genders if they are highly familiar with both the male and female speakers. In other words, infants may handle variability in the realization of words better when tested on familiar rather than unfamiliar voices.

2pSC11. The development of infants' sensitivity to modified spectral tilt: Fricatives, approximants, and vowels. Elizabeth Beach and Christine Kitamura (MARCS Auditory Labs., UWS, Bdg. 5 Bankstown Campus, Locked Bag 1797, Penrith South DC 1797, NSW, Australia)

In early infancy, speech perception is based on innate psychoacoustic thresholds allowing young infants to discriminate a wide range of speech contrasts. However, as infants accumulate knowledge of their native language, they begin attuning to native speech sounds: first vowels around 6 months; then consonants around 9–12 months. Now that hearing-impaired infants are being diagnosed and fitted with hearing aids early in life, there is a need to investigate how speech is amplified in infant hearing aids. This study examined whether infants would benefit from positive, negative, or unmodified spectral tilt. Spectral tilts of +6dB/octave and −6dB/octave (as found in hearing aids) were applied to three speech contrasts (fricatives, approximants, vowels) and in a third condition the contrasts remained unmodified. Normal-hearing 6- and 9-month-olds were tested using an habituation procedure to determine whether positive, negative, or unmodified tilt aids discrimination of the speech contrasts. The results showed 6-month-olds benefit when relevant frequency information is amplified, i.e., high-frequency for fricatives and approximants, low-frequency for vowels. Nine-month-olds, on the other hand, discriminated all contrasts best when unmodified. The developmental change between 6 and 9 months might be explained by infants shifting from an acoustic to a linguistic mode of speech perception.

1:30

2pSP1. Alternative signal processing models for broadband underwater propeller sounds. Les Atlas, Pascal Clark (Dept. of Elec. Eng., Univ. of Washington, Campus Box 352500, Seattle, WA 98195, atlas@u.washington.edu), and Ivars Kirsteins (Naval Undersea Warfare Ctr., Newport, RI)

Underwater propeller sounds often have audibly rhythmic characteristics. These sounds are commonly modeled as a broadband noise carrier multiplied by a rhythmic modulator, where analysis of the modulator wave form can provide information relating to the speed and identity of the source vessel. A natural assumption is to posit a purely periodic modulator, considering the rotary action of the propeller, which is useful for deriving maximum-likelihood estimates of the shaft rate [Lourens and du Preez, J. Ocean. Eng. **23**, 4, (1998)]. Indeed, recorded propeller data are unmistakably rhythmic, but the assumption of a strictly periodic or cyclical modulator wave form is questionable. A critical analysis of the periodicity assumption is presented and compared to three alternatives. Maintaining the product form in which the modulator wave form multiplies a random broadband carrier, the possible modulator signals are generalized to include: (1) almost-periodic functions expressible by nonharmonic trigonometric series; (2) multiplicative cascades of possibly complex-valued modulator functions; and (3) stochastic processes in which random state transitions constitute a sense of repeatability or rhythm. In this work, three modulator models are contrasted as estimators of periodicity, using actual propeller sound recordings to validate these estimates. [This work is supported by the Office of Naval Research.]

1:50

2pSP2. The propagation of noise in a dispersive medium. Leon Cohen (Dept. of Phys., City Univ. of NY, Hunter Coll., 695 Park Ave., New York, 10021)

If noise is generated at a particular region, it will generally propagate and be nonstationary in position and time. We present a phase space approach to understand the propagation of noise in a dispersive medium and to present methods to ascertain when the noise is stationary or quasi-stationary. The damping case is also discussed. In addition, we present approximate methods that allow one to study the statistical properties of the evolution of the noise field in space and time in a relatively simple way. A number of examples will be presented. [Work supported by ONR.]

2:10

2pSP3. Classification of shallow water passive sonar signals using stochastic channel model. Maya Gupta, Hyrum Anderson, and William Mortensen (Dept. of Elec. Eng., Univ. of Washington, Seattle, WA 98195)

This paper addresses the problem of classifying passive sonar signals propagating in shallow water channels. A key problem is that such signals are corrupted by noise and multipath, which we model stochastically in terms of the expected multipath and noise, and the variance of the multipath and noise. We assume that free-field (e.g., deep water) training signals are available. We show that for classification, the accuracy can be improved by not committing to an estimate of the channel or signal, but rather by marginalizing out the channel and noise uncertainty. Specifically, we propose variants of the quadratic discriminant analysis (QDA) classifier and the support vector machine classifier (SVM) that probabilistically account for the unknown channel effects, and which avoid ill-posed deconvolution. The proposed classifiers can work either directly on a time signal or on subband power features. Results on simulated data and real Bowhead whale vocalizations show that we can significantly improve classification performance over traditional methods over a range of signal-to-noise ratios. In addition, we will discuss the case where the classification decision can be made by multiple cooperating receivers, such as in a sonar network.

2:30

2pSP4. Finding physically motivated classification features using finite element models. Jack McLaughlin and Lane M.D. Owsley (Univ. of Washington, Appl. Phys. Lab., Box 355640, 1013 NE 40th St., Seattle, WA 98105)

Finite element models (FEMs) for simple shapes such as spheres, cylinders and pipes can be used to uncover potential features for classification by sonar systems. Analyses were conducted of the simulated, bistatic returns over a wide range of aspects using FEMs for a solid steel cylinder and a cement pipe all in free space. Salient characteristics noted in this way were then sought in field data collected

from the same or similar objects during the SAX04 experiment and two other data collections conducted in a test pond at the Naval Surface Warfare Center in Panama City, Florida. Characteristics robust enough to appear in both simulated data and field data are candidates to serve as classification features for similarly shaped objects. It is found that FEMs can provide important pointers to classification features that are closely tied to the physics of reflection. As such, the variability of these features in the face of object burial and multipath can be more easily assessed than statistical spectral features. [This work was supported by the U.S. Navy Office of Naval Research.]

2:50

2pSP5. Kirchhoff scattering from underwater targets modeled as an assembly of triangular facets. Ahmad T. Abawi (HLS Res., Inc., La Jolla, CA)

Scattering from underwater targets is a challenging problem, mainly because many of the techniques developed in scattering theory are for radar applications and, therefore, appropriate only in free space. Underwater scattering occurs in a waveguide, which in most cases requires a modification if not a reformulation of the methods developed for scattering from targets in free space. The most accurate solution of scattering from a target in a waveguide can be obtained by solving the wave equation in an environment that contains the waveguide and the target and simultaneously imposing boundary conditions on the boundaries of the waveguide and on the surface of the target. However, this technique is numerically intensive making it impractical in most cases of interest. As a means of offering a more practical solution, we show how to solve the scattering problem from a target in a waveguide by (1) modeling it as an assembly of triangular facets, (2) computing scattering from each facet analytically using the Kirchhoff approximation for each set of incident and scattered plane waves, and (3) combining the solutions coherently. We compare this solution with those obtained using more accurate methods such as the virtual source technique.

2pSP6. Change detection deconfliction process for sonar clutter items. John Dubberley and Marlin Gendron (Naval Research Lab. Code 7441, Stennis Space Ctr., MS 39529, john.dubberley@nrlssc.navy.mil)

When resurveying a seafloor area of interest during change detection operations, an automated method to match found bottom objects with objects detected in a previous survey allows the surveyor to quickly sort new objects from old objects. Here we will demonstrate a software system that accomplishes change detection. The change detection system contains modules for automatic object detection by geospatial bitmap technique, object collocation, feature matching using shadow outlining, scene matching by control point matching, and visualization and filtering capabilities. Emphasis will be placed on the new elements of the system, namely, shadow outlining and optional spatial filtering.

3:35

2pSP7. Processing techniques applied to underwater target echoes and their relationships. Brian H. Houston (Naval Res. Lab., Code 7130, 4555 Overlook Ave., Washington, DC 20375-5320, brian.houston@nrl.navy.mil), Joseph A. Bucaro (Naval Res. Lab., Washington, DC 20375-5320), Larry Kraus (Global Strategies (North America), Crofton, MD 21114), Harry J. Simpson (Naval Res. Lab., Washington, DC 20375-5320), and Timothy J. Yoder (Global Strategies (North America), Crofton, MD 21114)

Interest in acoustic scattering from underwater unexploded ordnance (UXO) has been increasing because of the growing need for sonar technology able to detect submerged UXO and to efficiently separate these detections from those due to natural and man-made clutter. Recent efforts range from laboratory and numerical studies seeking to understand the basic structural acoustic echo formation processes and the environmental effects on them to field exercises determining how well a particular detection /identification technology performs. This paper discusses several important scattering-based constructs, which have been utilized in both the basic UXO studies and the technology exercises as well. They include: (1) $\sigma(\omega, \theta)$, the frequency/angle-dependent scattering cross section; (2) standard imagery, oftentimes implemented with synthetic aperture arrays; (3) reflection tomography imaging; and (4) supersonic imaging using holographic techniques. Without a clear appreciation for the differences among the constructs, it is difficult to properly relate the results of the various studies. We have measured the broadband scattering from several underwater UXO targets using laboratory, rail-based, and AUV systems and processed the data using the above constructs. The use of a common, high quality UXO scattering data base in this process helps clarify the differences and relationships among the constructs. [Work supported by SERDP and ONR.]

3:50

2pSP8. Bistatic synthetic aperture sonar images of penetrable cylinders. Christopher Dudley and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814)

Bistatic synthetic aperture sonar (SAS) and acoustic holographic images and monostatic backscattering by penetrable tilted cylinders in water were investigated. Refracted rays internally reflected from the cylinder's backside often dominated the scattering. Ray theoretic models predict scattering enhancements for cylinders made of some isotropic and anisotropic materials. Experiments involved solid cylinders and liquid-filled cylindrical shells of polymers and fiberglass. The experiments used transient insonification and ka in the range of $9<ka<40$, where ka is a product of the acoustic wave number and the cylinder radius. Bistatic measurements used a hydrophone scanned along a line. Transversely isotropic fiberglass rods produced rich features in the images and in the backscattering plotted as a function of tilt and time. The timing of some features could be explained from a ray model based on properties of quasi-shear and quasi-longitudinal waves computed from the stiffness matrix measured for the fiberglass. Bright features for solid cylinders and liquid-filled shells were typically associated with refracted waves having phase velocities less than the speed of sound in water. For some tilt angles, radiated wavefronts were relatively flat producing enhanced farfield scattering. [Work supported by ONR.]

4:05

2pSP9. Bistatic synthetic aperture sonar and acoustic holographic imaging of a tilted circular elastic plate. Neil Tuazon and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, marston@wsu.edu)

Circular plates have axial symmetry and are sometimes used as components of items relevant to applications of sonar to detection and classification. Measurements of the backscattering spectrum as a function of tilt angle for an isolated circular plate reveal bright features associated with the excitation of compressional and flexural waves on the plate. Some of the features were previously found relevant to the interpretation of acoustic holographic images based on 2-D hydrophone scans close to a circular plate [B. T. Hefner and P. L. Marston, ARLO **2**(1), 55–60 (2001)]. In the present research, bistatic synthetic aperture sonar (SAS) and holographic images were constructed from line scans of a hydrophone at a large distance from

the plate using a method previously summarized [K. Baik, C. Dudley, and P. L. Marston, J. Acoust. Soc. Am. **121**, 3203 (2007)]. Because of elastic responses, the images are bright even when the receiver scan line does not intersect specular reflections from the plate. The radiation by the transient elastic waves excited on the plate can significantly increase the contrast of SAS and holographic images. [Work supported by ONR.]

4:20

2pSP10. Optical simulation of bistatic specular reflection by a rigid cone on a flat surface. Anthony R. Smith, Matthew D'Asaro, and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, asmith8@mail.wsu.edu)

To gain insight into the high-frequency scattering of sound by cone-shaped objects near flat reflecting surfaces, a small conical mirror was placed on a flat horizontal mirror and illuminated by a tilted laser beam. The symmetry axis of the cone was vertical. Light scattering patterns were recorded by imaging with a camera on a white vertical screen that intersected the scattering. Bright regions on the screen were associated with specular reflections from the cone and from the flat mirror. To determine which contributions depended on the presence of the flat mirror, the screen was also imaged with the cone on a nonreflecting surface. The patterns were recorded with the screen placed sideways relative to the laser beam as well as in front of the cone and behind the cone. The cone half-angle was 45 deg but the grazing angle of the laser beam could be changed. The bright patterns were described by a geometric analysis of bistatic reflection previously summarized [P. Marston, J. Acoust. Soc. Am. **124**, 2584 (2008)] modified so as to allow for images caused by the flat mirror. The pattern for a vertical circular cylinder on a mirror was also studied. [Research supported by ONR.]

4:35

2pSP11. Modelled Doppler and range resolutions of active pulses in simulated environments. Andrew Holden (Dstl Farnborough, Ively Rd., Farnborough, Hampshire, GU14 0LX, UK)

The ability of an active sonar waveform to simultaneously estimate the range and velocity resolution of a target can be predicted by the wideband ambiguity function. Although this gives good insight into the capabilities of different pulse types, it does not replicate a real active sonar where a transmitted pulse is propagated through an environment and the received pulse is cross-correlated with a number of frequency and time shifted replicas of the transmitted pulse. In order to predict this a ray trace model is used to calculate the travel time and received amplitude of each ray path from the transmitting sonar to a target and back to include seabed and sea surface scattering where complex broadband pulse types can be modelled using a sub-band approach. This allows the determination of Doppler and range resolution for a variety of pulse types including pulse trains of LFM pulses in simulated environments, especially highly reverberate shallow water environments.

2pUW1. Ralph Goodman, builder of laboratories. Samuel W. Marshall (P.O. Box 668, White Stone, VA 22578, swmiii@yahoo.com)

Ralph had an extraordinarily successful career in building programs and laboratories. He started with an overall vision of what was to be built while determining the principle obstructions. He carefully avoided early details which would most often be overtaken by events. In addition, he was an eminent scientist whose acumen in a number of technical areas permitted him breadth of very constructive technical leadership. Besides a history of how Ralph got into underwater acoustics and his first major position in management, some personal anecdotes will be presented to emphasize how he successfully dealt with people and with some very difficult situations in this and subsequent undertakings.

1:25

2pUW2. The Italian connection: Ralph Goodman's close ties to NATO over 45 years. Finn B. Jensen (NATO Undersea Res. Ctr., 19126 La Spezia, Italy, jensen@nurc.nato.int)

Ralph's enduring and very intense professional relationship with SACLANTCEN (now NURC) in La Spezia, Italy, started in September 1961 when he joined the Centre as a young scientist. He worked in Italy for two years publishing on "convergent zone propagation" and "reverberation from smooth ocean floors." This was also the time of his first sea trial, which on Ralph's watch nearly led to the ship running aground. His love for life in Italy and the NATO Centre as such led to many visits in the coming years. He returned in 1981 to become the first American director of SACLANCEN. His primary task was to plan and undertake the construction of a new NATO research vessel named Alliance, a task which involved many crucial decisions about ship specifications and performance, plus guidance to the in-house ship building team, and excruciating negotiations with NATO agencies to secure the funding. Ralph's broad scientific background and superb people management skills ensured the success, and his "yacht" is still one of the best research vessels around, here 20 years later. Ralph's tenure as director lasted an unprecedented 6 years and he left in 1987 having secured SACLANTCEN a top-rated seagoing capability for years to come.

1:45

2pUW3. Coupled ocean-acoustics studies at Navy and NATO laboratories: The legacy of Ralph Goodman. Steve A. Piacsek, Charlie N. Barron (Oceanogr. Div., Naval Res. Lab., Stennis Space Ctr., MS 39529, piacsek@nrlssc.navy.mil), and Michael Porter (HLS, Inc., La Jolla, CA 92037)

A brief history of collaborations between ocean and acoustic modelers is given under the directorships of Ralph Goodman at NORDA and SACLANT, and of continuing coupled modeling studies at NRL built on previous studies he sponsored. At NORDA the Numerical Modeling Division consisted of an acoustic and an ocean branch, one of the first known instances of such close-knit administrative units for ocean and acoustic modelers. At SACLANT, close collaborations were strongly encouraged by Ralph Goodman and the respective group leaders. The results of these studies eventually appeared among the first published papers on the effects of mixed layer and Gulf Stream properties on surface-duct propagation (*Computational Acoustics: Ocean-Acoustic Models and Supercomputing* (North Holland Press, 1990); *Oceanography and Acoustics: Prediction and Propagation Models* (AIP Press, 1994). At NRL, these studies were restarted recently: evaluation of sonic layer depth relative to mixed layer depth [JGR **113** (2008)]; the acoustic impact on marine mammals [AGU Ocean Sciences Meeting (2006)]; and the acoustic impact of propagating internal solitons [IEEE Journal of Ocean Engineering (2007)]. Examples will be given from some of these studies to show progress in the field.

2:05

2pUW4. Ralph Goodman and Hamiltonian acoustics. W. A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., UC San Diego, La Jolla, CA 92093-0238)

Much of the underwater acoustic community that has worked with ray theory starts from the eikonal-ray equations. Since these equations, which are solved numerically, can be derived from a high-frequency asymptotic expansion, Fermat's/Hamilton's principle is typically bypassed. Historically, the introduction of the Hamiltonian formulation of underwater acoustics ray has come from scientists with a background in classical physics and/or from researchers whose goals were to study complicated environments, chaos, etc., using the well developed formalism of Hamilton's equations and perturbation theory. Mostly, these latter applications go back to the 1980s. Among Ralph Goodman's earliest work in underwater acoustics is a paper [R. Goodman and R. B. Duykers, J. Acoust. Soc. Am. 34, 960–962 (1961)] in which he derived the Hamiltonian for convergence zone rays in the harmonic oscillator approximation and then solved the equations by inspection. This paper must be one of the earliest applications of the Hamiltonian formulation to underwater ray acoustics and a part of the beginning of an illustrious career in the underwater acoustics community.

2:25

2pUW5. Bubble research with Ralph Goodman at Penn State. Kenneth E. Gilbert (Natl. Ctr. for Phys. Acoust., Univ. of Mississippi, University, MS 38677)

During the years 1992–1998 at Penn State, I collaborated closely with Ralph Goodman on scattering from the near-surface oceanic bubble layer. Ralph's enthusiasm, physical insight, and encyclopedic knowledge of at-sea experiments proved to be invaluable. I will outline the research and discuss Ralph's contributions to graduate theses and scientific papers that were published. I will also give some personal observations on what it was like collaborating with Ralph.

2:45

2pUW6. Extending bubble measuremenets below 20 μm: in memory of Ralph Goodman's contributions. Helen Czerski and David Farmer (The Graduate Sch. of Oceanogr., Univ. of Rhode Island, S Ferry Rd., Narragansett, RI 02882)

No matter which aspect of underwater acoustics we worked on, conversations with Ralph Goodman invariably added insight and often motivated new lines of investigation. This was certainly true of our interest in measuring bubble size distributions. We discuss the extension of acoustical measurement of bubbles to radii below 20 μm, a topic of particular relevance to the study of optical scatter in the ocean. Extending the frequency range of a resonator to 1 Mhz would in principle allow measurement down to ~3 μm, but significant challenges arise due to the confounding effects of geometric scatter from larger bubbles. This problem becomes greater for measurements of smaller bubbles, requiring a careful analysis of the accuracy limits imposed on the inversion procedure. Preliminary steps along this path are discussed with examples drawn from recent field measurements.

3:20

2pUW7. Anomalous dispersion and pulse propagation in oceanic bubble clouds. Frank S. Henyey (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, frank@apl.washington.edu)

During a planning meeting for the Scripps pier bubble experiment, Ralph Goodman suggested we apply the Kramers-Kronig relations to bubble cloud data. By "we," I assumed he meant that I should do it. I applied the Kramers-Kronig relations to David Farmer's Scripps pier data from his modified Medwin resonators. This allowed a determination on which data had lower accuracy than the rest. Using the high accuracy data, I constructed a model of the complex sound speed. No formula relating bubble size distributions was needed. This model has anomalous dispersion in a frequency band that nearly coincides with a region in which the group speed is higher than the sound speed in bubble-free water. Summerfeld's theorem prohibits any signal from traveling that fast. The consequences for pulse propagation within bubble clouds was determined, using pulses having the same frequency spectrum as transmitted by Jerry Caruthers. The predicted nature of the received pulse is only partially described by Brillouin's studies, done before computers existed.

3:40

2pUW8. Conversations with Ralph about bubbles in the surf zone. Grant B. Deane (Marine Physical Lab., Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238, gdeane@ucsd.edu)

Ralph Goodman made many contributions to the field of oceanic bubbles. This talk will focus on conversations with Ralph about bubbles in the surf zone. Questions that Ralph asked about surf zone bubbles included: where are they, and what are their acoustical properties? These fundamental questions will be examined in the light of Ralph's own experimental and theoretical work, with some contributions from the author. [Work supported by the Office of Naval Research.]

4:00

2pUW9. Ralph Goodman's recent contributions on oceanic bubbles. Jerald W. Caruthers (Dept. of Marine Sci. Univ. of Southern Mississippi, 1020 Balch Blvd., Stennis Space Ctr., MS 39529, jerald.caruthers@usm.edu) and Steve Stanic (Naval Res. Lab., Stennis Space Ctr., MS 39529)

Many of us are never too old to have an esteemed mentor such as Ralph Goodman. We have for the past decade and a half had the pleasure and privilege of conducting research on oceanic bubbles with his help and advice. Over this period, bubble research has been his main focus. It is appropriate that we highlight his leadership and contributions with us on oceanic bubbles. This presentation will provide snapshots of a number of publications and presentations on bubbles since 1993. [Work supported by ONR and NRL.]

4:20

2pUW10. Shallow water horizontal signal coherence measurements with use of mobile acoustic sources to create synthetic aperture arrays. Philip Abbot, Ira Dyer, and Chris Emerson (OASIS, Inc., 5 Militia Dr. Lexington, MA 02421)

Horizontal signal coherence length was measured in shallow water using a reciprocal synthetic aperture array created from multiple signals radiated by a mobile acoustic source, and a slowly drifting omnidirectional receiver. The tests were conducted in September, 2008, in shallow water (125 m depth) of the South East China Sea. Source and receiver depths were 61 m. Twelve hyperbolic FM slides per minute were transmitted while the source moved horizontally at 2.5 m/s, maintaining a nearly constant range of ~6 km to the receiver. Received signals were matched-filter processed, phase-corrected to form an equivalent linear array, then coherently combined using a synthetic aperture time delay beamformer. The beamformer output signal gain versus the number of elements in the array, N (using $2 \leqslant N \leqslant 512$ transmissions), was compared to the theoretical limit (20 log, N). The coherence length, defined to be L/λ at a point 3 dB down from the limit, was determined. At 900 Hz, the correlation length was $L/\lambda \approx 40$ (N=7, over 40 s). At 600 Hz, it was $L/\lambda \approx 10$ (N=3 over 8 s). The degradation at 600 Hz is due to substantially smaller signal-to-noise levels at the element level. Partial coherence is observed at both frequencies, even at N=512.

4:35

2pUW11. Attenuation measurements across surface-ship wakes and computed bubble distributions and void fractions: A tribute to the contributions by Ralph Goodman on oceanic bubbles. Steve Stanic (Naval Res. Lab., Stennis Space Ctr., MS 39529, Steve.Stanic@nrlssc.navy.mil), Jerald Caruthers (Univ. of Southern Mississippi, Stennis Space Ctr., MS 39529), Ralph Goodman (Deceased), Edgar Kennedy, and Bob Brown (Naval Res. Lab., Stennis Space Ctr., MS 39529)

A series of three CW-pulsed signals were transmitted across a surface ship wake as the wake aged. Each transmission contained a set of four 0.5-ms-long pulses that ranged over frequencies from 30 to 140 kHz in 10-kHz steps. The acoustic attenuation across wakes that were due to varying bubble-size densities within the wakes were determined experimentally. From those data, estimates of the bubble densities as functions of the speed of the wake-generating ship, the wake's age, and acoustic frequency were calculated. From the bubble-density results, power-law fits and void fractions are calculated. The attenuation measurements were taken at 7.5-m intervals behind the wake-generating ship and continued for about 2 km. The experiment was run for wakes generated at ship speeds of 12 and 15 knot wakes. The bubble densities were observed to have power-law forms with varying parameters with the strongest, for early ages, having an exponent of -3.6 and a void fraction of 4×10^{-7}, and with both diminishing for older wakes, as might be expected. This work was Ralph Goodman's last contribution in underwater acoustics. [Work supported by the Naval Research Laboratory Program Element 62435N and the Office of Naval Research Code 321OA.]

4:50

2pUW12. Observations and theory of dispersion in rip currents at the Scripps Pier Bubble Experiment of 1997. Jerald W. Caruthers (Dept. of Marine Sci. Univ. of Southern Mississippi, 1020 Balch Blvd., Stennis Space Ctr., MS 39529, jerald.caruthers@usm.edu), Steve Stanic (Naval Res. Lab., Stennis Space Ctr., MS 39529), Jorge C. Novarini (Planning System, Inc., Long Beach, MS 39560), and Frank Henyey (Univ. of Washington, Seattle, WA 98105)

Two of the authors (Caruthers and Stanic), with help and advice from Ralph Goodman, were instrumental in planning and conducting the 1997 Scripps Pier Bubble Experiment. Ralph's participation was invaluable in making this effort a success. A number of institutions were involved in the

overall experiments, but the main experiments, conducted by the Naval Research Laboratory, centered on what was termed the "delta frame" [Caruthers *et al.*, J. Acoust. Soc. Am., **106**, 617–625 (1999)]. The delta frame was a triangle 10 m on a side with sources at two apexes and eight hydrophones distributed along the arms. Eight frequencies (39 to 244 kHz) were propagated from the two sources. The NRL personnel and other participants in the experiment published a number of detailed measurements and analyses. In the delta frame experiments, a significant amount of the data was relevant to sound-speed-dispersion analyses. Ralph was always keenly interested in dispersion, but we never fully analyzed, nor published those observations. With that oversight and regret in mind that the relevant analyses were not conducted during Ralph's lifetime, we have revisited that data in his honor. [Work supported by ONR and NRL.]

TUESDAY AFTERNOON, 19 MAY 2009 ALEXANDERS LOUNGE, 2:45 TO 3:45 P.M.

Meeting of Accredited Standards Committee (ASC) S1 Acoustics

P. Battenberg, Chair S1
Quest Technologies, Inc., 1060 Corporate Center Dr., Oconomowoc, WI 53066-4828

R. J. Peppin, Vice Chair S1
Scantek, Inc., 6450 Dobbin Road, #A, Columbia, MD 21045

Accredited Standards Committee S1 on Acoustics. Working group chairs will report on the status of standards currently under development in the areas of physical acoustics, electroacoustics, sonics, ultrasonics, and underwater sound, etc. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note — those meetings will be held in conjunction with the Standards Plenary meeting at 9:00 a.m. on Tuesday, 19 May 2009.

Scope of S1: Standards, specifications, methods of measurement and test, and terminology in the field of physical acoustics, including architectural acoustics, electroacoustics, sonics, and ultrasonics, and underwater sound, but excluding those aspects of which pertain to biological safety, tolerance and comfort.

TUESDAY AFTERNOON, 19 MAY 2009 DIRECTORS ROOM, 4:00 TO 5:00 P.M.

Meeting of Accredited Standards Committee (ASC) S12 Noise

R. D. Hellweg, Chair S12
Hellweg Acoustics, 13 Pine Tree Rd., Wellesley, MA 02482

W. J. Murphy, Vice Chair S12
NIOSH, 4676 Columbia Pkwy., Cincinnati, OH 45226

Accredited Standards Committee S12 on Noise. Working group chairs will report on the status of noise standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note — those meetings will be held in conjunction with the Standards Plenary meeting at 9:00 a.m. on Tuesday, 19 May 2009.

Scope of S12: Standards, specifications, and terminology in the field of acoustical noise pertaining to methods of measurement, evaluation and control, including biological safety, tolerance and comfort, and physical acoustics as related to environmental and occupational noise.

Session 3aAA

Architectural Acoustics: Measurement and Modeling of Scattering Effects

David T. Bradley, Chair
Physics and Astronomy Dept., Vassar College, Poughkeepsie, NY 12604-0745

Invited Papers

8:55

3aAA1. Scattering prediction and measurement in architectural acoustics. David T. Bradley (Phys. and Astron. Depart., Vassar College, 124 Raymond Ave., Poughkeepsie, NY 12604-0745, dabradley@vassar.edu)

Reflected sound energy typically exhibits a combination of both specular and diffuse behavior when acoustic waves encounter a solid surface. For specularly reflected sound, the angle of reflection is equal to the angle of incidence. A diffusely reflected sound is characterized by dispersion in both the spatial and temporal domains. The ability of a surface to diffusely reflect sound is characterized by the amount of scattering in its reflected energy, and can be determined using numerical prediction schemes and experimental measurement techniques. Although the study of scattering surfaces plays an integral role in several fields of acoustics, the development of these measurement and prediction procedures is relatively nascent, particularly in the field of architectural acoustics. An overview of the current state-of-the-art for these procedures will be presented along with an outline of possible future directions in this area of research.

9:15

3aAA2. Measurement and modeling of scattering in underwater acoustics: A potential value to architectural acoustics? Martin Siderius (Dept. of Elect. and Comput. Eng., Portland State Univ., 1900 SW 4th Ave., Portland, OR 97201, siderius@pdx.edu), David Bradley (Vassar College, Poughkeepsie, NY 12604-0745), and Lisa Zurk (Portland State Univ., Portland, OR 97201)

Scattering measurement and modeling techniques in underwater acoustics have undergone significant progress through several decades of research. The knowledge gained from this research can be applied to similar scattering problems found in above water systems, such as those typically seen in architectural acoustics. Underwater environments have inherently complex scattering behavior including multiple propagation paths and boundaries that are rough and spatially variable. Additionally, boundaries are often moving, which can introduce different Doppler shifts on multipath arrivals, referred to as Doppler spread. These complications make modeling underwater propagation and scattering a challenging problem. However, there are currently several models that are routinely used for predicting underwater acoustic behavior. In some cases, deterministic modeling can be used while in others the complexity only allows for a statistical description of the acoustic field. In recent years, acoustic communications have emerged as an important ocean application, and the innovations provided by these systems have pushed the limits of current techniques. An overview of these modeling and measurement techniques will be presented, and the lessons learned from recent advances will be reviewed in the context of identifying commonalities between underwater and architectural acoustics.

9:35

3aAA3. Fractal surfaces: Generation and acoustic scattering prediction. Derek R. Olson and David T. Bradley (Phys. and Astron. Dept., Vassar College, 124 Raymond Ave., Box 2529, Poughkeepsie, NY 12604)

Typical acoustical diffuser design results in diffuse sound scattering only for a limited frequency band, which is problematic given the breadth of the human audible frequency range. Surfaces exhibiting fractal geometries may address this problem due to their self-similarity over multiple scales. Stochastic fractals, such as the random midpoint displacement (RMD) fractal, are well-suited to this usage since they can be mapped onto physical surfaces appropriate for acoustical diffusers. In the current project, virtual RMD fractal surfaces were generated and then constructed using a 3-D printer. A pilot study has been conducted to determine the scattering properties of the fractal surfaces using a numerical prediction scheme carried out using the boundary element method (BEM). Experimental measurements of the scattering properties were also carried out according to ISO 17497. The numerical predictions and experimental measurements were contrasted to improve numerical prediction accuracy and optimize the fractal design parameters of acoustical diffusers. These parameters include surface roughness, fractal dimensionality, number of iterations, and the random number probability distribution function. The comparison of the numerical and experimental results will be presented along with effects of the fractal design parameters.

9:55

3aAA4. A suggested method to be used to measure the scattering coefficient of full-scale samples. Ron Sauro (NWAA Labs., Inc., 25132 Rye Canyon Loop, Santa Clarita, CA 91355, audio_ron@msn.com)

In attempting to follow ISO 17497-1 as a method for measuring full-scale scattering coefficients, it was observed that many of the recommended steps needed to be modified for those full-scale measurements. Variations were tried to aid in these measurements. These variations are described and suggested solutions to the problems observed are presented. It was observed that continuous rotation of the sample, rather than step action rotation, worked better for taking consistent data from the sample. A stable chamber environment is also necessary with humidity reaching at least 50% and temperature variations should not vary by more than 1°C throughout all four parts

of the test. It was also observed that a less directional source than recommended was needed so two dodecahedron loudspeakers were chosen to reproduce a combined weighted noise stimulus source. Six data microphones were placed at random locations and varying heights to collect data. Data were compared between the suggested method and the ISO-17497-1 standard.

10:15—10:30 Break

Contributed Papers

10:30

3aAA5. Investigating multifractals to quantify diffuseness in rooms. Noel W. Hart (Graduate Prog. in Archit. Acoust., Rensselaer Polytech. Inst., 2403 21st St. Apt. 5, Troy, NY, 12180, hartn@rpi.edu) and Ning Xiang (Rensselaer Polytech. Inst., Troy, NY, 12180)

Diffuseness, an important room acoustics parameter, currently has no accurate objective method of quantification. Most methods that claim to be able to quantify it require specialized equipment or guesswork. Multifractals present a recent method that allows diffuseness in rooms to be quantified by analyzing a single room impulse response [Loutridis, JASA **125**(3) (2009)]. This method will be verified by acoustical measurements in rooms of various degrees of diffuseness. Since this method has only been demonstrated in small rooms, its applicability towards larger rooms of different types is tested. Frequency dependency is also unknown and is investigated.

10:45

3aAA6. Prediction and tailoring of steady-state broadband sound fields in enclosures using absorption scaling and energy-intensity boundary elements. Donald Bliss, Krista Michalis, and Linda Franzoni (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708, dbb@duke.edu)

Enclosures with diffuse reflection boundaries are modeled with an energy-intensity boundary element method using uncorrelated broadband directional sources. An absorption-based perturbation analysis shows the spatial variation of acoustic field obeys certain scaling laws. A series expansion in terms of average absorption gives separate boundary integral problems at each order. The lowest-order solution has a uniform level proportional to the reciprocal of the average absorption. The next-order solution is independent of average absorption and primarily responsible for spatial variation of the acoustic field. This solution depends on the spatial distribution of absorption and input power sources, but not their overall level. For the primary spatial variation, the effects of the relative distributions of absorption and input power are linear and uncoupled. These distributions can be expressed in terms of constituent spatial modes corresponding to the ways absorption and input power can be distributed. Solved numerically once for each mode, the acoustic field can be expressed in terms of the modal amplitudes in closed form. These amplitudes can be adjusted to tailor the spatial variation. Examples include how to distribute absorption to minimize sound levels in one location, or how to achieve a uniform interior field. [Sponsor: NSF.]

11:00

3aAA7. Measuring the uniform diffusion coefficient: Synthesized aperture goniometer measurements. Philip W. Robinson, Ning Xiang (Architectural Acoust. Program, Rensselaer Polytechnic Inst.), and Peter D'Antonio (RPG Diffusor Systems, Inc.)

There are currently two methods to measure the diffusion/scattering from acoustical surfaces: reverberation chamber measurement and *in-situ* measurement using a semicircular array of microphones called a goniometer. Each of these methods has advantages and drawbacks. The reverberation chamber method accounts for random incidence, but produces inconsistent results for materials of the same profile but different absorption. It does not distinguish between one-dimensional and two-dimensional surface topologies, since the sample is rotated, and is also inapplicable to high absorption materials. The goniometer measurement quantifies directivity as well as diffusion, but presents challenges related to processing power, as many microphones are required to achieve reasonable resolution. Using a procedure akin to synthesized aperture radar, a 2.5° resolution polar plot of the 180° response is achieved by scanning eight microphones rather than employing a full array of 72. Also, since the direct sound and reflected sound arrive at the receiver in close succession when measuring low incident angles, special processing must be exercised in order to resolve the relationship between the sounds. This research addresses the challenges of the goniometer measurement and attempts to use a synthesized aperture goniometer to derive accurate diffusion and directivity properties of materials.

11:15

3aAA8. Measurement and improvement of the diffuse-reflection coefficients of profiled-wood surfaces. Chris Bibby and Murray Hodgson (Acoust. & Noise Res. Group, SOEH-MECH, Univ. of British Columbia, 3rd Fl., 2206 East Mall, Vancouver, BC, V6T 1Z3 Canada)

An apparatus and procedure were developed for measuring the diffuse-reflection coefficients of surfaces in an anechoic chamber according to the ISO-17497 method. This involves determining the proportion of incoherent energy in the impulse response measured in the presence of the surface. Surface absorption was measured by the reverberation-room method. The sound-absorption and sound-diffusion properties of two existing profiled-wood architectural panels, one with sinusoidal corrugations, the other comprising rectangular sections of different heights, were characterized. Investigations into how to improve the absorption and diffusion characteristics were made, and prototype surfaces tested and evaluated.

11:30

3aAA9. An *in-situ* diffusivity measurement method for diffuser design in concert halls. Jin Yong Jeon and Yong Hee Kim (Dept. of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea)

This study investigates an *in-situ* measurement method to evaluate the diffuseness of a sound field using scale model concert halls. The diffusers were applied to scale model concert halls in which the impulse responses at both the audience and stage area were observed. Both reflection number (RN) and reflection energy (RE) were used as *in-situ* diffusivity indices: RN is defined by the number of reflection rays of which critical amplitude level is within -30 dB after the direct sound, and RE defined by the integrated energy at the normalized impulse responses. Through the scale model measurements, it was observed that half of the side walls near the stage were effective for diffuseness of sounds both in auditorium and on stage. It was also found that the balancing of *in-situ* diffusivity is useful for diffuseness perception, which is subject to the level of the direct sounds.

11:45

3aAA10. Measurement of diffuse sound reflection from an impedance surfaces using one microphone by bayesian inversion. Gavin Steininger (Acoust. and Noise Control Res. Group–Dept. of Mech. Eng., Univ. of British Columbia, Vancouver, BC, Canada) and Murray Hodgson (Univ. of British Columbia, Vancouver, BC, Canada)

This paper discusses the use of inverse methods to find the absorption and diffusion characteristics of surfaces. An impedance surface in an anechoic chamber is excited by a pure tone source above it. The steady-state sound level is measured at n points above the impedance surface. The distribution of the n steady-state sound-pressure levels is assumed to be Gaussian. The set of mean or predicted values for this distribution is generated by finding the modulus of a modified Sommerfeld boundary element solution to the Helmholtz equation. The modification is to add multiple diffusely reflected waves each of which is additionally attenuated by a distribution that is proportional to $\sin(2\theta)\times G(\theta)^{D_\theta}\times H(\phi)^{D_\phi}$, where $G(\theta)$ is the piecewise function $[G(\theta)=\theta/\theta_{Spec},\ \theta\leqslant\theta_{Spec}$, and $[(\pi/2)-\theta]/[(\pi/2)-\theta]_{Spec}$ otherwise] and $H(\phi)=|(1-\phi)/\pi|$. The system of equations is then optimized for the specific impedance of the surface, the normal diffusion coefficient, and the azimuth diffusion coefficient (Z, D_θ, and D_ϕ) using Bayesian

inversion. This process is repeated for two surfaces (painted plywood over 16 inch studs and painted plywood over 16 inch studs with randomly placed wooden blocks) at six frequencies (250, 500, 1000, 2000, 4000, and 8000 Hz).

WEDNESDAY MORNING, 20 MAY 2009 GALLERIA NORTH, 8:00 TO 11.45 A.M.

Session 3aAB

Animal Bioacoustics and Acoustical Oceanography: Autonomous Remote Monitoring Systems for Marine Animals III

Marc O. Lammers, Chair
Hawaii Inst of Marine Biology, Kailua, HI 96734

Invited Papers

8:00

3aAB1. From mysticete song to odontocete echolocation: Monitoring cetacean sounds with high-frequency acoustic recording packages (HARPs). Sean M. Wiggins and John A. Hildebrand (Scripps Inst. of Oceanogr., 9500 Gilman Dr. La Jolla, CA 92093-0205, swiggins@ucsd.edu)

Marine mammals produce a wide range of sounds from 10s of Hz to 100s of kHz. To remotely monitor these various sounds with autonomous systems, instruments with wide bandwidths are required. A general purpose, autonomous, high-frequency acoustic recording package (HARP) is described that can record sounds ranging from low-frequency blue whale (Balaenoptera musculus) song to mid-frequency dolphin whistles and beaked whale sweeps to high-frequency dolphin clicks. In addition to monitoring marine mammals, sounds from fish, contributions from wind and rain, and anthropogenic sources such as ships and sonar also are recorded potentially allowing for the study of cetacean behavioral response to these sounds. HARPs have been deployed for periods of up to one year, in various configurations such as standard moorings, seafloor packages, and arrays, and in remote locations including the Arctic, Bering Sea, Gulf of California, around Hawaii, and offshore of Washington State and southern California. The various configurations of these deployments and the wide range of marine mammal monitoring data they have provided are discussed in addition to lessons learned from these studies. [Work supported by the U.S. Navy CNO-N45.]

8:20

3aAB2. Extending passive acoustic capabilities of autonomous recorders by using multiple hydrophones. Aaron Thode, Robert Glatts (Marine Phys. Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr., San Diego, CA 92109-0238), and William C. Burgess (Greeneridge Sci. Inc., Goleta, CA 93117)

Low-power data acquisition systems have attained sampling rates large enough to enable multielement hydrophone arrays to be deployed autonomously, at the cost of reducing the individual sampling rate per phone. This paper discusses what theoretical advantages bandlimited multielement recordings can provide over single-hydrophone data, including array gain for increased detection range, interfering noise source rejection, environmental inversion, and biological source tracking. These points are illustrated with data collected from an autonomous four-element vertical array off Queensland, Australia in 2003, and data collected from an autonomous eight-element, 21 m aperture vertical array deployed at 35 m depth in the Beaufort Sea in 2008. These examples also provide insight into the technical and logistical challenges required by such deployments, including deployment and recovery systems that do not endanger or entangle array cables. [Work supported by NPRB, logistics provided by Greeneridge Sciences and Shell Co.]

Contributed Papers

8:40

3aAB3. An autonomous, near-real-time buoy system for automatic detection of North Atlantic right whale calls. Eric Spaulding, Matt Robbins, Tom Calupca, Christopher Clark, Tremblay Tremblay, Amanda Waack, Ann Warde (Bioacoust. Res. Prog., Cornell Univ., 159 Sapsucker Woods Rd., Ithaca, NY 14850), John Kemp, and Kristopher Newhall (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

A moored buoy system for automatic detection of endangered North Atlantic right whale (NARW) upcalls was developed to provide near-real-time information on the presence of whales. The marine components include the WHOI buoy platform (mooring, hydrophone, power system, surface expression, and antennae) and Cornell buoy electronics (housing, analog interface hardware, GPS, embedded computer, detection engine, and telemetry hardware). Shore-side Cornell components include telemetry equipment, server hardware and processing software, database, and interfaces for data annotation, access, and visualization. The buoy hardware/software system is capable of capturing and ranking NARW upcall candidates as 2 s, 2000 Hz sampled audio clips. GPS location, timestamp, and other metadata associated with each audio clip are bundled together and uploaded via satellite for processing. Human analysts regularly annotate incoming data, resulting in a curated database of NARW detections. Periodic "health and status" data allow for confirmation that buoys are functional. Regular voltage reporting helps predict required maintenance. Following initial implementations of the system in 2005, a series of successes and failures have led to system improvements. Deployments have progressed from prototype near-shore units to an operational network continuously monitoring the shipping lanes off Boston to meet ship strike mitigation requirements. Upcoming features and capabilities will be discussed.

8:55

3aAB4. Right whale gunshot calls in the southeastern Bering Sea. Catherine L. Berchok, Laura J. Morse, Phillip J. Clapham (Natl. Marine Mammal Lab., NOAA/AFSC, 7600 Sand Point Way NE, Seattle, WA 98115-6349, Catherine.Berchok@noaa.gov), Holger Klinck, Karolin Klinck, David K. Mellinger (Oregon State Univ. & NOAA Pacific Marine Environ. Lab., Newport, OR 97365), Donald K. Ljungblad (Marine Acoust. Consultants, LLC, Elk Mountain, WY 82324-0006), Sue E. Moore (NOAA/S&T-PMEL, Seattle, WA 98115-6349), Francesco Scattorin (Universita di Pavia, 27100 Pavia, Italy), and Jennifer L. Keating (Zoological Society of San Diego, San Diego, CA 92112-0551)

The eastern population of the North Pacific right whale (Eubalaena japonica) is critically endangered. Following extensive historical whaling in the 19th century and large illegal catches by the USSR in the 1960's, it is likely that this population now numbers in the tens of animals. Little is known about the distribution, movements, migrations, or habitat use of this population, but the existing data suggest that it now occupies a reduced range compared to historical times. In 2007, NMML began conducting a multiyear study of the distribution, abundance, and habitat use of North Pacific right whales in the North Aleutian Basin and southeastern Bering Sea using aerial and vessel surveys. During the 2008 survey, directional sonobuoys were used 24 h a day to record right whale calls and obtain cross-bearings to the whales. Although previous work in the Bering Sea focused on detections of the right whale upsweep call, our findings suggest that the gunshot call is much more ubiquitous. Spatial and temporal trends of gunshot calls will be presented, and changes in gunshot call characteristics relative to observed surfacing sequences will be described. [Work supported by an interagency agreement from the Minerals Management Service.]

3aAB5. Environmental acoustic recording system (EARS) buoys for marine animal acoustics. George E. Ioup, Juliette W. Ioup, Arslan M. Tashmukhambetov, Lisa A. Pflug (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, geioup@uno.edu), Joal J. Newcomb (Stennis Space Ctr., MS), Natalia A. Sidorovskaia (Univ. of Louisiana at Lafayette, Lafayette, LA), Stan A. Kuczaj, Grayson H. Rayborn, James M. Stephens (Univ. of Southern Mississippi, Hattiesburg, MS), Christopher O. Tiemann, and Alan Bernstein (Univ. of Texas at Austin, Austin, TX)

EARS buoys were developed as autonomous, moored, underwater recording systems by the Naval Oceanographic Office (NAVOCEANO) to make long-term ocean ambient noise measurements. When the Littoral Acoustic Demonstration Center (LADC) was formed as a consortium of university and U.S. Navy scientists in 2001, the buoys were capable of measuring up to 1000 Hz for 1 yr. LADC added listening to sperm whales to its noise and propagation measurements. NAVOCEANO quickly modified the buoys to measure up to 5859 Hz for 36 days. The buoys, moored at depths from 550 to 950 m in the Gulf of Mexico, produced exceptionally clear recordings of sperm whale echolocation and coda clicks and recordings of other whales. EARS Generation 2 buoys are now capable of recording one channel to 96 kHz, or four channels to 25 kHz, for more than 13 days on four 120 Gbyte notebook disk drives. Experiments in the Gulf of Mexico and the Ligurian Sea have targeted both sperm and beaked whales. Audio results and visualizations of these recordings reveal rich detail of Odontocete clicks and enable new analyses, such as the identification of individual whales from the properties of their clicks. [Research supported by ONR and SPAWAR.]

3aAB6. Localization to verify the identification of individual sperm whales using click properties. Juliette W. Ioup, George E. Ioup, Lisa A. Pflug, Arslan M. Tashmukhambetov (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, jioup@uno.edu), Christopher O. Tiemann, Alan Bernstein (Univ. of Texas at Austin, Austin, TX), Natalia A. Sidorovskaia, Philip Schexnayder (Univ. of Louisiana at Lafayette, Lafayette, LA), Joal J. Newcomb (Stennis Space Ctr., MS), Stan A. Kuczaj, Grayson H. Rayborn (Univ. of Southern Mississippi, Hattiesburg, MS), and Rowena M. Carlson (SPAWAR Systems Ctr. Pacific, San Diego, CA)

Previous research to identify individual sperm and beaked whales from the properties of their echolocation and coda clicks using cluster analysis has been reported. Although reasonably consistent and robust results showing distinct classes (each corresponding to an individual) have been obtained with both self-organizing maps and *K*-means, no independent verification of these identifications has previously been available. However, data from a July 2007 experiment in the Gulf of Mexico should provide enough geometry information to verify some identifications. The Littoral Acoustic Demonstration Center deployed six environmental acoustic recording system buoys, measuring to 96 kHz for 9 days, to record sperm and beaked whale clicks in the northern Gulf of Mexico. Three buoys were in close proximity to enable multisensor detections of single clicks for possible localization, tracking, or bearing estimation sufficient to confirm the identification of individuals from cluster analysis. Displays of cluster classifications versus time coupled with location estimates for the clicks give evidence of the accuracy of the identifications. Though localization serves to verify the classification tool, click identification complements localization by separating sounds from multiple sources when several whales' clicktrains overlap, potentially enabling previously impossible tracking. [Research supported by SPAWAR and ONR.]

3aAB7. Detection of killer whale presence using low duty cycle recorders. Jeffrey A. Nystuen (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, nystuen@apl.washington.edu), M. Bradley Hanson, Candice Emmons (NOAA Northwest Fisheries Sci. Ctr., Seattle, WA), Paul Wade (NOAA Alaska Fisheries Sci. Ctr., Seattle, WA), and Jennifer Miksis-Olds (Penn State Univ., State College, PA)

Passive aquatic listeners (PALs) have been developed to make long-term (up to a year) autonomous measurements of the underwater ambient noise in the marine environment. Because of data storage limitations and low-power requirements, PALs have a very low duty cycle, of the order of 1 percent. In fact, they are optimized for acoustic rainfall detection and have been successfully used to measure wind speed and rainfall rate at sea using spectral components of the sound field. These geophysical sounds have relatively long time scales (minutes) compared to vocalizations of marine mammals (seconds) or mooring noise (chain clanking). Data collection was designed to detect and reject short temporal signals. However, these signals include marine mammal vocalizations. Consequently, the sampling strategy was modified to evaluate the temporal content of the data sample and save the temporal data sample only if it contains

a signal consistent with killer whale vocalizations. These sound bites have demonstrated detection of pod-specific vocalizations of resident-type killer whales, transient-type killer whales, bone crunching from likely killer whale predation (eating) on sea lions, and humpback and N. Pacific right whales.

3aAB8. Managing the passive acoustics data deluge. David A. Mann (Coll. of Marine Sci., USF, 140 7th Ave. S., St. Petersburg, FL 33701, dmann@marine.usf.edu)

Passive acoustic recording systems can generate large amounts of data, especially given the increasing availability of inexpensive flash memory. Thus it is easy to collect more data than can be efficiently analyzed. One approach to this problem is to minimize data collection on the recorder by performing real-time automated detection of acoustic targets of interest. An alternate approach, where one does not know what signals may be present, is to record large amounts of data over extended periods of time. DSGlab is an open-source database and data analysis system implemented with MATLAB that is designed to manage large amounts of raw data. The database aspect of the program allows querying of data by latitude, longitude, depth (or altitude). Each recorded data file is tagged with header information including lat/lon/depth, timestamp, sample rate, and calibration. The data analysis section processes the files according to a user-specified signal processing chain, which does not require a knowledge of programming to generate, and returns results to a database and to individual files. The results of signal processing can then be quickly browsed with the data viewer. The system is designed to allow inter-laboratory collaboration and data sharing.

3aAB9. Acoustic rediscovery of right whales in a former whaling area, the Cape Farewell Ground, between Greenland and Iceland. David K. Mellinger, Sharon L. Nieukirk, Karolin Klinck, Holger Klinck, Robert P. Dziak (Cooperative Inst. for Marine Resources Studies, Oregon State Univ. and NOAA Pacific Marine Environ. Lab., 2030 SE Marine Sci. Dr., Newport, OR 97365), and Phillip J. Clapham (NOAA Natl. Marine Mammal Lab., Seattle, WA 98115)

The North Atlantic right whale (*Eubalaena glacialis*) is one of the world's most endangered cetaceans, with only 300–350 animals believed alive. Most right whales are thought to range from Florida to Nova Scotia, though the whereabouts of a significant portion of the population remains unknown in both winter and summer. Here we describe an acoustic survey for right whales near the Cape Farewell Ground, a late 18th-century whaling area. Continuously recording autonomous hydrophone instruments were deployed at five sites for one year in 2007–2008, after which data were analyzed by automatic detection with manual checking for "up" calls of right whales. Over 2000 calls were detected in all, with calls found at all sites but mostly from near the Cape Farewell Ground. The data are consistent with a seasonal migration northeastward toward Iceland in July–August followed by return movement later in the fall, with the last detection in December. At one site, calling occurred in the fall on 17 separate occasions, suggesting a significant number of right whales present. A right whale photo-identified in 2003 at the Cape Farewell Ground was not in the North Atlantic right whale catalog, suggesting the possibility of a previously unidentified stock.

11:00

3aAB10. Sound production and behavior in an eastern North Pacific killer whale population: Implications for autonomous remote monitoring. Marla M. Holt, Dawn P. Noren, Candice K. Emmons (Marine Mammal Program, NOAA/NMFS Northwest Fisheries Sci. Ctr., 2725 Montlake Blvd. East, Seattle, WA 98112, Marla.Holt@noaa.gov), and Anna-Maria Seibert (Univ. of Munich, Planegg-Martinsried, 82152 Germany)

Remote acoustic monitoring is often used to determine the seasonal and spatial distributions of vocal animals, particularly when conditions of other monitoring approaches are limited. Additionally, sound production patterns might be used to infer important activities of free-ranging animals in the absence of other cues. Animals produce sounds during activities such as foraging and breeding, but such patterns are expected to vary between species /populations that are based on a variety of ecological factors. For example, fish-eating killer whales are more vocally active than mammal-eating killer whales, presumably since mammalian prey are sensitive to killer whale sounds. Southern Resident killer whales (SRKWs) are a fish-eating population found in coastal waters of Washington State and British Columbia. The goal of this study was to extend previous work on the behavioral correlates of sound production in SRKWs. We collected behavioral and acoustic data simultaneously over two field seasons and found that click occurrence as well as calling rates (calls/whale/min) were significantly higher when whales were foraging compared to traveling. Such patterns are useful for inferring events from remote acoustic monitoring. These results also indicate that communicative signals are particularly important during foraging activities in this population and have implications for noise disturbance.

11:15

3aAB11. Simultaneous acoustic tag and seafloor acoustic recorder detection of right whale calls in the Bay of Fundy. Susan E. Parks (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804), Christopher W. Clark (Cornell Univ., Ithaca, NY 14850), Mark Johnson, and Peter L. Tyack (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Passive acoustic monitoring is playing a growing role in marine mammal detection. Determining the range of detection for calls of a particular species in a particular location is important to assess the regional coverage provided by individual recording units. This study describes the comparison of right whale calls recorded by digital acoustic recording tags (Dtags) attached with suction cups to North Atlantic right whales and the detection of the same calls using a dispersed seafloor array of autonomous recorders. The seafloor array consisted of 5 units, spaced 6–10 km apart, continuously recording from July 29– August 17, 2005. Dtags were attached to a total of 14 individual right whales during this time period and 7 of these individuals produced a total of 88 tonal calls during tag attachment. The tag and related tracking of the whale provided information on call type, and the timing, depth, and approximate location of the whale producing the call. Tagged whale calls were audible on the seafloor array, and whale-recorder distances provided estimates of the acoustic detection range for right whales in the Bay of Fundy, Canada.

11:30

3aAB12. Annual variability of cetacean occurrence along the northeast coast of Iceland measured using ecological acoustic recorders. E.E. Magnusdottir, M.H. Rasmussen (Husavik Res. Ctr., Univ. of Iceland, Hafnarstett 3, 640 Husavik, Iceland, eem@hi.is), and M.O. Lammers (Hawaii Inst. of Marine Biology, Kailua, HI 96834)

In order to continuously monitor the annual density and habitat use of cetacean species at the NE coast of Iceland, we deployed two seabed mounted ecological acoustic recorders (EARs) in Skjalfandi Bay (66 deg 05 .929 N, 17 deg 25.262 W; 66 deg 03.070 N, 17 deg 39.811 W). The EAR is a microprocessor-based autonomous recorder. Each EAR was programmed to record for 1 min every 15 min. Both EARs will be retrieved every 3–5 months during a 1-year period. A custom Matlab program will be used to automatically detect and analyze target sounds. Target biological sounds re-

corded are primarily those produced by cetaceans and also by pelagic fish. Blue whales (Balenoptera musculus), humpback whales (Megaptera novaeangliae), minke whales (Balaenoptera acutorostrata), white-beaked dolphins (Lagernorhynchus albirostris), and killer whales (Orcinus orca) are well known to visit Skjalfandi Bay. In addition, it has been suggested that cod (Gadus morhua) is spawning in the bay in spring time. The results could reveal annual variability of inter- and intraspecies density of cetaceans and prey within the area. Acoustic monitoring may be an effective means of tracking diurnal and annual activity of cetaceans in a long-term manner and compare the activity to the presence and behavior of prey.

3aAO1. Information theory application to inversions of acoustic data from a continental shelf environment. David P. Knobles, Robert A. Koch, and Jason D. Sagers (Appl. Res. Labs., The Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713)

This research examines the uncertainty in waveguide parameter values obtained from acoustic inversion of data collected in range-dependent environments. To account for range-dependence in the environmental parameters, the number of inversion parameters must be increased. Generally, from a fixed data sample the uncertainty in the solution for individual parameter values increases as the number of inversion parameters increases, especially if the structure of the propagated acoustic field is sensitive to the additional parameters. This effect can be offset by prior information that reduces the volume of the parameter search space and to a limited extent by larger inversion data samples. How an inversion algorithm accounts for prior information is thus an essential issue to be addressed for range-dependent waveguides. Measurements made on the New Jersey shelf in 70–90 m of water provide an opportunity to study the effects of environmental range dependence on sound propagation and inversion processing. Inversions based on pre-existing geophysical information are combined with a maximum entropy approach to quantify the amount of information on the waveguide parameters that can be extracted from measured propagation over range-dependent tracks. Both towed sources emitting CW lines and impulsive sources are employed. [Work supported by ONR.]

3aAO2. Probability density functions of modal amplitudes and complex acoustic pressure in fluctuating shallow water waveguides. Kevin D. LePage (NATO Undersea Res. Ctr., Viale San Bartolomeo 400, 19126 La Spezia, Italy)

The polynomial chaos method is applied to the problem of predicting the probability density functions of complex modal amplitudes and acoustic pressure in the presence of water column sound speed fluctuations in shallow water waveguides. Results for both the intrusive implementation of the polynomial chaos technique, where the governing coupled mode differential equations for the complex modal amplitudes are augmented with the random states of the chaos expansion, and the non-intrusive method, where legacy codes can be run over an ensemble of ocean realizations and the results fitted by a truncated chaos expansion, are shown. Both methods give good agreement with Monte Carlo histograms of the modal amplitudes and the pressure field for slight water column variability, but the non-intrusive formulation shows more robustness for larger variability. The relative merits of PC expansions for the complex modal amplitudes vs the log amplitudes for the complex pressure amplitudes are also discussed.

3aAO3. Resolving spatial seabed variability by Bayesian inference of seabed reflection inversions. Jan Dettmer, Stan E. Dosso (School of Earth and Ocean Scinces, Univ. of Victoria, Victoria, BC V8W 3P6, Canada), and Charles W. Holland (The Penn State Univ., State College, PA)

This paper considers Bayesian inversion of seabed reflection-coefficient data for multilayer geoacoustic models at several sites with the goal of studying spatial variability of the seabed. Rigorous uncertainty estimation is of key importance to resolve spatial variability between measurement sites from the inherent inversion uncertainties. Geoacoustic uncertainty estimation is carried out including Bayesian model selection and comprehensive estimation of data error statistics. Model selection is addressed using the Bayesian information criterion to ensure parsimony of the parametrizations. Data error statistics are quantified by estimating full covariance matrices from data residuals, and *a posteriori* statistical validation is carried out. A Metropolis-Hastings sampling algorithm is used to compute posterior probability densities. Five experimental sites are considered along a track located on the Malta Plateau, Mediterranean Sea, and the inversion results are compared to cores and subbottom profiler sections. Differences between sites that exceed the estimated geoacoustic uncertainties are interpreted as spatial variability of the seabed.

9:20

3aAO4. A simplified model of frequency distortion in ocean acoustic signals by multiple interactions with a moving ocean surface and its use in oceanographic inversions. Stephen D. Lynch and Gerald L. D'Spain (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr. 0701, La Jolla, CA 92093-0701)

Received omnidirectional spectra of low frequency narrowband tones measured in a shallow ocean waveguide exhibit Doppler-shifted sidebands at frequencies whose offsets are integer multiples of the dominant surface wave frequencies. These observations suggest that higher order scattering is important. However, higher-order perturbation theory involving only a single surface interaction does not predict the observed relative sideband levels. In particular, the higher order sidebands were often observed to increase in relative level to the main spectral peak during smaller surface wave, and, therefore, smaller kh, conditions. A simplified model is presented that simulates the surface wave-induced frequency distortions as path-length modulation caused by the vertical motions of the surface. The model incor-

porates multiple interactions with the moving surface, and quantitatively predicts the effects on the received spectra of the spatial coherence of the surface waves along the propagation path. The model results are identical to those from higher order perturbation with a single interaction. The simplified nature of this model allows it to be readily used to invert for various properties of the ocean surface wave directional spectrum. [Work supported by ONR, Code 321(US).]

9:35

3aAO5. Particle filter source tracking in a changing geoacoustic environment. Caglar Yardim, Peter Gerstoft, and William S. Hodgkiss, (Marine Phys. Lab., 2038 Scripps Inst. of Oceanogr., Univ. of California, San Diego, 9500 Gilman Dr., La Jolla, CA 92093-0238, cyardim@ucsd.edu)

This paper addresses the problem of tracking the acoustic source parameters such as the depth, range, and speed in evolving geoacoustic environments. It is well known that inaccurate knowledge about the environmental parameters such as the sound speed profile (SSP), water depth, sediment, and bottom parameters may result in significant errors in source parameters. To counter this, a particle filtering (PF) approach is adopted here where the geoacoustic parameters are tracked together with the source location and speed in a range-dependent environment. This allows accurate, real-time updating of the environment the ship is moving in and hence source can be located at any time accurately. As a sequential Monte Carlo technique that can operate on nonlinear systems with non-Gaussian probability densities, the PF is an ideal tracking algorithm to perform tracking of source and environmental parameters and their evolving probability distributions. The algorithm is tested on a sloping environment with the SSP, water depth, and sediment parameters evolving as the ship moves. The change in the water depth created the well-known "source mirage effect," but the PF was still able to track the true source, geoacoustic parameters, and their evolving densities in this spatially varying environment. [Work supported by ONR.]

9:50

3aAO6. Statistics of mode amplitudes in shallow water environments: Effects of random linear internal waves and nonlinear internal wave packets. John Colosi (Naval Postgrad. School, 833 Dyer Rd., Monterey, CA 93943, jacolosi@nps.edu), Andrey Morozov, and Tim Duda (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

In shallow water environments there is presently an incomplete understanding of the relative acoustical importance of the random linear internal-wave field compared to nonlinear internal waves packets. Using the random coupled mode theory of [Creamer (1996)], the nonlinear internal wave mode coupling theory of [Colosi (2007)], and Monte Carlo numerical simulation we are able to demonstrate the important propagation physics when the two internal wave fields act alone, and simultaneously. Importantly, we find that for acoustic frequencies less than roughly 500 Hz and for propagation ranges of order 10s of kms mode propagation though the random internal wave field is very nearly adiabatic, and that cross mode coherences decay rapidly within the first 10 km. A surprising consequence of the decay of cross mode coherence is that the mean intensity will be to first order insensitive to nonlinear internal wave packets if they are located past the decoherence range. It will also be shown that uncorrelated modes have important implications for the approach to saturation. The adiabatic nature of mode propagation though the random internal wave field may have important implications for shallow water acoustic remote sensing.

10:05—10:30 Break

10:30

3aAO7. Inversion for range-dependent water column sound speed profiles in shallow water. Megan S. Ballard (Graduate Program in Acoust., Penn State, P.O. Box 30, State College, PA 16804-0030, msd200@psu.edu) and Kyle M. Becker (Penn State, State College, PA 16804-0030)

Spatial and temporal variability of the sound speed field in the water column can have a significant impact on acoustic propagation. It is difficult or sometimes impractical to measure fine scale variations in water column properties over an acoustic propagation path. When measurements are not available, water column properties must be approximated. In past work, inverse methods based on acoustic tomography and matched-field processing have been used to estimate mean water column sound speed profiles. The drawback of these methods is their inability to capture fluctuations in the water column sound speed profile. In this work, a perturbative scheme using modal wave numbers is used to obtain range-dependent features of the water column. Based on the work of Rajan *et al.* (1987), a technique has been developed to estimate water column sound speed profiles using historical data to constrain the inversion. This constraint allows for a robust inversion; the result is accurate both when the inputs are noisy and when the bottom is poorly known. The new technique is demonstrated using data from the Shallow Water 2006 (SW06) experiment. Inversion results are compared to *in situ* measurements from the towed CTD chain. [Work supported by NDSEG and ONR.]

10:45

3aAO8. The estimation of geoacoustic parameters via low frequencies (50–75 Hertz) for simulated shallow water test scenarios. A. Tolstoy (ATolstoy Sci., 1538 Hampton Hill Circle, McLean, VA 22101)

This work will demonstrate the success of using only a variety of low frequencies (50–75 Hz) for geoacoustic inversion in simulated SW06 environments. The environments include a variety of scenarios (a thin, medium, or thick sediment layer over a half-space), broadband sources at approximately 1 km range (rge), and a vertical array consisting of 16 phones whose depths are approximately known, i.e., we assume that array element localization was available so that we can estimate phone depths (zphi) to within about 1 m. The source depths (zsou) and water depths (D) are approximately determined via time domain crossings seen at the array [see A. Tolstoy, J. Acoust. Soc. Am. **123**, 3106 (2008)]. Additionally, the ocean sound-speed c(z) is assumed to be range-independent and approximately known, e.g., via measurements or archival data. The use of only the 50–75 Hz portion of the signal results in a need for less than perfect accuracy for zphi and c(z) while still giving excellent accuracy for estimated bottom parameters. Geometric parameters (such as rge, zsou, D, zphi) and c(z) would be more accurately determined by means of higher frequencies but this would require much more CPU time. Uniqueness of the final "solution" is achieved for all but the thin sediment scenario.

11:00

3aAO9. Detection and classification of typhoons using underwater acoustic sensors in the western Pacific Ocean. Barry Ma (Dept. of ECE, Portland State Univ., 1900 SW 4th Ave., Portland, OR 97201, barry@cecs.pdx.edu) and Y. J. Yang (Naval Acad., Tsoying, Kaohsiung, Taiwan)

About two years of underwater ambient noise were collected using Passive Aquatic Listeners (PALs) in the western Pacific Ocean. PALs were deployed using the bottom-mount or surface-mount buoys on the possible typhoon paths. Several episodes of intensive typhoon noise were recorded during the passage of these powerful tropical storms. These acoustic data are compared with other ancillary data for the classification of typhoons. Using the underwater ambient noise to classify the intensity of typhoons is a relatively reliable method. The instrument is placed away from the air-sea interface in a less destructible environment and provides relative *in situ* measurement of the wind speed. The ambient noise recordings from the deployment also include the biology, shipping, and other surface noises, but the noises from the typhoons are the most distinguishable against all other sources of noise. The noise budgets from different deployment sites are also presented.

3aBB1. Investigation of an ultrasound imaging technique to target kidney stones in lithotripsy. Anup Shah (Dept. of Urology, Univ. of Washington School of Medicine, 1959 NE Pacific St., Box 356510, Seattle, WA 98195, anupshah@u.washington.edu), Marla Paun, John Kucewicz (Univ. of Washington, Seattle, WA 98105), Oleg A. Sapozhnikov (Moscow State Univ., Moscow 119992, Russia), Manjiri Dighe (Univ. of Washington School of Medicine, Seattle, WA 98195), Hunter A. McKay (The Polyclinic, Seattle, WA 98122), Mathew D. Sorensen (Univ. of Washington School of Medicine, Seattle, WA 98195), and Michael R. Bailey (Univ. of Washington, Seattle, WA 98105)

Localization of kidney stones and targeting for lithotripsy can be challenges especially with ultrasound. However, twinkling artifact has been observed where Doppler ultrasound imagers assign color to the stone. We report a preliminary investigation from our observations in a porcine model and hypothesize why this artifact occurs. Glass beads, cement stones, and human stones were surgically placed into the renal collecting system through the ureter. The stones were imaged using several transducers and ultrasound imagers. In all cases, the twinkling artifact of the stone was observed, and its appearance and radiofrequency signature were unique from those of blood flow. Calcium oxalate monohydrate stones and smooth stones were not more difficult to image, contrary to previous reports. Increasing gain or placing the focal depth distal to the stone enhanced the artifact, but other user controls showed little effect. Twinkling started at the lateral edges of the stone and spread over the stone as gain was increased. The evidence supports the hypothesis that small motions induced by radiation force or elastic waves in the stone cause changes in received backscatter, particularly at imaging angles oblique to the stone surface. 3aBB2. Shock wave lithotripsy treatment at 60 shock waves per minute is an appropriate protocol to minimize tissue injury. Bret Connors, Andrew Evan, Philip Blomgren, Rajash Handa, Cynthia Johnson, James McAteer (Dept. of Anatomy, IU School of Medicine, Ms-5055, 635 Barnhill Dr., Indianapolis, IN 46202), Lynn Willis (IU School of Medicine, Indianapolis, IN 46202), and James Lingeman (Int. Kid. Stone Inst., Indianapolis, IN 46202)

Previous work has shown that the size of the renal hemorrhagic lesion caused by extracorporeal shock wave lithotripsy (SWL) is greatly reduced when shock waves (SWs) are delivered at 30 SWs/min instead of at the more commonly used rate of 120 SWs/min ($0.08 \pm 0.02\%$ versus $3.93 \pm 1.29\%$ of functional renal volume, $P=0.006$). However, slowing the SW rate to 30 SWs/min greatly increases treatment time. Consequently, we investigated whether an intermediate rate of 60 SWs/min also reduces lesion size compared to treatment at 120 SWs/min. Methods: one kidney in 12 juvenile pigs was treated at 120 SWs/min ($n=7$) or at 60 SWs/min ($n=5$) with an unmodified Dornier HM-3 lithotripter (2000 SWs, 24 kV). After lithotripsy, the treated kidneys were fixed and removed to determine lesion size. Results: SWL at 60 SWs/min significantly reduced the size of the morphological lesion compared to 120 SWs/min ($0.42 \pm 0.23\%$ versus $3.93 \pm 1.29\%$, $P=0.034$). This reduction in lesion size was comparable to the lesion produced at 30 SWs/min. Conclusions: SWL applied at 60 SWs/min produces significantly less renal injury than SWL at 120 SWs/min, and produces an equivalent level of injury as that seen at 30 SWs/min.

3aBB3. Renal heme oxygenase-1 upregulation after shock wave lithotripsy. Daniel L. Clark, Bret A. Connors, Andy P. Evan, Rajash K. Handa, and Cynthia D. Johnson (Dept. of Anatomy Cell Biology, Indiana Univ. Sch. of Medicine, 635 Barnhill Dr., Indianapolis, IN 46202, danlclar@iupui.edu)

Shock wave lithotripsy (SWL) is known to induce oxidative stress and a rapid inflammatory response in renal tissue. The purpose of this study was to determine the location and quantify markers for oxidative stress and inflammation in a porcine model of acute SWL-induced renal injury. The lower pole calyx of left kidneys of female pigs received 2000 shock waves at 24 kV/2 Hz from a Dornier HM3 lithotripter and subsequently monitored for 4 h. Heme oxygenase-1 protein (HO-1) was measured in renal microsomes by Western blot. Renal medulla HO-1/β-actin ratios were 1.186 ± 0.48 for treated pole (F2), 0.293 ± 0.23 for treated kidney upper pole, and 0.122 ± 0.075 for contralateral kidney ($n=6$). Thus, we observed an eightfold induction of HO-1 in renal medulla at F2 compared to the upper pole medulla of the treated kidney and the contralateral kidney medulla. In contrast, renal cortex at F2 did not show a similar HO-1 induction. The highly localized HO-1 induction in SWL-treated renal medulla parallels our previously reported finding of interleukin-6. These data together suggest that an early inflammatory response and oxidative stress appear primarily in the treated renal medulla within 4 h after SWL. [Work supported by NIH].

3aBB4. Low-energy shock wave pretreatment results in greater vasoconstriction and less injury in the kidney compared to high-energy shock wave lithotripsy treatment alone. Rajash K. Handa, Andrew P. Evan, Bret A. Connors (Dept. of Anatomy and Cell Biology, Indiana Univ. Sch. Med., Indianapolis, IN 46202), Lynn R. Willis, Sujuan Gao (Indiana Univ. Sch. Med., Indianapolis, IN 46202), Marla Paun, and Michael R. Bailey (Univ. of Washington, Seattle, WA 98115)

Pretreating the kidney with low-energy shock waves (SWs) before administering a clinical dose of high-energy SWs has been found to greatly decrease the hemorrhagic lesion that normally results from high-energy shock wave lithotripsy (SWL) treatment alone. We tested the hypothesis that this novel pretreatment SWL protocol results in a greater and/or earlier renal vasoconstriction than clinical SWL alone, which could potentially explain the reduced bleeding in the kidney. Anesthetized pigs were treated with a clinical dose of SWs (2000 SWs, 24 kV, 120 SWs/min) or the pretreatment protocol (500 SWs, 12 kV, 120 SWs/min + 3-min pause + 2000 SWs, 24 kV, 120 SWs/min) using the HM3 lithotripter. Sonography (color and pulsed ultrasound) was used to locate a resistance artery within the SW-treated pole of the kidney and to take resistance index (RI) measurements from the blood vessel to estimate the resistance /impedance to blood flow. The results demonstrated that RI increased (renal vasoconstriction) earlier and greater during the pretreatment protocol compared to normal clinical SWL. Constricted blood vessels would likely be less prone to rupture by SWs and, if broken, would bleed less—resulting in a smaller hemorrhagic lesion.

3aBB5. Efficiency of spark discharge in electrohydraulic lithotripsy. Yuri A. Pishchalnikov, Mark M. Kaehr, R. Jason VonDerHaar, Irina V. Pishchalnikova, and James A. McAteer (Dept. of Anatomy and Cell Biology, Indiana Univ. Sch. of Medicine, 635 Barnhill Dr., Indianapolis, IN 46202, yura@anatomy.iupui.edu)

Electrohydraulic lithotripters and SWT devices generate shock waves by discharge of a high-voltage capacitor through submerged electrodes. As the electrodes age, the interelectrode gap widens. How this affects the efficiency of spark generation was studied using a research HM3-clone lithotripter. Widening of the interelectrode gap (~0.3 mm with new electrodes; ~2.5 mm after 4000 discharges) increased the lag-time to breakdown (~0 to ~30 μs, respectively). Increased lag-time as electrodes aged was associated with partial discharge of the capacitor (leakage promoted by ~0.6 mS conductivity of the surrounding water), such that the average energy remaining at the capacitor at the moment of breakdown was reduced four times compared to new electrodes. However, with new electrodes almost 90% of the energy was lost in the circuitry rather than in the spark, as the resistance of the spark (R~0.03 Ω) was much smaller than the resistance of the remainder of the circuit—including the high-voltage switch and connective wires (r~0.23 Ω). With old electrodes, most of the energy was released in the spark, as the electric efficiency $R/(R+r)$ approached ~90%. The product of electric efficiency and capacitor energy agreed closely with both the acoustic energy and the volume of the primary bubble produced at spark discharge. 3aBB6. Bubble dynamics with tissue confinement in shock-wave lithotripsy. Jonathan B. Freund (Mech. Sci. Eng., Univ. of Illinois at Urbana–Champaign, 1260 W Green St., MC-244, Urbana, IL 61801, jbfreund@illinois.edu) and Ratnesh Shukla (Univ. of Illinois at Urbana–Champaign, Urbana, IL 61801)

Estimates are made of the effect of confinement by tissues on the action of small bubbles when subjected to strong pressure waves. The applications of interest are biomedical procedures involving short strong ultrasound bursts or weak shocks of the kind delivered in shock-wave lithotripsy. Confinement is anticipated to be important in suppressing mechanical injury and slowing the rate of its spread. We consider bubbles in a liquid such as blood within a small vessel in the tissue. A generalization of the Rayleigh–Plesset equation allows us to estimate the effect of the elasticity and viscosity of the surrounding tissue. Ranges of soft-tissue properties are estimated from a variety of different measurements available in literature. Solutions suggest that elasticity is insufficient to significantly alter bubble dynamics, but that viscosities from the mid-to-high range of those suggested might play a significant role in suppressing bubble action. Simulations in two space dimensions of a shocked bubble in a waterlike fluid interacting with a viscous material show that the much more complicated bubble jetting dynamics in this configuration is also significantly suppressed. The dynamics of this suppression is investigated.

3aBB7. Simulation of three–dimensional crack profiles in shock wave lithotripsy. Maddegedara Lalith Lakshman Wijerathne, Hide Sakaguchi (JAMSTEC, Yokohama Inst. for Earth Sci., 3173-25 Showa-machi, Yokohama 236-0001, Japan.), Kenji Oguni, and Muneo Hori (Univ. of Tokyo, Bunkyo-Ku, Tokyo 113-0032, Japan.)

Some of the experiments reported by Xufeng Xi and Pei Zhong in 2001 were simulated to explore the sources of crack initiation and propagation in shock wave lithotripsy (SWL). An interesting result they reported was the T-shaped crack pattern in plaster of paris cylinders, subjected to transverse pressure pulses. This nontrivial crack pattern and some others were simulated, in 3-D, using a numerical technique called PDS-FEM. According to this 3-D simulations, it was found that the interference of reflected and focused high pressure pulse, by the distal surface, and the lagging low tensile phase created high tensile regions in the cylindrical sample. These high stress regions initiate and drive two horizontal and vertical cracks leading to the T-shaped crack. Due to the lack of data, a typical lithotripter pressure wave profile and material properties for plaster of paris were used. The observed crack patterns were successfully regenerated in 3-D, irrespective of these approximations. The distances between the vertical crack and the distal face for the crack patterns of the experiments and numerical simulations are nearly $0.34\times d$ and $0.35\times d$, respectively (d=diameter). This quantitative comparison shows the potential applications of PDS-FEM for exploring and further development of SWL technology.

3aBB8. Shock wave interaction with cavitation bubble clusters generated in lithotripsy. Derek C. Thomas, Todd A. Hay, and Mark F. Hamilton (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029)

Collapse of cavitation bubbles generated in shock wave lithotripsy is essential to the comminution of kidney stones. After passage of the shock, however, if insufficient time has elapsed for the bubbles to dissolve, acoustic scattering from residual bubbles shields the stone from the next shock. Therefore, cavitation also limits the maximum firing rate. As important as collective bubble dynamics are to the efficacy of shock wave lithotripsy, behavior of the bubble clusters is among the least understood physical processes involved. A model was developed previously for the pulsation and translation of dynamically coupled spherical gas bubbles [Ilinskii *et al.*, J. Acoust. Soc. Am. **121**, 786 (2007)]. This model was augmented to account for interaction with the focused shock wave incident on the cluster at the order of the Born approximation. Diffraction of the shock wave is described by the KZK equation. The model predicts translation and coalescence of the bubbles due to transmission of the shock through the cluster. Predicted also is the acoustic wave scattered from the cluster, which in the forward direction is the leading order effect of the cluster on the transmitted shock wave. 3aBB9. Shock wave lithotripsy can alter urinary acid-base pH regulation. Rajash K. Handa, Bret A. Connors, Cynthia D. Johnson, Andrew P. Evan (Dept. of Anatomy and Cell Biology, Indiana Univ. Sch. Med., Indianapolis, IN 46202), Mahesh C. Goel, James E. Lingeman (Methodist Hospital Inst. for Kidney Stone Disease, Indianapolis, IN 46202), Elaine M. Worcester, and Fredric L. Coe (Univ. of Chicago, Chicago, IL 60637)

The renal papilla is particularly susceptible to injury by shock waves (SWs). Since the papilla is vital for urinary pH regulation, we hypothesized that shock wave lithotripsy (SWL)-induced damage of papillae will alter the pH of the urine. Experiments were conducted in four female adult Gottingen minipigs. The HM3 lithotripter delivered a total of 8000 SWs (24 kV, 120 SWs/min) among all papillae of one kidney, while the untreated, opposite kidney was used as control. The pigs were allowed to recover and 5 weeks later they were anesthetized. Serial urine collections were obtained from the SW-treated and untreated kidney. Urine was collected under mineral oil and immediately tested for its pH. Both kidneys were then perfusion fixed for histological analysis. Urinary pH was 0.17 units greater ($P<0.05$) in the SW-treated kidney compared to the untreated kidney. Histology showed scarring in all regions of the SW-treated kidney, with thick ascending limbs and collecting ducts having grossly abnormal morphologies indicative of cellular proliferation. These results suggest that SWL-induced injury can cause remodeling of nephron structures and long-term impairment in the regulation of urinary pH.

3aBB10. Ureteroscopic ultrasound technology to size kidney stone fragments: Proof of principal using a miniaturized probe in a porcine model. Mathew D. Sorensen, Anup Shah (Dept. of Urology, Univ. of Washington Sch. of Medicine, 1959 NE Pacific St., Box 356510, Seattle, WA 98195, mathews@u.washington.edu), Michael S. Canney (Univ. of Washington, Seattle, WA 98105), Oleg A. Sapozhnikov (Moscow State Univ., Moscow 119992, Russia), Joel M. H. Teichman (Univ. of British Columbia, Vancouver, BC V6Z 1Y6, Canada), and Michael R. Bailey (Univ. of Washington, Seattle, WA 98105)

Background: the ability to measure stone fragment size could help prevent attempting to extract too large a stone fragment. We evaluated the ability of a 1.2 mm (3.6 French) ultrasound probe to measure stone fragments in a porcine kidney. Methods: 15 human stones of three types (five each calcium oxalate, cystine, calcium phosphate) sized 3–7 mm were placed deep in a porcine kidney collecting system. The sound speed of each stone type was determined using a separate reference stone. A 2 MHz, 1.2 mm needle hydrophone was used to send and receive ultrasound pulses. Stone thickness was calculated as $d=c*t/2$ by determining the signal transit time through the stone, t, and the stone sound speed, c. Calculated stone thicknesses were compared to digital caliper measurements. Results: Stone size was determined for all 15 stones. Correlation between ultrasound-determined thickness and caliper measurements was excellent ($r^2=0.90$, $p<0.0001$) with ultrasound performing well in all three stone types. All stone measurements were accurate within 1 mm, and ten (66%) stone measurements were accurate within 0.5 mm. Conclusions: Ultrasound-based measurements are accurate and precise using a 3.6 French probe with stone fragments placed deep in a porcine kidney. 3aBB11. Ellipsoidal-reflector high intensity focused ultrasound system with integrated safety monitoring. Joshua Samuels and Vesna Zderic (Dept. of Elec. and Comp. Eng., The George Washington Univ., 801 22nd St. NW, Washington, DC 20052, zderic@gwu.edu)

High intensity focused ultrasound (HIFU) transducers can be created using concave piezo elements, acoustic lenses, phased arrays, or ellipsoidal reflectors. By using a 2 MHz cylindrical piezoelectric crystal and a brass ellipsoidal reflector, it was possible to use the base of the transducer to house specific devices which can be integrated into a safety system for the device. This system assists in focal point positioning, ablation confirmation, as well as assuring proper flow of coolant through the attached water pillow to couple the device. These methods combine to protect the patient and the device itself from improper use or dangerous positioning of the focal point within the tissue. The proposed system utilizes an unfocused 3.5 MHz ultrasound transducer to act as a rangefinder, determining the distance of the tissue from the transducer. A simple graphical user interface allows the maximum allowed depth of ablation to be user defined and a warning displayed if needed. A water pillow with integrated flow meter is used to provide cooling and coupling to the tissue. There is also a housed video camera in the device which could provide visual confirmation of ablation if used laparoscopically or for superficial lesions.

3aBB12. *In vivo* simulation of shock wave lithotripsy: Wave focusing in inhomogeneous materials. Jeffrey Krimmel and Tim Colonius (Caltech 1200 E California Blvd., MC 104-44, Pasadena, CA 91125, jkrimmel@caltech.edu)

Shock wave generation and focusing in electrohydraulic, electromagnetic, and piezoelectric lithotripters are simulated numerically. Inhomogeneities associated with wave propagation *in vivo* are modeled using data from The Visible Human Project. The approximate time-domain relaxation model of Yang and Cleveland (2005) was used to simulate attenuation and dispersion in the tissuelike media. The simulations utilize a MUSCL-type shock capturing scheme with adaptive mesh refinement (AMR). *In vitro* focal region pressure measurements compare favorably with available experimental data for each lithotripter type. Preliminary *in vivo* simulation results show significant dispersion associated with the nonuniform sound speed, including increases of up to 50% in focal pressure amplitudes and the presence of multiple pressure minima/maxima in the focal waveform. We will also discuss the extension of the AMR framework to account for cavitation via a previously developed ensemble-averaged continuous two-phase flow model.

3aBB13. Kidney stone tracking *in vitro* using an acoustic triangulation paradigm. Jonathan M. Kracht and Robin O. Cleveland (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

During shock wave lithotripsy, stones undergo motion which can place them outside the focal zone of the lithotripter. This results in shock waves being delivered that do not impact the stone but may injure tissue. Tracking stones using diagnostic ultrasound imaging (~4 MHz) has proven to be challenging. Here we employed an array of seven relatively low-frequency (~600 kHz) elements to detect scattered signals from an artificial kidney stone in the presence of a tissue phantom. Using an optimization routine, the time of flight to each element and array geometry were used to determine the most likely location of the stone. A comparison of threshold crossing and cross-correlation for detecting signal arrival indicated that while the former yielded faster computation time, the latter was more robust to noise. Stone position was determined to within 2 mm for locations within 10 mm of the focus. For distances beyond 10 mm, the optimization routine was not able to reliably predict stone location but could indicate that the stone was not within the focal region. [Work supported in part by NIH.]

11:30

3aBB14. Lung hemorrhage produced by exposure to underwater acoustic impulses. Diane Dalecki, Sally Z. Child, and Carol H. Raeman (Dept. of Biomedical Eng., and the Rochester Ctr. for Biomedical Ultrasound, 310 Goergen Hall, Univ. of Rochester, Rochester, NY 14627, dalecki@bme.rochester.edu)

Underwater acoustic impulse sources are used in various commercial and military applications. The objective of this study was to investigate the response of mammalian lung to exposure to underwater acoustic impulses. A laboratory-based acoustic exposure system was developed to investigate the bioeffects of underwater impulses. Underwater acoustic impulses were generated using a ten cubic inch air gun operated in a large water tank. Underwater acoustic impulses with peak pressure amplitudes ranging from 0 (sham) to 110 kPa were investigated. Experiments were performed with anesthetized adult mice. Each exposure consisted of five acoustic impulses with approximately 20 s between impulses. Mammalian lung hemorrhage can occur in response to exposure to underwater acoustic impulses. The pressure threshold for lung hemorrhage resulting from five air gun impulses was approximately 50 kPa. The extent of lung damage increased with increasing pressure amplitude. The results of this work are relevant to establishing safety guidelines for swimmers and divers exposed to underwater sound fields.

3aEA1. Wind turbines: Why they are noisy and what to do about it. Frits van den Berg (GGD, P.O. Box 2200, 1000CE Amsterdam, The Netherlands, fvdberg@ggd.amsterdam.nl)

Sound from modern, tall wind turbines is related to sleep disturbance and is, per decibel, more annoying than sound from common sources such as road or air traffic. Surveys among residents indicate that there are several reasons for this: the swishing character of the sound, the intrusiveness at night, and the visibility of the wind turbine(s). Residential reaction is also determined by the attitude towards wind turbines in the landscape and by economical benefits. From acoustical research different explanations have arisen as to why the sound is amplitude modulated. For a distant observer it is the result of the change in trailing sound level due to the change in wind that the revolving blades encounter. High night-time sound levels are due to an increase in rotor height wind speed simultaneously with a decrease in near-ground wind speed. Wind turbine design has been directed to higher yields per turbine. Less attention has been given to low noise blades and rotor speed reduction. Low noise design could also include a reduction in the modulation amplitude and more sophisticated speed reduction; viz., at high annoyance conditions. Also, involving residents in wind farm planning may have a high potential to reduce annoyance.

9:30

3aEA2. An overview of the acoustical activities at the National Wind Technology Center. Arlinda Huskey (NREL, NWTC, 1617 Cole Blvd., MS 3911, Golden, CO 80401, Arlinda_Huskey@nrel.gov), Moriarty Patrick, Jeroen van Dam (NREL, NWTC, Golden, CO 80401), Eric Simley, and Scott Palo (Univ. of Colorado)

The National Wind Technology Center (NWTC) has been involved in wind turbine acoustics since the 1980s. The areas of work include standards development, measurement and analysis, prediction code development, and acoustic arrays. Most measurements are conducted to the IEC 61400-11, a standard specifically for acoustic measurements of wind turbines. The NWTC is involved in the development of this standard. The standard results in reports of overall levels as well as tonality. The NWTC has also developed a semiempirical acoustic noise prediction code for wind turbines. Validation of this code with test data (both wind tunnel and field measurements) shows reasonable prediction accuracy for both airfoil self noise and turbulent inflow noise. Lastly, to assist with wind turbine noise reduction and to identify the loudest components an acoustic array was developed to better locate noise on wind turbines. This paper will describe the NWTC's past and current activities in wind turbine acoustics including test methods and results.

9:55

3aEA3. Ocean acoustic noise budgets: Application to the environmental assessment of offshore wind power generation. James H. Miller, Gopu R. Potty, Andres Nunez Perez (Dept. of Ocean Eng., Univ. of Rhode Island, Narragansett, RI 02882, miller@uri.edu), Kathleen Vigness Raposa (Marine Acoust., Inc., Middletown, RI 02842), and Jeffrey A. Nystuen (Univ. of Washington, Seattle, WA 98105-6698)

A noise budget is a listing of the various sources of acoustic noise and their associated ranking by importance. A number of different types of budgets can be conceived using various acoustic measures such as intensity, energy, or duration of maximum amplitude level. These budgets are typically parameterized by frequency and are usually computed over 1/3 octave bands. As part of the environmental assessment of the proposed offshore wind power generation project under the Rhode Island Special Area Management Plan (SAMP), noise measurements were made using the Passive Acoustic Listener (PAL) systems off the coast of Rhode Island prior to the installation of any wind power facilities. Two PALs were deployed within two miles of Block Island in water depths of 20 m from October 6 to November 11, 2008. The data included noise spectra and source identification every 3 min. Short snapshots of unusual sounds were also recorded. From this data, the ocean acoustic noise budget is computed with contributions from shipping, wind/waves, marine mammals, and rain from 500 Hz to 50 kHz. The ship noise data is correlated with ship traffic data from the Automatic Identification System (AIS). [Funding provided by the Rhode Island Office of Energy Resources.]

10:20

3aEA4. Prediction methodologies for tonal and broadband noise from horizontal-axis wind turbines. Brent Paul, Rudolph Martinez, Donald Thompson, and James Uhlman (CAA-Alion Corp., 84 Sherman St., Cambridge, MA 02140 bpaul@alionscience.com)

This paper describes a set of computational-analytic predictive tools for the following mechanisms of aerodynamic sound and vibration for a wind turbine's blades in ducted or open arrangements: (a) Infrasound and tonal low-frequency nearfield noise from the interaction of blades with a nonuniform meanflow that is steady in its own reference frame; (b) mid-frequency broadband noise from the "haystacked" chopping of an incident turbulent freestream; (c) high-frequency noise from self-generated turbulence near the trailing edge of each blade's suction side. Contributors to tonal mechanism (a) include the rotor's static loads as required by power generation (nearfield "Gutin" component of infrasound), and operation in a local wind shear or in the mean wake of the turbine's tower when set up as a downstream machine. These predictive tools include models of the spatially nonuniform mean and turbulent flows that typically strike a wind turbine's blades, as well as preprocessors of that information when made available by either field measurements or off-line calculations. The codes' physical content includes the possibility of uneven spacing for the turbine's blades and for their interaction with statistically inhomogeneous turbulence for mechanism (b). Sample predictions compare the codes' estimates of sound production to measurements from the open literature.

3aEA5. Methodologies to address limitations of the ISO9613-2 standard for wind turbine noise propagation modeling. Erik J. Kalapinski (Tetra Tech EC Inc., 133 Federal St., Boston, MA 02110, erik.kalapinski@tteci.com)

The accuracy of the noise propagation modeling results is dependent on: (1) the sound source data entered into the model as reported by wind turbine equipment manufacturers as specified under per IEC 64100-11 standard; (2) site specific topographical, meteorological, and terrain conditions; and (3) the propagation algorithms of the acoustic modeling standard that are applied. For wind energy facilities sited in the US, the ISO 9613-2 standard is most commonly used due to its proven effectiveness to accurately predict the sound levels at a distance for industrial and commercial projects in an outdoor environment. The propagation algorithms employed by the ISO 9613-2 standard account for geometrical divergence, atmospheric absorption, ground attenuation, screening effects, and favorable sound propagation conditions that would occur during omnidirectional downwind meteorological conditions. The purpose of this paper is to identify limitations inherent in the ISO 9613-2 standard to the specialized application of wind turbine acoustics and nonstandard atmospheric conditions. Methodologies are presented to more accurately describe atmospheric and lateral attenuation effects, which can result in significant uncertainties in the noise levels calculated both in proximity and at distant receptor locations.

11:00

3aEA6. Vibration analysis of turbine low-pressure bladed-disk in 500-MW fossil power plant. Dooyoung Lee, Youngchae Bae, Heesoo Kim, Yookryun Lee, Hongil Choi, and Hyun Lee (Hydro & Fossil Power Generation Lab., KEPRI, 103-16 Munji Yusung Daejon, Korea, 305-380, dylee@kepri.re.kr)

Many failures of turbine blades are caused by the coupling of aerodynamic forcing with bladed-disk vibration characteristics. Vibration analysis for an individual turbine blade does not include all the coupled characteristics of whole bladed-disk system. This paper shows the coupled vibration characteristics of a low-pressure (LP) turbine bladed-disk in a 500-MW fossil power plant for the purpose of confirming equipment integrity. In order to verify the finite element model, analytic and experimental modal analyses for a single blade were performed and reviewed with boundary conditions not only where both ends were free to move but also where its root was

fixed. Natural frequencies and corresponding mode shapes were calculated for the bladed-disk first, and then proximity of modes to sources of excitation was assessed by means of interference diagrams to examine resonance. The result of analysis was ascertained by being compared with a field test for the bladed-disk without centrifugal and aerodynamic forces. In addition, dynamic stress as well as steady stress which results from centrifugal and steady-state steam forces was also calculated at dangerous modes of operation. It is expected that these dynamic characteristics will be used effectively to identify the root causes of blade failures and to perform prompt maintenance.

Session 3aED

Education in Acoustics and ASA Student Council: Project Listen Up

James M. Sabatier, Chair
National Ctr. for Physical Acoustics, Univ. of Mississippi, University, MS 38677

Chair's Introduction—8:25

8:30

3aED1. A simple experiment for understanding resonant air columns. Theodore F. Argo, IV, Chad A. Greene, and Preston S. Wilson (Mech. Eng. Dept. and Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78712-0292, targo@mail.utexas.edu)

One goal of Project Listen Up is to enhance children's understanding of acoustics through engagement in basic acoustics experiments. This work proposes an experiment that examines the resonant frequencies of an air column. Equipment for this experiment consists of a small tunable oscillator circuit connected to a loudspeaker, which can also be used for other experiments in the kit. The experimenter will provide a cardboard tube, rubber band, plastic wrap, and sand. Resonance is demonstrated by placing the loudspeaker at the base of the tube, covering the top of the tube with a plastic wrap membrane, and placing sand grains on top of the membrane. As frequency is adjusted, the sand grains are excited at the resonance frequencies of the tube. Frequencies at which sand motion is observed can be compared to a simple algebraic model, which relates the length of the tube to the resonance frequencies of the system. An optional advanced experimental track investigates the effect of varying the length of the tube. This experiment develops intuition for the relationship between frequency and wavelength and builds understanding of resonant systems.

8:45

3aED2. Sound speed measurements in air using a variable sound source and tubes. Stanley A. Cheyne and Walter C. McDermott (Dept. of Phys. and Astronomy, Hampden-Sydney Coll., Hampden-Sydney, VA 23943)

Sound speed measurement using standing waves and tubes is a standard experiment in every introductory physics laboratory. It is an experiment that is relatively simple to understand both conceptually and mathematically. The idea behind this work is to reproduce the same experiment, at low cost, making it suitable for project listen up. Two approaches were made. The first was to design and construct a small, low cost, variable sound source that could be used to determine the resonances of several fixed length tubes. The device is simple in design and easy to use. As the frequency is varied, the resonances can be determined by listening with the ear. Once done, the sound speed can be easily calculated. The second method was to use a free, online, function generator as the sound source and repeat the experiment as previously discussed. Results of both methods will be given and demonstrated along with pros and cons of each.

9:00

3aED3. Why we have two ears—a hands-on experiment comparing monaural and binaural hearing. Ralph T. Muehleisen (Civil, Environ., and Architectural Eng., Illinois Inst. of Technol., 3201 S. Dearborn St., Rm. 228, Chicago, IL 60616)

Whether they fly, swim, crawl, or walk, vertebrates have binaural auditory systems. Two ears provide redundancy in case of injury to the auditory system, improve the ability to detect quiet sounds and, perhaps most importantly, improve the ability to localize sound. This paper describes a simple experiment in which two individuals work together to investigate the sound localizing abilities of a human using monaural and binaural hearing. In the experiment, one person sits blindfolded in the center of a circle and acts as a listener. The other person moves a sound source around a circle, equidistant from the listener while the listener attempts to locate the direction of the source. The experiment is repeated for both monaural (with an earplug in one ear) and binaural (using both ears) hearing and for impulsive and low frequency tonal sources. The experiment is best attempted in an environment with very few nearby reflecting sources such as the outdoors or a very large room.

9:15

3aED4. Two-dimensional normal modes: Experiment and finite element analysis. Uwe J. Hansen (Dept. of Chem. & Phys., Indiana State Univ., Terre Haute, IN 47809)

Bending wave propagation on a two-dimensional plate is reduced to standing waves with the imposition of boundary conditions. These standing wave patterns can be observed with sand, which accumulates near the nodal lines. These sand patterns are usually called Chladni patterns after Chladni, who first observed and described them. Using a simple lapel microphone, these mode patterns can also be illustrated by noting the phase shift when observing the near-field sound pattern very close to the vibrating plate. Both Chladni patterns and phase mapping of patterns will be illustrated. A relatively inexpensive software package enables finite element calculations of vibrating plates. Normal mode vibration can easily be illustrated in animation on a computer screen. Both the calculation process and the animation will be illustrated.

9:30

3aED5. Acoustics outreach and scouting: A merit badge proposal. Kent L. Gee, Brian E. Anderson, Tracianne B. Neilsen, and Scott D. Sommerfeldt (Dept. of Phys. and Astron., Brigham Young Univ., N283 Eyring Sci. Ctr., Provo, UT 84602, kentgee@byu.edu)

The success of the Girl Scouts of America (GSA) and the Optical Society of America's "Project Lighten Up" and the proposed "Project Listen Up" have prompted a discussion of how Scouting can be used as an outreach vehicle to interest today's youth in science and, more particularly, in acoustics. One possibility for this would be the drafting of a "Sound and Audio" merit badge for the Boy Scouts of America (BSA) or a similar activity award for the GSA. The BSA currently offers 121 merit badges for scouts, including varied topics such as archeology, rifle shooting, plumbing, truck transportation, and coin collecting. Although there are physical science-related merit badges (e.g., composite materials, chemistry, nuclear science), there is not a badge that deals directly with acoustics. This talk will outline how an acoustics-related merit badge may help engage youth interest in science and discuss ideas for possible badge requirements.

9:45

3aED6. Wave interaction effects for all ages. Scott D. Sommerfeldt (Dept. of Phys., Brigham Young Univ., N181 ESC, Provo, UT 84602, scott_sommerfeldt@byu.edu)

Wave interaction effects occur in many everyday situations. A number of important principles associated with these interactions can be readily demonstrated without the need for extensive and expensive equipment. Using two low-cost speakers, it is possible to easily demonstrate the basic principle underlying active noise control by placing the speakers close together and first wiring the speakers "in-phase" to achieve constructive wave interference and then wiring the speakers "out-of-phase" to achieve destructive wave interference. This setup results in a global attenuation of the sound field, making the audible effect easily discernible. The dependence of the interaction on frequency and spacing (kd) can be demonstrated by changing the frequency of the excitation signal. In addition, by separating the speakers the interaction of two waves to create a standing wave can be demonstrated, and the nodes/antinodes established can be audibly heard as the listener moves his/her ear through the field. Finally, these concepts can be used to understand why loudspeakers are mounted in enclosures. As the loudspeaker is placed in an enclosure the direct interaction of (out-of-phase) waves from the front and back of the loudspeaker cone is inhibited, thus resulting in increased radiation efficiency.

3aED7. A simple analytical demonstration of transient and steady-state response in a dissipative closed waveguide based on the d'Alembert solution. Jerry H. Ginsberg (G. W. Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405, jerry.ginsberg@me.gatech.edu)

Previously [J. H. Ginsberg, J. Acoust. Soc. Am. **119**, 1954–1960 (2006)], the d'Alembert solution of the wave equation was adapted to address the response to initial conditions of a one-dimensional waveguide whose terminations have an arbitrary real (possibly dissipative) impedance. The technique creates virtual images on the other (i.e., nonphysical) side of each wall to convert the closed waveguide to one of infinite extent. The present work extends the development to cases where an arbitrary velocity is applied to one wall. The imaging technique allows one to visually track the evolution of the spatial pressure profile and the relation of temporal waveforms at various locations. The relatively low level of mathematical skills entailed in the formulation makes the method accessible to students at all levels. Application of the technique to periodic excitation of the boundary leads to visual representation of various effects, including reverberation time and various resonance effects, such as uncontrolled growth in the absence of dissipation and approach to steady-state when dissipation is present. Sound files generated from the synthesized connect the physical and audible phenomena.

10:30

3aED8. Hands on and homemade coupled oscillators for Project Listen Up. Sean M. Mock and Murray S. Korman (Dept. of Phys., U.S. Naval Acad., Annapolis, MD 21402, m114518@usna.edu)

A coupled pendulum oscillator experiment recently developed within the U.S. Naval Academy Physics Department seems a possible candidate for the Project Listen Up initiative. A plexiglass frame supported by four legs suspends two 500 g masses 30 cm below by two chains of paper clips each, meeting in the shape of a V on either bob. A light spring (k=3.64 N/m) connects the two, completing the coupled oscillator system. Displacement of the oscillators was measured using Pasco motion sensors, a Vernier LabPro unit, and a laptop. LOGGERPRO and MATHEMATICA software helped compare theory with experiment. However, one does not need these resources to experiment with coupled oscillators—it can be improvised using ordinary household materials for young students! An inexpensive wooden picture frame with islet screws supports pendulums using two Dixie cups filled with sand or coins as masses. The possibilities for learning seem endless! A simple stopwatch, meter stick, fulcrum, and measuring cups are incorporated in experimental and theoretical comparisons, including the periods of normal modes. Students can explore density through balancing masses with volumes of water. Demonstrating beat frequencies from mistuned xylophone bars or guitar strings conveys a subtlety of the experiment without overpowering the young minds of future scientists.

10:45

3aED9. Helmholtz resonator experiment for Project Listen Up. Marianne C. Sparklin and Murray S. Korman (Dept. of Phys., U.S. Naval Acad., Annapolis, MD 21402, m096120@usna.edu)

The behavior of sound waves and resonant effects can be observed using Helmholtz resonators. Resonators are built from identical round wooden boxes purchased from a craft store. The tops are glued and drilled with hole diameters from 2–3 cm. We can study the resonant behavior as a function of hole diameter only. The end effect is large compared with the thickness of the orifice (0.6 cm). In the experiment, a swept tone (100–900 Hz) from a small speaker drove the resonator. One studied the output of the microphone located near the orifice. One could use a swept spectrum analyzer, a function generator, or tuning fork with varying weights to measure the resonant frequency of the box. A plot of hole diameter versus frequency can be compared with the theoretical Helmholtz resonant frequency prediction, which depends on the volume of the box, the cross sectional area, the sound speed of air, and the effective length of the hole. One can model the effective length of the resonator as the thickness of the top plus a constant times the diameter of the hole and get good agreement with the established end correction found in textbooks.

11:00

3aED10. The energy flow for a spherical acoustic lens: Ray and wave methods vs experiment. Cleon E. Dean (Phys. Dept., P.O.B. 8031, Georgia Southern Univ., Statesboro, GA 30460-8031, cdean@GeorgiaSouthern.edu) and James P. Braselton (Georgia Southern Univ., Statesboro, GA 30460-8093)

A simple classroom demonstration consists of a weather balloon filled with carbon dioxide, a sound source, and a microphone. Since the speed of sound is slower in carbon dioxide than in air at room temperature and pressure, the balloon acts as a positive spherical acoustic lens. The accuracy of ray methods in locating the acoustic focus versus a full-blown wave solution approach has been presented previously [Cleon E. Dean and James P. Braselton, "The energy flow for a spherical acoustic lens: ray vs. wave methods," J. Acoust. Soc. Am. **123**, 3520 (2008).] Theoretically, this problem presents particular difficulties if the sound source lies in the near field region. The sound emitter is treated as a dipole source equivalent to a rigid oscillating sphere of small size and amplitude of motion relative to the scatterer. The energy flux around the balloon has been visualized by both ray methods and by the acoustic energy flux vector field. The geometrical ray results and the energy flux vector field resulting from the wave solution are compared with experiment.

11:15

3aED11. The effect of the teaching-learning sequences connecting sound wave at microlevel and macrolevel on the student's understandings for sound transmission. Hyungjun Kim (Phys. Education Dept., Seoul Natl. Univ, Daehak-dong, Gwanak-gu, Seoul 151-742, che94@dreamwiz.com) and Junehee Yoo

Previous studies reported that students had some difficulties in understanding sound waves as longitudinal waves. In this research, most of teaching-learning sequences described sound waves at macrolevel, which were supposed as one source of these difficulties. So teaching-learning sequences connecting sound wave at microlevel and macrolevel were developed and effects were investigated. These teaching-learning sequences were focused on bridging between the movement of particles in air and movements of slinky springs and simulation using the EXCEL program. In addition to that, explaining wave phenomena at macrolevel by the movement of particles at microlevel was emphasized. Predict-observe-explain strategy was used. Evaluated worksheets and video-records were analyzed to figure out conceptual changes.

11:30

3aED12. Modal analysis for undergraduate laboratories and projects. Andrzej Kotlicki and Chris Waltham (Dept. of Phys. and Astronomy, Univ. of British Columbia, 6224 Agricultural Rd., Vancouver, BC V6T 1Z1, Canada)

Vibrational analysis of structures (musical instruments for example) requires a means of excitation, motion detection and a data acquisition system. None of these needs to be very expensive. We have constructed an impact hammer using a piezoelectric crystal from an old barbeque lighter; this provides rapid excitation at all frequencies up to 1 or 2 kHz. Motion detection is now possible using extremely light (less than 1 g) microelectromechnical systems (MEMS) accelerometers that cost only a few dollars each. Two-channel data acquisition at 44.1kHz per channel is available to anyone with a computer equipped with a soundcard. More flexible external systems are also available in the $200 range. Thus, modal analysis is easily within the budgets of undergraduate laboratories. In this presentation we will emphasize the calibration of the impact hammer and evaluation of the MEMS accelerometers.

8:05

3aNS1. Hearing loss litigation. Robert A. Dobie (Dept. of Otolaryngol., UC-Davis, Sacramento CA 95817)

Most hearing loss in American adults is attributable to aging, noise, or a combination of these two. While most claims for noise-induced hearing loss are handled administratively in workers compensation, litigation against employers, premises owners, and manufacturers of noisy equipment continues to pose interesting challenges. Issues of negligence often involve professionals with expertise in noise control, hearing conservation program management, product labeling, and human factors. There are usually two primary issues for clinician experts: How severe is the hearing loss, and what caused it? Audiologists and otologists can draw upon a mass of research to support reasonable opinions in cases with complete data sets. Unfortunately, important data from the past (e.g., changes in noise exposure and hearing loss over a career) are often impossible to obtain. Forensic consulting is terra incognita for most clinicians, requiring analyses and judgments that are rarely called for in clinical practice.

8:35

3aNS2. Minneapolis et al versus the Metropolitan Airports Commission. Paul Schomer (Schomer and Assoc., Inc., 2117 Robert Dr., Champaign, IL 61821, schomer@SchomerAndAssoc..com)

The city of Minneapolis has a law protecting the quietude in various land use areas, including residential areas. In this legal action, plaintiff asserted that the Metropolitan Airports Commission was adversely and significantly affecting the quietude of the residents in the 60–65 DNL zone and that a 5-dB noise insulation package in homes in that zone would ameliorate the situation. There were four tasks for plaintiff's expert witnesses; (1) Define quietude; (2) Show that without the airport quietude existed in the 60–65 DNL zone; (3) Quantify the impacts including annoyance, speech interference, and sleep disturbance; and (4) Quantify the benefits of a 5-dB noise insulation package. The results were a negotiated settlement for $128 million.

9:05

3aNS3. Qualification of an aircraft ground run-up enclosure using a novel sound monitoring and analysis approach. Kerrie G. Standlee (Daly-Standlee & Assoc., Inc., 4900 SW Griffith Dr., Ste. 216, Beaverton, OR 97005)

This paper describes a sound monitoring and analysis program developed to determine if a ground run-up enclosure (GRE) installed at the Portland International Airport was effective in reducing aircraft engine run-up noise radiated to residential neighborhoods during nighttime hours. A noise monitoring and analysis program was developed to fulfill conditions of approval imposed by the Oregon Department of Environmental Quality (DEQ) prior to the construction of the facility. A novel approach was developed whereby unattended sound level meters were used to collect one-second Leq and hourly statistical noise level data near the GRE and at community locations of interest. This data, combined with GRE usage data and weather data, was then subjected to a multistep analysis procedure. The process was found to be very effective at determining when ground run-up events caused community noise levels exceeding DEQ limits. By the end of the project, the procedure was being used to assess 99 percent of the run-ups occurring within the GRE. The sound monitoring and analysis procedure became a very reliable tool in demonstrating that the GRE complied with its conditions of approval.

9:35

3aNS4. Noise issues affecting litigation in condominiums. Jerry G. Lilly (JGL Acoust., Inc., 5266 NW Village Park Dr. Issaquah, WA 98027)

Serving as an expert witness in legal actions involving residential condominiums is often a harrowing and extremely challenging task, regardless of which side you represent. If you are representing the HOA, you have to educate your client so that they understand that the mere ability to hear your neighbor is not necessarily unusual and may not be grounds for a defect. If you are representing the architect, developer, or contractor, you have to educate them as to the code requirements as well as the various acoustical performance guidelines that will undoubtedly be introduced by the HOA. In either event, if you do not do your homework you are leaving yourself exposed to be grilled by opposing counsel (in deposition or at trial) without mercy. This presentation will discuss the author's experience in dealing with these issues, with specific emphasis on problems with the testing standards and performance guidelines that exacerbate the problem.

10:05—10:20 Break

10:20

3aNS5. Warning audibility in industrial accidents. John Erdreich (Ostergaard Acoust. Assoc., 200 Executive Dr., W. Orange, NJ 07052)

Industrial accidents related to warning audibility may be adjudicated in the worker compensation environment or in state courts. One factor that may determine whether the incident becomes a compensation case or a tort is if the employer could reasonably expect the situation to require an audible warning. The second factor to evaluate is the adequacy of the warning itself. Thus, it is the responsibility of the acoustician to educate the trier of fact about not only the science of audition, but also the state of the art in that represents a consensus of methods to provide such warnings. An example of such a case will be presented.

3aNS6. Can race car sound break windows? David Braslau (David Braslau Assoc., Inc., 1313 5th St. SE, Ste. 322, Minneapolis, MN 55414)

Sound from a special class of race cars was cited as cause for sudden breakage of a large pane of tempered glass in a private box that fell and injured a spectator below. Analysis of previously recorded race track noise from a similar track in Minnesota showed that sound levels could exceed the Hubbard rattle criteria but no conclusions could be drawn regarding breakage. Because of time constraints, sound level measurements from a race in Ohio of this vehicle class were taken by Campanella Associates for reference. Those measurements were compared with previously measured levels of other vehicle classes and found to be higher at some frequencies. Since a recorded demonstration performed by the plaintiff showed breakage of a similar pane of glass with an induced flaw and continuously applied sound at 70 to 80 Hz, a field test on a similar window with simulated sound levels based upon measurements from the special vehicle class race was performed with assistance from Synergistic Design Associates. A simulated sound level as high as 117 dBA was generated at the window without breakage. Some conclusions on potential glass breakage from incident sound will be presented. [Work supported by Johnson & Lindberg, P.A.]

11:05

3aNS7. Deficiency of the Massachusetts Pure Tone Noise Regulation. Michael Bahtiarian (Noise Control Eng. Inc., 799 Middlesex Trnpk., Billerica, MA 01821, mikeb@noise-control.com)

The Commonwealth of Massachusetts Department of Environmental Protection (MADEP) noise regulation has two parts. The first part involves overall A-weighted noise and requires that no source of sound be greater than 10 dB above the background noise. A second part states that no pure tones are allowed. A pure tone condition is defined by the MADEP as any octave band that is greater than the adjacent bands by 3 dB. The author was involved in community noise investigation that showed the deficiency of the pure tone requirement. A suburban community complained of bothersome noise from an industrial abutter. Noise measurements were taken by other consultants which did not register as a pure tone. The author was hired by the community group to conduct measurements on their behalf. Similar octave band measurements were taken with similar results. However, measurements with finer one-third octave band showed significant tonal activity. When compared to commercial standards for pure tones the tonal criterion was met. Further examination of narrowband data showed why the original octave band measurements were not registering pure tone conditions. The author will present his suggestion for changes to the MADEP regulation and welcomes input from others dealing with similar tonal requirements.

11:20

3aNS8. Uncertainty in field and laboratory acoustical testing: A challenge for the acoustical industry. John LoVerde and Wayland Dong (Veneklasen Assoc., 1711 16th St, Santa Monica, CA 90404, jloverde@veneklasen.com)

The statistical uncertainty in acoustical testing has been insufficiently studied in the acoustical community. There are a limited number of studies quantifying measurement uncertainties, especially in the field, but even where uncertainties have been documented, they are largely ignored in practice. As was documented in a previous case [LoVerde and Dong, J. Acoust. Soc. Am. **124**, 2441 (2008)], it is common practice to assume that the test results have low uncertainties (even if published uncertainties are large) and that variations in the results are due to variations in materials, errors in construction, etc. This can be particularly important in noise litigation, where acoustical ratings that are lower than expected are often automatically assumed to be due to construction defect, even though they may be within the expected range. Even without errors in construction, the uncertainties in the acoustical test procedure may be such that some assemblies will meet the relevant statutory requirements and other, nominally identical assemblies will fail. Recent experience and insight will be presented regarding the definition of a construction defect in acoustical assemblies, the overlap of responsibilities between contractors and designers, and the interpretation of building code requirements.

11:35

3aNS9. Designing petrochemical plants to permit retrofitting of any additional controls needed to meet community noise limits. Frank H. Brittain (Bechtel Corp., 2255 Peavine Valley Rd., Reno, NV 89523)

Designing petrochemical, power, or industrial plants to meet community noise limits can be expensive. To meet stringent limits, incremental costs often exceed one million dollars per decibel. There is considerable uncertainty, including: overly conservative or unrepresentative vendor noise data, limitations of ray-tracing software, questionable accuracy beyond 1000 m, lack of TL and absorption data below 125 Hz, unreliable IL data for pipe lagging at all frequencies, unexpected operating conditions, and vendors not meeting their equipment noise limits. Atmospheric effects can cause variations of A-weighted community noise levels of 25 dB at 100 m from a refinery, which can make meeting a not-to-exceed noise limit difficult and risky. Further, lack of experience with noise control of any participant (noise control engineer, project, owner, regulators, or vendors) can substantially increase uncertainty. Including sufficient noise controls to cover these uncertainties will be expensive, often overly conservative, and often unnecessarily expensive. One way to substantially lower costs and risks is designing the plant to permit delaying some but not all controls until start-up—if needed. This paper describes the planning needed to permit a partial reliance on retrofit controls, what type of controls can be delayed until start-up, and space allocation. Examples are included.

Physical Acoustics: Infrasound and Outdoor Sound Propagation

D. Keith Wilson, Chair
U.S. Army Cold Regions Research Lab., Engineering Research and Development Ctr., Hanover, NH 03755-1290

Contributed Papers

8:30

3aPA1. On tropospheric ducting in infrasound. Roger Waxler and Philip Blom (NCPA, Univ. of Mississippi, University, MS 38677, rwax@olemiss.edu)

Infrasound can propagate to ranges of many hundreds of km. Signals received on the ground at ranges of 200 km or more have propagated high into the atmosphere through the stratosphere and thermosphere. At shorter ranges, the propagation is dominated by structure in the lower atmosphere such as the jet stream and the atmospheric boundary layer. Theoretical results on the influence of the lower atmosphere on infrasound propagation will be presented.

8:45

3aPA2. On the fast arrivals seen in impulse propagation in the nocturnal boundary layer. Philip Blom and Roger Waxler (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

On clear dry nights over flat land, an acoustic duct forms in the atmospheric boundary layer. The duct is formed by a temperature inversion in the lowest few hundred m of the atmosphere and by the stiff wind, known as the nocturnal jet, which commonly develops above the temperature inversion. An impulsive signal undergoes strong dispersion as it propagates in the nocturnal duct and is received at long ranges from the source as an extended wave train consisting of a series of distinct arrivals followed finally by a low frequency tail. The first arrival is of interest here. Through its interaction with the nocturnal jet, the first arrival is often anomalously fast. Accompanying the increased propagation speed is a marked decrease in amplitude. It will be shown that an explanation for this behavior is given by geometrical acoustics.

9:00

3aPA3. Impulsive sound propagation in coastal regions. Xiao Di, Carrick Talmadge, Roger Waxler, Kenneth E. Gilbert (Natl. Ctr. for Phys. Acoust., Univ. of Mississippi, University, MS 38677), and David A. Conner (U.S. Army Aviation and Missile Command)

Influenced by the coastal temperature profile and wind profile, the resulting sound speed profiles in coastal regions have certain unique features, such as double inversion zones. As a result, long range sound propagation presents certain properties due to these features. An impulsive sound propagation experiment had been conducted in the morning hours of the summer of 2007 in the coastal Florida area. The test field was 7 km long. Three propane cannons were used during the experiment, located at each end of the test field and in the middle of the test field. Both upwind and downwind propagation data were collected and will be presented. The data showed that coastal region meteorology has a dominant effect on long range sound propagation. Simulated sound propagation results using measured meteorological data are compared with measured impulsive sound propagation data.

9:15

3aPA4. Investigation of dominant sources of pressure fluctuations and infrasonic wind noise in microphones. John Paul Abbott, Richard Raspet, Jeremy Webster, and Jiao Yu (Natl. Ctr. for Physical Acoust., Dept. of Phys. and Astronomy, Univ. of Mississippi, University, MS 38677)

Investigation of the time dependent relationship between the vertical wind velocity fluctuations and the pressure sensed on the ground as measured in an open field is done to determine if the turbulence-shear term of the Poisson equation is the dominant source of pressure fluctuations and infrasonic wind noise present in microphones, or some other source. The wind velocity was measured using a three-axis ultrasonic anemometer and six one-dimensional ultrasonic anemometers. The pressure was measured simultaneously using two half-inch free-field pressure microphones, one placed flush with the ground, the other at a height of 1 m above the first. The anemometers were also situated above and adjacent to the microphones. The three axis anemometer was set at a height of 1 m, and the six, one-dimensional anemometers, as a vertical array from a height of 0.1–2 m above the ground. As this is still an ongoing investigation, only a description of the experiment and the current findings are presented and discussed.

9:30

3aPA5. New models for wind noise measured in a flat surface under turbulent flow. Jiao Yu, Richard Raspet, Jeremy Webster, and JohnPaul Abbott (Natl. Ctr. for Physical Acoust. and Dept. of Phys. and Astron., Univ. of Mississippi, University, MS 38677, jyu2@olemiss.edu)

We have previously developed models for predicting the power spectral density of the wind noise pressure measured in a flat plate outdoors from the measured power spectral density of the turbulence and the measured wind velocity profile above the plate [Yu *et al.*, Proceedings of NCAD 2008, NoiseCon2008-ASME NCAD]. Recently we have corrected an error in the model for the logarithmic profile wind velocity gradient results and have developed an improved integration method. Also, we have developed a prediction for arbitrary wind velocity profiles using the previous single exponential model. Typical results comparing our predictions with our measurements are presented and analyzed. A simple algebraic fit to the prediction for the logarithmic profile fit form is also provided for use by others. [Research supported by the U.S. Army TACOM-ARDEC at Picatinny Arsenal, NJ.]

9:45

3aPA6. Calculations of wind noise underneath a foam covering at the ground surface. Jiao Yu, Richard Raspet, Jeremy Webster, and JohnPaul Abbott (Natl. Ctr. for Physical Acoust. and Dept. of Phys. and Astron., Univ. of Mississippi, University, MS 38677, jyu2@olemiss.edu)

A foam windscreen reduces the wind noise generated at a microphone. Similarly, a thin foam covering above a surface mounted microphone also lowers the wind noise level effectively. Recent research has focused on developing a physical model for calculating the wind noise pressure fluctuation spectrum measured by a foam covered microphone under a turbulent flow based on our current model for flush mounted bare microphones. The foam surface not only reduces the wind noise at the microphone, but also prevents direct exposure of the microphone to the flow, which reduces the measurement's sensitivity to details of the meteorological conditions. In this talk, the calculation model will be introduced, and the comparisons between our predictions with the model and our measurements down to low wave number will be presented and discussed. [Research supported by the U.S. Army TACOM-ARDEC at Picatinny Arsenal, NJ.]

10:00—10:15 Break

10:15

3aPA7. Study of the impact of input uncertainties on acoustic propagation. Bruce Ikelheimer, Micah Downing, and Michael James (Blue Ridge Res. and Consultants, 13 1/2 W. Walnut St., Asheville, NC 28801)

A modular system of acoustical tools has been developed that integrates the physical factors controlling the propagation of acoustical signals. First and foremost, this system provides a prediction of the noise from a source to a receiver location. This ray-tracing prediction takes into account the local terrain, changes in ground impedance, turbulence, and thermal and wind gradients. This propagation prediction is combined with a noise source that can handle fully three-dimensional, spectral source descriptions. The model uses a six-dimensional definition of the source location and orientation to select the radiation angle from the source to the receiver. Levels of audibility of the received signal are then calculated based on the received noise levels, the local ambient noise levels, and the expected listener acuity. Each input to the model has uncertainties with the potential to generate errors that cascade through the system. Differing atmospheric, terrain, and ground impedance conditions have been tested in our model both individually and in combinations to see how they interact. The goal is to have an understanding of the confidence level of audibility provided a known level of uncertainty on the input data.

10:30

3aPA8. Acoustic temperature measurement in a full-scale rocket noise field. Jarom H. Giraud, Kent L. Gee, John E. Ellsworth, and Derek C. Thomas (Dept. of Phys. and Astronomy, Brigham Young Univ., N283 ESC Provo, UT 84602)

Acoustic pressure measurements in high-amplitude sound fields are common, but acoustic temperature measurements are relatively rare. This is primarily because thermometers exhibit thermal lag and, consequently, a limited frequency range. In this study, a 1 μ diam platinum wire resistance thermometer was used to measure temperature fluctuations generated by propagating noise produced by a horizontally fired, static GEM-60 solid rocket motor. The data are compared with those calculated from the pressure data of a nearby 3.18 mm condenser microphone by assuming an ideal adiabatic process.

10:45

3aPA9. Rise times of low-energy, free-space propagating acoustic shocks. Thomas B. Gabrielson, Timothy M. Marston (Graduate Program in Acoust., Penn State Univ., PO Box 30, State College, PA 16804), and Mark S. Wochner (The Univ. of Texas at Austin, Austin, TX 78713-8029)

Characteristics of the "ideal" shock, a one-dimensional step change in pressure, are reasonably well established; however, the freely propagating shock with finite duration is challenging to model and measure. These challenges are reflected in an extensive body of literature over several decades. In this paper we present a method for producing free-space propagating shocks, measurements of rise time with minimal contamination by turbulence, and model results that account for spreading, absorption (including molecular relaxation), and nonlinearity. The shocks are produced using an acoustic pipe filter to condition the irregular pressure release of either balloon pops or starter-pistol shots. The shocks range in peak pressure from 10 to 1000 Pa and in rise time from 10 to 0.5 μs. Rise-time measurements are made using a custom piezoelectric polymer wideband microphone with a measurement range that overlaps with that of a diffraction-corrected 1/8-inch measurement microphone. The exponential-decay time constant beyond the pressure peak is typically less than 100 μs, which may be too rapid to permit development of characteristics associated with relaxation mechanisms: rise times over the entire range measured here are well predicted by accounting for classical and rotational absorption only.

11:00

3aPA10. Three-dimensional numerical simulation of sonic boom diffraction around buildings using a dispersion-relation-preserving scheme. Sang I. Cho and Victor W. Sparrow (Grad. Program in Acoust., The Penn State Univ., 201 Appl. Sci. Bldg., Univ. Park, PA 16802)

A finite difference time domain approach is used to model the temporally and spatially dependent pressure loading on a rigid structure due to an incident low-amplitude N-wave sonic boom. Analytically, one expects strong diffraction due to building corners and pressure doubling near rigid walls. The three-dimensional linear wave equation is sufficient to model the interaction between the structure and the low-amplitude sonic boom at the ground level. Applying a fourth-order dispersion-relation-preserving scheme and a four-level explicit time marching scheme, an excellent dispersion characteristic is achieved without sacrificing computational efficiency of the algorithm. NASA flight testing at Edwards, CA during the summer of 2006 is numerically simulated by matching the geometries of the simulated structure to the actual residential house used for the flight test and using the waveform of a recorded boom as the incoming wave for the simulation. A direct comparison to the experimental data allows the quantitative validation of the simulation results. The feasibility of using this model for calculation of the pressure loads on other structures can be determined based on the accuracy of this numerical solution. [Work supported by NASA. The authors appreciate NASA making the 2006 and 2007 flight data available for this work.]

Session 3aPP

Psychological and Physiological Acoustics: Impacts of Hearing Impairment

Peggy B. Nelson, Chair
Dept. of Speech, Language and Hearing Science, Univ. of Minnesota, Minneapolis, MN 55455

Contributed Papers

8:45

3aPP1. A personal perspective on unilateral hearing loss. Brian D. Dushaw (Appl. Phys. Lab., Univ. of Washington, 1013 N.E. 40th St., Seattle, WA 98105, dushaw@apl.washington.edu)

Although I have been unilaterally deaf since birth, only later in life have I realized the extent of this handicap and how I can best manage it. The effects of this hearing loss are complicated, being an interplay of physics, psychology, social interaction, etc. Because people are able to adapt, the extent of this "unseen" handicap is underappreciated. Responses by the public to an informative website (http://909ers.apl.washington.edu/~dushaw/SSD) suggest that this handicap has a universal nature. Obvious effects are the inabilities to locate sound or to bilaterally process sound signals. Less obvious effects are a heightened sensitivity to noise: as masking to a desired signal, as a fatigue factor, as an impediment to mental concentration. The difficulties encountered when talking over the telephone to someone who is speaking in a noisy environment may give one an appreciation of the effects. Even less obvious effects are the long-term social implications of the handicap: the tendency to ignore those on one's deaf side, the inability to function "normally" at noisy events such as parties, ASA receptions, etc., or a tendency to irritability in noisy environments. In this unscientific talk, I will attempt to highlight issues that may be deserving of additional study.

9:00

3aPP2. Masking period patterns of exponentially ramped and damped noises in hearing-impaired listeners. Jennifer Lentz and Yi Shen (Dept. of Speech and Hearing Sci., Indiana Univ., Bloomington, IN)

Noises that are modulated with either an exponentially rising (ramped), repeating modulator or a falling (damped), repeating modulator may evoke strong perceptual differences. To explore a possible cochlear contribution to these perceptual differences, masking period patterns (MPPs) of ramped and damped noises were measured for normal-hearing listeners at different stimulus levels and for hearing-impaired listeners. By time-reversing the ramped MPP, comparisons can be made between thresholds for which the masker power was the same between ramped and damped noises. Previous results showed that for normal-hearing listeners, the MPP of a ramped noise is considerably shallower than the MPP of a damped noise. The present results indicated that the differences between the damped and the time-reversed ramped MPPs were the largest at moderate stimulus levels and the smallest at low and high stimulus levels. Listeners with hearing loss exhibited no difference in the damped versus time-reversed ramped MPPs. Results will be discussed in terms of contributions of the cochlear nonlinearity and central auditory processes.

9:15

3aPP3. Modulation detection interference in listeners with cochlear hearing loss: Effect of modulation depth and onset delay. Jungmee Lee and Soonha Yook (Dept. of Speech, Lang. and Hearing Sci., Univ. of Arizona, 1131 E. 2nd St., Tucson, AZ 85721)

Modulation detection interference (MDI) was measured for listeners with normal hearing (NH) and cochlear hearing loss (HI). The signal was 1 kHz, and the interferer was 2 kHz. The stimuli level was 50 or 22 dB SL. The interferer was modulated with 8 Hz at various modulation depths (25, 50, 75, or 100%). The onset of signal was delayed by 0, 125, 250, 375, 500 or 625 ms relative to onset of the interferer. For NH subjects, MDI increased systematically with increasing modulation depth of the interferer. MDI almost disappeared with 375 or 500 ms onset delay except a condition with the interferer of 25% modulation depth where there was no MDI at all across different onset delay conditions. In contrast, for HI subjects, there was quite an amount of MDI even with the interferer of 25% modulation depth, and MDI was greater than NH for all modulation depths at 0 and 125 ms onset delays, suggesting that the perceived modulation depth of the interferer might be exaggerated for HI than for NH.

9:30

3aPP4. Frequency modulation detection, frequency selectivity, and speech recognition in noise by hearing-impaired listeners. Van Summers, Matthew Makashay, Joshua Bernstein (Army Audiol. & Speech Ctr., Walter Reed Army Medical Ctr., 6900 Georgia Ave., NW, Washington, DC 20307), Sarah Melamed, and Marjorie Leek (VA Medical Ctr., Portland, OR 97201)

Reduced ability to make use of temporal fine structure (TFS) information may contribute to deficits among hearing impaired (HI) listeners for speech recognition in competing background sounds. The broad tuning typically observed in HI listeners will produce more complex patterns of TFS as input to the auditory nerve, and these patterns may be more difficult to encode and/or interpret by higher auditory centers. In the current study, we tested HI listeners on a frequency-modulation (FM) detection task thought to require the use of TFS cues, on tone detection in notched-noise to assess frequency selectivity, and on speech recognition in continuous and modulated background sounds. Performance on the psychoacoustic tasks was tested at four frequencies (500, 1000, 2000, and 4000 Hz) at levels between 60 and 85 dB SPL (approximating the range of third-octave band levels in the speech stimuli). HI listeners with similar audiometric thresholds showed clear differences in frequency tuning, FM detection thresholds, and speech performance. Relationships between the psychoacoustic measures in the four frequency regions and between these measures and speech performance will be discussed.

9:45

3aPP5. Relative contributions of spectral and temporal cues for speech recognition in patients with sensorineural hearing loss. Li Xu, Ning Zhou, Katherine Rife, and Rebecca Brashears (School of Hearing, Speech and Lang. Sci., Ohio Univ., Athens, OH 45701)

The present study was designed to examine speech recognition in patients with sensorineural hearing loss (SNHL) when both temporal and spectral information in the speech signals were co-varied. Four subjects with SNHL were recruited to participate in consonant and vowel recognition tests that used speech stimuli processed through a noise-excited vocoder. The number of channels was varied between 2 and 32, which defined spectral information. The lowpass cutoff frequency of the temporal envelope extractor was varied from 1 to 512 Hz, which defined temporal information. Results indicate tremendously individual differences among the subjects with SNHL. For consonant recognition, patterns of relative contributions of spectral and temporal information were similar to those in normal-hearing subjects. The utility of temporal envelope information appeared to be normal in the hearing-impaired listeners. For vowel recognition, the performance plateau was achieved with numbers of channels as high as 16–24, much higher than expected, given that the frequency selectivity in patients with SNHL might be compromised. In order to understand how hearing-

impaired listeners utilize spectral and temporal cues for speech recognition, future studies will be necessary to elucidate the relationship between frequency selectivity as well as central processing capability and speech recognition performance using vocoded signals.

10:00—10:30 Break

10:30

3aPP6. Discrimination of formant-like glides in gated noise: Effect of sensation level. Peggy Nelson, Yingjiu Nie (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr. SE, Minneapolis, MN 55455, peggynelson@umn.edu), Magdalena Wojtczak, and Gordon Stecklein (Univ. of Minnesota, Minneapolis, MN 55455)

Listeners with sensorineural hearing loss (SNHL) do not experience masking release for speech in fluctuating noise, as normal-hearing listeners do. One hypothesis suggests dip listening may be difficult because frequency glides, or speech formant transitions, may be difficult to discriminate at low sensation levels when in the presence of fluctuating noise. Normal-hearing listeners were tested for their ability to discriminate 100-ms frequency glides with center frequencies of 800 and 2500 Hz. They were tested in quiet and in the presence of 500-ms of 8-Hz square-wave gated broadband noise at a signal-to-noise ratio of −10 dB. Listeners were tested at low (10–15 dB SL) and moderate (30–40 dB SL) signal levels. Preliminary results suggest that glide discrimination thresholds (measured as % change) are similar for low- and moderate-level stimuli in quiet; glide thresholds are poorer in gated noise than in quiet; and glide thresholds are poorest when low-level stimuli were presented in gated noise. These results suggest that when formants or glides are presented at low levels and in gated noise, discrimination abilities may be reduced. Implications for understanding masking release for speech by listeners with hearing loss will be discussed. [Work supported by NIH 5R01DC008306.]

10:45

3aPP7. Comodulation masking release and speech perception: Implications for dip-listening by cochlear implant patients. Antje Ihlefeld (MRC Cognition and Brain Sci. Unit, 15 Chaucer Rd, Cambridge CB2 7EF, England, antje1@gmail.com), Barbara G. Shinn-Cunningham (Boston Univ., Boston, MA 02215), and Robert P. Carlyon (MRC Cognition and Brain Sci. Unit, Cambridge CB2 7EF, England)

Compared to normal-hearing (NH) listeners, cochlear implant (CI) listeners struggle to identify speech when a source of noise interferes and do poorly when trying to listen in the dips of a modulated masker. In NH listeners, masker energy outside the spectral region of a target tone can improve target detection, a phenomenon referred to as comodulation masking release (CMR). Here we examined whether a comodulated flanking noise improves speech identification in a modulated noise masker, both for NH listeners identifying vocoded speech and for CI listeners. In experiment 1, NH listeners identified noise-vocoded speech (taken from a closed-set speech corpus) in a background of speech-shaped noise with or without a flanking narrow band of noise outside the spectral region of the target. The masker and flanker were either both 16-Hz square-wave modulated or were unmodulated. Performance was better in modulated than in unmodulated noise and, importantly, this difference was greatest when the comodulated flanker was present, consistent with the idea that CMR can introduce segregation cues between target and masker that help to listen in the dips of the masker. Experiment 2 tested CI listeners with the same experimental paradigm.

11:00

3aPP8. Masking release for speech in listeners with real and simulated hearing impairment. Joseph G. Desloge, Charlotte M. Reed, Louis D. Braida, Zachary D. Perez, and Lorraine A. Delhorne (Res. Lab. of Electron.s, Massachusetts Inst. of Technol., 77 Massachusetts Ave., Cambridge, MA 02139, jdesloge@mit.edu)

The current study examined the effects of audibility and age on the release of masking for speech in interrupted versus steady-state noise in listeners with real and simulated hearing loss. The absolute thresholds of each of ten hearing-impaired listeners were simulated in normal-hearing listeners through a combination of spectrally shaped masking noise and multiband expansion for the octave bands with center frequencies from 0.25–8 kHz. Each individual hearing loss was simulated in two groups of three normal-hearing listeners (one age-matched group and one non-age-matched group). The speech-to-noise ratio (S/B) for 50%-correct identification of HINT sentences was measured in backgrounds of steady-state noise and temporally modulated (10-Hz square-wave) noise at two overall levels for unprocessed speech and for speech that was amplified with the NAL-PR prescription. Results indicate that the magnitude of the release from masking (the difference in S/B obtained in steady-state versus interrupted noise) observed in individual hearing-impaired listeners was generally well produced in both groups of simulated-loss listeners. Thus, release of masking appears to be determined primarily by audibility regardless of age. Predictions of masking release derived from the Speech Intelligibility Index (SII; ANSI S3.5-1997) will be compared to the observed values. [Work supported by NIH-NIDCD R01 DC00117.]

11:15

3aPP9. Spectral modulation detection training in older adults with hearing loss. Andrew T. Sabin, Cynthia A. Clark (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr. Evanston, IL 60201, a-sabin@northwestern.edu), David A. Eddins (Univ. of Rochester, Rochester, NY 14618), Sumitrajit Dhar, and Beverly A. Wright (Northwestern Univ., Evanston, IL 60201)

Individuals with hearing loss are poorer than normal-hearing listeners at detecting patterns of peaks and valleys of sound level spread across audio frequency (spectral modulation detection)—an important skill for speech and music perception. In this preliminary report we examined whether listeners with hearing loss could improve on spectral modulation detection with practice. We trained older adults with sensorineural hearing loss ($n=7$) ~1 hr/day for 7 days to distinguish a 400–3200 Hz noiseband with a flat-spectrum from one with a 2 cyc/oct sinusoidal spectral modulation. Modulation depth was varied adaptively to determine the detection threshold. Their mean thresholds improved significantly from 18.9 to 12.8 dB. These listeners also improved at both a lower and a higher untrained spectral modulation frequency (1 and 4 cyc/oct), but showed no change on a measure of frequency selectivity. Interestingly, a separate group of younger normal-hearing adults who received the same training ($n=7$) did not improve on the trained (6.9 to 6.6 dB) or untrained conditions. Normal-hearing listeners had lower pre-training thresholds than individuals with hearing loss, and across all listeners the magnitude of individual improvement was correlated to pre-training threshold ($r=0.92$). Listener age and/or hearing loss could have contributed to these across-population differences.

11:30

3aPP10. Multidimensional perceptual scaling of musical timbre by hearing-impaired listeners. Kelly Fitz, Matt Burk, and Martin McKinney (Starkey Labs, 6700 Washington Ave., S., Eden Prairie, MN 55344, kelly_fitz@starkey.com)

We examine the impact of hearing loss and hearing aid processing on the perception of musical timbre. Our objective is to identify significant timbre cues for hearing-impaired listeners, and to assess the impact of hearing aid signal processing on timbre perception. Hearing aids perform dynamic, level-dependent spectrum shaping that may influence listeners' perception of musical instrument timbres and their ability to discriminate among them. Grey ["Multidimensional perceptual scaling of musical timbres," J. Acoust. Soc. Am. **61**, 1270 (1977)] showed that sustaining instrument tones equalized for level, loudness, and duration are distinguished primarily along three perceptual dimensions that are strongly correlated with the acoustical dimensions of: (1) spectral energy distribution, (2) spectral fluctuation, and (3) precedent high-frequency, low-amplitude energy. Following the work of Grey, we ask listeners having mild to moderately severe sensorineural hearing loss to rate pairs of synthetic musical instrument tones according to dissimilarity in aided and unaided conditions. We analyze the dissimilarity judgments to identify acoustical correlates for the significant dimensions of timbre discrimination. This analysis helps us to objectively estimate the impact of hearing aid signal processing on the ability of hearing-impaired lis-

teners to discriminate among musical instruments, an important component of musical listening.

11:45

3aPP11. The perceptual tone-noise ratio of iterated rippled noise in listeners with hearing loss. Marjorie R. Leek, Sarah Melamed, Michelle R. Molis, and Frederick J. Gallun (Natl. Ctr. for Rehab. Aud. Res., Portland VA Medical Ctr., 3710 SW US Veterans Hospital Rd., Portland, OR 97239)

Previous work has demonstrated that iterated rippled noise (IRN) produces a weaker pitch in hearing-impaired (HI) listeners than in normal-hearing (NH) subjects (e.g., Leek and Summers, 2001). In this study, the hypothesis was tested that the weaker pitch is a result of an increased perceptual noisiness of IRN for HI subjects. The tone-noise ratio (T/N) was developed by Patterson *et al.* (1996) to describe the relationship between the strength of the tone component and the strength of the noise component for a given IRN. The T/N was measured using an adaptive procedure to find the tone-plus-noise level that matched each IRN stimulus. Four NH and 4 HI subjects took part in the study. The stimuli were IRNs with delays ranging from 4 to 16 ms and with one to eight iterations. There was a significant effect of delay and of iteration number, with longer delays and more iterations producing greater T/N. There were no significant differences between subject groups. These findings suggest that the weaker complex pitch observed in listeners with hearing loss is not due to an abnormally noisy IRN percept but must be attributed to other impaired processing mechanisms. 3aSA1. Scan-based near-field acoustical holography on partially correlated fields: Theory and numerical experiments. Michael D. Gardner, Kent L. Gee, Alan T. Wall, Scott D. Sommerfeldt (Dept. of Phys. and Astronomy, Brigham Young Univ., N283 ESC, Provo, UT 84602), Daniel Manwill, and Jonathan D. Blotter (Brigham Young Univ., Provo, UT 84602)

Conventional near-field acoustical holography (NAH) requires a coherent field. For a coherent source, a scan-based approach can be used with one reference microphone to stitch the phase. For a noncoherent field, scan-based NAH can be performed if the virtual coherence technique is used. This technique uses multiple reference microphones to decompose the partial field into mutually uncorrelated partial fields, which are then processed by some NAH method. In particular, the statistically optimized near-field acoustical holography (SONAH) method is used with modified Tikhonov regularization. Numerical experiments are performed on a series of point sources with source strengths chosen to mimic the source characteristics of high-powered jets. The experiments are designed to aid in determining the proper number and location of reference microphones for doing NAH work on high-powered jet noise. [Work supported by Blue Ridge Research and Consulting and the Air Force Research Laboratory.]

8:45

3aSA2. Scan-based near-field acoustical holography on partially correlated fields: Laboratory experiments. Alan T. W, Michael D. Gardner, Kent L. Gee, Scott D. Sommerfeldt (Dept. of Phys. and Astron., Brigham Young Univ., N283 ESC, Provo, UT 84602, alantwall@gmail.com), Daniel Manwill, and Jonathan D. Blotter (Brigham Young Univ., Provo, UT 84602)

Forms of near-field acoustical holography (NAH) can be applied to source reconstructions of arbitrarily correlated extended sources, such as jet exhaust plumes. Prior to implementing NAH to reconstruct the jet noise source region of a military jet aircraft, laboratory experiments are being performed. These experiments utilize statistically optimized NAH (SONAH), coupled with the virtual coherence method, to reconstruct the radiation from correlated, partially correlated, and uncorrelated loudspeakers. Results from these experiments will be shown. Reconstructions of this type require the use of multiple reference microphones. However, little is known about how many should be used or where they should be placed. Successful reference placement strategies are being explored and commentary on these results will also be given. [Work supported by Blue Ridge Research and Consulting and the Air Force Research Laboratory.]

3aSA3. Near-field acoustic holography in conical coordinates. Tracianne B. Neilsen, Kent Gee, and Michael Gardner (Dept. of Phys., Brigham Young Univ., Provo, UT 84602, tbn@byu,edu)

Near-field acoustical holography (NAH) techniques can be optimized if the method capitalizes on the geometry of the noise source under investigation. Helmholtz-equation least squares method (HELS) uses the solutions of Helmholtz equation in spherical coordinates as basis functions for the pressure field. HELS is an efficient NAH technique if the source and the measurement surfaces are spherical in nature. For nonspherical cases, such as radiation from a plate or bar, it takes a large number of functions to represent the field. In these cases, there is also a question about where to place the origin of the wave functions. In search of a HELS-type method that could be applied to nonspherical sources, a study into the features of conical coordinates has been conducted. Because the Helmholtz equation is separable in conical coordinates, the solutions can be used, in a manner similar to HELS, as basis functions to represent the pressure field. For conical coordinates, the basis functions are spherical Hankel functions and Lame functions. This HELS-type formulation in conical coordinates could be a natural choice for NAH on conical sources and may be appropriate for NAH on jet noise. [Work supported by Blue Ridge Research and Consulting and Air Force Research Laboratory.]

9:15

3aSA4. Determination of ultrasonic vibration modes of a graded solid cylinder using a modified wave-expansion technique. Betsabe Manzanares-Martinez (Div. de Ciencias e Ingeniería, Unidad Regional Sur de la Universidad de Sonora, Boulevard Lzaro Crdenas 100, Navojoa, Sonora 85880, Mexico, betsabe@manzanares.uson.mx), Jin-Yeon Kim (Georgia Inst. of Technol., Atlanta, GA 30322-0355), and Arturo Baltazar (CINVESTAV-Saltillo, Ramos Arizpe, Coahuila 25900, Mexico)

Research on wave propagation in cylinders—hollow, solid, or graded—has been driven by its potential use in the inspection of long-span

engineering structures. Its practical application largely depends on the understanding of modal vibration inside the structure. Typically, the plane wave approach is used to model phase velocity, group velocity and dispersion curves in periodic systems. This proves cumbersome when used to model finite periodic structures, semifinite plates, or concentric cylinders. Here, a simpler approach to determine the vibration modes and dispersion curves of a solid concentric cylinder using a modified wave-expansion approach, used mostly in phononic crystals research, is proposed. The advantage of this technique is the possible application on a wide variety of cylindrical geometries and graded structures with various transverse sections. The results of the proposed technique are compared with those obtained by the resonance scattering theory for the simple case of a solid cylinder with a single core having different mechanical properties. [Work partially sponsored by SEP-CONACYT through project # 58951.

9:30

3aSA5. Three component time reversal imaging using nonlinear elasticity. Timothy J. Ulrich, II, Pierre-Yves Le Bas, Robert A. Guyer (Los Alamos Natl. Lab., EES-17, MS D443, Los Alamos, NM 87545, tju@lanl.gov), Brian E. Anderson (Brigham Young Univ., Provo, UT), Michele Griffa (EMPA, Duebendorf, Switzerland), and Koen Van Den Abeele (Katholieke Univ. Leuven Campus Kortijk, Kortrijk, Belgium)

The time reversed elastic nonlinearity diagnostic (TREND) has been shown to have the ability to image near surface nonlinear scatterers (e.g., cracks and disbonds) using the normal (out of plane) component of motion. This technique has been advanced with the addition of three-component vector wave field detection using laser vibrometry. This advancement provides the ability of TREND to detect and image features of various orientations, increasing its capability and decreasing the likelihood of overlooking features due to the inability to excite them. Furthermore, the ability to selectively focus each component of motion provides the means to investigate the mechanism of the nonlinear wave generation at the nonlinear scattering sites. Experimental data are presented from samples containing known defects (location and orientation) confirming the sensitivity of three-component time reversal imaging in both linear and nonlinear ultrasonics to feature orientation.

3aSA6. Parameter study for Structural Health Monitoring based on ambient noise cross-correlation. Najib Abou Leyla, Emmanuel Moulin, Jamal Assaad, Sebastien Grondel, and Christophe Delebarre (UVHC, IEMN-DOAE, Le Mont Houy, 59313 Valenciennes, France)

The possibility of performing Structural Health Monitoring in aeronautic structures using ambient noise cross-correlation techniques has been investigated in previous works. The applicability of such methods has been validated by checking the reproducibility and the potential in terms of damage detection. In this paper, a more detailed description of the acoustic phenomena involved is given. The influence of the different parameters (source characteristics, sensors and damage positions, etc.) on the cross-correlation function has been studied. A theoretic study is presented and used to develop a simple simulation tool based on multipath reflections of ballistic waves. The simulated results have been successfully compared to finite element results in simple cases. This tool is then exploited to characterize and quantify the influence of the significant parameters. Finally, some optimization solutions of the technique are proposed, and experimentally validated.

10:15

3aSA7. Detection of structural faults in pipelines with time reversal. Nicholas A. O'Donoughue, José M. F. Moura (Dept. of Elect. & Comput. Eng., Carnegie Mellon Univ., 5000 Forbes Ave., Pittsburgh, PA 15217, nodonoug,moura@ece.cmu.edu), and Yuanwei Jin (Univ. of Maryland Eastern Shore, Princess Anne, MD 21853)

The volatile nature of natural gas makes it extremely important to ensure that transport and distribution pipelines remain free from defects, as leakage can result in explosions. Current methods for testing buried pipelines rely on periodic excavation of a section of pipe and attachment of large acoustic or magnetorestrictive sensors. These systems, while reliable, suffer from a high cost-per-test ratio. To reduce the power requirements, we consider ultrasound embedded devices that could monitor the pipelines continuously. The problem with ultrasound is that, with buried pipes, the propagation is highly dispersive. We propose to use time reversal (TR), a signal processing technique, to refocus the signals and use, to our advantage, the dispersive nature of the environment. This paper will focus on the modes generated by various acoustic probing signals and the echoes received with and without TR. We argue that TR will be most beneficial when there are several dispersive modes present, a scenario avoided in conventional techniques. We will present simulation results for the detection of faults in a pipeline using PZFlex.

10:30

3aSA8. Acoustic detection of bolt detorquing in structures. Joe Guarino (Dept. of Mech. and Biomedical Eng., Boise State Univ., Boise, ID 83725-2075, jguarino@boisestate.edu) and Robert Hamilton (Boise State Univ., Boise, ID 83725-2075)

Recent interest in structural health of bridges and large buildings has lent new urgency to the development and enhancement of theories and methods in the field of nondestructive testing. We demonstrate a simple technique for acquiring data from an impact test using a basic electronic stethoscope. The continuous wavelet transform (CWT) is used to process and display the transient responses of a bolted joint in a structure with bolts installed in a properly tightened manner and bolts incorrectly installed. Results for tight and loose bolts are compared using the semblance analysis approach described by Cooper and Cowan ["Comparing time series using wavelet-based semblance analysis," Computers & Geosciences 34, 95–102 (2008)]. We enhance the interpretation of results using speaker-driven audio output synthesized from CWT and semblance analysis.

10:45

3aSA9. Selective excitation of microcantilever array using ultrasound radiation force. Thomas M. Huber, Daniel C. Mellema, and Brad Abell (Dept. of Phys., Gustavus Adolphus College, 800 College Ave., St. Peter, MN 56082)

The symmetric and antisymmetric eigenstates of a coupled pair of 500 956 m length microcantilevers were excited using the ultrasound radiation force. The excitation was produced using the difference frequency between the two sidebands of a double sideband suppressed carrier AM (DSB-SC-AM) waveform centered on 500 kHz that was emitted by a pair of focused ultrasound transducers. A laser Doppler vibrometer measured the frequency response and deflection shapes of the cantilever pair. When the waveforms sent to the transducer resulted in radiation force from both transducers with the same phase, it excited the 10.00 kHz symmetric state of the cantilever array while suppressing the 10.17 kHz antisymmetric state. Similarly, when the radiation force from the two transducers was 180 degrees out of phase, it selectively excited the antisymmetric state while suppressing the symmetric state. This ability to selectively excite different vibrational eigenstates is a unique capability of this noncontact for modal excitation.

11:00

3aSA10. Limiting performance of active vibration compensation in free multi-degree-of-freedom mechanical systems. Vyacheslav Ryaboy (Newport Corp., 1791 Deere Ave., Irvine, CA 92606, vyacheslav.ryaboy @newport.com)

Examples of free (not supported) mechanical system requiring active vibration control range from space structures to vibration-isolated platforms for sensitive equipment. While active damping systems reducing resonance vibrations of the structure received significant attention and reached practical implementation, active vibration compensation, or cancellation of forced vibration, is still problematic in complex systems. In this work, active vibration compensation is considered in frame of limiting performance approach that aims at estimating the best results attainable in the whole class of linear multi-degree-of-freedom systems. Several design goals are considered, including absolute and relative displacements of various points of the system. The resulting estimates are valid for all possible sets of internal ac-

tive forces. The limiting performance is estimated in terms of frequency domain and work performed by active forces on system displacements, which is considered a measure of the control effort. These estimates are expressed as exact inequalities in explicit analytical form. Active force distributions emerging from limiting performance analyses can assist in finding rational system configurations and optimal controls. Minimum active work, expressed in terms of passive subsystem parameters, provide a criterion for optimization of a structure as a potential host for an active vibration control system.

11:15

3aSA11. Response of a simple system made complex by attaching subsystems—an analytic study. John J. McCoy (School of Eng., The Catholic Univ. of America, Washington, DC 20064)

A deceptively simple dynamical system comprised of a grounded mass to which are attached *N*, a large number, sprung masses has received much attention. The reported studies mostly involve physical experiments or numerical simulations. Given the large number of physical parameters needed to describe any single system, such a research agenda requires one to address an excessive number of experiment scenarios. Thus, the motivation for the analytical study reported. The focus of the study is the net force the attached subsystems cause to act on the base system. This force, while "internal" to the coupled system, is a response measure of primary importance since it accomplishes the work that determines the energy flow to and from the base system. As demonstrated, a further reason for the focus is an ability to construct an asymptotically valid, analytic expression for this response measure. Further demonstrated, using the constructed expression, is a resolution of a complex "process," that describing the energy flow to the system, by the action of an external forcing, and through the system, as a combination of simple "sub-processes." The resolution requires describing the complex process in a time/frequency phase space; the sub-processes are "local" in the phase space.

11:30

3aSA12. Wave vector method for estimating acoustic vector quantities. Derek C. Thomas and Kent L. Gee (Dept. of Phys. and Astronomy, Brigham Young Univ., N283 ESC, Provo, UT 84602)

Acoustic vector quantities such as particle velocity and intensity are usually estimated using the finite-difference technique. We present an alternate method, termed the wave vector method, for estimating vector quantities in acoustic fields in which the reactive intensity is small relative to the active intensity. This method utilizes the same equipment necessary for the finite-difference method, yet reduces sensitivity to sensor phase mismatch at low frequencies and eliminates bias error at high frequencies. The method is developed for arbitrary sensor configurations, and numerical results are presented for the special case of a regular tetrahedral configuration. [Work supported by NASA Stennis Space Center and STI Technologies.]

11:45

3aSA13. Impact of spherical probe scattering on estimation of acoustic vector quantities. Curtis P. Wiederhold (Dept. of Mech. Eng., Brigham Young Univ., 435 Crabtree Bldg., Provo, UT 84602, curtis.wiederhold@gmail.com), Kent L. Gee, Derek C. Thomas, Scott D. Sommerfeldt (Brigham Young Univ., Provo, UT 84602), and Jonathan D. Blotter (Brigham Young Univ., Provo, UT 84602)

Multimicrophone probes are often used to measure energy-based acoustical quantities. In some cases, these probes consist of microphones mounted on the surface of a sphere, which, due to the high level of symmetry, permits scattering effects to be better characterized. Scattering of a plane wave incident on a rigid sphere has been modeled to observe how particle velocity and intensity calculations are affected by the presence of the sphere. These effects have been investigated for the traditional "finite-difference" method and a recently developed "wave vector" estimation method. In the computer model, 3-D surface plots were made showing the calculated error as a function of angle of the incident plane wave and frequency. It is shown that using the wave vector method and purposefully orienting the probe in the planar sound field generally results in the most accurate measurements. [Work supported by NASA Stennis Space Center and STI Technologies.]

3aSC1. Modulation of birdsong by resonance filters in the suprasyringeal vocal tract. Roderick A. Suthers (Medical Sci. and Dept. Biology, Indiana Univ., 1001 E. Third St., Bloomington, IN 47405, suthers@indiana.edu)

The sound generated in the avian vocal organ, the syrinx, is modified by the filter properties of the upper vocal tract before it radiates from the beak as song. Previous investigators have shown that the properties of this vocal tract filter are affected by changes in beak gape, but the basis of this effect remains controversial. In the present study, x-ray cinematography of singing birds was used to investigate the filter properties of the suprasyringeal vocal tract. These experiments show that the dimensions of the oropharynx and esophagus are actively controlled during song by motor patterns involving muscles of the hyoid apparatus. These song-related motor patterns, together with movements of the tongue, which modulate the opening from the mouth into the beak, adjust in real time the volume and

dimensions of the oropharynx and cervical esophagus so that the primary acoustic resonance of the upper vocal tract supports and tracks the fundamental frequency that is being generated by the syrinx. In juvenile Northern Cardinals, these song-related movements of the upper vocal tract first appear during subsong, while the beak is closed, and precede the changes in beak gape that typically accompany adult song. [Work supported by NIH.]

8:35

3aSC2. Source-filter interactions in birds—Theory and experimental evidence. Gabriel Mindlin, Ezequiel Arneodo (Dept. of Phys., Univ. of Buenos Aires, gabo.mindlin@gmail.com), and Franz Goller (Univ. of Utah, Salt Lake City, UT, goller@biology.utah.edu)

The diverse acoustic behavior of birds presents a rich source of natural vocalizations, some of which most likely reflect source-filter interaction. However, very little experimental evidence exists for the specific role of such interactions in shaping acoustic behavior or the functional relevance of the resulting acoustic features. As an example of how theoretical approaches can help explain acoustic observations, we discuss coexisting limit cycles in relaxation oscillators subjected to delayed feedback. The dynamical solutions of a nonlinear relaxation oscillator subjected to a delayed feedback are analyzed, and the equations under study are designed to model some aspects of the source-tract interaction in birdsong production. By deriving a phase equation for the system and analyzing its solutions, we are able to unveil analytical relationships between the parameters that lead to a variety of solutions. In particular, we study the coexistence of periodic solutions for similar pitch and first formant frequencies. These dynamical situations allow us to interpret the frequency jumps present in some birdsong syllables as an effect of the interaction between the source and the tract.

9:05

3aSC3. The epilaryngeal tube and air sacs in mammals as acoustic couplers—A review. Tobias Riede (Dept. of Biology, Univ. of Utah, 257 S 1400 E, Salt Lake City, UT 84112, t.riede@utah.edu) and Isao Tokuda (Japan Adv. Inst. of Sci. and Technol., Ishikawa, Japan)

The intralaryngeal space between glottis and the cranial edge of the larynx is called the epilaryngeal tube (synonyms are vestibulum larynges or supraglottal intralaryngeal space). Research on larynx models and in humans indicate that this part of the vocal tract filter can contribute to two important acoustic effects: (a) the singer's formant and (b) the enhancement of nonlinear source-filter coupling. The acoustic role of this structure in nonhuman mammals is unknown. Furthermore, in many species tube and sac-like cavities are attached to the epilaryngeal tube (laryngeal air sacs) and their function is equally little understood. In this presentation I will report on results testing the hypothesis that the shape (length and diameter) of the epilaryngeal tube in nonhuman mammals is related to morphological parameters (vocal fold morphology, larynx size, body size) and parameters characterizing the species vocal repertoire (repertoire size, maximum sound amplitude, fundamental frequency range, occurrence of nonlinear phenomena). Preliminary results indicate that the length of the epilaryngeal tube is a poor predictor of repertoire characteristics such as maximum sound amplitude and fundamental frequency range. However, species with a prominent epilaryngeal tube produce a large proportion of high fundamental frequency call types.

3aSC4. A possible role of nonlinear source-filter interaction in simulation of childlike speech. Brad H. Story (Dept. Speech, Lang., Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721)

Simulation (or synthesis) of natural-sounding childlike speech has long been a challenge. This is likely due, at least in part, to an incomplete understanding of the nonlinear interaction of the voice source and the vocal tract filter. Speech production by children is typically characterized by a fairly high fundamental frequency of phonation and a short vocal tract length that produces high formant frequencies. Together, these two characteristics suggest that low-numbered harmonics (including the fundamental frequency) may often, or even necessarily, be in close proximity to one or more of the formant frequencies. Such conditions may lead to a strong interaction of the acoustic pressures in the vocal tract and the glottal airflow, and possibly the vibration of the vocal folds. The purpose of this study was to use kinematic models of the vocal folds and vocal tract shape, scaled to approximately represent a 5-year-old child, to generate individual vowels and sentences. Waveshape and harmonic content of glottal area, glottal flow, and radiated acoustic pressure signals were compared across three vowels and one sentence. [Research supported by NIH R01-DC04789.]

3aSC5. Nonlinear source-tract interaction in singing. Ingo R. Titze (Dept. of Commun. Sci. and Disord., Univ. of Iowa, WJSHC, Iowa City, IA 52242 ingo-titze@uiowa.edu)

Most approaches to teaching singing are based on concept that there preferred vowel configurations for a given pitch. Speaking vowels are modified not only to create a variety of timbres, but also to support the sound source in self-sustained oscillation. Linear filter theory, traditionally applied to cans or strengthening by vocal tract coupling, or can it account for source bifurcations in vocal fold oscillation related to vowel selection. Singing are contrasted by selection of two fundamentally different mouth configurations, the megaphone shape and the inverted megaphone shape. With the megaphone shape (used by musical theatre and jazz), the second harmonic of the sound source is reinforced at all high pitches by keeping the first formant frequency high. With the inverted megaphone shape (used by classical singers of opera and art song), the second and third harmonics are reinforced by the second formant. A "lift" of the second harmonic over the first formant becomes a critical skill in acquiring a smooth timbre over a wide pitch range. [Work supported by NIH.]

All posters will be on display from 10:50 to 11:50. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 10:50 a.m. to 11:20 a.m. and contributors of even-numbered papers will be at their posters from 11:20 a.m. to 11:50 a.m.

3aSC6. Subglottal effects on the vowels across language: Preliminary study on Korean. Youngsook Jung (Speech Commun. Group, MIT, Cambridge, MA 02139, and Harvard-MIT Div. of Health Sci. and Technol., Cambridge, MA 02139)

Previous research suggested that subglottal resonances define vowel features [back] and [low] for English. In testing this hypothesis, we explored whether these vowel feature boundaries are independent of language. As preliminary research, we made recordings of speech and subglottal signals simultaneously for several adult Korean speakers. We found acoustic irregularities in F1 and F2 near subglottal resonances in Korean vowels. The boundary between [+low] and [−low] vowels agrees with speakers' first subglottal resonances (SubF1), while the boundary between [+back] and [−back] agrees with SubF2. In addition, we tested which of these hypotheses is correct for a low vowel in Korean, which has only one low vowel with no contrast of [+back] and [−back]: (1) the low vowel is always [+back] or (2) SubF2 is avoided but the low vowel is front or back depending on adjacent consonants. The measurements of F2 and F2sub were obtained in the context /CaC/, where C is a consonant. We found that SubF2 was always avoided for the low vowel. If the adjacent consonants were labial or velar, F2 of the low vowel was below SubF2, whereas if the consonants were alveolar, F2 of the vowel was above SubF2. [Supported by NIH /NIDCD Grant No. #DC00075.]

3aSC7. Automatic classification of consonant-vowel transitions based on subglottal resonances and second formant frequencies. Nancy F. Chen and Steven M. Lulich (Speech Commun. Group, MIT, 77 Massachusetts Ave., Cambridge, MA 02139)

A growing body of work indicates that subglottal resonances (SGRs) divide the frequency space of vowels and consonants into distinct regions in several languages [S. Lulich, J. Phonetics (in press), and references therein]. For instance, the second formant frequency (F2) of back vowels lies between the first and second subglottal resonances (Sg1 and Sg2), while for front vowels F2 lies at higher frequencies than Sg2. In alveolar stop bursts, F2 lies between Sg2 and the third subglottal resonance (Sg3). In this study, we build on previous work [S. Lulich, JASA **124**, 2558 (2008)] to automatically determine SGRs using locus equations computed from 405 consonant-vowel (CV) transitions produced by an adult male native speaker of American English. Consonants and vowels are then classified into place of articulation and front/back features based only on the relations between F2 and the SGRs. The mean hit rate across categories was 77%, while the mean false alarm rate was 12%. These results show relative improvements of miss and false alarm rates by 21% and 14% from a baseline experiment, where F2 without SGRs was used to perform the classification. Our knowledge-based approach of classifying CV transitions is potentially useful when vowel and consonant identities are unavailable.

3aSC8. Source-filter interaction in the opposite direction: Subglottal coupling and the influence of vocal fold mechanics on vowel spectra during the closed phase. Steven M. Lulich (Speech Commun. Group, MIT, 77 Massachusetts Ave., Cambridge, MA 02139, lulich@speech.mit.edu), Matias Zanartu (Purdue Univ., West Lafayette, IN 47907), Daryush D. Mehta (Harvard-MIT Div. of Health Sci. and Technol., Cambridge, MA 02139), and Robert E. Hillman (Harvard Med. School, Boston, MA 02114)

Studies of speech source-filter interaction usually investigate the effect of the speech transfer function (loading) on vocal fold vibration and the voice source. In this study we explore how vocal fold mechanics affect the transfer function throughout the glottal cycle, with emphasis on the closed phase. Coupling between the subglottal and supraglottal airways is modulated by the laryngeal impedance. Although coupling is generally thought to occur only during the open phase of vocal fold vibration, a posterior glottal opening and the vocal fold tissue itself can allow sound transmission, thereby introducing coupling during the closed phase as well. The impedance of the vocal fold tissue at closure is shown to be small enough to permit coupling throughout the phonatory cycle, even in the absence of a posterior glottal opening. Open- and closed-phase coupling is characterized using mathematical models of the subglottal and supraglottal airways, and the parallel laryngeal impedances of the membranous glottis, posterior glottal opening, and vocal fold tissue. Examples from sustained vowels are presented, using synchronous recordings of neck skin acceleration, laryngeal high-speed videoendoscopy, electroglottography, and radiated acoustic pressure.

3aSC9. Nonlinear flow-structure coupling in a mechanical model of the vocal folds and the subglottal system. Michael S. Howe (College of Eng., Boston Univ., 110 Cummington St., Boston, MA 02215) and Richard S. McGowan (CReSS LLC, Lexington, MA 02420)

An analysis is made of the nonlinear interaction between flow in a mechanical model of the subglottal vocal tract and a model of the vocal folds. The mean flow through the system is produced by a "lung cavity" that is assumed to be steadily contracting. The lungs are connected to a subglottal tube of length L. The model for the vocal folds is at the other end of the subglottal tube. This model is a simple, self-exciting single-mass mathematical model of the vocal folds used to investigate the sound generated within the subglottal domain and the unsteady volume flux from the glottis. In the case when the absorption of sound by the lungs is presumed small and when the subglottal tube behaves as an open ended resonator (when L is as large as half the acoustic wavelength) a mild increase in volume flux is predicted. However, the strong appearance of second harmonics of the acoustic field is predicted at intermediate lengths, when L is roughly a quarter of the acoustic wavelength. In the cases of large lung damping, however, only modest changes in volume flux are predicted to appear. [Work supported by DC-009229 to UCLA under subcontract.]

3aSC10. An impedance-based inverse filtering scheme with glottal coupling. Matias Zanartu (School of Elect. and Comp. Eng., Purdue Univ., 206 S. Martin Jischke Dr., West Lafayette, IN 47907, mzanartu@purdue.edu), Julio C. Ho (Purdue Univ., West Lafayette, IN 47907), Daryush D. Mehta (Harvard-MIT Div. of Health Sci. and Technol., Cambridge, MA 02139), Robert E. Hillman (Massachusetts General Hospital, Boston, MA 02114), and George R. Wodicka (Purdue Univ., West Lafayette, IN 47907)

Source-filter interactions in voice production arise from considering finite glottal impedances that are comparable with that of the vocal tract and/or the subglottal system. Besides the changes in the source behavior, finite glottal impedances also allow for acoustic coupling between the subglottal and supraglottal tracts. Vowel dependence on the subglottal acoustic pressure is evident in recordings of skin acceleration overlying the suprasternal notch. To obtain estimates of other physiologic signals from skin acceleration, an impedance-based inverse filtering scheme that considers acoustic coupling is proposed. The scheme is based on an electrical analog model of a dipole source and assembles multiple approaches to estimate the system impedances. An experimental platform considers simultaneous measurements of skin acceleration, flexible high-speed videoendoscopy, oral volume velocity, intraoral pressure, electroglottography, and radiated acoustic pressure. Recordings of sustained vowels, co-articulated gestures, and pitch glides provide a comprehensive data set to study tract coupling and source-filter interactions. Preliminary results provide insights into the interrelation among the measured signals and illustrate the tissue instabilities of the vocal folds during some of the gestures. Further evaluation in cases of vocal fold pathology is also planned, where source-filter interactions are expected to be even more pronounced.

3aSC11. Vocal inharmonicity analysis: A promising approach for acoustic screening for dysphonia. Samuel Matteson (Dept. of Phys., Univ. of North Texas, 1155 Union Circle 311427, Denton, TX 76203-5017, Samuel.Matteson@unt.edu) and Fang-Ling Lu (Univ. of North Texas, Denton, TX 76203-5017)

In the United States, 6.8% of men, women, and children report voice problems currently, while during their lifetime ca. 29% will complain of some dysphonia, often due to pathologies of the vocal folds. The authors (a physicist and a speech pathologist) describe an interdisciplinary approach that exhibits promise for detecting physiological abnormalities of the vocal folds from a spectral analysis of the overtone series of spoken tokens. This preliminary investigation shows that the normal human vocal fold emits overtones that are very nearly precise integral values of the fundamental. Physiological problems of the vocal folds, however, introduce mechanical nonlinearities that manifest themselves as frequency deviations from the ideal harmonic (that is, integral) values. The authors quantify this inharmonicity, describing and illustrating how one can efficiently obtain and analyze such data. They outline, as well, a proposed investigation to assess the clinical sensitivity and significance of the analysis discussed in this work in conjunction with laryngoscopic diagnosis of pathology.

3aSC12. Geometric dependence of phonation threshold pressure and phonation onset frequency. Zhaoyan Zhang (UCLA School of Medicine, 31-24 Rehab Ctr., 1000 Veteran Ave., Los Angeles, CA 90095-1794)

Dependence of phonation threshold pressure and phonation onset frequency on vocal fold geometry was numerically investigated in a continuum model of the vocal folds. The geometric parameters of interest include the medial surface thickness, vocal fold depths of the body, and cover layers. Changes in these parameters may occur either due to laryngeal muscle activation, vocal pathology, or aging. Simulations show that both threshold pressure and onset frequency increased with decreasing vocal fold depth. However, depending on glottal geometry, increasing medial surface thickness may either increase or decrease phonation threshold pressure and frequency. Variation of the medial surface thickness also led to phonation onset occurrence at a different eigenmode, leading to sudden changes in onset frequency and vocal fold vibration pattern. These numerical predictions were further supported by experiments using a self-oscillating physical model. The result of this study confirms previous findings that phonation onset occurs as a matching between the flow stiffness, which is proportional to subglottal pressure, and vocal fold stiffness, which scales with natural frequency squared and depends on geometry and boundary conditions of the vocal fold structure as well as material properties of the vocal folds. [Work supported by NIH.]

3aSC13. Analysis and synthesis of humpback whale songs. Pranab K. Dhar, Sangjin Cho, Jong-Myon Kim, and Uipil Chong (Univ. of Ulsan, Ulsan 680-749, Korea)

The humpback whale song is one of the most complex, non-human, acoustic displays in the animal kingdom. In this paper, we analyze and synthesize the humpback song using additive synthesis which is one of the most powerful techniques for the analysis, modification, and synthesis of complex audio or speech signals. This method creates complex sounds by adding together individual sinusoidal signals called "partials." A partial's frequency and amplitude are each time-varying functions, so it is a more flexible version of the harmonic associated with a Fourier series decomposition of a periodic waveform. Applying the fast Fourier transform to all overlapping frames (small time segments), we can detect peaks from the frequency spectrum of each frame and calculate the frequency, magnitude, and phase for all the peaks. These extracted parameters are then used as components of the sinusoidal signals (partials) for the synthesis process. This process finally reconstructs and concatenates each frame, generating the synthesized humpback song. We observed that this synthesized song resembles much more closely the original humpback song by the time/frequency domain representation and listening. In the future, we will analyze and synthesis other baleen whale songs with this powerful synthesis method. [Work supported by IITA (IITA-2008-(C1090-0801-0039)).]

3aSP1. Acoustics in granular porous media and the consolidation continuum. James G. Berryman (Earth Sci. Div. Lawrence Berkeley Natl. Lab, One Cyclotron, Dr. Berkeley, CA 94720, jgberryman@lbl.gov)

One key influence on acoustic wave propagation in granular porous media is the degree to which the solid constituent grains can be treated as fully consolidated, weakly and/or partially consolidated, or entirely unconsolidated. Well-known results of Gassmann and Biot all implicitly assume that the medium is fully consolidated, with welded contacts at the grain-to-grain interfaces. Such implicit assumptions are also present in standard bounding methods for elastic behavior, such as the Hashin-Shtrikman bounds of elasticity. Influence of reductions in the degree of consolidation can be quantified for partially or weakly consolidated media, and granular media having no welded contacts can also be treated as porous media for sound waves in the Biot-Gassmann sense when grains are experiencing sufficient overall confining stress. Methods recently developed to quantify wave propagation characteristics over the full range of possible behaviors in grain packs, as well as comparisons to experiments, will be presented.

8:20

3aSP2. Fabric dependence of poroelastic wave propagation. Stephen Cowin and Luis Cardoso (Dept. of Biomed. Eng., The City College, NY, NY 10031, cardoso@soe.ccny.cuny.edu)

The governing equations for wave motion in the linear theory of anisotropic poroelastic materials are developed and extended to include the dependence of the constitutive relations upon fabric. Fabric is a quantitative stereological measure of the degree of structural anisotropy in the pore architecture of a porous medium. With the addition of the second order symmetric tensor fabric variable, the formulation of wave motions in the poroelastic theory is consistent with the presentations of Biot and later authors. The dependence of all the material tensors in the Biot theory on the fabric tensor aligns the material tensors, so when a single direction that is a plane of material symmetry is selected, the equations simplify considerably. The customary polynomial of the sixth deg for the wave speeds of the anisotropic Biot theory in a selected direction reduces to three quadratic equations to solve for the wave speeds and attenuation. While the theory is applicable to any saturated porous material, the two longitudinal waves predicted by this model are measured in cancellous bone and used to derive the corresponding anisotropic elastic constants. Representative examples of bone loss are analyzed as a function of the porosity, tissue density, and fabric.

8:50

3aSP3. Anisotropic bone loss characterized using fabric-based poroelasticity. Luis Cardoso and Stephen Cowin (Dept. of Biomedical Eng., The City College, 138th St., and Convent Ave., NY, NY 10031, cardoso@engr.ccny.cuny.edu)

The current gold standard to assess bone loss is the bone mineral density (BMD) test, performed with a dual x-ray absorptiometry system. BMD measurements are highly correlated to bone mass when measured in spine, wrist, and femoral neck. However, the BMD cannot fully explain the decrease in bone strength and the associated risk of fracture because bone loss is not homogeneous, and does not depend on mass changes only. In this study, a fabric-based poroelastic model is used to determine the elastic constants of bone that have undergone disuse-osteoporosis and bone treated with an antiresorptive drug. Images from microCT are used to determine the porosity, density, and fabric on each group of specimens. These measurements are used in the proposed fabric-based poroelastic model to determine the sample's anisotropic elastic constants. These elastic constants are then compared to the ones obtained by ultrasound wave propagation measurement as previously described in the Cowin and Cardoso presentation. Image analysis and ultrasound wave propagation are both shown able to determine changes in anisotropic elastic constants during bone loss when used with the proposed anisotropic poroelastic model. This study provides the foundation to define a bone quality criterion beyond the sole determination of bone mass.

3aSP4. Effective medium models from x-ray microtomography images. Max Deffenbaugh, John Dunsmuir (ExxonMobil Res. and Eng. Co., 1545 Rte. 22 East, Annandale, NJ 08801, max.deffenbaugh@exxonmobil.com), Shiyu Xu (ExxonMobil Exploration Co., Houston, TX 77060), and Enru Liu (ExxonMobil Upstream Res. Co., Houston, TX 77252)

A novel method is described where an effective medium model is generated from a 3-D x-ray microtomography image of a rock sample. In contrast to current modeling practice, material phases are not assigned idealized geometries, like spheroids. Instead, strain concentration tensors are computed numerically for the true phase geometries observed in the 3-D image. In this method, a 3-D image of x-ray attenuation is converted into a 3-D elastic properties volume, the strain field is computed within the volume, and the strain concentration tensors, which quantify the contribution of each grain and pore type to the bulk elastic properties, are calculated from the strain field. From only one representative sample of a rock type and with no assumptions about grain or pore shape, an effective medium model is generated that specifies the effective elastic tensor as a function of the various mineral and pore volume fractions. The method is demonstrated by generating effective medium models for several rock types. These models can be used in hydrocarbon exploration to relate the velocities of seismic waves in a poroelastic reservoir to the porosity, structure, and composition of the rock matrix and the type and distribution of the fluid within the pore spaces.

3aSP5. Model parameter estimation of a porous seabed using *in situ* acoustic-probe and chirp-sonar reflection data. Altan Turgut (Naval Res. Lab., Acoust. Div., Washington, DC 20375)

The velocity dispersion and frequency dependency of attenuation in marine sediments are two important measures that provide the ability to test the validity of geoacoustic models as well as to estimate physical properties from the acoustic data. A widely-used Biot–Stoll theory for elastic-wave propagation in porous marine sediments seems to predict a narrow band of dispersion that was measured only in well-sorted granular marine sediments [A. Turgut and T. Yamamoto, J. Acoust. Soc. Am. **87**, 2376–2382 (1990)]. Recent measurements in silty-sand sediments show almost linear frequency dependency of attenuation and mild velocity dispersion within the 3–80 kHz frequency band. The newly measured attenuation and velocity dispersion curves are in good agreement with those predicted by an extended Biot theory for sediments with a distribution of pore sizes [T. Yamamoto and A. Turgut, J. Acoust. Soc. Am. **83**, 1744–1751 (1988)]. Simultaneous measurements of *in situ* acoustic-probe data and chirp-sonar reflection data are also used to estimate the model parameters of the extended Biot model. [Work supported by the Office of Naval Research.]

3aSP6. Cancellous bone as a poroelastic medium: Extracting underlying material properties from improved ultrasonic measurements of frequency dependent attenuation and phase velocity. James G. Miller, Christian C. Anderson, Adam Q. Bauer, Karen Marutyan, G. Larry Bretthorst, Mark R. Holland (Washington Univ., 1 Brookings Dr., St. Louis, MO 63130), Brent K. Hoffmeister (Rhodes College, Memphis, TN 38112), and Keith A. Wear (U.S. Food and Drug Administration, Silver Spring, MD 20993)

Cancellous bone can be modeled as a poroelastic medium consisting of a viscous fluid (marrow) and a stiff framework (trabeculae). Transmission of ultrasound through bone can result in fast and slow waves as well as mode conversion and multiple scattering, all of which can mask the underlying material properties of bone that determine fracture risk. Phase cancellation at the receiving transducer and interference effects in the field can further compromise the potential of bone sonometry for assessing bone quality. The attenuation coefficient is observed to increase approximately linearly with frequency, a fact that accounts for the use of broadband ultrasound attenuation (BUA) to characterize bone. Many laboratories report that the phase velocity of ultrasonic waves propagating through cancellous bone decreases with increasing frequency (negative dispersion). However, an increase in phase velocity with frequency (positive dispersion) would be expected based on the causality-imposed Kramers–Kronig relations. This apparent negative dispersion in bone can arise from interference between fast wave and slow wave longitudinal modes. Interference and phase cancellation at the receiver can also be sources of artifactual alterations in the attenuation and phase velocity. [Work supported in part by NIH R37HL40302 R01AR057433, NSF CBET-0717830].

3aSP7. Successful use of Bayesian inference to obtain the fast and slow wave properties of cancellous bone from sonometry measurements. Christian C. Anderson (Washington Univ., 1 Brookings Dr., St. Louis, MO 63130), Michal Pakula, Pascal Laugier (Univ. Paris 6, 75006 Paris, France), Adam Q. Bauer, Karen Marutyan, G. Larry Bretthorst, Mark R. Holland, and James G. Miller (Washington Univ., St. Louis, MO 63130)

Clinical trials have demonstrated that frequency dependent attenuation [broadband ultrasound attenuation, (BUA)] and speed of sound (SOS) provide an assessment of fracture risk. Previous studies from our laboratory of the "forward problem" show that the negative dispersion observed in cancellous bone can arise when signals consisting of overlapped fast and slow waves are analyzed as if only one wave is present. The present study examines the "inverse problem" using Bayesian probability methods suitable for recovering the underlying material properties from received transmission sonometry signals complicated by the presence of multiple signals. Transmission studies were carried out on bone mimicking phantoms and on specimens of femur condyles. Received rf signals served as input to our Bayesian algorithm. The program that implements the Bayesian calculations reconstructs the individual fast and slow waves and constructs the model output from parameters that maximize the joint posterior probability. Composite rf signals constructed by summing these waves were in excellent agreement with signals transmitted through bone-mimicking phantoms and were in good agreement with signals transmitted through bone samples despite the additional complexities arising from ultrasound propagation through the complex trabecular network. [Work supported in part by NIH R37HL40302 R01AR057433, and NSF CBET-0717830].

3aSP8. Geoacoustic inversion performed from two source-receive arrays in shallow-water waveguide. Alexey Sukhovich, Philippe Roux, and Marc Wathelet (LGIT, UMR CNRS 5559, Univ. Joseph Fourier, Grenoble, France, Alexey.Sukhovich@obs.ujf-grenoble.fr)

Raylike propagation of acoustic waves in a shallow-water waveguide between two vertical line arrays is investigated by applying a double beamforming algorithm, which performs time-delay beamforming on *both* emitting and receiving arrays and allows identification of eigenrays by their emission and reception angles and arrival times. From the intensity of each eigenray, it is possible to determine reflection coefficient from the bottom of the waveguide as a function of an angle of incidence. The procedure was initially tested in a small-scale tank experiment for an acoustic waveguide with either steel or Plexiglas bottom. By fitting an experimentally found reflection coefficient with a corresponding theoretical expression, an estimate for the speed of shear waves in the bottom material was obtained. Similar analysis was subsequently applied to the data obtained during an at-sea experiment, which was performed between two vertical transducer arrays in shallow-coastal waters of the Mediterranean. An angle-dependent bottom reflection coefficient was extracted and geoacoustic inversion was performed by fitting the data with theoretical calculations, in which bottom sediments were modeled as a multilayered system. Good agreement between experiment and theory was observed. Our results indicate possible application of eigenray intensity analysis based on double beamforming algorithm for geoacoustic inversion problems.

11:15

3aSP9. Monitoring stress related velocity variation in concrete with a 2×10^{-5} relative resolution using diffuse ultrasound. Larose Eric (Lab. de Geophys. interne et Tectonophysique, CNRS & Univ. J. Fourier, Grenoble, France) and Hall Stephen (CNRS & Grenoble Univ., Grenoble, France)

Ultrasonic waves propagating in solids have stress-dependent velocities. The relation between stress (or strain) and velocity forms the basis of nonlinear acoustics. In homogeneous solids, conventional time-of-flight techniques have measured this dependence with spectacular precision. In heterogeneous media such as concrete, the direct (ballistic) wave around 500 kHz is strongly attenuated and conventional techniques are less efficient. In this manuscript, the effect of weak stress changes on the late arrivals constituting the acoustic diffuse coda is tracked. A resolution of 2×10^{-5} in relative velocity change for stress change is attained. We are thus sensitive to stress change much lower than 50 kPa. This provides an original way to measure the nonlinear parameter with relatively small stress variations (less than 100 kPa).

3aUW1. Dynamic and acoustic modeling of discrete biologics for active sonar simulation. Brian R. La Cour and John E. Hamann (Appl. Res. Labs., The Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

A model is proposed for simulating the group dynamics and acoustic echoes of aggregate, discrete biologics in midfrequency (2–5 kHz) active undersea sonar. Using a Lagrangian description, group behavior is modeled by a set of Newtonian forces and stochastic perturbations on a collection of point masses. Interactions comprise a grouping force, which gives a characteristic separation distance, and an arrayal force, which tends to align the velocities of the group's constituents. The group dynamics is characterized in terms of their statistical and asymptotic properties and studied as a function of the model parameters. Several models for the acoustic response are considered and studied for both individual and aggregate response. Finally, the resulting synthetic echoes are compared against those of actual biologics measured on a midfrequency active sonar system. The synthetic echoes are found to reproduce well both the qualitative characteristics of measured biologics and the resulting tracking and classification features found in a typical active sonar signal and information processing chain.

3aUW2. Coherent backscattering effect from mid-frequency reverberation measurements in shallow-water. Karim G. Sabra (School of Mech. Eng., Georgia Inst. of Technol., 771 Ferst Dr. NW, Atlanta, GA 30332-0405)

The coherent backscattering (or backscattering enhancement) effect is a persistent interference effect which occurs between waves propagating in random media such as randomly distributed scatterers and rough surfaces. Previous experimental and theoretical studies in optics, acoustics, or seismology have demonstrated that the coherent backscattering results in a doubling of the recorded intensity reflected exactly in the backward direction with respect to any other direction. We will present experimental observations of the coherent backscattering effect from mid-frequency reverberation data (3–4 kHz) collected in shallow water off the west coast of Italy using various sensor array configurations. This demonstrates the presence of coherent effects in shallow water reverberation recordings from rough seabeds. Hence, coherent reverberation effects need to be accounted for to obtain accurate predictions of sea clutter levels. Furthermore, accurate rendering of the coherent backscattering effect could be used to simply verify and validate physics-based undersea clutter models. Practical implementation for the design of active sonar systems will be discussed. [Work supported by ONR, Code 321.]

3aUW3. Measurements and modeling of midfrequency clutter from fish aggregations over Georges Bank in the Gulf of Maine. Roger C. Gauss, Joseph M. Fialkowski, Richard Menis, Edward L. Kunz (Naval Res. Lab., Code 7140, Washington DC 20375-5350, roger.gauss@nrl.navy.mil), Timothy K. Stanton, Cynthia J. Sellers (Woods Hole Ocean. Inst., Woods Hole, MA 02543), and J. Michael Jech (NOAA NE Fish. Sci. Ctr., Woods Hole, MA 02543)

Broadband midfrequency acoustic measurements of fish backscattering were made with two complementary sonar systems in September 2008 at the northern slopes of Georges Bank in the Gulf of Maine. One system, towed near the surface, was downward-looking (short-range: < 0.2 km) and was used to image fish at high vertical resolution throughout the water column. The other system was horizontal-looking (relatively long-range: 1–10 km), consisting of a vertical source array and a horizontal receive array, and was used to image fish at high horizontal resolution. In this talk, the focus is on characterizing the longer-range data. Spectrogram analysis showed that the echoes had resonance frequencies in the 2–4 kHz band, consistent with scattering by Atlantic herring, while examination of normalized match-filter output revealed strong, spatiotemporally variable clutter. The associated probability-density functions

(PDFs) exhibited variable non-Rayleigh behavior. Several PDF models were fit to the data, with the K and Poisson-Rayleigh PDF models providing not only good fits, but physical insights into the clutter process (such as estimates of the expected number of discrete scatterers per unit area). These results provide an improved understanding of both fish behavior and the characteristics of fish aggregations as long-range clutter fields. [Work supported by ONR.]

3aUW4. Bioalpha, transmission loss and validation of scattering models in biologically intense shallow water environments. Orest Diachok (Appl. Phys. Lab. Johns Hopkins Univ., Laurel, MD 20723-6099)

Scattering and extinction by fish swim bladders are manifestations of the same phenomenon. Scattering causes reverberation from dispersed fish and distinct echoes from fish schools (clutter), and diminishes the magnitude of transmitted signals. The biological extinction coefficient (bioalpha) has been shown to have a large effect on transmission loss (TL) in several biologically intense, shallow water environments, including the Bristol Channel [Weston (1967)], Yellow Sea [Qiu *et al.* (1999)], Gulf of Lion [Diachok (1999)], and Santa Barbara Channel [Diachok (2005)]. Consequently, models of biological scattering must include the effects of bioalpha on TL in shallow water environments. The objectives of this paper are to review the experimental evidence of the effects of bioalpha on TL, and to describe and demonstrate the effectiveness of an analytical approach to modeling this phenomenon. Since it is not possible at present to predict the effects of bioalpha on TL from first principles (distributions of swim bladder dimensions, spatial distributions of number densities, and timing of diurnal changes in school structures and seasonal migration patterns are only approximately predictable), experiments designed to demonstrate the validity of scattering models in biologically intense, shallow water environments should include concurrent broadband TL measurements during both night and day.

3aUW5. Statistics of echoes from a directional sonar beam insonifying finite numbers of single scatterers and patches of scatterers. Dezhang Chu (NOAA/NMFS/Northwest Fisheries Sci. Ctr., Seattle, WA 98112) and Timothy K. Stanton (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

When a sonar beam sweeps across a field of scatterers, the echoes can fluctuate significantly from ping to ping. The fluctuations can be strongly non-Rayleigh because: (1) there can be a small number of scatterers in the beam; (2) the distribution of scatterers can be inhomogeneous or "patchy;" and (3) the echoes are weighted by the nonuniform response of the sonar beam. In this paper, a general formulation combining equations derived by Ehrenberg [Proc. Conf. Eng. Ocean Environ. 1, 61–64, (1972)] and Barakat [Optica Acta 21, 903–921, (1974)] is developed to account for a directional sonar beam involving an arbitrary finite number of scatterers, each with an arbitrary echo probably density function (PDF) and randomly located in the beam. Theoretical predictions are made, along with numerical simulations for validation, for a range of conditions, including: (1) different number of scatterers arbitrarily located in the beam and (2) different echo PDFs of the scatterers. Here, a "scatterer" could be an individual or a patch of scatterers whose dimensions are much smaller than the footprint of the sonar beam. Although the application is intended for volumetric patches, the formulation could be applied to areal patches under appropriate conditions. [Work supported by ONR.]

3aUW6. Comprehensive, integrated database of elements contributing to bottom and volume clutter. Kathleen J. Vigness-Raposa, William T. Ellison, Adam S. Frankel, David Zeddies, Cheryl L. Schroeder (Marine Acoust., Inc., 809 Aquidneck Ave., Middletown, RI 02842, kathleen.vigness@marineacoustics.com), Peter V. August, Christopher Damon, and Charles LaBash (Univ. of Rhode Island, Kingston, RI 02881)

Multiple components within and at the bottom of the water column can scatter acoustic signals, resulting in decreased sonar performance and compromised tactical decision making. Many of the biological organisms that contribute to acoustic clutter are also protected or managed species, integral to a fully functional marine ecosystem. In order to understand, predict, and model bottom and volume scattering, detailed descriptions of the spatial, spectral, and temporal variability of clutter elements are needed, along with reliable estimates of backscattering strength. All of these necessary components are dependent on marine wildlife databases. Efforts by several organizations have resulted in databases that provide pieces of the overall puzzle. Databases of distribution and abundance (Census of Marine Life's OBIS-SEAMAP), two-dimensional movement (Census of Marine Life's Tagging of Pacific Pelagics), and diving and movement behavior (Marine Wildlife Behavior Database) are examples of current, but disparate, projects. Ongoing efforts are consolidating inputs from such databases to predict realistic, spatially dependent bioclutter animats. By linking geospatial features of clutter elements in training and mission planning systems, sonar operators and designers can better predict and analyze the occurrence of target-like clutter. [Work supported by NAVSEA SBIR, ONR STTR, and NOAA.]

3aUW7. Modeling persistent clutter. Bruce K. Newhall (Johns Hopkins Univ., Appl. Phys. Lab, 11100 Johns Hopkins Rd., Laurel, MD 20723)

Clutter is the collection of targetlike returns from nontarget sources that are observed in active sonar use. Persistent clutter is the set of clutter returns that persist across multiple transmissions and thereby form false target tracks in sonar processing. The U.S. Navy is developing active sonar simulators for training purposes. Effective training requires physically realistic clutter simulation including modeling of persistent clutter. Potential physical sources of persistent clutter are discussed, and a variety of modeling approaches are reviewed. Measures of effectiveness for model comparison with persistent clutter data are given.

10:35

3aUW8. Exploring spatiotemporal distribution as a clutter simulation validation measure. Juan I. Arvelo, Jr. (The Johns Hopkins Univ., Appl. Phys. Lab., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099)

The amplitude distribution is widely used to compare modeled and measured undersea clutter [J. Arvelo *et al.*, JASA **120**, 3381 (2006)]. However, additional validation measures must be identified to ensure that clutter models are suited to realistically simulate active sonar displays and accurately emulate tracker performance. For example, the amplitude distribution ignores the stochastic arrangement of clutter at various space/time scales [V. Lupien, JASA **105**, 2187–2282 (1999)]. Active midfrequency vertical line array data from the ASIAEX 2001 experiment in the East China Sea is processed to explore the suitability of the clutter spatiotemporal distribution as a key validation measure. The vertical array permitted the separation of bottom from surface generated clutter. A physics-based seafloor clutter model [B. Newhall and J. Arvelo, JASA **118**, 2041 (2005)] was implemented to simulate the experimental scenario with known measured and inferred environmental conditions. Comparisons of the measured and simulated amplitude and spatiotemporal distributions uncovered significant effects that must be included to improve existing clutter models. [This effort was conducted under the auspices of the Undersea Warfare Business Area Independent Research and Development program of the Johns Hopkins University Applied Physics Laboratory.]

10:55

3aUW9. Midfrequency active sonar clutter statistics segregated by broad clutter types. James M. Gelb (Appl. Res. Labs., UT Austin, 10000 Burnet Rd., Austin, TX 78758, gelb@arlut.utexas.edu)

The empirical distributions of normalized matched-filter echoes from a midfrequency active sonar with hyperbolic frequency-modulated waveforms in a myriad of oceanic environments are studied for three broad clutter classes: bottom structures, diffuse compact clutter (e.g., seaweed), and compact nonstationary clutter (e.g., biologics). The distributions are characterized using the K distribution and the generalized Pareto distribution. Methods of parameter estimation are discussed, and parameters are computed for small subregions of the clutter fields. A plot of the Kolmogorov–Smirnov goodness-of-fit statistic of individual subregions is presented for each model and class to highlight the versatility of the models when applied to large quantities of data. Cumulants are computed from the data and are utilized as features in a classifier to demonstrate separability between the classes. An important aspect of this work is the use of distinct clutter classes as opposed to collectively characterizing all clutter as reverberation. Environmental effects are not considered, as the goal of this work is to determine the utility of local clutter estimation models in practical sonar processing systems where accurate environmental data is unavailable. [This work is sponsored by the Office of Naval Research undersea signal processing discovery and invention program.]

11:15

3aUW10. Simulation of rippled-sand sonar imagery with visual and statistical verification. Shawn F. Johnson (Graduate Prog. in Acoust., Appl. Res. Lab., 117 Appl. Sci. Bldg., State College, PA 16804)

Synthetic aperture sonar (SAS) imagery is often characterized by a decidedly non-Rayleigh pixel amplitude distribution, owing to its inherent high-resolution combined with speckle induced by the coherent image formation process. Recent work has shown increasing the resolution cell size by limiting the image bandwidth typically produces images with statistics tending toward a Rayleigh distribution. A caveat to this generalization is that the trend toward Rayleigh is dependent on orientation of the SAS system to strongly correlated sea-floor structures such as sand-ripples. A method has been developed to simulate rippled-sand sonar imagery at high-frequencies (i.e., on the order of 100 kHz), which accounts for nonsymmetric ripple shape, sediment acoustic properties, sonar to ripple orientation, system resolution, and coherent imaging induced speckle. This numerical simulation method is computationally inexpensive and compares well both visually and statistically with collected data over a wide range of orientation angles. Simulation methods will be presented with verification using SAS imagery collected by the Naval Surface Warfare Center: Panama City Division. [Work supported by ONR Grants No. N00014-04-1-0013 and No. N00014-06-1-0245, and Code 32.]

11:35

3aUW11. Experimental tests of models for high-frequency scattered envelope statistics. Anthony Lyons (Appl. Res. Lab., Penn State Univ., State College, PA 16804, apl2@psu.edu)

There has been, in general, a lack of quantitative comparison between high-frequency physics-based clutter model predictions and experimental data due mainly to difficulties in performing well-controlled at-sea experiments and obtaining necessary ground truth. To address this shortfall, experiments have been performed over the past 5 yrs to gather data with which to confront recently developed physics-based clutter models. The experimental data sets were obtained during experiments conducted off of Elba Island, Italy in May 2003 and at Seneca Lake, New York, in the summers of 2005 and 2006. Colocated high-frequency, broadband acoustic data and high-resolution environmental ground truth data were collected as part of these experiments. In all cases comparisons between model predictions and measured data showed promising similarities in *K*-distribution shape parameter estimates and their dependence on bandwidth, grazing angle, and seafloor type. The favorable model/data comparisons show that it is possible to link the scattered envelope distribution to measurable environmental properties, providing the foundation necessary for solving several important problems related to the detection of targets in non-Rayleigh clutter including performance prediction for different systems based on seafloor properties and extrapolation of performance to other systems and bandwidths.

3pAAa1. Impedance tube absorption testing of poly blend materials presently used in the carpet industry. Ruth Anne Mazur (Columbia College Chicago, 237 E. Wildflower Ln., Round Lake Beach, IL 60073, ruthie.mazur@sbcglobal.net)

Cyril M. Harris authored a paper in 1955 titled "Acoustical Properties of Carpet" in which absorption coefficients for carpet were examined according to specific parameters, including fiber content. Since then, new fibers and blends have been introduced into the carpet industry. This study aims to compare absorption coefficients found from testing of these newer fibers. New blends that are now commonly used and sold in the carpet industry include polyester, polypropylene, and polyurethane. Using a Bruel & Kjaer Two Microphone Impedance Measurement Tube and Bruel & Kjaer PULSE LabShop, normal incidence absorption coefficients are gathered in order to compare the coefficient curves for these materials. Testing is performed in accordance with the ASTM E 1050-98 standard. Preliminary testing on carpet with these fibers shows lower values from 3.5 to 6.5 kHz in the curves for polypropylene carpet with padding compared to other fibers with padding. Several parameters of the preliminary samples were not constant and may have affected the results. Ongoing analysis and testing of newer fibers will enable comparison with previous studies. Absorption coefficients and parameters for carpet available in acoustical modeling programs will also be assessed in relation to the results. [Work supported by Columbia College Chicago.]

3pAAa2. Felt panels for an art space. Jessamyn A. Newcomb (Dept. of Architecture, Virginia Polytechnic and State Univ., 201 Cowgill Hall (0205), Blacksburg, VA 24061)

The art building on Virginia Tech's campus is an adaptive reuse project. Despite its current function, the transformation of the space has left it acoustically ill suited for class instruction. This research focuses on absorption of specific frequencies through the use of felt panels to reduce noise and increase speech intelligibility for class instruction. Microperforated panels are proposed as a solution due to their simple structures and predictable wideband absorption characteristics. Benefits will be quantified by measuring pink noise decay in the building pre- and postpanel installation.

1:30

3pAAa3. Absorption coefficients part 1: Is square area enough? Ron Sauro, Michael Vargas (NWAA Labs., Inc., 25132 Rye Canyon Loop, Santa Clarita, CA 91355, audio_ron@msn.com), and Gary Mange (Western Electroacoustics Labs., Santa Clarita, CA 91355)

Attempting to correlate the measurements of absorption coefficients in ASTM-C423, ISO-354, and ISO-17497-1, it was observed that the results were varying to a large degree. An experiment was set up with 1 in., 6 lb density fiberglass panels having different shapes, sizes, and parameters. The shapes, sizes, and parameters of the panels are described in this paper. The types of experiments are also described along with the process that was used based on input from many of the members of the industry. The end results and conclusions are described in a paper titled "Absorption coefficients part 2: Is "edge effect" more important than expected?"

1:45

3pAAa4. Absorption coefficients part 2: Is "edge effect" more important than expected? Ron Sauro, Michael Vargas (NWAA Labs., Inc., 25132 Rye Canyon Loop, Santa Clarita, CA 91355, audio_ron@msn.com), and Gary Mange (Western Electro-Acoust. Labs., Santa Clarita, CA 91355)

Attempting to correlate the measurements of absorption coefficients in ASTM-C423, ISO-354, and ISO-17497-1, it was observed that the results were varying to a large degree. An experiment was set up as described in a paper titled "Absorption coefficients part I: Is square area enough?" It was observed that the edges of the sample had a significant effect on the absorption coefficient. The results of these experiments are presented in numerical and graphic form in this paper along with conclusions and suggested corrections to the "absorption coefficient" as used in all calculations in acoustics.

3pAAb1. Introduction to workshop goals. K. Anthony Hoover (McKay Conant Hoover, Inc., 5655 Lindero Canyon Rd., Westlake Village, CA 91362) and Bennett M. Brooks (Brooks Acoust. Corp., Vernon, CT 06066)

Many states require that architects obtain continuing education unit (CEU) credits annually, in order to maintain their registration or licensure. The American Institute of Architects (AIA) Continuing Education System (CES) offers continuing education courses, which may be given by third party providers. The Technical Committee on Architectural Acoustics (TCAA) is an AIA/CES Registered Provider. The goal of this workshop is to prepare members of the TCAA so that they may be authorized to present a short course which can earn attendees CEU credit. In order for TCAA members to qualify to meet the AIA requirements, they must attend this workshop, which is given in two parts. The first part will be devoted to the short course presentation material, which is in a standardized format. The second part of the workshop will focus on the AIA CEU Program registration and reporting requirements. Of course, anyone is free to register with the AIA to provide their own CEU program. However, the advantages of participating in this program are that the TCAA short course is already prepared, is preapproved by the AIA, and the registration fees are paid by the Acoustical Society of America.

1:25

3pAAb2. Architectural acoustics: Short course presentation material. K. Anthony Hoover (McKay Conant Hoover, Inc., 5655 Lindero Canyon Rd., Westlake Village, CA 91362)

The Technical Committee on Architectural Acoustics (TCAA) is a Registered Provider in the American Institute of Architects (AIA) Continuing Education System (CES). The TCAA has developed a standardized introductory short course for architects, called "Architectural Acoustics." An architect can earn one continuing education unit (CEU) by attending this short course, if it is presented by a qualified member of TCAA. The course covers topics in sound isolation, mechanical system noise control, and finish treatments. This paper will cover the course material in order to prepare and qualify potential presenters. There will be time at the end of the paper for questions and answers on the course material. In order to qualify as an authorized presenter for this AIA/CES short course, attendance at this workshop and membership in TCAA are required.

2:25

3pAAb3. Provider registration and reporting requirements. Bennett Brooks (Brooks Acoust. Corp., 30 Lafayette Sq., Ste. 103, Vernon, CT 06066)

The Technical Committee on Architectural Acoustics (TCAA) is a Registered Provider in the American Institute of Architects (AIA) Continuing Education System (CES). The TCAA has developed a standardized introductory short course for architects. The TCAA short course is called "Architectural Acoustics" and attendance at this 1-hour-long course can earn an architect one continuing education unit (CEU). This paper will cover the administrative requirements of the AIA/CES, to prepare potential presenters. These requirements include the proper handling of paperwork, so that AIA members may receive credit for the course. Also, the manner in which the course is given is dictated by AIA requirements. TCAA membership and attendance at this workshop are required to qualify as an authorized presenter for this AIA/CES short course.

3pAB1. Call localization of marine mammals using directional autonomous recorders. Susanna B. Blackwell, Charles R. Greene, Jr. (Greeneridge Sci., Inc., 1411 Firestone Rd., Goleta, CA 93117, susanna@greeneridge.com), Christopher S. Nations, Trent L. McDonald (WEST, Inc., Cheyenne, WY 82001), Aaron Thode (Univ. of California, San Diego, La Jolla, CA 92037), and A. Michael Macrander (Shell Exploration and Production Co., Anchorage, AK 99503)

Directional sensors of low-frequency acoustic waves have been used by navies in sonobuoys for submarine detection and localization for decades. Composed of an omnidirectional pressure sensor and two horizontal directional elements sensitive to particle motion, they provide information for determining the relative bearing to a sound source without ambiguity. They were adapted for bowhead whale monitoring in the mid-1980s and have been used in autonomous seafloor acoustic recorders since 2000. Applied to the coastal Beaufort Sea north of Alaska, fall bowhead migration was observed in detail during 2007 and 2008, providing a wealth of information on variability in the migration paths of calling whales and the influence of industrial sounds on the locations of calling whales. For example, many calls were detected within about 30 km of seismic survey activities, where received sound pressure levels from airgun pulses were often greater than 140 dB per 1 μPa. Also, seismic activities were correlated with statistically significant shifts in the whales' distance from shore, either offshore or inshore. However, interpretation of the results was challenged by the difficulty in distinguishing between a whale that ceases calling and a whale that deflects away from the study area. [Work supported by Shell Oil Co.]

1:20

3pAB2. Killer whale habitat use and prey fields from remote hydrophones and echosounders. Scott Veirs (Beam Reach Marine Sci. and Sustainability School, 7044 17th Ave NE, Seattle, WA 98115, scott@beamreach.org), Val Veirs (Colorado College, Colorado Springs, CO 80903), Jason Wood (The Whale Museum, Friday Harbor, WA 98250), Brian Moore, Bob McClure (BioSonics, Inc., Seattle, WA 98107), and Bob Otis (Ripon College, Ripon, WI 54971)

The Salish Sea Hydrophone Network has been providing live audio streams to listeners around the globe for the past three years. Five hydrophones around the core summer habitat of the endangered southern resident killer whales allow detection of killer whale presence and inference of pod identity based on call associations. Detection of calls, whistles, and clicks is accomplished automatically by spectral and time domain analysis and manually by a global network of trained human listeners. The hydrophone network is more effective than a sighting network for detecting killer whales during inclement weather and at night, and for generating real-time notifications to alert researchers and managers. Additionally, the live streams and archived recordings have enriched educational activities of local museums and aquariums. In 2008, the hydrophone at Lime Kiln State Park was supplemented by hydroacoustic surveys conducted using a Biosonics echosounder (200 kHz). From August through December the echosounder was deployed at 15 m depth to conduct a continuous, fixed, horizontal survey. Remote display technology was used to monitor the echosounder in real time while also listening to the live audio stream. The resultant time series of fish density and acoustic behavior of killer whales is presented.

1:35

3pAB3. Detecting humpback whale sounds in the Bering Sea: Confounding sounds in a cacophony of noise. Sara L. Heimlich, David K. Mellinger, Sharon L. Nieukirk, Holger Klinck (Cooperative Inst. for Marine Resour. Stud., Hatfield Marine Sci. Ctr., Oregon State Univ., 2030 S. Marine Sci. Dr., Newport, OR 97365), Kate Stafford, Sue E. Moore, and Phyllis J. Stabeno (Univ. of Washington, Seattle, WA 98105)

Humpback whales (*Megaptera novaeangliae*) are top predators of large zooplankton and forage fish, and one of the most common large whales in the Bering Sea. While present on feeding grounds, humpback whales produce nonsong sounds probably associated with feeding or social contacts. However, little is known about these highly variable sounds, and their detection is challenging. Recordings were collected during 2006–2007 at the long-term oceanographic moorings M2, M4, and M5 in the eastern Bering Sea. Passive acoustic detection of humpback whale calls in these recordings was confounded by a variety of other sounds, which fall within the same parameters as nonsong humpback vocalizations. An automatic algorithm that detects tonal sounds in the 300–950 Hz frequency band was used to find humpback calls. Raw detections were visually examined to verify the accuracy of the detections. This algorithm resulted in a significant number of wrong detections (false positives), especially sounds of bearded seals (*Erignathus barbatus*) and bowhead whales (*Balaena mysticetus*). An error rate was calculated to correct the high number of false detections, and further refinements were made to the automatic detection algorithm. The problems and possible solutions to detecting humpback whale sounds in complex acoustic recordings will be presented.

1:50

3pAB4. Monitoring cetaceans on seamounts in the Azores using passive acoustic techniques. Irma Cascão (Inst. of Marine Res., Dept. of Oceanogr. and Fisheries, Univ. of the Azores, Horta, Portugal, irmacascao@uac.pt), Marc O. Lammers (Univ. of Hawaii, Kailua, HI 96734), Monica A. Silva, Pedro Afonso, Rui Prieto, and Ricardo S. Santos (Univ. of the Azores, Horta, Portugal)

Seamounts are hotspots of marine life in the Azores, acting as feeding stations for diverse top predators, including cetaceans. Long-term monitoring of remote marine ecosystems is logistically difficult and expensive, involving high costs in terms of ship time and human resources, as well as being reliant on sea conditions. Passive acoustic methods are a highly efficient monitoring technique to study the distribution or abundance of

vocalizing cetacean species. In 2007, we began to deploy Ecological Acoustic Recorders (EARs)—two shallow (35 m) and two deep (190 m) units—around seamounts to explore and monitor the occurrence of cetaceans, their temporal patterns, and changing levels of activity. A wide variety of time series acoustic signals were collected, revealing the presence of different species of cetaceans and specific associations between species, based on their vocalization characteristics. Detections of vessels are being used to determine levels of activity at one of the study sites, Formigas bank marine reserve, making the EAR a useful tool to monitor protected areas. The EARs are an effective ecological instrument for monitoring cetaceans year-round and will provide a better understanding of the influence of seamounts on cetaceans' behavior.

3pAO1. Seabed characterization and model based processing: Past, present, and future. Martin Siderius (Dept. of Elect. and Comput. Eng., Portland State Univ., 1900 SW 4th Ave., Portland, OR 97201, siderius@pdx.edu)

One of the most active areas of research in acoustical oceanography has been the study of seabed acoustics. This has been partly motivated by the need for accurate sonar performance prediction, which often depends on knowledge of the seabed properties. There has also been significant research on environmentally adaptive and model based signal processing such as matched field processing. One of the obstacles to model based processing has been the required knowledge about seabed properties, which is needed as input. This dependency, in part, led to the innovation of matched field inversion methods to obtain seabed properties. In recent years, new algorithms have been introduced that use ambient noise (e.g., from breaking waves) as a surrogate sound source to probe the seabed and estimate geoacoustic properties. These noise methods have received much attention since measurements and processing are simple and the results are surprisingly good. In fact, current developments in noise processing may be the key to enabling model based methods that, in the past, were not considered practical. In this presentation a review of seabed inversion methods will be given with discussion about current developments in noise processing and the potential for renewed interest in model based processing.

3pBB1. Interaction of single biological cell with tandem microbubbles in microfluidics. Georgy Sankin, Fang Yuan, and Pei Zhong (Dept. of Mech. Eng. Mat. Sci., Duke Univ., 144 Hudson Hall, Durham, NC 27708, gns @duke.edu)

Coupled oscillation of two laser generated microbubbles (maximum radius = 28 μm) and associated shear stresses are investigated experimentally. Bubble-bubble interaction in a microchannel of 25 μm height is observed using high-speed video cameras and μPIV technique. Two liquid microjets moving in opposite directions can be generated when the second bubble is produced at the maximum size of the first one. The interaction of these tandem microbubbles with single cell leads to controllable poration of adjacent cell membrane and dye uptake. μPIV data are compared with cell viability at various bubble-cell distances and azimuthal orientations. This method provides a new approach for highly selective cell treatment in situ, applicable to targeted microinjection of macromolecules and gene vectors in microfluidics devices. [Work supported in part by NIH.]

3pBB2. Treating heterotopic ossification with shockwaves. Michael W. Chang (12340 NE 8th St., Ste. 101, Bellevue, WA 98005), Thanaphum Osathanon, and Cecilia Giachelli (Univ. of Washington, Seattle, WA 98195)

Heterotopic ossification (HO) is formation of lamellar bone in soft tissue, commonly seen among patients with burns, orthopedic fractures/procedures, brain/spinal cord injuries, muscle contusions, and rare hereditary disorders. Patients with HO experience pain and joint limitations, which further exacerbate their disability. Reduction of HO preventatively and/or for treatment has been attempted using medications, radiation, and surgery with limited success. Recent encouraging clinical HO outcomes using shockwave therapy have been discussed but treatment mechanisms were unclear. Mechanisms such as spallation, cavitation, squeezing, superfocusing, fatigue, and layer separation have been proposed for lithotripsy. Mineralized calcium phosphate macroporous nanofibrous fibrin scaffolds were used as a HO model to study treatment mechanisms. The HO was treated with electrohydraulic shockwave devices. The scaffold calcium contents decreased from 45.4(3.6) (untreated) to 20.9(18.1) (OssaTron, 0.71 mJ/mm2) and 27.5(23.5) ugCa/mg dry weight (EvoTron, 0.46 mJ/mm2) with 200 shocks (1 Hz). Scanning EM of the shockwave-treated HO supports separation of the calcium phosphate from the fibrin matrix probably contributed by shear and cavitation. Biological responses to shockwaves, such as inflammation, neovascularization, angiogenesis may also play important roles in clinical HO treatment. A unique clinical HO case is discussed to illustrate risks, benefits, and challenges from shockwave therapy.

1:15

3pBB3. Histotrispy: Urologic applications. William W. Roberts, Timothy L. Hall, Christopher R. Hempel (Dept. of Urology, Univ. of Michigan, TC 3879, 1500 East Med. Ctr. Dr., Ann Arbor, MI 48109-5330, willrobe@umich.edu), Zhen Xu, J. Brian Fowlkes, and Charles A. Cain (Univ. of Michigan, Ann Arbor, MI. 48109)

Histotripsy is an extracorporeal ablative technology that utilizes microsecond pulses of intense ultrasound to produce nonthermal, mechanical fractionation of targeted tissue. We have previously demonstrated the feasibility of histotripsy ablation in *in vivo* renal and prostate models. We sought to assess the chronic tissue response, tolerability, and safety of prostate histotripsy in a chronic *in vivo* canine model. Five acute and thirteen chronic canine subjects were anesthetized and treated with histotripsy targeting the prostate. Pulses consisting of three cycle bursts of 750-kHz ultrasound at a repetition rate of 300 Hz were delivered from a highly focused 15-cm aperture array. Prostates were harvested at 0, 7, 28, or 56 days after treatment. Transrectal ultrasound imaging provided accurate targeting and real-time monitoring of histotripsy treatment. Consistent mechanical tissue fractionation and debulking of prostate tissue was seen acutely and at delayed time points without collateral injury. Canine subjects tolerated histotripsy with minimal hematuria or discomfort. Only mild transient lab abnormalities were noted. Histotripsy is a promising noninvasive therapy for prostate tissue fractionation and debulking that appears safe and well tolerated without systemic side effects in the canine model.

1:30

3pBB4. Improving efficiency of ultrasound histotripsy sources by transmitting at the second harmonic frequency. Timothy A. Bigelow (Dept. of Elec. and Comput. Eng., Dept. of Mech. Eng., Iowa State Univ., 2113 Coover Hall, Ames, IA 50011, bigelow@iastate.edu)

Therapeutic ultrasound has shown potential for improving many aspects of medical care in recent years. Therapeutic ultrasound often involves high pressures or intensities, but pressures and intensities in tissue are limited by nonlinear propagation. The impact of nonlinear propagation is most severe for therapies involving cavitation where the peak rarefactional pressure plays the dominate role. As a result, in applications such as histotripsy, the size and power of the ultrasound source must be significantly increased in order to obtain the pressures needed *in vivo*. In this study, a new ultrasound source design was developed that will help mitigate the effects of nonlinear propagation. Specifically, sound was transmitted at both the fundamental and the second harmonic with the amplitude and phase of the second harmonic designed to counter nonlinear propagation effects for varying source powers from 10 to 500 W. The simulations demonstrated a 30% increase in the peak rarefactional pressure relative to a source where only the fundamental was transmitted when the appropriate phase was used for the second harmonic.

1:45

3pBB5. Skull flexure from blast waves: A mechanism for brain injury with implications for helmet design. William C. Moss, Michael J. King (Lawrence Livermore Natl. Lab., 7000 East Ave., Livermore, CA 94551, wmoss@llnl.gov), and Eric G. Blackman (Univ. of Rochester, Rochester, NY 14627)

Traumatic brain injury [TBI] has become a signature injury of current military conflicts. The debilitating effects of TBI are long-lasting and costly. Although the mechanisms by which impacts cause TBI have been well researched, the mechanisms by which blasts cause TBI are not understood. Various possibilities have been investigated, but blast-induced deformation of the skull has been neglected. From numerical hydrodynamic simulations, we have discovered that nonlethal blasts can induce sufficient flexure of the skull to generate potentially damaging loads in the brain, even if no impact occurs. The possibility that this mechanism may contribute to TBI has implications for the diagnosis of soldiers and the design of protective equipment such as helmets. [This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344].

2:00

3pBB6. Cavitation bubble activity during treatment of cortical bones by shock waves. Dorothée Bossis (CNRS LIP UMR 7623, 15 rue de l'Ecole de Medecine, 75006 Paris, France), Frederic Padilla, and Robin O. Cleveland (Boston Univ., Boston, MA 02114.)

Shock wave (SW) induced cavitation might be a physical effect by which bioeffects on bones are mediated, especially for SW treatment of bone nonunion. To assess the presence of cavitation and to study bubbles activity at the surface of cortical bones, we treated rat femurs with SWs using a clinical SW therapy device (Ossatron). Sequences of 14 images were acquired using a high speed camera capable of recording up to 100 million frames per second (Imacon). The sequences showed that for all voltage settings of the Ossatron a cloud of cavitation bubbles was induced at the surface of the bone. The bubbles near the surface of the bone appeared to form and act as a single larger bubble, which collapsed violently against the surface of the bone. For a voltage setting of 28 kV the collapse time was measured to be 720 micro-seconds after a single SW and reduced to 620 micro-seconds after 10 SWs at 1 Hz. In the case of a bone with an artificially fractured surface cavitation events were found to occur preferentially within the fracture gap. Cavitation might therefore be an important mechanisms in the SW treatment of bone defects.

2:15

3pBB7. Shock waves micro-damage induction in cortical bones: Comparison between experimental and simulations results. Frederic Padilla (Dept. of Mech Eng., Boston Univ., 110 Cummington St., Boston, MA 02115; CNRS LIP UMR 7623, 75006 Paris, France) and Robin O. Cleveland (Boston Univ., Boston, MA 02115)

Shock waves (SW) are considered a promising method to treat bone non unions. One potential mechanisms of action is the initiation of local microfractures, which may in turn trigger the start of bone healing. In this study, a set of eight intact rat femurs have been subjected to SWs (peak positive pressure of 40 MPa and peak negative pressure of -8 MPa, PRF of 2 Hz). The number of SW was varied from 50 to 1500. Micro-CT images of the specimens were acquired before and after treatment (16 microns resolution). In parallel, numerical simulations were used to quantify the stresses induced by SWs in cortical bone tissue. We used a 3-D FDTD code to solve the linear lossless equations that describe wave propagation in solids and fluids. A 3-D model of a fractured rat femur was obtained from micro-CT data. Results demonstrate that damages were induced in the bone tissues from 150 SWs. Comparison of the location of the induced damages on micro-CT images with predictions of maximum stresses by numerical simulations show that damages principally appeared in regions of highest stresses, suggesting that SW-induced tremendous stresses in bone tissue might be an important mechanisms implied in SW bone therapy.

2:30

3pBB8. Empirical angle-dependent tortuosity functions and sound transmission through cancellous bone. Keith Attenborough (Dept. of Eng., The Univ. of Hull, Cottingham Rd., Hull HU6 7RX, UK, k.attenborough@hull.ac.uk) and Haydar Aygun (Univ. of Hull, Hull HU6 7RX, UK)

Recent literature concerning the angle dependence of sound transmission through cancellous bone has suggested that it might be due either to elastic anisotropy or to microgeometrical anisotropy in the pore structure; e.g., an angle-dependent tortuosity. The elastic anisotropy approach has been found able to explain the observed variation in fast wave speed with angle better than the angle-dependent tortuosity at the cost of underpredicting slow wave speeds. In reality, it is likely that both influences are present in cancellous bone. Nevertheless the angle-dependent tortuosity approach has been revisited on the basis of orthotropic data for sound transmission through air-filled stereo-lithographical bone replicas [Attenborough *et al.*, JASA 118, 2779 (2005)]. [Work supported by Leverhulme Grant F/00181/N.]

2:45

3pBB9. Numerical simulation of propagation of acoustic and elastic waves in human head with fast integral equation solver. Elizabeth Bleszynski, Marek Bleszynski, and Thomas Jaroszewicz (Monopole Res., 739 Calle sequoia, Thousand Oaks, CA 91360)

An approach to numerical simulations of acousto-elastic waves in the human head is described, and simulation examples are presented. The primary goal of our work is to construct an efficient and high fidelity numerical simulation tool for investigating such effects as, e.g., acoustic energy transfer to the inner ear via non-airborne pathways. The solver employs a modified form of the volumetric Lippmann–Schwinger integral equation, adapted to high material-contrast problems, and an FFT based stiffness matrix compression implemented for distributed-memory systems enabling large scale (several million unknowns) simulations for realistic geometries. Some of the new aspects of the technique and its applications include (a) extension of the technique for problems involving large density contrasts,in situations involving elastic media; (b)improved, more economical, and more accurate Galerkin discretization scheme involving linear tetrahedral elements; (c) verification of the solver by comparison of its predictions with an exact analytical solution for a sphere composed with layers supporting both compressional and shear waves; (d) applications in representative numerical simulations of mechanisms of energy transfer to the inner human ear and

comparative analysis of the pressure distributions in a human head with and without the presence of noise protective devices, carried out with realistic geometry models. [Work supported by AFOSR].

3:00

3pBB10. Guided waves analysis using multiemitter and multireceiver arrays. Jean-Gabriel Minonzio, Marilyne Talmant, and Pascal Laugier (Universite Pierre et Marie Curie—Paris 6, Laboratoire d'Imagerie Paramétrique, CNRS LIP UMR7623, 75006 Paris, France)

Structural and material properties of elastic waveguides can be characterized by fitting measured to theoretical guided wave phase velocities. Here emitters and receivers are placed in contact on the same side of the waveguide (i.e., axial transmission geometry). Multireceiver arrays allow the determination of phase velocities using two-dimensional spatial-temporal Fourier transform, which requires a large distance probed by the receivers. Practical constraints, as in clinical inspection of cortical bones, may reduce the inspected spatial length and therefore the efficiency of this technique. We propose a technique which takes benefit of using both multiple emitters and multiple receivers. This approach derived from the DORT method adapted to the transmission problem. The singular values decomposition at different frequencies of the transmission matrix between the arrays give the invariants of transmission, which are linked with the guided modes. First, experiments carried out on different metallic plates are shown. Experimental velocities are in good agreement with Lamb waves theoretical values. In particular, zero group velocity resonance and negative phase velocities are shown. These results allows a good evaluation of the thickness and the transverse and longitudinal bulk waves velocities. Further applications concerning evaluation of elastic properties of cortical bone are finally mentioned.

WEDNESDAY AFTERNOON, 20 MAY 2009 EXECUTIVE SALON II/III, 1:00 TO 2:00 P.M.

Session 3pID

Interdisciplinary: Hot Topics in Acoustics

Paul E. Barbone, Chair
Dept. of Aerospace and Mechanical Engineering, Boston Univ., Boston, MA 02215

Invited Papers

1:00

3pID1. Hot topics in youth education outreach. Grace Klonoski (Optical Society of America, 2010 Massachusetts Ave., N.W., Washington, DC 20036-1012)

This presentation will focus on ways in which professional societies and their volunteers can make a lasting, positive difference in supporting the science and math learning of young students. The introduction will provide a brief overview of trends in student achievement in math and science and will discuss the availability of qualified teachers in the United States. Four features of effective learning environments will be described. The remainder of the presentation will be devoted to examples of how scientific communities can become directly involved in reaching out to students on a local and global scale. A variety of youth programs hosted by the Optical Society of America (OSA) and the OSA Foundation will be highlighted with an emphasis on the scope, goals, and quantitative results of each initiative. From a multilingual Web site that provides students, teachers, and parents with basic science information, lesson plans, and hands-on activities, to the production and worldwide distribution of "optics suitcases" that give students the opportunity to participate in hands-on demonstrations, OSA's recent efforts have benefited thousands of individuals in more than 20 countries. The planned collaboration between ASA and OSA to develop acoustics-focused classroom materials, a Web site, and demonstration kit will be described.

1:20

3pID2. Auditory attention and the active listener. Barbara Shinn-Cunningham (Cognit. and Neural Systems, 677 Beacon St., Boston, MA 02215)

Traditionally, psychoacousticians and auditory physiologists have focused on how stimulus properties affect perceptual abilities, measuring just-detectable differences in different acoustic attributes or thresholds for audibility of different sounds. However, in everyday settings with more than one audible sound source, these low-level abilities are often not the factors limiting understanding of an important sound source. Instead, the way the brain organizes sound and focuses attention has an enormous impact on what we actually hear and analyze out of an auditory scene. Recent studies in both perceptual and physiological acoustics are working to uncover how the intentions and goals of the listener influence processing of sound in the brain. This talk will review some recent advances in auditory neuroscience that demonstrate the importance of top-down attention on neural processing and perception of sound.

1:40

3pID3. Hot topics of signal processing in acoustics. Ning Xiang (Graduate program in Archit. Acoust., Rensselaer Polytech. Inst., Troy, NY, 12180) and David Chambers (Lawrence Livermore Natl. Lab., Livermore, CA 94551)

Signal processing is used to some extent in all areas of acoustics, such as extracting relevant information from acoustic measurements made either in the laboratory or in the field, processing signals and/or synthesizing data to cope with demanding tasks raised in acoustics. Techniques range from simple classical approaches based on Fourier transforms and Gaussian noise, to sophisticated model-based techniques that incorporate physical/parametric models of the acoustical system. In this paper we highlight new approaches to

signal processing that could be applied to a broad variety of acoustical problems. These include coded signals for architectural-acoustics, acoustical communications, and medium characterization, Bayesian methods for room acoustics, physical acoustics, and underwater acoustics including highly nonlinear problems with non-Gaussian noise, and extensions to the familiar Kalman filtering to nonlinear models. Examples of each approach will be shown that illustrate the advantages and disadvantages of each technique. Additional topics may be discussed as time allows.

WEDNESDAY AFTERNOON, 20 MAY 2009 PARLOR B/C, 1:00 TO 2:30 P.M.

Session 3pMUa

Musical Acoustics: Acoustics of Bagpipes

D. Murray Campbell, Chair
School of Physics and Astronomy, Univ. of Edinburgh, Edinburgh EH9 3JZ, U.K.

Chair's Introduction—1:00

Invited Papers

1:05

3pMUa1. An introduction to bagpipes of the world. Paul A. Wheeler (Dept. of Elec. & Comput. Eng., Utah Stat Univ., 4120 Old Main Hill, Logan, UT 84322-4120)

When one hears the term "bagpipe," the Great Highland bagpipe from Scotland comes to mind. There are actually several types of bagpipes played across Europe and the Middle East, each with its unique characteristics. This paper classifies bagpipes from around the world based on their construction and acoustic properties. These include: method of filling the bag (bellows versus mouth pipe), bag properties and materials, reeds (single or double), pipes used for chanters and drones (cylindrical or conical), and general characteristics of the instrument. The objective of this overview paper is to provide the background for more detailed papers in the session on bagpipes.

1:30

3pMUa2. A brief history and acoustical analysis of the great highland bagpipe. Stanley A. Cheyne (Dept. of Phys. and Astronomy, Hampden-Sydney Coll., Hampden-Sydney, VA 23943)

A brief history and analysis of the great highland bagpipe will be discussed. Although the bagpipe may have originated several thousands of years ago, the great highland bagpipe, distinguished by three drones and a chanter, is only a few hundred years old. A discussion of the components and operation will be given. In addition, spectral analysis of the drones and chanter will be discussed and how the harmonic content of the drones support the notes played on the chanter. A spectral analysis and sound pressure levels of chanter reeds of varying ages, strengths, and materials will also be presented.

2:00

3pMUa3. Tuning and tone quality of bagpipe drones. R. Dean Ayers (Phys. Dept., Southern Oregon Univ., 1250 Siskiyou Blvd., Ashland, OR 97520, ayersr@sou.edu) and Peter R. Nordquist (Southern Oregon Univ., Ashland, OR 97520)

Tunes are played on the Great Highland bagpipe using the tone holes of its conical chanter. The much quieter practice chanter has holes with the same spacings on a narrow cylindrical bore. Differences between spherical waves in a cone and plane waves in a cylinder give rise to striking differences in pitch and tone quality. Drone pipes do not need to fit into either the conical family or the closed-pipe family of reed woodwinds, because each drone produces only one note. A bass drone has three cylindrical segments, with diameters that increase in sequence, followed by an expansion chamber (bell and constricting cap) at the output end. Tuning slides between the cylinders create two additional expansion chambers with large diameters and adjustable lengths. (A tenor drone has two cylinders and one tuning slide.) Sound waves incident from either direction experience strong reflections at each jump in diameter, resulting in uneven standing waves and irregular input impedance curves that would be impractical for pipes with tone holes. Experimental results and computer models are used to relate the shape of a drone's air column to its tuning and tone quality. [Work supported by the Paul S. Veneklasen Research Foundation.]

Session 3pMUb

Musical Acoustics: Bagpipe Lecture and Concert

D. Murray Campbell, Chair
School of Physics, Univ. of Edinburgh, Edinburgh EH7 3JE, UK

Kevin Carr, a bagpipe performer will demonstrate and discuss various bagpipes from around the world.

Session 3pPA

Physical Acoustics: Influence of Temperature on Sound in Condensed Matter

Albert Migliori, Chair
Los Alamos National Lab., Los Alamos, NM 87545

Chair's Introduction—12:55

Invited Papers

1:00

3pPA1. Precise sound velocity measurements on solids and liquids at high pressure and high temperature with direct length measurement. Baosheng Li (Mineral Phys. Inst., Stony Brook Univ., Stony Brook, NY 11794, Baosheng.Li@sunysb.edu)

Sound velocity measurements at pressure and/or temperature provide important information in the material's structural behavior and physical properties under extreme conditions. With the application of synchrotron X-radiation sources, new developments have emerged to facilitate the study properties and structures of crystalline and amorphous materials. In the last decade, we have developed a unique technique for measuring sound velocity in a cubic type multianvil apparatus installed at X-17B2, National Synchrotron Light Source (NSLS) of Brookhaven National Lab, which allows us to conduct precise velocity measurements on crystalline and noncrystalline materials at various pressure and temperature conditions by conducting simultaneous X-radiation and ultrasonic interferometry measurements. In this paper, sound velocities at high temperatures for some ceramics and metals are measured to study the behavior and property change of these materials undergoing compression/expansion as well as phase transition and structural instabilities. This technique opens new opportunities for the study of materials that are of interest to many disciplines, such as earth science, materials science, and condensed matter physics.

1:25

3pPA2. The influence of grain structures on resonance behavior near phase transitions. Timothy W. Darling, Gunes Kaplan (Phys. Dept.-NTF Univ. of Nevada, 1664 N. Virginia St., Reno, NV 89557), James A. TenCate (Los Alamos Natl. Lab., Los Alamos, NM 87545), Ruth E. A. McKnight, and Michael A. Carpenter (Univ. of Cambridge, Downing St., Cambridge, UK)

Inhomogeneities such as grains or plastically deformed regions in materials locally change sound wave velocities and introduce scatter in the pattern of expected resonance frequencies. The accompanying variation in the components of the free energy may promote, or block, nucleation and growth of new phases near transition temperatures. Lanthanides and martensites are two groups of materials with complex phase structures where control of the phase transformation is important in technological applications. Complex oxide minerals with a wide variety of phase structures are important in understanding the behavior of the earth's crust. The influence on mechanical resonances of both the micro (meso) structures and the appearance and growth of phases near transition temperatures will be discussed. Experimental data on resonance behavior in inhomogeneous materials (largely lanthanides, transition metals, and silicates), where attempts have been made to control the scale and type of microstructure as they approach phase transitions will be presented. [This work receives support from DOE Grant No. DE-FC52-06NA27616 through the University of Nevada Terawatt Facility.]

1:50

3pPA3. Temperature dependence of elastic moduli for polycrystalline Pu: Comparison of alpha and gamma phases. I.R. Stroe (Worcester Polytechnic Inst., 100 Institute Rd., Worcester, MA 01609, izabela@wpi.edu), J. B. Betts, C. Pantea, A. Trugman, J. N. Mitchell, M. Ramos, F. Freibert, C.H. Mielke, and A. Migliori (Los Alamos Natl. Lab., Los Alamos, NM 87544)

The elastic properties of pure polycrystalline Pu were investigated as a function of temperature by resonant ultrasound spectroscopy. For both alpha and gamma phase, shear (G) and longitudinal (CL) elastic moduli were determined simultaneously and the bulk modulus (B) was computed from them. In alpha phase, G and B exhibit the same temperature dependence, but an unusually large change. This behavior together with a high Gruneiser parameter and an almost temperature independent Poisson ratio is attributed to the 5-f electron localization delocalization. In the gamma phase, G and B show anomalous temperature behavior: G decreases with temperature while B is near temperature independent. The Poisson ratio increases with temperature by 4%. This normal behavior of the Poisson ratio is unusual for Pu.

2:15

3pPA4. Stability of monitoring weak changes in multiply scattering media with ambient noise correlation: Laboratory experiments. Larose Eric, Hadziioannou Celine, Coutant Olivier, Roux Philippe, and Campillo Michel (Lab. de Geophysique interne et Tectonophysique, CNRS & Univ. J. Fourier, Grenoble, France)

Previous studies have shown that small changes can be monitored in a scattering medium by observing phase shifts in the coda. Passive monitoring of weak changes through ambient noise correlation has already been applied to seismology, acoustics, and engineering. Usually, this is done under the assumption that a properly reconstructed Green function as well as stable background noise sources are necessary. In order to further develop this monitoring technique, we performed a laboratory experiment in the 2.5 MHz range in a gel with scattering inclusions, comparing an active (pulse-echo) form of monitoring to a passive (correlation) one. Our results show that temperature changes in the medium can be observed even if the Green function (GF) of the medium is not reconstructed. Moreover, we establish that the GF reconstruction in the correlations is not a necessary condition: the only condition to monitoring with correlation (passive experiment) is the relative stability of the background noise structure.

2:30

3pPA5. Temperature variation of Young's modulus and elastic wave speed in a mixture of solid-particles in liquid. Hasson M. Tavossi (Dept. of Phys., Astronomy and Geosciences, Valdosta State Univ., 1500 No. Patterson St., Valdosta, GA 31698)

The variation of ultrasonic wave speed in the solid-liquid mixtures as a function of temperature is studied. The goal of this investigation is to determine temperature dependence of the elastic moduli of materials consisting of different size solid particles. The elastic wave speed in solids is assumed to be proportional to the square root of Young's modulus of the material. Elastic wave speed in the material is related to the variation of Young's modulus of the solid constituents. Also considered are temperature dependence of the wave attenuation, by scattering and absorption, and the effects of phonon modes, their amplitude and frequency, on the elastic moduli and wave dispersion in the material. Previous experimental data have shown a decrease in elastic moduli at the contact points of solid particles with increase in elastic wave frequency. Findings on the variations of elastic wave speed in solids with temperature and frequency are compared to analyze any similarity between the effect of wave frequency increase and temperature increase.

2:45

3pPA6. Resonant ultrasound spectroscopy studies of Fe-based superconductors. Veerle Keppens, Lindsey VanBebber, Yanbing Luan (Dept. Mater. Sci. and Eng., The Univ. of Tennessee, Knoxville, TN 37996), Michael A. McGuire, Athena Sefat, Brian C. Sales, and David Mandrus (Oak Ridge Natl. Lab., Oak Ridge, TN 37831)

The discovery of high superconducting transition temperatures in Fe-based compounds has generated a frenzy of experimental and theoretical research activities on these systems. Whereas doping is required to establish superconductivity, careful studies of the undoped materials are important to elucidate the underlying physics. Recently, resonant ultrasound spectroscopy measurements were carried out on the undoped oxypnictide system LaFeAsO as well as the oxygen-free systems $BaFe_2As_2$ and $Ba(Fe, Co)_2As_2$. The elastic response of the parent compounds shows a very gradual softening corresponding to the structural transition that characterizes these systems. Remarkably, this softening persists in the superconducting samples, even though the structural transition in these compounds is suppressed.

Session 3pSC

Speech Communication: Lexical Effects and Perceptual Processing in Speech (Poster Session)

Eric A. Vatikiotis-Bateson, Chair
Dept. of Linguistics, Univ. of British Columbia, Vancouver, BC V6T 1Z1, Canada

All posters will be on display from 1:00 p.m. to 3:20 p.m. To allow contributors an opportunity to see other posters, all contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 2:10 p.m. and contributors of even-numbered papers will be at their posters from 2:10 p.m. to 3:20 p.m.

Contributed Papers

3pSC1. Phonetic experience with specific words affects categorical perception of those words. Mark VanDam (Boys Town Natl Research Hospital, 555 N. 30 St., Omaha, NE 68131, vandamm@boystown.org) and Robert F. Port (Indiana Univ., Bloomington, IN 47405)

How does experience with specific words influence linguistic-phonetic categories? Listeners were trained over a five-session, listen-and-repeat task on a set of target words embedded in continuous speech and altered so that the initial stop consonant voice-onset time (VOT) was 80% longer than natural. Voicing boundaries were estimated before and after training using a two-alternative, forced-choice perceptual task on an eight-step VOT continuum. Stimuli were highly natural tokens by two stimulus talkers. Part 1 of the experiment asked whether exposure to lengthened forms would influence location of the voicing boundary, and, if so, whether that effect would generalize to similar forms. Results showed longer boundaries after exposure to lengthened VOTs for the trained forms, but lengthening did not generalize to new forms. Part 2 investigated voicing boundary locations as a function of lexical status (word, nonword) and usage frequency (high, low). Boundary locations indicated expanded VOT regions both for nonwords over words (opposite to the Ganong effect) and for high-frequency words over low-frequency words; neither lexical status nor usage frequency interacted with training. Results suggest a lexical sensitivity to low-level speech cues, thus offering support for a rich memory language model.

3pSC2. Were we or are we? Perception of reduced function words in spontaneous conversations. Natasha Warner, Dan Brenner, Anna Woods (Box 210028, Univ. of Arizona Dept. of Linguist., Tucson, AZ 85721-0028), Bejamin V. Tucker (Univ. of Alberta, Edmonton, AB, Canada T6G 2E7), and Mirjam Ernestus (Univ. Nijmegen, Nijmegen AH6500, the Netherlands)

Spontaneous, reduced pronunciations diverge greatly from citation forms. The quality of a single segment can change, e.g., /b/ in "about" surfacing as an approximant. But sounds, syllables, and entire words can also be deleted (e.g., "do you have time?" as [djutEm] with no acoustic trace of "have"). This work investigates the perception of reduced function words such as "he was" or "we were." Twenty-two young American English speakers' spontaneous conversations with close acquaintances were recorded. From these, we selected utterances containing items such as "he's/he was, we're/we were, got him/got them." When hearing an entire utterance, native listeners may clearly perceive "we were," but on hearing just the "we were" portion, they perceive an unambiguous "we're." The portion of the signal presented to listeners is manipulated to determine the contributions of local acoustic cues, speech rate and coarticulation, semantic and syntactic information, and overall bias toward present vs past tense. An auditory and a written task are also compared to separate the contribution of intonation from that of syntax/semantics. These results begin to elucidate the interplay of information sources listeners draw upon when parsing spontaneous speech. Future work will compare to non-native listeners' perceptions.

3pSC3. The roles of tone and syllable structure in Mandarin spoken word recognition. Yuwen Lai (Dept. of Linguist., Univ. of British Columbia, 2613 West Mall, Vancouver, BC V6T 1Z4, Canada) and Jie Zhang (Univ. of Kansas, Lawrence, KS 66044-3177)

The present study adopts the gating paradigm to investigate the roles of tone, onset sonorancy, and nasal coda in Mandarin spoken word recognition. Duration-blocked gates generated from eight monosyllabic quadruplets with matching frequencies of occurrence were used as stimuli. The initial consonant of each syllable formed the first gate, with later gates formed by 40 ms increments. Twenty-eight native Mandarin speakers from Beijing were asked to identify each gated stimulus by writing down the Chinese characters. Isolation point (IP) based on correct tone identification as well as overall correct word identification (correct onset, rhyme, and tone) were collected. Results from both conditions showed that tone 1 has an earlier IP than tone 4, which has an earlier IP than tones 2 and 3. Sonorant-initial syllables have an earlier IP than obstruent-initial syllables, but further analyses of covariance indicated that this is due to the fact that IP covariates with the duration of the initial consonant. Syllables without a nasal coda have an earlier IP than syllables with a nasal coda. This effect might be due to the interference of nasalization on tone perception or the delayed tonal contour realization due to the nasal coda [Xu, (1998)].

3pSC4. Duration and context speech rate as cues to lexical perception and word segmentation. Molly J. Henry, Laura C. Dilley, Louis N. Vinke, and Christopher J. Weinland (Dept. of Psychol., Bowling Green State Univ., Bowling Green, OH 43403, mjhenry@bgsu.edu)

Duration and speech rate are traditionally assumed to be filtered out before lexical lookup takes place, although these factors are known to influence phoneme perception. Here, the hypothesis was investigated that duration can affect both perceived lexical identity, as well as the perceived number and implied locations of word boundaries relative to the speech signal. Experiment 1 was a production study which investigated durations of vocalic portions of phonetically similar versions of target word strings which differed in their number of syllables (e.g., cease versus see us); these target word strings were spoken in semantically neutral context sentences. As expected, vocalic durations in target strings with fewer syllables were shorter than those with more syllables. In Experiment 2, the relative durations of vocalic portions of target strings in sentences from Experiment 1, as well as sentential context speech rate, were manipulated using speech resynthesis. Relative duration and context speech rate both affected the words that participants heard, as well as the implied number of phonemes and imputed locations of word boundaries. These findings indicate that duration plays a significant and underinvestigated role in spoken word recognition and word segmentation.

3pSC5. The spread and density of the phonological neighborhood can strongly influence the verbal transformation illusion. James A. Bashford, Jr., Richard M. Warren, and Peter W. Lenz (Dept. of Psychol., Univ. of Wisconsin-Milwaukee, P.O. Box 413, Milwaukee, WI 53201)

When a recorded verbal stimulus repeats over and over, adaptation occurs and listeners hear competing forms. Reports of these "verbal transformations" (VTs) were obtained for 36 consonant-vowel (CV) syllables that varied both in frequency-weighted neighborhood density (ranging from 12.73 to 90.42) and in neighborhood spread [i.e., for 18 CVs, changes at either phoneme position could yield real words (spread = 2) while for the remaining 18 CVs, changes at only one position could yield words (spread

$= 1)$]. The strength of the VT illusion, measured by the amount of time the stimuli were heard nonveridically during the 300-s repetition period, decreased substantially with both increasing neighborhood density [$r=-0.74$, $F(1,34)=42.6$, $p<0.0001$] and increasing spread [$r=-0.75$, $F(1,34) = 44.1$, $p<0.0001$]. Stepwise regression revealed that density and spread collectively accounted for approximately 70% of the variance in illusion strength [$F(1,33)\geqslant 10.0$, $p<0.003$ or better]. These effects are larger than, but generally consistent with, neighborhood effects obtained with other psycholinguistic tasks, and they suggest that VTs can provide a highly sensitive measure of lexical competition. [Work supported by NIH.]

3pSC6. Using auditory feedback during vocalization: Different mechanisms for utterance onset and pitch maintenance. Colin S. Hawco and Jeffery A. Jones (Dept. of Psych., Wilfrid Laurier Univ., 75 University Ave. West, Waterloo, ON N2L 3C5, Canada)

During vocalization, auditory feedback is used to attain and maintain a desired fundamental frequency (F0). The use of auditory feedback to control vocalization has been studied using adaptation studies, in which an F0 feedback alteration is maintained across many trials, and using midutterance perturbations, where a brief F0 change is introduced during an ongoing utterance. Participants vocalized during two blocks. In an adaptation block, a one semitone F0 shift was maintained for 40 trials, and midutterance perturbations were introduced by removing the feedback alteration. In a control block, a midutterance perturbation was introduced in trials, which were either unshifted or shifted randomly by one semitone at before the onset of vocalization (similar to the adaptation trials). F0 compensation to midutterance perturbations was identical in all conditions, and was always smaller than the compensation to a shift at utterance onset. These results are explained by a change in the control strategy at utterance onset and midutterance. At utterance onset, auditory feedback is compared to feedback predicted by a forward model to ensure the pitch goal is achieved. However, after utterance onset, the control strategy switches and stabilization is maintained by comparing feedback to previous F0 production.

3pSC7. Auditory-phonetic projection and lexical structure in the recognition of sine-wave words. Robert E. Remez, Kathryn R. Dubowski, Robin S. Broder, Morgana Davids, Yael S. Grossman, Marina Moskalenko, Jennifer S. Pardo, and Sara Maria Hasbun (Dept. of Psych., Barnard College, Columbia Univ., 3009 Broadway, New York, NY 10027, remez @columbia.edu)

Speech remains intelligible despite the elimination of canonical acoustic correlates of phonemes from the spectrum. Listeners tolerate distortion or spectral blur in tone analogs, noise band vocoded speech, and acoustic chimeras in utterances ranging from syllables to isolated words and sentences. A portion of this flexibility is attributable to short-term perceptual learning in auditory-to-phonetic projection, though exploiting the properties of lexical neighborhoods plays a role with utterances composed of words. New tests were conducted to estimate talker learning, segmental sensitivity, and lexical knowledge in this kind of perceptual versatility. Sine-wave versions of the easy/hard word lists were created, and the performance-level difference between the two lists was used to index the default reliance on lexical processes. Several kinds of preliminary exposure were used to induce sensitivity to a dimension of perceptual learning: sine-wave speech produced by the same talker, sine-wave speech of a different talker, natural speech of the same talker. A comparison of exposure effects on the performance level of easy/hard word recognition offered a clue about the differential contribution of talker-based, segment-based, and lexically-based attention in speech perception without canonical spectra. Implications for perceptual accounts based on cue likelihood will be discussed. [Work supported by NIDCD.]

3pSC8. Function words of lexical bundles: The relation of frequency and reduction. Shannon F. Lemke, Antoine Tremblay, and Benjamin V. Tucker (Dept. of Linguist., Univ. of Alberta, 4-32 Assiniboia Hall, Edmonton, AB, Canada, T6G 2E7, sflemke@ualberta.ca)

Studies of spontaneous speech have shown frequency effects on the amount of reduction produced by speakers, demonstrating that predictability facilitates production of a target word [Shi *et al.* (2005); Jurafsky *et al.* (2001); Bell *et al.* (2003)]. This paper investigates the amount of reduction produced in laboratory recorded speech and considers the effect of frequency on the duration of function words in four-word sequences. It is also found that the influence of frequency has an effect on holistically storing these bundles. An interaction between word position and the third-order transitional probability (ABC $\rightarrow$ D) has been established, indicating that greater third-order transitional probabilities predict shorter function word durations in the first and second positions of a bundle, and, therefore, involve more durational reduction. The current research shows that, just as frequency affects reduction in spontaneous speech, there is an effect in laboratory produced speech as well. These findings indicate that multiword sequences are stored as lexical units.

3pSC9. Basic word segmentation abilities emerge earlier in infancy than previously thought. Elizabeth K. Johnson (Dept. of Psych., Univ. of Toronto Mississauga, 3359 Mississauga Rd. North, Mississauga, ON L5L 1C6, Canada, elizabeth.johnson@utoronto.ca) and Amanda Seidl (Purdue Univ., West Lafayette, IN 47907)

English-learning 7.5- but not 6-month-olds extract word forms from fluent speech (Jusczyk *et al.*, 1999). Thus, English learners are thought to begin segmenting words from speech by 7.5 months. However, recent research has shown that when target words are flanked by a frequent and emotionally salient word (e.g., the infant's name), even 6-month-olds can extract words from speech (e.g., Bortfeld *et al.*, 2005). This suggests that basic word segmentation capabilities may emerge earlier than past studies have suggested. Using the Headturn Preference Procedure, we tested 6-month-olds' ability to segment utterance-flanked words from speech, e.g., "geff" from "At the circus we met a silly geff." Infants were familiarized with passages containing target words in utterance initial and final position, and then tested on their recognition of these words in isolation. A significant looking time difference to familiar versus unfamiliar words was found, indicating that 6-month-olds segmented the target words from speech. Six-month-olds' success at segmenting utterance-flanked words from speech is particularly interesting because infant-directed speech consists of short utterances containing many utterance-flanked words. Segmentation of utterance-flanked words could help infants learn the cues needed to extract harder utterance-medial words from speech (see Seidl and Johnson, 2006).

3pSC10. Phonological competition during the recognition of spontaneous speech: Effects of linguistic context and spectral cues. Susanne Brouwer, Holger Mitterer, and Falk Huettig (MPI for Psycholinguistics, P.O. Box 310, 6500 AH Nijmegen)

How do listeners recognize reduced forms that occur in spontaneous speech, such as "puter" for "computer"? To this end, eye-tracking experiments were performed in which participants heard a sentence and saw four printed words on a computer screen. The auditory stimuli contained canonical and reduced forms from a spontaneous speech corpus in different amounts of linguistic context. The four printed words were a "canonical form" competitor (e.g., "companion", phonologically similar to "computer"), a "reduced form" competitor (e.g., "pupil", phonologically similar to "puter"), and two unrelated distractors. The results showed, first, that reduction inhibits word recognition overall. Second, listeners look more often to the "reduced form" competitor than to the "canonical form" competitor when reduced forms are presented in isolation or in a phonetic context. In full context, however, both competitors attracted looks: early rise of the "reduced form" competitor and late rise of the "canonical form" competitor. This "late rise" of the "canonical form" competitor was not observed when we replaced the original /p/ from "puter" with a real onset /p/. This indicates that phonetic detail and semantic/syntactic context are necessary for the recognition of reduced forms.

3pSC11. Lexical access across different voices. Rochelle S. Newman (Dept. Hearing & Speech Sci., and Program in Neurosci. and Cognit. Sci. Univ. of Maryland, 0100 Lefrak Hall, College Park, MD 20742, rnewman @hesp.umd.edu)

In many real-world situations, listeners may be trying to attend to one individual while other voices are speaking in the background. These separate streams of sound hit the ear simultaneously. Within a single stream, research has investigated the extent to which lexical activation is limited by word boundary information. For example, Gow and Gordon (1995) found that multiple-word sequences such as "two lips" may activate words such as "tulips" despite the presence of acoustic cues to a word boundary in the middle of the sequence. Yet, no studies have examined whether lexical ac-

cess could "cross" signals entirely. In a series of four experiments, we test whether lexical access might (ever) cross talker boundaries. We find that when listeners hear two words spoken by two different voices (for example, a male saying "two" followed by a female saying "lips") they still activate the larger cross-voice word "tulips," despite the presence of strong cues to an acoustic boundary. [Work supported by NSF.]

3pSC12. Speaking rate modulates lexical competition in online speech perception. Eva Reinisch, Alexandra Jesse (Max Planck Inst. for Psycholinguistics, Wundtlaan 1, 6525XD Nijmegen, The Netherlands, Eva.Reinisch@mpi.nl), and James M. McQueen (Radboud Univ. Nijmegen, and Max Planck Inst. for Psycholinguistics, Nijmegen, The Netherlands)

Durational cues are used in online word recognition to disambiguate Dutch phrases such as "een(s) (s)peer" ["on(c)e (s)pear"]: The longer the [s], the more likely listeners consider the target to be [s]-initial [K. E. Shatzman and J. M. McQueen, Perc. Psychophys. **68**, 1–16 (2006)]. Here, a series of eye-tracking experiments show that speaking rate affects perception of duration and thus modulates lexical competition online. Listeners' eye-movements were recorded while they listened to sentences such as "Ze heeft wel eens peer gezegd" ("She once said pear"). Listeners had to click on printed targets (peer) presented on a computer screen with an [s]-initial competitor (speen; "pacifier") and two unrelated distractors. When the preceding context is faster, the critical [s] should sound longer and match better the beginning of "speen." Listeners indeed looked at the [s]-initial competitors more following fast than slow contexts. The opposite was found for [s]-initial targets (sneeuw; "snow") with non-[s]-initial competitors (neef; "nephew"). Context adjacent to the target (i.e., wel eens) influenced target perception more than nonadjacent context. Nonadjacent context, however, was sufficient to modulate competition when adjacent context was spoken at the same rate as the target. Amount of nonadjacent context at a given rate affected only off line categorization.

3pSC13. The nonaccommodation of speech errors. Andrea Gormley (Inst. of Cognit. Sci. Rm. 2222, Dunton Tower, Carleton Univ., 1125 Colonel By Dr. Ottawa, ON K1S 5B6, Canada, agormley@connect.carleton.ca)

Word-form speech errors are assumed to adapt to the unintended environment. For example, in the error 'bads cat' for intended 'bad cats,' the plural marker 's' assimilates to the voicing of the 'd' in 'bad.' This phenomenon, called accommodation, provides evidence that the component responsible for errors is processed before the phonological assimilation component. Previous work on accommodation relies on the researcher to detect accommodation [D. Boomer and J. Laver, Br. J. Disord. Commun. **3**, 1–12 (1968)]. Given that these studies are prone to perceptual bias, the conclusion that accommodation is the norm remains open. An acoustic analysis of errors was conducted to re-address this question. Thirty-two nonword tongue twisters, e.g., 'tiff tivv tivv tiff,' were designed to induce voicing errors on the coda. Because vowel lengthening before voiced codas is a phonological process in English, vowel length can be measured to detect accommodation. Errors were determined for each participant by measuring coda percent voicing and vowel duration in a control condition. Results from six participants (872 errors) show that while errors do accommodate (7.6%), nonaccommodation (40.7%) occurs more frequently. This result shows that errors do occur after phonological processing. [Work supported by OGS and Carleton University.]

3pSC14. Planning time effects of phonological competition: Articulatory and acoustic data. Christine R. Mooshammer (Haskins Labs., 300 George St., New Haven, CT 06511, tine@haskins.yale.edu), Louis Goldstein (USC, CA), Mark Tiede (MIT Res. Lab of Electron., MA), Manisha Kulshreshtha (Haskins Labs.,), Scott McClure, and Argyro Katsika (Haskins Labs.,)

One major cause for speech production variability and errors is competition between phonologically similar sequences in an utterance. Since one recent model of speech production planning [Nam (2004)] also posits a systematic relation between planning time and kinematic variability, we decided to directly investigate whether competition increases planning time, i.e., whether it takes longer to initiate a sequence such as "tape cape" compared with "tape tape." Effects of competition in the onset were compared to competition in the coda (e.g., "tape take"). Results from two studies are reported: articulatory latencies from a delayed naming task recorded using EMA (four speakers), and acoustic latencies from a delayed naming task, a simple naming task, and a picture naming task (ten speakers). Latencies were significantly affected by competition, i.e., latencies were longer for items like "tape cape" and "tape take" than for "tape tape." However, no significant differences were found in competition effects between onset and coda positions. Apart from latency, overall duration increased and clusters formed across words showed less overlap. Observed effects on latency were largest for picture naming, followed by simple naming and least for delayed naming. [Work supported by NIH DC008780.]

3pSC15. Color effects in audiovisual spoken word recognition. Rachael Frush Holt, Tessa Bent (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S Jordan Ave., Bloomington, IN 47405, raholt@indiana.edu), and Luis Hernandez (Indiana Univ., Bloomington, IN 47405)

Although the importance of the visual contribution to speech perception has been known for over 50 years, strong interest in audiovisual speech perception has emerged only recently. In developing a test of audiovisual sentence recognition, white balancing and color correcting (adjusting the whites, mids, and black bandwidths to compensate for the camera's inability to fully reproduce human eyesight color spectrum) improved visual-only spoken word recognition. No differences were found in audiovisual or auditory-only modalities. Although improvement was seen across all key words, those with more visible phonemes showed the greatest improvement. To further examine the effects of color in the audiovisual modality specifically, the original speech signal was replaced with a signal-correlated noise and presented to adults in one of three conditions: non-color-corrected, color-corrected, and color-inverted. Minimal speech cues were sufficient for overcoming performance decrements due to small, but not large, color disturbances. Furthermore, in the color-corrected condition, performance in visual-only and signal-correlated noise conditions were equivalent, whereas in the non-color-corrected condition, signal-correlated noise improved performance over visual-only. The results suggest that consideration of minor color disturbances is warranted if testing visual-only perception; however, significant color disturbances can cause decrements in audiovisual conditions, as well. [Work funded by the AHRF.]

3pSC16. Perception of voiced-only and noise-vocoded speech by a language-trained chimpanzee (*Pan troglodytes*). Lisa A. Heimbauer (1527 Pangborn Station Dr. Decatur, GA 30033, lisa.heimbauer@gmail.com), Michael J. Beran, and Michael J. Owren (Georgia State Univ., Atlanta, GA 30302-5010)

The ability of human listeners to understand speech even in altered or synthetic forms is argued to be evidence of uniquely human processing abilities. However, extensive early experience with speech may also contribute to this capability. To investigate this issue two experiments were designed to test the ability of Panzee, a 22-year-old language-trained chimpanzee, to recognize words in synthetic form. Like a human child, she was reared from infancy by human caregivers who routinely spoke to her. She communicates with humans by identifying words using graphical symbols (lexigrams). Experimental training and testing were conducted with two different sets of 24 familiar words presented one-per-trial in natural, voiced-only, or noise-vocoded forms, with Panzee choosing one of four lexigrams presented on a computer monitor. Experiment 1 showed equivalent performance with words heard in natural form versus voiced-only versions, resynthesized from only voiced components of a word. Noise-vocoded words presented in Experiment 2 simulated effects of hearing using a cochlear implant and were based on amplitude-modulated noise bands. Performance with these sounds was significantly higher than chance, but also lower than with natural words. Results suggest specialized processing mechanisms are not necessary to speech perception in the absence of traditional acoustic cues.

3pSC17. Identifying the common problems of English-to-Japanese consecutive interpretations performed by Japanese intepreting students. Kinuko Takahashi (Sophia Univ. #306, 4-1-10, Dai, Kamakura-city 247-0061 Japan, kinuko@dc4.so-net.ne.jp)

The purpose of the present paper is to identify the problems that Japanese interpreting students may encounter and to establish causes for them in the expectation that they may help devise a training method. It has been long wondered why some students become successful interpreters and others do not. In order to answer this question, the research was launched to identify the problems that interpreting students encountered. For this purpose, nine

interpreting students were asked to consecutively interpret four different English texts. It was discovered that the participants had a tendency for omissions of interpreting, and omissions occurred due to a number of causes. One of them was a problem of speech perception. One of the participants, for example, was not able to distinguish "breeze" from "bleed." To one of the participants, "attendance" sounded like "tendence." These problems seemed to require the participants to take more time to interpret. As a result, the participants failed to listen to the following parts, eventually making further omissions. Therefore, it is necessary for the participants to learn "top-down" processing of comprehension. However, it is necessary to examine the relation between the level of interpreting skills and speech perception ability.

3pSC18. Perceptual normalization for variation in speaking style. Antonia D. Vitela, Sarah C. Sullivan, and Andrew J. Lotto (Speech, Lang. and Hearing Sci., Univ. of Arizona, 1131 E. 2nd St., Tucson, AZ 85721, adv1@email.arizona.edu)

Ladefoged and Broadbent [J. Acoust. Soc. Am. **29**, 98–104 (1957)] demonstrated that listeners will shift their categorization of a target vowel as a function of acoustic characteristics of a preceding carrier phrase. These results have been interpreted as an example of perceptual normalization for variability resulting from differences in talker anatomy. The present study examined whether listeners would normalize for acoustic variability resulting from differences in speaking style within a single talker. Two vowel series were synthesized that varied between central and peripheral vowels (the vowels in "beat"-"bit" and "bod"-"bud"). Each member of the series was appended to one of four carrier phrases that were spoken in either a "clear" or "reduced" speech style. Participants categorized vowels in these eight contexts. A reliable shift in categorization as a function of speaking style was obtained for three of four phrase sets. This demonstrates that phrase context effects can be obtained with a single talker. However, the directions of the obtained shifts are not reliably predicted on the basis of the speaking style of the talker. Instead, it appears that the effect is determined by an interaction of the average spectrum of the phrase with the target vowel. [Work supported by NIH-NIDCD.]

3pSC19. Neural dynamics of speech perception: Phonemic restoration in noise using subsequent context. Sohrob Kazerounian and Stephen Grossberg (Dept. of Cognit. and Neural Systems, Boston Univ., 677 Beacon St., Boston, MA, 02215, sohrob@cns.bu.edu)

Phonemic restoration describes a class of auditory illusions during which broadband noise replacing a deleted phoneme can cause the perceptual restoration of the deleted phoneme. Phonemic restoration exemplifies the brain's ability to complete and understand speech and language in noisy environments. It also clarifies how both past and future acoustical events can contextually guide completion of a percept that is occluded by noise, and highlights that conscious speech is due to bottom-up and top-down contextual interactions that can operate across hundreds of milliseconds. This work develops a neural model that quantitatively simulates restoration phenomena, including the forward development in time of a conscious speech percept even in cases where future events control how previously presented acoustic events are heard. The model clarifies how acoustic items are stored in short-term working memory, and how they interact reciprocally with unitized representations of item sequences, or list chunks, to generate a resonant wave of activation that embodies the consciously heard percept. Model simulations clarify why the presence of noise is necessary for restoration to occur, and why in the absence of noise a silence gap is perceived. These properties are traced to the brain's ability to rapidly and stably learn language.

3pSC20. Towards produtive language mapping: A magnetoencephalography study of letter naming. Yang Zhang (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, Minneapolis, MN 55455), Wenbo Zhang, and Joel Landsteiner (United Hospital, St. Paul, MN 55102)

This study aims to examine the sensitivity and specificity of magnetoencephalography (MEG) integrated with magnetic resonance imaging (MRI) for productive language mapping using a simple letter naming task. Six healthy adult volunteers participated after screening for handedness and medical history of speech, language, hearing, and vision. The data were collected using a 148-channel whole-head MEG system (Magnes WH2500, 4D Neuroimaging, San Diego) at the Magnetic Source Imaging Laboratory in United Hospital, St. Paul. During the recording session in a magnetically shielded room, the subjects were instructed to pay attention to the visual stimuli and articulate the letter from the English alphabet as soon as it was shown on the screen. The averaged epochs and trial-to-trial raw data were analyzed using Brain Electrical Source Analysis (BESA) and BrainVoyager software. Although visual processing of the letters showed similar temporal and spatial activation patterns, letter naming did not show uniform activation patterns in the Broca's area. Large inter-subject variability was found in terms of superior temporal, inferior parietal, motor, and supplemental motor involvement. The results are discussed with respect to the technical challenges in implementing MEG with millisecond resolution for presurgical productive language mapping and potential risks of sensorimotor and language deficits.

3pSC21. An investigation of brain activation patterns in response to speechreading. Edward T. Auer, Jr. (Dept. of Speech-Lang.-Hearing, Univ. of Kansas, 1000 Sunnyside Ave., Rm. 3001, Lawrence, KS 66045, auer@ku.edu)

The ease of recognizing spoken words on the basis of optical input alone, or speechreading, is known to systematically vary as a function of the properties of the stimulus materials. The current study investigated the relationship between cortical responses and the intelligibility of the stimulus materials. Open-set identification performance outside the magnet was used to directly measure the intelligibility of the stimulus materials presented in the magnet as well as participant speechreading ability. fMRI was used to measure cortical response to viewing spoken word stimuli that were predicted to vary in their ease of identification. Videos of spoken words were contrasted with still face images in a block-design fMRI experiment. Blocks containing sets of words predicted to be easy speechread were contrasted with blocks predicted to be difficult to speechread. Preliminary analyses of cortical response to speechreading are consistent with previous studies [Hall *et al.*, J. Cog. Neuro. **17**(6), 939–953 (2005)]. Furthermore, evidence of increased activation in BA 37 and BA 44 for easy words versus hard words was obtained. These results are consistent with the hypothesis that specific areas are sensitive to the intelligibility of speech read stimuli. [Work supported by a grant from NIH/NIDCD (R01DC04856).]

3pSC22. Domain-specific processing of Mandarin tone. Yue Wang (Dept. of Linguist., Simon Fraser Univ., Burnaby, BC, Canada, V5A 1S6), Dawm Behne (Norwegian Univ. of Sci. and Technol., Trondheim, Norway), Angela Cooper, and Jung-yueh Tu (Simon Fraser Univ., Burnaby, BC, V5A 1S6 Canada)

Lexical tone has generally been found to be processed predominantly in the left hemisphere. However, given that tone is carried by a syllable or a word with segmental information and distinctive meaning, the processing of tone may not be easily disentangled from that of the phonetic segments and word meaning [P. Wong, Brain Res. Bull. **59**, 83–95 (2002)]. Indeed, previous research has not examined the lateralization of tone independent of segmental and lexical semantic information. The present study explores how syllable-based tonal processing in Mandarin Chinese interacts with these different linguistic domains. Using dichotic listening, native Mandarin participants were presented with monosyllabic tonal stimuli constructed with the following different linguistic attributes: (1) real Mandarin words with tonal, segmental phonetic, and lexical semantic information; (2) Mandarin nonwords with tonal and segmental, but no semantic information; (3) nonwords with non-Mandarin segments (i.e., no native segmental or semantic information); and (4) hums of tones (acoustic pitch information) without any segmental or semantic components. Results from these conditions show significant differences in lateralization patterns and are discussed in terms of the integration of acoustic as well as pre- and post-lexical linguistic domains in lexical tone processing. [Work supported by NSERC.]

3pSC23. Mismatch negativity reflects the affect of training on speech perception. McNeel Gordon Jantzen and Katherine Cella (Dept. of Psych., Western Washington Univ., 516 High St., Bellingham, WA 98225)

An adult's ability to perceive speech sounds that do not occur in their native language is influenced by the relationship between the new and native language phonology and by the individual's capacity to perceive acoustic differences. Individual differences are important: even after phonetic train-

ing, adults with similar language backgrounds exhibit significant individual differences in their ability to learn difficult non-native speech sounds [Polka (1991); Pruitt, Strange, Polka, & Aguilar (1990)]. Neurophysiologic changes due to learning are also reflected in the mismatch negativity (MMN) response and are indicative of the effects of training [Naatanen *et al.* (1993) and Kraus *et al.* (1995)]. The present experiment included two groups of six normal-hearing monolingual American-English speakers. The experimental group was trained to identify a voiced, unaspirated, dental stop consonant. The control group received no training on the dental. Electrophysiologic responses were measured for both groups in response to the dental and alveolar contrasts using a perceptual mapping procedure. Training improved the experimental group's ability to perceive the non-native contrast. Training effects were also reflected in the MMN response, as observed by increased duration and decreased onset latency.

3pSC24. The interaction of location with acoustic scale in concurrent speech recognition. David T. Ives, Martin D. Vestergaard, and Roy D. Patterson (Dept. of Physio., Development and Neurosci., Univ. of Cambridge, Downing St., Cambridge CB2 3EG, UK)

Location and acoustic scale cues have been shown to have a significant effect on the recognition of speech in multispeaker environments. The interaction of these two cues is less well understood. In this study, subjects are presented with two triplets of concurrent speech syllables with similar temporal envelopes, and asked to recognize a specific target syllable. The task was made more or less difficult by changing the location of the distracting speaker, the scale difference between the two speakers and the relative level of the two speakers. Scale differences were produced by changing the vocal tract length and glottal pulse rate of resynthesized speech: 32 scale differences were used. Location cues were produced by convolving heat-related transfer functions with the stimulus. The target speaker was located directly to the front of the listener and the distracting/masking speaker located from one of five locations (0, 4, 8, 16, 32 deg) on the 0 deg horizontal plane. Target-to-masker ratios of 0 and −6 dB were used. The results show that direction and scale differences cues do interact and this interaction is greatest when directional and speaker scale cues are small. [Research supported by the U.K. Medical Research Council (G0500221, G9900369).]

3pSC25. Does training improve consistency of roughness judgments in a matching task? David A. Eddins (Dept. of Otolaryngol., Univ. of Rochester, 2365 S. Clinton Ave., Rochester, NY 14618, David_Eddins@URMC.Rochester.edu), Rahul Shrivastav, and Sona A. Patel (Univ. of Florida, Gainesville, FL 32611)

Shrivastav *et al.* [J. Acoust. Soc. Am. **119**(5), 3340 (2006)] reported a matching task in which a square wave modulated sawtooth wave (signal) was matched to a series of vowels (standards) to estimate the magnitude of roughness in voices. Results suggested that listeners found it difficult to isolate roughness from other voice quality dimensions such as breathiness. In the present experiment, a brief training session was added prior to the matching task to ensure that listeners were attending to variations in roughness alone. This training consisted of a rank-ordering task in which listeners sorted the 34 test samples of the vowel /a/ in ascending order of roughness. For feedback, these rankings were compared to the rankings made by expert listeners. This criterion was used to ensure that all participants understood the dimension of voice quality under study. Listeners who met a specific eligibility criterion completed a modulation matching task to familiarize them with the matching task itself. Finally, thresholds for the roughness matching task were obtained and compared to thresholds obtained without training. The extent to which task-related training can help listeners make perceptual judgments for specific dimensions of voice quality will be discussed.

3pSC26. Masking release at low sensation levels. Peggy Nelson, Elizabeth Anderson Crump, Yingjiu Nie, and Michelle Hawkinson-Lewis (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr. SE, Minneapolis, MN 55455, peggynelson@umn.edu)

Previous results have shown that listeners with sensorineural hearing loss (SNHL) obtain about half of the masking release of their normal-hearing (NH) counterparts. When speech is amplified sufficiently, listeners with SNHL may score like NH listeners in quiet and in steady noise, yet may obtain only half of the expected release from gated noise. We hypothesize that some of that deficiency may occur because of the impaired listeners' low speech sensation levels, which results in decreased usefulness of the speech signal in the noise dips. In the current study, NH listeners were tested for their recognition of IEEE sentences in quiet, in steady noise, and in gated noise with the speech presented at varying sensation levels. At low levels (10–15 dB SL), NH listeners scored nearly 100% correct in quiet. In steady noise (at −10 dB signal-to-noise ratio) scores for low-level stimuli were also similar to those obtained at higher SLs. However, at low SLs in gated noise, NH listeners demonstrated less masking release than expected, suggesting that audibility of speech in the dips of noise is important for masking release even when performance in quiet and in steady noise seems optimized. [Work supported by NIH 5R01DC008306.]

3pSC27. Listening to natural versus cell phone speech on multiple simultaneous tasks. Srinivasan Nirmal Kumar (Dept. of Special Educ. and Commun. Disord., Barkley Memorial Ctr., Univ. of Nebraska-Lincoln, Lincoln, NE 68583) and Carrell Thomas (Univ. of Nebraska-Lincoln, Lincoln, NE 68583)

In typical listening environments, attention is often divided and may have different effects on automatic and controlled processes. Automatic processing is a fast, parallel process not limited by short-term memory, requires little subject effort, but requires extensive consistent training to develop. Controlled processing is a comparatively slow, serial process limited by short-term memory, requires subject effort, and little training to develop [Schneider and Shiffrin (1977)]. In the present study a methodology was developed to examine effects of controlled and automatic distracters on the perception of distorted speech. Specifically, perception of natural and cell phone speech was investigated while listeners performed simultaneous visual and motor tasks. Young, normal-hearing native speakers of English were presented with SPIN sentences [Kalikow *et al.* (1977)] in a background of multitalker babble [Bilger *et al.* (1984)] using natural and cell phone speech. Prior to the start of the experiment, participants had been trained on visual task using either consistent mapping technique or varied mapping technique. Word recognition scores, pursuit rotor performance, and visual task performance were compared for natural and cell phone speech. The relationship between consistently mapped and variably mapped distracters on perceptual and behavioral performance provides information necessary for more detailed models relevant to real-world environments.

3pSC28. Seeing a speaker's face helps stream segregation for younger and elderly adults. Alexandra Jesse (Max Planck Inst. for Psycholinguistics, Wundtlaan 1, 6525 XD Nijmegen, The Netherlands, Alexandra.Jesse@mpi.nl) and Esther Janse (Utrecht Inst. of Linguist. OTS and Max Planck Inst. for Psycholinguistics, Nijmegen, The Netherlands)

Listening to a speaker while hearing one or more competing speakers in the background can be a challenging task, especially for elderly adults. We show that younger and elderly listeners (above the age of 65) with varying degrees of age-related hearing loss benefit in stream segregation and speech processing from seeing the target speaker talk in addition to hearing an audio mix of a target and a competing speaker. This audiovisual benefit was found for response accuracy and speed in a phoneme monitoring task, where participants indicated by button press the occurrence of given target phonemes in the monitored speech of the target speaker. The audiovisual benefit was larger for younger than for older adults, despite their equivalent performance on auditory-only trials and in an off-line phoneme lip-reading task. Better lip-reading performance, however, predicted a larger audiovisual benefit. The audiovisual benefit was found for both highly visible phonemes (/p/) and poorly visible phonemes (/k/), but was modulated in its size by segmental visibility. The audiovisual benefit therefore arises from local segmental visual information but is also at least partially driven by audiovisual synchrony information that aids in attending to the target speaker.

3pSC29. The eyes' footprints on the ears: An investigation of short-term speech intelligibility change. Jing Liang (Dept. of Psych. and Ctr. for Cognit. and Social Neurosci., Univ. of Chicago, 5848 S Univ. Ave., Chicago, IL 60637, liang@uchicago.edu), Steven L. Small, and Howard C. Nusbaum (Univ. of Chicago, Chicago, IL)

Although observation of mouth movements improves auditory speech perception, the extent to which visual information aids speech perceptual learning and affects subsequent audio-only speech perception remains

unknown. The current study investigates whether visual speech information, specifically, the synchronized mouth movements of the talking face during training, helps the listener to perceive audio-only speech more effectively after training. An experimental group was trained to recognize audiovisual words presented in noise, while a control group was trained on the same audio speech signal in noise, but with no accompanying mouth movements. The control group provides a baseline estimate of what listeners can learn from the speech signal alone without visual information from the talker's mouth movements. Both groups were tested on audio-only speech in noise before and after training. All novel words were used in the pretest, training, and posttest. The results demonstrate that visual information aids learning to recognize audio-only speech in noise, suggesting visual information from a talker's mouth movements during training might change auditory coding of acoustic speech signals.

3pSC30. Effects of audio-visual speech information on recognition memory of spoken words. Kauyumari Sanchez, Rachel M. Miller, and Lawrence D. Rosenblum (Dept. of Psych., Univ. of California, Riverside, 900 University Ave., Riverside, CA 92521)

Audio-visual speech has generally been found to contain more usable information than audio-only speech. However, there is conflicting evidence of whether seeing the face of a speaker facilitates memory for spoken words [e.g., Sheffert *et al.*, Cog. Tech. **8**, 42–50 (2003)]. To address this issue, three experiments examined whether an audio-visual benefit would be observed on a word recognition task. Experiment 1 compared recognition of spoken words both presented and tested in audio-visual versus audio-only forms. Audio-visual word stimuli were recognized significantly better than audio-only words. Experiment 2 tested whether this benefit was due to the presence of visible articulatory information or simply more information in general. Recognition of words presented (and tested) in audio-only, audio-visual, and audio with accompanying static face image conditions were compared. Words presented in audio-visual (dynamic face) form were recognized better than audio-only and audio-static face stimuli. To test whether the benefit of audio-visual presentation was due to encoding, retrieval, or both, Experiment 3 crossed presentation modality (audio-only versus audio-visual) from presentation to test phases. Results showed that the audio-visual form is required in both encoding and retrieval to be beneficial.

3pSC31. Influence of visual speech information on the identification of foreign accented speech. Rebecca K. Reed and Edward T. Auer, Jr (Dept. of Speech-Lang.-Hearing, Univ. of Kansas, 1000 Sunnyside Ave., Rm. 3001, Lawrence, KS 66045, rxxr@ku.edu)

Seeing a native talker's face improves speech intelligibility in noise for native perceivers. The intelligibility of foreign accented speech (English spoken by native talkers of Mandarin) is more susceptible to the effects of noise than the speech of native talkers. [Rogers *et al.*, Lang Speech 47(2), 139–154 (2004)]. The current experiment investigated the influence of seeing the non-native talker's face on the intelligibility of speech presented in noise. Ten talkers (nine non-native and one native) were recorded producing 155 sentences each. Talker-specific speech shaped noise was mixed with the audio of the sentences. Eighty-one native perceivers of English (nine per non-native talker) responded to 20 sentences spoken by the native talker and 28 by the non-native talker in each condition (audio-alone, visual-alone, audiovisual). Open set identification responses were scored as percent words correct for each condition and talker. Preliminary analyses demonstrate that although seeing the non-native talker increases intelligibility, the gain is significantly reduced compared to the native talker. Results will be discussed in terms of potential sources of the audiovisual gain. These sources are hypothesized to be differentially sensitive to the distortions arising in non-native speech. [Work supported in part by NIH/NIDCD DC04856 and the University of Kansas, UGRA.]

3pUW1. Propagation focusing in the context of clutter statistics. Chris Harrison (NURC, Viale S. Bartolomeo, 400, 19126 La Spezia, Italy, harrison @nurc.nato.int)

Fluctuations in reverberation (clutter) from scatterers at long range in shallow water can be affected by many mechanisms. Their statistics, in particular the scintillation index, depend not only on the statistics of the scatterers (their physical distribution, shape, orientation, etc.) but on the outward and return propagation paths. Focusing effects due to forward scattering from weak undulations in the seabed will be presented. Existing Fresnel–Kirchhoff theory for monostatic, vertical incidence on a two-dimensional surface is adapted to demonstrate the behavior of the intensity's scintillation index in bistatic geometry. In addition, using a simulation of bistatic geometry and a one-dimensional surface, the intensity statistics are extended to include autocorrelation function and probability distribution. Bistatic geometries include source and receiver moving with constant separation, and moving source with fixed receiver. Fairly modest vertical undulations can result in significant fluctuation due to reflection focusing with scintillation indices possibly greater than unity.

Invited Paper

3pUW2. Estimating higher moments of shallow water reverbation for non-Gaussian scatterer distributions. Kevin D. LePage (NATO Undersea Res. Ctr., Viale San Bartolomeo 400, 19126 La Spezia, Italy)

Reverberation is described as a random process by which deterministic propagation components weight and sum scattering amplitudes over the sonar footprint. A method of estimating the second, third, and fourth monents of the scattered field pressure is described for scatterers which have a Chi Squared model for the amplitude pdf. Comparison of theoretical estimates of the fourth moment to Monte Carlo estimates of the same quantity obtained using a NRL 2-way parabolic equation PERM show good agreement. [Work supported by ONR.]

3pUW3. Measurement and modeling of broadband Bragg scattering from a sinusoidal surface. Dajun Tang and Darrell R. Jackson (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, djtang @apl.washington.edu)

While the mechanism of Bragg scattering is well known, most experimental work has been concentrated in the area of narrow band sound sources and in the far-field. Motivated by underwater detection problems in the presence of sediment ripple fields, we report laboratory measurements of broadband sound scattering from a sinusoidal surface machined on a polyurethane board. The surface has a wavelength of 8 mm and peak-to-peak height of 2 mm. Coherently scattered sound data were taken in near-field geometries and in the frequency band of 150–400 kHz. The measurement geometry is such that a broad range of Bragg angles corresponding to the frequency band are covered. We observe that the scattered sound demonstrates a down chirp time dependence when the incident sound is a short pulse. Models based on first order perturbation theory were developed which explain the observed scattered sound in both magnitude and phase. In addition, we also measured second order Bragg scattering. This motivates modeling efforts on higher order Bragg scatter. [Work supported by ONR.]

1:50

3pUW4. Validation of a physical model for surface clutter. Trudy L. Philip, Bruce K. Newhall, and Juan I. Arvelo (Johns Hopkins Univ. Appl. Phys. Lab., 11100 Johns Hopkins Rd., MS 8-220, Laurel, MD 20723)

There is a strong need to more accurately represent active sonar system false contacts in various environments and conditions for the purpose of active acoustic simulation and synthetic training. A computationally viable approach for the generation of physics-based false contacts in a raw beamformed time series that can be injected into a sonar processor was previously developed for bottom clutter. That model is now extended for clutter due to rough ocean surface scattering, and is compared with ASIAEX01 data. Considerations in extending the existing model include: characterizing appropriate statistics of the rough surface, adding surface scattering clutter to the sonar model, evaluating the realism of the simulation, and evaluating the computational burden (for real-time trainers). The output of the simulation was analyzed for those considerations and then compared to the data. The use of a vertical line array allowed physical mechanisms in the data to be isolated, and their clutter data statistics separately determined. After comparing data statistics to predictions, the need for additional modeled clutter mechanisms was assessed. This effort was conducted under the auspices of the Undersea Warfare Business Area Independent Research and Development program of the Johns Hopkins University Applied Physics Laboratory.

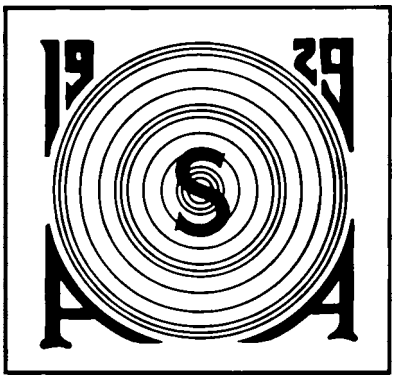
ACOUSTICAL SOCIETY OF AMERICA

R. BRUCE LINDSAY AWARD



Kelly J. Benoit-Bird

2009

The R. Bruce Lindsay Award (formerly the Biennial Award) is presented in the Spring to a member of the Society who is under 35 years of age on 1 January of the year of the Award and who, during a period of two or more years immediately preceding the award, has been active in the affairs of the Society and has contributed substantially, through published papers, to the advancement of theoretical or applied acoustics, or both. The award was presented biennially until 1986. It is now an annual award.

CITATION FOR KELLY J. BENOIT-BIRD

. . . for contributions in marine ecological acoustics

PORTLAND, OREGON• 20 MAY 2009

Kelly J. Benoit-Bird graduated from Maloney High School in Meriden, Connecticut where she was a member of the National Honor Society and was voted most likely to succeed by her classmates. She obtained a bachelor's degree with honors in 1998 from Brown University majoring in Aquatic Biology. In the fall of 1998, she enrolled at the University of Hawaii to work toward a Ph.D. in Zoology. As a graduate student, Kelly performed research on the properties of the mesopelagic boundary community, the foraging behavior of spinner dolphins, and the acoustic properties of deep dwelling Hawaiian lutjanid snappers. She earned a Ph.D. in 2003 and continued as a post doctoral fellow at the Hawaii Institute of Marine Biology, University of Hawaii, for another year.

Kelly's research while in Hawaii has involved the use of various acoustic techniques to study the ecology of the coastal ocean environment, including the sound scattering layer of micronekton in the mesopelagic boundary community around the Hawaiian Islands and the interaction of these organisms with higher trophic level predators, including spinner dolphins. She also participated in research to determine the acoustic backscatter characteristics of deep dwelling lujanid snappers, some of which are severely threatened in the main Hawaiian Islands.

In July of 2004, Kelly became an assistant professor in the College of Oceanic and Atmospheric Sciences at Oregon State University. Since that appointment, she has distinguished herself by her innovative application of multi-frequency acoustics to the investigation of the predator-prey dynamics of fish and zooplankton within planktonic thin layers. In another recent project, she demonstrated that the biomass and behavior of soft-bodied squid in the Gulf of California can be quantified with appropriate application of acoustics. She continues to push for new approaches to understanding ecological interactions across a range of spatial scales, using multibeam acoustics on autonomous underwater vehicles and well as from small vessels.

Kelly is truly one of the pioneers in the use of acoustics to address ecological issues in the marine environment. She already has 27 publications in peer reviewed journals in her young career. As a result of her skill and hard work, Kelly has made substantial contributions to the understanding of coastal ecological systems. Her contributions, together with a number of collaborators, have been reported for the first time in scientific journals. They include migration behavior of micronekton in the mesopelagic boundary community (MBC), acoustic properties of MBC organisms, interaction of spinner dolphins and MBC prey and sonar characteristics of lujanid snappers. The migration behavior was first reported in *Marine Ecology Progress Series* in 2001; acoustic properties of MBC organisms in the *Journal of the Acoustical Society of America (JASA)*, also in 2001; interaction of spinner dolphins and prey in *Behavioral Ecology and Sociobiology* in 2003 and *JASA* in 2009; and the sonar characteristics of lujanid snappers in two papers in *JASA* in 2003.

Kelly, by her outstanding use of graphics in displaying her experimental data and explaining her results, is perhaps the singular most influential individual contributing to a significant improvement in the quality of presentations in Acoustic Oceanography and Animal Bioacoustics sessions. Between the years 2000 and 2003, she won many best student paper awards at ASA meetings. It is a great accomplishment to win just one "Best Student Paper" award but to win two awards at same meeting is a unique achievement. Kelly accomplished this task not once, but twice. She also won another best student paper award in Acoustical Oceanography and she placed 2nd in Acoustical Oceanography at the First Pan-American/Iberian Meeting on Acoustics, in Cancun, Mexico. The total of five best student paper awards and one 2nd place finish is not only unheard of, but is hardly imaginable. What Kelly has achieved is absolutely unprecedented in the annals of the ASA. She was also one of the nine young presenters at the ASA's 75th Anniversary Celebration Plenary Session in New York in 2004.

Kelly's achievements have not been confined to ASA meetings. She won the Excellence in Communications Award at the 15th Biennial Conference on the Biology of Marine Mammals (by a non-student) in 2003 and the Best Young Presenter Award at the European Congress on Underwater Acoustics in 2004. Her outstanding research has won

her other awards, which include the Presidential Early Career Award for Scientists and Engineers FY 2005 (PECASE) in 2006, the Kavli Frontiers Fellowship from the National Academy of Sciences in 2007, and the Ocean Sciences Early Career Award of the American Geophysical Union in 2008.

We cannot think of anyone more deserving of the Bruce Lindsay award than Kelly Benoit-Bird.

CITATION FOR WINIFRED STRANGE

. . . for contributions to understanding speech preception.

PORTLAND, OREGON • 20 MAY 2009

Winifred Strange was born in Red Bluff, California, the younger of two girls born to Verdon Earl Strange and Winifred Rose Strange. Winifred is known by many as 'Pinky,' a nickname coined when her older sister commented on her rosy newborn appearance, and a name that persisted due to the flaming red hair and spirited personality that soon emerged. After graduating from Chico State College in California, Winifred became a graduate student in the Department of Psychology in the early 1970s, where she was acknowledged as one of the University of Minnesota's best teaching assistants. Pinky was the teaching assistant for an intense, yearlong graduate seminar taught by Professor James J. Jenkins, himself a legend at the University of Minnesota. An interdisciplinary group of graduate students interested in the new field of 'cognitive science' adopted the seminar's goal, which was to dissect, sentence-by-sentence, one of the most exciting new theories in cognitive psychology, described in MIT Professor Noam Chomsky's book *Syntactic Structures*. Pinky's highly spirited repartees with the graduate students convinced many of them to alter their careers and devote their lives to this field.

Winifred later married Jenkins, and became step-grandmother to 7, step-great grandmother to 5, and spiritual grandmother to one Christopher Chisolm, son of Richard Chisolm and Teresa Hnath-Chisolm. At the University of South Florida, where Winifred and Jim took faculty positions in 1982, they mentored a new generation of students. In 1998, Winifred took a faculty position at the City University of New York–Graduate School and University Center, where she continues today to play an important role in mentoring doctoral students.

Winifred's scientific contributions are in the area of adult speech perception. She was a pioneer in research on cross-language speech perception, in which she focused on the effects of perceptual training and nonnative language experience. Her work on vowel perception changed our notions of the extent to which speech sounds are processed using dynamic as opposed to static acoustic information. Most experiments conducted in the first 30 years of research on speech perception used stimuli that were generated by computer and contained steady-state formant frequencies. In experiments published in the *Journal of the Acoustical Society of America* beginning in the late 1980s, Strange showed that one could remove the steady-state centers of vowels, leaving only the formant transitions into and out of the vowel, and perception of the vowel remained excellent. These findings on "vowel-less" syllables were surprising, and were initially met with skepticism. However, further research produced a body of evidence that weakened alternative interpretations and led to the acceptance of the idea that the dynamic portions of the onsets and offsets of coarticulated vowels contributed importantly to vowel perception. From that point on, researchers had to take into account the fact that listeners were attuned to the dynamic properties of speech sounds, not just their static steady-state values.

One of the biggest challenges of this work is Winifred's continuing commitment to understanding how vowels are perceived in natural co-articulated syllables. Research taking the dynamic specification view in other languages is beginning to show how vowel spectral dynamics and their perception vary across languages. Recent work compares the influence of phonetic context, prosodic context, and speech style on the acoustic characteristics and the cross-language perception of languages such as English, German, Japanese, and French. Her detailed studies of how acoustic similarity relates to perceptual similarity has contributed importantly to an in-depth, and ecologically more valid, understanding of cross-language perception of vowels and of the language-specific influences of consonantal context on acoustic vowel characteristics.

Winifred Strange has contributed greatly to the Acoustical Society of America (ASA) as a past Associate Editor for Speech for the *Journal of the Acoustical Society of America*, as a Member of the Executive Council from 2001-04, and as an active member of the Speech Technical Committee. Winifred has worked behind the scenes on numerous projects, including the ASA's 75th Anniversary Celebration Committee. Many students and junior colleagues have been exposed to her contagious enthusiasm for our field, and

she continues to introduce new students to the ASA. Awarding the Silver Medal in Speech Communication to Winifred Strange recognizes her contributions to the science of speech communication as well as her many contributions to the Acoustical Society of America.

CITATION FOR THOMAS D. ROSSING

. . . for contributions to musical acoustics, leadership in science education, and service to the Society.

PORTLAND, OREGON • 20 MAY 2009

On rare occasions one encounters an individual, who combines excellence in a somewhat narrow field, and depth in many broad areas, with incisive intellectual curiosity, and a rare ability to share insights. Such a remarkable personality is Tom Rossing. Born in Madison, South Dakota, Tom received an undergraduate degree in physics and mathematics from Luther College, and went on to obtain MS and PhD degrees in Physics from Iowa State University. After three years in industry he spent 14 years on the physics faculty of St. Olaf College, six of those as department chair. As was the case for many of us Tom returned to his second love: Music. In the early 70's Tom established an acoustics research program at Northern Illinois University specializing in musical acoustics. That program became a center of excellence, a source of inspiration for innumerable students, a springboard for countless young scientists entering the field, and a resource for scientists in musical acoustics world-wide. Since 2004 he has been a visiting professor in the Center for Computer Research in Music and Acoustics (CCRMA) at Stanford University.

Tom quickly established his reputation with numerous publications on percussion instruments. Other research publications were followed by two extremely influential works: *The Science of Sound*, one of the most frequently used texts for a general science course aimed at music majors, and *The Physics of Musical Instruments,* co-authored with Neville Fletcher, an absolute must for anyone entering the field of musical instrument research. The volume on *Acoustics of Bells* in the Benchmark Papers in Acoustics Series was edited by Tom. His editorial comments, placing the individual papers in context, along with additional references, make this volume an invaluable reference work. He also edited the Springer *Handbook of Acoustics*, along with serving as author for three of the chapters. This resulted in a truly remarkable compendium. Tom has numerous entries in the *Encyclopedia of Acoustics* published by J. Wiley, in the Macmillan *Encyclopedia of Physics*, in the Focal *Encyclopedia of Electronic Media*, and in the New Grove *Dictionary of Music and Musicians*, where his biography is listed (immediately before Giacomo Rossini). His collaboration with A. J. Houtsma and W. M. Wagenaars in producing a compact disc of Auditory Demonstrations resulted in a marvelous tool for educators. He is the author of over 400 scientific publications, and holds 9 US and 11 foreign patents.

Collaborating with scientists from all corners of the globe, he has hosted young investigators and experienced scientists, thus stimulating research activities in musical acoustics at all levels. Among the many scientists who have passed through his laboratory are such notables as Neville Fletcher, Adrian Houtsma, Johan Sundberg, Bernhard Richardson, and Murray Campbell. In addition to serving as host, he has visited many laboratories and spent time working with colleagues in such places as the Massachusetts Institute of Technology; the Clarendon Lab at Oxford, England; Argonne National Laboratory, Illinois; University of New England, Australia; Royal Institute of Technology, Sweden; Institute for Perception Research, the Netherlands; Physikalisch-Technische Bundesanstalt, Germany; Ecole National Supérieure des Télécommunications, France; Luleå University of Technology, Sweden; University of California, San Diego; Fraunhofer Institute, Germany; University of Edinburgh, Scotland; Stanford University, CA; Seoul National University, Korea; and serving as visiting exchange scholar in China.

Two examples may serve as an indication of Tom's influence in more commercial ventures. Malmark Inc. sought him out to tap his knowledge of bells. This consultation eventually led to the development of an over-sized hand-bell cast in aluminum, the choice of the material dictated by Tom's insight into characteristics of bending wave propagation in bell structures. In another setting, a steel pan artisan in Switzerland, Felix Rohner, of Pan-Art contacted Tom. Insights gained from Tom about vibrational modes eventually led to the development of a new instrument, the "Hang," a hand-played steel instrument, which has gained popularity all over the world.

Tom's influence on Acoustical Society of America (ASA) activities is extensive. As a member of the committees on Education in Acoustics and Musical Acoustics he has organized numerous special sessions at meetings, as well as presenting tutorials on mu-

sical instruments and acoustics demonstrations. His service as editor of *ECHOES* has been truly enlightening, particularly his columns *Scanning the Journals* and *Acoustics in the News*. He also serves as associate editor for education for the *Journal of the Acoustical Society of America* (JASA) and associate editor for musical acoustics for *JASA Express Letters*. He served as chair of the Technical Committee on Musical Acoustics, and as a member of the Medals and Awards Committee and the College of Fellows Steering Committee. His endowment gift to the Acoustical Society Foundation led to the establishment of an ASA prize in education bearing his name.

With all these activities in musical acoustics, Tom did not neglect his deep commitment to quality education. In addition to numerous publications in *The Physics Teacher* and in the *American Journal of Physics*, the two major publications of the American Association of Physics Teachers (AAPT), he published several AAPT resource letters and collections of reprints relevant to physics teaching. He has conducted many teacher workshops, as well as summer courses for physics teachers. He wrote both a laboratory manual to accompany his *Science of Sound* text, and a manual to assist teachers in using the text for a course. He co-authored the text *Light Science* with Chris Chiaverina, where the pun in the title was clearly intentional, as well as a book *Teaching Light and Color*. He has been active in the Minnesota, Illinois, Chicago and California sections of the AAPT, and in 1991 served as national president of the AAPT.

Tom has been the recipient of several awards including Distinguished Research Professor, NIU; National Sigma Xi lecturer; Fellow of the ASA, the American Association for the Advancement of Science, the American Physical Society, and the Institute of Electrical and Electronics Engineers; Honorary membership in the Acoustical Society of India; the AAPT Robert Millikan Medal; the ASA Silver Medal in Musical Acoustics; and Distinguished Service Citations from ASA and AAPT.

Tom is justly proud of his children: Karen, pastor of a Lutheran congregation; Barbara, Professor of New Testament at Lutheran School of Theology at Chicago; Erik, in international business; Jane, Professor of Agricultural and Biological Engineering at Purdue University; and Mary, Mayor of Northfield, Minnesota.

If you plan to visit Tom at his home, you better bring along a musical instrument for an evening playing chamber music, or else be prepared for a great time singing madrigals. Otherwise look for him in the clarinet section of a local orchestra, or listen to him harmonize in a barbershop quartet at an ASA social.

Tom's well deserved international reputation not only makes this award appropriate, but it reflects on the values of a Society which has such deep appreciation for individuals whose contributions are so far reaching.

Session 4aAA

Architectural Acoustics and ASA Committee on Standards: Acoustics of Mixed Use Buildings

Steven D. Pettyjohn, Chair
The Acoustics & Vibration Group, 5700 Broadway, Sacramento, CA 95820-1852

Chair's Introduction—8:00

Invited Papers

8:05

4aAA1. Acoustical design of mixed-use buildings: The state of the art (and science). Robert P. Alvarado and Ethan C. Salter (Charles M. Salter Assoc., Inc., 130 Sutter St., Ste. 500, San Francisco, CA 94104, robert.alvarado@cmsalter.com)

Mixed-use developments integrate a variety of uses including residences, offices, shops, restaurants, and theaters into functional, living, and working communities. They are often located near rail, major roadways, and airports, which can generate significant levels of environmental noise and vibration that will need to be mitigated to meet Building Codes and project goals. This paper will detail project-specific issues, solutions, and experiences by Charles M. Salter Associates. Our experience has given us the opportunity to collaborate with various project stakeholders to achieve project goals within the constraints of aesthetics, budget, and space. Authors will present case studies which include acoustical design issues that have been incorporated during the design phase, coordinated during construction, and conveyed to the community that the project serves. Acoustical needs of mixed-use developments can vary based on applicable Codes, as well as project marketing goals and expectations of end users. Educating future owners and tenants about acoustics is important to reducing the design team and the developers' exposure to possible litigation, and also helps to maintain resident health, comfort, and property values. Robert Alvarado has managed hundreds of projects over the past 12 years. His mixed-use project portfolio includes international and domestic projects. Ethan Salter has consulted on dozens of projects throughout the country, including several incorporating sustainable design.

8:25

4aAA2. From an architect's perspective: Acoustical challenges in mixed-use buildings. Dale Farr and Karyn Goodfriend (Fletcher Farr Ayotte, Inc., 520 SW Yamhill, Ste. 900, Portland, OR 97204, kgoodfriend@ffadesign.com)

Incorporating acoustical design in mixed-use buildings can be architecturally challenging. Key issues impacting acoustical design decisions are: (1) the unknown—due to undetermined uses of commercial lease space; (2) the cost—clients do not want to pay for ideal acoustical design because they perceive it to be cost prohibitive. Often clients do not understand the importance of considering acoustic elements during the initial design process until complaints occur much later, postconstruction. Other elements impacting acoustical design are: apartments versus condominiums, existing buildings versus new structures; changes in lease space use; and the possible conflict of the acoustical design not meeting life/safety code. On each architectural project it is ultimately the goal to design to client criteria with a mission to deliver solutions that meet the most needs based on user programs. Often concessions must be made to find the best overall solution for the building and budget. This impacts all of the design consultants, which means designs need to be flexible and are sometimes less than ideal in segregation. It is worth discussing how architects successfully design for the unknown and justify inclusion of acoustical designers early on, while staying within budget.

8:45

4aAA3. Sound and vibration issues encountered in mixed use construction involving residential, office, and retail uses created from a combination of renovation and expansion of an existing space. Steven D. Pettyjohn (The Acoust. & Vib. Group, Inc., 5700 Broadway, Sacramento, CA 95820-1852, spettyjohn@acousticsandvibration.com)

Buildings housing mixed uses often encounter acoustic and vibration problems because expectations differ for the users and patrons. Mixed uses could include retail and office spaces; offices and residential; retail and residential; or, as in the case to be discussed, retail (restaurants) on the first floor, offices on the second floor, and residences on the upper two floors. An existing historic three-story concrete structure originally housing a car dealership in an urban area was renovated to provide all three uses. A fourth floor was added to provide a second floor of residential use. The offices and residential areas were designed to meet interior sound level standards from sources within and exterior to the building. The two restaurants were designed individually by their in house teams with only vibration standards provided by the building design group. The lack of coordination between restaurant and building design teams let to both sound and vibration problems that had to be corrected after construction was mostly complete. Construction teams for the restaurant groups were not familiar with such issues based on their previous installations. This paper discusses the myriad of problems and remedies and provides an outline of the issues that need addressing.

9:05

4aAA4. Low frequency sound problems found in mixed use buildings that house entertainment venues and residential developments and containment options. Scott W. Smith (Ballentine Walker Smith, Inc., Kennesaw, GA 30144, bwsacoustics@bellsouth.net) and Steven D. Pettyjohn (The Acoust. & Vib. Group, Inc., Sacramento, CA 95820-1852)

Many problems are to be expected when mixed use buildings include restaurants and residential spaces. When the residential spaces are condominiums and the restaurant becomes a nightclub, the sound problems multiply quickly. The low frequency sound produced in a nightclub featuring music catering to a young crowd is of particular concern. This is partially because of the difficulty of finding remedies once the building construction is complete. This is the situation that arose in a facility recently completed. The nightclub wanted to continue its operation while the condominium owners wanted a resolution of the problem. Sound tests were completed in the residential spaces during operation of the nightclub, but the low frequency content was not always the same, requiring multiple attempts to measure in the source and receiving spaces. Results of these measurements and the recommendations for correcting the problem are presented in this paper. The goal is to provide results of sound measurements made after the recommendations are implemented. Again, sound will be measured in the source and receiver spaces to understand how the noise reduction changed and compared with the predicted sound reduction.

4aAA5. An historic conversion: From a bank to a restaurant and residences. Ioana Pieleanu, Jeffrey Fullerton, and Benjamin Markham (Acentech Inc., 33 Moulton St., Cambridge, MA 02135)

A conversion of an old bank building in Boston's tony South End to a mixed-use building featuring retail on the ground floor and luxury condominiums above was completed in 2007. More recently, a new restaurant (garnering awards for its interior design and rave reviews for its food) has opened in one of the ground floor retail spaces directly below a particularly noise-sensitive resident. Consultants at Acentech worked on two aspects of the project: first, on the base building as consultants to the architect, and second, on the isolation between the restaurant and the second floor residences as consultants to the restaurant. Using this case study and extensive data measured on site, the authors will discuss best practices to achieve good sound isolation in mixed-use buildings, common pitfalls that result from working with existing historic structures, and some difficulties in achieving the high degree of sound isolation that some luxury condominium owners expect.

4aAB1. Auditory temporal summation in pinnipeds. Asila Ghoul (Univ. of California Santa Cruz Long Marine Lab., 100 Shaffer Rd., Santa Cruz, CA 95060), Marla M. Holt (Natl. Marine Fisheries Service, Seattle, WA 98112), Colleen Reichmuth, and David Kastak (Univ. of California Santa Cruz Long Marine Lab., Santa Cruz, CA 95060)

In addition to improving the understanding of auditory processing in pinnipeds, direct measures of temporal summation are relevant to the selection of signal parameters when conducting audiometric research, assessing the effects of signal duration on communication ranges, and evaluating the potential auditory impacts of anthropogenic signals. In the present study, individuals from three pinniped species were tested to determine how signal duration influenced pure-tone hearing thresholds. The psychophysical method of constant stimuli was used to obtain aerial thresholds for each subject at nine different signal durations ranging from 25 to 500 ms. Parameter estimates derived for a California sea lion (*Zalophus californianus*) from an exponential model of temporal summation yielded time constants (τ) of 176, 98, and 141 ms at frequencies of 2.5, 5, and 10 kHz, respectively. Preliminary results with a northern elephant seal (*Mirounga angustirostris*) at 5 kHz (this study), and a harbor seal (*Phoca vitulina*) at 2.5 kHz [M. M. Holt et al., J. Soc. Am. **116**, 2531 (2004)] show similar values for (τ), 134 and 144 ms, respectively. These time constants are similar to those of other mammals tested and do not appear to vary with respect to frequency.

8:45

4aAB2. Annual temporal patterning in the vocalizations of captive seals: Two long-term case studies. Colleen Reichmuth and Ronald J. Schusterman (Inst. of Marine Sci., Univ. of California Santa Cruz, 100 Shaffer Rd., Santa Cruz, CA 95060)

Seasonal changes in vocalizations occur in a variety of species. Factors such as the condition of conspecifics, physiological states that in turn may be related to environmental cues, and developmental and individual differences all potentially influence temporal changes in sound production. In the present study, the vocal behavior of two captive seals was monitored daily for over 10 yrs. Both seals were housed in the absence of conspecifics from the age of 1 yr extending past sexual maturity. The male harbor seal (*Phoca vitulina*) began characteristic underwater vocal displays at the age of 6. Intense periods of acoustic activity lasted weeks to months, overlapped with the breeding activity of local harbor seals, and comprised stereotypic sound emissions that were structurally similar to those reported for wild seals. The female northern elephant seal (*Mirounga angustirostris*) produced aberrant intense airborne vocalizations from the age of 4 that were annually synchronized to a period of approximately 5 weeks coinciding with estrous. Endogenous changes appear to trigger these behavioral cycles, presumably as a

result of hormonal changes associated with photoperiod. Vocalizations may be a noninvasive indicator of reproductive state and therefore may provide a useful management and conservation tool in captive settings.

9:00

4aAB3. A comparison of behavioral and electrophysiological measures of aerial hearing sensitivity in a Steller sea lion (*Eumetopias jubatus*). Jason Mulsow (Dept. of Ocean Sci., Univ. of California Santa Cruz, Earth and Marine Sci. Bldg., Santa Cruz, CA 95064) and Colleen Reichmuth (Univ. of California Santa Cruz, Santa Cruz, CA 95060)

A number of studies with odontocete cetaceans have demonstrated that hearing sensitivity measurements using electrophysiological auditory steady-state responses (ASSRs) can provide an efficient means of estimating a subject's behavioral audiogram. Expansion of ASSR methods to another marine mammal group, the otariid pinnipeds (sea lions and fur seals), holds the potential to increase the number of otariid individuals and species for which hearing sensitivity data are available. A within-subject comparison of ASSR and behavioral measures of aerial hearing sensitivity was conducted with an individual of the largest otariid species, the Steller sea lion. Psychophysical methods were used to obtain an unmasked aerial audiogram at 13 frequencies spanning a range of 0.125 to 34 kHz. Corresponding ASSR thresholds measured at frequencies of 1, 2, 5, 10, 20, and 32 kHz had differences (relative to behavioral thresholds) ranging from 1 dB at 20 kHz to 30 dB at 1 kHz. Overall, the ASSR audiogram was a fairly accurate predictor of the behavioral audiogram at frequencies of 2 kHz and above. Our results suggest that ASSR methods can be appropriately applied to otariid pinnipeds in estimating aerial sensitivity at frequencies of approximately 2 kHz and above.

9:15

4aAB4. Vibration characteristics of the tympanoperiotic complex in the bottlenose dolphin, *Tursiops truncatus*. Petr Krysl (Univ. of California, San Diego, 9500 Gilman Dr., La Jolla, CA 92093-0085), Ted W. Cranford (San Diego State Univ., San Diego, CA 92182), and John A. Hildebrand (Univ. of California, San Diego, La Jolla, CA 92093-0205)

Modal finite + boundary element analysis of a bottlenose dolphin's bony tympanoperiotic complex, including the ossicles, was performed to determine the mode shapes and natural frequencies. The goal was to gain insight into the transmission of sound pressure waves arriving through the soft tissues and transmitted across the bony components into the oval window of the inner ear. The finite element model of the bones was derived from CT scans with a 360 μm voxel resolution. In the first approximation the soft tissue was considered to be acoustically equivalent to an incompressible inviscid liquid, taken as infinite in extent. The added mass terms were computed with a boundary element model. The computed frequencies cover the range up to 160 kHz. The capacity of the natural vibration modes to excite motion of the stapes footplate was assessed by measuring the relative motion of the incudostapedial joint normalized by the normal displacement of the wet-surface of the ear bones. In addition to a quantitative assessment a number of qualitative observations may be made that could explain the function of the dolphin's ear complex. For example, the vibrational patterns are nontrivial and frequency dependent. [Work supported by the U.S. Navy CNO45.]

9:30

4aAB5. "Rivers" of sound in Cuvier's beaked whale (*Ziphius cavirostris*): Implications for the evolution of sound reception in odontocetes. Ted W. Cranford (Biology Dept., San Diego State Univ., 2674 Russmar, San Diego, CA 92182), Petr Krysl, and John A. Hildebrand (Univ. of California at San Diego, La Jolla, CA 92093)

Industrial CT scanning technology was used to collect the first x-ray tomograms from the head of an adult male Cuvier's beaked whale. These scans and tissue property measurements were used to construct a finite element model. Simulations revealed pathways for sound propagation into and out of the head. One intriguing result concerns a newly described gular pathway by which sound reaches the hearing apparatus. Propagated sound waves enter the ventral aspect of the head and form an acoustic "river" that flows toward the bony ear complexes through the internal mandibular fat bodies. The precise pathway and dimensions of the sound river vary with frequency, but it converges on the bony tympanoperiotic complex. A combination of tissue structures and air spaces act like an internal acoustic pinna that filters and concentrates the incoming sound. The river of sound apparently functions in concert with the absence of the medial bony lamina of the posterior portion of the mandible, a condition that exists in all toothed whales and their ancestral archaeocetes. The gular pathway and river of sound suggests that this is the primordial pathway for underwater hearing in whales and that Norris' jaw hearing mechanism was a more recent development.

9:45

4aAB6. Dall's porpoise (*Phocoenoides dalli*) echolocation click spectral structure. Hannah R. Bassett, Simone Baumann, Gregory S. Campbell, Sean M. Wiggins, and John A. Hildebrand (Marine Physical Lab, Scripps Inst. of Oceanogr., Univ. of California, San Diego, 9500 Gilman Dr., La Jolla, CA 92093, hbassett@ucsd.edu)

Dall's porpoise (*Phocoenoides dalli*) echolocation clicks have not been widely recorded. Concurrent with visual observations, acoustic recordings of free-ranging Dall's porpoise were made offshore of southern California using a towed hydrophone array with two elements of 250 kHz bandwidth. We examined 6035 clicks from 12 sessions totaling more than two hours over the course of seven days. The Dall's porpoise echolocations recorded were short (48–804 μs), narrow band (2–10 kHz [−3dB]) clicks with most peak frequencies between 117 and 141 kHz, but some as high as 198 kHz. Many clicks contained a multipulse temporal structure, resulting in stereotyped spectral peaks and notches. Two distinctive click types with different spectral banding patterns and peak frequencies (122.8 and 135.8 kHz) were observed. Spectral banding patterns have been used as a species identifier for Risso's dolphins and Pacific white-sided dolphins. These two dolphins and Dall's porpoise have similar head morphologies, which may play a role in producing clicks with spectral peaks and notches. This study shows that Dall's porpoise produce multiple click types, which may provide a tool for population classification, and that their clicks contain spectral banding patterns, which may provide insight into the mechanism by which such clicks are produced.

10:20

4aAB7. Analysis of most prominent signal features of humpback whale (*Megaptera Novaeangliae*) vocalizations towards the goal of autonomous acoustic classification. Ted Abbot, Owen Mayer, Vince Premus, Philip Abbot, and Ira Dyer (OASIS, Inc., 5 Militia Dr. Lexington, MA 02421)

Humpback whale vocalizations were recorded using hydrophones on glider systems off Alaska in January 2000, in Hawaii in February 2008, and in the Stellwagen Bank National Marine Sanctuary in October 2007 and July 2008. The vocalizations have been grouped into five call types based on the most prominent signal features. Only five call types are used because autonomous species classification relies on the most consistent and repeatable signal features rather than the full diverse range of humpback vocalizations. The five call types are upsweep (increasing frequency over time), downsweep (decreasing frequency over time), flute (increasing and decreasing frequency over time), tone (little or no change in frequency over time), and groan (commonly a social or feeding-related vocalization, frequently characterized by unstructured broadband sound). We present detailed statistical analyses of these call types including bandwidth, minimum and maximum frequency, duration, and slope. A comparative analysis across data sets shows the relative frequency of occurrence of each vocalization type and indicates the degree of temporal and geographic variation of Humpback vocalizations.

10:35

4aAB8. Is rejection of clutter achieved by disrupting perception of delay in bat sonar? Mary E. Bates (Dept. of Psych., Brown Univ., 89 Waterman St., Providence, RI 02912) and James A. Simmons (Brown Univ., Providence, RI 02912)

Big brown bats (*Eptesicus fuscus*) emit frequency-modulated (FM) biosonar sounds containing two prominent harmonics, FM1 (55–22 kHz) and FM2 (105–145 kHz), and perceive target distance from echo delay. Ordinarily, echoes from objects arrive with both harmonics at the same delay, although FM2 becomes progressively more attenuated than FM1 with increasing target distance and off-axis direction. Off-axis or long-range echoes naturally undergo lowpass filtering, which causes significant loss of acuity. Misalignment of FM2 with respect to FM1 or selective removal of low-end frequencies disproportionately affects the accuracy of delay perception. Delay acuity is sharp for echoes containing both harmonics, less sharp for echoes containing only FM1, and very poor for echoes containing only FM2. Acoustically unnatural highpass filtering to remove low-end frequencies from FM1 causes acuity to collapse. Attenuation of FM2 relative to FM1 by 3 dB decreases delay acuity, but shortening of the delay for FM2 by 48 μs counteracts amplitude-latency trading and restores delay acuity. Bats may have a spatial perceptual "fovea" covering a narrow zone in front of them for high-acuity perception surrounded by a zone of much lower acuity that suppresses the perceptual salience of background clutter. [Work supported by NASA RI Space Grant and ONR.]

10:50

4aAB9. Range discrimination of multiple objects from the echo spectrogram measured by using the frequency modulation sound. Ikuo Matsuo (Dept. of Information Sci. Tohoku Gakuin Univ., Sendai, 981-3193, Japan, matsuo@cs.tohoku-gakuin.ac.jp)

Using the echolocation, bats can capture moving objects in real 3D space. Bats emit the frequency modulation sound and can identify objects with an accuracy of less than a millimeter. To determine delay times of multiple objects requires estimating the sequence of delay separations by extracting temporal changes in the interference pattern of the echoes. The models to determine delay times of multiple objects from the simulated echoes by using the frequency modulation sound have been previously proposed. In order to extract the temporal changes, Gaussian chirplets with a carrier frequency compatible with emission sweep rates were used. The delay time for first object can be estimated from the echo spectrum around the onset time. The delay time for second object is obtained by adding the delay time for the first object to the delay separation between first and second objects (extracted from the first appearance of interference effects). Further objects can be located in sequence by this same procedure. In this paper, these echoes were measured from multiple closely spaced objects, and it was examined that this model could estimate each delay times of these objects.

11:05

4aAB10. The acoustic implications of sella length in horseshoe bats. Rolf Mülller (Dept. of Mech. Eng., Virginia Tech. & Inst. for Adv. Learning and Res., 150 Slayton Ave., Danville, VA 24540, rolf.mueller@vt.edu), Zhiwei Zhang (Shandong Univ., Hongjia Lou 5, 250100 Jinan, China), and Son Nguyen Truong (Vietnamese Acad. of Sci. and Technol., Hanoi, Vietnam)

Horseshoe bats emit their biosonar pulses through nostrils that are surrounded by elaborate baffle shapes (noseleaves). The shape and size of the different noseleaf shape elements can vary considerably between species. Here, the acoustic effects of the length of the sella have been investigated based on the noseleaf of Bourret's Horseshoe Bat (*Rhinolophus paradoxolophus*) which features an exceptionally long sella: High-resolution digital representations of the noseleaves of three specimens were used to vary the sella length below and above its natural value. A principal axis through the sella was used to define the direction of this scaling. The acoustic beamforming properties of the noseleaf were then assessed as a function of sella scale using numerical methods. It was found that elongating the sella narrows the biosonar beam of the second harmonic in elevation. Furthermore, the natural length of the sella in Bourret's Horseshoe Bat coincided with a fiducial point in the relationship between sella length and beamwidth, where the effect of sella length on beamwidth saturates. This allows the prediction of the natural sella length from its acoustic properties. The long sella in this species could, hence, be an adaptation to producing a narrow beam at comparatively low frequencies.

11:20

4aAB11. An evolutionary approach to perissodactyl vocalizations. David G. Browning (Phys. Dept., Univ. of Rhode Island, 2 Lippitt Rd., Kingston, RI 02881, decibeldb@aol.com) and Peter M. Scheifele (Univ. of Cincinnati, Cincinnati, OH 45267-0379)

Approximately 65 million years ago, dinosaurs were displaced by mammals. In a then highly forested world, the perissodactyls (odd-toed ungulates) became the largest group of large mammals, consisting of an estimated 15 families. We hypothesize that they started to develop a melodic component in their tonal vocalizations in order to provide identity in this restricted visibility setting. With time, large areas shifted to grassland, favoring mammals with compound stomachs, namely, artiodactyles (sheep, cattle, etc.) and resulting in the decline of the perissodactyls to only three families (equines, tapirs, and rhinos) today. Although all the remaining perissodactyls still retain a melodic component in their vocalizations, it appears to be less developed in those that adapted to the open grassland environment, such as the plains zebra. There a simple tonal call (as the artiodactyles have, too) is sufficient to draw attention; additional information can be obtained visually. On the other hand, those that continued in a forested location such as the Sumatran Rhino have developed a more lyrical call to compensate for reduced visibility.

11:35

4aAB12. Time domain, frequency domain, and spectrogram analysis of baleen whale songs. Pranab K. Dhar and Jong-Myon Kim (Univ. of Ulsan, 680-749, Korea, jongmyon.kim@gmail.com)

Whale song is the sound to communicate, and it shows a specific pattern of regular and predictable sounds made by some species of whales. In this study, different baleen whale songs were analyzed in terms of time domain, frequency domain, and spectrogram representation. More specifically, each whale song in the species was analyzed with a sound analysis tool in terms of peak frequency (frequency with peak energy), frequency range of song, and pattern of song production. Cordell North Canyon humpback whales produce the highest peak frequency (1,348 Hz) whereas North Eastern Pacific blue whales produce the lowest peak frequency (18 Hz). The humpback whales provide wide frequency range from 600 Hz to 2.8 kHz, but Atlantic Ocean fin whales provide short frequency range from 15 to 40 Hz. Patterns of song production for the species were also analyzed. Minke and right whales generate similar repeated song. However, humpback, bowhead, blue, and fin whales generate same repeated song. These evaluation techniques can provide solutions for characterizing specific features of whale songs. [Work supported by the MKE (Ministry of Knowledge Economy), Korea, under the ITRC (Information Technology Research Center) support program supervised by the IITA (Institute of Information Technology Assessment) (IITA-2008-(C1090-0801-0039)).]

4aBB1. Sonothrombolysis for acute coronary syndromes: Opportunities and challenges. Sanjiv Kaul (Cardiovascular Div., Oregon Health & Sci. Univ., Portland, OR 97239)

Percutanous interventions and pharmacological thrombolysis are the current options for treatment of acute coronary syndromes (ACS). The former is limited by its availability and the latter by its efficacy. Sonothrombolysis has been demonstrated to be effective in achieving tissue perfusion in the peripheral arteries as well as in cerebral arteries. Therefore, there is potential of using sonothrombolysis for the treatment of ACS. An ultrasound imaging and delivery system could overcome the issue of access while combining it with microbubbles and low dose thrombolytics could result in a high reperfusion rate. Furthermore, the direct effect of ultrasound on ishemic myocardium (release of nitric oxide and increase in myocardial blood flow despite total coronary occlusion) could be exploited to protect the myocardium until reperfusion has been achieved. The success of reperfusion could be assessed in real-time using microbubbles. In order to achieve these goals, we need to plan systematic *in vitro* and *in vivo* studies to better understand the mechanics of sonothrombolysis. We also need to develop 4D combined imaging and ultrasound delivery systems. Positive developments in this field can translate into a major impact on human health world wide.

8:20

4aBB2. Targeted microbubble technology and ultrasound-mediated gene delivery. Jonathan Lindner (Cardiovascular Div., Oregon Health and Sci. Univ., 3181 S.W. Sam Jackson Park Rd., Portland, OR 97239, lindnerj@ohsu.edu)

There is interest in harnessing the energy from ultrasound-microbubble interactions for therapeutic gain. Microbubbles (MB) can be used as vectors for ultrasound mediated gene delivery (UMGD). This process relies on coupling cDNA to MB that undergo cavitation resulting in delivery/transfection from controlled bioeffects. Proximity of gene-laden MB to the vessel wall is a critical determinant of UMGD, which may be enhanced by the use of targeted MB probes that bind to certain disease states. In this presentation, endothelial targeting strategies will be discussed together with their recent application to optimize UMGD. Flow chamber and intravital microscopy studies have been performed that demonstrate that the coupling of cDNA and MB surfaces does not interfere with binding of these agents to counterligands on the vascular endothelium. Imaging experiments have also been performed demonstrating that MB retention in tissue using an ischemia-targeting approach is possible with gene-laden MBs targeted to endothelial cell adhesion molecules. Finally, data on the relative transfection efficiency of reporter genes with UMGD using a targeted versus control MB vector approach will be discussed. The overall conclusion of the presentation is that the ability to target MB to disease-related molecules may increase both efficiency and specificity of tissue transfection.

8:40

4aBB3. Gas body destruction reduces the effective circulating dose of ultrasound contrast agent infused in rats. Douglas L. Miller, Chunyan Dou (Dept. of Radiology, Univ. of Michigan, 1301 Catherine St., Ann Arbor, MI 48109-5667, douglm@umich.edu), and Roger C. Wiggins (Univ. of Michigan, Ann Arbor, MI 48109)

Glomerular capillary hemorrhage (GCH) in rat kidney provides a model system for assessing *in vivo* gas body efficacy in diagnostic or therapeutic applications of ultrasound. Two diagnostic ultrasound machines were utilized: one monitored the second-harmonic B mode contrast-enhancement of the left kidney and the other exposed the right kidney for GCH production. Definity contrast agent was infused at 5 μl/kg/min for 300 s during shams and 1.5-MHz intermittent exposures at 2.3-MPa peak rarefactional pressure amplitude in groups of five rats. The left kidney image brightness enhancement, indicative of circulating gas body dose, was 18.4 au (decompressed arbitrary units) in shams with no GCH in histology. Exposure of the right kidney with a normal 1-s image interval induced 68.4% GCH but reduced the left kidney enhancement to 3.3 au, which implies substantial gas body destruction. Decreased exposure with 10-s interval reduced right kidney GCH ($P' < 0.001$) but only to 30.3% while ameliorating gas body destruction with 13.1-au left kidney enhancement. The effective *in vivo* gas body dose in rats may be reduced greatly due to gas body destruction in the small animal, complicating extrapolation to similar conditions of human exposure. [Work supported by NIH grant EB00338.]

9:00

4aBB4. Combined effect of ultrasound and liposomal doxorubicin on AT2 Dunning tumor growth in rats: Preliminary results. Lucie Somaglino (Inserm U556, 151 cours Albert Thomas, 69424 Lyon cedex 03, France and Univ. de Lyon, Lyon F-69003, France, lucie.somaglino@inserm.fr), Guillaume Bouchoux, Sabrina Chesnais, Anis Amdouni, Jean-Louis Mestas (Inserm U556, 69424 Lyon cedex 03, France), Sigrid Fossheim, Esben A. Nilssen (Epitarget AS, 0307 Oslo, Norway), Jean-Yves Chapelon, and Cyril Lafon (Inserm U556, 69424 Lyon cedex 03, France)

Previous in vitro studies conducted in our group have shown the feasibility of monitoring drug release from liposomes by an inertial acoustic cavitation index. We currently report in vivo experiments utilizing the cavitation index in combined treatment of AT2 Dunning tumor grafted rats with focused ultrasound and liposomal doxorubicin. Sixty-three rats were allocated into seven groups: control, low level ultrasound treatment, high level ultrasound treatment, free doxorubicin+high level ultrasound treatment, and liposomal doxorubicin, liposomal doxorubicin+low level ultrasound treatment, and liposomal doxorubicin+high level ultrasound treatment. Based on pharmacokinetic studies, it was decided to apply ultrasound to the tumor 48 h after drug injection. An experimental setup was built to perform repeatable and rapid sonications of tumors monitored by the cavitation index. Tumor growth was assessed for a period of 35 days after tumor inoculation. Results showed that liposomal doxorubicin significantly slowed down tumor growth. However, the synergy between ultrasound and liposomal doxorubicin could not be firmly demonstrated. The lack of synergy may be due to inefficient induction of drug delivery in vivo or too high liposome dosage hiding synergistic effects. [Work funded by the Norwegian Research Council (NANOMAT programme). Epitarget AS is acknowledged for the supply of liposomes.]

9:15

4aBB5. Ultrasound-enhanced drug delivery through sclera. Robin Shah and Vesna Zderic (Dept. of Elec. and Comp. Eng., The George Washington Univ., 801 22nd St. NW, Washington, DC 20052, zderic@gwu.edu)

Achieving an increase in drug delivery through the sclera is important in the treatment of the back of the eye diseases including macular degeneration, diabetic retinopathy, etc. Our objective is to utilize therapeutic ultrasound in enhancing drug delivery through the sclera. Porcine sclera was placed in a standard diffusion cell at a normal physiological temperature of 34 °C. Solution of sodium fluorescein, a hydrophilic drug-mimicking compound, was added to donor compartment, and receiver compartment was filled with saline. The sclera was exposed to ultrasound for 5 min (intensities 1.2–1.8 W/cm^2 and frequencies 0.5 to 5 MHz). After 60 min, solution samples were taken from the receiver compartment to determine the concentration of sodium fluorescein. The sclera permeability to the drug mimicking agent *in vitro* increased 3.5 times at 0.5 MHz (p-value of less than 0.05), 1.7 times at 1 MHz, 3.5 times at 3.5 MHz (p-value of less than 0.05), and 1.5 times at 5 MHz. The average temperature of the sclera during ultrasound exposure was 42 °C. No gross changes were observed in the sclera due to ultrasound application. Future work will focus on determination of optimal ultrasound parameters for the drug delivery through the sclera.

9:30

4aBB6. Direct observation of microbubble interactions with ex vivo microvessels. Hong Chen, Andrew A. Brayman, Michael R. Bailey, and Thomas J. Matula (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105, hongchen@apl.washington.edu)

The interaction between microbubbles with tissue is poorly understood. Experimental evidence, supported by numerical simulations, suggests that bubble dynamics is highly constrained within blood vessels. To investigate this further, a high-speed microimaging system was set up to study the effects of acoustically activated microbubbles on microvessels in ex vivo rat mesentery tissues. The microbubble-perfused tissues were placed under a microscope and insonified with MHz ultrasound. A variety of interactions was observed by a high-speed camera: arterioles, venules, and capillaries were all recorded to dilate and invaginate by activated microbubbles. For small diameter microvessels, dilation and invagination were nearly symmetric, and bubble-induced rupture of the vessel was observed at high pressure. For larger microvessels, the portion of the vessel nearest the bubble coupled the strongest to the bubble dynamics, and the extent of dilation was smaller than invagination. Tissue jetting toward the bubble was recorded in many cases. The interaction of multiple bubbles inside microvessels was also observed. Bubble oscillation, vessel wall velocity, and tissue jet velocity were quantitatively measured. Invagination of vessel walls, especially tissue jetting, may be the major mechanism for tissue injury by a bubble. [Work supported by NIH 5R01EB000350.]

4aBB7. Shell buckling enhances subharmonic behavior of phospholipid coated ultrasound contrast agent microbubbles. Jeroen Sijl, Timo Rozendal, Marlies Overvelde, Valeria Garbin, Benjamin Dollet, Nico de Jong, Detlef Lohse, and Michel Versluis (Phys. of Fluids Group, Univ. of Twente, Enschede, The Netherlands)

Subharmonic behavior of coated microbubbles can greatly enhance the contrast in ultrasound imaging. The threshold driving pressure above which subharmonic oscillations are initiated can be calculated from a linearized Rayleigh-Plesset-type equation. Earlier experimental studies on a suspension of phospholipid-coated microbubbles showed a lower threshold than predicted from traditional elastic shell models. Here we present an experimental study of the subharmonic behavior of individual BR-14 microbubbles (Bracco Research) with initial radii between 1.6 and 4.8 μm. The subharmonic behavior was studied as a function of the amplitude and the frequency of the driving pressure pulse. The radial response of the microbubbles was recorded with the Brandaris ultrahigh-speed camera, while the resulting acoustic response was measured with a calibrated transducer. It is shown that the threshold pressure is minimum near a driving frequency equal to half the resonance frequency of the bubble, as expected. We found a threshold pressure as low as 10 kPa for certain bubble sizes, which can be explained by the shell buckling model proposed by [Marmottant *et al.*, JASA (2005)]. We show that the origin of subharmonic behavior is a result of the discontinuous transition within the bubble shell from the elastic state to the tensionless buckling state.

10:00—10:30 Break

10:30

4aBB8. Shell buckling increases the nonlinear dynamics of ultrasound contrast agents at low acoustic pressures. Marlies Overvelde (Phys. of Fluids, Univ. of Twente, P.O. Box 217, 7500 AE Enschede, The Netherlands, m.l.j.overvelde@utwente.nl), Benjamin Dollet, Valeria Garbin (Univ. of Twente, Enschede, The Netherlands), Nico de Jong (Experimental Echocardiography, Thoraxcenter, Erasmus MC, Rotterdam, The Netherlands), Detlef Lohse, and Michel Versluis (Univ. of Twente, Enschede, The Netherlands)

The key feature of ultrasound contrast agents in distinguishing blood pool and tissue echoes is based on the nonlinear behavior of the bubbles. Here we investigate the nonlinear properties of the shell which lead to an increased nonlinear bubble response, especially at low acoustic pressures. The microbubbles were studied in free space away from the wall using the Brandaris camera coupled to an optical tweezers setup. The microbubble spectroscopy method [Van der Meer et al., JASA, **121**, 648 (2007)] was employed to characterize BR-14 microbubbles (Bracco, Geneva). For increasing applied pressures the bubble resonance curves become asymmetrical and the frequency of maximum response decreases, up to 50% at a pressure of 25 kPa. It was found that the skewing of the nonlinear resonance curve is the origin of the so-called thresholding behavior below resonance. Traditional bubble models account for a purely elastic shell predict linear behavior, whereas the shell buckling model by Marmottant et al. [JASA, **118**, 3499

(2005)], originally developed to predict compression-only behavior, captures the asymmetry of the resonance curve in great detail. The full understanding of the nonlinear behavior at low acoustic pressures opens a wealth of new possibilities in contrast-enhanced ultrasound imaging.

10:45

4aBB9. Influence of finite wall impedance on contrast agent bubble behavior near a membrane. Todd Hay, Marlies Overvelde, Benjamin Dollet, Valeria Garbin, Nico de Jong, Detlef Lohse, and Michel Versluis (Phys. of Fluids, Univ. of Twente, 7500 AE Enschede, The Netherlands)

Experiments investigating the radial dynamics of ultrasound contrast agent (UCA) microbubbles in the vicinity of an optically transparent membrane show that bubble oscillation amplitude and frequency of peak response decrease as bubbles move closer to the membrane (Overvelde *et al.* Proc. 19th Intl. Congr. Acoust., 2007). However, treating the membrane as a rigid wall predicts that the peak oscillation amplitude should increase at small standoff distances, contrary to experimental observations. Here we present a model describing UCA bubble dynamics near a locally reacting wall having finite acoustic impedance. If finite wall impedance is included in the model, the predicted bubble behavior is in good agreement with observations. The hybrid time-frequency domain model is based on a linear frequency domain solution [Ingard, J. Acoust. Soc. Am. **23**, 329 (1951)] which has been adapted to account for weakly nonlinear bubble oscillations and UCA shell dynamics. Wall impedance parameters are derived from independent experimental measurements. Comparisons between the model and data from microbubble spectroscopy experiments will be presented. [Work supported by the ASA Hunt Fellowship and NIH DK070618.]

11:00

4aBB10. Model for bubble dynamics in liquid near an elastic tissue interface. Todd A. Hay (Phys. of Fluids, Univ. of Twente, 7500 AE Enschede, The Netherlands), Evgenia A. Zabolotskaya, Yurii A. Ilinskii, and Mark F. Hamilton (The Univ. of Texas at Austin, Austin, TX 78713-8029)

A model is under development for the weakly nonlinear dynamics of a bubble in a blood vessel surrounded by tissue with elasticity and losses. The model requires knowledge of the radiation impedance of the bubble within the vessel, which is determined by the Green's function. As a first step toward this objective, the Green's function is derived for a bubble in a liquid half-space bounded by an elastic half-space. The method used to derive the Green's function follows an approach described previously for the response of an acoustically driven object in an elastic half-space [Zabolotskaya *et al.*, J. Acoust. Soc. Am. **124**, 2514(A) (2008)]. The Green's function is expressed in terms of its angular spectrum in a plane parallel to the interface, resulting in ordinary differential equations in the coordinate normal to the interface. Boundary conditions are satisfied at the interface and in the plane containing the source to obtain solutions of the differential equations, the inverse spatial Fourier transform of which yields the desired Green's function. Extension to multiple layers of tissue is straightforward. Calculations will be presented for the radiation impedance of the bubble near the interface. [Work supported by the ASA Hunt Fellowship and NIH DK070618.]

11:15

4aBB11. Determination of maximum response radius at therapeutic pressure levels. Kelsey J. Carvell and Timothy A. Bigelow (Dept. of Elec. and Comput. Eng., Iowa State Univ., 2011 Coover Hall, Ames, IA 50010, kcarvell@iastate.edu)

High-intensity, focused ultrasound therapy is a minimally invasive therapy technique that has shown potential in many therapeutic applications, especially when coupled with the cavitation of microbubbles. The purpose of this study was to determine the effect of pressure amplitude on cavitation resonance frequency/bubble size at therapeutic field levels. Earlier work has indicated that the resonance frequency depends on pressure amplitude; however, the investigation only considered pressure amplitudes up to 1 MPa [Ultrasonics **43**, 113 (2004)]. Our study was conducted by simulating the response of bubbles using the Gilmore-Akulichev formulation to solve for the bubble response. The frequency of the sine wave varied from 1–5 MHz while the amplitude of the sine wave varied from 0.0001–13 MPa. The resonance size for a particular frequency of excitation and amplitude was determined by finding the initial bubble size that resulted in the maximum bubble expansion relative to the initial size for an air bubble in water prior to the first collapse. Preliminary simulations indicated that this metric gave the correct resonance size for small excitations. These simulations demonstrated a downshift in resonance size with increasing pressure amplitude.

11:30

4aBB12. Subharmonic response from single, polymer-shell contrast agents subjected to high-frequency excitation. Parag V. Chitnis, Jonathan Mamou, Paul Lee, and Jeffrey A. Ketterling (Lizzi Ctr. for Biomedical Eng., Riverside Res. Inst., 156 William St., 9th Fl., New York, NY 10038)

Three polymer-shelled agents (nominal mean diameters of 0.56, 1.1, and 3.4 μm) from POINT Biomedical were investigated to determine the optimal parameter space for generating a subharmonic response from single agents when subjected to high-frequency (above 20 MHz) excitation. A flow phantom was constructed to restrict the flow of a dilute contrast agent solution to a small volume. Two single-element transducers, with nominal center frequencies of 40 and 20 MHz, were aligned such that they were confocal and orthogonal to each other, and their mutual focus was positioned within the flow phantom. The 40 MHz transducer was used in transmit/receive mode while the 20 MHz transducer was used passively in the receive mode. The radio-frequency backscatter signals from individual contrast agents were digitized simultaneously from both transducers under a variety of pulse durations (5–20 cycles), acoustic pressure levels (1.5–6.0 MPa), and driving frequencies (35–45 MHz). Echo signals from individual contrast agents were windowed and spectra were calculated. For each contrast agent, the magnitude of the subharmonic (20–MHz) response was normalized with respect to the magnitude of the fundamental (40–MHz) backscatter. Experimental results agreed closely with theoretical calculations. [Work supported by NIH EB006372.]

11:45

4aBB13. Dissolution and stabilization of contrast microbubble by its elastic shell. Kausik Sarkar and Amit Katiyar (Mech. Eng., Univ. of Delaware, Newark, DE 19716)

We have developed a model for gas transport from encapsulated contrast microbubbles used for ultrasound imaging and drug delivery. The model explicitly accounts for permeability of gas through encapsulation and encapsulation elasticity. We use it to investigate dissolution time and stability of a lipid-coated perfluorocarbon bubble such as Definity. Realistic values of material properties such as diffusivities, permeabilities, and Ostwald coefficients of air and octafluoropropane were used to find that the lifetime of hours for such a bubble is only possible at extremely low surface tension in the absence of shell elasticity. Dissolution dynamics is investigated for effects of various parameters such as initial mole fraction of octafluoropropane, initial radius, surface tension, and shell permeability. The dissolution dynamics scales with permeability, in that when the time is nondimensioanlized with permeability, curves for different permeabilities collapse on a single curve. For an elastic shell, one obtains stable bubbles when the appropriate condition on surface tension and encapsulation elasticity is satisfied. The condition varies with the level of air saturation of the surrounding medium. For the oversaturated case, the dynamics allows multiple branches of equilibrium solutions. Stability of these branches are numerically investigated and discussed.

Session 4aID

Interdisciplinary: Workshop on Preparing Articles for the Journal of the Acoustical Society of America (JASA) and JASA Express Letters

Ning Xiang, Chair
Architecture, Rensselaer Polytechnic Inst., Troy, NY 12180

Chair's Introduction—8:55

Invited Papers

9:00

4aID1. Achieving publication excellence in the Journal of the Acoustical Society of America. Ning Xiang (Graduate Prog. in Architect. Acoust., Rensselaer Polytech. Inst., Troy, NY 12180)

Publications in refereed acoustics journals are of significant relevance for scientists and acousticians in the acoustics-related fields. The Journal of the Acoustical Society of America (JASA) encourages authors to submit papers for JASA publication. In achieving publishing excellence, the JASA regularly publishes detailed, updated guidance and instructions. As a frequent reviewer, an author of JASA papers, and an Associate Editor of the JASA, this paper will provide an outline and overview of its peer-review process of the JASA to analyze possible reasons for successful and unsuccessful publication effort. This paper also discusses how to prepare qualified manuscripts, how to avoid unnecessary delays for publications in the JASA, and how to review manuscripts for JASA.

9:25

4aID2. Realities of publishing in a journal: Why should you submit, what should you submit, and what problems might you encounter? Allan D. Pierce (Acoustical Society of America, Ste. 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502)

Attractions of a journal are its widespread availability, its archival (forever!) nature, its priority in literature searches, and its prestige. Articles should be readable to others in the field, be significant, and original. JASA is selective and imposes standards. Perceived quality is often measured by the "impact factor," which may have very little to do with the extent to which the journal fulfills the mission of the Society. Of great frustration to the editors is that a substantial fraction of authors who submit papers seem to be somewhat clueless as to what is a reasonable topic and what is a reasonable scope for an article in JASA. Frustrating also is that most good work reported at Society meetings never gets submitted. The present talk critically discusses the selection process, its peer-review aspects, and its flaws. The selection process deals with realities, such as that willing and competent reviewers are hard to find and that submitted reviews are often inane, with carefully selected highly expert associate editors who can make authoritative decisions without absolute reliance on external reviews. Suggestions are given on how to prepare a suitable manuscript and on how to cope with the vagaries of the peer-review process.

9:50

4aID3. Important aspects of editorial procedures for the information of inexperienced authors. Keith Attenborough (Dept. of Design, Development, Environment and Mater., The Open Univ., Milton Keynes MK7 6AA, UK, k.attenborough@open.ac.uk)

Several matters concerning the quality of papers and the editorial process have emerged from editorial activities for three acoustically-related journals (Applied Acoustics, Acta Acustica combined with Acustica, and the Journal of the Acoustical Society of America). Each of the journals suggests particular criteria to reviewers as the basis for their reviews. These factors are compared and discussed. Each of the journals offers various editorial decision options. These options and the uses that are made of them are discussed. Two common factors that influence editorial and reviewer judgements on submission quality include (a) the use of English and (b) the provision of a comprehensive and critical literature review. An increasingly important consideration is the availability of good reviewers in areas related to the topic of the paper. Sanitized examples illustrating some of these points are offered.

10:15—10:25 Break

10:25

4aID4. Preparing a submission to the Journal of the Acoustical Society of America on applied projects in architectural acoustics. Lily M. Wang (Architectural Engr. Prog., Peter Kiewit Inst., Univ. of Nebraska–Lincoln, 1110 S. 67th St., Omaha, NE 68182-0681)

The Journal of the Acoustical Society of America (JASA) encourages authors to submit articles for publication that are based on more applied projects, such as those commonly found in the technical area of architectural acoustics. However, very few of this type have been published in the recent past. Suggestions on how such articles should be prepared and how they may meet the "significance" criterion will be given, from the viewpoint of a current JASA associate editor in architectural acoustics. Additionally a review of such articles that have been published in JASA within the past few decades will be provided.

10:50

4aID5. Manuscript preparation—How Acta Acustica united with Acustica compares with the Journal of the Acoustical Society of America. Dick Botteldooren (Dept. of Information Technol., Ghent Univ., Belgium, Dick.Botteldooren@intec.ugent.be) and Michael Vorlaender (RWTH Aachen Universivy, Germany)

Scientific writing is essential for academic progress and technical innovation. Rules and ethics for writing are well-defined, and detailed guidelines for authors are available. Nevertheless, journals have a specific flavor which is not only related to the focus of content. Thus, for authors preparing a manuscript, the choice of journal is an important issue. Based on survey material and analyses of past publications, differences between Acta Acustica united with Acustica (AA.A) and JASA will be highlighted. Journal policy has to deal with the variety of manuscript content covering the span from fundamental science to technical applied papers. The readers expect both, and this is even more important for society journals like JASA and AA.A. Review processes that guarantee equal quality of technical and purely academic contributions, yet keep in mind their own specificity, are accordingly difficult to set up. Recent changes in handling the review of technical and applied papers in AA.A will be discussed.

11:15—11:45 Panel Discussion

THURSDAY MORNING, 21 MAY 2009 STUDIO SUITE, 9:00 TO 11:15 A.M.

Session 4aMU

Musical Acoustics: Musical Perception and Modeling

Diana Deutsch, Chair
Dept. of Psychology, Univ. of California, San Diego, La Jolla, CA 92093-0109

Contributed Papers

9:00

4aMU1. Absolute pitch among students in an American music conservatory: Association with tone language fluency. Diana Deutsch, Kevin Dooley (Dept. of Psychol., Univ. of California, San Diego, La Jolla, CA 92093), Trevor Henthorn (Univ. of California, San Diego, La Jolla, CA 92093), and Brian Head (Univ. of Southern California, Los Angeles, CA 90089)

Absolute pitch (AP), the ability to name a musical note in the absence of a reference note, is extremely rare in the United States and Europe, and its genesis is unclear. The prevalence of AP was examined among students in an American music conservatory, as a function of age of onset of musical training, ethnicity, and fluency in speaking a tone language. Taking those of East Asian ethnicity, the performance level on a test of AP was significantly higher among those who spoke a tone language very fluently than among those who spoke a tone language fairly fluently, which was in turn higher than among those who were not fluent in speaking a tone language. The performance level of this last group did not differ significantly from that of Caucasian students who spoke only intonation language. An advantage to early onset of musical training was found, but did not interact with the effect of language. Further analyses showed that the results could not be explained by country of early music education. The findings support the hypothesis that the acquisition of AP by tone language speakers involves the same process as occurs in the acquisition of a second tone language.

9:15

4aMU2. The effect of musical experience on describing sounds with everyday words. Mihir Sarkar, Cyril Lan, Joseph Diaz, and Barry Vercoe (The Media Lab., Massachusetts Inst. of Technol., 20 Ames St., Cambridge, MA 02139, mihir@media.mit.edu)

Musicians often use non-technical words such as "warm," "sharp," or "sweet" to describe sound quality. Commonplace experience indicates that the descriptions of a sound by a diverse group of musicians may vary, suggesting that musical background may influence one's interpretation of a sound. A research study was carried out targeting 844 subjects of varying musical backgrounds where each subject had the chance to match various words to sound samples. Each subject was assigned to one or more musical categories (strings, woodwinds, electronic, percussion, brass) based on previous musical experience, and the results were compared across categories. Statistical measures were employed to determine if a correlation existed between musical background and survey responses. After analyzing the results from all sound-word combinations, it was determined that the musical background had no effect on the selection of words. Because of the nature of statistical hypothesis testing, the expected rate of false positives was greater than the proportion of statistically significant sound-word combinations. From the data collected in this user study, it is reasonable to suggest that the description of musical sounds is an innate skill that is not influenced by musical background and training.

9:30

4aMU3. A spectral analysis of the tuba mirum section of six live concert performances of Verdi's Requiem as conducted by Arturo Toscanini. Robert C. Chapman (11721 W. Brandt Ave., Littleton, CO 80127)

Arturo Toscanini conducted Verdi's Requiem 29 times with ten different orchestras between the years 1902 and 1951. Of these 29 performances, six of them were recorded between the years 1938 and 1951 with three different orchestras. An analysis of the Tuba Mirum section of this work was done to determine musical element consistency between different dates of performance and different orchestras. The Tuba Mirum section was selected because of the amount of control a conductor has to have over their musicians in order to obtain maximum musical effect. The musical elements considered in the analysis were rhythmical consistency, tempo, articulation, and dynamics. The amount of time to perform this section of music was also investigated.

9:45

4aMU4. Auditory effect of perturbing musical tones by interpolation with other musical tones. James W. Beauchamp (Dept. of Elec. & Comput. Eng. and School of Music, Univ. of Illinois at Urbana-Champaign, 1002 Eliot, Urbana, IL 61801, jwbeauch@uiuc.edu), Andrew B. Horner (Hong Kong Univ. of Sci. and Technol., Clear Water Bay, Kowloon, Hong Kong), and Richard H. Y. So (Hong Kong Univ. of Sci. and Technolgy, Clear Water Bay, Kowloon, Hong Kong)

The effect of blending variable amounts of a secondary tone with a primary tone by means of interpolating between their corresponding harmonic amplitudes was investigated. Original tones (bassoon, clarinet, flute, horn, oboe, alto saxophone, trumpet, and violin) were normalized with respect to fundamental frequency, duration, attack and decay times, and loudness; also, harmonic frequencies were flattened. However, the basic time variations of the tones' harmonic amplitudes were preserved. Interpolation was accomplished in the frequency domain using interpolation levels between 5 and 50%. While the effect of perturbation is highly dependent on the primary /secondary instrument pair, results show that the effect of a secondary instrument is heard most easily for primary instruments horn and bassoon and least easily for primary instruments trumpet and saxophone. On the other hand, clarinet and trumpet are heard most easily as secondary instruments, whereas bassoon and violin are slow to be heard. Discrimination scores were correlated with different spectrotemporal measures of the tone spectra: spectral incoherence, normalized spectral centroid deviation, and spectral irregularity. The only significant effect found was that primary instruments with high spectral incoherence tend to mitigate against perturbation by secondary instruments. [Work supported by Research Grants Council Grants 613806 and 613508.]

10:00—10:15 Break

10:15

4aMU5. Physical modeling of the piano: An investigation into the effect of string stiffness on the hammer string interaction. Charalampos Saitis (Computational Acoust. Modelling Lab., Music Technol./CIRMMT, Schulich Sch. of Music, McGill Univ., Montreal, QC, Canada, charalampos.saitis@mail.mcgill.ca), Sarah Orr, and Maarten van Walstijn (Queen's Univ. Belfast, Belfast, UK)

The stiff string wave equation has four solutions, two of which are fast-decaying waves introduced by the string stiffness. In the case of digital waveguide modeling of piano strings these are normally neglected. Some recent reports have suggested that all four traveling waves should be considered, at least at the neighborhood of interaction points (i.e., the hammer and the boundaries). This paper investigates the effect of omitting string stiffness in the context of sound synthesis of the piano by physical modeling. A stiff, lossy string with a spatially distributed hammer force excitation is implemented using both a finite-difference time-domain scheme and a digital waveguide model. The two models are designed so as to have the exact same features but for the two stiffness-related solutions. Numerical experiments are employed to study the contact force and string velocity signals for different initial hammer velocity values. The results generally confirm that the two fast-decaying waves have only a marginal effect on the overall string motion. However, small audible differences result for bass strings struck with high initial hammer velocities.

10:30

4aMU6. A real-time music synthesis engine for physical modeling of plucked string instruments. Huynh V. Luong (School of Comp. Eng. and Info. Tech., Univ. of Ulsan, Ulsan 680-749, Korea), Sangjin Cho, Jong-Myon Kim, and Uipil Chong (Univ. of Ulsan, Korea)

Music synthesis continues to offer huge potential possibilities for the creation of new musical instruments. One of the promising music synthesis techniques is physical modeling which produces output sounds that resemble much more closely their physical counterparts since it offers the potential of more intuitive control. However, this results in tremendous computational and I/O requirements, prohibiting real-time use in composition and live performance. To meet the performance requirements, we introduce a parallel processing engine. Whereas commercial digital signal processors such as TI TMS320C6x families use silicon area for large multiported register files, large caches, and deeply pipelined functional units, our parallel processing engine contain many more simple processing elements (PEs) for the same silicon area. As a result, our engine often employs thousands of PEs while possibly distributing and colocating PEs with the data I/O to minimize storage and data communication requirements. In this paper, we implemented physical modeling of a representative plucked Korean string instrument, called Gayageum, which has 12 silk strings. Our engine achieved 12-notes music synthesis in real-time at 44.1 kHz sampling rate for the physical modeling algorithms. This is in contrast to TI TMS320C6x, which achieves only single-note music synthesis. [Work supported by KOSEF, R01-2008-000-20493-0.]

10:45

4aMU7. Acoustical properties of pure sound piano wire. David Ripplinger, Brian Anderson, Tim Leishman, and William Strong (Dept. of Phys., Brigham Young Univ., Provo, UT 84602)

Pure sound piano wire is a stainless-steel wire that has only recently entered the U.S. market. Because of its different composition, which makes the wire more malleable, it should have a considerably lower amount of inharmonicity compared to regular steel wire. Measurements were conducted on several pianos with regular piano wire (Rosslau and Mapes) and pure sound in order to assess their differences in inharmonicity and tonal qualities. The pure sound wire produced measurably less inharmonicity than regular wire on the same kind of piano. However, this difference is much smaller compared to the difference between small and large pianos. This presentation will explain the methods of measurement and analysis, as well as simulations that were implemented in order to analyze the effect that inharmonicity has on the temperament, octave stretching, and interval patterns. [The Brigham Young University Department of Physics is acknowledged for the funding it provided for this research.]

11:00

4aMU8. Identification of impact sounds by professional percussionists. Ching-Ju Liu (Dept. of Communicative Disord., Univ. of Wisconsin, 1975 Willow Dr. Madison, WI 53706, chingjuliu@wisc.edu) and Robert Lutfi (Univ. of Wisconsin, Madison, WI 53706)

The present study was undertaken to determine the best of the ear's ability to identify the sounds of impact produced by the simplest of resonant objects (bars, plates, and membranes). We hypothesized that best performance would be achieved by professional percussionists who have had many years experience striking such objects to achieve desired nuances in sound. Five percussionists and five nonpercussionist musicians were recruited as participants from the University of Wisconsin School of Music. Additionally, 10 nonmusicians were recruited from the University at large. In a standard two-interval, forced-choice procedure, with and without feedback, listeners were asked to judge the impact sound corresponding to: (1) the greater force of impact; (2) the harder of two mallets; (3) the denser of the two objects struck; and (4) the point of mallet contact closest to the center of the object. Sounds were synthesized according to the equations of motion derived from a simple physical model which has been used in past studies [cf. Lutfi *et al.*, JASA 118, 393–404 (2005)]. Generally, the results provide little support for the hypothesis that professional percussionists are more adept than the rest of us at judging the properties of impact sounds. [Research supported by NIDCD.]

Session 4aNS

Noise, Architectural Acoustics and ASA Committee on Standards: Hospital Noise and Health Care Facilities

Erica E. Ryherd, Chair
Dept. of Mechanical Engineering, Georgia Inst. of Technology, Atlanta, GA 30332-0405

Invited Papers

9:00

4aNS1. The new comprehensive acoustical criteria for healthcare facilities. David M. Sykes and Gregory Tocci (Remington Partners, LLC, 23 Buckingham St., Cambridge, MA 02138)

New comprehensive acoustical guidelines for healthcare facilities were drafted for the American Institute of Architects and the American Hospital Association in 2005–6 by the 500-member TC-AA.NS.SC (Speech Privacy & Healthcare Acoustics) which is chaired by Gregory Tocci, David Sykes, and William Cavanaugh. Following two rounds of public review, these guidelines were approved for use by the Green Guide for Healthcare in 2007 and in early 2009 they were issued as the sole "Reference Standard" for two new LEED "Indoor Environmental Quality" credits. In early 2010, following two additional rounds of public review, the same guidelines will be released by the Facility Guidelines Institute and the American Society of Healthcare Architects (a division of the American Hospital Association) in the authoritative, code-level document, "FGI/ASHE Guidelines for the Design and Construction of Hospitals and Healthcare Facilities." Practitioners and researchers need to be aware of these criteria when designing acoustical solutions for healthcare facilities. This paper will present an overview of the guidelines. The speaker is co-chairman of the technical committee responsible for drafting the criteria and of ANSI S12 WG44, which is currently developing an additional new healthcare acoustics standard.

9:20

4aNS2. Comparing the sound environments in two critical care settings. Selen Okcu (GaTech, College of Architecture, Atlanta, GA 30332-0155), Erica Ryherd, and Craig Zimring (GaTech, Atlanta, GA 30332-0155)

Critical care nurses perform crucial tasks in complicated sound environments. The existence of many different noise sources (i.e., staff conversation, medical alarms, etc.) with different sound qualities cause nurses to experience constantly changing acoustic conditions while providing care for critically ill. Some of those acoustical qualities in critical care settings can negatively affect nurse well-being and task performance. In different critical care settings, the acoustic qualities can vary. Some architectural qualities of those settings can be an indicator of those variations. In this study, we documented the detailed objective and subjective sound environment of two critical care settings with different architectural layouts. The comparative analyses are used to understand the differences between two acoustic settings and the relationship between subjective and objective sound environments. Perceived qualities of the physical work environments are examined to explore the association between architectural features and acoustic qualities.

9:40

4aNS3. Evaluating the intensive care unit soundscape. Timothy Y. Hsu, Erica Ryherd (Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405, gth776e@mail.gatech.edu), and Kerstin Persson Waye (Gothenburg Univ., 405 30 Gothenburg, Sweden)

The intermittent sounds in hospital wards may induce arousal among patients leading to responses such as annoyance, sleep disturbance, and cardio-vascular reactions. The sound environment as a whole may also affect the efficiency and general health among the staff. A series of studies are being conducted by the authors to evaluate the modern hospital soundscape including occupant response. Collaborations between engineering and medicine are being utilized to assess the soundscape from both a quantitative and qualitative standpoint. This talk will focus on soundscape evaluations of intensive care units. This includes a pilot study performed in a medical-surgical intensive care unit (ICU) of a Swedish hospital. Patients were monitored for 24 hours during their stay in the ICU and both acoustic and physiological data were simultaneously recorded. Additionally, the staff wore dosimeters and completed perception questionnaires. The methodology and analyses of these detailed acoustic measurements and preliminary subjective results will be discussed. [Work supported by ASA and Swedish FAS.]

10:00—10:15 Break

10:15

4aNS4. Mechanical equipment and ambulances. Strange bedfellows of cardiovascular services. Chad N. Himmel and Jack B. Evans (JEAcoust., 1705 W Koenig Ln., Austin, TX 78756, himmel@jeacoustics.com)

A case study will be presented regarding vibration and noise control design for an existing heart hospital. Facility expansion within a crowded site necessitates sandwiching a suite of new cardiac catheterization laboratories between mechanical equipment rooms above and the hospital's main ambulance driveway below. The facility expansion also includes cardiac computed tomography, magnetic reso-

nance imaging, and nuclear imaging, plus cardiovascular care, treatment, and administrative support spaces. Procedure and support spaces can be disturbed by mechanical equipment noise and vibration and noise from ambulance siren. Cardiac procedure instruments and imaging can be disturbed by low frequency noise and vibration from building mechanical systems, ambulance traffic, and building occupants. Design criteria for permissible building vibration and continuous background noise will be presented along with relevant sources and bases. Measurement evaluation results for design will be contrasted with criteria. Measures incorporated in design to mitigate vibration and noise on catheterization laboratories will be discussed. Measures considered in design include structural floor "detuning" concepts, stiffened supports for catheterization laboratory C-arms, mechanical equipment vibration isolation mounts, and floating concrete floor systems for mechanical rooms. If available, postconstruction spectral analysis measurements of building noise and vibration will be presented.

10:35

4aNS5. Predicting structure-borne noise for new construction adjacent to medical facilities. Richard A. Carman (Wilson, Ihrig & Assoc., Inc., 5776 Broadway, Oakland, CA 94618) and Gary M. Glickman (Wilson, Ihrig & Assoc., Inc., New York, NY 10004)

When new building construction is conducted in close proximity to existing medical or medical research facilities, structure-borne noise due to construction activities generating vibration can cause impacts to the occupants of the existing building. Theoretical modeling of structure-borne noise is very complicated and can be extremely time consuming. The feasibility of the two primary candidates (i.e., FEA and SEA) for modeling this phenomenon is questionable, at least at this point, for a number of reasons that are discussed. It is possible that the time will come when a theoretical method can be used reliably to predict structure-borne noise transmission. In the meantime, using an empirical approach seems to be the most viable. A case study is presented of a facility for medical research involving mice. Preconstruction projections of structure-borne noise and vibration are compared to those measured with an extensive monitoring program employed during construction.

10:55

4aNS6. Vibration sensitivity of optical microscopes in the healthcare setting. Hal Amick and Michael Gendreau (Colin Gordon & Assoc., 150 North Hill Dr., Ste. 15, Brisbane, CA 94005, Hal.Amick@colingordon.com)

The paper examines vibration criteria for benchtop and articulated floor-supported optical microscopes, comparing published specifications with data measured in hospitals for diagnostic purposes. A case study of vibrations that degraded orthopedic microsurgery is of particular interest. Revisions and enhancements of published criteria are proposed.

Contributed Paper

11:15

4aNS7. Soundscape analysis of a neonatal intensive care unit (NICU) facility. Gary Siebein (School of Architecture, Univ. of Florida, Gainesville, FL 32611-5702, gsiebein@siebeinacoustic.com), Reece Skelton, Victoria McCloud, Robert Lilkendey, and Hyun Paek (Siebein Assoc., Inc., Gainesville, FL 32607)

A soundscape study was made of an existing NICU facility in a major urban hospital to document the nature and magnitude of sounds experienced by newborn infants in this environment. Focus group discussions were held with hospital administrators, NICU staff, design team members, and families of patients to determine the types of sounds that are heard in normal operation of the NICU. Long-term average sound level measurements of general sounds in the NICU were made for several work shifts. Short-term acoustical measurements of specific acoustic events were also made to obtain octave band sound level data for each of the activities, medical equipment sounds, and building infrastructure sounds that comprise the soundscape of the unit. Audio and video recordings of the specific acoustical events that comprise the soundscape of the NICU were also made. The acoustical measurements and soundscape analysis are used to evaluate proposed acoustical design criteria for NICU facilities compared to nonacoustic health risks reported in the literature.

4aPA1. Early years of the parametric array—An anecdotal history. David T. Blackstock (Appl. Res. Labs., Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029 and M.E. Dept., UT Austin, Austin, TX 78712-0292)

This review covers the period from 1960 to about the mid-1970s. Westervelt presented his theory of the parametric array at the June 1960 Acoustical Society Meeting, held at Brown Univ. In the same session, Bellin and Beyer reported experimental confirmation, primarily for the array in water. Despite the tantalizing properties of the parametric array—narrow low-frequency beam produced with a small source, absence of sidelobes, and potentially broadband operation—the acoustical community at first paid little attention. Berktay woke us up with a series of papers in the mid-to-late 1960s on possible applications. Interest in underwater parametric arrays then exploded, including attempts to make parametric receiving arrays practical. Definitive experimental confirmation of the parametric array in air was finally reported in 1973. However, practical applications of the airborne array did not appear until many years later.

8:20

4aPA2. Parametric acoustic arrays: A Bergen view. Halvor Hobæk (Dept. of Phys., Univ. of Bergen, Allegt. 55, N-5007 Bergen, Norway)

At the University of Bergen (UoB), Norway, research activity in physical acoustics started in the mid-1960s with investigations on the parametric acoustic array (PAA). The newly appointed professor in applied mathematics, Sigve Tjøtta, had some years earlier been at Brown University and was inspired by the concept at a fundamental level, but also wanted experimental confirmation. No previous acoustical activity existed at UoB. The PAA project was started as a master project at Department of Physics, where the main activity was in nuclear, high-energy, and ionospheric physics. Bellin and Beyer's experiment served as a model. The results provided new information on the axial and directional properties of the difference frequency wave field. Inspired by this, theoretical modeling continued along with further measurements. Other nonlinear effects like acoustic streaming (boundary layer, density gradient) were also investigated. In 1975, a project together with SIMRAD and Norwegian Technical University resulted in a bottom penetrating PAA, later commercialized as "TOPAS." Numerical modeling based on the KZK equation resulted in the "Bergen Code," still in use for computing nonlinear acoustic propagation problems. In later years activity at UoB has expanded to encompass linear physical acoustics of various sorts, occasionally using PAA as a tool.

8:40

4aPA3. Parametric acoustic array development at the U.S. Navy's New London, Connecticut laboratory. David G. Browning (139 Old North Rd., Kingston, RI 02881, decibeldb@aol.com), Mark B. Moffett (731 Annaquatucket Rd., North Kingstown, RI 02852), and William L. Konrad (54 Laurel Hill Dr., Niantic, CT 06357)

A brief history of the development of parametric acoustic sources at the U.S. Navy Underwater Sound Laboratory (USNUSL), and its successor, the Naval Underwater Systems Center is presented. Inspired by Robert Mellen, the Parametric Sonar Group was formed to explore the practical implications of Westervelt's idea for underwater acoustics. Spanning more than two decades, this research pursued various potential applications exploiting the unique characteristics of parametric sources, including echo-ranging in reverberant environments, communications involving voice, data, music, and video signals, target-strength measurements, bottom bathymetry, high-resolution sub-bottom profiling, and measurements of scattering and reflection from surfaces. Parametric source design procedures were developed, and guidelines were established for diagnosing and avoiding undesirable effects, such as difference-frequency instability and spurious nonlinearities, such as direct radiation from the projector, cavitation, and receiver nonlinearity. Theoretical models extended the Westervelt theory to realistic primary fields. For planar projector arrays, parametric source design curves, valid for levels in the primary far field, enabled designers to predict performance without resorting to computer calculations. To obtain source-levels and beam-widths within the primary near field, where the secondary signal is generated, a computer program, called CONVOL5 in its present configuration, can be used to obtain more detailed performance predictions.

9:00

4aPA4. Research on parametric arrays in Russia: Historical perspective. Lev A. Ostrovsky (Zel Technologies/Univ. of Colorado, Boulder, CO 80305)

This presentation is concerned with the Russian part of the history of parametric arrays (PAs). After the pioneering works of P. Westervelt in the United States and V. Zverev and A. Kalachev in Russia and a decade of relative isolation, Soviet and Russian researches became involved internationally in the work on the PAs and, more generally, of nonlinear acoustic beams. Several Russian institutions have been involved, including Moscow University, Andreev Institute of Acoustics in Moscow, Radiophysics Research Institute and Institute of Applied Physics in Gorky (now Nizhny Novgorod), Gorky University, Pacific Oceanological Institute in Vladivostok, and some others. Selected Russian contributions of different years are to be outlined in this talk, including: (1) The theory of nonlinear acoustic beams, e.g., the Khokhlov-Zabolotskaya- Kuznetsov equation and other models of nonlinear acoustic beams in application to the PA; (2) the limitation of the PA efficiency by shock wave formation; (3) possible enhancement of the PA radiation by bubble layers; (4) experiments in laboratory and in the ocean; and (5) some new developments such as generation of low-frequency shear waves by ultrasound beams with biophysical applications.

9:20

4aPA5. Reflections on the early days of parametric array research and development. Thomas Muir (Natl. Ctr. for Phys. Acoust., Univ. of Mississippi, One Coliseum Dr. University, MS 38677)

Following Westervelt's classic paper (1960/1963), there was a period of laboratory exploration, involving small-scale experiments and theoretical modeling, with Orhan Berktay's early work anticipating the significance of several practical applications. Robert Mellen organized the First International Symposium on Nonlinear Acoustics (ISNA) in 1968, which the preset author was privileged to attend. Research interest and momentum began to build, expanding to field and seagoing experiments, as well as computational modeling. Some of the seminal milestones and achievements of this period are identified and illustrated. These include theoretical work, which enabled new experiments, and vice versa, facilitated by research tool engineering. A number of classic problems were studied, including parametric transmission and the effects of finite amplitude attenuation. Applications to air, water, and sediment research evolved, including propagation and backscattering measurements, subbottom profiling, and modal effects and communication in shallow water. Parametric reception became a hot topic, along with its intricate signal processing. Focusing of finite amplitude beams was developed, involving the use of lenses, also utilized for steering and scanning parametric beams. The bandwidth capability of parametric interaction was recognized, as were parametric transients for echo-ranging. Imaging applications emerged for both harmonic and difference frequency radiations, and a spin-off to biomedical ultrasonics was forged. By the mid-1980s, a dozen ISNA symposia had been held and the field had blossomed.

9:40

4aPA6. Audio parametric arrays in air. Mark F. Hamilton (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029)

Following Westervelt's discovery and theoretical description of the parametric acoustic array reported at the 1960 meeting of the ASA at Brown Univ., and the measurements in both water and air at ultrasonic frequencies, confirming Westervelt's predictions qualitatively, reported by Bellin and Beyer at that same meeting, it was not until 1973 that Bennett and Blackstock reported convincing quantitative comparisons of theory and experiment for a parametric array in air. While their experiments produced difference frequencies in the audio range, not until the late 1990s did application of the parametric array to directional audio transmission in air achieve any commercial success. This presentation will briefly review the history of developments leading up to modern-day audio parametric arrays. Challenges associated with transducer performance, signal processing, and acoustical measurements specific to audio parametric arrays in air will be described. Features of several audio parametric arrays currently on the market will be discussed. Finally, results will be presented from an ongoing collaboration between the author's group at Univ. of Texas at Austin and Professor Pierre Khuri-Yakub's group at Stanford Univ. to create audio parametric arrays in air using capacitive micromachined ultrasonic transducers to transmit the ultrasonic primary beams.

10:00—10:20 Break

10:20

4aPA7. High-powered parametric acoustic array in air. Robert W. Haupt (MIT Lincoln Lab., Active Optical Systems Group, 244 Wood St., Lexington, MA 02420, haupt@LL.mit.edu)

MIT Lincoln Laboratory has developed a prototype high-powered parametric acoustic array (HPPAA) for standoff acoustic excitation in several applications. Parametric arrays offer a highly directional, narrow beam mechanism to deliver sound in air to desired targets typically within a 100 m range. However, a difficult challenge arises in generating sufficient sound power at difference-frequencies below 1000 Hz at a range which can be critical for many target types. An important objective of the HPPAA design maximizes the difference-frequency pressure amplitude at range by maximizing the end-fire array length established by the PAA. The design optimizes the trade-offs between the three characteristic lengths that control the resultant end-fire array length including the pump or carrier wave attenuation, PAA aperture, and acoustic saturation of air. In field demonstrations, the HPPAA generated a carrier wave pressure power approximately 155 dB re-20-microPa one meter from the PAA face while generating a 300 Hz difference-frequency SPL of 90 dB re-20-microPa 8 meters from the PAA. These sound pressure levels at a few hundred hertz may enable safe standoff excitation and detection of buried landmines and may be useful in standoff nondestructive testing (NDT) damage detection and imaging of structures.

10:40

4aPA8. The development of a 75 kilohertz phase steered active parametric sonar system for subseabed target detection. Paul Lepper and Bryan Woodward (Dept. Electric and Elec. Eng., Loughborough Univ., Loughborough, LE11 3TU UK, p.a.lepper@lboro.ac.uk)

Parametric sonar systems offer a number of potential advantages over conventional sonar's that has encouraged investigation and implementation of nonlinear acoustic effects into sonar systems by numerous groups since Westervelt's discovery reported in 1956. The work represented here describes the development of an active parametric sonar system utilizing a 75 kHz primary frequency signal with measured secondary frequency generation from 1–22 kHz using a 2-D 729 element square array arranged into 13 staves of 54 elements each. The array, dedicated computer controlled signal synthesis and power amplifier systems were developed and tested during trials on the Fisheries Research Services trails site on Loch Duich, Scotland. Primary and secondary frequency source levels of 245 dB *re* 1 μPa-m and 195 dB *re* 1 μPa-m at 7 kHz were measured with −3 dB full angle beam-widths of 3 and 2.5°–7° for frequencies 3–11 kHz, respectively. Individual control of the thirteen stave (channels) allowed in-pulse scanning and beam steering across a 36° sector including demonstration of real-time dynamic stabilization in one plane. Results will be presented for implementation of the system into a towed body sonar used during sediment classifications trials off the coast of France and for target detection tasks in Scotland.

11:00

4aPA9. The parametric array in Berea sandstone: definitive experiments. Pierre-Yves Le Bas, James A. TenCate, Robert A. Guyer, and Paul A. Johnson (Geophys., MS D443, Los Alamos Natl. Lab., Los Alamos, NM 87545, pylb@lanl.gov)

Previous measurements of the characteristics of the parametric array in sandstone by Johnson and Shankland [J. Geophys. Res. **94**, 17729–17734 (1989)] were difficult to perform and only qualitative. Scanning laser vibrometers (Polytec) now make parametric array measurements in rock easier. However, hysteresis and memory effects play a strong role in the dynamic behavior of rocks and have the potential to mess up the creation of the parametric array in the medium. Thus, an experimental study was performed to find out just how well the "classical" theory of nonlinear acoustics works for a granular solid, a sandstone. An array of alternating PZT disk transducers was epoxied to a large block of Berea sandstone (1.2, 0.4, 0.4 m), every other one broadcasting with separate frequency generators and amps. Primary frequencies were around 100 kHz; difference frequencies of 10 to 20 kHz were observed. Two-D beampattern scans were taken and the results compared with calculations based on classical theory. The agreement is surprisingly good with a beta of around 200 and a Q (inverse attenuation) of 50.

11:20

4aPA10. Laboratory applications of truncated parametric arrays. Victor F. Humphrey (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton, SO17 1BJ, United Kingdom, vh@isvr.soton.ac.uk.)

Parametric arrays have characteristics that make them ideally suited for use as versatile sources in the laboratory for performing a range of measurements and acoustic studies. Such measurements can exploit the wideband character of the source to provide detailed acoustic response characteristics of systems as a function of frequency, while the short pulses and narrow beamwidths enable multiple reflections and unwanted echoes to be resolved or minimized. However, the need to make measurements in the nearfield of the array means that truncation of the nonlinear interaction region with an acoustic low-pass filter is advisable in order to generate a region free of secondary-sources and simplify the interpretation of the results. This truncation also avoids the possible influence of hydrophone nonlinearity. The effects of truncation on the array characteristics are illustrated using both model and experimental results. A number of examples of the use of arrays in the laboratory are given, including their use to study acoustic scattering from structures and diffraction from baffles, and measurement of reflection and transmission properties of materials. These demonstrate how the characteristics of parametric arrays can be exploited to make detailed, accurate measurements of relevance to underwater acoustics under laboratory conditions.

11:40

4aPA11. Parametric projectors protecting marine mammals from vessel collisions. Edmund R. Gerstein (Leviathan Legacy Inc., 1318 SW 14th St., Boca Raton, FL 33486, gerstein2@aol.com), Laura A. Gerstein (Leviathan Legacy Inc., Boca Raton, FL 33486), and Steven E. Forsythe (U.S. Naval Undersea Warfare Ctr., Newport, RI)

Marine mammals are vulnerable to ship collisions. Measurements of controlled ship passages through vertical hydrophone arrays demonstrate a confluence of propagation factors and near surface effects that obscure the sounds of approaching vessels which then pose serious detection challenges for marine mammals. Joe Blue, who first identified these challenges, later conceived of a parametric method to mitigate them. A highly directional, dual-frequency parametric array has been developed to reduce collision risks by selectively alerting only those animals in the direct path of approaching vessels. The system projector is comprised of multiple elements, band-centered to transmit a high carrier frequency along with a lower side band signal. A single-side band modulation and phase-shift method are employed. The non-linearity of water then demodulates the mixed high frequency carrier into a lower frequency waveform audible to both manatees and whales. The bow mounted array projects a narrow beam directly ahead of vessels, and "fills in" acoustical shadows to alert marine mammals of approaching danger. Controlled field tests of the manatee device in Florida's NASA wildlife refuge are proving effective. Real-world deployments on select Navy and DOD vessels are planned this year and sea tests of a larger whale system will start next year. [Funded by U.S. Department of Defense, Navy Legacy Resource Management Program.]

Contributed Papers

9:00

4aPP1. Revealing and quantifying temporal aspects of envelopes of high-frequency stimuli that lead to enhanced processing of interaural temporal disparities. Leslie R. Bernstein and Constantine Trahiotis (Depts. of Neurosci. and Surgery (Otolaryngol.), Univ. of Connecticut Health Ctr., Farmington, CT 06030)

This presentation concerns evaluating which aspects of envelopes of high-frequency waveforms foster efficient discrimination of interaural temporal disparities (ITDs). The experiments were designed to assess, quantitatively, the explanatory capability of metrics including: (1) the normalized fourth moment of the envelope (Y), (2) the normalized interaural correlation of the envelope, and (3) the dead time between peaks or maxima of the envelope. An ITD-discrimination study was conducted employing raised-sine stimuli centered at 4 kHz [John *et al.*, Ear and Hearing **23**, 106–117 (2002)]. The parameters of the stimuli that could be varied using such stimuli include: (1) the exponent of the raised sine, (2) the frequency of modulation, (3) the depth of modulation, (4) the degree of phase-scrambling applied to the spectral components of the envelope, and (5) the degree of phase-scrambling applied to the spectral components of the waveform. This set of parameters permitted us to construct an ensemble of stimuli that pit one metric against another in a manner that reveals the relative salience of particular temporal aspects of the envelope. Results will be discussed both in terms of the characteristics of the external, physical stimuli versus the stimuli as processed by the auditory periphery. [Research supported by research Grant Nos. NIH DC-04147 and DC-04073 from the National Institute on Deafness and Other Communication Disorders, National Institutes of Health.]

9:15

4aPP2. Sensitivity to interaural level differences in high-rate high-frequency click trains: A functional magnetic resonance imaging assessment. G. Christopher Stecker and Susan A. McLaughlin (Dept. of Speech & Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, cstecker@u.washington.edu)

While the auditory cortex (AC) is known to be necessary for accurate sound localization, the nature of spatial representation in AC remains poorly understood. Past animal studies have quantified sensitivity to auditory spatial cues [e.g., interaural level difference (ILD)] across subregions of AC. In this study, functional magnetic resonance imaging (fMRI) was used to assess ILD sensitivity across the surface of human AC. Normal-hearing listeners were presented with narrowband Gabor click trains (4000 Hz center frequency, 3 ms interclick interval) that varied parametrically in ILD over a range of +/− 30 dB. Simultaneously, whole-head fMRI images were acquired using a sparse imaging paradigm at 3 Tesla (32-slice EPI, 3.0×3.0×4.5 mm resolution, TR=12 s). During imaging, listeners detected rare target changes in ICI. Hemodynamic responses of compact AC subregions in individual subjects were assessed quantitatively using statistical pattern recognition with two goals: (1) to identify contiguous AC regions that share common patterns of sensitivity to ILD, and (2) to quantify, in information-theoretic terms, the ability of those responses to differentiate stimuli differing in ILD.

9:30

4aPP3. Precedence effect in children and adults: Effects of heard and unheard echoes on localization accuracy. Ruth Litovsky, Shelly Godar, and Phillip Wesolek (Waisman Ctr., Univ. of Wisconsin, 1500 Highland Ave., Madison, WI 53705, litovsky@waisman.wisc.edu)

The precedence effect is thought to facilitate sound localization in reverberant environments through localization dominance. This is demonstrated at short lead-lag delays, when a single fused auditory image is heard whose perceived location is dominated by the leading source. We studied localization dominance in children ages 4–5 and in adults. Stimuli were brief noise bursts, with lead-lag delays ranging from 1–100 ms; the lead location varied along the azimuth (−60, −40, −20, 20, 40, 60 deg) and the lag was fixed at 0 deg. Subjects indicated the perceived location(s) of each heard source. Localization accuracy was computed for the lead and lag at each delay. On a separate task, with delays varying randomly, subjects indicated whether they heard one or two auditory events, and echo threshold was obtained. Results show that localization accuracy for the lead declined as delays increased, suggesting that as the lag became more audible its interference in the localization process increased. For most subjects, the interference was predictable from independent measures of fusion echo thresholds. The impact of the lag, a single simulated echo, on localization accuracy, was greater for children than adults. These data suggest that the precedence effect is less effective at facilitating sound localization in young children than in adults. [Work supported by NIDCD Grant R01DC008957.]

9:45

4aPP4. Real-virtual equivalent auditory localization with head motion. Griffin D. Romigh and Douglas S. Brungart (Air Force Res. Lab., Wright-Patterson Air Force Base, OH 45433)

Several researchers have shown that individualized head related transfer functions (HRTFs) can be used to produce virtual sounds that are equivalent in terms of localization to free field sounds. Thus far, however, these results have only been shown in studies that have required listeners to keep their heads stationary during the playback of the virtual sounds. In this study, we investigated the performance limits of a virtual auditory display system that incorporated individualized HRTFs but allowed free head motion during the localization process. One key aspect of the system is a high-speed HRTF measurement process that allowed a full set of individualized HRTFs to be measured in less than 4 min. This made it possible to make an HRTF recording and complete a localization task using the resulting HRTFs within the same 30-min experimental session. The results show that equivalent free-field and virtual localization performance was achieved when the virtual sounds were generated in the same session using specially-designed open-ear headphones that did not need to be removed during the headphone equalization process. This indicates that equivalent real-virtual closed-loop localization is possible even with the truncated, interpolated, minimum-phase HRTF filters that are required for practical, real-world virtual audio systems.

10:30

4aPP5. Head-related transfer function enhancement for improved vertical-polar localization. Douglas S. Brungart, Griffin D. Romigh, and Brian D. Simpson (AFRL/RHCB, Wright-Patterson Air Force Base, 2610 Seventh St., OH 45433)

Under ideal laboratory conditions, individualized head-related transfer functions (HRTFs) can produce virtual sound localization performance approaching the level achieved with real sound sources in the free field. However, in real-world applications of virtual audio, practical issues such as fit-refit variability in the headphone response and nonindividualized HRTFs generally lead to much worse localization performance, particularly in the up-down and front-back dimensions. Here we present a new technique that "enhances" the localizability of a virtual sound source by increasing the spectral contrast of the acoustic features that are relevant for spatial perception within a set of locations with nearly identical binaural cues (i.e., a "cone-of-confusion"). Validation experiments show that this enhancement technique can improve localization accuracy across a broad range of conditions, with as much as a 33% reduction in vertical-polar localization error for nonindividualized HRTFs measured on a KEMAR manikin; a 25% reduction in vertical-polar error for nonindividualized HRTFs measured on other human listeners; and a 33% reduction in vertical-polar error for individualized HRTFs presented under nonideal laboratory conditions (i.e., with headphone fit-refit variability). These results suggest that the proposed technique could provide benefits across a wide range of real-world virtual audio display applications. [Work sponsored by AFOSR.]

10:45

4aPP6. Azimuth dependency in auditory perception of speaker's facing angle. Hiroaki Kato, Hironori Takemoto, Ryouichi Nishimura, and Parham Mokhtari (NICT/ATR, 2-2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto 619-0288, Japan, kato@atr.jp)

In pursuit of an ultimately realistic human-to-human telecommunication technology, the ability to auditorily perceive the facing direction of a human speaker was measured. A male speaker sat on a pivot chair in an anechoic chamber and spoke a short sentence (about 5 s) while facing either of eight azimuth angles (0=listener's direction, 45, 90, 135, 180, 225, 270, or 315 deg). These angles were set solely by turning the pivot chair. Blindfolded listeners heard the spoken sentence at a distance of either 1.2 or 2.4 m from the speaker and were asked to indicate the speaker's facing angle. The average of errors between listeners' responses and actual speaker's facing angles was 23.5 deg. Further analyses showed a significant effect of the speaker's facing azimuth on the accuracy of listeners' responses. Listeners made remarkably small errors (6.6 deg on average) when the speaker faced the listener's direction (azimuth = 0 deg). The second smallest errors were observed for the back angle (azimuth = 180 deg). Few front-back confusions were observed. This dependency of listeners' accuracy was extensively discussed from the interest of effective acoustic cues obtained by a precise computer simulation as well as an ecological perspective.

11:00

4aPP7. Strength and cardivascular fitness predict time-to-arrival perception of looming sounds. John G. Neuhoff, Katherine L. Long, and Rebecca C. Worthington (Dept. of Psych., The College of Wooster, Wooster, OH, jneuhoff@wooster.edu)

Perceiving rapidly approaching sounding objects can be critical for survival. In studies of "auditory looming" perception, listeners consistently perceive sound sources as closer than they actually are, resulting in an underestimation of arrival time (Neuhoff, Planisek, and Seifritz, 2009; Rosenblum, Carello, and Pastore, 1987). This effect has been argued to provide an evolutionary advantage by allowing more time to prepare for the source. However, critical to this argument is the timely engagement of motor behaviors. Here, we tested the hypothesis that listeners with lower levels of physical fitness would have a larger anticipatory bias in perceived auditory arrival time, and thus a larger margin of safety in response to looming sounds. Listeners judged the arrival time of a three-dimensional looming sound. Physical fitness was measured using recovering heart rate after exercise and grip strength. Results show that the anticipatory bias in perceiving looming sounds is negatively correlated with physical fitness ($r=-0.41$). Those least prepared physically to interact with a looming sound source have a greater perceptual margin of safety. The findings are consistent with an evolutionary explanation of the anticipatory bias for looming sounds and provide evidence for fitness-based perception-action links between the auditory and motor systems.

11:15

4aPP8. How visual cues help us understand speech in a complex environment. Lingqiang Kong and Barbara Shinn-Cunningham (Cognit. and Neural Systems, 677 Beacon St., Boston, MA 02215)

At a cocktail party, visual cues may help a listener by showing them *where* or *when* to direct attention, *what* acoustic modulations a target utterance contains, and/or *what* articulatory gestures produce the target. Here, we investigated target speech intelligibility while varying the visual cues available in a complex, confusing auditory scene. In all cases, subjects listened for a target utterance in the presence of multiple masker utterances with similar grammatical structure spoken by the same talker. The timing and direction of the target (and maskers) varied randomly, increasing the uncertainty about where and when to focus auditory attention. The number of correctly reported target key words measured performance. Performance tended to improve as the amount of visual information increased, particularly when masker phrases came from the direction of the target. Performance was generally similar whether listeners saw full videos of the target talker from the correct direction or only a static image of the talker at the right time in the correct direction. However, temporal information about where and when the target occurred improved performance over knowing only target location. Results suggest that in these scenes, visual cues aid target understanding by indicating where and roughly when to direct attention.

11:30

4aPP9. Stimulus continuity is not necessary for the salience of dynamic sound localization cues. Ewan A. Macpherson (School of Commun. Sci. and Disord. and Natl. Ctr. for Audiol., Univ. of Western ON, 1201 Western Rd., London, ON, Canada, N6G 1H1, ewan.macpherson@nca.uwo.ca)

Correspondence between head rotation and resulting changes in interaural difference cues provides information about sound source location. We assessed whether source continuity or merely relative displacement is necessary for use of this dynamic localization cue. Low-frequency (0.5–1 kHz) noise-band targets, not correctly localizable in the absence of head motion or for motion duration <50 ms [Macpherson and Kerr, APCAM (2008)], were presented while the listener performed a practiced head rotation at 50 deg/s. The stimuli were either continuous (a single burst gated on and off as the head entered and exited a variable-width spatial window) or discrete (two 20 ms endpoint bursts, triggered as the head entered and exited the window). Human listeners reported the apparent location of the stimulus by orienting with their heads subsequent to the initial head rotation. The minimum head movement angle (MHMA) necessary to resolve front/rear ambiguity was measured for each stimulus type. Similar MHMAs of 5–10 deg were measured for continuous and discrete stimuli, suggesting that endpoint "snapshots'' providing only displacement information are sufficient for use of dynamic localization cues. That parallels the finding that stimulus continuity does not improve detection of source motion [Chandler and Grantham, J. Acoust. Soc. Am. 106, 1956–1968 (1992)]. [Work supported by NSF and NIH/NIDCD.]

11:45

4aPP10. Localizing a speech target in a multitalker mixture. Norbert Kopčo (Dept. of Cybern. and AI, Tech. Univ. of Košice, Letná 9, Košice, Slovakia, kopco@bu.edu), Virginia Best, and Simon Carlile (Univ. of Sydney, Sydney, Australia)

Despite the importance of spatial hearing in everyday listening, little is known about the accuracy of sound localization in a complex mixture of sounds. Here we measured, for the frontal audio-visual horizon, how accu-

rately listeners could localize a female-voice target amidst four spatially distributed male-voice interferers in a moderately reverberant room. To examine whether listeners can make use of *a priori* knowledge about the configuration of the scene, we compared performance when the interferer locations were fixed (in one of five known patterns) to when the locations varied from trial to trial. The presence of interferers disrupted target localization, even after accounting for reduced target detectability. Randomizing the interferer locations had a moderate influence, degrading performance in some configurations but improving it in others. All effects were magnified when the target-to-interferer intensity ratio was reduced. The results confirm that spatial perception is disrupted by interfering sounds, and that this disruption is modified to some extent by listeners' expectations about the spatial arrangement of the scene. 4aSAa1. A residual-potential boundary for time-domain problems in computational acoustics. Thomas L. Geers (Dept. of Mech. Eng., Univ. of Colorado, Boulder, CO 80309, geers@spot.colorado.edu)

For many years, researchers have sought theoretically exact time-domain computational boundaries that are temporally, spatially, and geometrically local. Unfortunately, spatial locality and geometric locality cannot be simultaneously achieved for exact boundaries. *Absorbing* boundaries offer spatial locality but not geometric locality, whereas *impedance* boundaries offer the latter but not the former. Following a brief discussion of these topics, a new, theoretically exact impedance boundary is introduced that is based on modal *residual potentials* for the spherical geometry. The new boundary produces a set of first-order, uncoupled ODEs for *nodal* boundary responses and a set of low-order, uncoupled stepping formulas for *modal* boundary responses. The two sets are coupled through nodal-modal transformation based on the orthogonal surface functions for the spherical boundary. Numerical results generated with the boundary are presented for selected benchmark problems. Finally, extension of the method to other separable geometries for the wave equation is discussed.

4aSAb1. Experimental validation of vibroacoustic reconstruction of a rectangular plate with different boundary conditions. Logesh Kumar Natarajan and Sean Wu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202)

This paper provides an experimental validation of vibroacoustic responses of a rectangular plate reconstructed using Helmholtz equation least squares (HELS) method. Experimental studies were conducted on baffled rectangular plates of different aspect ratios with free as well as clamped boundary conditions under random excitation. The radiated acoustic pressures were measured using a planar array of microphones at a very close distance to the plate surface and taken as input for the HELS codes. The normal surface velocity distributions were then reconstructed, and the results were compared against the benchmark data obtained using a laser vibrometer. The structural modes of the plate with different boundary conditions were compared with those obtained by experimental modal analysis. Good agreements were obtained for both clamped and free boundary conditions.

10:40

4aSAb2. Dynamic modeling of complex structures in a broad frequency range. Hongan Xu and Wen L. Li (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202)

A general method, the so-called finite substructurE method (FSEM), is presented for the dynamic analysis of complex structural systems. In this method, a complex structure is considered as a collection of a finite number of basic structural components such as beams, plates, and shells. Instead of seeking a numerical solution at a number of discrete or grid points, the current displacement solution is sought, over each component, as a continuous field in the form of Fourier series expansions. Thus, the number of degrees of freedom, which now represent the Fourier expansion coefficients, can be substantially reduced in comparison with a grid-based solution for the same spatial resolution. Mathematically, the resulting system tends to be better conditioned than those in the finite element methods as the number of DOF's increases with frequency. The robustness of this model for high frequency applications can be further improved by incorporating statistical processes into the modeling method to properly reflect the means or account for the uncertainties of certain input variables. The proposed substructure method is considerably different from the existing substructure techniques in that no modal data are required for any component. Numerical examples are presented to demonstrate the reliability of this method.

11:05

4aSAb3. Vibro-acoustic coupling of a rectangular cavity backed by a flexible panel with general boundary conditions. Jingtao Du, Zhigang Liu, Tiejun Yang (College of Power and Energy Eng., Harbin Eng. Univ., Harbin, 150001, People's Republic China), and Wen Li (Wayne State Univ., Detroit, MI 48202)

Vibro-acoustic coupling system composed of a rectangular cavity and a flexible panel is widely studied in the backgrounds of panel vibration analysis and active noise control in enclosed sound field either by sound or structural actuators, corresponding to ANC and ASAC, respectively. In the most of the current investigation, the boundary conditions of the flexible structure are limited to simple case, namely simply supported and/or clamped. As an important structural parameter, boundary condition has a great effect on the coupling characteristics of such vibro-acoustic system, and a good understanding on this phenomenon will be helpful to the system design as well as active noise control. In this presentation, the analytical model of a rectangular cavity backed by a flexible panel with general boundary conditions is developed. Two sets of improved 2-D and 3-D cosine series with supplementary terms are constructed to respectively describe the displacement and pressure distributions in the boundary structure and 3-D acoustic cavity. The aim of introduction of the supplementary terms is to overcome the potential discontinuity encountered along the structural boundary and the fluid–solid coupling interface respectively for the both fields mentioned above. Numerical calculations are carried out to show the effectiveness of the current method and to study the effect of the structure boundary on the coupling characteristics of the panel-cavity system.

11:30

4aSAb4. Semi-active shock control technique for two-stage vibration isolation system based on vibration absorption. Wanyou Li, Zhigang Liu, Xueguang Liu, and Xixia Chen (College of Power and Energy Eng., Harbin Eng. Univ., Harbin, 150001, People's Republic of China)

Active control of shock is more difficult due to its instantaneous nature. In this presentation, the use of vibration absorption is proposed to decrease the harm from shock. Simulation and experimental studies are carried out on a two-stage vibration isolation system. The dynamic model of the two-stage vibration isolation system with the semi-active vibration absorber installed is developed. The effect of various parameters of semi-active absorber is analyzed through numerical simulation. The correctness is also validated by the experimental studies. The results show that the optimal installed position is on the upper stage mass, and a set of the optimal absorber parameters exists to make the anti-shock effectiveness achieve best. Such best effectiveness is not affected by the shock amplitude, however, by the continuance time and the excitation waveform. A semi-active vibration reduction and shock resisting control system including electromagnetism semi-active vibration absorber, DSP controller, and constant current source; etc is also designed. The experimental studies on the control effectiveness and reaction time of such system are subsequently performed. It is demonstrated that such a system can work in two working conditions, namely, vibration reduction and shock resisting, these two statutes can transiently switch, and control the secondary shock response effectively.

4aSCa1. Static and dynamic approaches to understanding vowel perception. James M. Hillenbrand (Dept. of Speech Pathol. & Audiol., Western Michigan Univ., Kalamazoo, MI 49008, james.hillenbrand@wmich.edu)

The purpose of this paper is to provide a broad overview of work leading up to the current view that vowel inherent spectral change (VISC) plays a significant role in the recognition of vowel identity. Although seldom if ever explicitly stated, the view that implicitly guided vowel perception research for many years assumed that nearly all of the information needed to specify vowel identity was to be found in a cross section of the vowel spectrum sampled at a reasonably steady portion of the vowel. There is now a considerable body of evidence showing that VISC plays an important role in the recognition of vowel identity. Evidence comes from: (1) measurement studies showing that many nominally monophthongal English vowels show significant spectral change throughout the course of the vowel; (2) statistical pattern recognition studies showing that vowel categories are separated with far greater accuracy by models that take spectral change into account; and (3) perceptual experiments showing that vowel steady-states are neither necessary nor sufficient for conveying vowel identity. In spite of this evidence, a static view of vowel identity continues to be implicitly assumed in many studies of vowel quality. [Work supported by NIH.]

8:25

4aSCa2. Spectral change in the front vowels of North American English. Terrance M. Nearey (Dept. of Linguist., Univ. of Alberta, Edmonton, AB T6G 2E7, Canada)

Assmann and Nearey [J. Acoust. Soc. Am. **80**, 1297–1308 (1986)] coined the term "vowel-inherent spectral change" (VISC) to refer to change in spectral properties inherent to the phonetic specification of vowels. Although VISC includes the relatively large formant movements associated with acknowledged diphthongs, it was explicitly extended to include reliable (but possibly more subtle) spectral change associated with vowel categories of North American English typically designated as monphthongs. This paper reviews statistical evidence of VISC in the formant patterns in front vowels of /hVd/ syllables in three regional dialects of English: Dallas, TX [Assmann and Katz, J. Acoust. Soc. Am. **108**, 1856–1866 (2000)], Western, MI [Hillenbrand *et al.*, J. Acoust. Soc. Am. **97**, 3099–3111 (1995)] and Northern, AB (new data). Results suggest that VISC patterns may be useful characteristics for assessing dialect differences. Evidence is presented for the importance of VISC in vowel perception, including recent evidence from our laboratories regarding perception by second language learners. A progress report is provided on research into how VISC is best characterized parametrically and which temporal regions of a vocoid may be most effective in summarizing VISC patterns in varying consonantal contexts.

8:45

4aSCa3. Formant-frequency trajectories as acoustic correlates to speech perception. Michael Kiefte, Tara Collins (School of Human Commun. Disord., Dalhousie Univ., 5599 Fenwick St., Halifax, NS B3H 1R2 Canada), Christian Stilp, and Keith R. Kluender (Univ. Wisconsin, Madison, WI 53706)

Formant trajectories are excellent vowel discriminants; within vowel, they are nearly constant across speaker size, age, and sex, and across consonantal contexts. However, this model assumes that formant peaks are perceptually important and that human listeners track formant-frequency changes across time. Speech-recognition applications have avoided formant frequencies due to the difficulty of reliable formant tracking. In addition, it is not actually known whether human listeners do indeed follow formants perceptually across time. This paper presents results from several studies that examine the relationship between changing formant frequencies and perception. Alternative perceptual representations of vowels, such as global spectral shape, are precluded by evidence that individual formant amplitudes are largely ignored in vowel perception. In addition, where other spectral properties appear to have a perceptual effect, it is because stimuli have used formants that do not change. When formants are changing, perceptual effects of spectral shape properties disappear. In terms of human formant tracking, perceptual extrapolation of a formant sweep is mostly dependent on peak frequency and not other properties related to spectral shape. This demonstrates that listeners do indeed follow formant-frequency changes as auditory objects. Further research on formant frequency perception will be described.

9:05

4aSCa4. Vowel-inherent spectral change enhances adaptive dispersion. Keith R. Kluender, Christian E. Stilp, Timothy T. Rogers (Dept. of Psych., Univ. of Wisconsin, 1202 W. Johnson St., Madison, WI 53706, krkluend@wisc.edu), and Michael Kiefte (Dalhousie Univ., Halifax, NS Canada, B3H 1R2)

Despite wide diversity among particular vowel sounds used across the world's languages, there are profound systematicities across languages. Whether sets of three, five, seven, or more vowel sounds are used, vowels that comprise these sets have substantial commonality across languages. Using static measures of vowel spectra, Lindblom and colleagues have demonstrated principles of adaptive dispersion through which the compositions of vowel inventories can be predicted on the basis of maximizing perceptual distinctiveness among the vowels within a language. Here, we address whether introduction of vowel-inherent spectral change is consistent with principles of optimizing perceptual distinctiveness between vowels. We find that vowel-inherent formant trajectories generally serve to further disperse vowel sounds across time. Trajectories of formants for vowel sounds that are relatively close in static measures (formant center frequencies: beginning, center, end) tend to be relatively distinct as measured by angles in F_1, F_2, F_3 coordinates. In a complementary fashion, vowels that share similar trajectories have relatively distinct static characteristics. This perceptual efficacy of vowel-inherent spectral change maintains across multiple place-of-articulation contexts. Across the vowel space and across consonantal contexts, vowel-inherent spectral change serves to increase adaptive dispersion and enhance perceptual distinctiveness. [Work supported by NIDCD.]

9:25

4aSCa5. Vowel-inherent spectral change and the second-language learner. Catherine L. Rogers and Merete M. Glasbrenner (Dept. of Comm. Sci. and Dis., Univ. of South Florida, 4202 E. Fowler Ave., PCD1017, Tampa, FL 33620)

Relatively few studies have directly examined the use of vowel-inherent spectral change by second-language learners, perhaps because it represents one of the subtler cues to vowel identity. Nevertheless, understanding non-native listeners' perception of this cue and its integration with other cues to vowel identity can be regarded as a method of investigating the mastery of cues to vowel perception that is needed for native-like perception. While several studies of second-language speech perception have demonstrated differences in cue use by second-language learners, our investigation of the use of dynamic spectral cues and temporal cues by native and non-native listeners suggests that relatively early learners of English as a second language do not appear to use the dynamic spectral cue differently from native English speakers when other cues are preserved. Instead, early learners' vowel perception appears to be less robust to removal of multiple cues. This apparent difference in even early learners' ability to use cues to vowel identity independently of one another or to change listening strategy when one cue is degraded may explain a portion of the increased challenge that even relatively early learners of a second language appear to experience in understanding speech in noisy environments. [Work supported by NIH.]

9:45

4aSCa6. Vowel inherent spectral change in forensic voice comparison. Geoffrey Stewart Morrison (School of Lang. Studies, Australian Natl. Univ., Canberra, ACT 0200, Australia, geoff.morrison@anu.edu.au)

Two-parameter models of vowel inherent spectral change, such as dual-target or target-plus-slope models, have been found to be adequate for vowel-phoneme identification. More sophisticated curve-fitting models do not appear to outperform such two-parameter models. This suggests that if only simple cues such as initial and final formant values are necessary for signaling phoneme identity, then speakers may have considerable freedom in the path taken between the initial and final formant values. If the constraints on formant trajectories are relatively lax with respect to vowel-phoneme identity, then with respect to speaker identity there may be considerable information contained in the details of formant trajectories. Differences in physiology and idiosyncracies in the use of motor commands may mean that different individuals consistently produce different formant trajectories between the beginning and end of the same vowel phoneme. If within-speaker variance is substantially smaller than between-speaker variance, then formant trajectories may be exploited for forensic voice comparison. This paper reviews a number of forensic-voice-comparison studies (including studies conducted using the likelihood-ratio framework) which have extracted information relevant to speaker identity from formant trajectories. For the purposes of forensic voice comparison, models using parametric curves are found to outperform simple two-parameter models.

Session 4aSCb

Speech Communication: Vowel Perception and Production (Poster Session)

Peter F. Assman, Cochair
School of Behavioral and Brain Science, Univ. of Texas at Dallas, Richardson, TX 75083-0688

Geoffrey Stewart Morrison, Cochair

Contributed Papers

All posters will be on display from 10:10 a.m. to 11:30 a.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 10:10 a.m. to 10:50 a.m. and contributors of even-numbered papers will be at their posters from 10:50 a.m. to 11:30 a.m.

4aSCb1. Developmental study of vowel-inherent spectral change. Peter F. Assmann (Univ. of Texas at Dallas, Richardson, TX 75083), Terrance M. Nearey (Univ. of Alberta, Edmonton, AB, T6G 2E7, Canada), and Sneha V. Bharadwaj (Univ. of Texas at Dallas, Richardson, TX 75083)

Children's speech differs from adult speech in several important ways. First, children have smaller larynges and supra-laryngeal vocal tracts than adults, with the result that their formants and fundamental frequencies are higher. Second, the temporal and spectral properties of children's speech are inherently more variable, a consequence of developmental changes in motor control. Both of these sources of variability raise interesting questions for theories of talker normalization and vowel specification. In the present study we compare the pattern of time-varying spectral change in vowels from a database of vowel recordings from adults and children ranging in age from 5 through 18 years from the Dallas, Texas region. Preliminary findings indicate systematic age-related differences in the average frequencies of the formants, but the pattern of vowel-inherent spectral change is well preserved across the age span investigated.

4aSCb2. Cross-generational differences in dynamic formant patterns in vowels. Robert Allen Fox and Ewa Jacewicz (Speech Percept. and Acoust. Labs., Speech and Hearing Sci. The Ohio State Univ., Columbus, OH 43210-1002, fox.2@osu.edu)

As the position of a vowel changes within the vowel space across generations of speakers, so does its dynamic formant pattern. This study examines variation in the dynamic patterns of vowel formants across two age groups: children (8–12 years) and older adults from their grandparents' generation (51–65 years). The cross-generational changes in vowels /ɪ, ɛ, æ/ were examined for each of the three regional variants of American English spoken in Southeastern Wisconsin (affected by the Northern Cities Shift), Western North Carolina (affected by the Southern Vowel Shift) and Central Ohio (not considered to be affected currently by any vowel shift). The following vowels in children's productions were monophthongized as compared to those of their grandparents' generation: Wisconsin /ɪ, ɛ/ (but not /æ/), North Carolina /ɛ, æ/ (but not /ɪ/), and Ohio /ɪ, ɛ, æ/. In addition to the reduced formant movement, some of the children's vowels had a different direction of formant change. These cross-generational changes were assessed in a set of measures including formant trajectory length, spectral rate of change and angle of formant change. The measures were calculated from formant frequencies extracted at points in the vowels corresponding to 20, 35, 50, 65, and 80% of the vowel's duration. [Work supported by NIH.]

4aSCb3. Generational and dialectal effects on children's vowel identification. Ewa Jacewicz and Robert Allen Fox (Speech Percept. and Acoust. Labs., Speech and Hearing Sci. The Ohio State Univ., Columbus, OH 43210-1002, jacewicz.1@osu.edu)

This study examines vowel identification by 8–13 years old children who grew up in either Southeastern Wisconsin (whose regional variant is affected by the Northern Cities Shift) or Western North Carolina (affected by the Southern Vowel Shift). In the first identification task, the children responded to words edited from sentences which elicited both stressed and unstressed vowel exemplars. This speech material was produced by multiple talkers representing two generations (children and older adults who represent their grandparents' generation). In the second identification task, the children were presented with citation-form tokens produced by three generations of talkers (children, their possible parents, and their possible greatgrandparents). Both within- and across-dialect vowel identification was examined. The cross-generational results showed that some vowels were identified more accurately when spoken by children, some when spoken by adults and for others there were no cross-generational differences. The cross-dialectal results indicated generally more accurate identifications of vowels produced by talkers from the same dialect region as the listeners. For selected vowels, there were significant interactions between dialect and generation. As a whole, the study shows children's sensitivity to cross-generational vowel changes and the attunement to their own dialect. [Work supported by NIH.]

4aSCb4. Vowel detection and vowel identification in long-term speech-shaped noise. Kathleen O'Brien, Ashley Woodall, and Chang Liu (Dept. of Commun. Sci. and Disord., 1 University Station A1100, The Univ. of Texas at Austin, Austin, TX 78712)

Psychometric functions of vowel detection and vowel identification were measured in long-term speech-shaped noise (LTSSN) for normal-hearing listeners. A four-interval forced-choice procedure was used to examine the accuracy of vowel detection in LTSSN with speech level presented from −10 to +5 dB sensational level relative to vowel detection thresholds obtained from Liu and Eddins' study [J. Acoust. Soc. Am. **123**, 4539–4546 (2008)]. The accuracy of vowel detection was significantly influenced by vowel category and sensational level. The threshold of vowel detection for each vowel and each listener was defined as the speech level at which 70.7% accuracy of vowel detection was reached. Vowel identification was then measured in LTSSN with vowel levels presented from 0 to 12 dB sensational level relative to individual thresholds of vowel detection, using a close-set 12-choice procedure. Results suggest that vowel identification was significantly affected by vowel category and sensational level. Altogether, the results of vowel detection and vowel identification indicate that, given the same signal-to-noise ratio, vowels are not equally audible and identifiable. Moreover, given the same sensational levels, vowels do not have the same identifiability, possibly due to the fact that some vowels have dominant confusing vowels while others do not.

4aSCb5. Auditory representation of vowel quality. Andrew B. Wallace and Sheila E. Blumstein (Dept. of Cognit. and Linguistic Sci., Brown Univ., Box 1978, Providence, RI 02909, andrew_wallace@brown.edu.)

It is generally assumed that the early stages of speech perception involve the extraction of some kind of generalized auditory patterns or properties from the peripheral input. The auditory representation that results is of con-

siderable interest, since it serves as the input to higher-level, speech specific processes of phonetic perception. The current research examines this auditory representation using a priming paradigm, in which perception of vowel targets is facilitated when the targets are preceded by acoustically matched nonspeech stimuli. By manipulating the acoustic parameters of these nonspeech "prime" tones, it is possible to determine the role of these parameters in the auditory stages of vowel processing. Previous results [Wallace and Blumstein, J. Acoust. Soc. Am. **119**, 3245 (2006)] suggest a short window of analysis of no more than 25 ms. In Experiment 1, frequency of nonspeech primes was varied, with results suggesting broad frequency tuning. In Experiment 2, primes matched to both F1 and F2 of the target vowels were found to elicit a greater priming effect than would be predicted by summing the response to separately presented F1 and F2 primes, suggesting that the auditory representation of vowels encodes combinations of formant frequencies.

4aSCb6. Cross-dialect differences in vowel identification. Amy T. Neel and Cai S. Ewing (Dept. of Speech & Hearing Sci., Univ. of New Mexico, Albuquerque, NM 87131, atneel@unm.edu)

In this study, identification of vowels produced by Michigan speakers by listeners of two dialects, Michigan (Inland North) and New Mexico (Western) was examined. New Mexico listeners identified sets of ten vowels (i, ɪ, e, ɛ, æ, ɑ, o, ʌ, ʊ, u) from 30 speakers in the Hillenbrand *et al.* (1995) database. Their results were compared to the results from the Michigan listeners in the original study. Preliminary results from ten New Mexico listeners show that overall identification rates across the 30 speakers did not differ significantly between dialects. However, NM and MI listeners differed on identification rates for individual speakers and particular vowels. They agreed on the worst speaker but differed by as much as 11 percentage points for others. NM listeners performed worse on /ɛ/ and /ɑ/ but slightly better on /ʌ/ than MI listeners. To determine the nature of cross-dialect differences in perception, acoustic data such as vowel space area, formant dynamics, and duration characteristics will be examined, and the relation of acoustic data to identification scores will be presented.

4aSCb7. Effects of dialect on vowel acoustics and intelligibility. Austin L. Oder (Dept. of Speech-Lang.-Hearing, Univ. of Kansas, Dole Ctr., 1000 Sunnyside Ave., Rm. 3001, Lawrence, KS 66045, aoder@ku.edu), Sarah Hargus Ferguson (Dept. of Speech-Lang.-Hearing: Sci. and Disord., Univ. of Kansas, Lawrence, KS 66045), and Cynthia G. Clopper (Dept. of Linguist., Ohio State Univ., Columbus, OH 43210)

A great deal of recent research has focused on the phonetic variation of American English vowels from different dialects. This body of research continues to grow as vowels periodically and unconsciously undergo formant movements that become characteristic of certain dialects (e.g., the Northern Cities Chain Shift and the Southern Vowel Shift). Two experiments using the Nationwide Speech Corpus [Clopper and Pisoni, Speech Communication, **48**, 633–644 (2006)] are exploring whether the Midland dialect is more closely related acoustically and perceptually to the Southern or to the Mid-Atlantic dialect. Experiment 1 consists of acoustic analyses of 11 English vowels from each of the three dialects. In Experiment 2, 11 vowels in /hVd/ format recorded from speakers of the three dialects are being presented to speakers of a Midland dialect for identification. This study will thus further our understanding of acoustic and perceptual differences between the most marked dialects (Mid-Atlantic and Southern) and the least marked dialect (Midland). [Work supported by a University of Kansas Honors Program Undergraduate Research Award.]

4aSCb8. Spectral analysis of the vowels of the Peking dialect. Wai-Sum Lee (Dept. of Chinese, Translation and Linguist., City Univ. of Hong Kong, 83 Tat Chee Ave., Kowloon, Hong Kong)

The paper presents the spectral characteristics of the dorsal and apical vowels in open syllables of the Peking dialect. Results show that (i) of the dorsal category the high and low vowels are monophthongs, whereas the mid-back vowels and rhotacized ə are diphthongal; (ii) the two apical vowels are similar in F1 and F2, but differ considerably in F3, with a lower F3 for the retroflexed than the plain one; (iii) the extensive overlaps between the vowel ellipses for the unrounded mid-back vowel and plain apical vowel in the F1F2 plane and between those for the rhotacized ə and retroflexed apical vowel indicate that the difference in perceptual quality between the paired vowels may be attributed to the dynamic property of the formant frequencies; (iv) as expected, the average F-values for the vowels are higher for females than males, however, the patterns of positions of the vowel ellipses in the F1F2 plane between the two genders are similar; and (v) the scaling between female and male F-values is nonuniform across vowel categories and across formant frequencies. The formant data will also be discussed in connection with the quality descriptions of the vowels in the past studies of the Peking dialect.

4aSCb9. Voice identification accuracy using multivariate vowel formant analysis. Al Yonovitz and Elvan Moss (Dept. of Commun. Sci. and Disord., Univ. of Montana, Missoula, MT 59812, al.yonovitz@umontana.edu)

Accurate and automated voice or speaker identification has been a major goal for those involved in forensic issues. In addition, voice and speaker identification has many applications in security and business. Numerous previous efforts to derive features for speaker classification have failed to achieve a sufficiently low error rate. In this study a linear discriminant analysis was independently performed for vowel formants (F1, F2, F3) for each of ten vowels. The standardized canonical discriminant coefficients (SCDC) weighted each of the formants within a database of voices. These SCDC values were then linearly combined to form a single scalar for each vowel. An analysis that considered the multivariate data vector composed of the ten vowel scalars was then used for classification. This algorithm was tested by comparing single voice exemplars to other voices in the database. Accuracy was extremely high using vowel formant values for classification.

4aSCb10. A duration-dependent account of coarticulation for hyper- and hypoarticulation. Harvey M. Sussman (Dept. of Linguist. and Commun. Sci. and Disord., Univ. of Texas, 1 University Station, Austin, TX 78712, sussman@mail.utexas.edu), Bjorn Lindblom (Stockholm Univ., Stockholm, S10691, Sweden), and Augustine Agwuele (Texas State Univ., San Marcos, TX 78666)

Hyperarticulated and hypoarticulated speech are accompanied by spectral expansion and spectral reduction of vowel nuclei, respectively. These shifts in F1/F2 vowel space directly affect degree of anticipatory coarticulation in consonant + vowel sequences apart from traditional vowel context effects. Examining the opposite conditions of emphatic stress [Lindblom *et al.*, J. Acoust. Soc. Am. **121**, 3802–3813 (2007)] and faster speaking rates (Agwuele *et al.*, Phonetica, in press) it was shown that coarticulatory effects could be documented independently of the expected vowel expansion /reduction effects. A modified locus equation regression metric was used in both studies to isolate alterations in F2 transition onsets due to prosodic and speech rate conditions apart from vowel space shifts per se. The current study provides a unified empirical and theoretical account for the opposite coarticulatory effects by providing duration data as the common variable tying both studies together. Articulatory and acoustic simulations of deeper (emphasis) and shallower (increased tempo) closures are provided to explain the shifts of observed F2 onsets relative to predicted F2 onsets due simply to expanded/reduced vowel space.

4aSCb11. Variability of vowel productions within and between days. Shannon L. M. Heald and Howard C. Nusbaum (Dept. of Psych., Univ. of Chicago, 5848 S. Univ. Ave., Chicago, IL 60637, smbowdre@uchicago.edu)

Theories of speech production and speech perception assume that phonetic categories can be characterized by stable properties. For example, the notion of stable vowel targets is used to organize articulation, and such targets could serve as the acoustic basis for recognizing vowel categories. However, there is substantial variation in the acoustic patterns of phonetic categories. The lack of invariance between acoustic properties and the phonetic categories of speech has posed a theoretical problem for understanding human speech perception. Although most theories vary in how acoustic-phonetic variability is approached, theories treat such variability as inherent in speech production or statistically regular or noise. In order to begin to understand acoustic-phonetic variability, we examined the naturally occurring variability in speech production over time. Participants' productions of seven different vowels ([IH], [EE], [EH], [AW], [AH], [AE], [UW]) were recorded in nine sessions: at three specific times in the course of each testing day (9 a.m., 3 p.m., 9 p.m.), every other day, over the course of 5 days.

Formant frequencies and variability of formant frequencies were analyzed to assess how vowel categories change over time. We will discuss the results and consider the theoretical implications of these results.

4aSCb12. Acoustic vowel space in pre-/r/ contexts: Shetland and American English. Peter Sundkvist (Dept. of English, Dalarna Univ., SE-79188 Falun, Sweden, psn@du.se)

The acoustic space available to vowel systems in pre-/r/ contexts commonly differs from that of other phonetic contexts. In English this space has gradually shrunk, which relates to changes in the phonetic nature of /r/, having gone from more consonantal articulations (tap, trill) to approximant and often complex articulations that have a stronger effect on the production and perception of adjacent vowels (e.g., "bunched" and retroflex /r/). This paper contains an acoustic study of pre-/r/ vowel systems in Shetland and American English. F1–F3 values were obtained from steady state vowel portions from words spoken in isolation. The acoustic vowel spaces and the positions of contrastive items within these are compared and discussed in relation to the phonetic nature of /r/ and its effects on vowel formants. In contrast to American English, Shetland maintains a trill or tap as the principal realization of /r/, and the full range of vowel contrasts found elsewhere is supported before /r/. As Shetland is one of the most conservative English dialects in this respect, the study may also offer some insight into the acoustic characteristics of English pre-/r/ vowel systems of earlier periods and the pressures affecting such systems.

4aSCb13. Relative contribution of jaw and tongue to the vowel height dimension in American English. D. H. Whalen, Aude Noiray, Khalil Iskarous, and Leandro Bolanos (Haskins Labs, 300 George St., St. 900, New Haven, CT 06511, whalen@yale.edu)

Vowels are typically described according to three articulatory dimensions: height, frontness, and rounding. Other researchers propose a role for the jaw in the height dimension. In the present study, we measured the relative contribution of the tongue and jaw for vocalic height distinction in American English vowels. Tongue and jaw motions were collected in six adult speakers for six vowels from all portions of the vowel space, embedded in [hVd] sequences. Tongue shape was captured via HOCUS (Haskins Optically Corrected Ultrasound System) which combines digital ultrasound imaging at 127 Hz with optical three-dimensional tracking of infrared emitting diodes (IREDs) positioned on the speaker's head and probe for subsequent decoupling of tongue motion from the jaw motion. Results showed a consistent role of the tongue in creating the vocalic constriction for the six subjects investigated, though with some idiosyncratic strategies. Jaw contribution was more sizable for vowel pairs traditionally contrasted by height than for tense/lax pairs, confirming previous findings from x-ray studies. One new result is the dominance of tongue contribution over the jaw's, even for vowels distinguished by height. [Work supported by NIH grant DC-02717.]

4aSP1. Tutorial: Pattern recognition in acoustic signal processing. Mark Hasegawa-Johnson (Dept. of ECE, and Beckman Inst., Univ. of Illinois, 405 N Mathews, Urbana, IL 61801)

This tutorial presents a framework for understanding and comparing applications of pattern recognition in acoustic signal processing. Representative examples will be delimited by two binary features: (1) regression versus classification (inferred variables are continuous versus discrete); (2) instantaneous versus dynamic (inference algorithms consider only an instantaneous observation vector versus inference algorithms integrate observations with knowledge of system dynamics). (1. Regression) problems include imaging and sound source tracking using a device with unknown properties and inverse problems, e.g., articulatory estimation from speech audio. (2. Classification) problems include, e.g., classification of animal and human vocalizations and nonspeech audio events. Instantaneous classification and regression are performed using a universal approximator (neural network, Gaussian mixture, classification, and regression tree), regularized, if necessary, to reduce generalization error (resulting in a support vector machine, regularized neural net, pruned classification tree, or AdaBoost). Dynamic classification and regression are done by imposing a prior to characterize system dynamics. Depending on the prior, the resulting model may be called a hidden Markov model, finite state transducer, dynamic Bayesian network, or conditional random field (dynamic classification), or a Kalman filter, extended Kalman filter, or switching Kalman filter (dynamic regression).

4aSP2. Joint position/wave number and time/frequency features of signals. Leon Cohen (Dept. of Phys., Hunter College, 695 Park Ave., New York, NY 10021, leon.cohen@hunter.cuny.edu) and Patrick Loughlin (Univ. of Pittsburgh, Pittsburgh, PA 15261)

Joint position/wave number and time/frequency representations of nonstationary signals and noise yield features that may be used to classify signals. Among these are instantaneous frequency, group delay, instantaneous bandwidth, and other conditional, or local, moments. We present a review of these concepts and give examples from various fields. We also discuss how these features change when a pulse propagates through a dispersive medium and show that there are some moment features that are invariant to dispersion. We illustrate via simulation the utility of these dispersion-invariant features for classification of man-made objects (steel shells) in shallow water environments. Finally, we show how to transform equations of motion into phase space, and the advantages of this transformation, in terms of methods of approximation and characterization of signals and nonstationary noise. [Work supported by ONR.]

4aSP3. Testing for periodicity in speech waveforms. Betul Arda, Daniel Rudoy, and Patrick J. Wolfe (Statist. and Inf. Sci. Lab., Harvard Univ., Oxford St., Cambridge, MA 02138, patrick@seas.harvard.edu)

Speech waveform segments can roughly be categorized as voiced or unvoiced, in accordance with periodicity properties of the glottal source, and inferring this classification from data is in turn an important task underlying a variety of speech classification problems. This presentation describes a formal hypothesis testing framework for the detection of periodicity in general acoustic sources, with application to online voiced/unvoiced segmentation of speech signals. Beginning with the classical approach of Fisher, a variety of test statistics are proposed and analyzed in this context. Asymptotic analyses are provided, along with simulations to demonstrate the efficacy of such methods in the presence of compound periodicities, harmonic structure, and the low signal-to-noise-ratio environments typical of real-world speech applications. [Work supported in part by DARPA, NGA, and NSF.]

4aSP4. Entropy estimation using pattern matching in bioacoustic signals. John R. Buck (ECE Dept., Univ. of Massachusetts Dartmouth, 285 Old Westport Rd., N. Dartmouth, MA 02747, johnbuck@ieee.org) and Ryuji Suzuki (MIT, Cambridge, MA 02139)

Many bioacoustic signals consist of a sequence of discrete stereotyped sounds occurring in repeated patterns. A natural question to ask is how best to characterize the underlying structure of the source producing the sequence of sounds. The structure of the source manifests itself as constraints on the patterns observed in the sequence of sounds. These constraints determine how predictable the order of the sounds is. The information entropy of a discrete symbol sequence is a quantitative measure of how unpredictable the sequence is. A straightforward but biased technique for estimating the entropy of an unknown source is to substitute observed symbol frequencies into parametric models such as Markov models. More general nonparametric entropy estimators exploit the relationship between the entropy and the average length of matching patterns within the sequence. This nonparametric entropy estimate forms an upper bound on the amount of information conveyed by the sequence of sounds. Additionally, comparing entropy estimates from the parametric and nonparametric models provides a hypothesis test determining whether the parametric model sufficiently captures the constraints of the source. These techniques are illustrated in analyses of humpback whale songs and leopard seal calling bouts.

4aSP5. Classification of audio signals using generalized spatial fuzzy clustering. Huynh V. Luong (Univ. of Ulsan, Korea, huynhlvd@yahoo.com), Cheol Hong Kim (Chonnam Natl. Univ., Korea), and Jong-Myon Kim (Univ. of Ulsan, Korea)

With the increasing use of multimedia data, the need for automatic classification and retrieval of certain kinds of audio data has become an important issue. In this paper, we propose an efficient method of audio signal segmentation and classification from audiovisual database. While conventional methods apply thresholding to audio features such as energy and zero-crossing rate to detect the boundaries, causing misclassification for audio signals which contain certain audio effects such as fade-in, fade-out, and cross-fade, the proposed algorithm, called general spatial fuzzy c-means algorithm (GSFCM), solves the problem by taking into account the local spatial information which is weighted correspondingly to neighbor elements based on their distance attributes. GSFCM detects the boundaries between two different audio signals, classifies segments, and then extracts unique feature vectors. This results in the accurate detection and classification. Experiment results for the audio signal from TV news program at 44.1 kHz with 30-min long confirm that the proposed method outperforms conventional methods in terms of accuracy of the audio signal classification. These results demonstrate that the proposed method is a suitable candidate for audio-video indexing which is compressed by MPEG. 4aSP6. Detection and classification of defects in underground pipes using reflection coeffecients. Muhammad Tareq Bin Ali (School of Eng., Univ. of Bradford, BD7 1DP, UK, mtbinali@bradford.ac.uk)

Detection and classification of defects developed in underground pipes have been an important issue for a long time. A novel sensor has been developed to find defects (i.e., blockage, deformation, crack, etc.) in buried pipes. Theoretical analysis has been supported by the experimental results. The sensor consists of a speaker and four microphones. The location of the defect is determined by the reflected signal recorded in the microphones. The reflected signal from a particular defect is sent through filter banks to identify the signal properties, which are related to the property of the defect. Different types of defects have been simulated in the lab and in the field. The sensor has been found to locate and classify the defect considerably well.

4aSP7. Detecting and localizing pipe changes via matched field processing. A. Tolstoy (ATolstoy Sci., 1538 Hampton Hill Circle, McLean, VA 22101, atolstoy@ieee.org), K. Horoshenkov, M. T. Bin-Ali, and S. J. Tait (Univ. of Bradford, Bradford, UK)

In this work we shall demonstrate that the presence of some pipe changes, e.g., blockages can be detected via matched field processing given an array of two or more microphones. In particular, the location of such transient irregularities can also be determined using this technique. We shall show data processed with this technique for a variety of blockages in a variety of locations for a variety of pipes (concrete, PVC, and clay). There is no acoustic modeling of the fields required, and only the simple linear processor is applied. The method can be used to determine the location of change and its severity.

4aUWa1. Interpreting free-field scattering by metallic truncated cylinders and spherical shells. Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, marston@wsu.edu) and Kyungmin Baik (Inst. of Sound and Vib. Res., Highfield, Southampton S017 1BJ, UK)

When investigating the complications to the scattering caused by proximity of a target to a boundary, a detailed ray-based interpretation of free-field scattering is often helpful. For tilted metallic cylinders having flat ends, when ka exceeds about 10, strong contributions to the backscattering have been identified with the radiation of sound by guided elastic waves associated with meridional rays, helical rays, and face-crossing rays [K. Gipson and P. L. Marston, J. Acoust. Soc. Am. **107**, 112–117 (2000)]. These features also affect the frequency response as a function of tilt and bistatic synthetic aperture sonar (SAS) and acoustic holographic images [K. Baik, Ph.D. thesis, WSU, 2008]. When considering the response of shells to transient insonification, it can also be helpful to construct the time-frequency response and to interpret the response using ray-based methods [D. H. Hughes, Ph.D. thesis, WSU, 1992; S. F. Morse and P. L. Marston, J. Acoust. Soc. Am. **111**, 1289–1294 (2002)]. Correct interpretation of the time-frequency response requires detailed consideration of the dispersion and attenuation of elastic waves guided by the shell and the shape of the radiated wavefronts. When considering low-frequency scattering, the inertia of the target significantly influences the scattering. [Work supported by ONR.]

4aUWa2. Boundary effects on elastic signatures of proud tilted aluminum cylinders. Jon La Follett and Philip L. Marston (Phys. and Astronomy Dept., Washington State Univ., Pullman, WA 99164-2814, lafollej@mail.wsu.edu)

Synthetic aperture sonar (SAS) and frequency response as a function of tilt (acoustic color) are two methods used to study target backscattering. Close proximity to a boundary can affect both the SAS and spectral signatures of a target. To improve understanding of these effects, scaled tank experiments were carried out on solid aluminum cylinders having flat ends and length to diam ratios of 2:1 and 5:1. To partially simulate the mechanisms present when an object is resting on the ocean bottom and illuminated at shallow grazing incidence, the cylinders were suspended through the air-water interface of a tank. Monostatic measurements were obtained as the source /receiver was scanned along a line parallel to the interface to produce SAS images. Backscattering measurements were also made as the target was rotated in a plane parallel to the interface, with the source/receiver stationary, to give the spectrum (color) as a function of tilt. Some of the elastic features in the SAS images and the acoustic color diagrams could be interpreted using a previously developed ray-based theory of generalized Rayleigh waves [K. Gipson and P.L. Marston, J. Acoust. Soc. Am. **106**, 1673–1689 (1999);, **107**, 112–117 (2000)]. [Research supported by ONR.]

8:15

4aUWa3. Monostatic and bistatic measurements of targets resting on or buried under the seafloor. Joseph Lopes (Naval Surface Warfare Ctr.-Panama City Division, Panama City, FL 32407-7001, joseph.l.lopes@navy.mil), Kevin Williams, Steve Kargl, Todd Hefner, Eric Thorsos (Univ. of Washington, Seattle, WA 98105), Philip Marston (Washington State Univ., Pullman, WA 99164), Iris Paustian, and Raymond Lim (Naval Surface Warfare Ctr.-Panama City Division, Panama City, FL 32407-7001)

Measurements were conducted to investigate monostatic and bistatic scattering of targets resting on or buried under a seafloor. The measurements were performed in NSWC-PCD's Facility 383, which is a 13.7 m deep, 110 m long, 80 m wide test pool with a 1.5 m layer of sand on the bottom. Two synthetic aperture sonar (SAS) rail systems were utilized in the measurements, and they were placed perpendicular to each other and oriented so as to look at the same region of the bottom. This strategy allowed a particular target and environment configuration to be set up and studied for both monostatic and bistatic geometries. Targets included a 0.61 m diam stainless steel shell and two 0.3 m diam solid aluminum cylinders with lengths of 0.61 and 1.52 m. This paper summarized the measurement setup and instrumentation. A sample of the results of these measurements will be presented. Subsequent papers will provide detailed analysis and comparisons with predictions of models. [Work supported by the Office of Naval Research and the Strategic Environmental Research and Development Program.]

8:35

4aUWa4. Measurement and modeling of solid cylinders near interfaces. Kevin Williams (College of Ocean and Fishery Sci., Univ. of Washington, 1013 NE 40 St., Seattle, WA 98105, williams@apl.washington.edu), Joe Lopes (Naval Surface Warfare Ctr.–Panama City, Panama City, FL 32407), Eric Thorsos (Univ. of Washington, Seattle, WA 98105), and Philip Marston (Washington State Univ., Pullman, WA 99164)

Acoustic scattering from solid cylinders located near interfaces include effects due to energy interacting with those interfaces. Therefore, modeling cylinder response also requires models of scattering from and penetration across those interfaces. The simplest modeling can be carried out using a plane wave approximation. Using this approximation finite element results for a solid cylinder in the freefield are used to calculate the acoustic scattering of the same cylinder located near an interface. These calculations are compared to experimental data for cylinder target strength and possible reasons for differences seen are discussed. The physical mechanisms responsible for the cylinder's response are examined and cylinder surface displacements are shown. [Work supported by the Office of Naval Research and the Strategic Environmental Research and Development Program.]

8:55

4aUWa5. Modeling the low- to mid-frequency scattering from a proud cylinder: Boundary and near-field effects. Mario Zampolli (NURC, Viale San Bartolomeo 400, 19126 La Spezia, Italy) and Kevin L. Williams (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105)

A 2:1 aspect ratio solid aluminum cylinder is placed on the planar interface between two fluids (water/sand and water/air), with a point source radiating at frequencies for which the acoustic wavelengths range from 0.5 to 12 cylinder lengths. The distance between the source and the target is approximately 100 wavelengths, relative to the center frequency, and a vertical receive array is placed near the source. The problem is studied using a finite-element target scattering model, which is capable of treating axially symmetric objects via the decomposition of the unknowns into a Fourier basis around the axis of symmetry. Since the axis of the cylinder is parallel to the planar interface, the overall problem is not axially symmetric. Nevertheless, an approximate solution is obtained, which takes into account the interface reflection of the incident field, as well as the first bounce of the scattered field (via the Helmholtz–Kirchhoff integral with layered medium Greens functions). Small variations in the source and receiver positions cause large changes in the received signal, which can be explained by a Lloyd mirror-like interference resulting from the coherent addition of the point-sources and image point-sources with which the incident field and the scattered field can be described.

9:15

4aUWa6. Acoustic color of elastic objects near boundaries: High-fidelity, high-speed, 3-D finite-element modeling. David S. Burnett (Naval Surface Warfare Ctr., Panama City Div., 110 Vernon Ave., Panama City, FL 32407, david.s.burnett@navy.mil)

NSWC PCD has developed a computer simulation system for modeling the acoustic color (target strength versus frequency and aspect angle) of realistic 3-D objects that are near to or straddling the interfaces between different fluids. It employs high-fidelity finite-element modeling of acoustic scattering from elastic objects (fully 3-D physics throughout object and environment), implemented in a custom-designed, scalable-architecture, multiblade rack system that efficiently manages the modeling of different parts of the frequency spectrum. The system automatically runs hundreds of thousands of finite-element models, dynamically changing the mesh resolution and outer fluid boundaries of the models as they sweep over frequency, and it produces a variety of outputs, the principal one being an acoustic color contour plot. This paper will begin with a brief overview of the acoustic color simulation system, followed by the results of two experimental validations of the system: (1) scattering from an aluminum cylinder in free space, and (2) scattering from an aluminum cylinder straddling the interface between two different fluids. The simulated acoustic color results will be compared with experimental, numerical, and theoretical results presented in other papers in this session. [Work supported by ONR and SERDP.]

9:35

4aUWa7. Modeling of acoustic scattering by sphere on a planar seabed. Zhengliang Cao, Shuanping Du, Shihong Zhou, and Fangyong Wang (Hangzhou Appl. Acoust. Res. Inst., Hangzhou 310012, China)

A model of acoustic scattering from spherical target above a planar seabed is advanced to a condition of irradiation by a point source, with both of T matrix method and complex images method. Compared to the other model [J. A. Fawcett and R. Lim, J. Acoust. Soc. Am. **114**, 1406–1415 (2003)], this model could be used to calculate scattering field from target above a planar interface in three dimension space or by bounded source beam. Comparing some coefficients by complex images method with that by analytical formula or numerical quadrature, the computing method of the model is examined to be efficient and accurate. In addition, numerical examples of a rigid sphere and an elastic spherical shell are compared for scattering field from the target on a fluid seabed, and the scattering field dependent angle is investigated from the different of grazing angle of incident wave. [Work supported by the National Natural Science Foundation of China (Grant No. 10704068).]

4aUWa8. Three-dimensional structural-acoustics modeling and its validation for free-field and littoral environments. Saikat Dey (Global Strategies Group (North America), 2200 Defense Hwy., Ste. 405, Crofton, MD 21114, saikat.dey.ctr.in@nrl.navy.mil), Angie Sarkissian (Naval Res. Lab., Washington, DC 20375-5320), Eris S. Mestreau (Global Strategies Group (North America), Crofton, MD 21114), Brian H. Houston (Naval Research Lab., Washington, DC 20375-5320), and Larry Kraus (Global Strategies Group (North America), Crofton, MD 21114)

Accurate numerical modeling of structural acoustics scattering in littoral environments, in mid-to-high frequency regimes, presents several challenges, including the ability to model the truncation of the nonhomogeneous exterior domain with free surfaces. Additionally, the frequency-dependent nature of the problem introduces significant dispersion errors with increasing frequency. This makes low-order three-dimensional discretization prohibitively expensive for high accuracy computations. We present a modeling framework for three-dimensional acoustic scattering in littoral environments treated as two half-spaces defined as the fluid and the sediment, respectively. The fluid portion may terminate at a free-surface boundary. The sediment may be a damped fluid or poroviscoelastic solid. The model admits rigid or viscoelastic scatterer with complex three-dimensional shapes including internal structural details and fillings. Exterior domain truncation uses perfectly matched-layer (PML) approximations. An hp-finite-element approximation scheme is utilized to control dispersion errors providing high-accuracy solutions in mid-to-high frequency regimes. Large-scale three-dimensional problems consisting of millions of unknowns solved scalably using a combination of efficient multifrontal solvers and domain-decomposition (FETI-DP) techniques. Numerical results validating applications in free field as well as littoral environment against experimental data will be presented. [Work supported by HPCMP and ONR.]

10:20

4aUWa9. Coherent space-time-frequency processing to enhance the bistatic detection and classification of elastic shells in shallow water. Shaun D. Anderson and Karim G. Sabra (Woodruff School of Mech. Eng., Georgia Inst. of Technol., 771 Ferst Dr. NW, Atlanta, GA 30332-0405)

For underwater sonar, time-frequency analysis has been shown to be a powerful tool for detection and classification of man-made targets. For instance, with traditional monostatic systems, a key energetic feature of spherical shell is the coincidence pattern, or midfrequency enhancement, that results from antisymmetric Lamb-waves propagating around the circumference of the shell. The development by the Navy of mine countermeasure sonar systems, using a network of autonomous systems, provides a mean for multiple bistatic measurements, and thus potentially bistatic enhancement for target detection. However, time-frequency representations of bistatic simulations of scattered signals from spherical shell show that this coincidence pattern typically shifts in both time and frequency with respect to the monostatic case. Hence, this time-frequency shift is challenging for bistatic target detection algorithms based on standard array processing techniques. Design of robust multistatic sonar system based on the generalized space-time-frequency coherence of the bistatic measurements will be discussed. The influence of the source-receiver configuration and interface reflections on the proposed approach have been investigated numerically and experimentally using data collected in shallow water with an elastic spherical shell [Work supported by ONR Code321, N000140810087.]

10:35

4aUWa10. Experimental investigation of bottom target detection by single channel iterative time reversal. Yingzi Ying, Shengming Guo, Bingwen Sun, Li Ma (Inst. of Acoust., Chinese Acad. of Sci., 21 Beisihuanxi Rd., Beijing 100190, China, yingyz05@mails.gucas.ac.cn), Zhenghua Cai, Huamin Fu, and Bing Hu (Haisheng Technol. Ltd., Yichang 443003, China)

Iterative time reversal process will gradually lead echo waves to converge to a dominant narrowband resonant mode of the target and enhance the return level in noisy and reverberant environment. This technique is used in bottom target detection and an experiment has been performed in the Yellow Sea, China. The experiment is in a monostatic configuration, and the target, which is a 53 cm external diameter and 260 cm long stainless steel cylindrical shell with concrete interior, is resting on the seafloor, and the directional transceiver, which is a transmitter and receiver couple, is located right above the target. First, a broadband interrogation pulse is launched, and the echo is measured and a bandpass filter is applied to avoid transceiver response peak, then the signal is time reversed and retransmitted, and repeat above procedures iteratively. The bottom reverberation will gradually be suppressed, and the center frequency of converged signal corresponds to a target resonance frequency, which is different from inhomogeneous bottom response in no target case. The existence of target is determined by this important acoustic signature, and the results illustrate the feasibility of this method. [Work partially supported by the CAS Innovation Fund.]

4aUWb1. An overview of the waveguide invariant and some of its applications to signal processing. W. A. Kuperman, G. L. D'Spain, Peter Gerstoft, W. S. Hodgkiss, H. C. Song, and A. M. Thode (Marine Physical Lab., Scripps Inst. of Oceanogr., U.C. San Diego, La Jolla, CA 92093-0238)

While the waveguide invariant is a compact descriptor of certain aspects of acoustic propagation in the ocean, it also has a broad range of applications from describing acoustic fluctuations to assisting in various types of signal processing. After presenting a brief theoretical and experimental overview of the invariant in terms of both normal modes and rays, some applications to signal and array processing are discussed.

8:35

4aUWb2. Effect of shallow water variability on the waveguide invariant distribution. Daniel Rouseff (Appl. Phys. Lab., College of Ocean and Fishery Sci. Univ. of Washington, Seattle, WA 98105) and Valery Petnikov (Russian Acad. of Sci., Moscow 119991, Russia)

When mapped versus range and frequency, acoustic intensity often displays a regular pattern of striations, ribbons of high intensity. The trajectory of these striations may be described by the waveguide invariant, commonly designated as beta. While beta may be formally an invariant quantity, it is not necessarily a constant, particularly in highly variable shallow water environments. To study fluctuations in beta due to fluctuations in the environment, it is useful to generalize from an invariant scalar to the waveguide invariant distribution. Through data analysis and simulation, the waveguide invariant distribution is calculated for different locations including the New Jersey shelf off the United States and the Kamchatka shelf off Russia. The effects of isotropic and anisotropic internal waves are quantified. [Work supported by ONR and the Russian Foundation for Basic Research.]

8:55

4aUWb3. Waveguide invariant motion compensation for adaptive beamforming. T.C. Yang and Altan Turgut (Naval Res. Lab., Acoust. Div., Washington, DC 20375)

Performance of high-resolution adaptive beamformers is significantly degraded when moving sources and interferers are considered. For a source changing bearing, the motion effect can be compensated by integrating over beam covariant matrix. For a source changing range, the motion effect can be compensated by a frequency change using waveguide invariant theory [T. C. Yang, J. Acoust. Soc. Am. **113**(1), 245–260 (2003)]. Simulated data showed that the signal beam of a moving source is narrow as for a stationary case when motion compensation is applied. Also, interference power has been suppressed by 6–10 dB when the motion of the interferer does not match that of the source. Motion compensation algorithms were also applied to ship noise data from the passing merchant ships, collected on a bottomed horizontal array during the RAGS 2003 experiment at the New Jersey Shelf. Similar results are obtained indicating narrower beamwidths and selective suppression of signals from the passing merchant ships when proper motion compensation is considered. [Work supported by ONR.]

9:15

4aUWb4. Passive striation based geo-acoustic inversion using ships of opportunity. Kevin D. Heaney (OASIS Inc., 11006 Clara Barton Dr., Fairfax Station, VA 22039, oceansound04@yahoo.com)

The coherent interaction of acoustic multipaths leads to an interference pattern in range. As range changes, the locations of the peaks (and troughs) of this interference pattern shift (as the group velocities of the modes change) in a sometimes predictable fashion. The intensity pattern of a moving source, plotted as a function of range and frequency, is commonly referred to as striation patterns. These patterns are commonly observed in the passing of a loud surface vessel in the spectrogram of a single hydrophone. In this paper, a geoacoustic method is presented based upon the quantitative measure of striation slope (wave guide invariant parameter) and the striation spacing in frequency (reciprocal time spread). Both of these parameters are generally sensitive to the geo-acoustic parameters of the sediment. In 2003 this technique was applied to a passing surface ship [K. Heaney, IEEE JOE **29**(1), 43–50 (2003)] and to a range-

dependent benchmark case [K. Heaney, IEEE JOE **29**(1), 88–99 (2003)]. The approach in these papers compared the measured acoustic observables with those from a table predicted by the forward computation using the broadband PE. Current implementation of the algorithm uses a Gaussian beam code to efficiently compute the acoustic observables.

9:35

4aUWb5. Waveguide invariance for active sonar. Jorge E. Quijano and Lisa M. Zurk (Elec. and Comput. Eng. Dept., Portland State Univ., 1900 SW 4th Ave., Ste. 160, Portland, OR 97201)

Active sonar signal processing in shallow water has proven to be a challenging problem due to the strong interaction of sound with the boundaries of the channel and the dependence on typically unknown environmental parameters. This has motivated research on properties of acoustic propagation that are not sensitive to those factors, such as the waveguide invariance. The invariance principle has found application in passive sonar signal processing by relating the frequency content of a broadband source to the range between source and receiver. More recently, experimental evidence has suggested that a similar structure exists for active sonar. This structure provides additional information about the location of a target, and information can be exploited in sonar processing algorithms such as target tracking. Data from several sea experiments have been analyzed to determine the behavior of the active invariance, and tank experiments have been designed to confirm the presence of the range-frequency structure in signals reflected by a moving target. This presentation provides an overview of the active invariance phenomena and describes the performance of a target tracking formulation that incorporates invariance structure into the state space representation for improved performance.

9:55

4aUWb6. Environmentally invariant features for classification of active sonar signals. Patrick Loughlin (Depts. of Bioengineering and ECE, Univ. of Pittsburgh, 745 Benedum Hall, Pittsburgh, PA 15261, loughlin@pitt.edu) and Greg Okopal (Univ. of Pittsburgh, Pittsburgh, PA 15261)

Dispersion and damping (frequency-dependent spreading and attenuation) can be significant in shallow water sound propagation. These propagation-induced effects can be detrimental to classification of active sonar returns because the observed backscatter depends not only on the target, but also on the propagation environment and how far the wave has traveled, resulting in increased variability in the received signals. We address this problem by extracting propagation-invariant features from the wave that can be used in an automatic classifier. In this talk, we review various moment-like features we have developed that are invariant per mode to dispersion and damping. Simulations of the backscatter from different steel shells propagating in a channel with dispersion and damping are presented to demonstrate the classification utility of the various invariant features. [Work supported by ONR Grant N00014-06-1-0009.]

10:15—10:30 Break

10:30

4aUWb7. Wavguide invariant-based characterization of wideband active sonar clutter discretes. Ryan Goldhahn, Jeffrey Krolik (Duke Univ., ECE Dept. Hudson Hall 130, P.O. Box 90291, Durham, NC 27708, rag15@ee.duke.edu), and Charles W. Holland (Penn State Univ. Appl. Res. Lab, Appl. Sci. Bldg., State College, PA 16804)

In active sonar, clutter discretes can produce strong, target-like returns which often produce false alarms of water column targets. While false alarm reduction methods based on statistical feature-based classifiers often lack sufficient training data, matched-field based classifiers often suffer from model mismatch. A waveguide invariant-based approach for estimating the magnitude short-time Fourier transform (STFT) of reverberation returns was presented [Goldhahn *et al.*, J. Acoust. Soc. Am. **124**(5), 2841–2851, (2008)]. In this paper, the waveguide invariant properties of the reverberation are used to predict the frequency selective fading of strong clutter discretes. In particular, comparison of waveguide invariant-based magnitude STFT estimates are compared with predictions made using a model of frequency-selective fading from a clutter discrete. The results are further compared with real sonar returns collected during the SCARAB98 experiment off a shipwreck in the Malta Plateau. The results suggest that when accurate characterization of the geoacoustic environment are available, the estimated STFT magnitude spectrum obtained by using a propagation and scattering model compare favorably with those obtained by averaging the reverberation along waveguide invariant striations. [Work supported by ONR.]

10:50

4aUWb8. Investigation of bistatic invariance principles for active sonars. Altan Turgut and Roger Gauss (Naval Res. Lab., Acoust. Div., Washington, DC 20375)

Application of bistatic invariance principles to mid-frequency active sonar systems is investigated using data collected during two recent experiments conducted at the Malta Plateau and East China Sea. Low-frequency (350–650 Hz) and mid-frequency (1.5–3.5 kHz) LFM pulses were transmitted and direct-blast and return signals from an echo-repeater and several strong scatterers simultaneously recorded on a towed array, a drifting volumetric array, and a moored vertical line array. At low frequencies, application of bistatic invariance principles to target detection is demonstrated. At mid-frequencies, the spectrograms of the direct-blast signals showed regular striation patterns that were used to estimate the waveguide invariant parameter beta. However, both measured and simulated spectrograms of the signals scattered from an oil rig indicated the complexity of the striation patterns. More complex patterns of striations in the measured spectrograms might be due to azimuthal dependency of the scattering kernel, source /receiver motion, and low SNR. [Work supported by the Office of Naval Research.]

4aUWb9. Full spectrum acoustic wave propagation prediction. Cathy Ann Clark (Naval Undersea Warfare Ctr., 1176 Howell St., B1320, Rm 457, Newport, RI 02841, cathy.clark@navy.mil) and Kevin B. Smith (Naval Postgrad. School, Monterey, CA 93943)

An overview of a normal mode solution to the Helmholtz wave equation to describe the underwater sound field for a fixed point source in a plane multilayered medium which utilizes Bessel functions of order 1/3 is presented. The mode functions are continuous across turning points of the separated depth-dependent differential equation due to careful selection of

the representations to be used for Bessel function arguments in various regions of the complex plane. A quotient involving vertical wave number and phase is seen to behave as a constant through turning points, enabling the mode amplitude functions to remain analytic, changing from oscillatory to exponential on traversing the turning point, thus enabling smooth incorporation of the continuous spectrum. The method also provides vertical directionality at all field points without post-processing the complex acoustic field. Comparisons of model results to a limited number of measured data sets and benchmark propagation codes are presented. Derivation and verification of the solution for bottom-interacting modes, including shear and compressional reflection and transmission for a layered bottom, as well as an extension into horizontally varying, shallow water environments are also discussed. Portions of this work have been published in the IEEE Journal of Oceanic Engineering.

11:20

4aUWb10. Acoustic ranging and waveguide invariant parameter estimation using virtual arrays. Altan Turgut (Naval Res. Lab., Acoust. Div., Washington, DC 20375)

A method for estimating the range of an unknown broadband acoustic source in a waveguide [Thode *et al.*, J. Acoust. Soc. Am. **108**(4), 1582–1594 (2000)] is revisited and extended to estimate both waveguide invariant parameter "beta" and source range in shallow water. In the new method, two or more vertical arrays are used without requiring a signal sample from a guide-source. It was shown that both methods are mathematically identical and they both provide robust range estimation even when the reference signal sample is used from different time and/or different vertical array location. It was also demonstrated that an image processing tool, Hough Transform method, provides robust parameter estimation from virtual array output data. In addition, the parameter estimation method was validated under both summer and winter conditions by using incoherent noise data to localize and track merchant vessels and to estimate waveguide invariant parameter. [Work supported by the Office of Naval Research.]

11:35

4aUWb11. Passive ranging using the waveguide invariant. Kevin L. Cockrell and Henrik Schmidt (Dept. of Mech. Eng., Massachusetts Inst. of Technol, Rm. 5-204, 77 Massachusetts Ave., Cambridge, MA 02140, cockrell@mit.edu)

A range versus frequency spectrogram of an acoustic field due to a fixed source in a waveguide will exhibit striations whose slopes depend on the range to the acoustic source and the value of the waveguide invariant. While many authors have pointed out that the range to an acoustic source can be estimated from the slopes of the striations in the spectrogram, few have presented an explicit algorithm to do so. An algorithm for estimating the range is presented and tested on experimental data collected in a shallow water waveguide during GLINT08, an exercise performed off of Pianosa Island, Italy. The experimental data consist of a fixed broadband acoustic source emitting energy at frequencies from 300 to 800 Hz, with a hydrophone measuring the acoustic field along a 1.75-km track directly away from the acoustic source.

4pAAa1. Acoustical designs in a new children's hospital. Francis Babineau, Jr. (Johns Manville, 10100 W. Ute Ave., Littleton, CO 80127, francis.babineau@jm.com)

The importance of noise control and acoustic comfort in healthcare facilities has been well documented. This issue is even more critical in pediatric facilities, given the often frightening and stressful circumstances associated with a child being in a hospital. Recently, The Children's Hospital in Denver, CO constructed a new facility in neighboring Aurora, CO. The new facility was opened in Oct. 2007, and one of the design goals was to improve the acoustic environment by implementing evidence-based design strategies. However, one of the challenges in improving hospital acoustics is to do so without introducing additional infection control risks. As part of the project, a series of noise measurements were performed at the old hospital and in analogous locations in the new hospital, after the new hospital was occupied. This paper will present the results of the noise measurements and discuss the impact (positive and negative) of various design elements on the acoustic environment.

1:25

4pAAa2. Perceptions and expectations of speech privacy in healthcare environments. Kenneth Good (Acoust. Privacy Enterprises, LLC, P.O. Box 252, Mount Joy, PA 17552) and Nikki Rineer (Hope Within, 4748 Harrisburg Pk., Elizabethtown, PA 17022)

Most methods for evaluating speech privacy were developed for offices and corporate environments and from the point of view of productivity and distraction impacts on the listeners. How do these methods translate to healthcare and other environments where confidential containment of information is required by law? This case study will look at the objective measurements of speech privacy along with patient subjective impressions and expectations surveyed.

1:45

4pAAa3. Evaluation and control of the acoustical environment in a long-term-care facility. Murray Hodgson and Gavin Steininger (Acoust. and Noise Res. Group, SOEH-MECH, Univ. of British Columbia, 3rd Fl., 2206 East Mall, Vancouver, BC, V6T1Z3 Canada)

This paper discusses the acoustical evaluation of the Minoru Residence long-term-care facility, to respond to concerns by its staff regarding the acoustical conditions. A review of existing acoustical standards with an analysis of their applicability to health-care facilities was conducted for the problems observed in the Minoru Residence. Measurements were made of the acoustical characteristics: unoccupied and occupied noise levels, reverberation times, Speech Intelligibility Index, and noise isolation. They showed that background noise levels in several key areas including the Rehabilitation Office and the Patient Lounges exceeded acceptable values. Reverberation times were excessive in the entrance lobby and patient common areas. The Speech Intelligibility values in the Nurse Stations and Rehabilitation Offices were below acceptable values. The noise isolation was inadequate between the entrance lobby and office areas. Recommendations were made for the improvement of the acoustical conditions. These recommendations include the reinforcement of the Front Office façade, and the application of acoustical ceiling tiles to the Rehabilitation Office and the entrance lobby.

2:05

4pAAa4. Achieving green design acoustical standards in healthcare facilities. Peter Holst and Ethan Salter (Charles M. Salter Assoc., 130 Sutter St., Ste. 500, San Francisco, CA 94104, peter.holst@cmsalter.com)

With the advent of the green guide for healthcare, and the introduction of LEED health care, which both include acoustical design credits, the benefits of good acoustical design have been recognized for improving patient recovery rates as well as staff health and efficiency. The acoustical issues in designing health care facilities cross the spectrum of acoustical design: sound isolation/speech privacy, room acoustics, sound masking, mechanical noise/vibration, environmental noise, and project-specific features, such as MRI and helipads. It is the responsibility of the acoustical consultant to address each item with the design team to develop cost-effective solutions to meet the criteria established by the green standards. This paper will provide background information on the acoustical design challenges for healthcare facilities and will discuss general approaches that achieve the goals of green acoustical design. Specific examples from projects will also be included, drawing from experience in design of hundreds of health-care facilities, as well as documentation of credits achieved for numerous medical centers that plan to submit for LEED healthcare. This paper will be a valuable resource for acoustical consultants in the design of all types of healthcare facilities, such as hospitals, central plants, medical office buildings, and nursing facilities.

2:25

4pAAa5. Safe and sound? Sleep disruption in healthcare facilities. Joanne Solet (Psychiatry, Cambridge Health Alliance, Cambridge, MA 02138, joanne_solet@hms.harvard.edu), Orfeu Buxton (Brigham & Women's Hospital, Boston, MA 02115), Andy Carballeira (Cavanaugh-Tocci Assoc, Sudbury, MA 01776), and Jeffrey Ellenbogen (Massachusetts General Hospital, Boston, MA)

National healthcare quality surveys have found that noise in hospitals is an urgent concern, showing negative impact on patient satisfaction. The purpose of this study was to develop sleep arousal probability threshold curves to specific hospital-based sounds, demonstrating their impact on all stages of human sleep. Recordings were captured of hospital sound sources corresponding to specific categories identified as salient in the American Institute of Architects' Draft Interim Guideline on Sound and Vibration in Healthcare Facilities. Fourteen sounds were calibrated for dynamic presentation through a speaker array at the sleep lab to deliver rising 5 decibel-step exposures from 40 to 70dB(A). Noise-related EEG arousals were quantified using current AASM criteria and summed for each sleep stage by sound type and decibel level to calculate arousal probability threshold curves. The tested stimuli evoked a range of arousal thresholds. At the 50% arousal probability level, stimuli spanned 15 dB(A) Leq in Stage 2 sleep, 17 dB(A) Leq in REM sleep, and 30 dB(A)Leq in Stage 3, the deepest sleep. The findings provide evidence that repeated arousals in all sleep stages occur even in healthy young adults when hospital sounds exceed 45dB(A); responses vary widely by stimulus types.

2:45

4pAAa6. Canadian hospital acoustical evaluation. Hind Sbihi and Murray Hodgson (Acoust. Res. Group, SOEH/Mech., UBC, 2206 East Mall, Vancouver, BC V6T1Z3 Canada, murray.hodgson@ubc.ca)

The aim of this study was to evaluate the acoustic conditions of two wards in a research/teaching hospital in British Columbia, Canada. The selection of the wards was based on managerial staff needs and perceptions of issues related to the acoustical working environment with respect to privacy and also aggressive behaviors. The two selected units were an adult emergency department and a long-term care facility where the patients population was a mix of elderly with different mental and physical health conditions. The methods will include long-term noise measurements, building acoustical measurements and interviews with nursing staff. In particular, measurements will be made of the following acoustical parameters in the facilities: unoccupied and occupied noise levels; reverberation time; Speech Intelligibility Index; noise isolation. Results will be evaluated by comparing them with acceptability criteria. Identification of nonoptimal aspects of the facilities acoustical environments will result from the consideration and analysis of staff responses and comparison with published guidelines.

3:00

4pAAa7. A comparison of sound transmission loss on metal stud partitions as the stud configuration changes. Aaron Betit (Veneklasen Assoc., 1711 16th St. Santa Monica, CA 90404)

The draft "Interim sound and vibration design guidelines for hospital and healthcare facilities" drafted by the Joint Subcommittee on Speech Privacy of the ASA recommends STC 50 partitions between exam rooms with no masking sound provided. These partitions are typically constructed of multiple layers of gypsum board on single steel studs, which are widely believed to achieve the required ratings based on published test reports. However, virtually all laboratory testing is with 25 gauge studs 24 in. on center, whereas with a 15 ft floor to floor height typical of hospitals, 16 in. gauge studs installed 16 in. on center are often required for structural reasons. There is little published data on the changes in sound transmission loss changes with stud gauge and spacing. A testing program was established, and transmission loss (STC) tests were performed on drywall partitions with various configurations of stud gauges, spacing, and layers of drywall. Measureable decrease in transmission loss as the studs become heavier and as the spacing between studs decreases was measured. The results of the testing program are presented.

3:15

4pAAa8. Noise inside a government owned hospital. Sergio Beristain (Acoust. Lab., E.S.I.M.E., IPN, IMA, P.O. Box 12-1022, Narvarte, Mexico, D. F. 03001, sberista@hotail.com)

A hospital is under evaluation in order to find out the most important noise sources. Noise measurements were carried out within and outside of the hospital, It was found that noise from the neighborhood was not an issue, but noises from within the hospital were loud enough to cause at least some disturbance to the patients and workers. Obviously the larger noise was the one coming from the machinery room, where the laundry, emergency power plant, etc., are located, but also in some of the most important care and treatment rooms, the noise generated inside was well over of the recommended limits for an installation of this type. Some measurement results are presented together with the description of the environment.

THURSDAY AFTERNOON, 21 MAY 2009 GALLERIA SOUTH, 2:00 TO 4:55 P.M.

Session 4pAAb

Architectural Acoustics, ASA Committee on Standards, and Noise: Indoor Noise Criteria

Lily M Wang, Chair
Architectural Engineering, Univ. of Nebraska--Lincoln, Omaha, NE 68182-0681

Chair's Introduction—2:00

Invited Papers

2:05

4pAAb1. Proposed components of an "ideal" indoor noise criteria rating system. Lily M. Wang (Architectural Engr. Prog., Univ. of Nebraska-Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0681)

A number of studies have been conducted at the University of Nebraska on correlating human performance and perception to indoor noise criteria systems. Task performance and subjective perception data were gathered from subjects exposed to background noise conditions commonly due to mechanical systems, including some with tonal components and some with time-varying fluctuations. Results show that perceptions of annoyance and distraction are highly correlated to the character of the noise, but the current indoor noise criteria systems (such as noise criteria and room criteria) do not accurately reflect that relationship. This paper presents a proposal for what an indoor noise criteria rating system should ideally include, to quantify acceptable building mechanical system noise in commercial buildings. [Work supported by the American Society of Heating, Refrigeration and Air-Conditioning Engineers.]

2:30

4pAAb2. A case history comparing noise criteria. Jerry G. Lilly (5266 NW Village Park Dr., Issaquah, WA 98027)

A case history of an indoor HVAC noise problem in a new residential building will be presented. Noise measurements collected in the living room and in the bedroom of the impacted living unit will be examined using several of the available noise criteria methods including, NC, RC, NCB, and RNC (ANSI S12.2). Although the architect and the building owner believed that the HVAC noise was unacceptable, the measured noise levels met the NC, NCB, and RNC noise criteria. Only the RC method was able to accurately detect the problem.

2:55

4pAAb3. Evaluation of mechanical background noise outside the norm of generally accepted criteria. Andrew J. Boone and Michael R. Yantis (Sparling, 720 Olive Way, Ste. 1400, Seattle, WA 98101, aboone@sparling.com)

Cases are presented where mechanical background noise was found to be acceptable by clients, although it was above the threshold of conventional indoor noise criterion. Other instances are shown where noise levels fell within normal limits but were judged unacceptable. Examples include HVAC noise in offices and residences, chiller and other rooftop equipment noise in multifamily dwellings, and pump noise. Sound quality expectations and the perception of noise sources were found to play an important role in the evaluation of these noise sources.

3:20—3:35 Break

3:35

4pAAb4. Using indoor room criteria when the "room" is outside. Byron W. Harrison (TALASKE, 1033 South Blvd., Oak Park, IL 60302, byron@talaske.com)

Indoor noise criteria have applicability in the analysis of outdoor performance spaces. The presentation will provide an overview of the environmental noise issues at the Jay Pritzker Pavilion in Chicago, IL. The project design was largely influenced by noise concerns, in its physical form, audio design strategy, and building systems design. During the postconstruction tuning of the audio system a

number of parameters were adjusted to contend with the unusually low signal-to-noise ratio, including the overall loudness of amplified music, audio signal compression, the content and level of the acoustic enhancement system, and the approach to the active in-house mix of the audio system. An investigation was also undertaken to investigate the continuous and impulsive noise levels and frequency content at various times of day as compared with traditional environmental noise criteria and indoor room criteria. Subsequent studies regarding the impact of nearby construction noise on rehearsals and performances were influenced by the use of indoor noise criteria methods.

4:00

4pAAb5. The room noise criteria (RNC) metric. Paul Schomer (Schomer and Assoc., Inc., 2117 Robert Dr., Champaign, IL 61821, schomer@SchomerAndAssoc..com)

The recent ANSI S12.2:2008 room noise criteria contains both a survey and an engineering method to specify room noise criteria. The methods use A-weighting and extended NC, respectively. A new metric, titled like the standard, room noise criteria (RNC) is included as a diagnostic tool. It is based on human hearing and more correctly assesses low-frequency sound. In particular, it is sensitive to the standard deviation to random noise and/or low-frequency surging in the 16–125 Hz octave bands such as the sound that can be produced by HVAC systems or other devices. It provides a bridge between the NC and RC criteria by correctly predicting the need for the less stringent (at low frequencies) NC criteria when the HVAC system is well designed (no surging, moderate standard deviation) and also correctly predicting the more stringent (at low frequencies) RC criteria when the HVAC system noise has a large standard deviation and/or surging.

4:25

4pAAb6. Correlation of subjective and objective measures of spectral quality. Dakota M. Kelley and Lily M. Wang (Architectural Engr. Prog., Univ. of Nebraska—Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0681, dkelley@mail.unomaha.edu)

Common indoor noise criteria with spectral quality indicators have been compared to task performance and subjective noise perception. The analysis seeks to identify a relationship between criteria spectral quality ratings and human perception of common heating, ventilating, and air conditioning background noises. The three criteria evaluated include Balanced Noise Criteria, Room Criteria, and Room Criteria Mark II, due to their inclusion of rumble, hiss, or roar classifications. Study participants worked on typing, math, and verbal tasks while being exposed to various background noise signals, and then completed a questionnaire to describe their perception of the room acoustics. During the data analysis, background noise signals with a non-neutral spectral quality rating were weighted according to their respective spectral indicator, with greater weighting given to lower-frequency signals. Results demonstrate relationships between spectral quality designation and subjective perception of noise fluctuation and tonality. However, a relationship was not found between spectral quality designation and subjective perception of the same parameters (rumble, hiss, or roar). These findings warrant further investigation of the correlation between common criteria ratings and subjective perception. [Work supported by the Univ. of Nebraska Undergraduate Creative Activities and Research Experience Grant.]

4:40

4pAAb7. Acoustical criteria in a two-parameter system for evaluating impact noise insulation. John LoVerde and Wayland Dong (Veneklasen Assoc., 1711 16th St., Santa Monica, CA 90404, jloverde@veneklasen.com)

Experience indicates that impact noise complaints in multi-family joist-framed buildings fall into two broad classes: low frequency thudding from footfalls and mid- to high frequency noise from heel clicks, dragging furniture, etc. The authors have developed a two-parameter system for evaluating impact noise [LoVerde and Dong, J. Acoust. Soc. Am. **119**, 3220 (2006); **120**, 3206 (2006); **122**, 2954 (2007)] that offers considerable improvement over existing metrics (such as FIIC) in terms of both correlation with subjective reaction and comparison of materials intended for improving impact insulation. Based on this system, suggested criteria for impact noise levels are presented. The effects of various design parameters on noise levels are discussed.

3:00

4pAB1. Equine vocalizations: The start of a search for happiness. David A. Browning (Phys. Dept., Univ. of Rhode Island, 2 Lippitt Rd., Kingston, RI 02881, decibeldb@aol.com), Peter M. Scheifele (Univ. of Cincinnati, Cincinnati, OH 45267-0379), and Rebecca L. Pond (Univ. of Connecticut, Storrs, CT 06269)

As with all perissodactyls, the vocalizations of equines, specifically a horse's whinny, has a variable frequency (or melodic) component as well as just simple tonals. This appears to provide a primitive means of expression, simpler than any song or language but potentially more informative than the purely tonal moos or baahs of cattle or sheep (but a long way from the complexity of some birdsong). Sonograms are compared from in-barn whinnies recorded under apparently stressful (departure of a foal) and pleasant (arrival of the morning feed wagon) circumstances, with the same horse and various horses, to determine if distinctive patterns can be identified. We also compare these with greeting whinnies and departure whinnies. The ultimate goal is to be able to acoustically identify an expression of happiness.

3:15

4pAB2. A vocal repertoire of Asian elephants (*Elephas maximus*) and comparison of call classification methods. Sharon S. Glaeser (Dept. of Biology, Portland State Univ., P.O. Box 751, Portland, OR 97207, sharon@roguetechinc.com), Holger Klinck, David K. Mellinger (Oregon State Univ. and NOAA, Newport, OR 97365), Yao Ren (Marquette Univ., Milwaukee, WI 53201), Patrick J. Clemins (Arlington, VA 22203), Michael T. Johnson (Marquette Univ., Milwaukee, WI 53201), Mandy L. H. Cook, and Randy Zelick (Portland State Univ., Portland, OR 97207)

This study compares classification methods applied to an acoustic repertoire of the Asian elephant (*Elephas maximus*). Recordings were made of captive elephants at the Oregon Zoo in Portland, OR and of domesticated elephants in Thailand. Acoustic and behavioral data were collected in a variety of social contexts and environmental noise conditions. Calls were classified using three methods. First, calls were classified manually using perceptual aural cues plus visual inspection of spectrograms for differentiation of fundamental frequency contour, tonality, and duration. Second, a set of 29 acoustic features was measured for nonoverlapping calls using the MATLAB-based program Osprey, then principal component analysis was applied to reduce the feature set. A neural network was used for classification. Finally, hidden Markov models, commonly used for pattern recognition, were utilized to recognize call types using perceptually-weighted cepstral features as input. All manual and automated classification methods agreed on structural distinction of six basic call types (trumpets, squeaks, squeals, roars, rumbles, and barks), with two call types (squeaks and squeals) being highly variable. Given the consistency of results among the classification methods across geographically and socially disparate subject groups, we believe automated call detection could successfully be applied to acoustic monitoring of Asian elephants.

3:30

4pAB3. The hyena's laugh as a multi-informative signal. Nicolas Mathevon (ENES Lab, Univ. Jean Monnet, Saint-Etienne, France, mathevon@univ-st-etienne.fr) Aaron Koralek, Steve Glickman, and Frederic Theunissen (Berkeley, CA)

Many social mammals use vocalizations to encode information about sex, kinship, individual identity, and morphological cues, as well as motivational and physiological states. In spite of the importance of this multi-informative signaling for the maintenance of social groups, most investigations on information coding in vocal signals have focused on only one cue; e.g., individual identity. Using the opportunity of the captive colony of spotted hyenas *Crocuta crocuta* at the Field Station for the Study of Behavior, Ecology, and Reproduction (University of California, Berkeley), we recorded and analysed the hyena's giggle, one of the most well known calls of this large social African mammal. The acoustic analysis in both temporal and frequency domains was automated using a MATLAB customized routine. The fundamental frequency was tracked using two methods (cepstrum and autocorrelation) followed by a best guess using a Bayesian approach. The differences between giggles from different individuals or groups of individuals were assessed running a multiple analysis of variance (MANOVA in MATLAB), cross-validated by a permuted discriminant function analysis (pDFA, R software). The results show that the hyena's laugh encodes information about age, dominance status, and individual identity, giving to receivers some cues to assess the social position of an emitting individual.

3:45

4pAB4. An intelligent automated apparatus to assess absolute auditory thresholds in the laboratory mouse. Anna Pleuger (Charles Darwin Univ., Darwin, NT, Australia) and Al Yonovitz (The Univ. of Montana, Missoula, MT 59812)

The effectiveness of an intelligent behavioral training and testing apparatus was assessed by using this system to operantly condition mice. The method utilized an infrared grid that determined the location of the mouse and presented reinforcements for auditorily contingent bar-press behavior. The apparatus was fully automated. Absolute auditory thresholds were determined with the descending and ascending method of limits in the same group of C57BL/6 mice. There was a statistically significant difference between thresholds produced by these two methods, with the descending method producing more sensitive auditory thresholds. Thresholds were on average 4.4 dB lower and had smaller standard errors. Overall, the automated apparatus was a highly efficient and precise method for the operant conditioning of mice.

4:00

4pAB5. Social context influences acoustic communication in zebra finches. Clementine Vignal, Julie Elie (Univ. Jean Monnet, Saint-Etienne, France), Hedi Soula (INSERM U870, INSA, Lyon, France), and Nicolas Mathevon (Univ. Jean Monnet, Saint-Etienne, France)

During communication, a signal conveys information between an emitter and a receiver, but indirect receivers can eavesdrop on the interaction. In birds, communication has been demonstrated to often be under the influence of this eavesdropping. Social species show complex communication networks where audience drives individual behaviors. Zebra finches

(*Taeniopygia guttata*) are gregarious songbirds that live in social groups and form life-long pair-bonds. Previous studies showed that the vocal behavior of males highly depends on this audience effect. Males show mate calls preference over other female calls in the presence of an established male-female pair, but not in the presence of unmated male-female or male-male dyads. Males in social groups also show stronger vocal response to female calls than males in social isolation. In this study, we investigate whether female calls of varied social salience evoke differently male calling according to the audience. We show that social context modifies not only call rate in response to female calls of varied social salience, but also acoustic structure of evoked calls. Thus male distance calls are not stereotyped calls whose acoustic cues only convey bird's identity. We propose that fine spectral modifications of the calls could carry information about the emitter motivation.

4:15

4pAB6. Acoustic analyses of two undocumented sound patterns in the *Drosophila suzukii* and *D. takahashii* species subgroups. Yuwen Lai (Dept. of Linguist., Univ. of British Columbia, 2613 West Mall, Vancouver, BC V6T 1Z4, Canada), Shu-Dan Yeh (Stony Brook Univ., Stony Brook, NY 11794-5245), Jennifer Gleason (Univ. of Kansas, Lawrence, KS 66045), and John True (Stony Brook Univ., Stony Brook, NY 11794-5245)

Acoustic analyses of the courtship songs of the *suzukii* and *takahashii* subgroups in the *Drosophila melanogaster* species group were conducted. The primary and secondary pulse phases that are common in the *melanogaster* subgroup were not observed in these two subgroups. However, two undocumented sound patterns were discovered. *D. biarmipes* and *D. pulchrella* (*suzukii* subgroup) produce high amplitude, nonrhythmic "toot" sounds, which range from 82–158 ms in duration. The toot sound in *D. biarmipes* has a consistent dynamic frequency profile. It starts with an onset of 479 Hz and gradually falls to 422 Hz and then rises to 477 Hz. The toot sound in *D. pulchrella* has a significantly lower frequency when compared to *D. biarmipes*. Its frequency profile falls gradually from 352–259 Hz. In addition, a "turbo" sound was recorded in *D. prostipennis* (*takahashii* subgroup). It is composed of short, high frequency pulses (520 Hz) with 4 ms interpulse intervals. In the *melanogaster* subgroup, the parameters of pulses have been proposed to play an important role in female preference. The results of the present study suggest that there might be other parameters at play in the species investigated in the current study.

4:30

4pAB7. Recent insights on the mechanisms of frequency discrimination in cicadas (Hemiptera, Cicadoidea). Paulo J. Fonseca (Dept. de Biologia Animal and Centro de Biologia Ambiental, Faculdade de Ciências, Univ. de Lisboa, Bloco C2, Campo Grande, 1749-016 Lisboa, Portugal, pjfonseca@fc.ul.pt) and Axel Michelsen (Univ. of Southern Denmark, DK 5230 Odense M, Denmark)

Mate finding in cicadas is usually mediated by acoustic communication. Males produce a loud acoustic signal that is used to guide females toward singing males. The calling songs are frequently complex with changes in rhythm, amplitude modulation and, in many species, frequency modulation. Therefore, it is likely that the auditory organ encode some of those characteristics and that the nervous system may process the information and extract some species-specific parameters. The tympanic vibrations are transferred to the onion-shaped auditory organ, localized at some distance from the tympanum within the auditory capsule, through a stiff schlerotized apodeme. This configuration has raised problems to the understanding of how the different frequencies of the song, that Fonseca *et al.* (2000) have shown to be finely encoded at the level of the auditory interneurons in the cicada *Tettigetta josei*, are passed on to the auditory organ by the structures of the receptor. Using biophysical, electrophysiological, and anatomical measurements from the receptor structures of the cicada *Tettigetta josei*, a functional model that may allow for the above-mentioned frequency discrimination will be presented [Fonseca, P.J., Münch, D., and Hennig, R.M., "How cicadas interpret acoustic signals," Nature 405,297–298 (2000)].

4:45

4pAB8. Bayesian model-based technique for termites detection. Asif Mehmood (Dept. of Elec. Eng., Univ. of Mississippi, University Mississippi), Orwa Tahaineh, and John Seiner (Univ. of Mississippi, University, MS)

This paper presents a model-based approach to detect termites from their head banging acoustic signals, and is derived from Bayesian probability theory. The termite head banging is the loudest and most diagnostic sound that termites make, and can be utilized for termite detection. The laser Doppler vibrometry system is used to obtain the termite head-banging signals from infested wood. An algorithm based on Bayesian probability theory is developed to detect termites' presence. The atomic model that represents the termites' data is the sum of decaying sinusoidal signals. First the model selection is performed that tells us about the number of vibration frequency components present in the data under observation. Once the correct model is known, then the vibration frequency that corresponds to termites' head banging frequency is determined. The calculations are performed using the Markov chain Monte Carlo method. Monte Carlo integration is then used to approximate the marginal posterior probabilities for all the parameters, including the number of exponentials and whether a constant offset is present. The performance of this algorithm is evaluated by testing it on experimental data, and the results obtained reveal the excellent performance of the algorithm.

Biomedical Ultrasound/Bioresponse to Vibration: Cardiovascular Applications of Ultrasound Contrast Agents

John S. Allen, Chair
Dept. of Mechanical Engineering., Univ. of Hawaii, Honolulu, HI 96822

Chair's Introduction—1:15

Invited Papers

1:20

4pBB1. A new high frequency microultrasound system with applications in cardiovascular research. F. Stuart Foster (Sunnybrook Health Sci. Ctr., Univ. of Toronto, 2075 Bayview Ave., and VisualSonics Inc., 3080 Yonge St., Toronto, Canada)

The development of preclinical imaging using micro-MR, CT, PET, SPECT, optical, and ultrasound technologies has created a new paradigm for imaging in the laboratories of biomedical researchers. Once considered a luxury for isolated multiuser centers, microimaging platforms are now becoming mainstream in bioresearch where quantitative *in vivo* imaging measurements of biomarkers and other endpoints are becoming a requirement of these investigations. Microultrasound has come a long way from its inception in the mid-1990s. This paper will detail the progression of preclinical microultrasound from mechanical to array based imaging systems. The technology of high frequency array based ultrasound imaging will be reviewed including details on the transducers and beamformer used in the first commercially available system. Applications of this system in the areas of cancer and cardiovascular disease will be described. The development of high frequency microbubble contrast modes based on linear and nonlinear signal processing will be discussed with relevant examples including imaging of VEGFR-2 and CD31 expression in disease models. All experiments with animals were done under a protocol approved by the Sunnybrook or VisualSonics Animal Care Committees. [The author declares a significant financial interest in VisualSonics Inc.]

1:40

4pBB2. Identifying and controlling acoustic bioeffects. Robyn K. Schlicher (Dept. of Chem. and Biomolecular Eng., Georgia Inst. of Technol., 315 Ferst Dr., Atlanta, GA 30332, rschlicher@chbe.gatech.edu), Joshua D. Hutcheson, Daniel M. Hallow (Georgia Inst. of Technol., Atlanta, GA 30332), and Mark R. Prausnitz (Georgia Inst. of Technol., Atlanta, GA 30332)

Ultrasound exposure causes internalization of a wide variety of molecules in cells and tissues, especially in the presence of acoustic cavitation. However, high levels of uptake are often accompanied by cell death. This study first analyzed intracellular uptake and cell viability after exposure of porcine carotid arteries to ultrasound *ex vivo* by confocal microscopy and found that at moderate ultrasound pressure, there was extensive uptake by endothelial cells with little uptake by underlying smooth muscle cells, whereas at high ultrasound pressure there was extensive endothelial cell death and increase uptake by smooth muscle cells. To understand the mechanisms involved in cell uptake and death, sonicated DU145 cells were analyzed by high level microscopy, flow cytometry, and chemical analyses. This work showed that uptake was caused by transient wounds created in the cell membrane that resealed within minutes after sonication. It also identified and quantified seven different cellular responses to this wounding, including cell repair modes and four different death modes. To save cells from apoptotic death, which was found to be mediated by calcium, cells were exposed to a calcium chelator, which rescued approximately half of the apoptotic cells from death.

2:00

4pBB3. A predictive model using myocardial contrast echocardiography for patients presenting to the emergency department with chest pain and a nondiagnostic electrocardiogram. Sanjiv Kaul (Cardiovascular Div., Oregon Health and Sci. Univ., Portland, OR 97201)

Risk stratification of patients presenting to an emergency department (ED) with suspected cardiac chest pain (CP) and an undifferentiated electrocardiogram (ECG) is difficult. We hypothesized that a risk score incorporating clinical, ECG, Rand contrast echocardiography variables [regional function (RF) and myocardial perfusion (MP)] obtained at the bedside would accurately predict adverse events in occurring within 48 h of ED presentation. A logistic risk model was developed in the initial 1166 patients (cohort 1), and validated in another 720 patients (cohort 2). Any abnormality or ST-T changes on ECG (OR 2.5, 95% CI:1.4–4.5, $p=0.002$, and OR 2.9, 95% CI:1.7–4.8, $p=0.001$, respectively), abnormal RF with normal MP (OR 3.5, 95% CI:1.8–6.5, $p=0.001$), and abnormal RF with abnormal MP (OR 9.6, 95% CI:5.8–16.0, $p=0.001$) were found to be significant multivariate predictors of nonfatal myocardial infarction or cardiac death. The estimate of the probability of concordance for the risk model was 0.82 for cohort 1. Likewise, in cohort 2, the c-index for the risk model was 0.83. In conclusion, a model based on variables obtained at the patient's bedside can be used to accurately risk stratify patients presenting to the ED with suspected cardiac CP and a nondiagnostic ECG. Its application could enhance care of CP patients in the ED.

2:20

4pBB4. Diagnostic ultrasound combined with targeted microbubbles improves recovery following acute coronary thrombosis. Evan Unger, Terry Matsunaga (Dept. of Radiology, Univ. of Arizona, 1501 N. Campbell Ave., Tucson, AZ 85724), Feng Xie, and Thomas Porter (Univ. of Nebraska Medical Ctr., Omaha, NE 68198)

Forty-five pigs with acute coronary artery occlusions—low MI pulse sequence (CPS) to guide high MI (1.9 MI) pulses during infusion of platelet-targeted MBs or non-targeted MBs. Third group received no ultrasound/MB. All groups received pro-urokinase, heparin, and aspirin. Angiographic recanalization rates, resolution of ST elevation, and wall thickening were analyzed. Pigs receiving MB had more rapid replenishment of risk area (RA) (80% versus 40% for MB; $p=0.03$) and higher epicardial recanalization rates (53% versus 7% for pro-urokinase alone; $p=0.01$). Replenishment of contrast within RA with MB showed higher recanalization rates and higher rates of ST resolution (82% versus 21% for pro-urokinase alone; $p=0.006$). ST resolution occurred in six pigs (40%) with MB who did not have epicardial recanalization; five had recovery of wall thickening. Conclusions: IV MB with brief high MI DUS guided by CPS improves both epicardial recanalization rates and microvascular recovery.

2:40

4pBB5. Delivery of drug, or gene, to blood vessel wall using intravascular ultrasound and microbubbles. John Hossack (Biomed. Eng., Univ. of Virginia, Charlottesville, VA 22908-0759)

Atherosclerotic arteries are routinely treated using balloon angioplasty followed by stent placement. We developed a concept for a new therapy to prevent restenosis involving using ultrasound and microbubble-based drug/gene carriers. A number of early *in vitro* and *in vivo* results are presented. In particular, data for delivery of antiproliferative gene via microbubbles ruptured via catheter-based intravascular ultrasound (IVUS) at the site of vessel injury *in vivo* in a pig coronary artery are presented. Optimal design of a modified IVUS catheter is discussed. The proposed catheter includes a bubble port, an elongated single element transducer to provide radiation force to cause the bubbles to traverse to the vessel wall, and a bubble rupture transducer. The bubble rupture transducer is ideally coincident with an imaging IVUS scanning single element or annular phased array. These requirements provide the impetus to develop enhanced designs of both PZT based transducers and silicon micromachined transducers. In our initial pig study, transfection efficiency was measured using fluorescence microscopy and quantified as the percent of vessel perimeter cells expressing red fluorescent protein. We observed $23.3\pm6.0\%$ transfection in the treated vessel whereas the control exhibited $3.6\pm2\%$ transfection.

3:20

4pBB6. Direct numerical simulations of bubble collapse near a tissue surface with the ghost fluid method. Hiroyuki Takahira and Kazumichi Kobayashi (Dept. of Mech. Eng., Osaka Prefecture Univ., 1-1 Gakuencho, Naka-ku, Sakai, Osaka 599-8531, Japan, takahira@me.osakafu-u.ac.jp)

The collapse of an air bubble induced by the interaction of an incident shock wave with the bubble near a gelatin or bone surface is investigated by using an improved Ghost Fluid Method (GFM). The motions of three phases for air inside the bubble, water, and gelatin (or bone) are solved directly by coupling the GFM with the level set method. The results show that the strong shock waves are generated not only when the bubble rebounds but also when the liquid-jet impacts the downstream surface of the bubble; the shock waves result in the depression of the gelatin (or bone) surface. Also, the penetration of the bubble into the depression of the gelatin surface is simulated successfully, which is in qualitative agreement with the experiment by Kodama and Takayama [Ultrasound in Med. & Biol. **24**, 723–738 (1998)]. It is also shown that the impulsive pressure at the bone surface caused by the bubble collapse is higher than that at the gelatin surface because the bubble collapse is accelerated by the high-pressure field generated by the reflection of the incident shock wave at the bone surface.

3:40

4pBB7. Acoustic characterization of echogenic liposomes: Attenuation and quantitative backscatter. Jonathan A. Kopechek (Dept. of Biomedical Eng., Univ. of Cincinnati, 231 Albert Sabin Way, MSB 6163, Cincinnati, OH 45267, kopechja@uc.edu), Tyrone M. Porter (Boston Univ., Boston, MA), Constantin-C. Coussios (Univ. of Oxford, Oxford, UK), Stephen R. Perrin, Jr. (Univ. of Cincinnati, Cincinnati, OH), Shaoling Huang, David D. McPherson (Univ. of Texas Health Sci. Ctr., Houston, TX), and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH)

Echogenic liposomes (ELIPs) are being developed for use as ultrasonic contrast agents and as drug carriers for ultrasound-targeted drug delivery. Physical and acoustical characterization of ELIPs is necessary in order to determine the optimum parameters for diagnostic and therapeutic applications. In this study, ELIP samples at concentrations of 10, 20, and 50 μg/ml were exposed to ultrasound in pulse-echo mode at center frequencies of 2.25, 3.5, 7.5, 10, 15, and 30 MHz. The received echoes were analyzed to determine the attenuation and backscatter coefficients and the results were compared to a theoretical computational model. The sample chamber contained two 50-μm tungsten wires as reference scatterers. The echoes from the wires were acquired before and after addition of ELIP to determine the attenuation coefficient. The backscatter coefficient was determined by averaging the square of the RF amplitude between the wires and accounting for transducer parameters. Each transducer was calibrated and characterized in deionized water using PVDF hydrophones. The peak attenuation coefficient occurred at 7.5 MHz while the backscatter coefficient increased with frequency. This was in agreement with the computational model. These results provide important information for determining the optimum acoustical parameters for ELIP exposure in diagnostic and therapeutic applications. [Work supported by NIH 2RO1 HL059586-04A2 and ASA Hunt Postdoctoral Research Fellowship.]

4:00

4pBB8. Delivery of targeted echogenic liposomes in an *ex vivo* mouse aorta model. Kathryn E. Hitchcock, Jonathan T. Sutton (Dept. of Biomed. Eng., Univ. of Cincinnati, 231 Albert Sabin Way, MSB 6163, Cincinnati, OH 45267, hitchcke@email.uc.edu), Danielle N. Caudell, Gail J. Pyne-Geithman, D. Phil. (Univ. of Cincinnati, Cincinnati, OH), Melvin E. Klegerman, Shaoling L. Huang, Deborah Vela, David D. McPherson (Univ. of Texas Health Sci. Ctr., Houston, TX), and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH)

Optimal ultrasound parameters to enhance delivery of therapeutic-loaded echogenic immunoliposomes (ELIP) into the arterial wall are being developed for the treatment of atherosclerosis. The aim of this work was to determine whether anti-ICAM-targeted, rhodamine-labeled ELIP (Rh-ELIP) would adhere to and penetrate the vascular endothelium in atheromatous murine arterial segments with intravascular flow treated with 1-MHz continuous wave ultrasound (CW US). A broadband focused hydrophone, confocally aligned with the artery and 1-MHz transducer field was used as a passive cavitation detector (PCD). Arteries were insonified with 1-MHz CW US (0.49 MPa peak-to-peak pressure), and the PCD was used to verify the duration of the resulting stable cavitation. Perivascular saline was collected and analyzed spectrofluorometrically for the presence of Rh-ELIP. Arteries were prepared for histological analysis by a pathologist blinded to the exposure conditions. Arteries exposed to Rh-labeled ELIP and 1-MHz US exhibited greater adherence of Rh-ELIP to the vascular endothelium and greater passage of Rh-ELIP across the vessel wall. No damage was detected in any of the arteries on histology. These studies will aid in the development of a strategy for improving atheroma treatment without causing ultrasound-related tissue damage.

4:15

4pBB9. 120 kilohertz ultrasound-enhanced thrombolysis in a porcine intracerebral hemorrhage model. Azzdine Y. Ammi (Dept. of Biomedical Eng., Colleges of Medicine and Eng., Univ. of Cincinnati, 231 Albert Sabin Way, Cincinnati, OH 45267, ammia@ohsu.edu), Saurabh Datta (Siemens, CA), Stephen R. Perrin, Jr, Shauna L. Beiler, Christian R. Beiler, Kenneth R. Wagner, and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH 45267)

Ultrasound acts synergistically with thrombolytic agents, such as recombinant tissue plasminogen activator (rt-PA), to accelerate thrombolysis. The aim of the study was to demonstrate the efficacy of 120-kHz ultrasound-enhanced rt-PA thrombolysis in a porcine hemorrhagic stroke model *in vivo*. Clots were formed by infusing 3 ml of autologous blood into the frontal white matter of 30 mixed-bred Yorkshire pigs (20.5–3.1 kg) and incubated for 3 h. For these nonsurvival studies, six pigs received rt-PA alone (0.3 cc of 0.107 mg/ml), six received ultrasound alone, six received rt-PA plus ultrasound, six were sham-exposed (saline only), and six were controls (no ultrasound or rt-PA treatment). The clots receiving ultrasound treatment were insonified with a peak-to-peak pressure of 0.48 MPa *in situ* (80% duty cycle, and PRF of 1.7 kHz) for 30 min. Clots treated with rt-PA alone exhibited a volume loss of 55.0% and clots treated with rt-PA and 120-kHz ultrasound had a significantly higher volume loss of 75.2% and a higher penetration of rt-PA. Thus, 120-kHz pulsed ultrasound enhancement of thrombolysis has been demonstrated both *in vitro* and in an *in vivo* porcine hemorrhagic stroke model.

4:30

4pBB10. Modelling of oscillations of a microbubble in an elastic vessel. Sergey Martynov, Eleanor Stride, and Nader Saffari (Univ. College London, Torrington Pl. London WC1E 7JE, UK, s.martynov@ucl.ac.uk)

Encapsulated microbubbles have been extensively investigated as contrast agents for diagnostic ultrasound imaging and more recently for therapeutic applications such as drug delivery. However, theoretical models for microbubble dynamics exist either for encapsulated bubbles in an infinite volume of liquid, or for unencapsulated bubbles in a confined volume. In the present study, a finite-element method is applied to quantify the effects of both encapsulation and confinement in a blood vessel upon a microbubble's response to ultrasound. The effect of encapsulation is examined for polymeric and surfactant coatings. Elastic deformations of the vessel wall are described using a lumped-parameter model, treating the wall as a thin membrane. It will be shown that even at low acoustic pressures (10 kPa), the bubble oscillations can be significantly modified as a result of confinement. In particular, the frequency spectrum of the oscillations of a confined bubble is characterized by two modes. For relatively soft vessels, a high-frequency mode dominates, with the eigenfrequency increasing with the vessel stiffness. The eigenfrequency of the low-frequency mode decreases with the vessel length. The results will be discussed in the context of diagnostic and therapeutic applications.

4:45

4pBB11. Electrocardiogram-gated imaging of a mouse heart using a high-frequency annular array. Jeffrey A. Ketterling, Jonathan Mamou (Riverside Res. Inst., Lizzi Ctr. for Biomedical Eng., 156 William St., New York, NY 10038), and Orlando Aristizábal (Skirball Inst. of Biomolecular Medicine and New York Univ. School of Medicine, New York, NY 10016)

Gated imaging is a technique in which M-mode data, referenced to a feature of an ECG signal, are acquired at a series of lateral positions and then reassembled into B-mode images to achieve high effective frame rates. It is only effective for imaging objects with periodic motion. Annular arrays and synthetic focusing allow for an improved depth of field (DOF) and resolution versus single-element transducers. Here, a five-element, 35-MHz annular array was utilized in combination with ECG and respiratory gating to image adult mouse hearts. An experimental system was assembled to permit appropriate triggering conditions and to collect all 25 transmit-to-receive echo data sets from the annular array at a series of lateral positions. The system was initially tested with a hexagon-shaped target that rotated at 10 revs/s and generated a trigger each rotation. After system testing, data were acquired from an adult mouse heart using a trigger in phase with the R-wave of the ECG signal. The synthetically-focused B-mode images showed several cardiac cycles over a 1200 ms duration captured at 100 fps over a 1-cm depth and a 6-mm width. Data from the mouse heart were acquired with conventional monocycle excitation and also with coded excitation.

5:00

4pBB12. High-frequency imaging with targeted ultrasound contrast agents under vascular flow conditions. Pavlos Anastasiadis (Dept. of Mech. Eng., Univ. of Hawaii at Manoa, 2540 Dole St., Honolulu, HI 96822, pavlos@hawaii.edu) and John S. Allen (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Targeted ultrasound contrast agents (UCA) were conjugated with biotinylated ligands, which allow them to adhere to specific diseased sites of interest. The overall adhesion of contrast agents is influenced by both the flow mediated gene expression and the local hydrodynamic forces acting on the contrast agents' trajectories. The ability to bind under pulsatile flow conditions and scatter sound at high frequencies is important for potential applications involving intravascular ultrasound. Human aortic endothelial cells (HAECs) in a flow chamber were exposed to a steady shear pretreatment over 12 h using a peristaltic pump system and subsequent pulsatile waveforms. To stimulate an inflammatory reaction in the HAECs, cells were subsequently exposed to rhTNF945; (Roche Pharmaceuticals). Different flow rates were applied, and the binding efficacy of targeted UCA was evaluated. Real-time transendothelial electrical impedance measurements and simultaneous acoustic measurements were performed on the same specimen with a scanning acoustic microscope. Applications related to targeting plaque in blood vessels are discussed. [This work was supported by the National Institutes of Health Grants NIH 2 P20 RR016453-05A1 and NIH 2 G12 RR0030161-21.]

4pNSa1. Soundscape approach in progress—Report on the current stage. Brigitte Schulte-Fortkamp (TU-Berlin, Inst. of Fluid Mech. and Eng. Acoust., Einsteinufer 25, D-10587 Berlin, Germany)

Soundscapes have become an important issue in environmental acoustics. Following Soundscape workshops in Vancouver, Salt Lake City, and Miami, a Soundscape Symposium took place in Berlin, Germany, and brought together expertise from all over the world to work on concepts, approaches, analyses, applications, as well as source- and pattern recognition with respect to Soundscapes. Therefore, acousticians, architects, city planners, engineers, psychologists, sociologists, and the people concerned were invited. The aim of the workshop was to define Soundscapes for future work. Moreover, concepts, approaches, analyses, and applications were related to the categorization of Soundscapes as urban, cultural, and wilderness, also focussing on source and pattern recognition. This paper will report on the results to outline the next steps towards standardization.

1:25

4pNSa2. Integrating soundscape analysis into the National Environmental Policy Act process: A case study. George Luz (Luz Social and Environ. Assoc., 4910 Crowson Ave, Baltimore, MD 21212, Luz-Assoc.@msn.com)

A challenge for the proponents of soundscape analysis within the U.S. is how to integrate subjective observations with the quantitative requirements of the National Environmental Policy Act (NEPA), which, historically, emphasize physical measurements of all pollutants, including sound pollution. This paper describes a case study in which an attempt is made to integrate the subjective impressions of a soundscape analysis with objective measurements of equivalent sound level (LEQ). The occasion for this effort was a Base Realignment and Closure (BRAC) action in which the proposed reuse for a former military installation is park and recreational use. The quantitative framework for this study was a graphic used by the U.S. Army Environmental Hygiene Agency (USAEHA) during the 1980s in which the 24 h pattern of outdoor noise exposure is displayed as the minimum, average, and maximum values of 10 min LEQ over the course of a week of measurements. Although the intent of the USAEHA approach had been to determine conformance of military residential areas to Army guidelines, their method for displaying measurement data proved to be amenable to soundscape analysis as well.

1:45

4pNSa3. Soundscaping the aesthetic—Beyond measurement and assessment. Alexander U. Case (Sound Recording Technol., Univ. of Massachusetts Lowell, 35 Wilder St., Lowell, MA 01854, Alex_Case@uml.edu)

Soundscape in the context of community noise alone risks missing the important subjective reactions people have to the aesthetic value of any sound environment. The music recording and film sound industries have been recording sounds for art and entertainment, without regard for objective assessment, for more than a hundred years. Soundscape design has the opportunity to borrow from the time-tested recording, signal processing, and playback techniques developed by recording engineers where appropriate, learning from their search for emotional, intellectual, and uniquely human reactions. An introduction to nonobjective recording techniques is presented, with emphasis on some of the more counter-intuitive parts of the recording craft.

4pNSa4. A study on the modified urban soundscape of a city due to introduction of elevated structures. Kalaiselvi Ramasamy and Ramachandraiah Alur (Dept. of Civil Eng., IIT-Madras, India)

The urban soundscape of cities in a developing country like India are slightly varied by virtue of the fact that the composition of the traffic is heterogeneous accompanied by variance in road geometry and varying density of the buildings on the either side of the road and other community noise sources. Urban planning plays a vital role in organizing a city's traffic flow. To avoid congestion of traffic streams introduction of flyovers in the traffic flow happens to be a common feature in many urban environments. Through introduction of flyovers an increase or decrease in environmental noise characteristics occurs. In this paper a noise mapping study has been attempted along with field measurements of L10, L50, L90, and Leq to understand the soundscape of the city due to such types of modified topography. It also describes how the local characteristics of the city and changed topography alters the soundscape of the city. The theoretical computation of noise levels has been carried out using the sound plan software. It is observed that a reasonable reduction of Leq occurs in the immediate vicinity of noise sensitive areas of significant buildings such as hospitals and educational campuses.

4pNSb1. Overview of on-going Federal Aviation Administration and National Park Service collaborative research efforts in support of the National Parks Air Tour Management Act. Cynthia Lee (U.S. Dept. of Transportation, Res. and Innovative Technol. Admin., Volpe Ctr., 55 Broadway, RVT-41, Cambridge, MA 02142, Cynthia.Lee@dot.gov)

In support of the National Parks Air Tour Management Act of 2000 (NPATMA), the FAA and NPS are developing air tour management plans (ATMPs) for approximately 100 national parks. ATMP objectives are to develop acceptable and effective measures to mitigate or prevent significant adverse impacts, if any, of commercial air tour operations upon the natural and cultural resources of and visitor experiences in national parks and abutting tribal lands. In accordance with NPATMA, any methodology adopted by a federal agency to assess air tour noise under this Act shall be based on reasonable scientific methods. Both agencies acknowledge that additional research is needed. This paper presents an overview of Volpe Center contributions to the collaborative effort by the FAA and NPS to develop improved methods to (1) quantify park soundscapes (natural and non-natural); (2) enhance computer modeling capabilities through aircraft source noise database expansion and advanced research into the factors which affect aviation noise propagation for complicated environments, such as national parks; and (3) assess the effects of aircraft overflights on park visitor experience, including the metrics used in these assessments. Improved methods developed in these efforts will also be used to support other agency projects related to aviation noise.

2:55

4pNSb2. Visitor perception of park soundscapes: An approach and research plan. Paul Schomer (Schomer and Assoc., Inc., 2117 Robert Dr., Champaign, IL 61821, schomer@SchomerAndAssoc..com) and G. Randy Stanley (Natl. Park Service, Fort Collins, CO 80525)

In the United States, much of the research on the soundscape in national parks and wilderness areas has centered on so-called dose-response relations with the aim of stating: How much manmade noise is unacceptable? Based on their experience in urban areas, this approach has been advocated primarily by the aviation noise community. But there is another school of thought. Visitors to national parks are guests and patrons of what the park has to offer. Just as juries of listeners are used to judge the sound quality of automobiles and home-appliances, juries of listeners could also be used to judge the sound quality in national parks. The current plan is to develop outdoor sound quality measurement and prediction methods and standards by which the U.S. National Park Service can accomplish their assessments of the acoustic ambient. This paper discusses the plan for this measurement protocol development and indicates some standards to be developed.

3:15

4pNSb3. "The Grand Canyon" versus "Soundscape of Nowhere (continued)". Dickson J. Hingson (Sierra Club—Natl. Parks and Monuments Committee)

More than 21 years have elapsed since the National Parks Overflights Act mandated the prompt "substantial restoration" of the natural quiet of the aircraft-noise imperiled soundscape of the Grand Canyon National Park. However, as of 2008, long-anticipated, critical compliance benchmarks have still not been timely met in the Park. The past two Administrations have not conformed to specifications/standards/deadlines set or appropriate to the NPS under its legal mandates. However, every battle has its turning point. *Will 2009 be the turning point to a quiet Canyon?* Success will require immediate NPS application of long-established restoration standards (based on "audibility"), Park zoning considerations, and buttressing with emerging supplemental noise indicators, which trigger loudness and temporal impulsiveness mitigations. Effectiveness of imminently anticipated management actions in the form of a soon forthcoming 2009 environmental impact statement and stepped up political oversight will be examined. These will pit restoration of the authentic Grand Canyon wilderness soundscape against the current, unsavory option: "the Soundscape of Nowhere." The protracted Grand Canyon imbroglio illuminates similarly unmet, pressing restoration needs, along with the need for increased executive /congressional oversight, re low-altitude air tour noise unacceptably continuing at similarly impacted, famed national parks, which otherwise remain subject to long-term, aviation noise impairment.

3:35

4pNSb4. A case for the importance of context for soundscape research in parks and protected areas. G. (Randy) Stanley (Natural Sounds Prog., U.S. Natl. Park Serv., 1201 Oakridge Dr., Ste. 100, Ft. Collins, CO 80525, Randy_Stanley@nps.gov) and Paul Schomer (Schomer and Assoc., Inc., Champaign, IL 61821)

Over the past decade or so, there have been a number of research studies, summarized herein, that indicate context is a potentially important intervening variable in assessing the soundscape in a park or wilderness area. Context is primarily provided by the corresponding visual landscape but may, in testing situations, be provided in other ways such as a verbal or written description. Context has been shown to be important in sound quality testing of automobile and product sounds, but its importance in assessing environmental sounds is less well documented. This paper discusses these various issues and suggests possible courses of action.

4pNSb5. The acoustical status of U. S. national parks. Kurt Fristrup (NPS Natural Sounds Program, 1201 Oakridge Dr., Ste. 100, Fort Collins, CO, 80525)

Acoustical monitoring data have been collected for more than 40 national park units, spanning a wide range of regions, resources, and park purposes and values. Comparative analyses of these data reveal the extent of noise pollution in national parks. Transportation noise is audible in many wilderness areas more than 30% of the daylight hours, with peak hourly levels approaching 70%. Peak levels from noise events can be more than 50 dB above the natural background under air tour routes, and between 10–20 dB above background for high altitude aircraft. Hourly Leq values can be as much as 6 dB above natural levels. These data also reveal the degree to which various noise metrics covary in these natural settings. This information helps inform selection of a compact set of metrics that can assess several functional impacts of noise while minimizing redundancy.

4:10

4pNSb6. Baseline sound monitoring plan for Grant-Kohrs Ranch national historic site. Robert C. Maher (Elec. & Comput. Engr., Montana State Univ., 610 Cobleigh Hall, Bozeman, MT 59717-3780, rob.maher@montana.edu)

Grant-Kohrs Ranch National Historic Site (GRKO), located just north of Deer Lodge, Montana, is a working cattle ranch commemorating the heritage of cowboys and stock growers in the history of the American West during the 19th and 20th centuries. The U.S. National Park Service (NPS) maintains the site according to its charter as a working ranch, with all the sights, sounds, and sensations associated with ranching. The cultural soundscape of the working ranch is considered essential to visitor enjoyment and understanding. Several anticipated changes in the neighboring community of Deer Lodge may affect the visitor experience at GRKO, including anticipated expansion of the local airport, increasing interstate highway traffic, and proposals to establish a rifle shooting range nearby. Because GRKO currently has no data characterizing the natural and cultural sounds of the park, this project was commissioned to monitor and evaluate the natural, cultural, and community sounds that comprise the ambient acoustic environment of the historic site over the period of one calendar year. The baseline acoustical data are analyzed and documented in a format suitable for management purposes by the NPS (the sponsor of this study), and by the NPS Natural Sounds Program Office.

4pPA1. Evaluation of parametric array technology for acoustic landmine detection. Murray S. Korman (Dept. of Phys., U.S. Naval Acad., Annapolis, MD 21402, korman@usna.edu), Antal A. Sarkady and Frederick R. Tolle (U.S. Naval Acad., Annapolis, MD 21402)

There has been interest in using the parametric array for obtaining a highly directional low frequency source in acoustic landmine detection [M. S. Korman, J. Acoust. Soc. Am. **122** (2007)]. Earlier experiments used a 0.5 m commercial parametric array made up of 70 elements located 1.5 m directly over the target. The array was driven by a 110–1100 Hz swept sine audio modulated 65 kHz tone. A VS 1.6 inert plastic antitank landmine was buried 2.5 cm deep in dry sifted masonry sand in a concrete box. The laser Doppler vibrometer to microphone rms response was sufficient to measure the "on target" to "off target" contrast ratios of 20 and 3 for peaks near 850 and 1050 Hz, respectively (upon signal averaging) but missed the largest peak near 150 Hz (where the SPL was 40 dB per 20 μPa) among others. Recent "forward looking" experiments aligned the array beam axis at 30° from grazing. Sweeping from 110–210 Hz (1600 points) at 16 s/sweep and signal averaging 20 sweeps produced a contrast ratio of 10 for resonance at 148 Hz. Considerable improvement in SPL is necessary in order to make this technology practical for low frequency applications. [Work supported by ARL.]

4pPA2. Spatial phase-inversion technique for parametric source with suppressed carrier. Tomoo Kamakura, Hideyuki Nomura, and Shinichi Sakai (Dept. of Electronis, Univ. of Electro-Commun.s, 1-5-1, Chofugaoka, Chofu-shi, Tokyo 182-8585, Japan)

Two planar projectors with the identical rectangular apertures are placed side by side. Both the projectors are radiating bifrequency ultrasound beams of finite amplitude in the air. The frequencies are 40 and 42 kHz but the initial phases are different. Especially, two extreme cases are considered: one is conventional in-phase driving, and the other is phase inversion driving. Sound pressure profiles were measured along and across the sound beam axis for the primary waves and the difference frequency wave of 2 kHz. The second and third harmonic components of the difference frequency were measured as well. Obviously, the pressure levels of the primary waves were suppressed considerably near the beam axis due to phase cancellation when the driving signals were out-of-phase by 180 degrees. The beam pattern of the difference frequency was, however, almost the same as the case where the signals were in phase. Interestingly, the pressure levels of the harmonics were reduced more than ten decibels. The validity of experimental results has been supported by good agreement with the theoretical predictions based on the Khokhlov-Zabolotskaya-Kuznetsov model equation. [Work supported by JSPS.]

4pPA3. Infrasound-convection nonlinear interaction. Konstantin Naugolnykh (Earth System Res. Lab., NOAA/Univ. of Colorado/Zeltech, Boulder, CO 80305)

The temperature stratified atmospheric layer is unstable and convection flow can be developed in such an area. Convection happens because warm less dense air goes up while cooler air comes down. The presence of infrasound produces modulation of convection flow and the sound wave amplification. The process of infrasound-convection nonlinear interaction is considered in the present paper. The equations of a compressible fluid convection are derived, which is characterized by the modified Rayleigh number, in comparison to this number for the incompressible flow, and condition of infrasound amplification is obtained. The increment of infrasound amplification turned out to be proportional to the Rayleigh number.

4pPA4. Sonar material acoustic property measurements using a parametric array. Victor F. Humphrey (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton, SO17 1BJ, UK, vh@isvr.soton.ac.uk.), Stephen P. Robinson, Graham A. Beamiss, Gary Hayman (Natl. Physical Lab., Teddington, Middlesex, TW11 0LW, UK), John D. Smith (DSTL, Porton Down, Salisbury, Wiltshire, SP4 0JQ, UK), Michael J. Martin (QinetiQ Ltd., Farnborough, Hampshire GU14 0LX, UK), and Nicholas L. Carroll (QinetiQ Ltd., Park, Winfrith Newburgh, Dorchester, Dorset, DT2 8XJ UK)

The use of a parametric array as an acoustic source for measuring the acoustic properties of materials for use in sonar systems is considered. Techniques of measuring the wideband transmission and reflection properties of limited size test panels are described and the advantages of using a parametric array in terms of reducing edge diffraction errors are discussed. Results for a range of materials under ambient pressure over the range 10–200 kHz are presented to illustrate the potential of the technique. The implementation of the approach in a pressure vessel at the UK National Physical Laboratory is also described and illustrated with example results obtained over the frequency range 2–50 kHz for two test objects that have predictable behavior. The potential of the technique is also illustrated with experimental results for viscoelastic test panels for hydrostatic pressures up to 2.8 MPa.

4pPA5. Parametric array application for long range ocean sounding. Konstantin Naugolnykh (Earth System Res. Lab., NOAA/Univ. of Colorado /Zeltech, Boulder, CO 80305) and Igor Esipov (N. Andreev Acoust. Inst., 4 Schvernik St., Moscow, Russia)

The parametric array (PA) is a nonlinear transducer that generates narrow, sidelobe-free beams of low frequency sound, through the interaction of high frequency pump waves. PA was suggested by Peter J. Westervelt, winner of the Lord Rayleigh Medal, at the same time this devise invention was underway in the Soviet Union made by Zverev and Kalachev. Remarks of PA applications for long distance ocean sounding is presented in the present paper. Experimental test of a high-frequency PA was made on the Black Sea coast by Esipov *et al.*, and investigations of powerful PA characteristics was performed in a ocean by Andebura *et al.*, in 1990. Then large-scale ocean vortices sensing at a distance of 1000 km was realized by Esipov *et al.* [Acoust. Zh., **40**(1), 71–75 (1994)]. In both experiments, the transducer of R/V "Boris Konstantinov" was used with parameters: pump wave power

$W=20$ kW, pump wave frequency $f=3$ kHz, parametric signal frequency $F=230$–700 Hz. Obtained results indicate the efficiency of PA application for long distance ocean sounding. [Work supported by ISTC project 3770 and NATO Grant No. ESP.NR.NRCLG 982524.]

4pPA6. Observing Atlantic herring by parametric sonar. Olav Rune Godø (Inst. of Marine Res., PO Box 1870, N-5817 Bergen, Norway, olav.rune.godoe@imr.no), Kenneth G. Foote (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Johnny Dybedal (Kongsberg Defence & Aerosp. AS, Stjoerdal, Norway), and Eirik Tenningen (Inst. of Marine Res., Bergen, Norway)

Atlantic herring (*Clupea harengus*) has been observed in situ by the Kongsberg TOPAS PS18 parametric sub-bottom profiling sonar, with nearly horizontal transmit and receive transducer arrays mounted flush on the hull of R/V G. O. Sars, at N71.4 E16.3. The primary frequencies are in the band 15–21 kHz, with nonlinearly generated difference frequencies in the band 0.5–6 kHz. The beamwidths are 6–10 deg depending on frequency and range, but with exceedingly low sidelobes. The observation of herring in schools and layers was accomplished with the vessel both at rest and sailing at its ordinary survey speed of 10 knots. The observations with the parametric sonar were confirmed by concurrent, synchronized observations with the Simrad EK60/38-kHz scientific echo sounder and by trawling with a pelagic net. The herring length varied from 28.0–36.5 cm. Present work suggests that parametric sonar will become a powerful new tool in marine ecosystem studies, enabling the numerical density of schooling and shoaling fish to be determined, and the size of swimbladder-bearing fish to be estimated by detection of swimbladder resonance. [Work partly supported by Norwegian Research Council Grant no. 184705.]

4pPA7. Range compensation function for echo integration in transducer near fields, with special reference to parametric sonar. Kenneth G. Foote (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, kfoote@whoi.edu)

Range compensation functions are applied to echo signals so that the corresponding range-compensated echo intensity equals the volume backscattering coefficient to within a multiplicative constant. For echo integration in a transducer far field, the transmit and receive pressure fields each decrease inversely with range r, and the well-known range compensation function, applied to intensity, is $r^2\times10^{\alpha r/5}$, where α is the absorption coefficient. For echo integration in a transducer near field, the range compensation function is that of the far field modified by a multiplying factor. This factor is, approximately, the ratio of the square of the surface integral of the field intensity at r due to extrapolation from the far field, assuming inverse range dependence of the amplitude, to the product of the surface integrals of transmit and receive intensities at r. This general range compensation function is developed for the special case of echo integration with a parametric sonar in which scatterers are ensonified in a region where the nonlinearly generated difference-frequency field is growing and echoes are received in the far field of a collocated, linearly operating transducer. It is evaluated numerically for the Kongsberg TOPAS PS18 parametric subbottom profiling sonar, with primary-frequency band 15–21 kHz and difference-frequency band 0.5–6 kHz.

3:05

4pPA8. Standard-target calibration of a parametric sonar over the difference-frequency band, 1–6 kilohertz. Kenneth G. Foote (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, kfoote@whoi.edu), Johnny Dybedal (Kongsberg Defence & Aerosp. AS, N-7501 Stjoerdal, Norway), and Eirik Tenningen (Inst. of Marine Res., N-5817 Bergen, Norway)

The Kongsberg TOPAS PS18 parametric sub-bottom profiling sonar operates over the frequency band 15–21 kHz, with nonlinearly generated difference-frequency radiation in the band 0.5–6 kHz. The TOPAS transducer mounted on R/V G. O. Sars is flush with the hull in the near-horizontal plane. The sonar has been calibrated by the standard-target method using a 280-mm diam sphere of aluminum alloy 6082 T6 [K. G. Foote *et al.*, J. Acoust. Soc. Am., **121**, 1482–1490 (2007)]. The target was suspended beneath the vessel at each of three ranges, successively 100, 200, and 300 m. Because of conditions in Soerfolla fjord on Dec. 10, 2008, the target sphere was moving slowly relative to the vessel. Its instantaneous position was determined by geometrical considerations through synchronous observation with the Simrad EK60/38-kHz scientific echo sounder, with split-beam transducer mounted approximate to the TOPAS transducer. Data were collected for a number of parameter settings for each of three signal types: continuous wave, chirp, and Ricker pulse. Measurements are compared with predictions based on laboratory measurements of the frequency-dependent sensitivities of the parametric transmitter and conventional linear receiver, using a range-compensation function based on theoretical nearfield modeling. [Work partly supported by Norwegian Research Council Grant No. 184705.]

4pPA9. Resonant mode conversion in superfluid 4 helium and in solids. Steven L. Garrett (Graduate Program in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804)

One component of the success of the Westervelt analysis of the parametric array was that sound propagation in most gases and liquids exhibit very little dispersion. Therefore, the pump waves and their nonlinearly generated product propagate at very nearly the same speed. When an acoustic medium can support more than one sound mode with different propagation speeds, then a parametric array can be created by the nonlinear interaction of the two slower sound waves to produce the faster wave, if the slow wave propagation directions are not collinear. Bulk superfluid helium, at temperatures below 2.1 K, will support a slower (thermal) sound mode and a faster (mechanical) sound mode. An experiment performed in 1977 will be described that used a waveguide to create thermal (temperature-entropy) sound waves while controlling their angle of intersection. A mechanical (pressure-density) wave was produced and its amplitude determined the thermodynamic coupling constant between density changes and the Galilean invariant square difference in the normal and superfluid particle velocities that characterize the thermal sound wave amplitude. An earlier experiment will also be described that demonstrated the nonlinear conversion of two shear waves to a longitudinal wave in aluminum. [Work supported by the Office of Naval Research.]

4pPA10. Quantum acoustics, the second law and the end fire array. Seth Putterman (Dept. of Phys., UCLA, Los Angeles, CA 90095) and Paul H. Roberts (UCLA, Los Angeles, CA 90095)

The fundamental nonlinear interaction which leads to the scattering of waves and to the end fire array yields a Boltzmann equation for sound, a one fluid theory of superfluid helium [S. Putterman, P. H. Roberts, Physics Letters, **89A**, 444 (1982)] and a route to the

quantum theory of interacting phonons [M. Cabot, S. Putterman, Phys. Lett. **83A**, 91 (1981)]. Along with a review of these consequences of nonlinear classical acoustics the conundrum of the consistency of the second law of thermodynamics with the Hamiltonian nature of the end fire array will be exposed but not resolved [S. Putterman, P. H. Roberts, Phys. Rep., **168**, #4 (1988)].

4pPA11. Acoustic nonlinearity in fluorinert. Cristian Pantea, Dipen N. Sinha, Curtis F. Osterhoudt, and Paul C. Mombourquette (Los Alamos Natl. Lab., MPA-11, MS D429, Los Alamos, NM 87545, pantea@lanl.gov)

Fluorinert FC-43 nonlinearity was investigated using two approaches: (i) a finite amplitude method with harmonic production and (ii) a nonlinear frequency mixing in the fluid with consequent beam profile measurement of the difference frequency. The finite amplitude method provides information on the coefficient of nonlinearity, β, through the amplitudes of the fundamental and the second harmonic, at a certain transmitter-receiver distance. A calibrated hydrophone was used as a receiver in order to obtain direct pressure measurements of the acoustic waves in the fluid. The role of transmitter-receiver distance in β determination is investigated. In the second approach, a single transducer is used to provide two high-frequency beams. The collinear high-frequency beams mix nonlinearly in the fluid resulting in a difference frequency beam and higher order harmonics of the primaries. The difference frequency beam profile is investigated at lengths beyond the mixing distance. The experimental data are compared with the KZK theory.

4pPA12. Flow through orifices caused by large-amplitude asymmetric sound waves: Theory and experiment. Peter J. Westervelt (Dept. of Phys., Brown Univ., Providence, RI 02912, abwpjw@cox.net)

When the displacement amplitude of an acoustic wave consisting of equal parts fundamental and second harmonic exceeds the diameter of a circular orifice, steady flow is generated whose direction is determined by the phase of the two wave components [P. J. Westervelt, Ph.D. thesis "The interaction of a finite amplitude acoustic wave with small obstacles and orifices," (MIT, 1951)]. Some applications to semipermeable biological membranes are discussed. [Work supported by the Office of Naval Research].

THURSDAY AFTERNOON, 21 MAY 2009 GRAND BALLROOM I, 1:00 TO 4:00 P.M.

Session 4pPP

Psychological and Physiological Acoustics: Physiology; Aging; Hearing Loss (Poster Session)

Kathryn H. Arehart, Chair
Dept. of Speech, Language and Hearing Science, Univ. of Colorado at Boulder, Boulder, CO 80309

Contributed Papers

All posters will be on display from 1:00 p.m. to 4:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 2:30 p.m. and contributors of even-numbered papers will be at their posters from 2:30 p.m. to 4:00 p.m.

4pPP1. Effect of stimulus onset delay on auditory cortex neural responses to voice pitch feedback perturbation. Roozbeh Behroozmand and Charles R. Larson (Speech Physiol. Lab., Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208)

It has previously been shown that the auditory neural responses to voice F0 feedback perturbation are suppressed during active vocalization compared to passive listening to the playback. However, a study in primates showed that the vocalization-induced suppression enhances auditory sensitivity to feedback perturbation. This evidence suggests that the cortical neural responses to self-vocalization reflect suppression to vocal onset and excitation in response to perturbations in voice pitch feedback. In this study, we investigated the effect of stimulus onset delay on cortical neural responses to voice F0 feedback perturbation. Event-related potentials (ERPs) were recorded in human subjects in response to simultaneous (0 ms) and delayed (500 ms) PSS (+200 cents) during active vocalization and passive listening conditions. Results showed that, for the delayed PSS, the P200 peak magnitude was larger during vocalization compared with passive listening. This finding suggests that vocalization enhances auditory cortex responsiveness to deviations in voice pitch feedback following the onset of vocalization. This enhancement might be due to changes in tuning properties of auditory neurons by the vocal motor system that helps to detect and correct for vocal errors during speech production.

4pPP2. Event-related potential correlates of online monitoring of auditory feedback during vocalization. Colin S. Hawco, Jeffery A. Jones, and Todd R. Ferretti (Dept of Psych., Wilfird Laurier Univ., 75 University Ave. West, Waterloo, ON N2L 3C5, Canada)

When speakers hear the fundamental frequency (F0) of their voice altered, they shift their F0 in the direction opposite to the perturbation. The neural mechanisms underlying this response are poorly understood. In the present study, event-related potentials (ERPs) were used to examine the neural mechanisms used to detect alterations in auditory feedback during an ongoing utterance. Participants vocalized for 3 s, and heard their auditory feedback shifted by 0, 25, 50, 100, or 200 cents for 100 ms midutterance. In two sessions, participants either vocalized at their habitual pitch, or matched a target pitch. A mismatch negativity (MMN) was observed, with the amplitude positively related to the size of the perturbations. No differences were found between sessions. The F0 compensation response was found to be smaller for 200 cent shifts than 100 cent shifts, and a positivity was observed in the ERPs for a 200 cent shift. This result suggests that a 200 cent shift may be perceived as externally (rather than internally) generated. The

presence of an MMN, and no earlier (N100) response suggests that the underlying sensory process used to identify and compensate for errors in midutterance may differ from feedback monitoring at utterance onset.

4pPP3. Ictal and interictal changes in central auditory processing. David B. Daly and David M. Daly (Box 210855, Dallas, TX 75211, dave.daly @stanfordalumni.org)

Disordered functioning manifest in seizures can also give rise to subtle, pervasive interictal changes. We have used sets of synthesized acoustic stimuli, concurrent EEG and AED blood-level monitoring to evaluate changes in a 24-year old female with focal seizures. During ictus patient becomes mute, she can hear but not comprehend, and may then be briefly amnestic. EEG revealed sharp/slow waves over left anterior temporal regions, with occasional bilateral discharges. Levels of two AED fluctuated 50%, with peaks 2 h apart. Performance on 4-min sets of auditory testing with ge-ye and be-de-ge fluctuated from well defined ($p<0.001$) near either peak AED, to near-chance levels; three-choice vowel sets were well defined throughout. Disruptions, which involved contralateral homologous areas as well as surrounding ipsilateral areas, are consistent with augmented inhibition.

4pPP4. Measures of wideband power reflectance in otosclerotic ears. Marcin Wróblewski (Graduate Ctr., City Univ. of New York and Dept. of Otolaryngol., NYU Langone Medical Ctr., 550 1st Ave., NBV 5E5, New York, NY 10016, marcin.wroblewski@nyumc.org), Arlene C. Neuman, Nancy Jiang, and Anil K. Lalwani (NYU Langone Medical Ctr., New York, NY 10016)

Wideband reflectance (WBR) is a new method of evaluating middle ear function. While several studies have reported WBR data obtained from persons with normal hearing and from children with otitis media, few data have been reported describing results typical of other types of middle ear pathology. The purpose of the present study was to collect data from a group of persons with clinically diagnosed otosclerosis and to compare the measures of WBR (including reactance, resistance, impedance magnitude, and transmittance) to measures obtained from persons with normal middle ear function. WBR data were collected from 17 preoperative and 18 postoperative otosclerotic ears as well as from 57 ears without middle ear pathology. Measures from four otosclerotic ears allowed for a direct comparison of pre- and postoperative middle ear function. There was a variety of responses from ears with otosclerosis. Preoperatively, while some otosclerotic ears showed a pattern reported in previous case studies (i.e., increased WBR below 1000 Hz indicating enlarged middle ear stiffness), others fell within the normal range. Postoperatively, some ears showed a pattern typical of an increased mass component of middle ear impedance (i.e., decreased WBR below 1000 Hz), while others fell within the normal range.

4pPP5. Comparison of measurements at ambient pressure on clinical immittance and wideband acoustic transfer function systems. Kim Schairer, Brooke Morrison, Ellyn Steininger, and Cynthia Fowler (Univ. of Wisconsin, 1975 Willow Dr., Rm. 373, Madison, WI 53706)

The purpose of the study was to compare acoustic admittance recorded using probe tones of 226, 678, and 1000 Hz on a clinical immittance system with admittance and reflectance recorded on a wideband acoustic transfer function (WATF) system. The WATF system uses a click probe, which yields measurements across a broad range of frequencies with one test, whereas multiple tests are required at individual frequencies on the clinical system. Thus, the WATF system has the potential to provide more information in a shorter amount of time. The hypothesis was that admittance would be comparable between the two systems, which would provide support for clinical use of the WATF system. Measurements were taken at ambient pressure (i.e., 0 Da Pa) in the ear canals of adults with normal hearing and middle-ear function. Because the clinical system reports only information at the tympanometric peak by default, the data at 0 Da Pa were manually recorded by entering the cursor mode. In general, the results at all three probe frequencies support the hypothesis, although the relationship was stronger for the two higher probe tone frequencies. The clinical implications and effect of analysis bandwidth on the WATF system will be discussed.

4pPP6. An electroacoustical analog for estimating sound pressure level at the tympanic membrane at high frequencies. Janice L. LoPresti (Knowles Electron.s LLC, 1151 Maplewood Dr. Itasca, IL 60143, janice.lopresti@knowles.com), Karrie Recker, and Tao Zhang (Starkey Lab., Inc., Eden Prairie, MN 55344)

For various applications, it is useful to know the sound pressure level (SPL) at the tympanic membrane (TM). However, measuring the SPL close to the TM is not clinically feasible, due to safety and discomfort concerns. Therefore, it is desirable to estimate the SPL at the TM using measurements away from the TM. This is challenging at high frequencies where the effect of canal geometry becomes significant as the wavelength of the acoustical source becomes comparable to the dimensions of the canal. In this study, an electroacoustical analog was used to estimate the SPL at the TM for ten participants. The analog is comprised of a transducer (i.e., sound source), occluded ear canal, and the middle ear [Pascal *et al.* (1998)]. The ear model was optimized for each individual using a 2-parameter fit using real ear measurements further away in the canal. The optimization did not require inputs that may be difficult to obtain such as the exact canal geometry. A simulated transfer function was created and applied to each measured real-ear response to generate the estimated response at the TM. The model was verified using the SPL measured at the TM.

4pPP7. Evidence for dynamic cochlear processing in otoacoustic emissions and behavior. Kyle P. Walsh, Edward G. Pasanen, and Dennis McFadden (Dept. of Psych., Ctr. for Perceptual Systems, Univ. of Texas at Austin, 1 University Station A8000, Austin, TX 78712)

Psychophysical research suggests that active cochlear processing may partially explain temporal effects observed in certain auditory masking tasks [Strickland (2001), (2004)]. To investigate this possibility, this study examined the relationship between subjects' psychophysical performance and the responses of their cochleas to the same stimulus waveforms. Stimulus-frequency otoacoustic emissions (SFOAEs) were recorded in the ear canal using a nonlinear procedure. The results showed that the nonlinear SFOAE to a brief tonal signal (4 kHz, 10 ms, 60 dB SPL) in a background noise (100–6000 Hz, 400 ms, 25 dB/Hz) increased in magnitude (with signal delay) over a similar time course to subjects' improvement psychophysically in detecting the same signal. Manipulation of the noise bandwidth revealed that the increases in SFOAE magnitude and the improvement in psychophysical detection both were caused primarily by off-frequency components of the noise: lowpass components for SFOAEs, and lowpass or highpass components for psychophysics. These findings are consistent with a change in the slope of the cochlear input-output function from highly compressive to less compressive over the duration of the background noise, a change that might be attributable to negative feedback from the efferent system. [Work supported by NIDCD.]

4pPP8. Parameters for the estimation of loudness from tone-burst otoacoustic emissions. Michael Epstein (Dept. of Speech-Lang. Path. and Aud., Ctr. for Commun. and DSP [ECE Dept.] Auditory Modeling and Processing Lab., Northeastern Univ., 1600 Massachusetts Ave., Boston, MA 02115, m.epstein@neu.edu) and Ikaro Silva (Northeastern Univ., Boston, MA 02115)

There is evidence that tone-burst otoacoustic emissions (TBOAEs) might be useful for estimating loudness, but appropriate analysis parameters for loudness estimation must first be examined. The purpose of the present work was to collect TBOAE measurements and loudness estimates across a wide range of levels in the same listeners. Both measures were recorded for 1- and 4-kHz stimuli and then analyzed using a wide range of parameters to determine which parameter set yielded lowest mean-square-error estimation of loudness with respect to a psychoacoustical, cross-modality-matching procedure and the inflected exponential (INEX) loudness model. The present results show strong agreement between 1-kHz loudness estimates derived from TBOAEs and loudness estimated using cross-modality matching, with TBOAE estimation accounting for a significant portion of the variance. Additionally, the results indicate that analysis parameters may vary within a reasonable range without compromising the results (i.e., the estimates ex-

hibit some parametric robustness). The lack of adequate parametric optimization for TBOAEs at 4 kHz suggests that measurements at this frequency are strongly contaminated by the ear-canal resonances, meaning that deriving loudness estimates from TBOAEs at this frequency is significantly more challenging than at 1 kHz. [Work supported by Capita Foundation.]

4pPP9. The sensitivity of hearing by the resonance in *in vivo* human ear canal. Wei-De Cheng (Taiouan Interdisciplinary Otolaryngol. Lab., Chang Gung Univ.), Jen-Fang Yu (Chang Gung Univ.), Kuo-Wei Huang, Shang-Peng Chang (Chang Gung Univ.), and Chin-Kuo Chen (Chang Gung Memorial Hosp.)

This study is to discuss the sensitivity of human hearing sounds at different depths of ear canal, and to construct the measurement scales which can be the reference for the sound measurement and research in the future. Eighteen subjects aged from 20 to 30 years old with normal hearing and middle ears were studied. The pure tone audiometer and impedance audiometer were utilized to exam the frequency threshold of subjects. The real ear measurement was also utilized. The intensities of stimuli were 40, 50, 60, 70, and 80 dB SPL. The measured depths to the tympanic membrane were 0.5, 1.0, 1.5, and 2.0 cm, respectively. The gain of ear canal by different frequencies at 500, 1000, 2000, 4000 Hz was measured. Based on the results, there was moderate negative correlation between the resonance of ear canal and hearing. The larger the gain of ear canal was, the better the hearing of the subject would be. Consequently, the sensitivity of hearing for normal people would be affected by the resonance of ear canal. The resonance of each subject would be changed similarly at different measurement depths.

4pPP10. The effects of quinine on frequency selectivity, temporal resolution, and speech recognition in quiet and noise. Erica J. Williams and Sid P. Bacon (Dept. of Speech and Hearing Sci., Arizona St. Univ., PO Box 870102, Tempe, AZ 85287-0102, ejw@asu.edu)

Quinine causes a temporary disruption of outer hair cell (OHC) function, and thus can be used to examine the role of OHCs on auditory perception. In the present study, frequency selectivity, temporal resolution, and speech recognition were measured before, during, and after a quinine-induced hearing loss. Normal-hearing listeners ingested 5.76–11.43 mg/kg body weight of quinine, resulting in 5–15 dB of hearing loss. Frequency selectivity was estimated by comparing the level of a noise masker needed to mask a fixed-level, 2-kHz signal when the masker contained a spectral gap at 2 kHz and when it contained no gap. Similarly, temporal resolution was estimated by comparing the masker level needed to mask the 2-kHz signal when the noise masker contained a temporal gap and when it did not. Speech recognition thresholds were measured in quiet and in the presence of a masker (speech-shaped noise or time-reversed speech) fixed at 70-dB SPL. Signal level was varied adaptively to estimate 50% correct recognition. Quinine resulted in reduced frequency selectivity and reduced temporal resolution. Quinine also elevated speech recognition thresholds in quiet (by 7 dB on average), but the thresholds in the presence of the maskers were unaffected. [Work supported by NIDCD and AAA.]

4pPP11. Behavioral responses to harmonic complex tones with missing fundamental frequencies by chinchillas in the presence of low-pass masking noise. William P. Shofner (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, wshofner @indiana.edu)

The pitch associated with the missing fundamental (F0) is one of the principal psychological attributes of human pitch perception. Behavioral responses to missing F0 stimuli were measured in chinchillas using operant conditioning and stimulus generalization. Animals were trained to discriminate between harmonic complex tones having a 500-Hz F0 and a 125-Hz F0. When animals were tested with tone complexes having the same F0s, but where the F0s were missing, responses were similar to those obtained when the F0s were present, suggesting that missing F0 sounds were perceptually equivalent to F0 present sounds. In the presence of low-pass masking noise, responses to F0 present and missing F0 stimuli were similar, suggesting that the percept was not due to the reinsertion of the F0 through cochlear nonlinearities. When the F0s of test stimuli were systematically varied, gradients in behavioral responses were observed, suggesting the existence of a psychological dimension related to F0. When the F0 and spectrum were varied independently, responses were related to the F0 rather than to spectral differences among test stimuli. The results indicate that chinchillas possess a pitchlike perception of the missing F0 that is unlikely to arise from cochlear distortion products. [Work supported by NIDCD R01 DC005596.]

4pPP12. Temporal modulation transfer functions in listeners with real and simulated hearing loss. Joseph G. Desloge, Charlotte M. Reed, Louis D. Braida, Lorraine A. Delhorne, and Zachary D. Perez (Res. Lab. of Electron., Massachusetts Inst. of Technol., 77 Massachusetts Ave., Cambridge, MA 02139, jdesloge@mit.edu)

Temporal modulation transfer functions (TMTFs) were obtained in nine listeners with moderate to profound sensorineural hearing loss (age range of 21 to 69 years). The hearing loss of each impaired listener was simulated in a group of three age-matched normal-hearing listeners through a combination of spectrally-shaped masking noise and multi-band expansion. TMTFs in both groups of listeners were measured in a broadband noise carrier as a function of modulation rate in the range of 2 to 1024 Hz using a 3I, 2AFC procedure. The presentation level for the unmodulated broadband noise (whose duration was 500 ms) was set to be the maximum of either 70 dB SPL or the level such that noise was 10 dB above the lowest hearing threshold. The listeners with simulated hearing loss thus received signals at the same SPL and SL as their hearing-impaired counterparts. The shape of the TMTF curves (defined as the measured threshold of modulation in dB as a function of frequency of modulation) and the interpolated DC values of the function (using an exponential fitting procedure) were generally similar for listeners with real and simulated hearing loss. [Work supported by NIH-NIDCD R01 DC00117.]

4pPP13. Forward-masking functions in listeners with real and simulated hearing loss. Louis D. Braida, Joseph G. Desloge, Charlotte M. Reed, Lorraine A. Delhorne, and Zachary D. Perez (Res. Lab. of Electron., Massachusetts Inst. of Technol., 77 Massachusetts Ave., Cambridge, MA 02139, ldbraida@mit.edu)

Forward-masking functions were obtained in eight listeners with moderate to severe sensorineural hearing loss (aged 21–69 years). The hearing loss of each impaired listener was simulated in a group of three age-matched normal-hearing listeners through a combination of spectrally shaped masking noise and multiband expansion. Forward masking was measured in both groups of listeners for probe signals at frequencies of 500, 1000, 2000, and 4000 Hz using an on-frequency masker and two off-frequency maskers (0.55 and 1.15 times the signal frequency) under a 3I, 2AFC procedure. The probe signal was presented at 5 dB SL; signals and maskers were gated with 5-m on/off times with a steady-state duration of 0 ms for probe signals and 100 ms for maskers; and values of masker-offset time to signal-onset time were in the range of 0 to 100 ms. Findings will be described in terms of the slopes of the masking functions for each combination of probe and masker frequency and the ratio of the slopes obtained with on- relative to off-frequency maskers. Preliminary results suggest that the slope ratios observed for the hearing-impaired listeners were generally well-reproduced in normal-hearing listeners with simulated hearing loss. [Work supported by NIH-NIDCD R01 DC00117.]

4pPP14. A comparison of gap-detection thresholds through audition and touch in listeners with real and simulated hearing impairment. Charlotte M. Reed, Joseph G. Desloge, Zachary D. Perez, Lorraine A. Delhorne, and Louis D. Braida (Res. Lab. of Electron., Massachusetts Inst. of Technol., 77 Massachusetts Ave., Cambridge, MA 02139, cmreed@mit.edu)

Gap-detection thresholds were measured in listeners with real and simulated hearing loss under conditions of auditory or tactile presentation. The audiometric thresholds of each of ten listeners with sensorineural hearing loss (21–69 years of age) were simulated in groups of age-matched normal-hearing listeners through a combination of spectrally shaped masking noise and multiband expansion. The leading and trailing markers for the gap-detection task were 250- and 400-Hz sinusoids with a nominal duration of 100 ms. Gap-detection thresholds for a nominal baseline gap of 0 ms were measured for four different combinations of leading and trailing markers (250–250, 250–400, 400–250, and 400–400 Hz) using a 3I, 2AFC procedure. Auditory measurements were obtained for monaural presentation over headphones using a marker level set to be equal to the maximum of 70 dB SPL or 10 dB SL. Tactile measurements were obtained using sinusoids

presented to the left middle finger through an Alpha-M AV-6 vibrator at a level of 25 dB SL. Results are discussed in terms of (a) spectral-disparity effects of leading and trailing markers; (b) relation of thresholds for auditory versus tactile presentation; and (c) comparisons of results from listeners with real and simulated hearing loss. [Work supported by NIH-NIDCD R01 DC00117.]

4pPP15. Effects of several variables on temporal-order identification in young and elderly listeners. Daniel Fogerty, Diane Kewley-Port, and Larry Humes (Speech and Hearing Sci., Indiana Univ., 200 S. Jordan, Bloomington, IN 47405, dfogerty@indiana.edu)

Four measures of temporal-order identification were completed by young ($N=35$, 18–31 years) and elderly ($N=151$, 60–88 years) listeners under various stimulus conditions. Experiments spaced over several months used forced-choice constant-stimuli methods to determine the smallest stimulus onset asynchrony (SOA) between brief (40 or 70 ms) vowels that enabled identification of the stimulus sequence. Vowels in four words (pit, pet, pot, put) served as stimuli. The four measures of temporal-order identification were: (1) monaural two-item sequences; (2) monaural four-item sequences; (3) dichotic two-item vowel-identification sequences; and (4) dichotic two-item ear-identification sequences. All listeners identified the vowels in isolation with better than 90% accuracy. Results indicated that elderly listeners performed significantly poorer on monaural and dichotic temporal-order identification tasks than young listeners, although a large overlap in group distributions was observed. For both groups, the two-item dichotic task was significantly harder than two-item monaural. Increasing the attentional demands of the monaural task by randomizing the stimulus ear did not explain this difference. Using shorter duration stimuli did not alter performance in the monaural task but did improve performance in the dichotic task. Significant learning occurred for elderly listeners but not enough to eliminate the age-group differences. [Work supported, in part, by NIA.]

4pPP16. Level-dependent changes in detection of a silent gap in fluctuating noise carriers. Amy R. Horwitz, Jayne B. Ahlstrom, and Judy R. Dubno (Dept. of Otolaryngol.-Head and Neck Surgery, Medical Univ. of South Carolina, 135 Rutledge Ave., MSC 550, Charleston, SC 29425, horwitar@musc.edu)

Changes in detection of a silent gap in a noise carrier with increasing carrier bandwidth and level may reveal effects of basilar-membrane nonlinearities on envelope fluctuations. Gap-detection thresholds are higher for narrowband than broadband noise carriers due to increased confusion between the imposed gap and inherent fluctuations of the narrowband noise. For narrowband more than broadband carriers, the "effective" magnitude of envelope fluctuations may be reduced by compressive effects of the active cochlear mechanism. To test these assumptions, detection of a gap was measured in 50-Hz-wide and 1000-Hz-wide noise carriers as a function of carrier level. Younger and older adults with normal and impaired hearing listened to carriers presented in quiet and in a low-fluctuation broadband masker. As carrier level increased, masker level also increased, maintaining a fixed difference between carrier and masker levels to minimize sensation-level effects on gap detection. For younger adults, gap detection measured in quiet improved as expected with increasing carrier level. Further, gap detection measured in the masker improved as carrier level increased for the 50-Hz carrier, but declined for the 1000-Hz carrier. Discussion will focus on effects of carrier level, bandwidth, subjects' age and thresholds, and hypothesized relations to basilar-membrane nonlinearities. [Work supported by NIH/NIDCD.]

4pPP17. Minimum audible angles in children who use bilateral cochlear implants. Cynthia M. Zettler, Shelly Godar, and Ruth Y. Litovsky (Waisman Ctr., Univ. of Wisconsin-Madison, 1500 Highland Ave., Madison, WI 53705)

Over 5000 children worldwide have received bilateral cochlear implants (CI) so that the auditory skills that rely on inputs to both ears, such as sound localization, may be improved. In this study, localization acuity was measured with minimum audible angles (MAA), the smallest discriminable distance between two locations in the frontal azimuth plane. It is unclear whether children who use bilateral CIs can attain MAAs comparable to their acoustically hearing peers, and if so, the extent to which exposure to bilateral hearing is necessary. Children having 3–36 months of bilateral experience participated. Stimuli were spondaic words presented at an overall level of 60 dB ($\pm$ 4 dB rove). Every child with >5 yrs of auditory experience performed the task, whereas some of the children with <5 yrs of experience could not perform the task. In the former group, children with >2 yrs of bilateral experience were the best performers (MAA thresholds $<15°$), compared to children in the latter group who completed the task (MAA thresholds $>30°$). Results suggest that in children who receive bilateral CIs the two overall factors that impact performance are overall time in sound and amount of time with bilateral experience. [Work supported by NIH DC R01008365.]

4pPP18. The impacts of age and absolute threshold on binaural lateralization. Frederick J. Gallun, Anna Diedesch, and Erin Engelking (Natl. Ctr. for Rehabilitative Auditory Res., Portland VA Medical Ctr., Portland, OR, 97239, Frederick.Gallun@va.gov)

Listeners varying in audiometric thresholds (70-dB range) and in age (52-year range) lateralized complex tones relative to a diotic standard. Stimuli were composed of one, two, three, or six tones amplitude modulated at a rate of 75 Hz. Carrier frequencies were selected from a set of seven values (roughly log-spaced between 700 and 7000 Hz) and sensation levels were equated across listeners. Baseline performance was obtained for one- and two-component signals and the effects of diotic interference were assessed with two-, three-, and six-component signals. For all signals, the dichotic components contained interaural differences in time (whole-waveform delay), level, or both across a range of values. Listeners with higher audiometric thresholds performed more poorly in all conditions, despite the use of equivalent sensation levels. Diotic interferers reduced performance, but there were no additional impacts of age or absolute threshold. Statistical analyses indicated that the impacts of age were primarily due to the co-occurring increases in pure-tone thresholds, suggesting that: (1) absolute threshold is a better predictor of binaural ability than age and (2) reduced sensitivity to binaural differences is not addressed by presenting stimuli at equivalent sensation levels. [Work supported by VA RRD CDA-2 C4963W.]

4pPP19. Age-related differences in the time it takes to form auditory images of broadband noises. Mengyuan Wang (Dept. of Psych., Human Commun. Lab., Univ. of Toronto at Mississauga, 3359 Mississauga Rd. North, Toronto, ON L5L 1C6, Canada, mengyuan.wang.pku@gmail.com), Bruce Schneider (Univ. of Toronto at Mississauga, Toronto, ON L5L 1C6, Canada), Yanhong Wu, Xihong Wu, and Liang Li (Peking Univ., Beijing, 100871, China)

When correlated noises are presented over earphones to the two ears, listeners typically form a fused compact image of the noise. However, when the noises presented to the two ears are independent, listeners tend to hear two noises: one on the left and the other on the right. In Experiment 1 we determined the minimum duration required to form auditory images by asking listeners to distinguish between a 1-s presentation of independent noises to the left and right ears, and another 1-s presentation in which the noise was correlated for x ms before switching to two independent noises. In Experiment 2, one of the noises was correlated throughout the 1-s presentation; the other started off uncorrelated before switching to correlated. Younger adults performed better than older adults in both experiments. However, the performance of younger adults was better in Experiment 2 than in Experiment 1, whereas the reverse was true for older adults. The implications of these results for age-related changes in auditory scene analysis will be discussed. [This work was supported by the National Natural Science Foundation of China, the Natural Sciences and Engineering Research Council of Canada, and the Canadian Institutes of Health Research.]

4pPP20. Temporal processing as a function of age: Interaural time difference discrimination. John H. Grose, Sara K. Mamo, Emily Buss, and Joseph W. Hall (Dept. OHNS, Univ. N. Carolina at Chapel Hill, 170 Manning Dr., Chapel Hill, NC 27599-7070, jhg@med.unc.edu)

Older listeners often exhibit auditory temporal processing deficits. This study tested for temporal deficits in presenescent hearing. Three age groups participated: younger (18–28 yr); middle-aged (40–55 yr); older (63–75 yr). All had normal lower frequency hearing (thresholds $\leq$ 20 dB HL, 250–2000 Hz). Exp. 1 measured ITD discrimination for tone frequencies from

250–1500 Hz (65 dB SPL). Stimuli were two 100-ms tone pulses (75-ms rise, 25-ms fall). The pulses were diotic in the standard stimulus; the signal had an ITD (random lead/lag) imposed on the trailing tone pulse. Older listeners generally had higher ITD thresholds than Younger listeners. Middle-aged and Younger listeners performed similarly at low frequencies but the middle-aged tended to hit ceiling (z radians) at lower frequencies. Exp. 2 measured discrimination of So and Sτ signals as a function of frequency. Stimuli were tonal carriers modulated at 5 Hz (4 periods). Standard AM tones were diotic; signal tones alternated between So and Sz during successive modulator periods. Middle-aged listeners often performed slightly poorer than younger listeners, but better than older listeners. These results suggest that temporal processing deficits are evident in the pre-senescent auditory system. [Work supported by NIDCD 5-R01-DC01507.]

4pPP21. Quality judgments for music signals by normal-hearing and hearing-impaired listeners. Kathryn H. Arehart (Dept. Speech Lang. and Hearing Sci., Univ. of Colorado, Boulder, CO 80309), James M. Kates (GN ReSound and Univ. of Colorado, Boulder, CO 80309), and Melinda C. Anderson (Univ. of Colorado, Boulder, CO 80309)

Noise, distortion, nonlinear signal-processing algorithms, and linear filtering can all affect the sound quality of a hearing aid or other audio device. Most hearing-aid research concentrates on speech, but music reproduction can also be an important factor in user satisfaction. In this presentation, quality judgments are made for several different music signals by normal-hearing and hearing-impaired listeners. The music signals include orchestral classical music, jazz instrumental, and vocal. The signal processing uses a simulated hearing aid. The noise and nonlinear signal degradations include additive noise, multitalker babble, peak-clipping distortion, quantization noise, multichannel compression, spectral subtraction. Linear filtering conditions include bandwidth limitation, spectral resonance peaks, and spectral tilt. Conditions combining noise and nonlinear processing with linear filtering are also included. Subject ratings of the degraded music will be presented, along with comparisons of the ratings of music with that of speech for the same set of processing conditions. In addition, the subject ratings will be compared predictions using quality metrics based on auditory models.

4pPP22. A speech quality metric based on a cochlear model. James M. Kates (GN ReSound and Univ. of Colorado, Boulder, CO) and Kathryn H. Arehart (Univ. of Colorado, Boulder, CO)

Noise, distortion, nonlinear signal-processing algorithms, and linear filtering can all affect the sound quality of a hearing aid. The sound quality, in turn, can have a strong impact on the success of the device. The general approach in designing a quality metric is to compare the degraded signal with a clean (unprocessed) reference signal; the comparison generally involves comparing one or more features extracted from the signals. In this presentation, features are extracted from a computationally efficient model of the auditory periphery. The model includes the middle ear, an auditory filter bank, dynamic-range compression, two-tone suppression, and loudness scaling. The first step is a metric for noise, distortion, and nonlinear signal processing. The noise and nonlinear metric focuses on differences in the short-time signal behavior. The second step is a metric that focuses on the changes in the long-term average spectrum caused by linear filtering. The third and final step is to merge the noise and nonlinear metric with the linear filtering metric to produce a composite sound quality metric that can be applied to an arbitrary signal-processing system. The metrics give correlation coefficients better than 0.94 in comparison with quality ratings made by normal-hearing and hearing-impaired listeners.

4pPP23. Preference and performance for hearing-aid gain-compression prescriptions, based on a preliminary model of impaired sensitivity to tone intensity. Julius L. Goldstein (Hearing Emulations LLC, at Ariel Premium, 8825 Page Ave., St. Louis, MO 63114, julius@hearem.com), Michael Valente (Washington Univ., St. Louis, MO 63110), Metin Oz, and Peter Gilchrist (formerly at Hearing Emulations LLC)

A cochlearlike preliminary model was synthesized by joining a model of loss of cochlear "tip" gain, representing mild hearing loss, with a model for greater loss that translates the residual range for tone intensities into nonlinear "tail" expansion. Normal tip gain was modeled as 40 dB with square-root compression. Tail expansion was modeled with upper bounds for residual hearing at normal LDL of 100 dB HL, or at levels increasing by half decibel per decibel hearing loss above 40 dB; the latter provides less compression. A digital hearing aid comprising six octave-bandwidth (0.25–8 kHz) linear amplifiers with AGC was simulated to test alternative prescriptions with 32 experienced users of hearing aids. Preference for prescriptions with high or low compression and 4 or 8 kHz bandwidth was tested with clean speech repeated at input levels of 40, 60, and 80 dB SPL. The alternative best perceived as "mild," "comfortable," and "loud" was chosen; if uncertain, "either" was chosen. Performance was measured with intelligibility scores for low-probability speech sentences in noise (SPIN) at 8 dB signal to noise ratio and 70 dB SPL input. Independent of preference, high-compression prescriptions provided inferior performance, resulting from excessive increase in compression with hearing loss. [Work supported by NIDCD.]

4pPP24. A cochlearlike model of equal loudness levels for impaired and normal hearing: A new basis for hearing-aid gain-compression prescriptions. Julius L Goldstein (Hearing Emulations LLC, at Ariel Premium, 8825 Page Ave., St. Louis, MO 63114, julius@hearem.com)

Mean psychophysical data on most comfortable and uncomfortable tone levels as a function of hearing loss [Pascoe, 13th Danavox Symp. 153–183 (1988); D. M. Schwartz *et al.*, The Hearing J. **41**, 13–17 (1988)] is interpolated for other loudness levels by representing impaired auditory response as a modification of the idealized normal cochlear mechanical response to tones: linear at low and high sound levels joined by power-law compression of the low level "tip" gain. Denoting the low- and high-level nonlinear transitions as stimulus thresholds for compression and decompression, hearing loss elevates the compression threshold without changing the decompression threshold, until the compressive region is eliminated. Further hearing loss converts the compression threshold into a threshold for power-law "tail" expansion. Mean psychophysical data, represented by multiple regression lines, are fit exactly by an analytical solution for the normal model parameters. Estimates for thresholds of approximately 15 and 95 phons and tip gains of 40–52 dB are physiologically plausible for the normal cochlea. Normal equal loudness levels updated by Suzuki and Takeshima [Y. Suzuki and H. Takeshima, J. Acoust. Soc. Am. **116**, 918–933 (2004)] allow reliable extension of the model to low frequencies with estimates of auditory high-pass linear acoustic processing and of normal low-frequency tip gains. [Work supported by NIDCD.]

4pPP25. A weighting-function-based approach to subjectively modify the frequency response of a hearing aid. Andrew T. Sabin, Nicole Marrone, and Sumitrajit Dhar (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60201, a-sabin@northwestern.edu)

While approaches that modify the frequency response of a hearing aid based on a listener's subjective preference have demonstrated some success, they also have several limitations. Namely, these approaches (1) consider a small set of potential frequency-gain curves (FGCs) and (2) they converge on the final FGC, which makes the outcome dependent upon the starting point. Here we present a new approach that addresses these problems by (1) considering a much larger initial set of FGCs, and (2) using a method that is not convergence based. First, the listener rates the clarity of short samples of speech filtered by a set of maximally different probe FGCs. A weighting function is then computed, where the weight given to each ~1/3 octave frequency band is proportional to the normalized slope of the regression line between the listener's rating and the within-band gain of the probe FGC. Next, the listener rates the clarity of speech samples filtered by the weighting function, which is multiplied by one of several, randomly ordered, scaling coefficients. The final FGC is the scaling coefficient that receives the maximum rating, multiplied by the weighting function, added to a hearing-loss-specific correction factor. Results will be compared to current fitting strategies.

4pPP26. Effects of aging and irrelevant-dimension fluctuation on frequency doscrimination: Interference at late information-processing stages. Praveen Jajoria (Medical Sch., Univ. Texas Medical Branch, Galveston, TX 77555–0570) and Blas Espinoza-Varas (Dept. Commun. Sci. & Disord., Univ. Oklahoma Health Sci. Ctr., 1200 N. Stonewall, Oklahoma City, OK 73104)

Deficits in the ability to extricate relevant from irrelevant information at the perceptual level (i.e., selective attention) could help diagnose age-related cognitive decline at an early stage. Much experimental evidence supports this generalization, but there is debate as to where and how the irrelevant information interferes with the relevant one. To address this question, effects of irrelevant duration or level differences on pure-tone frequency discrimination thresholds (FDTs) were studied in healthy, normal-hearing, young and older adults. Target tones were presented either in isolation or followed by a distracter tone after a 90- or 350-ms silent interval; both tones were 1000 Hz, 80 ms, and 70 dB SPL. Irrelevant differences occurred simultaneously with relevant frequency differences or sequentially, in the distracter. With both presentation formats and silent intervals, FDT elevations (i.e., interference) were much larger in older than in young adults if the irrelevant differences were in level, but if they were in duration, FDT elevations were small in both groups. Since it occurs both simultaneously and retroactively (i.e., sequential), and depends on the similarity of relevant and irrelevant dimensions, the interference seems to take place at relatively late rather than early information-processing stages.

4pPP27. Dual-task costs in speech recognition by older and younger listeners. Karen S. Helfer, Jamie Chevalier, and Richard L. Freyman (Dept. of Commun. Disord., Univ. of Massachusetts, 358 N. Pleasant St., Amherst, MA 01003)

This study examined performance of younger and older adults when they carried out two auditory tasks simultaneously versus when performing each task in isolation. One task was to repeat a target sentence spoken by a male talker, presented simultaneously with two masking sentences spoken by two other male talkers. The second task was to judge whether neither, one, or both voices in the two-talker masker complex was presented time-reversed. Data were collected in both spatially-separated and colocated conditions. Results showed substantial individual variability within both subject groups as well as a strong effect of trial type order. Performance by most listeners declined to a greater extent for the natural/time-reversed task than for the speech recognition task during divided attention, even though subjects were instructed to give the two tasks equal weight. Importantly, requiring listeners to divide attention decreased or eliminated the spatial separation advantage for listening to speech in a competing speech situation. The poster will discuss differences noted between the two groups in overall performance as well as in the costs of dividing attention. [Work supported by NIH DC01625.]

4pPP28. Perceptually important acoustic features of environmental sounds. Laurie M. Heller, Benjamin Skerritt, and Emily Ammerman (Dept. of Cognit. and Linguistic Sci., Brown Univ., Box 1978, Providence, RI 02912, Laurie_Heller@brown.edu)

Listeners were asked to indicate the sources of dozens of sound events presented over headphones. The sounds were environmental sounds made by solid objects, liquids, and/or air undergoing a variety of actions taken from the website www.auditorylab.org. Each listener gave a series of responses about possible sources for each sound so that a similarity matrix could be constructed. The results of data reduction point to a manageable set of perceptual classes of sound events that can be described with a small number of distinctive spectro-temporal acoustic features. These features will be related to the attributes of the events that generated each class of sounds. Results for normal-hearing listeners will be analyzed in detail and preliminary results from hearing-impaired listeners will be previewed. [Work supported by NSF 0446955 and RI STAC.]

4pPP29. The incongruency advantage in elderly versus young normal-hearing listeners. Brian Gygi (Speech and Hearing Res., Veterans Affairs Northern California Health Care System, Martinez, CA) and Valeriy Shafiro (Rush Univ. Medical Ctr., Chicago, IL)

Previous research [Gygi & Shafiro (2007); Leech *et al.* (2007)] reported that environmental sounds heard in contextually incongruous naturalistic auditory scenes are better identified than sounds contextually congruous with the scene (e.g., rooster crowing in a farm ambience versus rooster in an office ambience). This incongruency advantage (IA) averages about four-to-five percentage points in p(c) and has been observed in both well-trained and naïve young normal hearing listeners [Gygi and Shafiro (2008)] and in children [Leech *et al.* (2007)]. One aspect of the IA is that it appears to be level-dependent, in that the effect is not present for lower sound/scene ratios (So/Sc). For experienced young listeners, the IA appears at a So/Sc of −15 dB. However, for naive young listeners, it is not manifest until −7.5 dB. A group of elderly normal-hearing listeners were tested and exhibited an IA only at So/Sc of −9 dB and above. The results show that the incongruency advantage are complex effects resulting from a combination of peripheral and central factors. [Research supported by the Merit Review Training Grant from the Dept. of Veterans Affairs Research Service, VA File # 06-12-00446, the National Institute for Aging, and the Rush Univ. Medical Center.]

4pSAa1. Synchronization of mechanical phase oscillators. David Mertens, Richard Weaver (Dept of Phys., Univ. of Illinois, 1110 W. Green St., Urbana, IL), and John Koliniski (Div. of Eng. and Appl. Sci., Harvard Univ., Cambridge, MA)

The Kuramoto model of a large number of weakly interacting phase oscillators exhibits a phase transition to synchronization. The literature has seen analytic theory and numerical simulations for both the Kuramoto model and sundry generalizations. Most real-world systems (e.g., flashing fireflies) imperfectly match the model, and their synchronization behaviors can therefore be taken to be in merely qualitative support of the theory. Here a mechanical system with well-understood microphysics is presented. A number N (of order 50) of eccentrically weighted DC motors (cell phone vibrators) is mounted on a plate. Each motor radiates into the plate and responds to its motion. If the plate dynamics is dominated by a single normal vibration mode the system is well described by finite-N Kuramoto

equations. Transitions to synchronization are observed in accord with theoretical expectations based on the quality factor of the plate, the number of motors, the ratio of the motor mass to the plate mass, and the natural speed of the motors. Calculations and results on a rich generalized-Kuramoto model are also presented, in which the plate dynamics entails many normal modes of vibration, and for which the governing equations resemble those of a laser.

4pSAa2. Analysis and prediction of underwater sound radiation from a cylindrical pile driven by an impact hammer. Mardi C. Hastings (Appl. Res. Lab., Penn State Univ., P. O. Box 30, State College, PA 16804, mch26 @psu.edu)

A vibroacoustic model for sound radiation from a submerged pile was developed to predict sound pressure levels generated during offshore construction activities. It was implemented in MATLAB and verified with measured data reported in the literature. The modal response of a cylindrical pile to hammer impact is first determined. Contributions from all dominant modes are then summed at various ranges to produce a two-dimensional spatial mapping of sound pressure level. The analysis was used to investigate the effects of pile material, size, and geometry on radiated sound pressure levels. Results indicate that smaller diameter piles of the same material do not necessarily produce lower sound pressure levels, but rather shift the peak sound pressure levels to higher frequencies. Because these basic parameters affect bandwidth as well as sound levels, there is no simple way to classify source level and frequency. Peak sound pressure levels generated underwater by driving steel piles with impact hammers into the sea bottom can easily exceed 200 dB re 1 μPa at a range of 10 m, so accurate prediction of the sound field is needed to assess potential risks to the environment.

4pSAa3. On vibroacoustic modal analysis of arbitrarily shaped vibrating structures. Huancai Lu (SeeSound 360, 3649 Glenwood Ave., Windsor, ON N9E 2Y6, Canada, huancai.lu@gmail.com) and Sean Wu (Wayne State Univ., Detroit, MI 48202)

Vibroacoustic modal analysis based on Helmholtz least squares method (HELS) is presented in this paper to explore the inherent dynamic characteristics and correlation of structural vibration and sound radiation of arbitrarily shaped vibrating structures. A series of mutually orthogonal vibroacoustic components is established by decomposing the normal velocity and normal acoustic intensity, which are reconstructed on source surface using HELS, in an orthogonal space through singular value decomposition (SVD). By further analyzing the vibration efficiency and radiation efficiency, the contribution of each of individual modal components to the resultant structural vibration and sound radiation can then be quantified. Therefore one is allowed to identify the vibroacoustic modal components that are most responsible for resultant structural vibration and sound radiation. The test object is a clamped and baffled thin rectangular steel plate, which was excited by a shaker and tested in a semianechoic chamber. The reconstructed normal surface velocities of the plate are validated against the results scanned by laser equipment. The vibration efficiency and radiation efficiency of the vibroacoustic modal components are examined, and the correlation between structural vibration and sound radiation of components at several frequencies is analyzed.

4pSAb1. Role of slowness mapping in determining the directions of acoustic and seismic signals. Qamar A. Shams, George R. Weistroffer, John W. Stoughton (NASA Langley Res. Ctr., M.S. 238, Hampton, VA 23681), and Allan J. Zuckerwar (Analytical Services Mater., Hampton, VA 23666)

Slowness mapping is a method to estimate the angle of arrival of plane waves propagating across a sensor array. A review of time-delay estimation and its application to slowness vector estimation, the forward model, the inverse model, azimuth estimation, and elevation estimation will be presented. A method for performance grading with "out-of-bounds" conditions is described, and in the special case of subsurface acoustic sensors, a method for discriminating against seismic signals. The method has been applied to locate the direction of Space Shuttle and other rocket launches, infrasonic emissions from clear air turbulence, and incidental sources found in the environment.

4pSAb2. Experimental validation of alternate integral-formulation method for predicting acoustic radiation based on particle velocity measurements. Zhi Ni and Sean Wu (Wayne State Univ., 5050 Anthony Wayne Dr. Detroit, MI 48202)

This paper presents experimental validation of an alternate integral-formulation method (AIM) for predicting acoustic radiation from an arbitrary structure based on the particle velocities measured by a laser Doppler anemometer (LDA) and double hotwire sensor over a hypothetical surface enclosing a target source. Both the normal and tangential components of the particle velocity on this hypothetical

surface are measured and taken as input data to AIM codes to predict acoustic pressures in the exterior region. The results thus obtained are compared with those measured by microphones at the same locations. Measurement limitations are discussed and an error analysis of LDA measurement is presented.

3:15

4pSAb3. Visualization of vibrations measured with a multi-channel optical vibration sensor. Jun Hasegawa and Kenji Kobayashi (Dept. of Electron. and Comp. Syst., Takushoku Univ., 815-1, Tatemachi, Hachioji-shi, Tokyo 193-0985, Japan, jhase@es.takushoku-u.ac.jp)

Displacement-type sensor units made of optical fibers were developed to realize multi-points measurement of vibrations with high spatial resolution. Each sensor unit has the displacement resolution of 10 nm within the dynamic range of more than 90 dB, the frequency bandwidth of up to 80 kHz. Up to 64 sensor units can be arrayed as a multi-channel sensor head, with the minimum gap between sensor units of 4 mm. It means that the spatial resolution for the multi-points measurement is 4 mm. The calibrating method with the measuring object was developed to realize accurate measurements. During the calibration phase, the object is kept stand-still, and only the sensor head moves by the linear actuator. Thus, the calibration data can be obtained just before the measurement. Several arrangements of the sensor system is available depending on the object to be measured, such as line vibration, surface vibration, and the 3D movement of small object. The developed system has been used for the measurement of the actuators for vibratory microinjection and the measurement of artificial heart valves. Those results showed the advantage of the system. 4pSAb4. Acoustic sensor structural configuration study. Bill B.B. Zhang and W. Steve Shepard, Jr. (Dept. of Mech. Eng., The Univ. of Alabama, Box 870276, Tuscaloosa, AL 35487, sshepard@eng.ua.edu)

This work examines the configuration requirements for a sensor being developed to provide information about the location of an acoustic source. The continuous sensor's vibrational response, caused by a traveling acoustic wave, is used in an inverse method to reconstruct the forces in that wave. A finite-length beam supported on an elastic foundation is the candidate structure. The impact of changing various structural parameters on the beam's vibration response is examined analytically using finite element methods. A goal in configuring the beam sensor is to obtain a response with enough dynamic information to accommodate a successful force reconstruction. Some of the configuration parameters of interest include the beam material, geometry, thickness, and the elastic foundation properties. The excitations used in the study consist of transient waves with differing numbers of sinusoidal half-cycles. Because background noise has the potential to impact the force reconstruction, various amounts of white noise are added to the simulated response values prior to performing the traveling wave reconstruction. Tikhonov regularization and the L-curve method are used. Results obtained from the simulations show that this sensor model is effective in identifying moving wave loads. [Work supported by NSF Sensor Innovation and Systems.]

Session 4pSC

Speech Communication: Second Language and Cross-Linguistic Speech (Poster Session)

Megha Sundara, Chair
Dept. of Linguisitcs, Univ. of California at Los Angeles, Los Angeles, CA 90095-1543

Contributed Papers

All posters will be on display from 1:00 p.m. to 4:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 2:30 p.m. and contributors of even-numbered papers will be at their posters from 2:30 p.m. to 4:00 p.m.

4pSC1. An acoustical comparison of English tense and lax vowels. Byunggon Yang (Dept. of English Education., Pusan Natl. Univ., 30 Changjundong Keumjunggu, Pusan 609-735, South Korea, bgyang@pusan.ac.kr)

Several studies on the pronunciation of English vowels point out that Korean learners have difficulty producing English tense and lax vowel pairs. The acoustic comparisons of those studies are mostly based on the formant measurement at one time point of a given vowel section. However, the English lax vowels usually show dynamic changes across their syllable peaks and subjects' English levels account for various conflicting results. The purposes of this paper are to compare the temporal duration and dynamic formant tracks of English tense and lax vowel pairs produced by five Korean and five American males. Results showed that both the Korean and American males produced the vowels with comparable durations. The duration of the front tense-lax vowel pair was longer than that of the back vowel pair. From the formant track comparisons, the American males produced the tense and lax pairs much more distinctly than the Korean males. The results suggest that the Korean males should pay attention to the F1 and F2 movements, i.e., the jaw and tongue movements, in order to match those of the American males. Further studies are recommended on the auditorily acceptable ranges of F2 variation for the lax vowels.

4pSC2. The production of new versus similar vowels by Korean-English bilingual children. Soyoung Lee (P.O. Box 413, Enderis Hall 855, Univ. of Wisconsin-Milwaukee, 2400 E Hartford Ave., Milwaukee, WI 53201) and Gregory Iverson (Univ. of Maryland, College Park, MD 20742-5121)

The purpose of this study was to compare the vowel productions of Korean-English bilingual children with those of monolingual English and Korean-speaking children. Flege (1987) hypothesized that equivalent clas-

sification prevents adult L2 learners from establishing separate phonetic categories for similar phones (which occur in both languages) but not for new L2 phones. This hypothesis, however, has not been fully tested in bilingual children. The present study examined twenty 5-year-old Korean-English bilingual children who had been exposed to both languages for at least 2 years along with their age-equivalent monolingual counterparts, for a total of 60 children. Nine English vowels and six Korean vowels were elicited using picture cards. First and second formant frequencies for similar (/i, ɛ, u, o, a/) and new (/ɪ, ɔ, ɨ, æ, i/) vowels were measured. Vowels which were categorized as new were not appreciably different from those of monolinguals, suggesting that bilingual children produce new vowels authentically, consistent with the Flege hypothesis. However, the findings were mixed with respect to similar vowels. Bilingual children produced English vowels similarly to monolingual English-speakers, but their Korean vowels differed from those of monolingual Korean children, implying influence of the dominant (English) over the less-dominant language (Korean).

4pSC3. Acoustic features and inteilligibility of American-English vowels for English, Chinese, and Korean talkers. Su-Hyun Jin, Chang Liu, and Sangeeta Kamdar (Dept. of CSD, Univ. of Texas Austin, 1 University Station, Austin, TX 78712)

Sixteen American-English vowels including 12 monothongs and 4 diphthongs were recorded in a phonetic context of /hVd/ from young English (E), Chinese (C), and Korean (K) talkers. The Chinese and Korean talkers were bilingual and had stayed in United States up to 6 years. Two sets of experiments will be discussed: acoustic analysis and intelligibility of English vowels produced by the three groups of talkers. Results of acoustic analysis showed that there was no significant difference in F1×F2 vowel space among the three groups of talkers. In addition, the three groups of talkers showed great similarity in F2/F1 ratio across the 12 monothongs. Vowel durations had significantly greater variability across vowel categories for the Chinese and Korean talkers than for the English talkers, indicating that, besides producing spectral differences among vowels, Chinese and Korean talkers also attempted to generate durational difference among vowels to make each vowel distinguishable from others. More acoustic features such as spectral tilt and formant transition in the diphthongs and the effects of acoustic features on vowel perception by native English listeners will be discussed. Furthermore, the relationship between the vowel intelligibility and the second language experience of non-native talkers will be examined.

4pSC4. How regional dialect effects second language learning. Mu-Ling Teng (No. 1001, Univ. Rd., Hsinchu, Dept. of Foreign Lang. and Lits, Natl. Chiao Tung Univ., Taiwan 300, ROC), Yi-Chu Ke, Chu-ting Chen, Bo-hong Lu, Lai-Iok Ip, Ho-hsien Pan (Natl. Chiao Tung Univ., Taiwan), Shih-wen Chen (Natl. Tsing Hua Univ., Taiwan), and Hsiu-Min Yu (Chung Hua Univ., Taiwan)

This paper discussed dialect effects on L2 learning. Data from advanced English-learning students were separated into groups according to geographic regions: Northern, Middle, and Southern parts of Taiwan. Subjects were asked to read out loud eight English words, namely, "heed," "hid," "head," "had," "hod," "hawed," "hood," and "who'd." Acoustic information, such as F1 and F2, were measured; also, since Taiwanese English learners tend to use temporal cues to distinguish tense and lax vowels, duration of each word were also measured. Comparing the vowels read by the subjects with native speakers, we found that the Northern group had very similar patterns with native speakers in both spectral and temporal cues. As for the Middle group, the vowel shape was going upper right in the vowel chart and the duration pattern was quite distinctive from native speakers. Furthermore, all the subjects from the Southern part of Taiwan speak both Mandarin and Taiwan Min and their vowel spaces were the most deviated from native speakers, from which we assumed that PAM model (Best, 1993, 1995) could give a reasonable explanation: they have two vowel systems that could be referenced from, thus they might easily get confused. However, several problems still need further examination.

4pSC5. Production of prosodic cues by Beijing Mandarin speakers in second language (L2) English. Karen A. Barto-Sisamout (SLAT Office, P.O. Box 210014, Univ. of Arizona, Tucson, AZ 85721, kabarto@email.arizona.edu)

Does the prosody of speakers' first language (L1) influence their prosody in their second language (L2)? The current work investigates this topic for a tone language, Beijing Mandarin (BMan), as L1, and an intonation/stress language, English, as L2. English uses F0 contours as part of the intonation system, to signal syllabic prominence in a word, word prominence in a phrase, and the difference between questions and statements. In English there is a pitch peak delay, where the F0 peak occurs after the stressed syllable in two-syllable stress-initial words. Conversely, BMan uses F0 contours lexically, as a lexical tone language, and the F0 peak is on the stressed syllable. The production of these F0-related prosodic cues is investigated with BMan and Native English production of English narrow and broad focus statements and questions, with measurements of F0 contours on accented and unaccented words, pitch peak delay on accented words, and F0 levels in statements and questions. The goal is to learn if BMan speakers lexically specify tone of certain word types in English like in their L1, or realize F0 contours intonationally, like English speakers, or, finally, if they use an intermediate system different from L1 and L2.

4pSC6. Limited effects of early language learning on second language speech production. Tetsuo Harada (School of Education, Waseda Univ., 1-6-1 Nishi Waseda, Shinjuku, Tokyo 169-8050, Japan, tharada@waseda.jp)

Knightly *et al.* (2003) report long-term production benefits of childhood second language (L2) exposure in a naturalistic setting. However, it is unknown whether or not their finding will apply to classroom L2 learning. This study compares the production of voice onset time (VOT) in English and Japanese and closure duration of singletons and geminates in Japanese by English-speaking university students ($n=15$) who graduated from a Japanese immersion program (early learners) and adult learners of Japanese ($n=15$) with no exposure to Japanese in childhood (late learners). The informants were asked to repeat several target words including initial /p, t, k/ for VOT, and medial /p, t, k/ and /pp, tt, kk/ for singletons and geminates in a sentence frame. Both VOT of the initial stops and closure duration of the medial stops were measured. The results show that the production of VOT and closure duration by the early learners was not significantly different from that of the late learners ($p=0.71$ and $p=0.13$, respectively). The findings may hypothesize that there are only limited effects of classroom L2 exposure in childhood on L2 speech production in adulthood. [Work supported by Grant-in-Aid for Scientific Research (C) 20520527.]

4pSC7. The effect of oral proficiency on production of rhythm in spontaneous second language (L2) Japanese speech. Irina Shport (Dept. of Linguist., Univ. of Oregon, Eugene, OR 97403, ishport@uoregon.edu)

This study addresses the question of whether oral proficiency in Japanese second language (L2) speech has a unique correlation with acoustic characteristics of rhythm production that is independent from segments. Among four rhythm measures used (V%, VarcoV, VarcoC, VI-M), only two measures were different for the spontaneous L2 Japanese speech of beginning and intermediate learners. The interlanguage rhythm of less proficient speakers of Japanese was characterized by lower variability in duration of vocalic stretches (VarcoV) and higher variability in duration of consonantal stretches (VarcoC), $p < 0.05$. For both VarcoV and VarcoC values, the distribution of the individual speakers' rhythm scores was much tighter and on target for the intermediate students than for the beginning students. Furthermore, VarcoV values were significantly correlated with number of utterance-final vowels, and VarcoC values were correlated with number of obstruent clusters. In sum, the findings suggest that rhythmic differences in spontaneous L2 speech have an epiphenomenal nature stemming from the segmental structure of Japanese: the acquisition of mora-timed rhythm by learners of Japanese seems to be contingent upon the target-like production of segments which varies with proficiency level of learners.

4pSC8. Cross-linguistic differences in prosodic organization: Evidence from a repetition task. Emily Nava and Louis Goldstein (Dept. of Linguist., Univ. of Southern California, GFS 301, Los Angeles, CA 90089)

The prosody of languages such as English and Spanish has been characterized as exhibiting different rhythmic organizations. English has been hypothesized to organize syllables into feet, with one stressed syllable per foot. Spanish is among the languages whose prosody has been hypothesized to not include the foot, despite the existence of lexical stress in Spanish. We tested the hypothesis that these potential differences in organization would

lead to systematically different responses when speakers were asked to entrain a sequence of syllables with a metronome at an increasing rate, and that L1Spanish/L2English speakers would continue to exhibit the Spanish pattern in their English. Speakers of all three types were recorded producing a single repeated syllable, or a sequence of two alternating syllables, in time with a metronome, whose rate increased monotonically after a stabilization period. At slower speech rates, English speakers produced each word as a separate foot with a corresponding pitch accent, while at increased speech rates, two words were grouped together into a single iambic foot with one pitch accent. Spanish speakers and L1Spanish/L2English speakers are expected to shorten both vowels, employing a symmetric strategy (as opposed to the asymmetric strategy of English speakers) to keep pace with the metronome. [Work supported by NIH, NSF.]

4pSC9. Effect of word length on vowel production by Mandarin and American speakers: Comparison of [i] and [ɪ]. Chung-Lin Yang (Dept. of Linguist., Indiana Univ., Bloomington, IN 47405, cy1@indiana.edu)

Yang (2008) found that Mandarin speakers' productions of [eɪ] and [ɛ] (as in *gate-get*) showed much less difference than Americans made. In addition, they made a smaller distinction in disyllables than in monosyllables. The current study compares the production of [i] and [ɪ] (*beat-bit*) in the same conditions. Target-vowels were embedded in Stop-V-Stop context in carrier sentences. Vowel durations were measured after stop release until final closure. Formant measurements were made at two time-points for each token. Preliminary analysis extends previous results of reduced contrast between tense and lax vowels by the Mandarin speakers to vowels [i]-[ɪ] and also shows greater reduction of the contrast in disyllabic words relative to monosyllables. The Mandarin speakers' formants for [i]-[ɪ] were almost identical in the disyllabic words, and their duration ratios were not significantly different, whereas American speakers' measurements were very different between two vowels and the same in disyllables as monosyllables. The current study provides further evidence for an effect of word length on English vowel contrasts by Mandarin speakers.

4pSC10. Short-term cross-linguistic interactions in bilinguals' vowel production. Matthew T. Carlson, Howard Nusbaum, and Shannon L. Heald (Dept. of Psychol., Univ. of Chicago, 5848 S. Univ. Ave., Chicago, IL 60637, carlsonmt@uchicago.edu)

Evidence suggests that the languages of a bilingual interact, and research has examined how first language (L1) phonetic categories influence second language (L2) acquisition. Although there may be substantial cross-linguistic interaction in the early stages of L2 learning, less is known about acoustic-phonetic variability when the bilingual's systems are more stable. This study examines L1 and L2 phonetic interaction, testing how the production of vowels in one language affects vowel production in the other. L1 and L2 vowel productions are compared for late English-Spanish bilinguals in an English-dominant environment. Five Spanish vowels and their English equivalents are examined. Subjects completed two experimental sessions, focusing respectively on L1 and L2, on separate days. Each session contained three blocks in which subjects produced vowels in isolation: two blocks in the target language separated by a block in the non-target language. Word cues were given to ensure the proper language for each block. Productions from first and third blocks of each session (i.e., in the same language) are compared to determine if intervening use of the other language affects subsequent vowel production. Implications are discussed for L1 and L2 phonetic representation, the status of a bilingual's languages, and second language acquisition.

4pSC11. Individual differences in the perception of vowels in a second language. A. Lengeris (Dept. of Speech Hearing and Phonetic Sci., Univ. College London, 2 Wakefield St., London WC1N 1PF, UK, a.leggeris@ucl.ac.uk)

Individuals may differ in their ability to learn the sounds of a second language (L2), but the origin of this variability remains uncertain. The present study examined whether individual differences in L2 vowel processing are related to individual differences in L1 vowel and/or nonspeech processing. Greek learners of English were given a large battery of perceptual tests examining their (1) identification of natural Greek vowels in noise, (2) identification and discrimination of synthetic Greek vowels in quiet, (3) identification of natural English vowels in quiet and in noise, (4) identification and discrimination of synthetic English vowels in quiet, and (5) discrimination of a nonspeech (F2 only) continuum in quiet. Preliminary results show a large degree of variability between individuals not only in L2 but also in L1 and nonspeech tasks. However, despite this variability, the participants were consistent in their performance across speech and nonspeech tasks, a finding that supports an auditory acuity rather than a speech-specific explanation for the individual differences in performance found in the data.

4pSC12. Perception of second-language stress and vowel quantity by English learners of Czech. Václav J. Podlipský (Dept. of English and American Studies, Palacký Univ., Krizkovskeho 10, 77180 Czech Rep., vaclavjonaspodlipsky@centrum.cz)

L2 acquisition may involve reattuning the perceptual system so that a cue becomes utilized for a new linguistic purpose. For instance, if vowel duration cues stress in L1 (like in English), whereas in L2 it marks phonological vowel quantity (like in Czech) it is of interest how the perception of stress and of vowel quantity will interact. Previous studies tested if stress affects vowel-quantity perception in such languages; this study explores conversely if vowel quantity affects stress perception in English learners of Czech. Since stress is word-initial in Czech, a word-boundary detection task was used, where stress either fell on a long vowel (stress and vowel length coincided) or on a short vowel, but there was a long vowel distracter in an adjacent syllable (stress and vowel length conflicted). Seventeen L1-English-L2-Czech and 69 Czech listeners were tested. Unexpectedly, natives scored slightly but significantly ($p<.05$) better when stress and vowel length conflicted than when they coincided. The opposite was true for the non-natives who were only at chance when stress and vowel length conflicted. No correlation between the non-native scores and various indices of L2 proficiency was found. It is concluded that learners transferred L1 perceptual strategies to the L2.

4pSC13. Identification and discrimination of tonal pitch in speech and nonspeech stimuli for Chinese- and English-native speakers. Chang Liu (Dept. of Commun. Sci. and Disord., The Univ. of Texas at Austin, 1 University Station A1100, Austin, TX 78712)

Given that Chinese is a tonal language while English is not, the present study is to examine how language background affects tonal identification and discrimination in speech and nonspeech signals for Mandarin-Chinese and American-English native speakers. The fundamental frequency (f0) contour was systematically manipulated from tone 2 (rising), to tone 1 (level), and to tone 4 (falling) for three types of signals: Chinese vowels /ɑ/, English vowels /æ/, and tonal sweeps. Both groups of listeners showed categorical perception in the identification of tones 1, 2, and 4, while Chinese-native speakers showed sharper boundaries across tonal categories than English-native speakers. Just-noticeable difference (JND) in tonal pitch was also measured for the standard tone 1, tone 2, and tone 4 of the three types of signals. JND was significantly smaller in speech stimuli for Chinese-native speakers than for English-native speakers, but quite comparable between the two groups of listeners for nonspeech stimuli. There results indicate that tonal pitch may be perceived specifically in speech stimuli, and for nonspeech stimuli, the capacity to process the tonal sweeps is similar across listeners with different language backgrounds.

4pSC14. Tonal confusion patterns in Mandarin by Cantonese listeners. Jung-yueh Tu (Dept. of Linguist., Simon Fraser Univ., 8888 Univ. Dr., V5A1S6 Canada, jta31@sfu.ca)

It is well-attested that linguistic experience affects the perception of non-native sounds. The vast majority of research on L2 perception has been carried out on segmental features from the perspective of phonetic similarity between the L1 and L2 sound systems. The general goal of this study is to expand our understanding of cross-linguistic comparison in non-native speech perception, focusing on the somewhat understudied area of perceptual assimilation at a suprasegmental level. More specifically, it deals with comparisons of prosodic systems in two tone languages, Mandarin and Cantonese. The current study examined perception of Mandarin tones by Cantonese listeners. In Experiment 1, Mandarin tones were presented and the Cantonese listeners were requested to identify which tone they heard. In Experiment 2, the Cantonese listeners were instructed to rate how similar each Mandarin tone was to a Cantonese tone. Preliminary results suggest that tonal confusion errors may result from not only the similar acoustic

properties of the tone pairs but also perceptual assimilation between L1 and L2 tonal contrasts. These findings are discussed in terms of the effects of L1 prosodic system on L2 perception and how perceptually assimilation patterns predict listeners' perception performance at the domain of lexical tones.

4pSC15. Acoustic-phonetic characteristics of naturally-elicited clear speech in British English. Rachel Baker and Valerie Hazan (Speech Hearing and Phonetic Sci., UCL, Chandler House, 2 Wakefield St, London WC1N 1PF, UK, rachel.baker@ucl.ac.uk)

Clear speaking styles are characterized by enhancements of specific acoustic-phonetic aspects of the speech signal. However, most studies of casual and clear speaking styles have been based on read speech recorded in laboratory conditions, both normally and when instructed to speak clearly. In this study, casual and clear speech produced by 40 talkers of southern British English was elicited in unscripted dialogues between two talkers via a series of "spot the difference" picture tasks, based on the "diapix" task developed by Bradlow and collaborators. In the "casual speech" condition, the two talkers conversed normally while doing the task. In the "clear speech" condition, to simulate communication between a normal-hearing talker and a talker with a cochlear implant, one of the talkers heard the other talker's speech passed through a three-channel vocoder. Additionally, talkers read sentences containing specific keywords that also occur in the diapix task, both normally and when instructed to speak clearly. Preliminary acoustic-phonetic analyses of the speech corpus will be presented. The clear speech elicited from the diapix and "read speech" conditions will be compared to ascertain whether clear read speech shows similar characteristics to clear speech elicited in more natural communicative situations. [Work supported by ESRC.]

4pSC16. Korean listeners' perception of consonant clusters in English. Gwanhi Yun (Dept. of English, Daegu Univ., 15 Naeri, Jinryang, Gyeongsan, Gyeongbuk, Korea 712-714, ghyun@daegu.ac.kr)

Perception experiments were conducted to see whether Korean listeners perceive the illusionary vowel in the legitimate sequence of English consonants, especially in onset positions. Korean listeners were presented three types of licit consonant clusters in English (e.g., sC in spee; Cy in kyoo; obstruent + approximant in plee) and had to choose between the original sequence and vowel-repaired sequence. First, Korean listeners did not perceive the illusionary inserted vowel between two consonants with all three types of onset clusters (sC, Cy, OA). Perception of the insertion of unmarked vowel was obtained only 20.1 %, while consonant clusters (disallowed in Korean) were not repaired in perception. Second, perceptual repair with illusive vowels was adopted the most in the sequence of obstruents and approximants (pree; 36 %), next of s+consonant (spee; 20%), and the least of Cy sequences (pyoo; 15%). Our result indicates that loanword phonology might be primarily computed on the basis of the phonological grammar of the borrowing language rather than perceptual assimilation based on phonetic-fine representation [Peperkamp *et al.* (2008)] . Further, it shows that perceptual repair by illusory vowels in the illicit onset clusters are gradual, not categorical unlike phonetic implementation of loanword phonology.

4pSC17. Improved learning of a non-native phonetic contrast by combining active task performance with passive stimulus exposures. Nicole Marrone and Beverly A. Wright (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, n-marrone @northwestern.edu)

Adults can learn to hear the phonetic distinctions of another language with practice. It is commonly assumed that such improvements require active performance of the target task throughout training. However, we have seen that, for other perceptual tasks, similar performance gains can be achieved by replacing some active-performance trials with passive stimulus exposures. Here we examined the learning of a non-native phonetic contrast using several training protocols that varied in the proportion of active and passive trials during the practice period. Native, monolingual English speakers were trained to identify a Thai phonetic contrast along a voice-onset-time continuum. A group given half active training and half passive exposures showed as much improvement in the category boundary as a group given active training for the entire practice period. The active-passive group out-performed a group given half active training and half training on an unrelated task with no passive exposures. Finally, a group given only passive stimulus exposures showed the least improvement. Results suggest that learning a non-native phonetic contrast via active task performance can be reinforced by passive stimulus exposures. Therefore, active-passive training could be useful in real-world speech training applications. [Work supported by NIH/NIDCD.]

4pSP1. A tutorial on nonstationarity detection in acoustic signals: Parametric and nonparametric approaches. Patrick J. Wolfe (Statist. and Inf. Sci. Lab., Harvard Univ., Oxford St., Cambridge, MA 02138, patrick@seas.harvard.edu)

This tutorial provides an overview of nonstationarity detection in acoustic signals, focusing on model-based parametric approaches as well as more flexible nonparametric ones. The techniques discussed are presented in the context of speech and audio waveforms, with several real-world examples given, but also apply more broadly to any class of acoustic signals that exhibits locally stationary behavior. Many such waveforms, in particular information-carrying natural sound signals, exhibit a degree of controlled nonstationarity, and are often well modeled as slowly time-varying systems. The tutorial first describes the basic concepts of such systems and their analysis via local Fourier methods. Parametric approaches appropriate for speech are then introduced by way of time-varying linear predictive models, along with nonparametric approaches based on variation of time-localized estimates of the power spectral density of an observed random process. [Work supported in part by DARPA, NGA, and NSF.]

4pSP2. Bayesian source tracking in an uncertain ocean environment. Stan E. Dosso and Michael J. Wilmut (School of Earth and Ocean Sci., Univ. of Victoria, Victoria B.C. V8W 3P6, Canada)

This paper considers matched-field tracking of a moving acoustic source in the ocean when acoustical properties of the environment (water column and seabed) are poorly known. The goal is not simply to estimate source locations, but to determine localization uncertainty distributions, thereby quantifying the information content of the tracking process, and to use this information to probabilistically predict future source locations. To this end, a Bayesian formulation is applied in which source and environmental parameters are considered random variables constrained by noisy acoustic data and by prior information on parameter values (e.g., physical limits for environmental properties) and on interparameter relationships (limits on source velocity). Source information is extracted from the posterior probability density (PPD) by integrating over unknown environmental parameters to obtain a time-ordered series of joint marginal probability surfaces over source range and depth. Given the strong nonlinearity of the localization problem, marginal PPDs are computed numerically using efficient Markov-chain Monte Carlo methods, including Metropolis-Hastings sampling over environmental parameters (rotated into principal components and applying linearized proposal distributions) and heat-bath Gibbs sampling over source locations. Several approaches to estimating optimal tracks, track uncertainties, and future source locations from the set of marginal-probability surfaces are considered.

4pSP3. Adaptation of tandem hidden Markov models for non-speech audio event detection. Mark Hasegawa-Johnson, Xiaodan Zhuang, Xi Zhou, Camille Goudeseune, and Thomas Huang (ECE Dept. and Beckman Inst., Univ. of Illinois, 405 N. Mathews, Urbana, IL 61801)

Non-speech audio event detection (AED) could be used for low-cost, spatially diffuse surveillance applications, e.g., monitoring of vehicle activity in a national park, or of footsteps in a hallway. Experiments have shown that non-speech AED benefits from the dynamic inference strategies such as the hidden Markov model (HMM), but that the acoustic features useful for non-speech events may not be the same as those useful for speech. One possible solution is a tandem HMM: an HMM whose observation vector is constructed from the output of an instantaneous discriminative classifier, e.g., a neural network. The use of tandem HMMs for non-speech AED is hindered, however, by the relatively small size of most non-speech-audio training corpora. This talk will demonstrate that tandem HMMs can be trained to detect non-speech audio events using a novel form of regularized training: Baum–Welch back-propagation (as proposed by Bengio *et al.*), using the conjugate-gradient adaptive form of the Baum–Welch auxiliary function (as proposed by Lee *et al.*, and as commonly used in maximum *a posteriori* HMM adaptation).

3:45

4pSP4. Statistical signal characterization in ocean acoustic tomography and geoacoustic inversions. Michael Taroudakis and Kostas Smaragdakis (Dept. of Mathematics, Univ. of Crete and FORTH/IACM, Knossou Ave, 71409 Heraklion, Greece, taroud@math.uoc.gr)

A performance study of a statistical characterization of an underwater acoustic signal in relation to geoacoustic inversion or tomography problems is presented. The method of characterization has been presented by Taroudakis *et al.* [JASA **119**, 1396–1405 (2006)] and is based on the use of an appropriate distribution law which describes the statistics of the sub-band coefficients of the signal wavelet transform. The method has been applied with synthetic data simulating tomographic experiments with low-frequency sources in shallow environments for the estimation of the water column and bottom properties. In this work the inversion procedure incorporating a genetic algorithm is applied in shallow water environments with simulated noisy data to assess the performance of the method and its limitations under realistic conditions.

4pSP5. Wavelet-based neural networks applied to automatic detection of road surface conditions using tire noise from vehicles. Wuttiwat Kongrattanaprasert, Hideyuki Nomura, Tomoo Kamakura (Dept. of Elec. Eng., Univ. of Electro-Commun.s, 1-5-1 Chofugaoka, Chofu-shi, Tokyo 182-8585, Japan, wuttiwat@ew3.ee.uec.ac.jp), and Koji Ueda (Nagoya Electric Co., Ltd., Miwa-cho, Ama-gun, 490-1294, Japan)

The detection of road surface conditions is an important process in efficient road management. In particular, in snowy seasons, prior information about the road conditions such as an icy state, helps road users or automobile drivers to obviate serious traffic accidents. This paper proposes a novel approach for automatically detecting the states of the road surface from tire noises of vehicles. The method is based on a wavelet transform analysis, artificial neural networks, and the mathematical theory of evidence. The proposed method employs the wavelet transform using multiresolution signal decomposition techniques. The proposed classification is carried out in sets of multiple neural networks using learning vector quantization networks. The outcomes of the networks are then integrated using the voting decision-making scheme. It seems then feasible to detect passively and readily the states of the surface, i.e., as a rule of thumb, the dry, wet, snowy, and slushy state, automatically.

4:30

4pSP6. Discrimination of blasting sounds, music, and wind noise using a Gaussian mixture-model classifier. D. Keith Wilson (Cold Regions Res. and Eng. Lab., U.S. Army Engineer Res. and Development Ctr., 72 Lyme Rd., Hanover, NH 03755, D.Keith.Wilson@usace.army.mil) and Michael J. White (Construction Eng. Res. Lab., U.S. Army Engineer Res. and Development Ctr., Champaign, IL 61822)

Wind noise and acoustic signals were recorded outdoors with a horizontally oriented, square, 7×7 microphone array having an intersensor spacing of 0.914 m. Even with this very small spacing, the wind noise was found to have very little spatial correlation at frequencies above 15 Hz, thus indicating that the turbulent eddies responsible for the wind noise distort very rapidly. This property can be used to distinguish wind noise from acoustic signals possessing similar frequency content. To demonstrate this idea, wavelet processing was applied to recordings with predominantly wind

noise, propane cannon blasts, and unsteady but persistent sounds (music). A set of features involving ratios of the wavelet coefficients at different frequencies and between different microphones was then formulated. Three of the features relate to the time-domain shape of the signals, two to the spectral content, and three to the spatial correlation. A Gaussian-mixture-model classifier was trained with the feature statistics of the three signal types, and classifier predictions were then compared against an independent test data set. Results indicate a 96.6% correct classification rate of the signals. Signal shape features reliably distinguish the blasting and music, whereas the coherence features reliably distinguish the wind noise from acoustic signals.

4:45

4pSP7. Audio enhancement of biomechanical impact data. Joe Guarino, Wes Orme, and Wayne Fischer (Dept. of Mech. and Biomedical Eng., Boise State Univ., Boise, ID 83725-2075, jguarino@boisestate.edu)

Analysis and interpretation of impact data from a force transducer or accelerometer can be augmented and enhanced using audio playback. Trends and differences which may be difficult to identify using data imagery can be elucidated and reinforced by converting digital data from a force plate to an audio signal, which can then be played through a high-quality speaker system. The audio stream can be processed using standard acoustical methods such as tempo and pitch shifting, which can emphasize frequencies and tone bursts for improved signal characterization. We apply audio enhancement to data from two separate biomechanical studies: (1) a drop landing experiment for the investigation of gender differences in impact upon landing and (2) an experiment for the investigation of impact differences between cleated and noncleated shoes on artificial turf. The continuous wavelet transform (CWT) is used to process data from a force plate in both studies. Results are compared using the semblance analysis approach described by Cooper and Cowan ["Comparing time series using wavelet-based semblance analysis," Computers Geosciences 34, 95–102 (2008)]. Interpretation of results is enhanced using speaker-driven audio output synthesized from the CWT and semblance analysis.

4pUW1. Exact and approximate techniques for scattering from targets embedded in a layered medium. Ahmad T. Abawi and Michael B. Porter (HLS Res., Inc., La Jolla, CA 92037)

To be able to accurately compute scattering from a target embedded in a layered medium (waveguide), the scattering and propagation problems must be solved as a single boundary value problem. This is accomplished by solving the wave equation in an environment that contains both the target and the waveguide and satisfying boundary conditions on the surface of the target and the boundaries of the waveguide. One way that this can be accomplished is by the use of the virtual source technique, which replaces the target with a collection of sources whose amplitudes are determined from the boundary conditions on the surface of the target. This method converts the problem of scattering from a target in a waveguide to a multisource propagation problem. In this paper, the virtual source technique is used to compute scattering from a target in a waveguide and various ways to speed up computation are examined. These include the use of various propagation models to propagate the field produced by the virtual sources to the receiver. Various solutions are compared and the advantages and disadvantages of each model are discussed.

2:35

4pUW2. Bistatic specular reflection by a proud cone: Experiments and interpretation. Jon La Follett and Philip L. Marston (Phys. and Astronomy Dept., Washington State Univ., Pullman, WA 99164-2814, lafollej@mail.wsu.edu)

For sufficiently small grazing angles of illumination, specular backscattering of high frequency sound by a proud cone having a vertical symmetry axis is not observed from geometric considerations. Observations from scaled tank experiments suggest, however, that specular scattering from a conical target in this configuration can be observed at shallow grazing angles bistatically. Bright features in the scattering corresponded to sound that had interacted with the flat boundary and the cone and to direct acoustic reflections from the cone. Feature locations were in agreement with a geometric analysis of bistatic reflection [P. Marston, J. Acoust. Soc. Am. **124**, 2584 (2008)] modified so as to allow for images caused by the flat surface. Data were obtained by suspending the apex of a small solid aluminum cone through the air-water interface of a tank. The cone was illuminated from below at grazing incidence and the free surface simulated the ocean floor. Bistatic measurements were obtained by scanning a hydrophone along a line parallel to the interface at varied depths. Data were also obtained from a truncated cone. [Research supported by ONR.]

2:55

4pUW3. Excitation of low frequency modes of solid cylinders by evanescent waves: Mode properties and coupling. Aubrey L. Espana, Philip L. Marston (Dept. of Phys. and Astron., Washington State Univ., Pullman, WA 99164-2814), and Kevin L. Williams (Univ. of Washington, Seattle, WA 98105)

When using sound to detect objects buried beneath the seafloor, situations arise in which the incident acoustic wave has a significant evanescent component. This situation has been simulated in tank experiments [Osterhoudt *et al.*, IEEE J. Ocean. Eng. (in press)] and the simulation was used to investigate scattering mechanisms. In prior work, the backscattering of evanescent and ordinary-propagating waves from small solid aluminum cylinders was studied [Espana and Marston, J. Acoust. Soc. Am. **124**, 2584 (2008)]. It was determined that a strong low frequency mode could be excited when the cylinder was highly tilted in a horizontal plane. With increasing simulated burial depth, the spatial decay rate of the backscattering was enhanced compared to the spatial decay rate of the evanescent soundfield. This resonance has since been driven by evanescent waves when the cylinder is highly tilted in a vertical plane. This alternate method of excitation also showed an enhanced spatial decay rate with increasing simulated burial depth. FEM simulation of the free-field response of the cylinder reveals that this mode causes a rocking motion of each end of the cylinder and it is plausible that evanescent waves could also excite this type of response. [Work supported by ONR.]

3:15—3:30 Break

3:30

4pUW4. Burial depth dependence of the bistatic scattering amplitude for cylinders illuminated by evanescent waves using two–dimensional finite elements. Nicholas R. Cerruti, David B. Thiessen, and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, ncerruti@wsu.edu)

Prior research examined the dependence on simulated burial depth of the low-frequency scattering by small targets illuminated by evanescent waves [P. L. Marston, A. L. Espana, C. F. Osterhoudt, and D. B. Thiessen, J. Acoust. Soc. Am. **122**, 3034 (2007)]. The backscattering amplitude from targets with localized coupling displayed a spatial decay rate approximately twice that of the evanescent wave. An extended reciprocity relation was proposed which accounts for the more general case of a bistatic observation in the water column above the sea floor. In the bistatic case the spatial decay rate may differ from the case of backscattering. The present research concerns the testing of generalized reciprocity for small circular cylinders using two-dimensional finite elements. The calculated spatial decay rate for low-frequency bistatic scattering follows the generalized reciprocity condition when the predicted decay rate (for the specified observation scattering angle) exceeds the spatial decay rate of the incident evanescent wave. This computational result includes agreement with the double decay-rate case of backscattering. The calculations indicate that bistatic observation can significantly reduce the spatial decay rate of the signal dependence on burial depth. [Work supported by ONR.]

3:50

4pUW5. Bistatic and monostatic scattering from elastic structures using boundary element methods in free space and near plane boundaries. Ralf Burgschweiger, Martin Ochmann (Beuth Hochschule fuer Technik Berlin, Luxemburger Str. 10, D-13353 Berlin, Germany, burgi@tfh-berlin.de), and Ingo Schaefer (Forschungsanstalt der Bundeswehr fuer Wasserschall und Geophysik, D-24148 Kiel, Germany)

The bistatic and monostatic numerical calculation of the pressure scattered from structures composed of elastic materials and possibly filled with another material is one of the main purposes for the detection of underwater objects. For this reason, the sound pressure scattered from spherical objects placed in and filled with fluid will be calculated in the frequency domain. The results of an in-house developed BEM-package which supports single and multiple fluid-structure-interactions will be compared with analytical solutions based on spherical wave functions and with results of commercial BEM/FEM applications. Performance optimizations of the calculation process for the uncoupled rigid and coupled monostatic case as a result of using a parallelized matrix creation and solution with a specific variant of the direct solving process will be presented. We will also compare results for a cubic structure, placed in water above a finite plane boundary, with an equivalent half-space solution that incorporates a suitable half-space Green's function and could be used for fast approximations in the mid- and high-frequency range.

4:10

4pUW6. Synthetic aperture sonar simulations of cylindrical targets. Steven G. Kargl, Kevin L. Williams, Eric I. Thorsos (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40 St., Seattle, WA 98105, kargl@apl.washington.edu), and Joseph L. Lopes (Naval Surface Warfare Ctr., Panama City, FL 32407)

Cylindrical targets of finite length can be used as reference targets not only for calibrating an existing SAS system, but more importantly, for testing new classification and identification algorithms. With only a few well-characterized measurements available for proud and buried cylindrical targets, numerical simulations of the acoustic response of these targets offer the potential to realize an unlimited set of target orientations with respect to the source and receiver locations. This paper discusses recent progress with our acoustic scattering models and the generation of a set of pings suitable for SAS processing. SAS images generated from numerical simulations are compared to SAS images generated from data collected during the recent pond experiment 2009 (Pondex09) at NSWCPCD's facility 383. The target is a solid aluminum cylinder with a 0.3 m diam and length of 0.61 m. [Work sponsored by ONR and SERDP.]

4:30

4pUW7. Wavefront curvature and near-field corrections for scattering by targets buried under sea-floor ripple. Raymond Lim, Gary S. Sammelmann, and Joseph L. Lopes (Naval Surface Warfare Ctr. Panama City Division, Panama City, FL 32407)

Curvature of the incident field wavefront has been implicated in discrepancies between modeled and measured pressure fields scattered at shallow grazing angles from targets buried under ripple in NSWCPCD's test pond, where the range to the target is limited to about 10 m. Improvements on our attempts to correct for these and other near-field effects in existing incident-plane-wave-based models is described here. Explicit numerical integration of incident field expansion coefficients as well as the basis functions needed to formulate the transition matrix solution for the scattering process is used in order to create a reliable benchmark for comparisons with simpler corrections and measured data. It is found that some care must be exercised in performing the required two-dimensional wave vector integrals because the ripple wave vector can cause integration to be unstable in the perturbative terms accounting for ripple effects. Results are compared with recent modifications of existing sonar simulations and data collected in NSWCPCD's test pond. [Work supported by ONR and SERDP.]

4:45

4pUW8. Bistatic scattering from underwater unexploded ordinance and the impact of burial. Joseph A. Bucaro (SET, Inc., Naval Res. Lab., 4555 Overlook Ave., Code 7130, Washington, DC 20375-5320, joseph.bucaro.ctr@nrl.navy.mil), Brian H. Houston (Naval Res. Lab., Washington, DC 20375), Larry Kraus (Global Strategies Group (North America), Crofton, MD 21114), Harry J. Simpson, David C. Calvo, and Louis R. Dragonette (Naval Res. Lab., Washington, DC 20375-5320)

Interest in exploring various sonar approaches for detecting underwater unexploded ordnance (UXO) has been growing in large part because of the strong support of the Strategic Environmental Research and Development Program (SERDP). Among the many issues now being explored are the following two fundamental questions: what are the broadband acoustic scattering characteristics associated with typical submerged UXO, and how are these impacted by the bottom sediment? Recently, the authors reported laboratory grade, *monostatic* acoustic scattering measurements on UXO targets in the free field. In the present study, further echo measurements are obtained on UXO both to infer what merits may exist for exploiting *bistatic* echo responses as well as to address the effect of sediment on the target echo characteristics. The measurements, which were carried out in the NRL sediment pool laboratory and free-field facilities, include bistatic *free-field* scattering for three source directions viz. 0°, 45°, and 90°, and bistatic measurements in the sediment facility with the target *proud, half-buried*, and *fully buried*. The data suggest that access to bistatic echo information in operations aimed at detecting submerged UXO-like targets could provide an important capability, especially for buried targets. [Work supported by SERDP and ONR.]

5:00

4pUW9. The broadband in-water structural acoustics of unexploded ordinance: Tank comparisons with at-sea rail measurements. Harry J. Simpson, Brian H. Houston, Mike L. Saniga, Joe A. Bucaro (Naval Res. Lab., Code 7130, 4555 Overlook Ave., Washington, DC 20375-5320), Alain R. Berdoz, and Larry A. Kraus (Global Strategies Group (North America) Inc., Largo, MD 2077)

Free field, proud, and buried laboratory measurements of unexploded ordinance (UXO) are compared to at-sea rail-based measurements of the same UXO. The Laboratory for Structural Acoustics (LSA) at the Naval Research Laboratory consists of a 1 million gallon, deionized water, indoor cylindrical tank (17 m diam by 15 m deep) and an indoor rectangular tank (10 m by 8 m) laboratory, with a 3 m deep sand bottom and 4 m of water column. These pristine laboratory measurements are used to explore the physical acoustics of the sound-structure interactions that can be used to validate models and to understand the structural acoustic features that may be measured in littoral environments. These laboratory results are compared and contrasted with measurements made on the same UXO in St. Andrews Bay near Panama City, Florida using a rail-based synthetic aperture sonar (SAS). The structural acoustics responses of the UXOs in this shallow water, 8 m deep, sandy-mud bottom environment are compared with the pristine results from the LSA. [Work supported by SERDP and ONR.]

5:15

4pUW10. Long-range low frequency shallow water acoustic propagation and bottom penetration experiments for underwater unexploded ordinance. Harry J. Simpson, Mike L. Saniga, Brian H. Houston (Naval Res. Lab., Code 7130, 4555 Overlook Ave., Washington, DC 20375-5320), Alain R. Berdoz, Philip Frank, Steve W. Liskey, and Larry A. Kraus (Global Strategies Group (North America) Inc., Largo, MD 20774)

Among the many issues now being explored in the acoustic detection underwater unexploded ordinance (UXO) in shallow water is the impact of propagation and bottom interaction. Here, we report on long range (1 km) propagation measurements in a littoral environment at the sediment-water interface in the 1 kHz–12 kHz frequency band. The water channel studied was an 8 m deep arm of St. Andrews Bay, Panama City, Florida. The medium grain sandy bottom had a compressional waves peed of 1700 m/s, and the wavespeed in the water was 1539 m/s. A dense array of point pressure measurements (1 cm vertical sampling) were acquired for a synthetic vertical aperture starting from 2 m above and going through 2 m below the interface and at three ranges, 78, 485, and 990 m. The results show deep penetration into the sediment at long ranges for frequencies below 5 kHz. The data are examined using a two-fluid parabolic equation model, and the overall environmental acoustics are discussed including the nature of sediment penetration due to evanescent waves, multipath, and interface roughness.

5aAA1. An application of the finite difference time-domain method to the study of coupled volumes. Jonathan M. Botts and Ning Xiang (Program in Architectural Acoust., Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, bottsj@rpi.edu)

A finite difference time domain (FDTD) scheme is applied to study the behavior of sound energy decay in coupled-volume systems. This particular method takes into account frequency dependent wall impedance as well as source characteristics. In time-domain method, impulse responses are direct results of numerical calculation and transient effects specific to coupled volumes can be visualized. In addition to examining traditional acoustic metrics, this model allows for the investigation of the sound energy flows in the system. The numerical calculations will also be compared with experimental scale model measurements. Though limited to low frequencies due to computational load, this method will demonstrate many advantages over geometric acoustic models and other wave based models for the study of coupled volumes.

8:15

5aAA2. One-dimensional transport equation models for sound energy propagation in long spaces. Yun Jing (Graduate Program in Architectural Acoust., Sch. of Architecture, Rensselaer Polytechnic Inst., Troy, NY 12180), Edward Larsen (Univ. of Michigan, Ann Arbor, MI 48109), and Ning Xiang (Rensselaer Polytech. Inst., Troy, NY 12180)

In this paper, a three-dimensional transport equation model is first presented to describe the sound energy propagation in a long space. Then the three-dimensional model is reduced to a one-dimensional model by approximating the solution using the method of weighted residuals. The one-dimensional transport equation model directly describes the sound energy propagation in the long dimension and deals with the sound energy across the cross-section by prescribed functions. The one-dimensional transport equation model consists of a coupled set of N transport equations. Only $N = 1$ and $N = 2$ are discussed in this paper. For larger N, although the accuracy could be improved, the calculation time is expected to be significantly longer, which diminishes the advantage of the one-dimensional model over the three-dimensional model in terms of the computational efficiency. Some simulation results are provided in comparison with the ray-tracing based approach, which show good agreement.

8:30

5aAA3. Reciprocal maximum-length and related sequences in the generation of natural, spatial sounding reverberation. Uday Trivedi, Eric Dieckman, and Ning Xiang (Graduate Prog. in Architectural Acoust., School of Architecture, Rensseleaer Polytechnic Inst., Troy, NY 12180, triveu@rpi.edu)

The development of artificial reverberation has made considerable progress in recent years. In this research, a unique approach utilizing reciprocal maximum-length sequences and related sequences is taken in generating a natural, spatial sounding reverberation. Additionally, an algorithm to shape and vary spaciousness within the context of an artificially generated reverberation is implemented. Results are verified through experimental measurements and subjective testing methods in a multichannel format. This work sheds light on alternative methods of generating artificial reverberation outside of commercially available systems. As a result, a direct application to room modeling techniques can be drawn with this work. Extensions of this research will comprise of investigations in objective and subjective behaviors of double-sloped energy decays in acoustically coupled spaces. From an educational perspective, outcomes of this research can serve as a foundation in ear-training for acoustics students seeking a broadened understanding of perceived reverberation in varying contexts.

8:45

5aAA4. Optimized overdetermination for interior Helmholtz problem coupled solvers. Alexander Bockman, Paul Calamia, and Ning Xiang (Dept. of Architectural Acoust., RPI, 110 8th St., Troy, NY 12180, bockma@rpi.edu)

The use of points of overdetermination, so-called CHIEF points, in numerical solutions to exterior Helmholtz problems for the elimination of spurious modes is well established. Further, the number and relative position of such points in two-dimensional radially symmetric geometries has been demonstrated theoretically. Since CHIEF points require lower computational overhead than collocation nodes, strategic use represents an opportunity for the improvement of predictions with maximal efficiency. Given the differing uniqueness properties of solutions to the interior and exterior problems, the former allows for development of optimization in the absence of competing priorities. Theory for two- and three-dimensional analytical cases is developed and subsequently extended to general geometries. Localization with respect to subdomains of spatial decomposition is investigated as well.

9:00

5aAA5. Evaluation of the newly developed equation for noise barrier within an enclosed space. Lau Siu-Kit (Archit. Eng. Prog., 203C Peter Kiewit Inst., Univ. of Nebraska-Lincoln, 1110 South 67th St., Omaha, NE 68182-0681, sklau@engineer.com and) and Kwok-Wai Lam (The Hong Kong Polytechnic Univ., Hung Hom, Kowloon, Hong Kong)

Indoor barrier can be employed to ensure the privacy of speech in open-plan offices and to shield the noise generated by the machines in plant rooms. However, existing publications on diffraction and noise reduction by barrier inside an enclosed space using the classical theory is limited by the assumption of diffuse field. Recently, a new formula for estimating the barrier insertion loss inside an enclosed space was proposed by Lau and Tang [J. Sound Vib. **20**, 50–57 (2009)]. It is simple and is sufficiently accurate in engineering practice. In the present study, this new formula is proposed to estimate the insertion loss of a vertical partition between two flat rooms. The performance of the new formula is compared with that of the classical diffuse-field theory. The results indicate that the new formula provides more realistic and practical predictions of the insertion loss of the partition between two flat rooms than existing approaches. [The work described in this paper was supported by a grant from the Hong Kong Polytechnic University (Project A/C code: G-U362).]

9:15

5aAA6. Design and testing of a variable acoustics production studio with reflection free zone control room. Jon Mooney, Seth Harrison (KJWW Eng. Consultants, 623 26th Ave., Rock Island, IL 61201, mooneyjw@kjww.com), and Jon Brennan (Curtis, Inc., Cincinnati, OH 45203)

The new home of Curtis, Inc. in Cincinnati, OH, includes a recording studio and control room designed and tested by KJWW Engineering Consultants. The recording studio features adjustable wall treatments, which may be opened in varying degrees to adjust absorption and diffusion within the room. The adjoining control room has been designed to position the recording engineer inside a reflection free zone (RFZ). This design directs speaker reflections from the front of the room away from the recording engineer, extending the initial time delay (ITD) without requiring a dead front end. The control room also features unique wall and ceiling treatments, which serve not only as variable binary diffusers and absorbers but also as storage cabinets. These design elements allow for broad adjustment of the control room acoustics. The configurable design of the recording studio and control room coupled with exceptional sound isolation enable this facility to create flexible recording and listening environments. This paper will present an overview of: 1. The recording studio and control room designs; 2. The changes required during construction and their effects; 3. Acoustical measurements, quantifying the variable response of the rooms; 4. Operation of the rooms and preferred settings.

9:30

5aAA7. The acoustic shell of the Plaza de La Fe in Managua, Nicaragua. Russ Altermatt (Altermatt Assoc., Inc., 522 SW 5th Ave., S-1200, Portland, OR 97204)

The Plaza de La Fe, the Plaza to the Faith, of Pope John Paul II, in Managua, Nicaragua, is the site of many celebrations for the people of Nicaragua. At one end of the plaza, a performance, acoustic shell was constructed as a focus for performances in the plaza. The acoustic shell has a very large capacity, for full orchestra and choir, at a minimum. It supports multiple band setups on the same stage depending on the celebration requirements. The shell is used for all types of performances and presentations, be they multiband, dance, classical music, or speech. In spite of significant concavity of the overall design, the shell elements were also molded to provide directional sound reflections both to the plaza and to the performers on the stage. This presentation will show the progress of the project from design, through construction. The acoustic shell was inaugurated with an attendance of over 100,000 in Jan. 2005.

9:45

5aAA8. Classroom sound systems: Not a Green substitute for proper classroom acoustics. Richard F. Riedel (Riedel Audio & Acoust., 443 Potter Blvd., Brightwaters, NY 11718, riedelaudio@optonline.net)

The author will discuss the negative environmental impact that individual classroom sound systems create when used as a substitute for good acoustical design. School systems are being targeted by marketers of classroom sound systems and being convinced that they are a cost effective alternative to the standards that are put forth by ANSI S12.60-2002. This paper presents estimates of the potential waste that is created by these systems through future disposal of outdated technology and batteries used in these devices. The presentation will put forth suggestions for the dissemination of this information by interested parties to schools in their immediate vicinity.

10:00

5aAA9. Did paleolithic cave artists choose resonant locations for paintings? David Lubman (DL Acoust., 14301 Middletown Ln., Westminster, CA 92683, dlubman@dlacoustics.com)

Paleolithic artists were surely impressed by the acoustical properties of their cave dwellings. Since many inhabited caves and grottoes were highly reverberant, it is compelling to speculate that cave acoustics importantly influenced ancient artists. One imaginative suggestion is that Paleolithic artists intentionally chose the most resonant locations for painting. This thesis was proposed by Iegor Reznikoff and Michel Dauvois in the Bulletin de Ia Societe Prehistonque Francaise **85**, 238–246 (1988) and was engagingly described by British archaeologist Chris Scarre ["Painting by resonance," Nature (London) **338**, 382 (1989)]. Scarre found this thesis consistent with "the likely importance of music and singing in the rituals of our early ancestors." The researchers found a greater density of paintings where sonic resonances were judged strongest. However, that finding may be spurious: the same result is predictable from painterly rather than sonic considerations. Painters would likely choose nonporous rather than porous rocks to conserve pigment. Since nonporous rocks are generally highly sound reflective, nonporous rock locations tend to be highly resonant. Since porous rocks tend to absorb sound, porous rock locations are less resonant. Thus the higher density of cave paintings found at resonant locations may not imply the artists' preference for resonance.

10:15

5aAA10. Tehran concert hall—a virtual specimen indicative the conversion processes from architectural design to acoustical remedies. H. Azad (Dept. of Architecture, Camp. of Fine Arts, Univ. of Tehran, Enghelab st. Tehran, Iran, hassan.azad@gmail.com)

Over the last year of the B.Sc. period it was investigated by the author to design a 1200-seat concert hall as the thesis project. Now the quoted project has been enriched by the acoustical aspects of the concert hall design regarding the acquired capabilities during the M.Sc. studies. It has become prevalent these days to peruse and analyze the acoustical parameters of enclosures through the different acoustical simulation software such as Odeon 9, CATT-Acoustics 8, EASE 4.1, and Ramsete 2.5, either before or after their construction as an objective assessment but interpreting this data is a real challenge. [H. Azad. "Ali Qapu: Persian Historical Music Room?". Auditorium Acoustics Conference (2008), Oslo.] The variable height stage canopies taking into account their shape and materials is investigated by calculations with ray-tracing computer model to provide a large part of the audience with early reflections and to create good ensemble conditions for the musicians on stage. The diffusers design as a geometrical shape with design factors of height, surface coverage and orientation in addition to their location will be studied computer aided to improve the acoustics in this virtual concert halls.

Animal Bioacoustics and Signal Processing in Acoustics: Signal Processing Techniques for Subtle or Complex Acoustic Features of Animal Calls

Ann E. Bowles, Chair
Hubbs Sea World Research Inst., 2595 Ingraham St, San Diego, CA 92109

Chair's Introduction—7:30

Invited Papers

7:35

5aAB1. Distinguishing FM-modulated bowhead whale calls from airgun and other biologic signals using image processing, feature extraction, and neural networks. Aaron Thode, Delphine Mathias (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr., San Diego, CA 92109-0238), Susanna Blackwell, Katherine Kim, and Charles Greene, Jr. (Greeneridge Sci. Inc., Goleta, CA 93117)

The detection and identification of repetitive or stereotyped bioacoustic signals in raw acoustic data are typically accomplished via matched filtering or spectrogram correlation techniques. However, the detection of FM-modulated sweeps that have variable frequency-modulated contours or bandwidths is still an active challenge. The problem is made more complex by the possible presence of other frequency-modulated signals such as airguns or other biologics. To provide a specific example, in 2007 and 2008 directional autonomous recording packages (DASARs) were deployed in the Beaufort Sea to monitor the annual migration of the bowhead whale (*Balaena mysticetus*) population during seismic exploration activities. A portion of these data sets has been manually analyzed, providing an opportunity to characterize the miss and false alarm rates of various FM-modulated detection and classification methods. Here literature and software on bioacoustic FM-contour tracing and classification are reviewed, with a particular emphasis on the use of contour tracing, image segmentation, feature extraction, and neural networks for identifying species-distinctive sounds. A combination of these methods, when applied to the Arctic data set, has been found to reduce the false alarm rate by a factor of 5, while preserving a miss rate of less than 20%. [Work supported by Shell Oil Co.].

7:55

5aAB2. A graph search algorithm for delphinid whistle contours. Marie A. Roch, Bhavesh Patel (Dept. of Comp. Sci., San Diego State Univ., 5500 Campanile Dr., San Diego, CA 92182-7720), Melissa S. Soldevilla, and John A. Hildebrand (Scripps Inst. of Oceanogr., Univ. of California, San Diego, La Jolla, CA 92093-0205)

A graph search algorithm is presented to extract tonal contours from audio signals in a fully automated manner. The algorithm is capable of tracking multiple contours simultaneously. Search is done in the spectral domain, with contours being treated as paths through a phase-magnitude space. A graph search formalism is combined with dynamic programming techniques to track candidate paths that may overlap or cross. Disambiguation of path crossings is accomplished by examining a combination of slope and the derivative of phase. The algorithm is general in nature and applicable to tonal calls from many animals with little modification. We target this work specifically toward delphinid whistles and demonstrate its efficacy on calls from bottlenose (*Tursiops truncatus*), short- and long-beaked common (*Delphinus delphis* and *D. capensis*), and Risso's (*Grampus griseus*) dolphins recorded in the Southern California Bight. Characterizing the complete contour will permit the development of call comparison techniques that take into account finer grained detail than the typically used contour statistics (e.g., number of inflection points, minimum, and maximum frequencies). [This work is sponsored by the Office of Naval Research.]

5aAB3. Noise-resistant acoustic measurements implemented in user-friendly software. David K. Mellinger (Cooperative Inst. for Marine Resources Studies, Oregon State Univ. and NOAA Pacific Marine Environ. Lab., 2030 SE Marine Sci. Dr., Newport, OR 97365)

Searching for vocalizations in lengthy marine recordings can be significantly enhanced by annotations indicating times, frequencies, and other characteristics of calls. Defining optimal search features, however, is difficult. For instance, one may wish to find harbor seal "roar" vocalizations, which extend up to 6 kHz, last 3–10 s, and have a broadband, non-tonal sound quality. What features best characterize such sounds? Marine recordings often contain vocalizations recorded at low signal-to-noise ratios, and it is essential that call measurements be consistent across different background noise levels. For instance, bandwidth is traditionally measured by manually indicating lower and upper frequency bounds in a spectrogram, and then subtracting the two. However, for vocalizations that fade at higher frequencies, like harbor seal roars, such bandwidth measurements can vary by a factor of three from low-noise to high-noise environments. Here we describe measurements, based principally on Fristrup's "Acoustat" approach, that have consistent values at variable noise levels. For instance, bandwidth is measured as the standard deviation of frequency, weighted by the per-frequency-bin normalized intensity. A set of noise-robust measurements have been implemented, including measures for duration, amplitude and frequency modulation, and many others. Implementation of these measurements in easy-to-use Ishmael and MATLAB software is described.

8:35

5aAB4. Signal processing challenges in the analysis of stereotyped killer whale calls produced in social contexts. Ann E. Bowles (Hubbs-SeaWorld Res. Inst., 2595 Ingraham St., San Diego, CA 92109, abowles@hswri.com), Jessica L. Crance, and Juliette S. Nash (Univ. of San Diego, San Diego, CA 92108)

Research on call development and usage by individual killer whales has been limited by signal processing challenges, which include (1) more than one simultaneously operating source, (2) a pulse-burst production mechanism, (3) a complex repertoire (7–17 calls), (4) gradation with nonstereotyped call types, (5) presence of nonstereotyped features encoding state (e.g., arousal), and (6) vocal matching among callers. To date, the most successful signal processing efforts have targeted tonal, modulated "screams." However, analysis of other component types (bursts, resting call), parsing of calls into components, and reliable classification of calls continue to require the intervention of a human brain. Under controlled laboratory conditions, using data from seven whales at SeaWorld San Diego, these characteristics were analyzed by ear and using traditional statistical methods. The work showed that important insights could be gained by comparing these call characteristics among individuals and social contexts. However, estimates of the sample sizes needed to show significant differences among individuals suggest that automation will be essential. Use of the human ear as a signal processor could also introduce biases. Efficient automation would greatly improve the study of individual call usage. [Work supported by the Hubbs-SeaWorld Society and SeaWorld San Diego.]

5aAB5. Feature vector selection for identifying killer whale individuals. Nicole Nichols, Les Atlas (Dept. of Elect. Eng., Univ. of Washington, Box 352500, Seattle, WA 98195, nmn3@u.washington.edu), and Ann Bowles (Hubbs-Seaworld Res. Inst., San Diego, CA 92109)

One hindrance to studying whales is the simple act of identifying individuals. The source filter model of human speech is a potentially useful model for killer whale vocalizations. With this assumption, evaluation of vocal model based optimizations for human speaker recognition was performed with a whale dataset. (Twenty one calls of type 1a or 1b, from four captive Icelandic killer whales.) Feature vectors were extracted from sound samples, which reduce dimensionality while encapsulating the identifying characteristics. Recognition accuracy is highly dependent on choosing a feature vector, which can accurately divide the sample space. Cepstral coefficients are the standard used for human speaker recognition. Modulation envelopes are known to be important for perception and have been shown to improve speech recognition performance [Kingsbury *et al.*, Speech Commun. **25**, 117–132 (1998)]. Modulation spectrograms were examined and sampled across acoustic frequency at the fundamental modulation rate of the call to extract modulation feature vectors. Visual analysis of modulation spectrograms note a possible pattern unique to individual whales. Presented herein is analysis of these patterns based on linear discriminant functions and hidden Markov models. 5aAB6. Rhythmic analysis of sperm whale broadband acoustic signals. Natalia Sidorovskaia, Philip Schexnayder (Dept. of Phys., Univ. of Louisiana at Lafayette, UL Box 44210, Lafayette, LA 70504-4210, nas@louisiana.edu), Alexander Ekimov, James Sabatier (Natl. Ctr. for Phys. Acoust., University, MS 38677), George E. Ioup, and Juliette W. Ioup (Univ. of New Orleans, New Orleans, LA 70148)

Rhythmic analysis of sperm whale clicks, based on the static Fourier transform, was previously reported in the literature as a tool for extracting the acoustic signature of individual sperm whales [Andre and Kamminga, J. Mar. Biol. Ass. U.K. (2000)]. A new approach, originated from the algorithm developed for human motion analysis [Sabatier and Ekimov, "A Review of Human Signatures in Urban Environments Using Seismic and Acoustic Methods," Proc. IEEE (2008)], is applied to study time-dependent periodicity in sperm whale signals recorded in the Gulf of Mexico. The new approach for rhythmic analysis of sperm whales clicks, which are used for navigation purposes, shows the presence of stable temporal periodicity that could possibly be attributed to the acoustic portrait of individuals. [Research supported in part by SPAWAR.]

5aAB7. Sei whale localization and vocalization frequency sweep rate estimation during the New Jersey Shallow Water 2006 experiment. Arthur E. Newhall, Ying-Tsong Lin, James F. Lynch, and Mark F. Baumgartner (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, anewhall@whoi.edu)

The Shallow Water 2006 (SW06) experiment was conducted in the Mid-Atlantic continental shelf off the New Jersey coast. A fast-sampling, 48-channel hydrophone array system recorded a number of sei whale (*Balaenoptera borealis*) vocalizations during this time. This system had 16 hydrophones on the vertical line array (VLA) component covering the water column from 13-m depth to the bottom (80 m) and 32 hydrophones on the 480-m horizontal line array (HLA) component that lay on the bottom. The sei whale receptions on the arrays are low-frequency (less then 100 Hz) downsweep chirps and have the typical acoustic modal arrival pattern seen in shallow-water, low-frequency sound propagation. Due to acoustic modal dispersion, the frequency sweep durations observed from the receptions are found to be longer than the original signal. A horizontal beamforming technique using the HLA component is implemented to determine the bearings to whales. The whale location along the determined bearing and the frequency sweep rate of original whale sound are simultaneously estimated using the VLA component with a multiple-parameter optimization technique. This optimization technique is based on acoustic normal mode theory and is designed to compensate for the effect of acoustic modal dispersion.

5aAB8. The challenge of nonlinear dynamics in understanding mammalian vocalization. Michael J. Owren (Dept. of Psych., Georgia State Univ., PO Box 5010, Atlanta, GA 30302-5010, owren@gsu.edu)

Recent advances in vocal-fold physiology have shown that nonlinear dynamics play a central, but largely unexplored role in mammalian vocalization. Understanding that role is crucial to coming to grips with vocal signaling as a form of communication, as the "nonlinear phenomena" associated with coupled-oscillator systems like the larynx strongly shape their acoustic output. Those acoustics in turn are necessarily central to understanding both signaler and perceiver roles in the communication process. Issues that are fundamentally affected by the nonlinear nature of mammalian vocalization include categorizing sounds in acoustics and perception, breaking a repertoire into constituent call-types, understanding the identity cuing potential of various sound-types, and the relative roles of cognition and emotion in vocal production and perception. However, progress is being impeded by a general lack of accessible, quantitatively based, and objective tools to help in detecting, identifying, and measuring nonlinear phenomena in vocalizations. So far, researchers trying to include such events in their analyses have been limited to visual inspection of spectrograms, subjective classification, and simple counting. A pressing need thus exists for development of accessible, yet necessarily rather sophisticated tools for use in identifying and measuring occurrences of nonlinear phenomena in mammalian vocal acoustics.

10:20

5aAB9. Quantifying noise in animal acoustic signals. Tobias Riede (Dept. of Biology, Univ. of Utah, 257 S 1400 E, Salt Lake City, UT 84112, t.riede@utah.edu)

Variability in noisy calls or call segments is often difficult to quantify but critical in order to understand animal acoustic communication. Such components represent a large proportion of animal acoustic signals and they are behaviorally meaningful. Such elements have also collectively been labeled as nonlinear phenomena. Three approaches are reviewed. The harmonics-to-noise ratio (HNR) can be related to perceptual characteristics of an acoustic signal as well as to the mechanism of its production. The HNR seems to be a useful numeric parameter to quantify vocal variability. Two problems with the procedure will be outlined. The nonlinear measure (NLM) is designed to provide an overall estimate of the strength of nonlinearity in a signal. The rationale is that if signal noise reflects low-dimensional chaos as produced through nonlinear processes, deterministic-nonlinear modeling will produce a relatively small error component. A stochastic linear model, on the other hand, will produce a relatively large error component when applied to such signals. In a third approach, utterances can be segmented in the temporal domain into harmonic and noisy components for separate analyses. Noise-specific procedures are used to analyze nonlinear phenomena. Advantages and disadvantageous of all three procedures are exemplified with sounds from mammals and anurans.

10:40

5aAB10. Parametric and holistic approaches to analyzing primate vocal signals for acoustic markers of caller identity, emotional state, and external context. Drew Rendall and John Vokey (Dept. of Psychol., Univ. of Lethbridge, Lethbridge, AB T1K3M4, Canada)

Vocal signals can be acoustically differentiated according to a variety of intrinsic and extrinsic dimensions. Among the most commonly investigated sources of signal differentiation in primates are those that mark the identity of the caller, potential variation in the caller's underlying emotional or motivational state, and external environmental factors associated with signaling (e.g., the presense of predators or food). We analyzed a corpus of grunt vocalizations recorded from wild baboons for acoustic cues associated with these three dimensions. Grunts were collected from eight adult female baboons in two different behavioral contexts: 1. When approaching other females to handle their infants, and; 2. When embarking on an extended foraging excursion. Both contexts were further subdivided into conditions associated with low- versus high-arousal for callers. Analysis of the signals involved two different approaches: 1. A parametric analysis of specific acoustic features logically connected to either vocal-fold activity or supralaryngeal filtering (i.e., Fo and resonance properties) combined with principle components analysis (PCA) dimension reduction and discriminant analysis call classification; 2. A holistic analysis of the global spectral structure of entire signals that combined a PCA-based eigenvector decomposition and neural network classification of the calls. We compare results of the two analysis strategies.

11:00

5aAB11. Decoding the information contained in the alarm calls of Gunnison prairie dogs. Con Slobodchikoff, William Briggs, and Patricia Dennis (Dept. Biol. Sci, Northern Arizona Univ., NAU Box 5640, Flagstaff, AZ 86011, Con.Slobodchikoff@nau.edu)

Gunnison prairie dogs have been shown to produce alarm calls that incorporate information about predators [Slobodchikoff *et al.*, Anim. Behav. **42**, 713–719 (1991)], such as the species of predator and also a description of the color and general size of the predator. The alarm calls contain a series of harmonics that encode this information. The calls have been analyzed with discriminant function analysis (DFA) and classification techniques such as self-organizing neural networks. These tools have been able to show that very specific information is encoded in the calls. However, exactly how this information is encoded into the signal has proven to be elusive. We show examples of the specific information that is encoded, and present a hypothetic model of how that information is encoded into the signals.

11:20

5aAB12. Processing acoustic features of animal vocalizations using classification procedures. Sean F. Hanser, Brenda McCowan (Dept. of Vet Med. Population Health and Reproduction, Univ. of California, 1 Shields Ave., Davis, CA 95616, sfhanser@ucdavis.edu), Laurance R. Doyle (SETI Inst., Mountain View, CA 94043), and Ann E. Bowles (Hubbs-SeaWorld Res. Inst., San Diego, CA 92109)

Remote methods for classifying age, sex, group membership, or individual identification of animals that live in visually obscured environments are extremely valuable tools for field biologists, but reliable identification of individual callers still presents important challenges. Acoustic features of animal vocalizations can be processed to extract caller identification using a variety of sophisticated classification techniques, but the exact classification process can be difficult to justify rigorously and challenging to repeat on novel data. A feature extraction and classification process that is clear, simple, and repeatable would be a major benefit to wildlife studies. Classification and regression trees (CART) generate intuitive and clear processes for handling multidimensional acoustic information. Examples of CART applied to Mexican spotted owl (*Strix occidentalus lucida*) and humpback whale (*Megaptera novaeangliae*) vocalizations will be provided. These CART results will be compared to other classification techniques, particularly neural networks. CART performance was comparable, but had the advantage that it yielded explicit classifiers used to categorize vocalizations, making it easy to integrate into acoustic surveying systems. This promises to be a valuable tool for conservation and management of these and other endangered species.

11:40

5aAB13. Hidden Markov models for the analysis of animal vocalizations. Patrick J. Clemins (525 N Pollard St., Apt. 419, Arlington, VA 22203, patrick@clemins.name) and Michael T. Johnson (Marquette Univ., Milwaukee, WI 53201)

Hidden Markov models (HMMs) are commonly used to model sequential data, including time series such as vocalizations. HMMs are uniquely suited to model time series because of their ability to implicitly align samples and to be linked together to create flexible recognition patterns for vocalizations with repeating patterns, such as bird and whale songs. HMMs require less human interaction and manual tuning for successful recognition and are inherently more noise resistant than template-based techniques. Due to their statistical basis, HMM-based recognition systems can incorporate additional statistical models. One such example is a language model, which can be designed to include *a priori* knowledge about the structure of the vocalizations, such as syllable repetition patterns. HMMs have become the most popular recognition model in speech processing, and this experience has been applied to a variety of vocalization analysis tasks including individual identification, song classification, call type recognition, and physiological state determination. Classification results from complete HMM-based systems for a variety of tasks and species will be discussed.

5aBB1. Improved impulse response for hydrophone measurements in therapeutic ultrasound fields. Michael S. Canney (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), Vera A. Khokhlova, Oleg A. Sapozhnikov (Univ. of Washington, Seattle, WA), Yuri A. Pishchalnikov (Indiana Univ. School of Medicine, Indianapolis, IN), Adam D. Maxwell (Univ. of Michigan, Ann Arbor, MI), Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

The accurate measurement of pressure waveforms in high intensity focused ultrasound (HIFU) fields is complicated by the fact that many devices operate at output levels where shock waves can form in the focal region. In tissue ablation applications, the accurate measurement of the shock amplitude is important for predicting tissue heating since the absorption at the shock is proportional to the shock amplitude cubed. To accurately measure shocked pressure waveforms, not only must a hydrophone with a broad bandwidth ($>$100 MHz) be used, but the frequency response of the hydrophone must be known and used to correct the measured waveform. In this work, shocked pressure waveforms were measured using a fiber optic hydrophone and a frequency response for the hydrophone was determined by comparing measurements with numerical modeling using a KZK-type equation. The impulse response was separately determined by comparing a measured and an idealized shock pulse generated by an electromagnetic lithotripter. The frequency responses determined by the two methods were in good agreement. Calculations of heating using measured HIFU waveforms that had been deconvolved with the determined frequency response agreed well with measurements in tissue phantom. [Work supported by NIH DK43881, NSBRI SMST01601, NIH EB007643, and RFBR.]

8:40

5aBB2. Development of a high intensity focused ultrasound (HIFU) hydrophone system. Mark E. Schafer (Sonic Tech, Inc., 23 Brookline Ct., Lower Gwynedd, PA 19002, marks@sonictech.com) and James Gessert (Sonora Med. Sys., Longmont, CO 80503)

The growing use of high intensity focused Ultrasound (HIFU) has driven a need for reliable, reproducible measurements of HIFU acoustic fields. A reflective scatterer approach, incorporating several novel features for improved bandwidth, reliability, and reproducibility has been demonstrated [M. E. Schafer, J. Gessert, and W. Moore, Proc. IEEE Ultrasonics Symposium, 1739–1742 (2005)]. Several design improvements which have increase the signal-to-noise ratio of the system, and potentially reduced the cost of implementation, are now presented. For the scattering element, an artificial sapphire material is used to provide a more uniform radiating surface. The receiver is a segmented, truncated spherical structure with a 10 cm radius, made from 25 micron thick, biaxially stretched PVDF, with a Pt-Au electrode on the front surface. A specialized backing material provides the stiffness required to maintain structural stability, while at the same time providing both electrical shielding and ultrasonic absorption. This new receiver design has improved the noise performance by 8–12 dB; the new scattering sphere has reduced the scattering loss by another 14 dB, producing an effective sensitivity of −298 dB re 1 microVolt/Pa. The design trade-off still involves receiver sensitivity with effective spot size. However, the reduced cost and improved repeatability makes the overall design more robust for routine HIFU system measurements.

9:00

5aBB3. Characterization of high-intensity focused ultrasound systems by extrapolating from field measurements conducted in the quasi-linear regime. Samuel M. Howard (592 E. Weddell Dr., Sunnyvale, CA 94086, sh@ondacorp.com)

The purpose of this talk will be to discuss a method for characterizing HIFU fields where hydrophone measurements are made by reducing the electrical power input to the system until quasi-linear field propagation conditions are achieved, and until the pressure levels are safe for the hydrophone used. Radiation force measurements of total power are then used to scale up the results. This allows for reliable measurements which do not damage the hydrophone, and avoids complications from involving the many harmonics which can be generated in water which are usually not so strongly present in tissue. Advantages and disadvantages of the method will be discussed.

9:20

5aBB4. Temperature estimation and protocol assessment for monitoring high intensity focused ultrasound therapy with diagnostic ultrasound. Gavriel Speyer, Peter J. Kaczkowski, Andrew A. Brayman, and Lawrence A. Crum (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105-6698, gavriel@u.washington.edu)

Characterizing the performance of diagnostic ultrasound (DU) for monitoring high intensity focused ultrasound (HIFU) therapy is essential for identifying effective treatment protocols. Such protocols ensure accurate therapy monitoring in media with known thermal and perfusive properties. The protocols are specified by treatment duration, transducer motion, and the DU acquisition characteristics. The HIFU transducer is constrained to move in the plane perpendicular to its axis, with the DU positioned to capture the focal plane of the HIFU transducer. Differences in RF backscattering observed between two frames, one captured before and one after treatment, are known to result from a temperature distribution generated by the heat deposited during therapy. A functional expansion for the heating is used which provides minimum variance coefficient estimates for stationary backscattering by averaging the Fisher information matrix. We show through approximation, simulation, and experiment that these functions attain the Cramer-Rao bound independent of the particular heating applied or the RF backscattering encountered. Estimator accuracy is thus determined by the material properties, including the spatial correlation, and the protocol employed. Temperature estimates accurate to well within one degree Celsius are possible, and the estimation algorithm is implemented efficiently to enable near real-time monitoring. [Work supported by NIH Grant 5R01CA109557.]

9:40

5aBB5. Ultrasound-guided high intensity focused ultrasound therapy—Safety concerns from a clinical perspective. G. R. ter Haar (Inst. of Cancer Res. and Royal Marsden NHS Trust, Downs Rd., Sutton, Surrey SM2 5PT, UK, gail.terhaar@icr.ac.uk)

The use of high intensity focused ultrasound (HIFU) in surgical applications has continued to grow at a rapid pace. Nevertheless, safety concerns limit the adoption of ultrasound guidance due to the persistent lack of real-time monitoring and quantitative measures of clinical endpoints. Imaging and temperature estimation using magnetic resonance remains the preferred approach for guidance and monitoring in much of the Western world, while ultrasound imaging has seen wide use in China. Recent reviews of clinical outcomes have raised new regulatory concerns in China and are likely to increase scrutiny elsewhere. Still lacking are near real-time measures of *in situ* parameters such as acoustic power, heating rate, or temperature, from which clinical endpoint metrics may be obtained with acceptable accuracy. Furthermore, therapy planning remains a semiquantitative process, producing highly variable results, particularly in the absence of feedback. This presentation provides an update on the clinical impact of insufficient quantification of ultrasound-guided HIFU therapy.

10:00—10:30 Break

10:30

5aBB6. *Ex vivo* monitoring of high intensity focused ultrasound treatment. Xinliang Zheng and Shahram Vaezy (Dept. of Bioengineering, Box 355061, Univ. of Washington, 1705 NE Pacific St., Seattle, WA 98195, xlzheng@u.washington.edu)

High intensity focused ultrasound (HIFU) is a therapeutic modality that can produce coagulative necrosis of tissues noninvasively. The present study investigated the feasibility of monitoring lesion formation during HIFU treatment using ultrasound backscattered signal, specifically for treatments that do not result in hyperecho in ultrasound images (i.e., thermal lesion with no obvious boiling involved). *Ex vivo* chicken breast tissue was used and a sequence of two-dimensional radiofrequency (RF) signal was collected for each exposure as a function of time. For each frame in the RF sequence, one-dimensional cross correlation coefficient was calculated between every A-mode line of RF signal and the same line 5 seconds later. A series of experiments was performed with different HIFU treatment durations. The results showed that there was a decrease in the maximum coefficient value in the focal region during HIFU exposure, and a threshold value could be determined to be associated with the time that a thermal lesion was formed. Tissue dissection was performed to confirm the presence of a thermal lesion. This RF analysis technique has shown promise in detecting location and dimension of thermally-induced lesions, as well as being capable of real-time treatment monitoring to guarantee effective and efficient HIFU therapy.

10:45

5aBB7. Impact of temperature on bubbles excited by high intensity focused ultrasound. Wayne Kreider, Michael R. Bailey (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, wkreider@u.washington.edu), Oleg A. Sapozhnikov (Moscow State Univ., Moscow 119992, Russia), and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

Bubble-enhanced heating is a current topic of interest associated with high intensity focused ultrasound (HIFU). For HIFU treatments designed to utilize acoustic radiation from bubbles as a heating mechanism, it has been reported that useful bubble activity diminishes at elevated temperatures. To better understand and quantify this behavior, a model has been implemented that couples the thermodynamic state of a strongly driven spherical bubble with thermal conditions in the surrounding liquid. This model has been validated over a range of temperature conditions against experimental data from the collapses and rebounds of millimeter-sized bubbles. With this model, the response of a micron-sized bubble was simulated under exposure to MHz/MPa HIFU excitation, while various surrounding liquid temperatures were considered. Characterizing the bubble response through the power spectral density of pressure radiated from the bubble, model calculations suggest that bubble collapses are significantly attenuated at temperatures above about 70°C. For instance, the acoustically radiated energy at 80°C is an order of magnitude less than that at 20°C. These results suggest that the efficacy of bubble-enhanced heating may be limited to temperatures below 70°C. Moreover, temperature will affect hydrophone measurements used to passively assess cavitation activity. [Work supported by NIH DK43881 and NSBRI SMST01601.]

11:00

5aBB8. Development of a tomographic cavitation sensor for quality assessment of clinical high intensity focused ultrasound systems. Stuart Faragher, Miklós Gyöngy (IBME, Univ. of Oxford, ORCB, Oxford OX3 7DQ, UK), Mark Hodnett, Adam Shaw (Natl. Physical Lab., Teddington TW11 0LW, UK), and Constantin-C. Coussios (Univ. of Oxford, ORCB, Oxford OX3 7DQ, UK)

High-intensity focused ultrasound (HIFU) fields are known to nucleate and excite inertial and noninertial cavitation in tissue and tissue-mimicking materials once a threshold negative acoustic pressure is reached. In the context of ablative HIFU treatment, inertial cavitation has been correlated with significantly enhanced rates of heating, while in histotripsy, cavitation is the very mechanism that causes tissue damage. Characterizing the extent of the cavitation region produced by clinical HIFU devices is therefore important to ensure safe, efficient, and effective treatment. A novel, multielement sensor is being developed to enable accurate axial and radial mapping of the cavitation region during HIFU exposure by passive detection and tomographic reconstruction of the broadband emissions arising from bubble collapse. Computational modeling has shown that the application of a cross-correlation algorithm to simulated received signals has the potential to localise individual sources of emissions with submillimeter accuracy. Initial experimental validation of models has been conducted using a prototype device developed in collaboration with the National Physical Laboratory. Future work will involve the refinement of the sensor design and reconstruction algorithm to improve spatiotemporal resolution, along with the development of a tissue mimicking material which matches the acoustic properties and cavitation threshold of real tissue.

11:15

5aBB9. A Schlieren system for optical visualization of ultrasonic fields. Peter J. Kaczkowski, Michael R. Bailey, Vera A. Khokhlova, and Oleg A. Sapozhnikov (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, peter@apl.washington.edu)

Ultrasonic field mapping is an essential component of transducer characterization and of beam forming verification. Such measurements are commonly performed by displacing a hydrophone over a range of points within the field; these procedures can be time-consuming. A calibrated hydrophone can provide accurate measurements of the field, subject to limitations of bandwidth and aperture of the device. A rapid qualitative 2D measurement of the spatial acoustic field can be obtained by optical means, in which the change in optical index due to the presence of acoustic pressure is imaged using a schlieren approach. This technique illuminates a transparent refracting acoustic medium using a plane collimated source and then focuses the transmitted light using a lens or mirror. In the absence of acoustic field, all of the light focuses to a small spot; acoustically induced refractive index perturbations cause some of the light to focus elsewhere. Obscuring the primary focal spot of unperturbed light with a mask permits imaging only the perturbations in the acoustic medium. We will describe a mirror-based schlieren system for imaging continuous as well as pulsed fields and with color corresponding qualitatively to the intensity of the field. [Work supported by NIH CA109556 and EB007643.]

11:30

5aBB10. Improved range-discriminating ultrasonic vibrometer. James Martin, Michael Gray, and Peter Rogers (Georgia Inst. of Technol., School of Mech. Eng., Atlanta, GA 30332-0405)

Improvements have been made to a previously reported continuous-wave ultrasonic vibrometer with range discrimination capabilities. In its current realization, the vibrometer incorporates a high-speed 16-bit arbitrary waveform generator as a signal source. The waveform generator shares a sample clock with the data acquisition system so that both the real and apparent spectral purity of each of the tones in a multitone carrier signal is preserved in the measurement. The new configuration provides increased control over the characteristics of the transmitted signal. It permits the exploitation of the full bandwidth capabilities of all of the hardware components of the system by removing a limit to the number of tones in the carrier. It also permits the relative phases of individual tones to be optimized in order to reduce the crest factor of the transmitted signal and better exploit the dynamic range of other system components. A further improvement in dynamic range has been achieved with an analog subtraction of the transmitter-receiver crosstalk, which is normally the largest received-signal component, prior to digitization. The improved vibrometer has been used to image shear wave fields in both tissue phantoms and inert tissue samples. [Work supported by ONR.]

5aNS1. The City of Portland responds to urban gentrification through an investigation of noise sources within the boundaries of north Portland neighborhoods. Adam C. Jenkins and Julie A. Wiebusch (The Greenbusch Group, Inc., 1900 W. Nickerson St., Ste. 201, Seattle, WA 98119)

The North Portland area is a vibrant community, supporting residential populations, a wildlife reserve, and an active commerce. As Portland continues to attract new residents and residential areas expand in North Portland, the conflict between the residential desire for a peaceful environment and the commercial requirement to efficiently conduct business become more critical. The sustainability of the North Portland residential communites relies on planning decisions based on a well-defined understanding of the sound characteristics of the community. The City of Portland chose to study North Portland to better understand noise within its boundaries. The resulting noise mapping will serve as a tool for the City to use in future planning.

8:15

5aNS2. Noise mapping in Portland Oregon: The need to develop an approach to accurately depict the health impacts of short duration automotive racing noises emanating from a variety of motorized race events at the Portland International Racetrack facility. Paul van Orden (City of Portland Oregon, 1900 SW 4th Ave., Portland, OR 97201, pvanorden@ci.portland.or.us)

The City of Portland Oregon is in the final phase of completing its efforts to map one quadrant of the city in conjunction with the Greenbusch Group of Seattle Washington. The selection of this section of the city was identified for its notable concentration of noise sources ranging from the normal transportation related road, railway, and international airport sounds, to the unique and constantly varying tonal quality of automobile and motorcycle race groups at an international automotive raceway facility. The challenge to identify an appropriate method or standard to accurately depict the impact of these short term track races and drag races offers a unique opportunity to expand on the value of the noise mapping approach for long term urban planning efforts.

8:30

5aNS3. Prediction of noise from Portland International Raceway using environmental noise computer modeling techniques. Angus M. Deuchars (Arup Acoust., 560 Mission St., Ste. 700, San Francisco, CA 94105, angus.deuchars@arup.com)

An environmental noise computer model of Portland International Raceway has been constructed to evaluate noise mitigation at local noise sensitive receptors from making site wide changes to raceway infrastructure. There is little precedent of environmental noise computer modeling of raceways, and this paper presents the methodologies that were used to develop the computer model. Field measurements were made at the racetrack according to European Union Harmonoise methods to determine sound power levels of race vehicles; noise predictions were made using ISO 9613 pt 2 prediction model implemented using SOUNDPLAN software. Results from field measurements and predictions are presented to demonstrate accuracy of the computer model. Additionally, the innovative steps used to construct the computer model using sound plan are also presented.

8:45

5aNS4. A revised standard method for ground impedance measurement. Keith Attenborough and Shahram Taherzadeh (Dept. of Design, Development, Environment & Mater., The Open Univ., Milton Keynes MK7 6AA, UK, k.attenborough@open.ac.uk)

ANSI S1.18 (1998) for ground impedance measurement has been revised to combine the previously existing template method with direct deduction of impedance from data for the complex level difference between vertically separated microphones. It has been found that, despite the improved sensitivity at low frequencies that should be achievable through use of a longer range, the combined approach ceases to give reliable information for horizontal source-receiver separations of more than 1 m. The revised standard contains four worked examples: three grass-covered ground surfaces and a gravel road. The first example has been used to show that although use of consecutive measurements with a single microphone produces data that is usable with the template method, the phase information is not sufficiently robust to allow direct impedance deduction. In the three grassland examples, the widely used single parameter model is found to overpredict the real and imaginary parts of ground impedance at lower frequencies. The fourth example shows that the geometries prescribed in the standard are not appropriate for determining impedance spectra of relatively hard surfaces but are sufficient to establish that the surface is acoustically hard.

9:00

5aNS5. Sampling strategies for incorporating uncertainty and turbulent scattering into outdoor sound propagation calculations. Matthew S. Lewis, D. Keith Wilson (U.S. Engineer Res. and Development Ctr., 72 Lyme Rd., Hanover, NH 03755, D.Keith.Wilson@usace.army.mil), and Chris L. Pettit (U.S. Naval Acad., Annapolis, MD 21402)

The accuracy of mean sound-level estimates derived from different sampling methods is studied. The methods considered are Monte Carlo sampling (MCS), Latin Hypercube sampling (LHS), and Latinized Centroidal Voronoi Tessellation sampling (LCVTS). The goal is to determine which sampling method converges most rapidly to the actual mean sound level. The approach involves a model acoustic atmosphere, based on surface-layer similarity theory and a relaxation model for the ground, with sound fields calculated numerically with a parabolic equation solver. The range of consequences of epistemic uncertainty due to imperfect knowledge of the atmospheric and ground variables is examined through a simplified probabilistic model. Random (aleatory) uncertainty due to turbulent scattering also is considered. The samples are drawn randomly within the domain of uncertainty of the environmental variables. When only epistemic uncertainty is present owing to imprecise knowledge of the environmental variables, LCVTS is found to converge to an accurate estimate with the fewest number of samples, followed by LHS and then MCS. When random turbulent scattering is present, however, the sampling method has little effect on convergence.

9:15

5aNS6. Construction noise action area model. Larry J. Magnoni (Wash. St. Dept. of Trans., Env. Svs., Acoust., Air Quality, Energy Sec., 15700 Dayton Ave. N., PO Box 330310, Shoreline, WA 98133, magnonil@wsdot.wa.gov)

A model developed by the Washington State Department of Transportation to be used by biologists to determine the action area for highway construction projects is presented. The model conservatively estimates the distance at which construction noise would match ambient background sound levels. The model propagates the combined maximum sound level (Lmax) for project construction equipment spherically over the soft and hard site characteristics to a point where it would converge with the ambient hourly equivalent (Leq) sound level. The ambient Leq sound level can be input into the model from actual measurements, documented reference sources, or from a table based on population density [Federal Transit Authority (FTA) Noise Assessment Guidance (2006)]. The model then combines the ambient sound level with the traffic sound level based on the national mean emission curves. The input for traffic volume, vehicle type, and speed is propagated cylindrically from the source until the traffic source drops to the ambient level. A macro, that applies a general atmospheric and molecular absorption adjustment to the calculated distances, produces the action area circumference both graphically and numerically as it relates to each of the sound sources. [Work supported by the Federal Highway Administration (FHWA) (1978).]

5aNS7. Analysis of pile driver exhaust and impact noise. Edward Zechmann and Charles Hayden (Robert A. Taft Bldg., 4676 Columbia Pkwy., C-27, Cincinnati, OH 45226)

In July 2008, NIOSH accomplished a preliminary noise survey focused on gathering impulsive noise data from pile drivers. The purpose of the noise survey was to better understand the noise characteristics of pile drivers. NIOSH gathered time record data of H-beam piles being driven into hard rock. This data was used to characterize the frequency content of the major impulsive events (impact and exhaust cycles). Knowing the frequency content is necessary to apply existing or develop new noise controls, since many noise controls are frequency dependent. Gathering the frequency content of a pile driver's impulsive noise signal is typically difficult using off-the-shelf measurement and analysis equipment and software. Reliable time record data is necessary to confidently extract the frequency content from the signal. NIOSH has developed an Impulsive Noise Meter laptop program to properly gather and analyze these impulsive signals. By analyzing the third octave band peak levels of each impact and exhaust cycle of the pile driver operation, the frequency dependence was determined. Results of this analysis showed the frequency content varied as the pile was driven further into the ground. This implies that broad spectrum noise controls are necessary to control those noise emissions.

9:45

5aNS8. Are hybrid cars too quiet? Ryan L. Robart and Lawrence D. Rosenblum (Dept. of Psych., Univ. of California, Riverside, 900 University Ave., Riverside, CA 92521)

The increase in availability of alternative fuel vehicles has elicited concerns for pedestrians who might not hear the approach of these quieter cars. Three experiments tested the relative audibility of hybrid vehicles (in their electric mode) and internal combustion engine (ICE) cars. Binaural recordings were made of the cars approaching from either the right or left, at 5 mph. Subjects were asked to listen to these recordings over headphones and press one of two buttons indicating from which direction the car approached. Subjects' accuracies and reaction times were measured. The first experiment revealed that (sighted) subjects were able to determine the approach direction of the ICE cars substantially sooner than the hybrid cars. A second experiment added the natural background sounds of idling engines to the stimuli. The addition of background sound disproportionately hindered perception of the hybrid cars, so that they could not be localized until very close. A final experiment testing both sets of stimuli with blind subjects revealed the same pattern of results. Implications of these results for pedestrian safety will be discussed. [Work supported by a grant from the National Federation for the Blind.]

10:15

5aNS9. Impulse noise reduction for hearing protectors. William Murphy (Natl. Inst. for Occupational Safety and Health, Div. Appllied Res. and Technol., Hearing Loss Prevention Team, 4676 Columbia Pkwy., MS C-27, Cincinnati, OH 45226-1998, wjm4@cdc.gov)

In 2009, the United States Environmental Protection Agency will propose a revision to the federal regulation for the labeling of hearing protection devices, 40 CFR 211 Subpart B. One of the new features of the proposed rule was the measurement of an impulse noise reduction rating for hearing protection devices. Measurement of impulsive sounds is challenging technically from an acoustics perspective. This paper will report on the performance of an acoustic shock tube used to generate impulses between 140 and 170 dB peak sound pressure level. The calibration methods for the microphones will be discussed and the measurements for a variety of hearing protectors will be presented. Typical earmuffs are capable of impulsive noise reduction ratings of between 20 and 35 dB. Earplugs provide similar range of performance. Combinations of earmuff and earplug have yielded impulse peak reductions of more than 50 dB. The reduction of the impulse peak level should provide a means to predict exposure at the ear when a hearing protector is worn in an impulsive noise environment.

10:30

5aNS10. Noise barriers based on recycled materials. Jose Sanchez-Dehesa, Victor Garcia-Chocano, Daniel Torrent, Francisco Cervera, and Suitberto Cabrera (Wave Phenomena Group, Polytechnic Univ. of Valencia, Camino de vera s.n., ES-46022 Valencia, Spain, jsdehesa@upvnet.upv.es)

Two-dimensional sonic crystals consisting of arrays of cylinders fabricated with recycled materials (rubber crumb) are proposed to reduce efficiently the noise. The attenuation by these barriers is produced by a combination of sound absorption by the rubber crumb and Bragg reflection by the ordered cylinders. Experiments performed in an anechoic chamber support the predictions by the multiple scattering theory. An optimization method is also reported to develop sound barriers for traffic noise. [Work supported by Spanish MICIIN.]

10:45

5aNS11. Quenching of bandgaps by flow noise. Jose Sanchez-Dehesa (Wave Phenomena Group, Polythecnic Univ. of Valencia, Camino de vera s.n., Spain, ES-46022, jsdehesa@upvnet.upv.es), Tamer Elnady, Adel Elsabbagh, Wael Akl, Osama Mohamady (Ain Shams Univ., Cairo, Egypt), Victor Garcia-Chocano, Daniel Torrent, and Francisco Cervera (Polythecnic Univ. of Valencia, ES-46022, Spain)

We report an experimental study of acoustic effects produced by wind impinging on noise barriers based on two-dimensional sonic crystals with square symmetry. We found that the attenuation strength of sonic-crystal-bandgaps decreases for increasing values of low speed. A quenching of the acoustic bandgap appears at a certain speed value that depends of the barrier filling ratio. For increasing values of low speed, the data indicate that the barrier becomes in a sound source because of its interaction with the wind. We conclude that flow noise has paramount importance in designing acoustic barriers based on sonic crystals. [Work supported by Spanish AECI.]

5aNS12. Leakage identification for a vehicle firewall sound transmission by beamforming technique. Yuri Ribeiro (GM do Brasil, Indaiatuba, Sao Paulo, Brazil), William Fonseca, and Gerges Samir (Fed. Univ. of Santa Catarina, Florianopolis, SC, Brazil)

The acoustic phased array is a powerful tool for identification and quantification of noise sources on complex systems. Acoustic sources generate waves which propagate through space to the N microphones of the array. The acoustic pressures are sampled and converted to time series data and processed using either time domain or frequency domain delayed and averaged. The output of signal processing is a colored image with relative sound pressure levels distribution. In this paper application of beamforming technique is used to identify leakage areas in a vehicle firewall. Two acoustic rooms are used and the firewall was installed in the apertures inbetween with careful control of noise flank paths. Source room was excited with white noise and a phased array microphone was used to measure the sound field in the anechoic receiving room. The firewall was evaluated both with all holes sealed and with the regular pass-through components installed. Two different acoustic insulators were also tested on the firewall. The results show clearly the areas of leakage with relative noise levels at each test configuration.

5aPA1. Using sound radiation to characterize binary collisions of polypropylene balls. J. Riner and A. Petculescu (Dept. of Phys., Univ. of Louisiana, P.O. Box 44210, Lafayette, LA 70504)

An acoustic method to check the validity of Hertz's law and characterize the source characteristics of binary collisions is proposed. The technique uses a goniometer equipped with a microphone to detect the sound produced by collisions between two solid polypropylene balls. The collisions are the result of a projectile ball falling from rest and striking a rigidly mounted target ball. The acoustic field in both the horizontal and the vertical plane is sampled and the maximum and minimum pressures, as well as frequency content, are studied. The power spectrum has a dominant peak at approximately 10 kHz. Radiation in the horizontal plane is found to be mostly symmetric about the collision point while there is an observed asymmetry in the vertical plane, which can be used to infer the characteristics of the source of audible sound. The acoustic signals are likely generated by the relative accelerations of the two balls and not by the normal vibrational modes, which were measured to start at about 73 kHz. [Work funded by the Louisiana Board of Regents.]

8:45

5aPA2. Pulse propagation in a hyperlattice. Joseph Dickey (Adv. Technol. Lab., The Johns Hopkins Univ., 810 Wyman Park Dr., Baltimore, MD 21211)

The classical dynamics and pulse propagation are presented for a series of latticelike structures whose spatial dimensionality ranges from one to four: four representing a hyperlattice. The lattices are connected 1-D wave bearing systems of varying lengths and can illuminate some aspects of higher dimension structures. Short pulses are launched at an arbitrary point, reverberate throughout the entire structure, and detected at another point. Some aspects of increasing dimensionality are illustrated with particular emphasis on the transition from three to four spatial dimensions. In a hypothetical 4-D world where only three are observable, the classical conservation laws and causality do not hold. The lack of causality is illustrated at each step in dimensionality by showing the "unexpected" pulse returns from the next higher dimension.

9:00

5aPA3. Scattering of compressional waves by a cavity in an elastic solid: Geometric interpretation and beam illumination. Likun Zhang and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, zhanglikun@wsu.edu)

Aspects of the scattering of short-wavelength compressional waves by an empty spherical cavity in an elastic solid may be predicted geometrically from the elastic wave reflection coefficient for a plane surface and the curvature of the reflecting surface. When the outgoing wave is a shear wave, it is necessary to include the modified ray-tube parameters associated with mode conversion. Related geometrical considerations are also helpful for interpreting the scattering of a compressional wave Bessel beam by an empty spherical cavity centered on the beam in an elastic solid. The exact solution in that case follows from a generalization of the scattering analysis for acoustic Bessel beams [P. L. Marston, J. Acoust. Soc. Am. **121**, 753–758 (2007)]. A modified analysis gives the directional dependence of the shear waves resulting from mode conversion for a cavity on the axis of a compressional wave Bessel beam. For both plane wave and Bessel beam illumination, the scattering pattern can depend strongly on the value of the Poisson ratio of the solid.

9:15

5aPA4. Measurement of acoustic wave frequency by Bragg light diffraction. R. Farkhad Akhmedzhanov (Dept. of Phys., Navoi State Mining Inst., 27a Yuzhnaya St., Navoi 210100, Uzbekistan, farkhad2@yahoo.com)

The new technology is offered for measurement of acoustic wave frequency. The method is based on using the Bragg light diffraction on the hypersonic transversal acoustic wave in a gyrotropic crystal. As is well known, the intensity of diffracted light in this case is strongly dependent from the quantity of specific rotation of polarization vector. As a result, using the standard calibration of light intensity it is possible to measure the changes of acoustic wave frequency. Measurements of the diffracted light intensity have been carried out in several points along the direction of the acoustic wave propagation. The applied sample of LiNbO3 was oriented along the crystallographic axis of the third order with the accuracy of 10′. The plane-polarized transverse acoustic waves were excited in the frequency range from 900 MHz to 1.2 GHz. The results obtained at the average frequency 1.0 GHz were shown, that the intensity of diffracted light intensity is sensitive parameter to the change of the transverse acoustic wave frequency. The dependence of the diffracted light intensity from the quantity of specific rotation frequency was used for determination of the acoustic wave frequency by the appropriate model equation accurate within 0.1%.

9:30

5aPA5. Acoustic cavities with radial sonic crystals. Daniel Torrent and José Sánchez-Dehesa (Wave Phenomena Group, Polytechnic Univ. of Valencia, Camino de Vera s.n. ES-46022, datorma1@upvnet.upv.es)

Radial sonic crystals in two and three dimensions are introduced. These materials have the property of leaving the acoustic wave equation invariant under radial displacements, and then they present a "radial band structure" similar to that of one dimensional sonic crystals. Finite shells of radial sonic crystals can be used as resonant cavities. The radiation pattern of these cavities will be reported. For example, it will be shown that a cavity can be used as a dipolar source by placing a monopole inside the cavity. Finally, physical realization of radial sonic crystals is discussed in two and three dimensions [Work supported by Spanish MICIIN and Consolider Program.]

9:45

5aPA6. Acoustic cloaking in two and three dimensions. Daniel Torrent and José Sánchez-Dehesa (Wave Phenomena Group, Polytechnic Univ. of Valencia, Camino de Vera s.n. ES-46022, datorma1@upvnet.upv.es)

The cloaking theory is analyzed in two and three dimensions. It is shown that cloaks require materials with some special properties not known in nature, mainly, they need to be fluid-like materials with anisotropic, inhomogeneous, and locally divergent acoustic properties. The anisotropy problem is solved with the help of the so-called "metamaterials", the inhomogeneous behavior is implemented with stratified scatterers and the divergence of the parameters is avoided with the concept of "imperfect cloaks", which transforms the scattering cross section of an object of radius R in that of an object of radius $R' \ll R$. [Work supported by the Spanish MICIIN and the Consolider Program.]

8:35

5aUW1. The effects of scattering from heterogeneities in porosity during sound propagation through sand sediments. Brian T. Hefner, Darrell R. Jackson (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698), and Joseph Calantoni (Naval Res. Lab., Stennis Space Ctr., MS 39529)

Sand sediments are inherently heterogeneous due to the random packing of the grains. For sound propagation through fluid-saturated sediments, these heterogeneities may lead to scattering from the coherent fast compressional wave into incoherent slow compressional waves or shear waves. This loss of energy from the fast compressional wave may account for the increase in high-frequency attenuation above that predicted by Biot theory. In a previous talk, we presented preliminary results of applying perturbation theory to Biot theory in order to model scattering from heterogeneities in the porosity [Hefner *et al.*, J. Acoust. Soc. Am. **120**, 3098 (2006)]. This theory has since been refined to properly account for scattering into both the slow compressional wave and the shear wave. In order to apply this theory to a given sand sediment, knowledge of the covariance function for the spatial variations in the porosity is required. Results of the theory will be presented for several different analytic covariance functions, as well as for covariance functions measured in simulated and real unconsolidated granular materials.

8:50

5aUW2. Sand acoustics: The effective density fluid model, Pierce/Carey expressions, and inferences for porous media modeling. Kevin Williams (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, williams@apl.washington.edu)

Recently, Pierce and Carey [JASA-EL **124**, EL308–EL312 (2008)], presented a low-frequency analysis of sound propagation in sand/silty sediments. Here, equivalent expressions are presented using a low frequency expansion of an unconsolidated version of Biot porous medium theory (i.e., the effective density fluid model (EDFM)). The resulting expression for attenuation allows identfication of the nondimensional parameter in the Pierce /Carey result in terms of physical parameters. One of the important aspects of the Pierce/Carey derivation is that they show how to account for the inertial effects due to the relative grain/fluid density. The agreement between the Pierce/Carrey and EDFM low-frequency attenuation expressions motivates further frequency and relative grain/fluid density analyses of attenuation and sound speed. The general inference of these analyses is that any model that ignores inertial effects due to differences in grain and fluid density is missing a key piece of physics that makes it incomplete. Wood's equation is one such model and since the Buckingham model uses Wood's equation, it is another example. The point being that the use of the mass density to handle inertia in a porous medium is a low-frequency approximation. [Work supported by the Office of Naval Research.]

9:05

5aUW3. Acoustic measurement of fines. Wayne Carpenter (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, 1 Coliseum Dr., University, MS 38677, wocarpen@olemiss.edu), Daniel Wren, Roger Kuhnle (USDA-ARS-NSL, Oxford, MS 38655), and James Chambers (Univ. of Mississippi, University, MS 38677)

The measurement of sediment particles $<$100 microns in diameter suspended in water has received little attention; however, particles of this size can account for a large fraction of the material transported in streams and rivers. In order to advance the current state of knowledge, the use of acoustic techniques as a surrogate measurement for the concentration of fine sediment particles in water is investigated. Both backscatter and attenuation will be evaluated as potential measurement techniques using a laboratory tank. Based on experience with the use of 1–5 MHz frequencies for backscatter measurements of particles in the 100–1000 micron size range, initial work will focus on the use of a frequency of approximately 20 MHz. The attenuation and backscatter due to a range of concentrations of bentonite and kaolinite will be reported.

9:20

5aUW4. High-frequency acoustic properties of water-saturated sediments: Laboratory study. Jean-Pierre Sessarego, Rgine Guillermin (CNRS/LMA, 31 Chemin Joseph Aiguier, 13402 Marseille, France), and Anatoly N Ivakin (Univ. of Washington, Seattle, WA 98105)

This study was performed in controlled laboratory conditions using several broadband transducers to cover a wide frequency range from 200 kHz to 3MHz. Various types of sediments were used: natural medium and coarse sand, and glass beads with corresponding mean sizes. Sound speed and attenuation were measured and compared with predictions of Biot theory. The

theory failed to predict both high attenuation and negative dispersion of sound speed observed at very high frequencies (above 500 kHz for medium sands), which can be assumed an effect of strong grain scattering. All the measurements were performed at different times to ensure the repeatability of the results. A comparison of results obtained for natural sands with those for artificial sediment (glass beads) of the same mean size, allowed observing the influence of the grain shape on the reflected and backscattered signals. Also, the influence of the transducer directivity diagram on the sediment reflectivity was observed. This effect is discussed and shown to be essential in the case of strong incoherent scattering observed for coarse sediments. Finally, the time-frequency contents of the reflected signal were analyzed. It was found to be very sensitive to the granular structure of the sediment. [Work supported by CNRS and ONR.]

9:35

5aUW5. Direct numerical simulation of the acoustic virtual mass of granular media. Joseph Calantoni (Marine Geosciences Div. Naval Res. Lab., Stennis Space Ctr., MS 39529, joe.calantoni@nrlssc.navy.mil) and B. Todd Hefner (Univ. of Washington, Seattle, WA 98105-6698)

The theory of acoustic virtual mass in granular media hypothesizes that during sound propagation, energy is transferred out of the direction of propagation and into rotational and transverse degrees of freedom that act as an additional virtual mass, thus decreasing the sound speed. We use a discrete element model that explicitly simulates the motions and interactions of every particle in a finite volume to examine the theory of acoustic virtual mass. Simulations are fully three-dimensional where the physical properties, such as size, density, and shape (typically spherical), of every grain may be uniquely specified. Normal and tangential forces at grain-grain contact points are modeled with springs and friction, respectively. Depending on the material of interest (e.g., quartz grains), several normal contact force laws are available including linear elastic, linear elastoplastic, and Hertzian. Likewise, the tangential contact force is typically modeled with a stick-slip behavior using a linear spring and friction, but other variations are available. Sound speed and attenuation are calculated by propagation of pulses through the simulated materials and these results are compared to the predictions of theory with and without the virtual mass term.

9:50

5aUW6. Synthesizing the shape of sand grains. David R. Barclay and Michael J. Buckingham (Scripps Inst. of Oceanogr., Marine Phys. Lab., Univ. of California, San Diego, 9500 Gilman Dr., La Jolla, CA 92093-0238, dbarclay@mpl.ucsd.edu)

Digitized outlines of sand grains from a dozen locations have been acquired using an optical microscope. A Fourier decomposition of the outline is calculated providing a spectral description of the grain's shape. By averaging over several hundred grains, the normalized power spectrum of each sand sample is returned. The desert sands, beach sands, and marine sediments measured all exhibit the same inverse-power-law dependence on the harmonic number, n, varying as $n^{-10/3}$ for $2 \leqslant n \leqslant 20$. This "universal" spectrum provides the basis of a numerical technique for synthesizing the irregular outline of a sand grain: the outline is represented as a random pulse train in which identically shaped microasperities, with normally distributed amplitudes, are randomly superimposed on the perimeter of a circle. Carson's theorem links the power spectrum of an individual microasperity to that of the real grains and constrains the synthetic outlines to have the identical statistical properties as the outlines of the measured samples. Visually, it is difficult to distinguish between the synthesized and real outlines. This numerical technique for synthesizing irregular outlines of grains has potential for investigating the random-packing of realistically rough particles through computer simulation. [Work supported by the Office of Naval Research.]

10:20

5aUW7. Uncertainty estimation of sound attenuation in marine sediments at low frequencies. Yong-Min Jiang and N. Ross Chapman (School of Earth and Ocean Sci. , Univ. of Victoria, P.O. Box 3055 Victoria, BC, V8W 3P6 Canada, minj@uvic.ca)

Marine sediment attenuation at low frequencies (under 5 kHz) is generally difficult to be directly measured by *in situ* probes embedded in the sediment, partly due to the very short propagation distances. An alternate experimental technique is to use single bottom bounce signals received by a vertical line array. The frequency dependence of the sediment attenuation is first obtained by comparing the amplitude differences of the sea floor reflection and the sub bottom layer reflection at different frequencies. The absolute attenuation is then obtained by using the previously estimated sound speed and layer thickness. Inherently there is uncertainty introduced in each stage of the attenuation estimation procedure. To evaluate the uncertainty of the attenuation estimate, the standard deviation of the signal fluctuation is mapped to the intermediate result first, and then Bayesian inversion results of the sound speed and the layer thickness are included in the final attenuation estimates. This uncertainty analysis is demonstrated by the estimation of the sediment attenuation from the low frequency chirp data collected in a variable water column environment in the Shallow Water 06 experiment. [Work supported by ONR Ocean Acoustics.]

10:35

5aUW8. On the use of acoustic particle motion in geoacoustic inversion. Steven E. Crocker (Naval Undersea Warfare Ctr., 1176 Howell St. Newport, RI 02841), James H. Miller (Univ. of Rhode Island, Narragansett, RI 02882), Paul C. Hines, and John C. Osler (Defence R&D Canada Atlantic, Dartmouth, NS B2Y 3Z7, Canada)

Geoacoustic inversion estimates sediment properties based on one or more parameters of an observed acoustic field via inverse mathematical methods. The observed acoustic parameter is usually derived from the acoustic pressure measured at one or more locations. Recent advances in acoustic sensor technology have enabled the simultaneous measurement of the acoustic pressure and particle motion in three dimensions. The additional information provided by such acoustic vector sensors can be used to improve the performance of existing and novel geoacoustic inversion techniques. Current research seeks to use the additional information that is provided by the acoustic vector sensor to pose new inverse problems for the estimation of seabed sediment properties. In particular, data collected during the Sediment Acoustics Experiment 2004 (SAX04) included acoustic pressure and particle acceleration from a small number of acoustic vector sensors arranged in a vertical line, spanning the water-sediment interface. A variety of waveforms were transmitted into the seabed to measure the direct, reflected, and transmitted waves. Experiment details, forward modeling, inversion methods, and results are discussed. [Work supported by ONR.]

10:50

5aUW9. Study of interface wave generation and shear wave velocity estimation. Hefeng Dong (Dept. of Elect. and Telecom., Norwegian Univ. of Sci. and Technol., NTNU, No-7491 Trondheim, Norway and School of Earth and Ocean Sci., Univ. of Victoria, BC, V8W 3P6 Canada) and Ross Chapman (Univ. of Victoria, BC, V8W 3P6 Canada)

Estimation of the shear wave velocity profile versus depth and shear wave attenuation in the upper sediment layers has been an important research topic in underwater acoustics. The shear wave velocity profile is insensitive to hydrophone data measured in water column, while dispersion of the interface wave propagating along the water and sea bottom boundary (the Scholte wave) is closely related to shear wave velocity variation with depth in the upper sediment layers. However, due to the exponential decay of the amplitude of the interface waves, there may be no interface waves generated and recorded in a conventional underwater experiment configuration where the sources and receivers (vertical and/or horizontal hydrophone array) are located in the water column with distance (measured by wavelength of the interface wave) away from water bottom interface. In this paper the conditions in which interface waves can be generated, recorded, and visualized are studied by numerical experiments in the underwater environment. The conditions include source strength, frequency band, source–receiver configuration, and signal-to-noise ratio, etc. Examples are given for estimating of shear wave velocity profile with depth by inverting dispersion curves of recorded interface waves in real data. [Work supported by NFR under Contract No. 186923/I30.]

4pSW1. Acoustic correlates of Tone 3 and Tone 4 in Mandarin. Chia-Hsin Yeh (1627 Spartan Village Apt. L, East Lansing, MI 48823)

Perceptual similarity between Tone 2 and Tone 3 in Mandarin was widely discussed in previous studies [Moore and Jongman (1997), Huang (2004), Bent (2005)]. Other tonal contrasts are hardly addressed. However, recent findings of Mandarin tones show that Tone 3 and Tone 4 are confusing in terms of descent slope. A big difference between previous studies and current ones is kinds of Tone 3 stimuli: previous studies used isolated Tone 3, namely, 214, and current studies used derived Tone 3, namely, 21, which is coarticulated with other tones. Spectrographic analysis was conducted. Descent slope and height of starting pitch were found critical between Tone 4 and derived Tone 3. Then three continua with ten instances for each were synthesized in respect of three different factors, descent slope, height of starting pitch, and height of ending pitch, which makes 30 stimuli total in three experiments, an AXB discrimination test, an identification test, and a lexical decision test. Results show that starting pitch height is a salient acoustic factor for 30 Mandarin natives, although descent slope was predicted more important. In addition, lexicon has an influence on ambiguous instances between endpoints of Tone 3 and Tone 4. Current findings may make contributions to understanding of perception, articulation, and lexicon during speech processing.

4pSW2. Intelligibility of foreign-accented speech in noise for younger and older adults. Sarah Hargus Ferguson (Dept. of Speech-Lang.-Hearing: Sci. and Disord., Univ. of Kansas, Dole Ctr., 1000 Sunnyside Ave., Rm. 3001, Lawrence, KS 66045, safergus@ku.edu), Kyung Ae Keum, Allard Jongman, and Joan A. Sereno (Univ. of Kansas, Lawrence, KS 66045)

In a previous experiment [Ferguson *et al.*, J. Acoust. Soc. Am. **118**, 1932 (2005)], young listeners with normal hearing, older adults with essentially normal hearing, and older adults with hearing loss were found to be similarly affected by the presence of a foreign accent on a word identification task in various listening conditions. This result stands in sharp contrast with an extensive literature demonstrating that the negative effect of speech distortions such as noise, reverberation, and time compression is disproportionately great for older versus younger adults. The conclusions of the previous study, however, were tempered by the presence of floor effects in the data for the older adults with hearing loss identifying accented speech in noise (12-talker babble at a signal-to-babble ratio of +3 dB). The present experiment extended the earlier one by presenting the same monosyllabic word materials to new groups of young normal, elderly normal, and elderly hearing-impaired listeners in three new signal-to-babble ratios: +6 dB, +9 dB, and +12 dB. The results will be discussed in terms of their implications for older adults interacting with foreign-accented speakers in healthcare settings. [Project supported by University of Kansas General Research Fund.]

4pSW3. The aquisition of sonorant voicing. Jagoda Sieczkowska (Inst. of Nat. Lang. Processing, Univ. of Stuttgart, Azenbergstr. 12 D-70174 Stuttgart, Germany, jagoda.sieczkowska@ims.uni-stuttgart.de)

In the view of Exemplar Theory phonetic variants of words are stored by speakers in their memory as a set of exemplars organized into clusters and grow stronger or decay over time depending on language experience (Bybee, 2002). In Polish and French sonorant consonants in clusters are devoiced word finally, which does not occur in German and English because of phonotactical constraints. A study based on automatic speech alignment and voicing profile extraction from Polish, French, German, and English speech corpuses aims at defining voicing sonorant temporal structure and voicing profile acquisition. The hypothesis is that Polish and French native speakers transfer their L1 exemplars during L2 acquisition of English and German and thus devoice sonorant. After extracting voicing profiles from recordings of native Polish and French speakers speaking English and German as an L2/L3, comparison of voicing profiles of English and German native speakers will be made in order to define the exemplar transfer.

4pSW4. Perceptual adaptation to sinewave-vocoded speech across languages. Tessa Bent (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, tbent@indiana.edu), Jeremy L. Loebach (Macalester College, Saint Paul, MN 55105), Lawrence Phillips, and David B. Pisoni (Indiana Univ., Bloomington, IN 47405)

Listeners rapidly adapt to many forms of degraded speech. What level of information drives this adaptation (e.g., acoustic, phonetic, lexical, syntactic), however, remains an open question. In the present study, three groups of listeners were passively exposed to sinewave-vocoded speech in one of three languages (English, German, or Mandarin) to manipulate the level(s) of information shared between the training languages and testing language (English). Two additional groups were also included to control for procedural learning effects. One control group received no training, while the other control group was trained with spectrally rotated English materials. After training, all listeners transcribed eight-channel sinewave-vocoded English sentences. The results demonstrated that listeners exposed to German materials performed equivalently to listeners exposed to English materials. However, listeners exposed to Mandarin materials showed an intermediate level of performance; their scores were not significantly different from the German or English groups but were also not significantly different from the two control groups. These results suggest that lexical access is not necessary for perceptual adaptation to degraded speech, but rather similar phonetic structure between the training and testing languages underlies adaptation to degraded speech. [Work supported by NIH-NIDCD T32 DC-00012 and R01 DC-000111.]

4pSW5. Assessment of perceptual assimilation before and after training. James D. Harnsberger (Dept. of Commun. Sci. and Disord., Univ. of Florida, Gainesville, FL 32611, jharns@ufl.edu)

Many non-native speech sounds are challenging to perceive and, ultimately, to acquire. The development of a model of cross-language speech perception and learning has been hampered by, among other issues, the high variability commonly observed in the perceptual assimilation of non-native contrasts due to phonetic context, talker, and a variety of indexical properties of speech. This variability may reflect persistent patterns in perception that influence learning, or it may represent only an early sensitivity to low-level phonetic detail that is attenuated as experience increases. To examine this issue, the perceptual assimilation by native speakers of American English of a variety of voicing and place contrasts from Hindi was assessed be-

fore and after training in a paired-associate word learning task. Training utilized tokens from four of the six talkers used in perceptual assimilation tasks. The purpose of the study was to determine whether or not assimilation patterns could be greatly modified and/or simplified over the course of word learning in the laboratory. If limited training resulted in large changes in perceptual assimilations, then models of cross-language speech perception and learning will need to rely on assimilation data elicited via procedures that result in stable and repeatable patterns.

4pSW6. Production of disyllabic Mandarin tones by children. Puisan Wong (Dept. of Speech Commun. Arts and Sci., Brooklyn College, CUNY, 2900 Bedford Ave., Brooklyn, NY 11210, pswRes.@gmail.com) and Winifred Strange (CUNY Grad Ctr., New York, NY 10016)

Two- to six-year-old children's productions of Mandarin lexical tones in familiar disyllabic words were examined to determine the time course of tone development and the effect of complexity of fundamental frequency contours (f0) on rate of acquisition. Disyllabic tone (DT) productions of 44 children and 12 of their mothers were elicited in a picture naming task and were low-pass filtered to eliminate lexical information. Judges categorized the DTs based on the filtered stimuli without lexical support. Adults' and children's DTs were categorized with 96% and 65% accuracy, respectively. Tone accuracy increased while intersubject variability decreased with age. Children as old as 6 years did not attain adultlike accuracy. Different DT combinations developed at different rates. DTs with more complex f0 contours were more difficult for children. Substitution patterns and acoustic analysis revealed that when producing tones with large transitions at the syllable boundary, children tended to modify the f0 in the first syllable to reduce the f0 shift at the boundary of the first and second syllable, resulting in more errors in the tones in the first syllable than in the second syllable. The results suggest physiological constraints on tone development. [Work supported by NIH 5F31DC8470 and NSF.]

4pSW7. Effectiveness of a perceptually weighted measure on automatic evaluation of a foreign accent in a second language. Hiroaki Kato (NICT/ATR, 2-2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto 619-0288, Japan, kato@atr.jp), Shizuka Nakamura (GITI, Waseda Univ., Shinjuku-ku, Tokyo 169-0051, Japan), Shigeki Matsuda (NICT/ATR), Minoru Tsuzaki (Kyoto City Univ. Arts, Nishikyo-ku, Kyoto 610-1197, Japan), and Yoshinori Sagisaka (GITI, Waseda Univ./NICT, Tokyo, Japan)

An empirical study is carried out to achieve a computer-based methodology for evaluating a speaker's accent in a second language as an alternative to a native-speaker tutor. Its primary target is the disfluency in the temporal aspects of an English learner's speech. Conventional approaches commonly use measures based solely on the acoustic features of given speech, such as segmental duration differences between learners and reference native speakers. However, our auditory system, unlike a microphone, is not transparent: it does not send incoming acoustic signals into the brain without any treatment. Therefore, this study uses auditory perceptual characteristics as weighting factors on the conventional measure. These are the loudness of the corresponding speech segment and the magnitude of the jump in loudness between this target segment and each of the two adjacent speech segments. These factors were originally found through general psychoacoustical procedures [H. Kato et al., JASA, **101**, 2311–2322 (1997); **104**, 540–549 (1998); **111**, 387–400 (2002)], so they are applicable to any speech signal despite the difference in language. Experiments show that these weightings dramatically improve evaluation performance. The contribution of psychoacoustics to evaluation methodology of second language speech is also discussed. [Work supported by RISE project, Waseda Univ. and KAKENHI 20300069, JSPS.]

4pSW8. Effects of "catch" trials on the discrimination of American English vowels by native Japanese speakers. Takeshi Nozawa (Lang. Education Cntr., Faculty of Economics, Ritsumeikan Univ. 1-1-1 Nojihigashi, Kusatsu, Shiga 525-8577, Japan)

Native Japanese speakers' ability to discriminate American English vowels was tested in two different formats, in both of which they heard three stimuli per trial. The three stimuli in each trial were produced by three different talkers. In AXB format, subjects were to decide if the second stimulus included categorically the same vowel as the first or the third stimulus. In other words, the subjects knew that one of the three stimuli was categorically different from the other two. In the other format, the subjects heard three stimuli in each trial, and chose one stimulus that includes a categorically different vowel from the other two. Each vowel contrast was tested by different trials which contained an odd item out, and catch trials which contained three tokens each from each of the vowel contrast pairs. Subjects were visually presented with four boxes on a computer screen with the numbers 1, 2, and 3, and "No." The "No" button was provided when no differences were detected The results reveal that with catch trials included, discriminating American English vowels is a lot more difficult. The results imply the Japanese subjects' susceptibility to talker variance and inability to discriminate American English vowels categorically.

4pSW9. A twin study of speech perception and production in first and second language among Chinese children learning English as a second language. Simpson Wai-Lap Wong, Dorothy Bishop (Dept. of Experimental Psych., Univ. of Oxford, S. Parks Rd., Oxford, OX1 3UD, UK, wlswong@gmail.com), and Connie Suk-Han Ho (Univ. of Hong Kong, Hong Kong)

The faculty of language processing in our brain develops with the constraint of our genetic dispositions and also our experiences. Do the same genetic influences affect learning of phonology in L1 and L2? This study examines the genetic and environmental effects on the individual differences on L1 and L2 speech perception and production among Chinese children learning English as a second language. By employing a twin-study design, 150 pairs of monozygotic and 150 pairs of same-sex dizygotic twins aged from 4 to 11 were tested. Children's speech perception and production in both languages were assessed with an AXB speech perception task of minimal word pairs and two picture naming tasks, respectively. Children's nonverbal IQ was also measured. Scores of accuracy will be computed for each task. Analyses will be conducted to consider the relationship between accuracy in perception and production in L1 and L2, to estimate the extent of genetic contribution to speech perception, and to determine whether heritable individual differences are accounted for by a common factor, or whether different factors influence proficiency in L1 and L2.

4pSW10. Lexical frequency, orthographic information, and first-language effects on second-language pronunciation. Ron I. Thomson (Dept. of Appl. Linguist., Brock Univ., 500 Glenridge Ave., St. Catharines, ON L2S 3A1, Canada, rthomson@brocku.ca) and Talia Isaacs (McGill Univ., Montreal, QC H3A 1Y2, Canada)

In L2 speech learning, lexical frequency may play a facilitative role, whereby perception and production of sounds found in high-frequency lexical items will develop before the perception and production of the same categories found in low-frequency lexical items (see Munro and Derwing, 2008). Orthographic information may also facilitate learning by disambiguating L2 sounds (see Erdener and Burnham, 2005), particularly in known words. This study examines the role of lexical frequency, orthographic information, and a learner's L1 in the development of L2 speech perception and production. Thirty-eight Mandarin and Slavic participants were asked to repeat a word list comprising ten target English vowels, each embedded in three separate monosyllabic verbs and varying in lexical frequency. Recordings of the L2 productions were obtained under three counter-balanced conditions: (1) after hearing an auditory prompt accompanied by the written form of the word; (2) after hearing an auditory prompt with no written form provided; and (3) with no auditory prompt but the written form provided. To measure L2 performance, L1 English listeners were asked to identify the vowel they perceived in each recorded item. Results were examined to determine what influence lexical frequency and orthographic information might have had on L2 performance.

4pSW11. A closer look at perceptual epenthesis in cross-language perception. Lisa Davidson and Jason Shaw (Dept. of Linguist., New York Univ., 726 Broadway, New York, NY 10003, lisa.davidson@nyu.edu)

Previous studies have shown that listeners have difficulty distinguishing non-native CC sequences from their CVC counterparts (e.g. Japanese [ebzo]-[ebuzo], English [zgamo]-[zəgamo]). Some have argued that the phonology "repairs" non-native consonant clusters with vowel insertion ("perceptual epenthesis"), causing listeners to respond that CC and CVC sequences are the same. Production studies, however, have shown that speak-

ers produce non-native CC sequences many ways, including epenthesis, changing C1, deleting C1, and prothesis. To test whether these other repairs of non-native clusters are also difficult to distinguish, English listeners (n=37) participated in an AX discrimination task that paired C1CVCV stimuli with CəCVCV (epenthesis), əCCVCV (prothesis), CVCV (deletion), or C2CVCV (C1 change). Each of these repairs caused some difficulty and there was an interaction between repair type and manner combination (stop-stop, stop-nasal, fricative-stop, fricative-nasal). Listeners were more accurate when C1 was deleted (81% accurate), followed by epenthetic and C1 changes (both 77%), then by prothesis (59%). Furthermore, compared to previous studies testing only the epenthetic repair, presenting listeners with various repair types dramatically improves discrimination in the epenthesis condition. These results indicate that perceptual epenthesis may be a task effect and that top-down phonological influences are more complex than previously assumed. [Research supported by NSF.]

4pSW12. Native and non-native clear speech production. Rajka Smiljanic (Linguist., Univ. of Texas at Austin, 1 University Station B5100, Austin, TX 78712-0198) and Ann Bradlow (Northwestern Univ., Evanston, IL 60208)

Previous work established that both native and non-native clear speech increase intelligibility for native and proficient non-native listeners. However, non-native clear speech enhanced intelligibility less than native clear speech. In this study, we examine native and non-native conversational and clear speech productions with an eye on the differences in hyperarticulation strategies that may underlie a smaller clear speech intelligibility benefit. Results revealed a slower conversational speaking rate for non-native talkers compared with native talkers. Clear speaking rate was similar for both groups suggesting a limit in the speaking rate decrease in intelligibility enhancing clear speech. The durational distinction between tense and lax vowels was increased less in non-native speech due to the smaller speaking rate decrease in clear speech. Analyses of the stop voice onset time (VOT) showed that non-native talkers lengthened the voiced category in the negative VOT direction, while the voiceless category was lengthened less in clear speech. Finally, examination of vowel space expansion in clear speech revealed differences between the two talker groups reflecting non-native talkers' inexperience in producing some of the vowel targets. Combined, these results suggest that a complex interaction of articulatory difficulty, proficiency, and native language background determines levels of non-native clear speech intelligibility.

4pSW13. Measuring sensitivity to short-term deviations in acoustic cue correlation. Kaori Idemaru (Dept. of East Asian Lang. and Lit.s, Univ. of Oregon, Eugene, OR 97403) and Lori L. Holt (Carnegie Mellon Univ., Pittsburgh, PA 15213)

Listeners are sensitive to correlations among the multiple probabilistic acoustic cues that define speech categories. In English stop consonant productions, for example, fundamental frequency (f0) is strongly correlated with voicing. Reflecting this regularity, perception of syllables varying in voice onset time is shifted with changes in f0. Such sensitivity to the long-term regularities of a language must be balanced with enough flexibility that speech perception is able to accommodate deviations from these regularities, such as those that may arise variations from idiolect, dialect, or accented speech. The present experiments manipulate short-term acoustic cue correlations experienced in online perception to investigate the interplay between sensitivity to long-term and short-term acoustic cue correlation. Using overt categorization and eyetracking, the present results indicate that speech categorization is influenced by local shifts in acoustic cue correlations that deviate from long-term regularities of English. These experiments further examine the time course of this short-term learning and the degree to which it generalizes. The data suggest that listeners continually monitor speech input for regularity and tune online speech perception in relation to these regularities.

4pSW14. Articulatory analysis of foreign-accented speech using real-time MRI. Joseph Tepperman (Viterbi School of Eng., Univ. of Southern California, 3740 McClintock Ave., EEB 400, Los Angeles, CA 90089, tepperma@usc.edu), Erik Bresch, Yoon-Chul Kim, Louis Goldstein, Dani Byrd, Krishna Nayak, and Shrikanth Narayanan (Univ. of Southern California, Los Angeles, CA 90089)

We present the first study of nonnative English speech using real-time MRI analysis. The purpose of this study is to investigate the articulatory nature of "phonological transfer"—a speaker's systematic use of sounds from their native language (L1) when they are speaking a foreign language (L2). When a non-native speaker is prompted to produce a phoneme that does not exist in their L1, we hypothesize that their articulation of that phoneme will be colored by that of the "closest" phoneme in their L1's set, possibly to the point of substitution. With data from three native German speakers and three reference native English speakers, we compare articulation of read phoneme targets well documented as "difficult" for German speakers of English (/w/ and /dh/) with their most common substitutions (/v/ and /d/, respectively). Tracking of vocal tract organs in the MRI images reveals that the acoustic variability in a foreign accent can indeed be ascribed to the subtle articulatory influence of these close substitutions. This suggests that studies in automatic pronunciation evaluation can benefit from the use of articulatory rather than phoneme-level acoustic models. [Work supported by NIH.]

4pSW15. The perception of speech and nonspeech analogs by first- and second-language speakers. Paul Iverson, Anita Wagner, and Stuart Rosen (Res. Dept. Speech Hearing and Phonetic Sci., University College London, 2 Wakefield St., London WC1N 1PF, UK)

There are marked differences in how native speakers of Sinhala and English perceive the English /w/-/v/ distinction; Sinhala speakers who have learned English as a second language are typically near chance at identification and have less than half the discrimination sensitivity of native English speakers. This poor discrimination ability is remarkable because the acoustic cues for /w/ and /v/ are varied, being contrastive in formant frequencies, amount of frication, and amplitude envelopes. The present project explored these differences in auditory sensitivity by manipulating speech and nonspeech stimuli, with the aim of investigating how close an auditory stimulus needs to be to natural speech in order for cross-language perceptual differences to emerge. Synthesized VCV speech stimuli were created to model natural recordings. Nonspeech stimuli were created by removing dynamics from the stimuli (e.g., flat pitch and amplitude, no formant movement), producing a "buzz" that was acoustically similar to the speech stimuli. Discrimination results for these stimuli will be reported for native speakers of Sinhala and English, in order to evaluate whether cross-language specialization for speech may occur at a precategorical auditory-phonetic level of processing, or whether specialization is contingent on the stimuli being perceived as intelligible speech.

4pSW16. Proficiency instrumentation for cross language perception studies. Jared Bernstein (Pearson, 299 S. California Ave., Ste. 300, Palo Alto, CA 94306, Jared.Bernstein@Pearson.com)

Studies in cross language speech perception sometimes use self-reported values of language proficiency as an independent variable. In relation to other measurement methods, proficiency self-reports have been found susceptible to several sources of bias including demographic variables and proficiency level itself [S. Yamashita, *Six Measures of JSL Pragmatics*, U. Hawaii Press (1996)]. An inaccurate scaling of an independent variable can limit the precision of performance models that are based on that variable's relation to the dependent variable. This paper presents a convenient method (Versant tests) for measuring spoken language proficiency that locates subjects on a 60 point scale with a standard error measurement of less than 3 points, thus reliably locating subjects into 20 levels along a linear continuum of proficiency. The testing procedure takes about 15 minutes to complete. The test-retest reliability of Versant scores for spoken English and Spanish are 0.97 and 0.96, respectively, both with correlations greater than 0.85 with independent human rated tests. The development, operation, and psychometric properties of the Versant tests are presented briefly, along with examples of their use in evaluating language instruction programs and standard listening comprehension tests.

4pSW17. Why do adults vary in how categorically they rate the accuracy of children's speech? Eden Kaiser (Prog. in Linguistic, Univ. of Minnesota, 214 Nolte Ctr., 315 Pillsbury Dr. SE, Minneapolis, MN 55455, kaise113@umn.edu), Benjamin Munson (Univ. of Minnesota, Minneapolis, MN 55455), Fangfang Li (Univ. of Lethbridge, Lethbridge, AB T1K 3M4, Canada), Jeff Holliday (Ohio State Univ., Columbus, OH 43210), Mary Beckman (Ohio State Univ., Columbus, OH 43210), Jan Edwards, and Sarah Schellinger (Univ. of Wisconson-Madison, Madison, WI 53706)

In a recent experiment using continuous visual analog scales (VAS) to examine adults' perception of children's speech accuracy, listeners varied in the extent to which they categorically perceived children's English and non-English productions [Munson *et al.*, American Speech-Language-Hearing Association (2008)]. Some listeners utilized all points on the VAS line for their responses, while others grouped responses around discrete locations on the line. It is hypothesized that differences in categoricity of responses across listeners might relate to listeners attending to either categorical linguistic information (i.e., identifying phonemes in a word, which would promote more categorical labeling) or gradient indexical information (i.e., identifying the child's sex or age, which would promote more continuous labeling). If this is true, it should be possible to elicit differences in categoricity of fricative "goodness" judgments in individual listeners by priming them to listen to linguistic variables (by interleaving fricative judgment trials with trials in which they categorize the vowel spoken by the child) or indexical variables (by interleaving fricative judgment trials with trials in which they identify the child's sex). This paper reports on an experiment designed to test this. Results will help us better understand individual response patterns in cross-language speech perception experiments.

4pSW18. Perceptual studies of two phonological voicing patterns. Scott Myers (Dept. of Linguist., 1 Univ. Sta. B5100, Univ. of Texas, Austin, TX 78712, s.myers@mail.utexas.edu)

Two of the most common phonological patterns in the world's languages are final devoicing and regressive voicing assimilation. In final devoicing, there is a contrast in obstruent voicing generally, but in word-, phrase-, or syllable-final position, only voiceless obstruents are allowed (e.g., Dutch, Russian, Walloon). In regressive voicing assimilation, the first of a sequence of two obstruents is required to agree with the second in voicing (e.g., Russian, Catalan, Hebrew). These phonological patterns can be related to patterns of speech production: anticipation of the spread glottis posture in pause and laryngeal coarticulation within consonant clusters. The studies reported here investigate the perceptual consequences of these coarticulatory effects. Native speakers of English listened to words contrasting in the voicing of the final consonant (cease/seize) and identified which word they heard. The words were excised from utterance-final position or from phrase-medial position preceding a vowel, nasal, a voiced obstruent, or a voiceless obstruent. The subjects averaged about 90 percent correct identification. But they still displayed a significant bias toward identifying as voiceless the final consonant in utterance-final words as well as in words preceding a voiceless obstruent. This pattern of identification errors could be the diachronic basis of the phonological patterns.

4pSW19. The relationship between speech perception and production in second language learners. Bing Cheng (English Dept., Inst. of Intil. Studies, Xi'an Jiaotong Univ., Xi'an, China, 710049) and Yang Zhang (Univ of Minnesota, Minneapolis, MN 55455)

This study aims to examine the relationship between perception and production skills in second language learners. Thirty-nine Chinese college students who have received at least eight years of English-as-a-second-language (ESL) education in school participated in the study. The data were collected using two programs: HearSay from Communication Disorders Technology Inc., Indiana, and a perceptual test program developed by Yang Zhang at the University of Minnesota. Digital recordings of each participant's production of the individual words used in the perceptual test program were rated in the scale of 1 to 5 by two native speakers of English. Results demonstrated the existence of complex relationships between perception and production in ESL learners. Overall, the consonants demonstrated a significant positive correlation between perception and production ($p<0.01$) with voicing showing strongest effect. Vowels, on the other hand, did not show significant correlations in any of the five categories examined: tense/lax, high/low, front/back, diphthong, and vowel insertions. Four patterns were identified for the individual phonemes: (a) good perception and good production, (b) poor perception and poor production, (c) good perception and poor production, and (d) poor perception and good production. The results are discussed with respect to speech learning models and practical instructional approaches.

4pSW20. Indexical perception in Chinese: The influence of first-language (L1) Taiwanese on second-language (L2) Mandarin. Yufen Chang (2451 E. 10th St., Apt. 909, Bloomington, IN 47408, yufchang@indiana.edu)

A pilot study on indexical perception in Chinese hypothesized that L1 Taiwanese speakers' L2 Mandarin production could be detected as having a nonnative accent. If the nonnative accent was detectable, what phonetic properties (the phonetics of consonants or vowels, or the prosody) did L1 Taiwanese speakers' Mandarin exhibit such that these attributes entailed indexical information? Additionally, the study argued that L1 Mandarin speakers would show higher sensitivity to the nonnative accent than L1 Taiwanese speakers. The results have shown that only in sentence production, the sentences being either low-pass filtered or unfiltered, could the L1 Taiwanese talkers be possibly indexed correctly. It was also found that the listeners perceived more accurately when they encountered retroflex stimuli in monosyllabic word condition. Based on these findings, it was concluded that the prosody and the retroflex consonants seemed to reveal much of the talker's L1 information. However, concerning the hypothesis that L1 Mandarin speakers were more sensitive to the nonnative accent, the results did not support this. The findings in this pilot study are preliminary, given the fact that the corpus was small. A bigger-scale study is being carried out to gain more insights into indexical perception in Chinese.

4pSW21. Automatic auditory discrimination of vowels in simultaneous bilingual and monolingual speakers as measured by the mismatch negativity (MMN). Monika Molnar, Shari Baum, Linda Polka (McGill Univ., 1266 Pine Ave. W, Montreal, H3G 1A8 Canada, monika.molnar@mcgill.ca), Lucie Menard (Universite du PQ à Montréal, Montreal, Canada), and Karsten Steinhauer (McGill Univ., Montreal, H3G 1A8 Canada)

MMN responses reflect whether language users have developed long-term memory traces in response to phonemes and whether they are able to perceive small acoustic changes within speech sound categories. Subtle acoustic changes within phonemes are often irrelevant to monolingual perceivers, but can be crucial for bilingual perceivers if the acoustic change differentiates the phonemes of their two languages. In the present study, we investigated whether bilinguals are sensitive to such acoustic changes. We recorded MMN responses from monolingual (English, French) and simultaneous bilingual (English/French) adults using an auditory oddball paradigm in response to four vowels: English [u], French [u], French [y], and an acoustically-distinct (control) [y]. In line with previous findings, monolinguals were more sensitive to the phonemic status of the vowels than to the acoustic properties differentiating the sounds. Bilingual speakers revealed a different pattern; they demonstrated overall slower discrimination responses to all sounds, but showed almost equal sensitivity to phonemic and phonetic /acoustic differences. The results suggest that bilingual speakers exhibit a more flexible but less uniquely-specified perceptual pattern compared to monolingual speakers.

4pSW22. Comparison between Japanese children and adult's perception of prosodic politeness expressions. Takaaki Shochi (Div. of Cognit. Psych., Kumamoto Univ., Kurokami 2-40-1, Kumamoto City, 860-8555, Japan, shochi38@gmail.com), Donna Erickson (Showa Univ. of Music, Kawasaki-city, Kanagawa pref., 215-0021, Japan), Albert Rilliard (LIMSI-CNRS, BP 133 F-91403 Orsay cedex, France), Kaoru Sekiyama (Kumamoto Univ., Kurokami 2-40-1, Kumamoto city, 860-8555, Japan), and Veronique Auberge (Domaine Universitaire, BP46 F-38402 Saint Martin d'Heres cedex, France)

Previous work examined the contribution of audio and visual modalities for perception of Japanese social affects by adults. The results showed audio and visual information contribute to the perception of culturally encoded expressions, and show an important synergy when presented together. Multimodal presentation allows foreign adult listeners to recognize culturally encoded expressions of Japanese politeness which they cannot recognize with an audio-only stimuli. This current work analyzes the recognition performance of politeness expressions by Japanese children 13 to 14 years old.

Stimuli, based on one sentence with an affectively neutral meaning, are performed with five different expressions of politeness. Subjects listen three times to each stimulus and judge the intended message of the speaker. The stimuli are presented as audio-only, visual-only, audio-visual. Listeners rate the social status of the hearer and the degree of politeness on a nine-point scale ranging from polite to impolite. The results are analyzed to capture the relative ability of adults and children to use both modalities to recognize social affects. [This work was supported in part by Japanese Ministry of Education, Science, Sport, and Culture, Grant-in-Aid for Scientific Research (C) (2007–2010): 19520371 and SCOPE (071705001) of Ministry of Internal Affairs and Communications (MIC), Japan.]

4pSW23. Do you want to pronounce correctly in a foreign language? Start music lessons!. Barbara E. Pastuszek-Lipinska (School of English, Adam Mickiewicz Univ., al. Niepodleglosci 4, 61-874 Poznan, Poland)

Music education is one of the human activities that requires the integration of all human senses and the involvement of all cognitive processes: sensory, perceptual, and cognitive learning, memory, emotion, and auditory and motor processes, music has tended to figure only marginally in an approach to second-language acquisition. In the presentation will be reviewed recent research results on the influence of music lessons on second language speech processing. The presentation will draw a comparison between second language acquisition processes and first language acquisition processes. It will be also provided concise review of the possible explanations of the influence of music on second language speech processing. The review will include acoustic, phonological, neuroscientific, and psycholinguistic approaches.

4pSW24. Mandarin-English bilinguals' accented first-language (L1) vowel production. Haisheng Jiang (School of Lang. and Lit., Univ. of Aberdeen, Aberdeen, AB24 3FX, UK, h.jiang@abdn.ac.uk)

The L1 phonetic categories established in childhood may undergo modification when similar L1 and L2 sounds interact in the process of L2 learning [J. Flege, *Speech perception and linguistic experience: Issues in cross-language research* (1995)]. In this study, Mandarin vowel production by the Mandarin-English bilinguals was presented to Mandarin as well as English listeners for goodness rating. The results showed that both Mandarin-English bilinguals of high L1 use and those of low L1 use differed significantly from Mandarin monolinguals in the production of /y/, a vowel with no counterpart in English. An analysis of inter-speaker variability indicated that some individual Mandarin-English bilinguals, including both speakers of high L1 and low L1 use, were accented in the production of /y/, /aj/, and /au/. Possible acoustic properties contributing to their accentedness were identified. L2 English learning led to some Mandarin-English bilinguals carrying some English characteristics in their L1 Mandarin vowel production. This study provides further evidence for the claim that the L1 phonetic system established in childhood is susceptible to change. It contributes to the less well-studied field of L2 influence on L1.

4pSW25. Assessing phonetic talent in second language performance: The relationship between perception abilities in the native and the second language and production. Matthias Jilka (Institut of English Linguist., Univ. of Stuttgart, Heilbronner Str. 7, 70174 Stuttgart, Germany, jilka@ifla.uni-stuttgart.de), Giusy Rota (Univ. of Stuttgart, 70174 Stuttgart, Germany), and Susanne Reiterer (Univ. of Tuebingen, 72076 Tuebingen, Germany)

An extensive project that aims to assess innate phonetic talent is introduced. It investigates language performance of 103 native speakers of German in their native language, in English and (to a limited degree) in Hindi. The project's original priority is to establish a talent score that serves as the basis for a neurolinguistic study which attempts to find correlates between phonetic talent and brain anatomy/function. For this purpose tasks investigating neurobiological, psychological, and other factors influencing performance are also conducted. Innate talent is to be distinguished from superficial proficiency by limiting or eliminating the influence of interfering factors such as language experience. The test subjects are investigated with respect to different manifestations of their production (e.g., quasi-spontaneous speech, reading), perception (e.g., discrimination, identification), and imitation abilities in both German and English. A first analysis of the interactions between all perception and production scores shows a significant correlation at the level of $p < 0.05$. The correlation is especially high ($p < 0.01$) between perception tasks involving the interpretation of intonational features of both English and German and production abilities (again both in German and English), suggesting a certain cross-language predictive power.

4pSW26. Speech perception assessment and training system (SPATS-ESL) for speakers of other languages learning English. James D. Miller, Roy Sillings, Charles S. Watson, and Diane Kewley-Port (Commun. Disord. Technol., Inc., 501 N. Morton St., Sta. 215, Bloomington, IN 47404)

The SPATS software system, originally developed for the hearing-impaired, has been modified for use with ESL learners with TOFEL (pbt) scores near and well above 500. SPATS-ESL includes the identification of syllable constituents: onsets, nuclei, and codas, as well as sentence recognition. The syllable constituent tasks include the progressive introduction of increasing numbers of constituents until the learner becomes adept at the identification of 45 onsets, 28 nuclei, and 36 codas presented by eight talkers in a variety of phonetic contexts. The sentence task emphasizes increasing speed and decreasing errors in the recognition of short, meaningful sentences spoken by a variety of talkers. The sentences are presented in a background of multi-talker babble at five signal-to-noise ratios: +10, +5, 0, −5, and −10 dB. The syllable constituent and sentence tasks are interleaved throughout training. In constituent training, SPATS uses a proprietary training algorithm, Adaptive Item Selection (AIS), which automatically focuses training on individuals' items of intermediate difficulty and is independent of their language history. Proctored tests allow certification of a learner's English speech perception in relation to native-speaker performance.

4pSW27. On-line perception of lexical stress in English and Spanish: The effects of sentence intonation and vowel reduction. Marta Ortega-Llebaria (Dept. of Spanish and Portuguese, Univ. of Texas at Austin, Austin, TX 78712, ortegallebaria@att.net)

Previous research shows that speakers of stress-accent languages rely on pitch-accents to perceive word stress in sentences spoken with declarative intonation, while in unaccented sentences, like post-focal contexts, they rely on other cues, i.e., duration in Spanish or vowel reduction in English. However, there is no experimental evidence on the effect that sentence intonation has in the "on-line" perception of word stress across languages. This experiment examines whether listeners detect word stress faster in unaccented stretches of speech that are preceded by a landmark in the sentence melody, i.e., the focal pitch-accent that always precedes a post-focal sentence, than in unaccented contexts not preceded by a landmark, i.e., reporting clauses. Results show that Spanish listeners identified target words at the beginning and end of post-focal contexts with similar reaction times, while in reporting clauses, target words placed at the end were identified faster than those placed at the beginning. Preliminary results for English show no significant differences. Thus, Spanish listeners re-weight cues to word stress on-line taking into account the patterns of sentence intonation. Sentence melody does not have such a strong effect in English, possibly because vowel reduction is a sufficient cue to an effective perception of word stress.

4pSW28. A cross-language study of compensatory response to formant-shifted feedback. Takashi Mitsuya, Ewen N. MacDonald (Dept. of Psychol., Queen's Univ., Kingston, Canada), David W. Purcell (Univ. Western Ontario, London, Canada), and Kevin G. Munhall (Queen's Univ., Kingston, Canada)

Previous experiments in speech motor learning have demonstrated that the perception of our own voice while we speak plays a role in the control of fundamental and formant frequencies and vocal amplitude. When feedback is changed in real time, subjects alter speech production in attempt to compensate for the perturbation. By testing Japanese talkers in their native and a less familiar language (as well as English-speaking controls), we examine how this perception-production process is influenced by language. In the first study, native Japanese speakers produced an English word with formant-shifted feedback. In the second experiment, native Japanese speakers produced a Japanese syllable with altered feedback and produced an

English word that contained a similar vowel with normal feedback. The results were compared with data from English controls and suggest that the compensatory behavior is not language dependent.

4pSW29. Linguistic experience's influence on foreign accent detection in short, slightly accented speech. Hanyong Park (Speech Res. Lab., Indiana Univ., 1101 E. 10th St., Bloomington, IN 47405, hanypark@indiana.edu)

This study examined how a listener's linguistic experience affects the detection of foreign accent in short, slightly accented speech. Two factors were considered: Age of arrival in a second-language (L2) speaking country (AOA), and length of residence in that country (LOR). Two listener groups with the same native language (L1: Korean) but with different AOA and LOR judged the nativeness of short stimuli produced by 4 Korean-English bilinguals and 2 native speakers of American English. The stimulus length ranged from the vowel /a/ to monosyllabic and disyllabic English words. To investigate the listeners' sensitivity patterns to different linguistic structure, the monosyllabic corpus included stimuli having both natural (i.e., CV) and unnatural syllable structures (i.e., CCV, CVC, and CCVC) as well as various segments in terms of Korean phonotactics. Results show that: (1) more experienced with L2 led to higher sensitivity to a foreign accent; (2) AOA affects foreign accent detection more than LOR; and (3) the non-native listeners were not sensitive to different linguistic structures, except in different CCV types by the more experienced listeners. The results suggest that a listener's sensitivity to a foreign accent develops up to a certain degree, according to L2 experience.

4pSW30. Asymmetries in the mismatch negativity response to vowels by French, English, and bilingual adults: Evidence for a language-universal bias. Linda Polka, Monika Molnar, Shari Baum (School of Commun. Sci. and Disord., McGill Univ., 1266 Pine Ave. W., Montreal, QC Canada, linda.polka@McGill.ca), Lucie Menard (Universite du Qubec à Montréal, QC Canada), and Karsten Steinhauer (McGill Univ., Montreal, QC, Canada)

In infants, discrimination of a vowel change presented in one direction is often significantly better compared to the same change presented in the reverse direction. These directional asymmetries reveal a language-universal bias favoring vowels with extreme articulatory-acoustic properties (peripheral in F1/F2 vowel space). In adults, asymmetries are observed for non-native but not for native vowel contrasts. To examine neurophysiological correlates of these asymmetries we recorded MMN responses from monolingual (English, French) and simultaneous bilingual (English/French) adults using an oddball paradigm with four vowels: English [u], French [u], French [y], and an acoustically-distinct [y]. All vowels were tested in four conditions with each vowel serving as deviant and standard. Within each vowel pair, MMN responses were larger and earlier when the deviant vowel was more peripheral. This pattern was consistent across the language groups and was observed for within-category (within [u]; within [y]) and for cross-category vowel pairs ([u] versus [y]). Findings indicate that a bias favoring peripheral vowels is retained in the neural pre-attentive processing of vowels in adults. As in infant behavioral findings, this bias is independent of the functional status of the vowel pair. Implications for the natural referent vowel model [Polka and Bohn (2003)] will be discussed.

4pSW31. The effect of accent on toddlers' story comprehension and word recognition. Brittan A. Barker and Lindsay E. Meyer (Dept. of COMD, Louisiana State Univ., 63 Hatcher Hall, Baton Rouge, LA 70803)

The current study sought to enrich the developmental research and contribute to the ever-growing knowledge about talker-specific spoken language processing by examining the affect of accent on toddlers' ability to comprehend a story. A total of 24 children aged 30–42 months participated in the first study employing a between-subjects design. Talker accent (native versus non-native) served as the independent variable and story comprehension accuracy served as the dependent variable. It was predicted that the children listening to the story in their native accent would perform significantly better on the comprehension task than those listening to the non-native accent. The hypothesis was not supported; there was no significant difference between the listeners' performance [$t(22)=.169$, $p>.05$]. An ongoing, follow-up study was conducted to further explore the surprising results. The affect of accent on word recognition skills in these same children is currently being tested. The complete data set of the second study will be presented. It is hypothesized that the toddlers will have significantly more difficulty recognizing the words spoken in a non-native accent. These results would echo previous talker-specific word recognition results [Ryalls and Pisoni (1997)] and suggest that talker-specific information may affect low-level speech perception but not higher-level language comprehension.

4pSW32. Cross-linguistic variation in language similarity classification. MaryAnn Walter (Dept. of Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, m-walter@northwestern.edu)

This study aims at identifying factors that make language sound structures seem more or less similar to English, and how those similarity judgments change according to the listener's native language. Listeners from four different native language groups (English, Mandarin Chinese, Korean, and Turkish) sorted a group of 17 genetically and geographically diverse languages in terms of their sound-based distance from English. Placements of individual languages were analyzed, as well as groupings of similarly ranked languages and correlations among overall ranking structures of the different groups. Bilingual listeners exhibit more variability in their rankings than monolingual English speakers, rank their own language as less similar to English than other groups do, and rank languages of neighboring groups the least similar to it of all. Ranking correlations between language groups are significant, varying somewhat in magnitude depending on geographical proximity and typological/genetic relatedness of the listener group languages. This reflects the presence of consistent groupings within ranking structures for all language groups, which depend on sound-based factors such as the presence of perceptually salient speech sounds. These results enable predictions about relative intelligibility among international English users, native and non-native. [Work supported by a Mellon Postdoctoral Fellowship awarded by the Woodrow Wilson Foundation.]

4pSW33. Acoustic similarities between front rounded and back unrounded vowels as evidenced by French /ø/ and /u/ produced by Japanese-speaking learners. Takeki Kamiyama (Laboratoire de Phonetique et Phonologie (UMR 7018) CNRS/Sorbonne Nouvelle, 19, rue des Bernardins, 75005 Paris, France, Takeki.Kamiyama@univ-paris3.fr)

French high back rounded /u/ is characterized by a concentration of energy in the low frequency zone ($<$ 1000 Hz) due to the grouping of the first two formants, and midhigh front rounded /ø/ by a balanced distribution of formants, with F2 located around 1500 Hz. Japanese-speaking learners of French (JSL), who have difficulty differentiating /ø/ and /u/ both in perception and production, tend to produce, for both, Japanese-like /u/, which is fronted and less rounded, with a formant structure similar to that of French /ø/. Our perception experiment using 18 tokens each of /u y ø/ produced by five JSL shows that the 16 native speakers of French (NF) tested perceived mainly /ø/ when they heard those stimuli intended as /u/ by JSL but produced with a high F2 between 1100 and 1600 Hz, with a mean goodness rating of 2–4.5 out of 5 for /ø/. Another perception test conducted with stimuli synthesized using Maeda's articulatory synthesis (VTCalcs) shows that the 16 NF examined tended to identify vowels synthesized as front rounded vowels and back unrounded vowels both as front unrounded ones (/ø/ and /æ/, respectively), which indicates the acoustic similarities of both types of vowels.

4pSW34. Relation of perception training to production of codas in English as a second language. Teresa Lopez-Soto (Dept. of English Lang., Univ. of Seville, Palos de la Frontera, Sevilla 41004, Spain and Indiana Univ., Bloomington, IN 47405) and Diane Kewley-Port (Indiana Univ., Bloomington, IN 47405)

A preliminary study has been conducted to discover whether moderate amounts of speech perception training improve accurate production even though production is not trained. The study recruited one group of eight Spanish adults who had resided less than 10 years in the USA. A set of 13 word-final English consonants was selected for training from a SPATS software module. On days 1 and 5, the group participated in both perception and production tasks with the 13 codas (pre- and post-tests). On days 2–4, the group trained with feedback for 1 h mostly with VC syllables and occasionally with sentences (speech recorded from multiple talkers). Results show: (1) with 3 h training, Spanish listeners' perception improved significantly across the 13 codas, with greater improvement on consonant clusters than on singletons; (2) for consonants not accurately produced in the pretest, many substantially improved after only perception training; (3) several consonants

with large gains in perception also showed the large improvements in production. The results from this study suggest that training only with perception can improve speech production. Experience with this protocol lays the groundwork for a series of studies to examine how perception and production are linked in learning a new language.

4pSW35. Confusion direction differences in second language production and perception. Yen-Chen Hao and Kenneth de Jong (Dept. of Linguist., Indiana Univ., 322 Memorial Hall, 1021 E. 3rd St., Bloomington, IN 47405)

This study examines differences between confusions found in productions and perceptions of learners of English. Twenty Korean EFL learners engaged in three tasks involving obstruents placed in different prosodic positions: (a) identification of native English productions, (b) reading from orthographic prompts, and (c) mimicry of native English productions. Recordings of reading and mimicry were presented to 50 native English listeners for identification. This paper compares patterns of errors found for 10 intervocalic obstruents before and after a stress, since previous studies showed that Korean does not exhibit stress-induced differences in consonant allophones. Similarity estimates using Luce's similarity choice model were regressed across the two intervocalic positions. We found robust correlations despite allophonic differences in English, suggesting a component of L1 transfer in all three tasks. Examining bias parameters, however, revealed systematic differences in the direction of the resulting errors, which is task-dependent. Identification and mimicry tended to underestimate allophonic shifts due to stress, and so to create more voiceless to voiced errors in post-stress environments. Reading productions exhibited error directions in exactly the opposite directions, suggesting Korean learners produced the stress but not the corresponding allophonic variations. These patterns indicate very different error outcomes in production and perception.

4pSW36. Maintenance of /e-ɛ/ in word-final position as a phonemic and morphemic contrast in Canadian French. Franzo Law, II and Winifred Strange (Program in Speech-Lang.-Hearing Sci., CUNY Graduate Ctr., 365 5th Ave., New York, NY 10016, flaw@gc.cuny.edu)

Many dialects of French have merged /e-ɛ/ to /e/ in word-final context. The present study investigated the stability of this contrast in Canadian French. Productions of four Canadian French-dominant speakers (two monolingual, two bilingual) were recorded and analyzed. Real (e.g., "thé") and nonsense (e.g., "gispais") words ending with /e/ or /ɛ/ were used, as well as real and nonsense verbs distinguished morphosyntactically by the same vowel contrast (e.g., first person singular future "parlerai" versus first person singular conditional "parlerais"), all embedded in carrier sentences. Results showed that participants maintained spectral and duration distinction for the vowel contrast when preceded by labial, coronal, and back stops in real and nonsense words. All participants showed varying degrees of coarticulation for /e/ when preceded by /r/; /e/ was spectrally lower than in other contexts. Three of the four participants maintained a stable distinction in morphosyntactic context: monolinguals exhibited the best retention of the distinction, whereas the bilinguals had partially or completely overlapping distributions, merging /e-ɛ/ to /ɛ/, not /e/. These patterns suggest difficulties in perception of this contrast for English late L2 learners of French, due to the fact that this contrast is not phonotactically possible in English. [Work supported by NIH F31DC008075.]

4pSW37. On prosodic variation and pronunciation aptitude: A case study of German speakers of English. Volha Anufryk and Grzegorz Dogil (Azenbergstr. 12, 70174 Stuttgart, Germany)

The present study investigates prosodic variation, as realized by L1 German speakers of varying pronunciation aptitude (below-average, average, and above-average) in comparison with native speakers of English. The results demonstrate the frequency of distribution of various pitch contours in read and spontaneous speech samples, English and German, on both the phonological (ToBI pitch accents and boundary tones) and phonetic levels. The latter is analyzed using a parametric intonation model (Moehler 2001). On the phonological level the rising contours, i.e., boundary tones and pitch accents, have a wider distribution in German as well as English productions of the German subjects as compared to the L1 English speakers. In German the percentages in all the aptitude groups are almost equal covering about 50% of all contours. Their English language realizations, on the other hand, are marked by a scarcer distribution of the rising pattern, with the highest percentages in the below-average and average groups and lowest by the above-average speakers. Consequently, there is a clearcut tendency for the native pattern in the German speakers' samples. Nonetheless there is evidence for accommodation to the English variation pattern, which is strongest in the above-average aptitude group.

4pSW38. Native and non-native vocal imitation by vocalists and nonvocalists. Terry L. Gottfried and LaDonna Hayden (Dept. of Psychol., Lawrence Univ., P.O. Box 599, Appleton, WI 54912, gottfrit@lawrence.edu)

Several studies [e.g., Slevc and Miyaki, Psychol. Sci. **17**, 675–681 (2006)] have demonstrated that musical ability predicts phonological accuracy in second language learning. The present study examined whether vocal musicians' diction training affected their immediate imitation of familiar (English nonwords) and unfamiliar (Mandarin) syllables. Participants were 19 nonmusic majors (recruited from introductory linguistics) and 19 vocal music majors (who had completed three of four vocal diction classes). All participants heard a list of eight English nonwords and eight Mandarin words from a recording and repeated each word or nonword to the best of their ability. These recordings were rated (by two bilingual judges) on the overall accuracy of word repetition and vowel and consonant accuracy. Participants, regardless of group, repeated English nonwords more accurately than Mandarin words. Vocalists repeated both English nonwords and Mandarin words more accurately than the nonvocalists. This could indicate that vocalists' experience in diction training improved their ability to repeat any speech sound. Acoustical analyses of these vocal imitations are currently being conducted, and future studies will examine whether musicians without diction training are better than nonmusicians in vocal imitation.

4pSW39. Gestural drift in Spanish-English speakers. Stephen Tobin (Dept. of Psych., Univ. of Connecticut, 406 Babbidge Rd., Unit 1020, Storrs, CT 06269-1020, stephen.tobin@uconn.edu)

Voice onset times (VOTs) and second vowel formants (F2s) of native speakers of Spanish were examined to extend findings on perceptually guided changes in speech production [M. L. Sancier and C. A. Fowler, J. Phon. **25**, 421–426 (1995)]. Participants were recorded producing English and Spanish sentences after stays in the U.S. and in Spanish-speaking countries. Participants' English and Spanish VOTs were both significantly shorter after a stay in a Spanish-speaking country than after a stay in the U.S., supporting previous findings. While S1's F2s were significantly lower following exposure to Spanish, as expected based on earlier results [A.R. Bradlow, J. Acoust. Soc. Am. **97**(3), 1916–1924 (1995)], S2's F2s increased. We attribute this effect to gender, pending further data acquisition. We propose that not only inter-gestural timing but also the gestural targets themselves are affected by ambient language. The systematic effect of language exposure on F2 is consistent with language-specific articulatory settings [B. Honikman (1964); Gick et al., Phonetica **61**, 220–233 (2004)].

4pSW40. Vowel duration in Mexican heritage English. Kenneth Konopka and Janet Pierrehumbert (Dept. of Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, k-konopka@northwestern.edu)

Mexican heritage English (MHE) speakers in Chicago comprise a unique population of native English speakers; their speech is often regarded by non-ethnic (NE) speakers as Spanish-accented English in spite of the fact that they may have low or no proficiency in Spanish. Vowels were analyzed from recordings of wordlist readings by MHE, NE, and adult Mexican ESL speakers (L2E) from a single Chicago community ($N=15$F, 10F, and 12F, respectively). The analyses indicate that MHE vowel durations correspond to NE durations for the dimoraic (long) vowels, but correspond to the Spanish-accented vowels of L2E for the monomoraic (short) vowels. Thus the range of duration between short and long vowels is compressed for MHE vowels, reflecting the NE norm for long vowels, and the Spanish-influenced minimum for short vowels. Sociophoneticians often rely on vowel formant frequency plots to provide a quantitative measure of dialect identity that may correlate with a variety of regional and social factors. The current study provides evidence that vowel duration is a phonological contrast in the MHE dialect that reflects the influence of language contact on vowel properties that are not captured by vowel plots alone.

4pSW41. The perception of intermediate phonological relationships. Kathleen Currie Hall (Dept. of Linguist., Ohio State U., 1712 Neil Ave, Columbus, OH 43210, kchall@ling.osu.edu)

It has been shown that pairs of segments that are allophonic in a language are perceived as being more similar than pairs that are contrastive in a language [Boomershine et al., (2008)]. There is also evidence that neutralized contrasts in a language are perceived as more similar than non-neutralized contrasts [Hume and Johnson (2003)]. Third, there is evidence that phonological relationships should be defined along a continuum of predictability, rather than as a categorical distinction between "allophonic" and "contrastive" [Hall (2008)]. In combination, these facts predict that pairs of segments that fall along a cline of predictability of distribution should also fall along a cline of perceived similarity. This paper presents results of a perception experiment that tests this prediction by examining the perceived similarity of four pairs of sounds in German: (1) [t]-[tʃ], which is almost fully contrastive (unpredictably distributed); (2) [t]-[d] and (3) [s]-[ʃ], which are each partially contrastive (partially predictably distributed); and (4) [x]-[ç], which is almost fully allophonic (completely predictably distributed). If the notion of a cline of predictability is correct, these four pairs will align themselves along a cline of similarity with [t]-[tʃ] being rated as the most distinct and [x]-[ç] as the most similar.

5aSWa1. Accounting for the accented perception of vowels: Universal preferences and language-specific biases. Ocke-Schwen Bohn (English Dept., Arhus Univ., J.-C.-Skous Vej 5, DK-8000 Arhus C, Denmark) and Linda Polka (School of Commun. Sci. and Disord., Montreal, PQ, H3G1A8, Canada)

Strange things happen in cross-language and second-language vowel perception: Nave non-native listeners have been reported to rely on acoustic properties which are nonfunctional in their L1 and dysfunctional for the perception of non-native vowels; naïve non-native listeners' perception is guided by a preference for vowels that are peripheral in the articulatory/acoustic vowel space; and, in general, naïve non-native listeners' perception is not well predicted by comparative analyses of vowels of the native and the non-native language. This presentation reviews the accented perception of vowels by focusing on two forces which shape non-native vowel perception: universal perceptual preferences which non-native listeners (and infants) bring to the task of vowel perception, and perceptual biases which non-native listeners transfer from their native to the non-native language. Strange and her colleagues have shown that these biases cannot be predicted from acoustic comparisons; rather, they have to be examined directly through assessments of the perceived cross-language similarity of vowels. This presentation addresses several of the still unresolved questions regarding the design and the interpretation of perceptual assimilation tasks used to account for the accented perception of vowels. [Work supported by Danish Research Council for the Humanities, Canadian Natural Sciences and Engineering Research Council.]

5aSWa2. Articulating the Perceptual Assimilation Model (PAM): Perceptual assimilation in relation to articulatory organs and their constriction gestures. Catherine T. Best (MARCS Auditory Labs, Univ. Western Sydney, Locked Bag 1797, Penrith NSW 1797, Australia, and Haskins Labs, 300 George St., New Haven, CT 06511, c.best@uws.edu.au), Louis Goldstein (Univ. Southern Calif., Los Angeles, CA 90089-1693), Michael D. Tyler (Univ. Western Sydney, Penrith NSW 1797, Australia), and Hosung Nam (Haskins Labs, New Haven, CT 06511)

A core premise of the Perceptual Assimilation Model of non-native speech perception (PAM) [Best (1995); Best & Tyler (2007)] is that adults perceive unfamiliar non-native phones in terms of articulatory similarities/dissimilarities to native phonemes and contrasts. The implied attunement to native speech emerges early: As infants begin to discern the articulatory organization of native speech, language-specific effects in non-native speech perception appear (≈6–10 months). Given that non-native phones, by definition, deviate phonetically from native ones, how can we characterize articulatory similarity in concrete, testable ways? The Articulatory Organ Hypothesis (AO) [Studdert-Kennedy & Goldstein (2003); Goldstein & Fowler (2003)] offers a possible approach, positing that infants decompose the oral-facial system into distinct articulatory organs (e.g., lips, tongue tip, tongue dorsum) and are sensitive to their actions in producing vocal tract constrictions. Thus, between-organ contrasts should be easily perceived/learned by infants and adults, whereas detection of within-organ contrasts must become attuned to the distribution of differing constriction locations/types by that organ in input speech. We discuss articulatory, attunement modeling, and perceptual evidence consistent with these predictions, and present a revised version of PAM that incorporates the AO Hypothesis and related principles of articulatory phonology [Browman & Goldstein (1991)]. [Work supported by NIH.]

Session 5aSWb

Speech Workshop: Research and Applications to Second Language (L2) Speech Perception

Susan G. Guion, Chair
Dept. of Linguistics, Univ. of Oregon, Eugene, OR 97403-1290

Invited Papers

10:30

5aSWb1. Accent and intelligibility from an applied perspective. Murray J. Munro (Dept. of Linguist., Simon Fraser Univ., 8888 University Dr. Burnaby, BC V5A 1S6, Canada)

Listeners are remarkably sensitive to non-native patterns of speech, whether they are presented with full sentence productions, or with very short or severely degraded speech, including noisy, filtered, and temporally disrupted utterances. Furthermore, even phonetically unsophisticated listeners can reliably scale accents. From the standpoint of second language (L2) users, speaking with a detectible accent has important social consequences. One is that L2 speech is sometimes less intelligible or may require listeners to allocate more processing resources than does native speech. However, evidence also indicates that some salient phonological markers of L2 status have little or no impact on listener comprehension. Distinguishing these from accent features that reduce intelligibility is a critical concern in language pedagogy. Another consequence noted in empirical research is that accent stereotyping and negative social evaluation of accented speakers are linked to discrimination in remuneration, employment, and services. They may also be implicated in the exploitation of L2 speakers through questionable claims about the value of "accent reduction." This synthesis of previous and new research findings highlights a number of issues concerning methodology and interpretation in L2 speech research that are relevant to language teaching and assessment, and to human rights litigation. [Research supported by SSHRC.]

11:05

5aSWb2. The role of linguistic experience in lexical recognition. Andrea Weber (Max Planck Inst. for Psycholinguistics, Wundtlaan 1, 6525 XD Nijmegen, The Netherlands, andrea.weber@mpi.nl)

Lexical recognition is typically slower in L2 than in L1. Part of the difficulty comes from a not precise enough processing of L2 phonemes. Consequently, L2 listeners fail to eliminate candidate words that L1 listeners can exclude from competing for recognition. For instance, the inability to distinguish /r/ from /l/ in *rocket* and *locker* makes for Japanese listeners both words possible candidates when hearing their onset (e.g., Cutler, Weber, and Otake, 2006). The L2 disadvantage can, however, be dispelled: For L2 listeners, but not L1 listeners, L2 speech from a non-native talker with the same language background is known to be as intelligible as L2 speech from a native talker (e.g., Bent and Bradlow, 2003). A reason for this may be that L2 listeners have ample experience with segmental deviations that are characteristic for their own accent. On this account, only phonemic deviations that are typical for the listeners' own accent will cause spurious lexical activation in L2 listening (e.g., English *magic* pronounced as *megic* for Dutch listeners). In this talk, I will present evidence from cross-modal priming studies with a variety of L2 listener groups, showing how the processing of phonemic deviations is accent-specific but withstands fine phonetic differences.

11:40

5aSWb3. Designing the foreign language learning environment: From basic research towards product development. Reiko Akahane-Yamada (ATR Learning Technol. Corp., 2-2-2, Hikaridai, Seika-cho, Soraku-gun, Kyoto, 619-0288, Japan, yamada@atr-lt.jp)

In order to examine the acquisition of English by native speakers of Japanese, a series of training studies were conducted under various environments, that is, in the laboratory, at schools, or in virtual spaces over the Internet, and learners of various ages participated. The results demonstrated that web-based training methods using computers can improve even adult learners' ability to perceive and produce L2, and that the acquisition of phonological categories plays an important role in the language learning. Based on these results, an L2 training system, dubbed ATR CALL BRIX, was developed by putting emphasis on speech learning. The system is a collection of training tools for speech perception, production, and comprehension. Each component focuses on the acoustic-phonetic, prosodic, lexical, or semantic decoding level of spoken language. Speech analysis and pronunciation evaluation tools are also provided. The target users vary from children to adults and from beginners to advanced learners. The content is designed with Learning Object concept and each component is adjustable on the learner characteristics and curricula. The system is already in the market. It is suggested that the cross-language and L2 acquisition studies are readily applicable to designing actual foreign language learning environment. [Work supported by JSPS.]

All posters will be on display from 1:30 p.m. to 3:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 2:15 p.m. and contributors of even-numbered papers will be at their posters from 2:15 p.m. to 3:00 p.m.

5pSWa1. Foreign accented speech: Energetic or informational masking? Lauren Calandruccio, Christina Yuen, Sumitrajit Dhar (The Roxelyn and Richard Pepper Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 N. Campus Dr., Evanston, IL 60208, lauren.calandruccio@gmail.com), and Ann Bradlow (Northwestern Univ., Evanston, IL 60208)

Normal-hearing monolingual listeners whose native language is English experience a release from masking when the competing speech stimuli are spoken in a language other than English [e.g., K. J. Van Engen and A. R. Bradlow, J. Acoust. Soc. Am. **121**, 519 (2007)]. It is unclear whether this release is due to the fact that the masking speech is not spectrally matched to the target speech (energetic influence), or that listeners are unable to understand the masking speech and therefore find it less "distracting" when spoken in a non-native language (informational influence). This study investigates listeners' recognition of English speech presented in the presence of a continuum of five two-talker babble maskers. The two-talker maskers (all created using male voices) include English babble, Mandarin-accented English babble with high intelligibility, Mandarin-accented English babble with moderate intelligibility, Mandarin-accented English babble with low intelligibility, and Mandarin babble. We hypothesize that, due to increased informational masking across the accented English continuum (from unaccented to heavily accented) in the masker speech, we will observe a increase in the target English speech intelligibility. These data will provide insight into the balance of energetic and informational influences on the release in masking observed for monolingual listeners when listening to English in a noncompeting masker language.

5pSWa2. Perceptual training really matters: evidence of a study with English as a foreign language (EFL) vowels. Denize Nobre-Oliveira (Federal Ctr. of Technolog. Education of Santa Catarina, Av. Mauro Ramos 950, Florianopolis, SC, Brazil, 88020-300, denizenobre@yahoo.com.br) and Andreia S. Rauber (Univ. of Minho, Campus de Gualtar, Braga, Portugal 4715-057)

This study aimed at: (i) investigating the perception of English vowels by Brazilian English as a foreign language (EFL) highly proficient speakers, and, based on the findings; (ii) designing and testing perceptual training tasks that could possibly minimize perception difficulties by EFL learners. Two experiments were conducted. Experiment 1 tested vowel perception by means of an identification test elaborated with synthetic stimuli. The results showed that the vowels most often misidentified were /i/, /I/, /E/, /æ/, /U/, and /u/, and that duration does not seem to play a role on the perception of each vowel, suggesting that participants rely primarily on spectral cues. Experiment 2 then tested the effect of perceptual training of the difficult vowels by means of exposure to both natural and synthetic stimuli (with spectral manipulation). The training on these vowels was given over a 3-week period to 29 Brazilian EFL learners, which were divided into the natural stimuli (NatS) group and the synthesized stimuli (SynS) group. The results show that: (i) both experimental groups improved significantly after training; (ii) there was more improvement in the SynS group than in the NatS group; and (iii) knowledge acquired with artificially enhanced stimuli was transferred to stimuli produced naturally. [Work supported by CAPES (Committee For Postgraduate Courses in Higher Education, Brazilian Ministry of Education) grants to both authors.]

5pSWa3. Perception of Arabic and Japanese vowel length contrasts by native versus non-native Japanese listeners. Kimiko Tsukada (Dept. of Int. Studies, Macquarie Univ., NSW 2109, Australia ktsukada@mq.edu.au) and Yukari Hirata (Colgate Univ., Hamilton, NY 13346)

The perception of short versus long vowel contrasts in Arabic and Japanese was examined for native Japanese [(NJ), $n=5$] and non-native Japanese [(NNJ), $n=5$] listeners. The length contrast is phonemic in both languages. The question addressed was whether experience with Japanese helps NNJs to process the length contrast in Arabic. The listeners' discrimination accuracy was assessed in an AXB test. The stimuli were CV_1C words in Arabic and CV_1CV words in Japanese (where V_1 was either short or long). As expected, NJs were more accurate than NNJs in discriminating the Japanese contrast. While NJs made more errors in Arabic than Japanese, NNJs showed a similar level of discrimination accuracy for the two languages. Finally, the number of errors for the Arabic stimuli was comparable for NJs and NNJs. Thus, the between-group difference existed for the Japanese but not for the Arabic contrast. The possibility that familiarity with phonetic characteristics of a recently acquired language may influence the processing of sounds in an unknown language with similar characteristics to the target language will be discussed. Native Arabic perception is currently under investigation. [Work supported by Macquarie University New Staff grant.]

5pSWa4. Perception of English voiceless alveolar and postalveolar fricatives by Korean speakers. Yunju Suh (Dept. of Linguist., Stony Brook Univ., Stony Brook, NY 11794, yunjusuh@gmail.com)

Korean lacks place contrast of coronal fricatives before i. Yet three alveopalatal fricatives, fortis, lenis, and labialized, occur in this context. Fortis and lenis alveopalatals are intermediate between English alveolar and postalveolar in spectral peak location, though fortis has peak at higher frequencies, and thus is closer to English s. Peak location of labialized alveopalatal is the lowest, largely overlapping with that of English ʃ. The presence of L1 contrast among alveopalatals seems to facilitate Korean listeners' perception of English si-ʃi contrast, especially that between plain and labialized alveopalatals. Korean listeners were presented with eight-step continuum of English si (step 1) to ʃi (step 8), and asked to identify them with an L1 category. The percentage of fortis answer gradually decreased from steps 1 to 4, as lenis answer gradually increased. Labialized answer appeared below 3% until step 4, and increased above 68% at step 5, indicating categorical change of the percept from plain to labialized alveopalatals. There was no categorical change from fortis to lenis, presumably because Korean fortis-lenis contrast involves complex acoustic cues such as vowel f0, frication duration, and amplitude difference between harmonics, in addition to frication noise frequency.

5pSWa5. Electrophysiological indices of vowel discrimination in late bilinguals. Carol A. Tessel, Arild Hestvik, Dolors Girbau, Richard G. Schwartz, and Valerie L. Shafer (The Graduate Ctr.-CUNY, 365 5th Ave., Speech and Hearing-7th floor, New York, NY 10016, ctessel@gc.cuny.edu)

The purposes of the current study are: (1) To investigate discrimination of a vowel contrast not found in Spanish by late learners of English with Spanish as a first language; (2) to assess whether the use of natural consonant-vowel-consonant stimuli and multiple exemplars will show the same pattern of results as found in studies using synthetic stimuli; and (3) examine whether better speech perception as examined by the event-related potential, mismatch negativity (MMN) correlates with greater language usage as measured by a language background questionnaire. The results indicate that late-bilinguals are slower at discriminating the vowel contrast than the English monolinguals, as indexed by MMN. Monolingual English listeners showed significant MMN from 200 to 300 ms, whereas for late learners of English, the MMN was significant 50 ms later between 250 and 300 ms. Both groups showed excellent behavioral discrimination of the vowel contrast. Results also suggest that vowel category reshaping is less flexible in adult learners of a second language. The results will be discussed in relation to language usage.

5pSWa6. Allophonic alternations influence non-native perception of stress. Christine E. Shea and Suzanne Curtin (Dept. of Linguist., Univ. of Calgary, 2500 University Dr. NW, Calgary, AB T2K ON4, Canada)

We examined the identification of stressed syllables by adult L2 Spanish learners to see if it is influenced by an allophonic alternation driven by word position and stress. We utilized the Spanish voiced stop-approximant alternation, where stops occur in word onsets and stressed-syllable onsets. If L2 learners track the distribution of this alternation, they should link stops to stressed syllables in word onset position and approximants to unstressed, word medial position. Low- and Intermediate-level L1 English/L2 Spanish learners, Native Spanish and monolingual English speakers listened to a series of CVCV nonce words and determined which syllable they perceived as stressed. In Experiment 1, we crossed onset allophone and vowel stress. In Experiment 2, we alternated the onset allophone and held the vowel steady. Our results show that less experienced groups were more likely to perceive stressed vowels and approximant onset syllables as stressed. This suggests that learning the interplay between allophonic distributions and their conditioning factors is possible with experience. L2 learners track distributions in the input and this, in turn, influences their perception of other properties in the language, in this case, syllable stress. Native language distributions and target language proficiency play a role in this process.

5pSWa7. Lexical encoding of the second language vowel length contrasts. Jeong-Im Han (Dept. of English, Univ. of Konkuk, Hwayang-dong 1, Gwangjin-gu, Seoul, 143-701, Korea, jhan@konkuk.ac.kr)

Given the previous results for the L2 learners' processing difficulties of suprasegmentals as compared to segmentals, this study tests whether L2 late learners lack a proper phonological representation of suprasegmentals they could use to encode those contrasts. In Experiment 1, two groups of Korean late learners of Japanese (beginner versus advanced) as well as Japanese controls took a simple AX discrimination of the nonword pairs that varied in vowel length only, and showed that both groups of Korean learners had no difficulty to perceive the acoustic differences of the long versus short vowels in Japanese. However, in Experiment 2, when the same groups of learners participated in a more demanding lexical decision task using word-nonword pairs with vowel length differences, they had much difficulty in the use of such vowel length to access the lexicon. Even though there was significant improvement between the beginner and the advanced groups, there were still significant differences between the advanced group and the Japanese natives. These results suggest that L2 late learners might have a true processing deficits for suprasegmental properties in their phonological representation which were not in their L1, which cannot be easily eliminated with a significant exposure to L2.

5pSWa8. Perception of complex word-initial onsets in English by native speakers of Japanese. Mieko Sperbeck (Dept. of Linguist., City Univ. of New York, the Graduate Ctr., 365 Fifth Ave., New York, NY 10016, msperbeck@gc.cuny.edu)

Past studies have shown that English L2 learners whose native languages have relatively simple syllable structure have different degrees of difficulty in producing complex syllable and word onsets in English. For instance, more marked clusters (e.g., /bj/) were harder to produce than the less marked ones (e.g., /pj/) for Japanese learners of English [E. Broselow and D. Finer, Second Language Research 7, 35–59 (1991)]. However, what is unknown is whether such difficulties reflect problems in perceiving complex syllable structures. The current study tested Japanese L2 learners and American English controls in a categorial ABX discrimination test of eight contrasts between nonsense words with consonant cluster onsets CC(C)VCV versus CəC(C)VCV sequences (e.g., /spani/versus/səpani/) and included /sp, sk, pl, bl, kl, gl, spl, skl/ clusters. Words were imbedded in short sentences to increase task difficulty. Results showed that overall accuracy by the Japanese group was significantly poorer than for the Americans (72% and 98% correct respectively). Certain clusters were harder for Japanese listeners (e .g., 76% correct for /pl/ but 64% for /bl/). Productions of the words were also obtained and are related to perceptual performance.

5pSWa9. Discrimination of Mandarin disyllabic tone contrasts by American English-speaking adults and children. Shari Berkowitz (CUNY Graduate Ctr., Speech Acoust. and Percept. Lab., 365 Fifth Ave., New York, NY, 10016, shariellen@gmail.com)

Most research on cross-language perception of Mandarin tones has used monosyllabic stimuli, despite the fact that Mandarin words are predominantly disyllabic. Previous work on disyllable discrimination (Berkowitz and Strange, 2007) suggested that perception by English-speaking adults is influenced by coarticulation and context effects. In this series of studies, subsets of stimuli were chosen to attempt to isolate the effects of fundamental frequency height, contour, turning point and timing on English speakers' ability to perform a same/different task. Three balanced blocks of approximately 10 min each were given, to keep the task appropriate for preschoolers. Feedback conditions varied; some subjects received feedback throughout and others on the first block only. Early results suggest that discrimination of disyllabic Mandarin stimuli is easier for American English speakers if the differences between disyllables occur at onset or offset of the complete utterance; differences in the middle pose more of a challenge. Subjects appear to evaluate disyllabic contours as a whole, rather than on a syllable-by-syllable basis. Implications for future research and training protocols will be discussed.

5pSWa10. Factors inducing cross-linguistic perception of illusory vowels. Jiwon Hwang (Dept. of Linguist., Stony Brook Univ., Stony Brook, NY 11794-4376, jihwang@ic.sunysb.edu)

Japanese speakers tended to hear an illusory vowel in illegal consonant sequences (Dupoux *et al.*, 1999). Korean has no sequences of stop followed by nasal; therefore, it is expected that Korean speakers would perceive an illusory vowel in stop-nasal. In an identification task comparing Korean and English listeners on stimuli along a continuum that ranged from no vowel (igna/ikna) to a full vowel (igVna/ikVna), Korean listeners reported the presence of a vowel significantly more often than English listeners, even when there is no vowel in the stimuli. However, this effect was found only when the stop was voiced, even though [kn] and [gn] are both illegal Korean sequences. In an AXB discrimination task, Korean participants had more difficulty discriminating 'stop-nasal' from 'stop-V-nasal' than English participants, again only when the stop was voiced. The results suggest that voicing, rather than simple illegality, induces bias toward perception of illusory vowel in Korean. This is explained by the fact that in Korean, voiced stops occur only prevocalically in intersonorant position (as an allophone of voiceless obstruents). This voicing effect is reflected in Korean L2 learners' production patterns in which they insert a vowel more often in voiced stop-nasal sequences than in voiceless stop-nasal sequences. [Work supported by NSF BCS-07460227.]

5pSWa11. Individual differences in the perception of final consonant voicing among native and non-native speakers of English. Bruce L. Smith (Dept. of Commun. Sci. and Disord., Univ. of Utah, 390 S. 1530 E., Rm. 1201, Salt Lake City, UT 84112, bruce.smith@hsc.utah.edu) and Rachel Hayes-Harb (Univ. of Utah, Salt Lake City, UT 84112)

Various studies have provided modest evidence supporting the ideas: (1) that non-native listeners outperform native listeners in judging productions by other non-native speakers with whom they share a first-language (L1) background and (2) that non-native listeners are more accurate judging productions by subjects with whom they share an L1 background than they are judging speech contrasts of native English speakers. Research regarding these issues has typically been based on group findings, so it is not clear to

what extent these tendencies may occur among individual listeners. The present investigation reports findings for 15 native English (NE) listeners and 15 non-native listeners (native Mandarin: NM), who made judgments about English voiced/voiceless minimal pairs produced by six other NE and six other NM talkers. When listening to the six NM talkers, fewer than half of the 15 NM subjects performed better than the range shown by the 15 NE listeners. Further, the 15 NM listeners were more accurate than the 15 NE listeners in judging the voicing contrast for just two of the six NM speakers. Thus, limited evidence was found that individual, non-native subjects demonstrate patterns that might have been expected on the basis of previous group findings.

5pSWa12. Perceptual confusions of American English vowels and consonants in Arabic-English bilinguals. Valeriy Shafiro (Dept. Comm. Disord. Sci. Rush Univ. Medical Ctr., 600 S. Paulina Str.,1015 AAC, Chicago, IL 60612), Anatoliy Kharkhurin (American Univ. of Sharjah, Sharjah, UAE), and Erika Levy (Columbia Univ., New York, NY 10027)

This study investigated the perception of American English (AE) vowels and consonants by proficient adult Arabic-English bilinguals studying in the United Arab Emirates (UAE). The native language of all participants was Arabic, and their average age of English acquisition was 6 years. In a closed set format, 29 participants were asked to identify 12 AE vowels presented in /hVd/ context and 20 AE consonants in three vocalic contexts: /ɑCɑ/, /iCi/, and /uCu/. Overall vowel identification was 70% correct. The three least-accurately identified vowels were /ɑ/, /ɔ/, /æ/, which were 17%, 38%, and 54% correct, respectively. Most confusions were found among low and back vowels. Overall, perception of consonants was more than 90% correct in all three vocalic contexts. The most errors on consonants were found for /ð/, i.e., 63% and 46% correct in /ɑCɑ/ and /iCi/ contexts, respectively. In both contexts, /ð/ was most frequently confused with /v/. However, identification of /ð/ in /uCu/ context was far more accurate; i.e., 97% correct. These results suggest a phonetic context effect on the cross-language perception of consonants.

5pSWa13. Experience with foreign accent influences non-native (L2) word recognition: The case of th-substitutions. Adriana Hanulikova and Andrea Weber (Max Planck Inst. for Psycholinguistics, Nijmegen, The Netherlands)

Effects of mispronunciations on word recognition are often explained in terms of perceptual similarity: the less similar mispronunciations are to target words, the more lexical activation is disturbed. Using th-mispronunciations that occur in foreign-accented English, this study investigated whether, irrespective of perceptual similarity, experience with mispronunciations influences word recognition. While Dutch speakers of English frequently substitute voiceless *th* with /t/ (e.g., /tɛft/ for *theft*), German speakers prefer /s/ (e.g., /sɛft/); the perceptually close /f/ occurs infrequently in both groups. Four eye-tracking experiments examined whether familiar substitutions cause stronger lexical activation than less familiar ones. German and Dutch participants listened to sentences spoken with a German or Dutch accent (e.g., "Now you will hear /tɛft/"), while they were looking at a display with four printed words (e.g., *theft*, *left*, *kiss*, *mask*). The time course of lexical activation was measured as a function of amount of looks to printed th-words after hearing mispronounced words with a /t/, /s/, or /f/ substitute. Irrespective of the heard accent, th-words were fixated more often when hearing /t/ for Dutch listeners but /s/ for German listeners, while /f/ never outperformed the accent-specific dominant substitute. The results suggest an influence of accent-specific experience on L2 word recognition.

5pSWa14. Cross-linguistic evidence for the influence of native language prosody in infant speech segmentation. Suzanne Curtin (Depts. of Psych. and Linguist., Univ. of Calgary, 2500 University Dr. NW, Calgary, AB T2N 1N4, Canada, scurtin@ucalary.ca), Linda Polka, Shani Abada (McGill Univ., Montreal, QC H3G 1A8, Canada), and Reaper Sally-Joy (Univ. of Alberta, Alberta, Canada)

Research using artificial languages with English-learning infants has shown both prosodic and distributional cues are used for speech segmentation by 7 months. When these cues conflict, infants younger than 7 months rely on distributional cues while older infants rely on prosodic cues). In the present study we assessed the role of prosodic information in segmentation when it is not favorably aligned with distributional cues, to determine whether language-specific rhythmic biases guide segmentation as suggested by studies using natural speech. Two continuous streams of naturally produced syllables (English and French) were constructed using nines syllables that are permissible in both languages. Within each stream statistical cues were manipulated independently of language-appropriate stress cues. English- and French-learning 8-month-olds were familiarized with their native language stream and then present test probe strings to determine what syllable sequences were extracted from the stream. Probes were selected to assess the role of stress cues in segmentation. Findings show that English infants make use of a trochaic template; Canadian-French infants show a weaker and less focused reliance on stress cues to segment words from connected speech. These cross-linguistic differences reflect processing biases that may be set by language experience and/or elicited by speech input properties.

5pSWa15. Individual gains from auditory training of English vowels for Greek native speakers. A. Lengeris (Dept. of Speech Hearing and Phonetic Sci., Univ. College London, 2 Wakefield St., London WC1N 1PF, UK, a.leggeris@ucl.ac.uk)

Several studies have shown that high-variability auditory training can improve the perception of second-language (L2) sounds by adult learners. However, even when testing a homogenous L2 group, considerable differences are commonly found between individuals not only in pre-training performance but also in how each trainee responds to training. Additionally, it is not clear what aspects of perceptual processing are actually being trained. To address these issues the present study trained Greek native speakers in perceiving the vowels of Southern British English. The trainees received five sessions of high-variability auditory training (including multiple words spoken by multiple talkers). The pre- and post-training tests included identification and discrimination tasks in L1 (Greek) and L2 (English), and a nonspeech (F2 only) discrimination task. Preliminary results show significant improvement in the trainees' identification of L2 vowels, but no significant change in their L2 discrimination. The relationships between pre-training L1, L2, and nonspeech performance and gains in L2 identification for individuals will be discussed.

5pSWa16. Vowel quantity and quality perception in Finnish and Estonian speakers. Stefan Werner (General Linguist. and Lang. Technol., Univ. of Joensuu, Finland, stefan.werner@joensuu.fi) and Einar Meister (Tallinn Univ. of Technol., Estonia)

Vowel quality perception in quantity languages might be expected to be unrelated to duration of the vowels since duration is used to realize phonemic duration oppositions. Our studies, both earlier reported ones and our latest project, indicate, though, that vowel-intrinsic duration changes have a consistent effect on vowel identification in Estonian and Finnish speakers. Our latest experimental setup for investigating perceptional effects of microduration consists of two blocks, first a set of tests to identify the subject's formant-based categorial boundaries between vowel pairs on the close-open axis, then the accordingly selected listening tests presenting formant-wise ambiguous vowel exemplars produced with varying durations. Results from ten Estonian and ten Finnish speakers will be presented. In addition, the phenomenon observed will be compared with formant structure and duration perception in languages where these parameters co-vary (e.g., English) and thus an influence of sub-phonemic durational changes on vowel perception would seem much likelier.

5pSWa17. The phonotactic influence on the perception of a consonant cluster /pt/ by native-English and native-Polish listeners: A behavioral and ERP study. Monica Wagner and Valerie L. Shafer (Ph.D. Prog. in Speech-Lang.-Hearing Sci. The Graduate Ctr., 365 Fifth Ave., New York, NY 10016-4309, mpwspl@aol.com)

The perception of the cluster /pt/ in word onset in native-Polish and native-English adult listeners was compared using behavioral and event-related potential (ERP) measures to explore the language-specific phonotactic influence on speech perception. Acoustic-phonetic features of phonemes vary with context and phonotactic rules specify all allowable phoneme contexts. Both native-Polish and native-English groups are exposed to the cluster /pt/ in their language but only one group, native-Polish, experience the cluster in the context examined, word onset. Word onset consonant cluster /st/ is used as a control. Participants were asked to determine whether

they heard the second word of a pair as consisting of two syllables or three (e.g., pteva versus peteva). Behavioral results revealed that Polish listeners perceive the /pt/ cluster with greater accuracy than English listeners. ERPs revealed late components that differ for the two language groups reflecting linguistically-relevant aspects of the /pt/ contrast and early components that are essentially the same in the two language groups reflecting physical-acoustic differences. ERP results suggest the /st/ contrast to be more salient than the /pt/ contrast consistent with the higher behavioral accuracy for the /st/ cluster. These findings support the suggestion that psychoacoustic salience of acoustic-phonetic features influences speech perception.

5pSWa18. The roles of second-language experience and accent in speech recognition in noise. Melanie Preece-Pinet and Paul Iverson (UCL, Dept. of Lang. Sci., Chandler House, 2 Wakefield St., London WC1N 1PF, UK, m.pinet@ucl.ac.uk)

Previous work has demonstrated that there is an interaction between native (L1) and non-native (L2) accents in speech recognition in noise, with listeners being better at L1 or L2 accents that match their own speech. This study investigated how L2 experience modulates this talker-listener interaction. L1 southern British English (SE) and L1 French listeners with varying L2 English experience (inexperienced FI, experienced FE, and bilinguals FB) were tested on the recognition of English sentences mixed in speech-shaped noise that was spoken with a range of accents (SE, FE, FI, Northern Irish, and Korean-accented English). The results demonstrated that FI listeners were more accurate with strongly accented FI talkers, and were progressively worse for the other accents, perhaps based on accent similarity. The SE listeners, however, had a strong advantage for SE speech, but were similarly poor at understanding the other accents. Their recognition processes were thus selectively tuned to their own accent, rather than having the graded sensitivity of FI listeners. FE and FB listeners were more similar to SE listeners as their experience with English increased. The results thus suggest that increased exposure to L1 speech changes both the intelligibility of accents and the selectivity of accent processing.

5pSWa19. Second language word segmentation in a fluent speech listening task. Tuuli M. Adams (Dept. of Linguist., New York Univ., 726 Broadway, New York, NY 10003, tuuli.adams@nyu.edu)

Extracting words from a continuous speech stream is a complex task involving the integration of multiple linguistic cues. Like infants, adults have been shown to use both distributional information through statistical learning, and metrical and intonational information, when segmenting words in a second language. This study investigates adults' native language influence on speech segmentation, and the extent to which linguistic knowledge is augmented by exposure to fluent, natural speech in a second language. In the experiment, English listeners completed a word learning task in an unfamiliar language, Finnish. Next, they listened to a fluent speech passage which contained learned words, as well as syllable sequences controlled for the same frequencies and transitional probabilities as the real words. English speakers have been shown to use acoustic stress cues to locate word boundaries, and while Finnish has a regular stress pattern, other phonotactic patterns could affect English listeners' segmentation abilities. Afterwards, they completed a forced-choice identification task, choosing from pairs of real and non-words, including incorrectly segmented syllable sequences, to identify the token which is more likely a word in Finnish. The behavioral data are analyzed for patterns reflecting the integration of native language linguistic knowledge and statistical learning abilities.

5pSWa20. Assessing the contribution of second language experience and age of learning in Catalan/Spanish bilinguals' perrception and production of English sounds. Natalia Fullana and Ian R. A. MacKay (Dept. of Linguistcs, Univ. of Ottawa, 70 Laurier Ave. East, Ottawa ON, K1N 6N5 Canada, fullnat@gmail.com)

Previous research in immersion settings has shown that an early age of onset of second language (L2) learning, together with long-term exposure to the L2, are determinant factors for perceiving and producing L2 sounds accurately [e.g., Flege, MacKay, & Meador (1999)]. However, research in formal learning contexts has resulted in negative evidence for an early age of learning advantage [e.g., Garcia-Lecumberri & Gallardo (2003)] or in divergent experience effects (Cebrian, 2003, 2006). This study aimed to further examine the contribution of the factors of age of onset of L2 learning (AOL) and experience in a foreign language learning environment. Catalan/Spanish bilinguals studying English at university, with AOLs of 4 to 14 years and a minimum of 7 years of formal instruction, performed an AXB discrimination task, a picture narrative, and a delayed sentence repetition task. Results revealed that Catalan/Spanish bilinguals with somewhat longer exposure to English and an earlier AOL tended to discern English sounds at higher correct rates. By contrast, a great degree of variability was found across the bilinguals' extemporaneous and prompted production of English segments. Findings are discussed in terms of current models of L2 speech acquisition and their application to formal learning settings. [Work supported by postdoctoral fellowship from the Ministerio de Educacion y Ciencia and the FECYT (Spain).]

5pSWa21. Asymmetric development of perception and production of lexical stress in Korean second-language (L2) learners of English. Jeonghwa Shin and Shari/R. Speer (Dept. of Linguist., Ohio State Univ., 1712 Neil Ave., Columbus, Ohio 43210, jshin@ling.osu.edu)

This study explores perception and production of lexical stress information in L2 English learners whose L1 employs a fixed rhythmic pattern at the lexical level. Nineteen English L1 speakers and 14 Korean L2 learners of English were trained to learn 16 minimal stress nonword pairs with picture referents which are segmentally disambiguating in the last syllable (/dʒákunaɪ/ vs /dʒakúnəɹ/). The eye-tracking perception experiment revealed that English L1 speakers exploited lexical stress information of the first two syllables to spot the target word in the instruction, "Click on the (target word)," whereas Korean L2 learners' identification of the target word was delayed until the last syllable. In their production of words in a carrier, "This is the (target word)," however, L2 learners used loudness and durational cue to indicate alternative prominence of the first two syllable as did English L1 speakers. These results imply the development of production and processing of lexical stress in L2 word learning can be asymmetrical. This asymmetry is attributable to the L1 which has a fixed (T)HLH accentual phrase pattern at the lexical level and thus provides little incentive for the lexically specified stress processing. [Work supported by Linguistics Dept., Ohio State University.]

5pSWa22. Do first-language (L1) phonemic categories play a role in the perception of second-language (L2) phonemic contrasts? A look from the perception of Cantonese codas by Mandarin speakers. Patrick Chun Kau Chu (School of Psych., The Univ. of New South Wales, Sydney, Australia and Dept. of Linguist. and Modern Lang., The Chinese Univ. of Hong Kong, Hong Kong, China, patrickhk83@hotmail.com)

This study investigated whether the phonological system of L1 or universal hierarchy of perceptual similarities has a larger effect on Mandarin speakers' perception of Cantonese phonemic categories. In Mandarin and Cantonese, there are differences in the distribution of nasals and plosives in the coda position. Both nasals (/m/, /n/, and /ng/) and plosives (/p/, /t/, and /k/) are possible codas in Cantonese while only nasals (/n/ and /ng/) can appear in the coda position in Mandarin. Non-native phonemic categories (e .g., /t/) will be assimilated to a native phonemic category (e.g., /n/) if L1 plays a larger role while assimilation to a non-native phonemic category (e .g., /p/ or /k/) may support the idea that universal hierarchy of perceptual similarities plays a more important role. An AX discrimination task is carried out to see whether Mandarin and Cantonese speakers can discriminate these six phonemic contrasts in Cantonese monosyllabic words. Results showed that Mandarin speakers have poorer discrimination ability in the later type (e.g., /t/ vs /k/) than the former type (e.g., /t/ vs /n/). This suggests that the Perceptual Assimilation Model may need to take universal hierarchies of perceptual similarities into account when predicting L2 learners' discrimination ability in a second language.

5pSWa23. Implicit learning of non-native speech stimuli. Eleni L. Vlahou, Athanassios Protopapas (ILSP/Athena, Artemidos 6 & Epidavrou, GR-151 25 Maroussi, Greece, evlahou@ilsp.gr), and Aaron Seitz (Univ. of California-Riverside, Riverside, CA 92521)

Previous studies have induced robust adult learning of non-native natural speech stimuli using explicit instructions and feedback. Here, Greek adults were exposed to non-native Hindi phonemes for six sessions in which they were unaware of the phoneme distinctions and the phonemes had no relevance to their main task. Stimuli were natural recordings of CV syllables (a

retroflex or dental unvoiced stop followed by [a]) from a Hindi speaker. On each trial, participants heard two identical dental sounds and two retroflex sounds differing in intensity by an adaptively varied amount between 0.5–3 dB. The explicit task was to identify which pair differed in intensity, while the implicit learning goal was the phonetic contrast. After training, participants were tested on explicit phonetic identification and discrimination of trained and untrained stimuli spoken by the same and a novel speaker. The trained group outperformed an untrained group who were administered the same tests. Our results are compatible with a perceptual learning model where task-irrelevant stimuli (Hindi sounds) are learned due to a systematic pairing with task targets (intensity difference). Learning did not extend to the novel speaker, in agreement with previous studies showing that variability in training is crucial for generalization.

5pSWa24. Duration as a phonetic cue in the categorization of /i:/-/ɪ/ and /s/-/z/ by spanish/Catalan learners of English. Eva Cerviño and Joan C. Mora (Dept. Filologia Anglesa, Universitat de Barcelona, Gran Via 585, 08007-Barcelona, Spain, ecervino@ub.edu)

Previous research has shown that Spanish/Catalan learners of English (SCLs) rely on duration rather than spectral cues in the categorization of contrastive English vowel pairs such as /i:-/ɪ/, despite length being nondistinctive in Spanish/Catalan. Native English speakers (NESs) rely more heavily on V-C duration ratio than on glottal pulsing in the perception of voicing contrasts in -VC contexts. This study investigated whether SCLs' overreliance on duration in vowel categorization also applied to consonants in contexts (-VC) where lack of closure voicing makes duration the main cue to voicing for NESs. SCLs ($N=40$) and NESs ($N=15$) participated in two lexical decision tasks consisting of /f/+V+/t/ stimuli drawn from two 8-step continua with shortened (/i:/) and lengthened (/ɪ/) vowels; and /p/+/i:/+C stimuli drawn from six 8-step continua with simultaneously and independently modified vowels and final consonants (/i:s/-/i:z/). Manipulating duration had a significant effect on SCLs' categorization of /i:/ and /ɪ/, but not on SCLs' categorization of /s/ and /z/, suggesting that SCLs made use of duration as a cue to vowel categorization, but did not use duration as a cue to voicing. These results are interpreted and further discussed in light of Bohn's Desensitization Hypothesis and McAllister's Feature Hypothesis.

5pSWa25. Phonetic cue-weighting in the acquisition of a second language: Evidence from Greek speakers of English. Anastasia Giannakopoulou, Maria Uther (Ctr. for Cognition and Neuroimaging, Dept. of Psychol., Brunel Univ., Uxbridge, Middlesex, UB8 3PH, UK), and Sari Ylinen (Univ. of Helsinki, PL 9, Helsinki, 00014, Finland)

The most difficult speech-sound contrasts for foreign-language learners are often the ones that have multiple phonetic cues, especially if the cues are weighted differently in the foreign and native languages. Greek speakers of English were studied to determine on what basis they are making discrimination and identification between English vowels. The use of spectral and duration cues of English vowel minimal pairs (e.g., "beat" versus "bit") in Greek speakers were studies using perception and discrimination tasks. There were two forms of perceptual, minimal pair identification tasks. One used natural stimuli and the other used matched vowel duration words to "force" the use of spectral cues. Performance was impaired for Greek speakers across both perceptual identification tasks compared to native speakers. But performance was the worst for Greek speakers for the matched duration condition. Interestingly, an AB-X discrimination task with the same stimuli did not hamper the performance of the Greeks compared to the English in the same way. Pilot data from Greek children also showed similar patterns of performance across conditions to the Greek adults, but with a somewhat reduced ceiling. These results are discussed in terms of the strategies used to acquire new languages.

5pSWa26. Role of rhythmic and intonational cues in language discrimination. Chad Vicenik and Megha Sundara (Dept. of Linguist., 3125 Campbell Hall, UCLA, Los Angeles, CA 90095)

Languages differ in rhythm as well as intonation. Research indicates that adult listeners are able to use rhythm to discriminate between two languages from different rhythm classes [Ramus Mehler, (1999)]. For languages within the same rhythm class, adults are able to use to use intonation to discriminate between languages like English and Dutch, but only when one of the languages is familiar [Ramus and Mehler, (1999); Pijper, (1983)]. It remains unclear if the rhythmic differences between languages in the same rhythm class are enough to support language discrimination. In this paper, we tested American English listeners' ability to categorize re-synthesized American English and German sentences or American and Australian English sentences from which all segmental information had been removed. English and German are from the same rhythm class and differ in intonation; whereas American and Australian English can be thought to be rhythmically identical, but differ in intonation. Subjects were tested in three conditions: (a) with only intonational cues; (b) with only rhythmic cues; and (c) both intonational and rhythmic cues. Preliminary results indicate that listeners rely on rhythm, but not intonation, to distinguish between English and German, and only on intonation to distinguish between American and Australian English.

5pSWa27. Discrimination of American vowels in disyllables mixed in speech babble by experienced Japanese and Russian learners of English. Kikuyo Ito, Yana, D. Gilichinskaya, and Winifred Strange (Speech Acoust. and Percept. Lab., CUNY-Graduate Ctr., 365 Fifth Ave., New York, NY, 10016-4309, kikuyoito@hotmail.com)

Previous studies in this laboratory examining speeded discrimination of American English (AE) vowels in quiet by Japanese (JP) and Russian (RU) late L2 learners indicated differences in relative difficulty of non-native contrasts that were predictable from L1 phonological differences. Response latencies were a sensitive measure of continuing L2 perceptual difficulties. In the present study, the same task (a speeded categorial ABX task with disyllabic stimuli) was administered to Japanese and Russian listeners, with stimuli mixed in speech babble at three levels (SNR 0, 6, 12). Eight experimental contrasts (four with spectral plus duration differences and four with spectral differences only) and four control contrasts were tested in lists with both vowel contrast and noise level varying randomly. Results indicated that both L2 groups performed more poorly than native AE control subjects on many of the experimental contrasts, including those differentiated by duration as well as spectral differences. Again differences in relative perceptual difficulty across L2 groups emerged. Perceptual assimilation patterns and performance on a test of English fluency and pronunciation (versant) were correlated with discrimination performance across individuals. [Work supported by NSF.]

5pSWa28. Phonetic accommodation in conversations between native and non-native speakers. Midam Kim (Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, midamkim@gmail.com)

We explored phonetic accommodation during native speaker interactions (four native English pairs and four native Korean pairs) and native–non-native interactions (four native–non-native pairs, all speaking English). Speakers engaged in a collaborative picture description task that lasted approximately 20 min. Utterances from relatively early and late in the task were subsequently presented to native English listeners (or Korean listeners, for the Korean-language dialogues), who were asked to carry out *XAB* similarity judgments, where X=one talker's utterance and A/B=early and late utterances from the partner. Phonetic accommodation is indexed by how frequently listeners select the "late" utterance as sounding more similar to the target utterance. An independent group of native English speakers rated the nonnative utterances for degree of accentedness. Phonetic convergence was observed for native-native conversations (English or Korean), and this was stronger when speakers shared the same or similar dialects. In native–non-native conversations, none of the native speakers converged towards a non-native partner, while non-native speakers showed different patterns depending on their proficiency, with greatest convergence for moderately accented nonnatives. The results suggest that phonetic accommodation can occur cross-linguistically, and that it may be constrained both by speakers' dialect and by their language proficiency.

5pSWa29. Speeded discrimination of American English vowel contrasts by Spanish-speaking late second-language (L2) learners. Jason Rosas, Arsenia Barias, Yana D. Gilichinskaya, and Winifred Strange (Speech Acoust. and Percept. Lab., CUNY-Graduate Ctr., 365 Fifth Ave., New York, NY 10016-4309)

This study is the third in a series exploring discrimination of American English (AE) vowel contrasts by late L2-learners of English whose native languages have small vowel inventories (Japanese, Russian, Spanish). On a speeded ABX task, adult Spanish-speaking listeners discriminated multiple

AE vowel contrasts including adjacent height pairs that differed in both spectral and duration parameters, front/back pairs (differing only in spectral characteristics, and four nonadjacent control pairs). It was hypothesized that Spanish listeners, who do not distinguish native vowels based on duration, would have difficulties with both types of experimental contrasts, relative to control pairs. Additionally, mean reaction time (RT) difference scores (relative to mean RTs for control pairs) for Spanish listeners were expected to be slower than for AE controls. Preliminary findings confirm these predictions. Differences in relative difficulty of experimental pairs compared with earlier data for Japanese and Russian L2-learners showed L1-specific patterns of performance that were related to L1/L2 perceptual similarity patterns. Spanish subjects also completed the Versant Test, an English language proficiency examination conducted by phone. A correlational analysis of discrimination accuracy and speed with Versant Test fluency and pronunciation measures will be presented. [Work supported by NSF.]

5pSWa30. Spoken word recognition in quiet and noise by native and non-native listeners: Effects of age of immersion and vocabulary size. Astrid Z. Doty, Catherine L. Rogers (Dept. of Comm. Sci. and Dis. and Psych., Univ. of South Florida, 4202 E. Fowler Ave. PCD1017, Tampa, FL 33620), and Judith B. Bryant (Univ. of South Florida, Tampa, FL 33620)

In spoken word recognition, high-frequency words with few and less frequently occurring minimal-pair "neighbors" (lexically easy words) are recognized more accurately than low-frequency words with many and more frequently occurring neighbors (lexically hard words). [Bradlow and Pisoni, J. Acoust. Soc. Am.,106, 2074–2085 (1999)] found a larger "easy-hard" word effect for non-native than native speakers of English. The present study extends this work by specifically comparing word recognition by non-native listeners with either earlier (age 10 or earlier) or later (age 14 or later) ages of immersion in an English-speaking environment to that of native English speakers. Listeners heard six lists of 24 words, each composed of 12 lexically easy and 12 lexically hard target words in an open-set word-identification task. Word lists were presented in quiet and in moderate background noise. A substantially larger easy-hard word effect was obtained only for the later learners, but a measure of oral vocabulary size was significantly correlated with performance for the non-native listener groups only. Thus, the increased easy-hard effect for non-native listeners appears to be better explained as an effect of phonetic proficiency and/or the effect of vocabulary size on the structure of lexical neighborhoods than as an effect of language competition.

5pSWa31. Perceptual adaptation to foreign accented speech. Melissa Baese-Berk (Dept. of Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, m-baese@northwestern.edu)

Previous research on native listener adaptation to foreign-accented adaptation has demonstrated that training on a single non-native speaker results in talker-dependent learning (i.e., training does not generalize to new talkers). However, training on multiple foreign-accented speakers from a single language background results in talker-independent, but accent-dependent learning (i.e., training generalizes to new speakers of the trained accent, but not to new accents). The current study extends these findings, examining whether training on multiple accents can result in accent-independent learning. Native English listeners were trained on recognition of foreign-accented speech by five speakers from different language backgrounds. They were then tested on the speech of two novel speakers. One of the speakers was a native speaker of a language included in the training set (Mandarin), and the other was a native speaker of a language not included in the training set (Slovakian). Listeners demonstrated better performance on both the Mandarin and Slovakian tests than untrained control subjects, demonstrating accent-independent learning after training on multiple foreign accents. This suggests that individuals in multilingual communities, who are exposed to significant variation in the input, may be able to achieve highly flexible speech perception systems.

5pSWa32. Effects of audiovisual auditory and articulatory training on second-language (L2) vowel category learning. Cristina Aliaga-Garcia (Departamento de Filologia Inglesa y Alemana, Universitat de Barcelona, Gran Via Corts Catalanes 585, 08007 Barcelona, Spain, cristinaaliaga@ub.edu)

Cross-language speech perception research has documented learners' difficulties in using and accessing L2 durational and spectral information. This study investigated the short-term effects of two types of audiovisual high-variability phonetic training—auditory versus articulatory training—on the perception of the 11 English RP monophthongal vowels. Bilingual Catalan /Spanish learners of English ($N=20$ in each training condition) and one control group ($N=20$) were tested before and after training. Perceptual gains were assessed through a four-choice categorization task with natural CVC words, a forced-choice categorization task based on four synthesized /hVd/ continua (/i:/-/ɪ/, /æ/-/ʌ/, /ʌ/-/ɑ:/ and /u:/-/ʊ/), and an AX discrimination task including 16 contrasting pairs. Significant perceptual accuracy gains were obtained in both auditory and audiovisual conditions. Pre- and postcategorization of synthesized vowels suggests that vowel perception improved, and that both training modalities had a similar positive effect on the learners' use of spectral and duration information in vowel categorization. These results are further discussed in terms of input effects on vowel category learning and the reweighting of acoustic cues through phonetic training.

5pSWa33. Semantic contextual cues and listener adaptation to foreign-accented English. Page Piccinini (2146 Sherman Ave., Apt. 1D, Evanston, IL 60201, p-piccinini@u.northwestern.edu) and Ann Bradlow (Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, abradlow@northwestern.edu)

The context surrounding words can facilitate word recognition for native and non-native listeners. However, for degraded speech signals, (e.g., with noise), non-natives may lose the ability to take advantage of contextual cues unless the speech is clearly produced [Bradlow and Alexander (2007)]. This study investigated whether: (1) foreign-accented speech degrades the signal such that natives show reduced ability to take advantage of context, and (2) both native and non-native listeners adapt to foreign-accented speech. Native and non-native listeners were exposed to accented speech in two blocks. In each block, half the sentence final words were in high and half were in low predictability contexts. Listeners were asked to identify sentence final words. In a single talker condition, natives benefited from context and adapted to the accent; non-natives could not use context but showed adaption. In a multitalker condition, natives neither benefited from context nor adapted to the accent. Non-natives benefited from context and adapted; however, the context effect was only seen when listener and speaker L1 matched. These results suggest that accented speech disrupts the native ability to take advantage of context, but this can be overcome by adaptation to the speaker. Non-natives benefit substantially from a talker-listener L1 match.

5pSWa34. Perception of dialectal variation: Can speakers of Western Canadian English perceive New Zealand English /r/-sandhi? Verona J. Dickout and Benjamin V. Tucker (Dept. of Linguist., Univ. of Alberta, 4-32 Assiniboia Hall, Edmonton, AB, Canada T6G 2E7)

The current study investigates perception of New Zealand English /ɾ/-sandhi by speakers of Western Canadian English. It investigates whether speakers of Western Canadian English can differentiate between intrusive-/r/ (e.g., *sawing* [sæoɹəŋ]) and linking-/r/ (e.g., *soaring* [sæoɹəŋ]) of /ɾ/-sandhi across morpheme boundaries and across word boundaries (e.g., linking: *boar and*, intrusive: *boa and*). Reaction time and accuracy were recorded in a two-alternative forced choice experiment. Stimuli showed significant acoustic differences between the linking-/r/ and intrusive-/r/ environments, with intrusive-/r/ having a shorter duration than linking-/r/. Participants were highly accurate and faster at recognizing words with linking-/r/ (e.g., *soaring*) and extremely inaccurate and slower at recognizing intrusive-/r/ (e.g., *sawing*). Participants' responses to linking-/r/ at a morpheme boundary were significantly more accurate and faster than responses with linking-/r/ across word boundaries. The results of this experiment address the phonetic variability present in cross-dialect perception and begin to investigate strategies listeners utilize to accurately perceive speech.

5pSWa35. Perception of phonemic and allophonic contrasts in English- and Spanish-learning infants. Morgan Meredith (Commun. Sci. & Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, morgan.leigh@me.com) and Jessica Maye (Northwestern Univ., Evanston, IL 60208)

Infants from monolingual English- and Spanish-speaking homes were compared in their perception of two phonetic contrasts that differ in their phonemic status in the two languages. The contrast [d]-[ð] is phonemic in English but allophonic in Spanish; while the contrast [d]-flap is phonemic in Spanish but allophonic in English. Infants ranged from 6 to 16 months of age. Each infant was tested on discrimination of both contrasts. For half of the infants the stimuli were produced by a Spanish speaker, while for the other half of the infants the stimuli were produced by an English speaker. Data collection from Spanish-learning infants is still in progress. However, preliminary results indicate that infants in the youngest age group (6–8 months) are able to discriminate the [d]-flap contrast regardless of infant language background, while the [d]-[ð] contrast is discriminated poorly at this age in both language groups. English-learning infants lose sensitivity to the allophonic [d]-flap contrast with age, and it is not until 14–16 months that discrimination of the phonemic [d]-[ð] contrast improves in these infants. Spanish-learning infants are expected to remain proficient at discriminating the phonemic [d]-flap as they age and to remain poor at discriminating the allophonic [d]-[ð] contrast. [Work supported by NIH1R03HD048538 to JM.]

5pSWa36. The effects of linguistic experience on the perception of breathy phonation. Christina Esposito (Dept. of Linguist., Macalester College, 1600 Grand Ave., St. Paul, MN 55105, esposito@macalester.edu)

This study investigates the role linguistic experience has on the perception of phonation and the acoustic properties that correlate with this perception. Listeners from Gujarati (contrasts breathy versus modal vowels), Spanish (no breathiness), and English (allophonic breathiness) participated in two tasks. In the visual sort, subjects sorted breathy and modal vowels from a variety of languages into two groups based on perceived similarity of the talkers' voices. In the multidimensional scaling task, listeners heard pairs of Mazatec vowels, and moved a slider to indicate perceived similarity of vowels in each pair. Results showed that judgments were more uniform across subjects who had breathy categories present in their native language and varied across subjects who lack a breathy category. Despite allophonic breathiness, English listeners did no better at distinguishing phonations than Spanish listeners. The perceived similarity among the stimuli correlated with measurable acoustic properties (H1-H2, H1-A3, H1-A1, etc.). H1-H2 was the most salient acoustic property for Gujarati listeners (which correlates with their production of breathy vowels). English listeners relied weakly on the measure H1-H2, which is associated with the production of phonation in English. In addition, Spanish listeners, despite lacking a breathy category, relied on H1-H2 and H1-A1.

5pSWa37. Native language experience influences the perceived similarity of second language vowel categories. Thomas A. Farmer, Ran Liu, Neha S. Mehta, and Jason D. Zevin (Dept. of Psychiatry, Sackler Inst. for Develop. Psychobiol., Weill-Cornell Medical College, Box 140, New York, NY 10021, taf22@cornell.edu)

Most studies of L2 speech perception seek to characterize—at least implicitly—how the similarity among L2 speech sound categories is shaped by L1 experience. Intercategory similarity for native language speakers is rarely considered, however. Here, we derive two indices of graded intercategory similarity for a front vowel series (pin, pen, and pan): One from an off-line perceptual similarity judgment task and a second from online measures of arm-movement trajectories in a word recognition task. Both tasks revealed graded effects of intercategory similarity, but the similarity spaces differed between language groups. Both groups perceived /ae/ and /E/ to be most similar, but the native Italian speakers perceived /I/ to be equally similar to /E/ and /ae/, whereas English speakers perceived the /I/ and /E/ to be more similar than /I/ and /ae/. The Italian speakers' performance in both tasks suggests a similarity space that is dominated by dimensions that are contrastive for /I/ with respect to the other vowels. This may reflect a compensatory strategy for L2 vowel perception that may derive from experience with the distributional properties of their native vowels.

5pSWa38. The role of linguistic experience in the hemispheric perception of Mandarin tone. Shuang Lu (Prog. in Linguist., Univ. of Florida, Gainesville, FL 32611-5454, shuanglu@ufl.edu), Vincent J. van Heuven (Leiden Univ., 2300 RA Leiden, the Netherlands), and Ratree Wayland (Univ. of Florida, Gainesville, FL 32611-5454)

The current study investigated whether and to what extent lexical tone is processed as linguistic information by native Mandarin listeners, early Mandarin-Dutch bilinguals, second year Dutch students of Chinese, and monolingual Dutch students. Dichotic listening task was conducted in each of the four groups in order to determine to what extent the processing of lexical tones in Mandarin was lateralized to the left hemisphere. The majority of native Mandarin listeners revealed a right-ear advantage (REA) corresponding to a left-hemisphere lateralization in the perception of Mandarin tones. Similar to the native Chinese listeners, the Dutch-Mandarin bilinguals also exhibited an REA. Moreover, the left-hemisphere dominance was even more evident for these proficient bilinguals than for the native listeners. However, the Dutch listeners without any experience with Mandarin or other tonal languages showed no ear advantage. For the second year Chinese major listeners, five listeners revealed an REA, while others exhibited a bilateral pattern. The results suggested that there is a tendency for a right-ear advantage corresponding to left-hemisphere superiority for listeners with at least some basic experience of Mandarin tones.

5pSWa39. Category formation and lexical encoding of a new contrast. Isabelle Darcy, Laurent Dekydtspotter, Rex A. Sprouse (Dept. of Second Lang. Studies, Indiana Univ., 1021 E Third St., Bloomington, IN 47405, idarcy@indiana.edu), Christiane Kaden, John H. G. Scott, Vance Schaefer, and Michael McGuire (Indiana Univ., Bloomington, IN 47405)

The question whether category formation is a prerequisite for U.S.-English learners of French to encode a non-native contrast in lexical representations is investigated, looking at front [y-œ] and back [u-ɔ] rounded vowels. An ABX categorization experiment revealed no group difference between advanced ($N=18$) and inexperienced learners ($N=18$). Both made significantly more errors than French controls ($p<0.01$) on the [u-y] contrast, despite a good global discrimination (15% error). The possibility that minimal pairs of difficult contrasts (e.g., *sourd* [sur] deaf vs *sur* [syr] sure) are stored as homophones was tested in a lexical decision task with repetition priming. French words and non-words were paired with either themselves (*repetition*) or a minimal-pair-counterpart (*minimal pair*) in a 260 item list. Correct RTs were measured for each item. Given a comparable RT-advantage on the *repetition* and the *minimal pair* condition, merged lexical representations were assumed. Advanced learners, like native speakers, showed no RT-advantage for *minimal pair* conditions; inexperienced learners displayed significant facilitation for [u-y] and [ɔ-œ] minimal pairs (but not [i-y] control condition). This suggests that successful lexical contrast is possible for advanced English-French users despite persistent perception errors—the hallmark of an insecure category establishment—presenting an argument for the dissociation of both mechanisms.

5pSWa40. Relationship of prosody by Spanish speakers of English as a second language on the perception of intelligibility and accentedness by native English listeners. Paul Edmunds (Dept. of Linguist., Univ. of New Mexico, MSC06 3850, 1 University of New Mexico, Albuquerque, NM 87131)

The degree to which prosodic features related to English lexical stress affect the perception of factors such as intelligibility and accentedness by native English listeners was investigated. Acoustic analyses of English multi-syllabic words spoken by native Spanish speakers who learned English as a second language (ESL) were used to determine the values of the acoustic correlates of lexical stress of these speakers on a set of target words. Values for vowel duration, intensity, and fundamental frequency produced by the Spanish ESL speakers were compared to those values produced by native English speakers. Prosodic variation observed in the ESL speakers was used to formulate a range for manipulations to the target words. To focus solely on prosody and not take into account consonant and vowel quality, manipulations, using the PSOLA algorithm in Praat, were done to the

voices of native English speakers. These manipulations captured increases and decreases in duration, intensity, and fundamental frequency on vowels that should or should not carry lexical stress in a particular target word. Listeners rated the resynthesized tokens for factors such as intelligibility and accentedness, and the results suggest that a speaker's prosody alone can influence a native listener's judgments on these variables.

5pSWa41. The benefit of variation in cross-language perception of voice onset time (VOT). Meghan Sumner (Dept. of Linguist., Margaret Jacks Hall, Bldg. 460, Stanford Univ., Stanford, CA 94305-2150)

Listeners are consistently able to adjust to perceptually ambiguous sounds (Norris *et al.*, 2003; among others). When listeners are exposed to sounds ambiguous between two phonetic categories, boundaries adjust to the ambiguous signal. Perceptual learning has been suggested to account for adjustment to unfamiliar accents. It is not necessarily true, though, that this flexibility extends to more extreme cases of variation. Many sounds in accented speech are unambiguously mapped to the wrong category (e.g., unaspirated voiceless stops in French-accented English are perceived as voiced by native English listeners). We examined English listeners' perception of accented English in a perceptual learning paradigm with two exposure conditions: native French VOT mean and range in words that are lexically unambiguous (e.g., poach, *boach, not pet bet). Perceptual learning completely fails when listeners are exposed to the mean VOT, and in fact, this is coupled with an expanded voiced category, even though the words are lexically biased. Listeners make large adjustments when exposed to a range of VOTS, even those that are not good exemplars of English voiceless stops. The results are counter to models that suggest less variability improves learning, and suggest that variability in speech is used by and beneficial for listeners.

5pSWa42. The impact of native inventory versus native contrast on vowel discrimination. Marc Ettlinger (The Roxelyn and Richard Pepper Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, marc@northwestern.edu) and Keith Johnson (Univ. of California, Berkeley, Berkeley, CA 94720)

Theories of speech perception differ as to whether experience with sounds or with sound contrasts is more important when discriminating novel sounds. To explore this question, 21 American English, 16 Turkish, and 16 French speakers were tested on their ability to discriminate high front vowels in German (/i/~/y/~/Y/~/I/). The crucial difference between the participant languages is that English only uses the tense-lax contrast (/i/~/I/), while Turkish and French only use the rounding contrast (/i/~/y/). If contrast is crucial, then English speakers should be better at discriminating /y/~/Y/, whereas if the inventory is crucial, then they should be better at discriminating /I/~/Y/. The results of a fixed discrimination task show that there is no significant effect of language and that the tense-lax contrast (/i/~/I/; /y/~/Y/) is universally more easily discriminated than the rounding contrast (/i/~/y/; /I/~/Y/). The results of a rating task do reflect an influence of language, however with English-listeners rating /I/~/Y/ as more distinct and French and Turkish speakers rating /y/~/Y/ as more distinct. So, because English has /I/, but no rounding contrast, what matters in the perception of new sounds is not experience with contrasts, but rather experience with particular sounds.

5pSWb1. Experience with computerized speech-perception training (SPATS-ESL) for speakers of other languages learning English. James D. Miller, Roy Sillings, Charles S. Watson (Commun. Disord. Technol., Inc., 501 N. Morton Str., Sta. 215, Bloomington, IN 47404), Isabelle Darcy, and Kathleen Bardovi-Harlig (Indiana Univ., Bloomington, IN 47405)

SPATS-ESL evolved as it was used by volunteers and as a supplement to classes in the Intensive English and English Enhancement Programs at Indiana University (Bloomington). These trials with eighty ESL-learners representing 12 L1s resulted in the curriculum described in the companion poster. Before training, the ESL learners exhibited significant problems with perceiving spoken English. These were greatest for syllable nuclei, least for syllable onsets, and intermediate for syllable codas. Recognition of spoken sentences was also inferior to that of native speakers of English. Improvement on all tasks including sentence recognition was proportional to the total time spent with SPATS. Based on the data and on reasonable extrapolations therefrom, many ESL-learners, after 20–30 hours of spaced practice with SPATS-ESL, appear to be approaching the performance of native-speakers of English on all SPATS-ESL tasks. Responses to questionnaires and comments indicate that the participants believed that SPATS-ESL training (a) was useful, (b) should be used in other classes, (c) helped them understand native speakers in real-life situations, and (d)would help them to improve their pronunciation of English. More advanced students were more enthusiastic about SPATS-ESL than less advanced students. Individual and group data supporting these generalizations and extrapolations will be presented.

5pSWb2. The role of selective attention in the acquisition of English tense and lax vowels by native Spanish listeners: Comparison of three training methods. Maria V. Kondaurova (Dept. of Otolaryngol., Head and Neck Surgery, Indiana Univ. Sch. of Medicine, 699 West Dr., RR044, Indianapolis, IN 46202, mkondaur@iupui.edu) and Alexander L. Francis (Purdue Univ., West Lafayette, IN 47906)

This study investigates the role of two processes, cue enhancement (learning to attend to acoustic cues which characterize a speech contrast for native listeners) and cue inhibition (learning to ignore cues that do not), in the acquisition of the American English tense and lax ([i] and [ɪ]) vowels by native Spanish listeners. This contrast is acoustically distinguished by both vowel spectrum and duration. However, while native English listeners rely primarily on spectrum, inexperienced Spanish listeners tend to rely exclusively on duration. Twenty-nine native Spanish listeners, initially reliant on vowel duration, received either enhancement training, inhibition training, or training with a natural cue distribution. Identification results demonstrated that, although listeners in all training groups increased their reliance on spectrum while decreasing reliance on duration, inhibitory and enhancement methods were significantly better than natural distribution training. Adaptive training was also more successful than the other methods for increasing be-

tween category distinctiveness on a discrimination task. These results suggest that phonetic learning may involve two distinct cognitive processes, cue enhancement and cue inhibition, that function to shift selective attention between separable acoustic dimensions. Moreover, cue-specific training (whether enhancing or inhibitory) appears to be more effective for the acquisition of second language speech contrasts.

5pSWb3. Investigating non-native category learning using a video-game-based training paradigm. Sung-joo Lim and Lori L. Holt (Dept. of Psychol., Carnegie Mellon Univ., 5000 Forbes Ave., Pittsburgh, PA 15213, sungjol@andrew.cmu.edu)

Adults have difficulty learning non-native speech categories, presenting an opportunity to study adult learning and plasticity with non-native speech categorization. Long-term training within laboratory-based response-feedback paradigms has produced modest non-native category learning in previous studies. The current study investigates the effectiveness of a video-game-based categorization training paradigm, found to be effective in learning novel nonspeech auditory categories [W. Holt, (2005)], to train native Japanese adults to categorize English /r/ and /l/. This approach emphasizes functional associations between sound categories and players' responses to video-game characters rather than overt phonetic categorization. Although categorization is not explicit in the game it is helpful to overall performance, providing a functional and perhaps more ecologically valid training signal than traditional feedback in standard laboratory training procedures. Japanese participants who played the game for about 2.5 h across 5 days with /r/ and /l/ sounds matched to game characters showed more nativelike perception of English /r/ and /l/ than control participants who played the game with nonspeech sounds. Listeners' categorization performance furthermore reflected regularities of the /r/-/l/ input distributions. In particular, variability across second-formant (F2) frequency may have encouraged listeners to shift perceptual cue weights toward more nativelike use of third formant (F3) frequency.

5pSWb4. Perception-production loop in native–non-native dialogs: Phonetic convergence. Natalie Lewandowski and Grzegorz Dogil (Inst. for Natural Lang. Processing, Univ. of Stuttgart, Azenbergstr. 12, 70174 Stuttgart, Germany, natalie.lewandowski@ims.uni-stuttgart.de)

The present study investigated the relation between the ability to adapt to the speech of a foreign language dialog partner and the individual variable of language talent. It was assumed that the actual degree to which one can converge to another speaker's pronunciation actually depends on his/her ability to pay attention to fine phonetic detail, to encode it, and to immediately reuse it in running speech—which was defined as phonetic talent. In order to analyze convergence in dialog, ten speakers of German (classified into two groups according to their proficiency and talent) performed a Diapix-task with a British and an American English conversational partner. Our main research goal can be described as follows: Does phonetic talent play a role in the perception-production loop and influence the process of accommodation towards a foreign dialog partner? The statistical analysis of the acoustic measurements revealed a significant effect for the factor talent across the American/British English conditions and also within the AE condition, indicating that the talented speakers have converged more. All results will be discussed assuming an underlying dynamic process, possibly involving a simultaneous interplay of convergence as well as divergence within a conversation.

5pSWb5. Second language influence on perception of first language phonotactics. Cynthia Kilpatrick (UCSD Linguist., 9500 Gilman Dr., #0108, La Jolla, CA 92093-0108)

The results of a speech perception experiment are reported, examining the responses of speakers of the same L1 (Spanish) with varying experience in the L2 (English). Three groups of speakers participated in a wordlikeness rating task in Spanish, in which nonce words were presented in sets that varied as to whether the final consonant of the word was phonotactically legal or illegal: (1) bilinguals who learned both English and Spanish before the age of 5, (2) L1 Spanish speakers that learned English after the age of 12, (3) monolingual speakers without communicative exposure to a second language. All groups differed significantly in the strength of their overall ratings, even though all speakers were technically native speakers of Spanish. In addition, for both the bilingual and second language speakers, ratings for legal vs illegal codas were significantly different. For monolingual speakers, on the other hand, ratings for legal and illegal codas were similar, but response times for these two conditions were significantly different. These results support the idea that native speaker judgements are affected by the extent of language experience that a speaker possesses, and the processing of phonotactic legality may not proceed similarly for monolingual, second language, and bilingual speakers.

5pSWc1. Automatic selective perception (ASP) of first-language (L1) and second-language (L2) speech: A working model. Winifred Strange (Speech Acoust. and Percept. Lab., CUNY-Graduate School, 365 Fifth Ave., New York, NY 10016-4309, strangepin@aol.com)

In this model, speech perception by adults is characterized as an active, information-seeking process whereby native listeners detect the most reliable acoustic parameters that specify phonetic segments and sequences, using highly over-learned, automatic selective perception routines. In laboratory perceptual tasks, differentiation of native (L1) phonetic contrasts is rapid and robust in suboptimal listening conditions even when the listeners focus on other levels of language structure, or indeed on another task. In contrast, late L2 learners must employ greater attentional resources in order to extract sufficient information to differentiate phonetic contrasts that do not occur in their native language. Phonetic and phonological modes of speech perception are described, which can be tapped in the laboratory by manipulations of stimulus complexity and task demands. These experimental manipulations reveal complex interactions between the linguistic experience of listeners and phonetic similarity relationships between L1 and L2 phonological inventories. Illustrative experimental evidence from studies of vowel perception using perceptual assimilation (cross-language identification), speeded discrimination, discrimination in speech babble, and brain indices of discrimination (MMN) will be presented to provide operational definitions of these concepts. Similarities and differences from other current theories of cross-language and L2 speech perception will be discussed. [Work supported by NIH, NSF.]

6aSWa1. Infant magnetoencephalography studies exploring neural links between sensory and motor representations for speech. Patricia K. Kuhl (Univ. of Washington, Inst. for Learning & Brain Sci., Mailstop 357920, Seattle, WA 98195-7920, pkkuhl@u.washington.edu)

The adult brain exhibits anatomical and functional specialization specific to speech, but we have little information regarding the infant brain. Recent adult neuroimaging studies show that speech processing is left-lateralized and that two regions of the brain, the superior temporal (ST, auditory area) and inferior parietal (IF, motor area), contribute to the brain's response to speech. To explore brain activation to speech and nonspeech in infants, we used magnetoencephalography to image the whole brain. Experiment 1 examined infants at three ages: newborn, 6 months, and 12 months. Infants showed significant ST activation to both speech and nonspeech stimuli. IF activation was not observed in newborns but in the two older groups of infants we observed synchronous IF and ST activation that was unique to speech. Experiment 2 investigated the nature of this perceptual-motor coupling for speech—specifically, we asked whether synchronous activation reflects the detection of speech signals per se, or whether it signals the recognition of experienced (native-language) speech. Native, non-native, and nonspeech analogs were used to test these alternatives. Our results elucidate the developmental time course of the sensory-motor connections for speech, and address longstanding theoretical issues in speech perception.

9:40

6aSWa2. Bilingual beginnings as a lens for theory development. Janet F. Werker, Suzanne Curtin, and Krista Byers-Heinlein (Dept. of Psych., Univ. of British Columbia, 1236 West Mall, Vancouver, BC V6T 1Z4, Canada, kbyers@psych.ubc.ca)

Phonetic categories become language specific across the first months of life. However, at the onset of word learning there are tasks in which infants fail to utilize native language phonetic categories to drive word learning. In 2005, we advanced a framework to account for why infants can detect and use phonetic detail in some tasks but not in others (Werker and Curtin, 2005; see also Curtin and Werker, 2007). In this framework, PRIMIR (processing rich information from multidimensional, interactive representation), we argue that by their first birthday, infants have established language-specific phonetic category representations, but also encode and represent both subphonetic and indexical details of speech. Initial biases, developmental level, and task demands influence the level of detail infants use in any particular experimental situation. On some occasions phonetic categories are accessed, but in other tasks they are not given priority. Recently, we have begun studying infants who are exposed to two native languages from birth (Werker and Byers-Heinlein, 2008). In the current paper, we will review recent work on speech perception and word learning in bilingual-learning infants. This will be followed by a discussion of how this research has lead to advances in, and changes to, PRIMIR.

6aSWb1. Phonetic variability in bilinguals' acquisition of native-vowel category contrasts. Laura Bosch and Marta Ramon-Casas (Dept. of Basic Psych., Univ. of Barcelona, 171 P. Vall d'Hebron, Barcelona 08035, Spain)

Previous research has shown that bilingual infants and toddlers follow a slightly different developmental pattern in building and stabilizing some native vowel contrastive categories, compared to monolingual populations. Once in the lexical stage, bilingual toddlers do not always show the expected mispronunciation effect when presented with familiar words in which a vowel change has been introduced. To better understand bilinguals' protracted process in setting the boundaries for certain, perceptually close, native vowel categories, a phonetic analysis of the input characteristics was undertaken. Speech samples containing target words with Catalan mid-front vowel sounds were recorded from two groups of Catalan-speaking mothers from monolingual and bilingual environments, differing in the use of their L2 (Spanish). First and second formant values of the target vowels were obtained and compared between groups. The vowels were always correctly and contrastively produced, but bilinguals' formant values differed significantly from monolinguals': categories were closer in space and greater variability in production was found. Young bilinguals' sensitivity to phonetic variability in the words they hear may constrain the development of neat representations of contrastive vowel categories in the early lexicon. [Work supported by CONSOLIDER 2010 Program (CSD2007-012).]

11:05

6aSWb2. How are speech sound categories acquired in bilingual first language acquisition? Megha Sundara and Adrienne Scutellaro (Dept. of Linguist., UCLA, 3125 Campbell Hall, Los Angeles, CA 90095-1543, megha.sundara@humnet.ucla.edu)

For bilingual infants, phonetic categories of the two languages develop interdependently. This is supported by the differences in time course and trajectory of development of phonetic perception between Spanish-Catalan bilingual and monolingual infants (Bosch and Sebastián-Gallés, 2003a, 2003b, 2005; Sebastián-Gallés and Bosch, in press). Bosch and Sebastián-Gallés argue that for similar phones, at least initially, infants track statistical regularities across the two languages. This results in a temporary inability of bilingual infants to discriminate acoustically similar phonemes. Research on French-English bilingual infants shows a different pattern. There is evidence that French-English bilingual infants may not differ from their monolingual peers in discrimination of phonetic contrasts (Burns *et al.*, 2007; Sundara *et al.*, 2008). In this talk, data will be presented from Spanish-English bilingual infants to evaluate how development of phonetic perception is affected by (a) frequency of phones and (b) the rhythmic (dis)similarity of the two languages to which bilinguals are exposed.

11:40

6aSWb3. The development of English vowel perception in monolingual and bilingual infants: Neurophysiological correlates. Valerie L. Shafer (Program in Speech-Lang.-Hearing Sci., The Graduate Ctr., CUNY, 365 Fifth Ave. NY, NY 10016)

This research examines the maturation of I-E vowel discrimination, in terms of neurophysiological responses, in infants exposed monolingually to English or bilingually to English and Spanish. The vowels [I] as in "pit" and [E] as in "pet" contrast meaning in English but not in Spanish. Bilingual exposure to English and Spanish alters the distribution of phonetic information heard by an infant and may alter the timecourse of vowel category development in the two languages [e.g., L. Bosch and N. Sebastian-Galles (2003)]. The goal of the current study is to examine whether there is evidence from brain responses indicating differences in the development of this English vowel category as a function of amount of English versus Spanish in the input. Preliminary results reveal that both monolin-

gually and bilingually exposed infants and children show evidence of good discrimination of the English vowels, but that the groups with bilingual exposure more often show increased contribution of the right hemisphere to discrimination compared to the groups receiving monolingual exposure. It is not currently clear why these hemispheric differences are found, but they may be related to differences in how attention is allocated in processing the vowels. [This research was supported by NIH HD46193.]

Contributed Papers

All posters will be on display from 1:30 p.m. to 3:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 2:15 p.m. and contributors of even-numbered papers will be at their posters from 2:15 p.m. to 3:00 p.m.

6pSWa1. English vowel perception by native speakers of European Portuguese and Mandarin. Andreia S. Rauber (Ctr. for Humanistic Studies, Univ. of Minho, Campus de Gualtar, Braga, Portugal 4715-057, arauber @ilch.uminho.pt)

This study investigated the perception of eight American English stressed syllabic monophthongs (/i, I, E, æ, V, O, U, u/) by two groups of nonnative listeners: Portuguese and Chinese. Each group was formed by 15 English as a foreign language (EFL) learners, with an upper-intermediate level of English proficiency, all undergraduate students at a Portuguese university. An identification test was designed to investigate how the participants would perceive the English vowels, which are not present in their first language (L1) inventory as stressed monophthongs (/I, æ, V, U/ in the case of the Portuguese speakers, and all vowels but /i, u/ in the case of the Mandarin speakers). The large number of target vowels played as stimuli allowed a cross-language analysis of vowel distribution in the acoustic space: for the two groups of EFL listeners, it was more difficult to perceive the English vowels located in a high density area of the English vowel space than those in less crowded areas. For the two groups of speakers, the vowels /æ/ and /U/ had the greatest misidentification rates.

6pSWa2. Does the native language use of duration affect the perception of non-native length contrasts? Yukari Hirata (Dept. of East Asian Lang. and Lit., Colgate Univ., 13 Oak Dr., Hamilton, NY 13346, yhirata@colgate.edu) and Motoko Ueyama (Univ. di Bologna, 47100 Forli, Italy)

This study compared native Italian (NI) and American English (NE) speakers' abilities to perceive Japanese phonemic length contrasts. Japanese has both vowel and consonant length contrasts, Italian has only consonant length contrast, and English has neither. The study examined to which extent the differential use of duration in their native languages affects their abilities to perceive length contrasts in an unfamiliar language. Twenty-two monolingual NI speakers perceived Japanese words in isolation and in sentences and were asked to identify the number of moras in target words, e.g., /o.do.t.ta/ as four moras. Their test scores were compared to those of 18 NE participants [Hirata (2004)] in an analysis of variance. Group (NE, NI) was a between-subjects factor, and context (isolation, sentences) and word type (long vowels, geminates, combination, and short segments) were within-subjects factors. While there was no main effect of group (NI: 44.6%; NE: 39.5%), there was a significant three-way interaction. The NI group scored significantly higher than the NE group on words with geminates spoken in sentences (43.3 vs 31.1%). Results are discussed as to whether the perception of non-native length contrasts is driven by language-specific ability [McAllister *et al.* (2002)] or by more general auditory ability [Bohn (1995)].

6pSWa3. Linguistic experience in tone perception. James Kirby (Phonology Lab., Dept. of Linguist., 1010 E 59th St., Chicago, IL 60637, jkirby@uchicago.edu)

This paper examines the effect of regional dialect on tone perception. Thirty speakers of Northern and Southern Vietnamese performed an AX discrimination task using natural speech tokens of Northern (NVN) speech. NVN distinguishes six tones, three of which are produced with creaky voice, while Southern Vietnamese (SVN) distinguishes only five tones, none of which are canonically produced with creaky voice; however, both groups of listeners have shown some sensitivity to voice quality as well as F0 cues (Brunelle, 2008). While the results of hierarchical cluster analysis show both Northern and Southern listeners broadly group tones by F0 onset, multidimensional scaling shows the effects of dialect-specific perception: despite some familiarity with NVN speech, SVN listeners did not adjust their perceptual cue space when listening to NVN talkers. As a result, tones with similar F0 profiles but different voice qualities were more likely to be confused by SVN listeners. This is consistent with studies showing that perceptual processes are organized in a language-specific fashion, with the acoustic cue space weighted by phonological relevance to L1 perception (Werker and Tees, 1999; Strange, 2002). It is argued that language-specific prosodic as well as segmental experience affects speech processing at the prelexical level.

6pSWa4. Cross-linguistic interpretation of duration. Ellen Broselow, Jiwon Hwang (Dept. of Linguist., Stony Brook Univ., Stony Brook, NY 11794-4376, ellen.broselow@stonybrook.edu), and Nancy Squires (Stony Brook Univ., Stony Brook, NY 11794)

In Korean, intervocalic [l] is realized as tap ([tal]/[tar-i] 'moon /moon+nom'). In English loanwords, however, intervocalic /l/ is generally adapted as a geminate lateral ([sollo] 'solo' but [sara] 'Sarah'). We present evidence from event-related potentials supporting an analysis in which Korean listeners perceive intervocalic single [l] (illegal in Korean) as geminate [ll], reinterpreting the English [r-l] contrast in terms of the Korean [r-ll] contrast ([dari] 'bridge', [dalli] 'differently'). Korean and English participants heard two sets of oddball paradigms, [ele-elle] and [ene-enne]. In both cases, the acoustic difference is the same, 48 versus 98 msec. However, the nasal pair represents a cross-category contrast in Korean ([kanan] 'poverty', [kannan] 'newborn') while the lateral pair represents a noncontrastive difference. Consistent with studies showing a stronger mismatch negativity (MMN) to cross-category changes than to within-category changes, Korean listeners displayed a significantly larger MMN for the nasal pair than for the lateral pair. In contrast, English listeners (for whom the pairs do not differ in categorical status) did not show significantly different responses to the durational changes in nasals versus laterals. Korean listeners' relatively weak

response to durational differences in laterals suggests that their adaptation pattern reflects inaccurate mapping of the acoustic signal to phonological representations. [Work supported by NSF BCS-07460227.]

6pSWa5. Informational masking in first- and second-language speech recognition. Kristin J. Van Engen (Dept. of Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208, k-van@northwestern.edu)

Human speech recognition in noisy conditions is modulated by cognitive factors such as language background. For example, noise is more detrimental to non-native listeners than native listeners (e.g., van Wijngaarden *et al.*, 2002), and when noise is a speech signal, native-language noise is more detrimental than foreign-language noise for listeners attending to native-language speech targets (e.g., Van Engen and Bradlow, 2007). It is not clear, however, whether this increased interference is primarily due to the native status of the noise or to the greater similarity between target and noise. To address this issue, English speech recognition in the presence of English and Mandarin babble was assessed for monolingual English listeners and L2 English listeners whose L1 is Mandarin. Results showed that intelligibility for both groups was lower in English versus Mandarin babble; that is, L2 listeners experienced more difficulty in same-language noise versus native-language noise. However, monolingual English listeners showed a greater release from masking in Mandarin noise than did L1 Mandarin listeners. The informational masking imposed on speech targets by interfering speech noise, therefore, is dependent both on the linguistic and/or acoustic similarity between the noise and the target and on the listeners' experience with the languages involved.

6pSWa6. Discrimination of English, French, and Spanish liquids by Japanese listeners. Tomohiko Ooigawa (Graduate School of Foreign Studies, Phonet. Lab., Sophia Univ., 7-1 Kioi-cho, Chiyoda-ku, Tokyo, Japan, ooigawaferchichi@gmail.com)

The present study examines the discrimination of English, French, and Spanish intervocalic liquids' contrasts (English /l/-/r/, French /l/-/r/, and Spanish /l/-/r/, /l/-/rr/, /l/-/rr/) by native speakers of Japanese. The results show that the Japanese listeners discriminated the contrasts of French liquids and Spanish trill versus lateral/tap at the rate of more than 95%. On the other hand, they poorly discriminated the contrasts of English liquids and Spanish tap versus lateral. This study discusses whether the current models on second language speech perception account for the phenomena. It has been said that native speakers of Japanese have difficulty in distinguishing the contrasts of liquids both productively and perceptually. A lot of empirical studies on the perception of English liquids by Japanese listeners have been carried out so far. However, there are few empirical studies on the perception of other languages' liquids by Japanese listeners. This is the first study which compares the discrimination of the liquids of the three languages by native speakers of Japanese. In the experiment, utterances of /peCV/ were recorded from the native speakers of the three languages. AXB task was used for the perception experiment.

6pSWa7. Discrimination of four English vowel contrasts by Catalan learners varying in language experience. Lucrecia Rallo Fabra (Univ. of the Balearic Islands, ctra. Valldemossa, km. 7,5, 07122 Palma de Mallorca, Spain)

PAM-L2 (Best and Tyler, 2007) hypothesizes that discrimination of L2 sounds can be predicted from the perceptual relatedness of L2 categories to L1 categories. Catalan EFL learners encounter serious difficulties to discriminate some English vowel contrasts, partly because Catalan has a smaller vowel inventory than American English. This study presents data from a perceptual discrimination test in which three groups of EFL learners varying in experience with English were asked to discriminate a series of potentially difficult English vowel pairs. The discrimination task consisted in picking the odd item out of three stimuli which were heard one after the other at 1.3-s intervals. The target vowel stimuli occurred in CVC syllables produced by six native English talkers. Four vowel contrasts were tested: /*opena-/invv*/, /*eh-/aelig*/, /i-/*smallI*/, and /u-/*smallU*/. As predicted by PAM-L2, "category-goodness" contrasts /i-/*smallI*/ and /u-/*smallU*/ were fairly well discriminated, the "single-category" contrast /*opena-/invv*/ was poorly discriminated. The "uncategorized" contrast /*eh-/aelig*/ failed to meet PAM-L2 predictions, learners failed to distinguish these two vowels although the contrast was predicted as relatively easy to discriminate. Language experience did not have a significant effect on ease of discrimination. These results suggest that PAM-L2 assimilation patterns can also be extended to EFL learning.

6pSWa8. Language preference in monolingual and bilingual infants. Linda Polka, Ayasha Valji (School of Commun. Sci. and Disord., 1266 Pine Ave. W., McGill Univ., Montreal, QC H3G 1A8, Canada, linda.polka@mcgill.ca), and Karen Mattock (Lancaster Univ., Fylde College, Bailrigg, Lancaster LA1 4YW, UK)

Previous research shows that infants in single-language families have some basic language discrimination abilities at birth which improve rapidly over the first 6 months of life, and that attention to the rhythmic properties of language supports these skills. Babies in monolingual families also prefer listening to their native language over an unfamiliar language when presented samples produced by one bilingual or two monolingual talkers. In this study we investigate the emergence of language-specific speech processing in bilingual infants by comparing language preference patterns in monolingual English, monolingual French, and bilingual English-French infants using a three-way language preference test. Listening times were measured to passages of adult-directed speech from three rhythmically different languages (English, French, Japanese; three talkers per language). Ten-month-olds in the monolingual groups listened equally to all three languages. However, 10-month-old bilinguals showed a significant preference for each native language over Japanese; listening times to English and French were not different. Individual bilingual 10-month-olds preferred the more prevalent native language in their input. These findings indicate bilingual infants listen more selectively when they encounter different languages. The implications of these findings for understanding speech processing in early bilingual acquisition will be discussed. [Work supported by SSHRC.]

6pSWa9. The perception of Georgian ejective stops by native English speakers. Christopher S. Doty and Susan G. Guion (Dept. of Linguist., 1290 Univ. of Oregon, Eugene, OR 97403-1290, cdoty@uoregon.edu)

The present study examined the perception of Georgian voiced, voiceless aspirated, and ejective stops by native speakers of English. It was motivated by the observation that languages with three stop-manner series often borrow voiceless aspirated stops as ejectives in a systematic manner. This is likely due to the perceptual similarity between aspirated stops in source language and the ejective stops in the borrowing language. To test the hypothesized perceptual similarity between aspirated and ejective stops, five English speakers were asked to listen to stops which varied in manner of articulation (voiced, voiceless aspirated, ejective) that were produced by a speaker of Georgian. Participants heard three productions at the same place of articulation, one of which differed in manner, and were asked to identify the the oddball stop. The results indicated that the contrast between voiceless aspirated and ejective stops was correctly identified less often than the other two contrasts (voiced versus aspirated, voiced versus ejective) [$p<0$ .05]. No significant difference was found for the other contrasts. These data are supported by the results from a second task, in which the same participants performed a forced-choice identification and goodness rating task with the same productions.

6pSWa10. Perception-production relationship in French vowel learning in adulthood. Erika S. Levy (Speech-Lang. Pathol., Biobehavioral Sci., Teachers College, Columbia Univ., 525 W. 120th St., Box 180, New York, NY 10027, elevy@tc.columbia.edu) and Franzo Law, II (City Univ. of New York-Grad. Ctr., New York, NY 10016-4309)

The present study examined the extent to which perceptual performance by American English (AE) individuals predicted their accuracy in producing second-language (L2) Parisian French (PF) vowels. Three groups of AE participants (no, moderate, and extensive French-language experience) participated in two perceptual tasks (categorial discrimination and perceptual assimilation), and a production (repetition) task involving PF /y-œ-i-a-u/ in bilabial /rabVpa/ and alveolar /radVta/ contexts within a phrase. Results from perception tasks correctly predicted overall production difficulties and effects of language experience and consonantal context in L2 production. Paralleling their perceptual patterns, front rounded vowel productions by AE participants were mislabeled more often as back rounded vowels than as front vowels by native-French speakers. PF /œ/ was produced more accurately with greater L2 experience. Production accuracy of /y/ was also

greater with extensive experience, a finding not expected based on minimal language-experience effects on /y/ perception. Productions of PF /u/ were identified approximately twice as accurately in bilabial context as in alveolar, in a pattern consistent with discrimination performance. Thus, PF /u/ may be considered a "similar" vowel in alveolar context, but not in bilabial, suggesting an allophonic level of representation in L2 learning, both in perception and production.

6pSWa11. Time-course of perception of Mandarin Chinese tones. Chiung-Yun Chang and Robert Allen Fox (Speech Percept. and Acoust. Labs., Speech and Hearing Sci. The Ohio State Univ., Columbus OH 43210-1002, chang.553@osu.edu)

The current study examines the effects of dialect variation on the time-course of lexical tone identification by native and non-native listeners of Mandarin Chinese. Listeners were asked to identify the tone of an isolated Chinese word presented without a precursor phrase. All stimuli were exemplars of V, CV, or CVC combinations that represented real words in Mandarin when produced with any of the four possible lexical tones. Words were produced by multiple talkers with a wide range of F0 values. The dialect of the talkers was also systematically varied. Half were native speakers of Beijing Mandarin, and the other half were native speakers of Taiwanese Mandarin. Preliminary acoustic analysis showed significant differences in tonal realization of the four lexical tones, especially Tone 3. There were three groups of listeners: native speakers of Beijing Mandarin and Taiwanese Mandarin and native English speakers who were learning Beijing Mandarin. A gating task was utilized to determine the temporal location in the token when the lexcial tone was correctly identified and to examine the nature (and time course) of tone confusions. Results will be discussed in terms of the effects of dialect and F0 variation of the stimuli and the native language of the listener.

6pSWa12. Perception or production? Training effects on cross-language phonological awareness tasks in Mandarin-speaking children. Pi-Yu Chiang and Susan Rvachew (School of Commun. Sci. and Disord., McGill Univ., 1266 Pine Ave. West, Montreal QC H3G1A8, Canada, piyu.chiang@mail.mcgill.ca)

This study investigated training effects of perception-based and production-based English activities on the acquisition of phonological awareness of English sound structures by 58 Mandarin-speaking kindergarten-aged children in Taiwan. Children were randomly assigned to one of two experimental conditions or a control condition. Experimental groups participated in a learning session of four English words: band, nest, brick, and stool, with a perceptual or articulation focus on clusters, which do not exist in Mandarin. Outcome measures examined subjects' ability to match words on the basis of shared onset or coda, and to elicit common units in both Mandarin and English before and after training. Significant gain in English onset common unit test scores was observed for the production training group, relative to the control group, especially in trials containing the trained clusters: br- and st-. Perception group however did not show an improvement over time across all measures. Between-group differences were not observed for English codas, Chinese onsets, or Chinese codas. Findings revealed that clearly articulating non-native words with unfamiliar syllable structures could assist children to isolate onsets in explicit phonological awareness tasks, independent of exposure to alphabetic orthography, generally thought to be critical in explicit phonological awareness (e.g., Gombert, 1992).

6pSWa13. Learn to Listen (L2L): Perception training system for learners of English as a second language. Diane Kewley-Port (Commun. Disord. Technol., Inc. and Indiana Univ., Bloomington, IN), Kanae Nishi (Commun. Disord. Technol., Inc. and Boys Town Natl. Res. Hosp., Omaha, NE), Hanyong Park, James D. Miller, and Charles S. Watson (Commun. Disord. Technol., Inc. and Indiana Univ., Bloomington, IN)

Computer software (L2L) is being developed for comprehensive perception training of English by second language learners. Our goal is to facilitate generalization of post-training improvement of phoneme perception to the perception of running speech. Three studies are reported for two groups of adult listeners, one Korean and the other Spanish. In study 1, large sets of confusable phonemes were identified from an assessment task for each group. Then training sets for consonants in CV nonsense syllables and vowels in familiar real words were selected and recordings from multiple talkers were obtained. Materials for the word-in-sentence (WIS) task were developed with a single low-context carrier phrase which contained three words from the vowel training. In study 2 new Korean and Spanish listeners were trained using a protocol that included a pre-test, eight hours of training, a post-test, and one hour using the WIS task. Training results showed: (1) both Korean and Spanish listeners improved from pre- to post-tests for vowels and consonants; (2) in vowel identification, Koreans outperformed Spanish by 34% (3) vowel identification in the WIS task appeared easier than in word-only task, a result confirmed by a study using the WIS task without training (study 3). [Work supported by NIH.]

6pSWa14. Effects of linguistic and musical experience on non-native perception of Thai vowel duration. Angela Cooper and Yue Wang (Dept. of Linguist., Simon Fraser Univ., 8888 Univ. Dr., Burnaby, B.C. V5A 1S6 Canada, akcooper@sfu.ca)

Previous research has suggested a relationship between musical experience and L2 proficiency. The present study investigated the influence of musical experience on non-native perception of speaking-rate varied Thai phonemic vowel length distinctions. Given that musicians are trained to discern temporal distinctions in music, we hypothesized that their musical experience would enhance their ability to perceive non-native vowel length distinctions as well as their sensitivity to temporal changes as a function of speaking rate. Naive native English listeners of Thai, with and without musical training, as well as native Thai listeners, were presented with minimal pairs of monosyllabic Thai words differing in vowel length at three speaking rates in an identification task and a discrimination task. For identification, participants were asked to identify whether a word contained a long or short vowel. For discrimination, participants heard three successive words and were asked to indicate whether the second word had the same vowel length as the first or last word. The results show significant group differences in identification and discrimination accuracy within and across speaking rates, suggesting that listeners' perception of phonetic categorical versus temporal acoustic variations differs as a function of linguistic and musical experience.

6pSWa15. Increased second-language vocabulary size is associated with more consistent second-language vowel categorization and better discrimination. Rikke L. Bundgaard-Nielsen (MARCS Auditory Lab., Univ. of Western Sydney, Bankstown Campus, Bldg. 1, Locked Bag 1797, Penrith South DC, NSW 1797, Australia, r.bundgaardnielsen@uws.edu.au), Catherine T. Best, and Michael D. Tyler (Univ. of Western Sydney, NSW 1797, Australia)

Improvement in second-language (L2) perception has been posited to asymptote early in L2 learning when the L2 vocabulary is still small, whereas a large L2 vocabulary curtails perceptual learning [PAM-L2: Best and Tyler (2007)]. We extend this proposition by suggesting that early L2 lexical development facilitates establishment of phonological categories in a manner analogous to toddlers' L1 acquisition before versus after the vocabulary explosion. According to this revised view, L2 speech should be assimilated more consistently to phonological categories, and cross-boundary contrasts discriminated more accurately, by learners with large versus small L2 vocabularies. We applied a novel whole-system approach to evaluate perception of L2 vowels with respect to the L1 vowel system. Japanese learners of Australian English with under 12 weeks of L2 immersion completed labeling and goodness ratings on all Australian vowels, using all mono- and bi-moraic Japanese vowels and vowel combinations. They also completed discrimination tasks on four L2 vowel contrasts, representing a range of PAM-L2 contrast types, and a L2 vocabulary size assessment. Learners with larger vocabularies had more consistent vowel assimilation and more accurate cross-boundary discrimination than those with smaller vocabularies, supporting the proposition that lexical development supports L2 phonological acquisition. [Work supported by NIH and MARCS/UWS.]

6pSWa16. The perception of Norwegian word tones by second language speakers. Wim A. van Dommelen and Olaf Husby (Dept. of Lang. and Comm. Studies, NTNU, N-7491 Trondheim, Norway, wim.van.dommelen@hf.ntnu.no)

The present study is concerned with the perception of Norwegian word tones by second language speakers. The phonological system of Norwegian involves two different tones that are used to distinguish a relatively large

number of word pairs. Earlier studies have shown that native speakers of Norwegian are able to identify the word tones almost error-free. The aim of the present study was to investigate word tone perception by speakers of a tonal language (Mandarin Chinese) and a non-tonal language (German). These two groups as well as a control group of native listeners identified manipulated stimuli with tonal contours varying between tone 1 and tone 2. It appeared that the L2 users had less sharp transitions than the natives, the Chinese subjects performing somewhat better than the Germans. In addition, native speakers categorized tokens of tone 1 and tone 2 words produced by the L2 speakers and indicated on a five-point scale how sure they were in their judgment. In an acoustical analysis the fundamental frequency contours of the L2 test words were analyzed and subsequently used for comparison with native categorization results. The implications of the found correlations between production and perception are discussed.

6pSWa17. Prominence perception: Conflicting cues and linguistically encoded bias. Miran Kim (Dept. of Linguist., State Univ. of New York at Stony Brook, S201 SBS Bldg., Stony Brook, NY 11794, mrkim@ic.sunysb.edu)

Beyond the commonly known fact that prominent syllables are greater in amplitude, higher in F0, and longer in duration, this study examines cross linguistic patterns in the perception of prominence. Particularly, identification of stress placement is tested in a situation where F0 and duration happen to be in conflict (e.g., H+L* bitonal pitch accent). Three languages are selected considering their prosodic characteristics such as phonological role of prominence and rhythm (stress-timed/syllable-timed): English, Spanish, and Korean. A new-language-learning setting is devised to collect production data based on which the patterns of phonetic realization of stress are directly compared among the language groups. CVCVCV pseudowords, where C=m, n, k, s and V=a, (e, i), are used for both production and perception experiments. F0 and duration are manipulated in order to create conflicting cues that are suitable for the purpose of the perception experiment. Stressed syllables are consistently realized with higher F0 together with longer duration across the groups, though to different extents. The perceptual sensitivity to the durational manipulation is found to vary among the groups. Linguistic implications are discussed referring to the phonological role(s) of F0 and duration in each language as well as to the relationship between production and perception.

6pSWa18. Perceptual attunement in infants at risk of reading disabilities. Christine Kitamura and Anna Herald (MARCS Auditory Lab., Bldg. 5, Bankstown Campus, Univ. of Western Sydney, Locked bag 1797, Penrith South DC, NSW, 1797, c.kitamura@uws, edu.au)

Impaired phonological processing has been found to have a reciprocal casual association with the reading ability of people with reading difficulties. Further, there is growing evidence that problems in phonological processing are present at birth as research shows that infants with a family history of these disorders have atypical neural electrical responses (ERPs) to speech stimuli. However, the nature of the phonological deficit is not clear. This study examined the phonological development of at-risk 9- to 12-month-old infants (n=18) and a control group (n=18). Their discrimination performance was evaluated using the habituation-dishabituation task to test their ability to discriminate the confusable native contrast, /fa-tha/ and the non-native contrast, /k'i-q'i/ from Werker and Tees (1984). In line with core phonological deficit hypothesis and hereditary accounts of reading difficulties, infants' attunement to their native language was significantly correlated with parental phonological ability measured using Pseudoword Decoding Test of the WIAT-II. The at-risk infants easily discriminated both native and non-native contrasts, whereas the control infants discriminated the native contrast but could not discriminate the non-native one. These results indicate that at-risk infants do not attune to their native language at the same rate as their peers.

6pSWa19. Effects of visual cues and phonetic contexts in perception of non-native contrasts by Cantonese learners of english. Bin Li (Dept. of Chinese, Translation & Linguist., City Univ. of Hong Kong, Hong Kong SAR, China)

Visual articulatory information, in addition to audio features, is integrated in L1 and L2 speech perception automatically and unconsciously [McGurk and MacDonald (1976); Rosenblum *et al.* (1997); Hardison (2003); Hazan *et al.* (2005)]. Previous literature on consonant perception has reported that visual aid is most significant with places of articulation, and that with manners, except with /r/ and /l/, has received little attention due to lack of research significance. Contrary to the commonly held idea, however, that the articulation of [l] and [n] is visually similar, our examination on video recording of three native English speakers' production of words contrasting [l] and [n] syllable initially suggests visual differences in advancement of tongue tips. This study investigates effects of such visual information in the identification of the non-native contrast by Cantonese learners of English. Results show that the relatively more distinct visual information can only help Cantonese speakers better perceive the two sounds in certain contexts, and in others cause more confusion.

6pSWa20. Do words in the native language influence second-language speech perception? Evidence from Japanese listeners' perception of English words that exist as Japanese loanwords. Keiichi Tajima (Dept. of Psych., Hosei Univ., 2-17-1 Fujimi, Chiyoda-ku, Tokyo 102-8160, Japan, tajima@hosei.ac.jp)

It is well known that native-language (L1) sound structure influences adult learners' perception of second-language (L2) speech. However, it is not as clear whether L2 speech perception can also be influenced by L1 mental lexicon. Specifically, L2 words may be inaccurately perceived if familiar loanword counterparts exist in L1 and if these loanwords have different sound patterns from the original words. To examine this, the present study took advantage of Japanese loanwords from English (e.g., Japanese /sutoresu/ from English "stress"), which typically undergo syllable structure changes, and investigated whether Japanese listeners can accurately perceive the syllable structure of English words even when loanwords exist in Japanese. Thirty native Japanese listeners were asked to count syllables in 189 English words spoken by a native English talker, and rate their subjective familiarity with the English words and their loanword counterparts transcribed in Japanese katakana orthography. Results indicated that syllable-counting accuracy (65% on average) was not influenced by familiarity with the English words nor with the Japanese loanwords. Results suggest that even though loanwords resemble the original words in their sound and meaning, knowledge of such words in L1 does not necessarily influence perceptual processing of L2 words. [Work supported by MEXT and JSPS.]

6pSWa21. Predicting second language (L2) identification rates from first language (L1) mapping data: Similarity patterns for English and Korean obstruents in pre- and poststressed intervocalic, and postvocalic positions. Hanyong Park (Speech Res. Lab., Indiana Univ., 1101 E. 10th St., Bloomington, IN 47405, hanypark@indiana.edu) and Kenneth J. de Jong (Dept. of Linguist., Indiana Univ., Bloomington, IN 40405)

Park and de Jong [J.Phon, **36**, 704–723 (2008)] found that listeners' identification rates of second language (L2) categories can be predicted from mapping data, provided the L2 category has a high degree of subjective correspondence to native language (L1) categories. The current study examines whether identification rates can be predicted for consonants in different prosodic locations, and hence, whether the reliance on L1 categories is the same, regardless of prosodic position. Forty native Koreans identified /p b t d f v θo/ in pre- and poststressed intervocalic, and postvocalic positions, in nonsense English words, using both Korean and English labels, and also gave gradient evaluations of their identifications. The mapping data were used to predict confusion rates for the L2 identification data, finding results for prestress intervocalic consonants similar to the previous study for word-dinitial consonants; stop identification rates were well-predicted, but fricatives are systematically much better than predicted. In poststress position, however, fricative identification rates were very well predicted, suggesting that fricatives were treated as "similar" to L1 categories. These results indicate that the degree of assimilation of an L2 to an L1 category is heavily dependent on prosodic location. [Work supported by NSF BCS-04406540.]

6pSWa22. Perception of foreign accent in Japanese and Brazilian Portuguese: Prosodic and segmental factors. Masahiko Komatsu (School of Psychol. Sci., Health Sci. Univ. of Hokkaido, Ainosato 2-5, Sapporo, 002-8072 Japan, koma2@hoku-iryo-u.ac.jp)

Japanese sentences read by Japanese-descent Brazilians (L2) and native Japanese speakers (L1) were rated by native Japanese speakers, and Portuguese sentences read by native Japanese speakers learning Portuguese (L2)

and Japanese-descent Brazilians (L1) were rated by Brazilians. The raters evaluated three types of samples: (a) sounds without spectral properties (representing prosodic features); (b) *F*0-flattened sounds (representing segmental features); and (c) unmodified sounds. In both languages, the perceptual scores of L1 and L2 samples were separated most clearly in (c), followed by (b) and (a). Both the scores of (a) and (b) showed strong correlations with (c) in L2. These suggest that both prosodic and segmental features play a role in the detection of foreign accent, but the latter has a greater effect. *F*0 characteristics varied between speaker groups rather than languages. The speaking rate in L2 was correlated with the perception scores. The effect of segmental features was greater in L2 Portuguese than in L2 Japanese, i.e., greater in less fluent speech. Foreign accents in both languages share common properties although having some differences. [This work is the revised version of Komatsu and Kimoto (2008) and Komatsu (in press), and partially supported by KAKENHI (20242010) and HSUH Kotaisa grant.]

6pSWa23. Acquisition of new phonetic categories by bilingual and monolingual groups: Role of metalinguistic awareness and feature generalization. Divya V. Gogoi (Linguist. Program, Univ. of Florida, P.O. Box 115454, Gainesville, FL 32611) and James D. Harnsberger (Dept. of Commun. Sci. Disord., Univ. of Florida, Gainesville, FL 32611)

The present study examines the role of feature generalization and metalinguistic awareness in the perception and learning of novel non-native speech contrasts by 40 bilingual speakers (Bengali–English and Spanish–English) and 20 monolingual speakers of American English. Bilinguals, unlike monolinguals, employ certain cognitive and linguistic skills during lexical processing and word learning attributed as metalinguistic awareness. This awareness in turn, can be applied in mastering unfamiliar phonetic features in a third language. A second issue concerns the role that native phonetic features may play in the development of new phonetic categories involving same phonetic features (feature generalization hypothesis). To explore both factors, a high variability perception training paradigm was used to examine the acquisition of novel non-native speech contrasts (containing dental/alveolar-retroflex place distinction in various manners) from a target language, Malayalam. A consonant identification procedure was used throughout the training and testing phases of the experiment to examine post-test and generalization performance across groups. Productions of the stimuli were also recorded at the pretest and posttest phases. In addition, perceptual assimilation patterns were analyzed from consonant assimilation and discrimination scores before and after training.

6pSWa24. Dutch listeners' perception of Korean stop triplets. Mirjam Broersma (Radboud Univ. Nijmegen, Donders Inst. for Brain, Cognition and Behaviour, Ctr. for Cognition, P.O. Box 9104, 6500 HE Nijmegen, The Netherlands, mirjam@mirjambroersma.nl)

This study investigates Dutch listeners' perception of Korean stop triplets. Whereas Dutch distinguishes prevoiced and voiceless unaspirated stops, Korean distinguishes fortis, lenis, and aspirated stops. Here, perception of fortis, lenis, and aspirated bilabial (/pp/-/p/-/ph/), alveolar (/tt/-/t/-/th/), and velar (/kk/-/k/-/kh/) stops is investigated. In Dutch, VOT is the most important perceptual cue for initial stop voicing. Korean fortis stops fall within the VOT range of Dutch voiceless stops; VOTs of lenis and especially aspirated stops are longer than Dutch VOTs. Therefore, Dutch listeners were expected to distinguish fortis stops more accurately from the other two than lenis and aspirated stops from one another. In a phonetic categorization experiment, Dutch listeners categorized Korean stops in naturally recorded CVs as fortis/lenis, lenis/aspirated, or fortis/aspirated. Indeed, for all places of articulation, fortis stops were distinguished relatively accurately from the other two stops. The most difficult distinction was between lenis and aspirated stops (both outside the Dutch VOT range), the easiest distinction between fortis and aspirated stops (the former within the Dutch VOT range, the latter the most remote from Dutch VOTs). Thus, although all Korean VOT category boundaries are outside the Dutch VOT range, the distance from Dutch VOT values affected Dutch listeners' categorization.

6pSWa25. Effects of native language and amount of experience on crosslinguistic perception. Juli Cebrian (Dept. Filologia Anglesa, Fac. Filosofia i Lletres-Edifici B, Univ. Autonoma de Barcelona, Bellaterra 08193, Spain, juli.cebrian@uab.es)

Models of second language (L2) speech learning draw on the notion of perceptual similarity to make predictions about L2 perception and production difficulty. Crosslinguistic perceived similarity is commonly assessed by means of perceptual assimilation tasks involving identification of target stimuli and goodness of fit ratings. Further, experience with an L2 may affect the perception of not only target language vowels but also native vowels. This paper reports the results of a crosslinguistic perception study involving English and Catalan vowels and diphthongs. The study assessed the perceived similarity of the two vowel systems by testing native speakers of each language on sounds from both their native language and the foreign language. Vowels were presented in CVC syllables. The effect of learning a second language was investigated by comparing the performance of language learners and monolingual speakers on the same task. The comparison between the two monolingual groups indicated a symmetry in the pattern of crosslinguistic perceived similarity while the effect of experience was found to vary with different vowels. The results are discussed in light of current theories and their predictions for second language perception and production. [Work supported by Grants HUM2005-02746/FILO (Spanish Ministry of Education) and 2005SGR00864 (Catalan Government).]

6pSWa26. Experience effects on the categorization of a native vowel contrast in highly proficient Catalan-Spanish bilinguals. Joan C. Mora (Dept. Filologia Anglesa, Universitat de Barcelona, Gran Via 585, 08007-Barcelona, Spain, mora@ub.edu) and Marianna Nadeu (Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801)

The present study investigated the effect of experience on highly proficient adult Catalan-Spanish bilinguals' ability to categorize two contrastive native vowel categories, /e/ and /ɛ/. Experience was operationalized as self-reported amount of use of Catalan on a daily basis. Because Spanish has a single mid front vowel /e/ in the area of the perceptual vowel space of the Catalan mid vowels /e/ and /ɛ/, categorization and discrimination speed and accuracy was hypothesized to vary as a function of amount of use of Catalan and Spanish, more experienced Catalan speakers performing faster and perceiving the contrast more categorically. All participants ($N=43$) were L1-Catalan bilinguals, but differed as regards the amount of use of Catalan ($N=14$, $M=62.1$, range 40–70 vs $N=29$, $M=91.4$, range 80–100). Experience effects were assessed through the categorical perception paradigm: categorization and AXB discrimination tasks based on stimuli drawn from a 10-step vowel continuum (/e/-/ɛ/). Response latency data revealed that the high-use-of-Catalan group outperformed the low-use-of Catalan group, suggesting that greater use of Catalan on a daily basis improved bilinguals' ability to categorize and discriminate this vowel contrast. These results are interpreted as being consistent with the view that L1 and L2 experience affects the perception of L1 sounds.

6pSWa27. The influence of lexical access and linguistic context on second-language (L2) speech perception. Mara Haslam (Dept. of Linguist., Univ. of Utah, 255 S. Central Campus Dr., Rm. 2300, Salt Lake City, UT 84112, m.haslam@utah.edu), Albert Jarvi (Univ. of Illinois Urbana-Champaign, Urbana, IL 61801), and Rachel Hayes-Harb (Univ. of Utah, Salt Lake City, UT 84112)

Research on the perception of novel phonemic contrasts by second language (L2) learners typically employs tasks such as identification and discrimination. These tasks allow researchers to study L2 speech in a highly controlled setting. However, they differ in important ways from natural communication, which normally requires learners to (1) access lexical representations of words containing novel contrasts, and (2) interpret linguistic context (e.g., syntax, semantics, discourse) while simultaneously perceiving /producing novel contrasts. This study investigated whether learners/ perceptual performance with respect to novel contrasts is mediated by whether or not tasks require lexical access (LA) and/or the simultaneous interpretation of linguistic context (SILC). Native English speakers learned Ukrainian auditory nonword pairs differentiated by palatalization contrasts along with pictured "meanings." An ability to distinguish the words was tested in tasks differing on the two dimensions (LA and SILC). Performance was most accurate in the noLA + noSILC task, least accurate in the LA + SILC and noLA + SILC tasks, and intermediate in the LA + noSILC task, indicating that both LA and SILC appear to depress perceptual accuracy. However, the effect of SILC is stronger than that of LA. Future directions and implications for the study of L2 perception/production will be discussed.

6pSWa28. Word-level rhythm in non-native English. Rachel E. Baker (Dept. of Linguist., Northwestern Univ., 2016 Sheridan Rd., Evanston, IL 60208-4090, r-baker2@northwestern.edu), Laurent Bonnasse-Gahot (Ecole des Hautes Etudes en Sci. Sociales, Paris 75006, France), Kristin J. Van Engen, Melissa Baese-Berk, and Midam Kim (Dept. of Linguist., Northwestern Univ., Evanston, IL 60208-4090)

Motivated by traditional rhythm class typologies, studies of language-learners' rhythm typically focus on the syllable or segment level. Studying word-level rhythm lets us explore the effects of lexical features (e.g., part of speech, predictability) on word durations in non-native speech. This study examined whether native and non-native English can be distinguished by variation in the realization of English lexical features, and whether non-native-like word-level rhythm leads to a stronger foreign accent. Word durations were measured in English paragraphs read by 12 native American English (AE), 20 native Korean, and 20 native Chinese speakers. AE listeners rated the "accentedness" of these speakers. AE speakers showed greater within-speaker word duration variance than non-natives, and non-native speakers with greater variance received more native-like accent ratings. Increased AE variance had two causes. AE speakers had shorter relative durations for function words than non-natives. AE speakers also showed greater variance in their content word durations than non-natives, perhaps due to differences between words with and without pitch accents. However, both AE and non-native speakers produced shorter second mentions of words than first mentions, showing sensitivity to lexical predictability. Overall, these findings implicate word-level rhythm as an important and complex feature of foreign-accented English.

6pSWa29. English vowel contrast perception on monolingual and bilingual 4- to 7-year olds: Behavioral and neurophysiological evidence. Yan Yu, Nancy Vidal, Hia Datta, Jennifer Gerometta, and Valerie Shafer (Speech-Lang.-Hearing Sci., the Graduate Ctr., City Univ. of New York, New York, NY 10016)

The role of simultaneous bilingual language exposure on speech perception development has been far from definitive. Behavioral literature has been controversial in terms of whether bilingual children keep pace with their monolingual peers [Burns *et al.* (2007); Sundara *et al.* (2006)]. The purpose of the current study is to: (1) investigate whether bilingual exposure to Spanish and English affects processing of speech stimuli that are phonemic only in English in children from 4–7 years of age; (2) whether the event-related potential (ERP) measures correlate with the behavioral measure (e.g., phoneme identification). Phonetically similar vowel contrasts (I versus E) were presented in an oddball paradigm while ERPs were collected from 65 scalp sites. Vowel discrimination and vowel identification were carried out using I-E vowel continuum. Preliminary analyses suggest that there is no difference in how monolingual and bilingual children behaviorally identify this vowel contrast. In terms of the ERP responses, children in both groups showed vowel discrimination as indexed by the presence of mismatch responses (MMRs). Younger children tended to still have a positive MMR that preceded the adult-like negative MMR. Individual patterns of response will be discussed in relation to amount of English versus Spanish exposure.

6pSWa30. Using voice quality to learn non-native tonal categories. Kristine M. Yu (Dept. of Linguist., Univ. of California, Los Angeles, 3125 Campbell Hall, Los Angeles, CA 90095, krisyu@humnet.ucla.edu)

An artificial language learning experiment will be used to study if voice quality can be used to learn tonal systems. Cross-linguistically, tone, and voice quality can co-vary in different ways. For instance, Mazatec (Jalapa de Diaz), has three phonation types (modal, breathy, creaky) fully crossed with three level tone levels [Ladefoged *et al.* (1988)], while Mandarin has creaky phonation in Tone 3 and Tone 4, which are also distinguished from one another and Tone 1 and 2 by f0 contour [Davison (1991); Belotel-Grenié and Grenié (2004)]. The goal of the study is to investigate if English listeners unfamiliar with tone languages can use phonation-type contrasts to learn tonal contrasts in artificial tone languages differing in how tone and voice quality co-vary. There will be a comparison of how learners generalize from training to novel stimuli for artificial languages where voice quality and tone contrasts are correlated and uncorrelated cues.

6pSWa31. Intelligibility of Spanish-accented English words in noise. Jonathan Dalby (Dept. of Audiol. and Speech Sci., Indiana Univ.-Purdue Univ., Fort Wayne, 2101 E. Coliseum, Ft. Wayne, IN 46805, dalbyj@ipfw.edu) and Catherine L. Rogers (Univ. of South Florida, Tampa, FL 33620)

The intelligibility of Mandarin-accented English sentences, even those spoken by highly proficient non-native speakers, is degraded more than is native speech when presented to native listeners in noise [Rogers *et al.* (2004)]. Comprehension of accented speech may require more processing time than native speech even when presented in quiet [Munro and Derwing (1995)]. These effects are similar to effects found by Pisoni and his colleagues for synthetic, as compared to natural speech [Winters and Pisoni (2003)] and together suggest that the ability of native listeners to adapt relatively quickly and effectively to accented speech [Bradlow and Bent (2008); Clark and Garrett (2004)] may come at the expense of increased cognitive effort. The present study examines the effects of noise on the intelligibility of Mandarin-accented isolated words from speakers representing a wide range of oral English proficiency based on connected-speech measures. A subset of these words, those with the highest open-set identification scores as rated by a jury of 10 native listeners, will be presented for identification to a second jury at four signal-to-noise ratios: quiet, +10, 0, and −5 dB. Results are compared to those found for connected speech from the same group of talkers. [Work supported by NIH-NIDCD.]

6pSWa32. Infant dialect discrimination. Jennifer Phan and Derek M. Houston (Dept. of Otolaryngol., Indiana Univ. School of Medicine, 699 West Dr., Indianapolis, IN 46202, jphan@iupui.edu)

To understand speech, infants must differentiate between phonetic changes that are linguistically contrastive and those that are not. Research has shown that infants are very sensitive to fine-grained differences in speech sounds that differentiate words in their own or another language. However, little is known about infants' ability to discriminate phonetic differences associated with different dialects of their native language. Using a visual habituation procedure, 7-, 11-, 18-, 24-, and 30-month olds were tested on their ability to discriminate two linguistically equivalent variants of the diphthong (/aI/)—one produced in their native dialect (North Midland American English) versus one produced in a non-native dialect (Southern American English). Seven-month olds discriminated the variants but 11-month olds did not. Infants from 18–30 months of age did not demonstrate statistically significant discrimination, but they did show a trend toward discrimination with increasing age. The findings suggest that dialect discrimination follows a U-shaped course of development. Because 11-month olds demonstrated the poorest dialect discrimination performance, we are currently assessing their ability to discriminate linguistically different speech sounds varying in degree of acoustic similarity. Preliminary findings suggest that both language experience and acoustic differences may influence infants' discrimination of phonetic contrasts in the native language. [Work supported by NIH-NIDCD Grant (R01DC006235), an IUPUI Educational Enhancement Grant, and grants from the IUPUI UROP and SROP Programs.]

6pSWa33. Perception of second-language (L2) production by first-language (L1) speakers of different dialectal backgrounds: The case of Japanese-speaking learners' /u/ perceived by French and Quebec native speakers. Marie-Claude Tremblay (Dept. of Linguist., Univ. of Ottawa, 70 Laurier Ave. E., Ottawa, ON Canada, K1N 6N5, mtrem075@uottawa.ca) and Takeki Kamiyama (CNRS/Sorbonne Nouvelle, 75005 Paris, France)

The high back rounded /u/ of Parisian French (PF) is characterized by a concentration of energy in the low frequency zone (< 1000 Hz) due to the grouping of the first two formants, while Quebec French (QF) has a "lax" variant [ʊ] in closed syllables (as in "*soupe*"), with its F2 amounting to 1000–1100 Hz [P. Martin, "Le système vocalique du français du Québec. De l'acoustique à la phonologie." *La linguistique*, **38**(2), 71–88 (2002)]. Japanese-speaking learners of French (JSL) tend to produce French /u/ with high F2 as in Japanese /u/, which in turn tends to be perceived by PF lis-

teners as /ɸ/. Do QF listeners show different behavior because of their lax variant of /u/? Our perception experiment using 18 tokens each of /u y ɸ/ produced by five JSL showed that the 16 PF listeners examined perceived those stimuli of /u/ with F2 between 1000 and 1100 Hz as /u/ and /ɸ/ almost equally often, but considered as very poor exemplars of either of them. By contrast, the 16 QF listeners tested identified the same stimuli of /u/ almost always as /u/ with a better goodness rating than NF listeners'. These findings suggest that native speakers' judgment about non-native speakers' production might depend on the native dialect of the listener.

6pSWa34. Adapting second language phonemic perception training to common instructional situations: Pitfalls and progress. Thomas R. Sawallis and Michael W. Townley (English Dept., Univ. of Alabama, Box 870244, Tuscaloosa, AL 35487, tsawalli@bama.ua.edu)

Adult language learners improve both perception and production of difficult target language phonemic contrasts through high variability phonetic training (HVPT) on minimal pairs. This training entails two alternative forced choice identifications with feedback of a corpus encompassing multiple talkers, tokens, and phonological contexts. This technique, refined most notably by Pisoni and colleagues [Bradlow *et al.* (1999)], has been little used in real pedagogical situations, due partly to inconvenient protocols (e .g., 1 h, 3 days per week, for 3 weeks) and partly to the difficulty of developing a robust presentation routine attractive to students. We have attacked these problems, and after two semesters of pilot work refining the training presentation (of English /r-l/ to Japanese, Korean, and Chinese native learners), we expect this semester to have students who receive a full complement of training at ~15 min, 2–3 days per week, throughout the term. Results will be presented and compared with previous research, and we will discuss some of the difficulties (technological, practical, and especially social) that were overcome for the sake naturalistic pedagogical application.

6pSWa35. Effects of first-language (L1) voicing assimilation rules on the second-language (L2) perception of English word-final consonants by Polish and Hungarian listeners. Marisa A. Monteleone (Dept. of Linguist., The Graduate Ctr., City Univ. of New York, 365 Fifth Ave., New York, NY 10016)

This study explores whether knowledge of a L1 regressive voicing assimilation rule interferes with perception of word-final voicing contrasts in an L2. Due to a regressive voicing assimilation rule, voicing in word-final consonants is neutralized in both Hungarian and Polish. American English (AE) maintains a voicing contrast in this same context. In a perception task, 11 native Hungarian and 12 native Polish listeners identified AE word-final consonants (e.g., [s]-[z]) followed by voiced versus voiceless consonants. In a separate task, they identified the same consonants with the following consonantal context removed. The Hungarian and Polish listeners performed less accurately when the following context was present than when it was removed, suggesting that word-final perception was influenced by the interference of the L1 rule.

6pSWa36. Cross-language differences in the uptake of place of articulation. Anita E. Wagner (Dept. of Speech, Hearing and Phonetic Sci., Univ. College London, London, UK)

There are cross-language differences in the use of coarticulatory cues for fricative identification. Listeners with spectrally similar fricatives in their native phoneme inventories rely more on the information in the surrounding vowels than listeners with spectrally distinct fricatives. The present study examined whether such cross-language differences result in differences in the temporal uptake of information specifying fricatives. In a gating study native listeners of Dutch and Italian, both languages with spectrally distinct fricatives were compared with Spanish and Polish listeners. The Spanish fricative inventory contains the spectrally similar labiodental and dental fricatives. The Polish fricative repertoire contains postdental, alveolar, and alveolopalatal fricatives. The questions addressed were whether the presence of spectrally similar fricatives leads to: (1) reliance on cues, which are secondary for listeners with distinct fricatives; (2) an uptake of information specifying place of articulation in particular for fricatives; (3) an uptake of information from coarticulatory cues preceding or following the consonant. Listeners identified fricative and stop targets in gated CV and VC syllables. The results show that listeners optimize their uptake of information to the demands of their native phoneme inventories and rely on more sources of information only for distinctions between several similar places of articulation.

6pSWa37. Coarticulatory influences on the perception of nasal vowel height and the role of language experience. C. Elizabeth Goodin-Mayeda (Dept. of Spanish and Portuguese, Univ. of California, Los Angeles, 5310 Rolfe Hall, Los Angeles, CA 90095, cegoodin@ucla.edu)

That a listener's first language affects the perception of a second language is generally undisputed. In addition to linguistic experience, acoustic effects of coarticulation have been shown to influence speech perception [Abramson *et al.* (1981); Krakow *et al.* (1988); Mann (1986) and others]. For example, nasalization of vowels has been shown to affect the perception of vowel height due to its spectral consequences in the region associated with vowel height [Beddor and Strange (1982); Krakow *et al.* (1988); Ohala (1986); Wright (1975)]. While some effects of coarticulation appear to produce the same perceptual shifts crosslinguistically [Mann (1986)], it is not clear that all coarticulatory influences are language independent [Krakow *et al.* (1988)]. The current study seeks to investigate the relationship between acoustic effects of coarticulation and linguistic experience. Since Portuguese has allophonic and (surface) contrastive nasalization [Wetzels (1997)] and Spanish does not have phonological nasalization in any context [Solé (1992)], adult speakers of these languages were tested, using synthetic stimuli, for perception of contextualized nasal vowels (i.e., nasal vowels adjacent to tautosyllabic nasal consonants) and noncontextualized nasal vowels (i.e., nasal vowels with no adjacent nasal consonant). Results indicate that coarticulatory influences of nasalization are language dependent.

6pSWa38. Perception of consonant length by Russian and American listeners. Olga Dmitrieva (Dept. of Linguist., Stanford Univ., Margaret Jacks Hall, Bldg. 460, Stanford, CA 94305, dmitro@stanford.edu)

An experimental investigation of Russian geminates revealed that intervocalic, post-stress, and word-initial geminates have an earlier perceptual boundary in relation to the average singleton duration in these positions. This provides an articulatory and perceptual advantage for geminate production and discrimination, which may explain cross-linguistic preference for these types of geminates. The proximity of the boundary to the average singleton means that a smaller articulatory effort is needed to reach the geminate status; its greater distance from the average geminate means that fewer intended geminates are misperceived as singletons, hence less danger of perceptually driven neutralization. To confirm that this generalization holds across languages a group of monolingual American English listeners was tested in addition to Russian listeners. The results strongly suggest that perception of the contrast between geminates and singletons has a linguistically universal basis. Speakers of American English—a language without phonemic consonant length—showed a pattern of responses very similar to that of the Russian listeners, in particular for post-stress and intervocalic geminates. The consistency of the results in both languages further supports the hypothesis that the observed shift in perceptual boundary is responsible for cross-linguistic dominance of intervocalic and post-stress geminates.

6pSWa39. Cross-linguistic perception of the epenthetic vowel in obstruent + liquid clusters in Spanish. Carlos Ramirez (Dept. of Hispanic Lang. and Lit., Univ. of Pittsburgh, 1301A Cathedral of Learning, Pittsburgh PA 15260, cjramirez@hotmail.com)

This research explores the perception of the epenthetic vowel (EV) that occurs in the obstruent + liquid clusters in Spanish. The perceptibility of EV and its effect in the cluster is analyzed in Spanish native speakers and English native speakers learning Spanish at different levels: beginners; intermediate; and advanced. For this study, two tests were used: a perceptual identification test and a discrimination test (AXB protocol). The study explores the effect of linguistic and prosodic variables such as place and manner of articulation, voicing, type of liquid, and stress. The statistical analysis was conducted using mixed logit models, which can better account for subject and item random effects. This procedure, in contrast to other analyses, builds a model that predicts the effect of each factor. The results show that the different groups use different cues. For English speakers, place, voicing, and stress are predictors for the beginner and intermediate group (WaldZ $= 0.000 p < 0.000$) whereas only voicing is a predictor for the advanced group (WaldZ $= 0.008 p < 0.01$). For the Spanish native speakers voicing

and stress are predictors (WaldZ = 0.02$p < 0.05$). The results suggest that perceptual cues vary according to L1 and proficiency level.

6pSWa40. Language background influences the emergence of voice onset time production and perception. Andrea A. N. MacLeod (Pavillon Vandry, Univ. Laval, PQ, QC G1S 3H3, Canada), Susan Rvachew, and Linda Polka (McGill Univ., Montreal, QC H3G 1A8, Canda)

This study investigates the production and perception of voice onset time (VOT) among preschool children who acquired English and French simultaneously compared to monolingual peers of these two languages. Children participated in this study at the age of 18 months and returned at 24 months for a second session. During each session the children took part in a visual habituation procedure to evaluate discrimination of VOT using edited natural /b/+ vowel and /p/ + vowel syllables in a task format developed by Houston et al. (2007) to assess individual performance. In this task, three VOT values (produced by several talkers) were presented to the children: one within adult norms of the language for voiced bilabial consonants; one within the adult norms of the language for voiceless bilabial consonants; and one between the means for the voiced and voiceless consonants. The children also participated in a structured play session, and their spontaneous productions of word initial stops were acoustically analyzed to measure VOT. Preliminary analysis indicates that accuracy in discriminating VOT precedes production of voicing contrasts for all groups, and monolinguals appear to have developed adultlike perception and production of voicing at a younger age than their bilingual peers.

6pSWa41. Perception of Moroccan Arabic geminates by native English speakers. Bozena Pajak (Dept. of Linguist., Univ. of California San Diego, 9500 Gilman Dr. #108, La Jolla, CA 92093, bpajak@ucsd.edu)

Adult listeners often have difficulty perceiving phonetic distinctions that are not contrastive in their native language (e.g., Lisker and Abramson 1970, Miyawaki *et al.* 1975, Trehub 1976, MacKain *et al.* 1980, Werker *et al.* 1981, among others). However, the same contrast may be perceived with more or less difficulty depending on the environment in which it is embedded. This study investigated the perception of geminate consonants in Moroccan Arabic by native English speakers who had not had previous exposure to the geminate-singleton contrast. The geminates [ss] and [zz] were paired with singleton counterparts in four different environments: medial-intervocalic ([assa]-[asa], [azza]-[aza]); medial-consonant-adjacent ([assta]-[asta], [azzda]-[azda]); initial-vowel-adjacent ([ssa]-[sa], [zza]-[za]); and initial-consonant-adjacent ([ssta]-[sta], [zzda-[zda]]). The words were recorded by a native Moroccan Arabic speaker, and subsequently used as stimuli in a perception experiment (AX discrimination task; 80 participants). The sensitivity to the geminate-singleton contrast was measured by calculating A-prime scores (Grier 1971) and performing an ANOVA. The analysis showed a significant main effect of environment [$F(3,237)=28.7$; $p<0.001$]. The participants performed above chance, and their perception of the geminate-singleton contrast was best in the medial-intervocalic environment ($A'=0.83$), worse in the medial-consonant-adjacent ($A'=0.73$) and initial-vowel-adjacent environments ($A'=0.74$), and worst in the initial-consonant-adjacent context ($A'=0.58$).

6pSW42. Stop-like modification of dental fricatives in Indian English: A preliminary study to perceptual experiments. Chi D. Chu (Dept. of Linguist., Dartmouth College, 4954 Hinman, Hanover, NH 03755, chi.chu@dartmouth.edu) and Nancy F. Chen (MIT, Cambridge, MA 02139)

Stop-like modification of dental fricatives occurs in both American English and foreign accents of English (Zhao, Ph.D. thesis, 2007). This study examines stop-like word-initial /ð/ in Indian English to determine its frequency and compare it with American English. Acoustic analysis on unscripted telephone recordings of 40 Indian English speakers showed that of 161 total word-initial /ð/ instances, 61% were stop-like. The modification occurred most frequently in utterance-initial contexts, after stops, and after fricatives, and least after vowels and liquids. The variable occurrence of the modification across many contexts suggests that it may result from physiological conditions rather than from a phonological rule. If the modification is physiologically conditioned, differences in modification frequency between dialects may indicate dialectal differences in articulation. For example, comparison with American English showed that stop-like /ð/ was more common in Indian English across all contexts, particularly after fricatives, consistent with the tendency of Indian English to substitute bilabial stops for labiodental fricatives (e.g., /f/ and /v/), which provides a context more conducive to stop-like /ð/. Further investigation of varying cross-dialectal frequencies of stop-like modification could uncover additional dialectal differences in articulation and determine how such articulatory differences might affect cross-dialect perception.

6pSWb1. Newborn infant perception of vowels is affected by ambient language. Christine Moon (Pacific Lutheran Univ., Dept. of Psych., Tacoma, WA 98447, mooncm@plu.edu), Hugo Lagercrantz (Karolinska U. Hospital Solna, S-171 76 Stockholm, Sweden), and Patricia K. Kuhl (Univ. of Washington, Seattle, WA 98195)

Behavioral research has shown that by 6 months of age, infants show an effect of experience with native language vowels. In a previous study of category organization, infants in Sweden and the United States treated a vowel prototype as equivalent to variants of the vowel in the native, but not the non-native language. In the current behavioral study of Swedish and U.S. neonates, results were consistent with those of the 6-month-olds. Eighty infants ($M=32.8$ h since birth) in Washington State and Stockholm participated in a procedure in which non-nutritive sucking activated one of 17 stimuli (a prototype and 16 variants) from the same vowel category. Twenty infants in each country heard their native vowel, and 20 the non-native vowel. The vowels were English /i/ and Swedish /y/. Stimuli were serially and randomly activated by the onset of a sucking bout, and once a stimulus was activated, frequency of presentation was infant-controlled. The dependent measure was number of sucks for each stimulus. For the non-native vowel only, the mean number of sucks was significantly higher for the prototype than the mean for the 16 variants. This suggests that category organization of vowels begins *in utero*.

6pSWb2. Visual speech information improves discrimination of non-native phonemes in late infancy. Robin K. Panneton (Dept. of Psycholoty, Virginia Tech., Blacksburg, VA, panneton@vt.edu)

Initially, human infants are able to discriminate a change from one speech phoneme to another, whether or not the speech contrasts are native or foreign. By the end of the first postnatal year, the ease with which infants discriminate non-native phonemes diminishes, indicating a progressive attunement toward language-relevant speech. However, studies in this area have employed procedures lacking dynamic bimodal information (e.g., faces and voices). Given rapid improvements in visual perception across the first postnatal year, as well as a strong propensity to look at and process faces, it is possible that infants would benefit from visual speech in both native and non-native perception. Across two experiments, discrimination of auditory plus visual Hindi phoneme contrasts was studied in 11-month-olds (English-learning, using digital movies of female Hindi speakers). Several conditions were contrasted: (a) face plus voice using infant-directed speech (IDS); (b) face plus voice using adult-directed speech (ADS); (c) nonface plus voice with IDS; and (d) nonface plus voice with ADS. Overall, infants discriminated non-native contrasts when accompanied by a dynamic face, and especially if delivered in IDS. These results suggest a developmental pattern toward increasing use of multimodal information by infants in their processing of speech, and that early phonological representations for native language may include visual speech information.

6pSWb3. Brain, behavioral, and sociocultural factors in bilingual language learning. Adrian Garcia-Sierra, Maritza Rivera-Gaxiola, Barbara Conboy (I-LABS, Univ. of Washington, Fisheries Ctr. Bldg., Box 357988, Seattle, WA 98195-7988), Harriet Romo (Univ. of Texas, San Antonio, San Antonio, TX 78201), Lindsay Klarman, and Patricia Kuhl (Univ. of Washington, Seattle, WA 98195-7988)

Previous behavioral studies have shown improved sensitivity to native-language contrasts and reduced sensitivity to non-native phonetic contrasts when comparing 6–8- and 10–12-month-old monolingual infants. It has been argued that exposure to language dedicates neural networks to the acoustic properties of native-language speech, and that, in adulthood, this commitment interferes with nonnative speech processing [native language neural commitment or (NLNC)]. There are very few studies on how early speech perception in bilinguals relates to future language advancement. Recently it has been shown that infants' early native-language speech perception skill predicts their later success at language acquisition. In the present investigation, we examined how brain measures of speech perception in bilingual infants and socio-cultural factors of their environment predict later vocabulary growth. Our results showed excellent neural discrimination of both English and Spanish phonetic contrasts in 12-month-old infants, distinguishing them from monolingual infants. To our knowledge, this is the first study of bilingual infants using a brain measure to show that bilingual infants' speech specialization includes both languages by the end of the first year of life.

6pSWb4. Bilinguals mind their language (mode): Vowel perception patterns of simultaneous bilingual and monolingual speakers. Monika Molnar, Linda Polka (McGill Univ., 1266 Pine Ave. W, Montreal, H3G 1A8 Canada; monika.molnar@mcgill.ca), Lucie Menard (Univ. du Qubec à Montréal, Montreal, Canada), and Shari Baum (McGill Univ., Montreal, H3G 1A8 Canada)

It is well-established that the speech perception abilities of monolingual speakers are highly tuned to the sounds of their native language, and that this language specificity affects how monolingual speakers distinguish the sounds of a non-native language. The present study addressed how the speech perception skills of simultaneous bilingual speakers, who are native speakers of two languages, may be affected by control of active language mode. We tested monolingual (English and French) and simultaneous bilingual (English/French) adults in an identification and rating task with 42 vowels along a continuum from a high back rounded vowel (/u/) to a high front rounded vowel (/y/) that are both phonemic in French, with only the back vowel represented in English. Bilinguals completed the task in three language modes: English, French, and bilingual. As expected, monolingual speakers demonstrated a language-specific perceptual pattern for the vowels. Bilingual participants displayed different perceptual patterns in each active language mode to accommodate the vowel categories relevant in the target language. These findings indicate that simultaneous bilinguals rely on a finely detailed perceptual space and are flexible as they adapt their perception to different language environments.

6pSWb5. Korean-English bilinguals' perception of phonetic contrasts in their two languages. Jessica Maye (Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, j-maye@northwestern.edu), Jenna Luque (Northwestern Univ., Evanston, IL 60208), Thomas Farmer (Cornell Univ., Ithaca, NY 14850-2824), Yubin Lee, and Midam Kim (Northwestern Univ., Evanston, IL 60208)

Korean speakers are known to find English /r/-/l/ difficult to discriminate, and English speakers have trouble discriminating Korean voicing contrasts. We tested Korean-English bilinguals' perception of these difficult phonetic contrasts to examine the effects of age of acquisition and language dominance on bilinguals' perception in their two languages. All bilingual participants were native Korean speakers but varied in age of English acquisition. Some reported English to be their dominant language, while others were Korean-dominant. Participants completed a 2AFC task in which they were asked to click on one out of a pair of pictures. On key trials the pictures formed a minimal pair (e.g., rock versus lock). The same task was completed once in English (key items contained the /r/-/l/ contrast) and once in Korean (key items contained the plain versus tense voicing contrast). Earlier exposure to English led to greater accuracy and faster response on the English task. However, neither age of acquisition nor language dominance affected performance on the Korean task. These results suggest that earlier exposure to a second language improves perception in that language, but that loss of dominance in a first language does not impair phonetic processing of that language.
