consistent with the earlier studies of Houtsma and Smurzynski (1990) and Bernstein and Oxenham (2005, 2006a). It seems that increasing the level of the noise to ensure that distortion products were masked was sufficient to eliminate the phase effects when F0DLs were small. The results therefore suggest that the phase effects found by Moore *et al.* (2006a) in conjunction with small F0DLs may have been produced by distortion products, rather than by the coding of F0 via the TFS of unresolved harmonics.

At least one puzzle remains. In the studies of Houtsma and Smurzynski (1990) and Bernstein and Oxenham (2003), the transition between good and poor performance occurred for N values between about 9 and 12, whereas in the present study the transition occurs between N values of 6 and 7. One possible reason is that the present study used only three harmonics, whereas the earlier studies used 12 or 13 consecutive harmonics. At face value, the larger number of harmonics does not provide a very satisfactory explanation if (as often assumed) it is the lowest harmonics present that primarily determine performance. On the other hand, the larger number of harmonics may provide more spectral (and timbral) stability, making the rove of the lowest harmonic less perceptually distracting. Another possibility relates to the range of F0s tested. In the present experiment, when $N=6$, the nominal F0 of the complex was about 286 Hz. This is higher than the F0s used by either of the earlier studies. In fact, a more recent study by Oxenham and Keebler (2007) found that even when 12 harmonics were present, the transition from good to poor performance occurred for values of N between 9 and 12 only when the F0 was either 100 or 200 Hz; for F0s of 300 Hz or higher, the transition occurred for values of N between 6 and 9, more in line with the current results. Thus, it may be that the apparent discrepancy between the present results and those of earlier studies is related more to the underlying F0 than to the number of harmonics presented. This conjecture should be explicitly tested by studying the effects of the number of harmonics present on the transition point between low and high F0DLs.

IV. EXPERIMENT 3: REDUCING THE AUDIBILITY OF DISTORTION PRODUCTS WITH LOWPASS NOISE

A. Rationale

The results of experiment 2 showed that the effect of phase on F0DLs only became apparent when F0DLs were poor, consistent with the idea that unresolved harmonics are coded by the temporal envelope and not TFS. It was suggested that the effect of the background noise was to mask distortion products. Another possibility is that the higher noise level used in experiment 2 interfered with the ability of listeners to use the TFS cues, via some form of direct masking of the stimulus components, rather than the distortion products. The aim of the present experiment was to test this hypothesis by using a lowpass-filtered noise with a cutoff frequency below the frequency of the lowest component present. The predictions were as follows: if the effect of the noise was to interfere with TFS processing, then reducing the on-frequency noise by lowpass filtering should result in an improvement in performance and a restoration of the phase effects observed by Moore *et al.* (2006a); on the other hand, if the main effect of the noise was to mask the distortion products, then lowpass filtering the noise should have little effect on the pattern of results, so long as the cutoff frequency is set such that the noise still masks the distortion products.

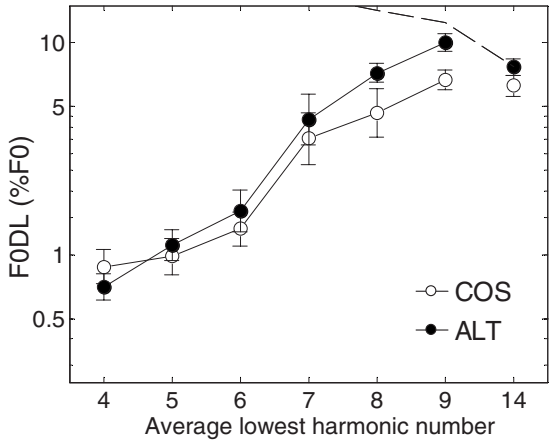

FIG. 4. As in Fig. 3, except that the noise was lowpass filtered with a cutoff frequency below the stimulus components but above the frequency of the likely distortion products.

B. Methods

The stimuli and procedure were the same as those used in experiment 2, with the exception that the high-frequency cutoff of the background noise was varied from trial to trial and was set such that it was 0.5F0 Hz lower than the lowest component presented in the two intervals of each trial. In this way, the noise energy did not directly overlap with any of the stimulus frequency components, but the cutoff frequency was always higher than the nearest distortion product in the spectrally lower of the two complexes (corresponding to the $2f_1$-f_2 distortion product, where f_1 and f_2 are the frequencies of the lower two components of the complex). Nine normal-hearing listeners participated in this experiment (aged between 18 and 22 yr); four of the subjects had also taken part in at least one of the previous experiments.

C. Results and discussion

The mean results across the nine listeners are shown in Fig. 4. Thresholds were somewhat lower overall than in experiment 2, suggesting that removing the "on-frequency" background noise had some effect. However, the overall pattern of results was very similar to that found in experiment 2 (Fig. 3), with low F0DLs for values of N up to 6 and higher F0DLs beyond that.

The search for low F0DLs in conjunction with significant phase effects was carried out in the same way as was done in experiments 1 and 2. The cutoff F0DL was found to be 2.42%, and the highest value of N for which the COS F0DL fell below the cutoff was again 6. At this value of N a paired t-test revealed no significant effect of phase [$t(8)=1.63$, one-tailed $p=0.071$].

Overall, neither experiment 2 nor experiment 3 provides support for the idea that phase effects can occur when F0DLs are small if potential distortion products are masked.

V. EXPERIMENT 4: F0DLS FOR COMPLEXES AT LOW SENSATION LEVELS

A. Rationale

This experiment provided a further test of whether the background noise was interfering with TFS processing, rather than just masking distortion products, by presenting the stimuli in quiet. To reduce the possibility that listeners could detect and use distortion products, the stimuli were presented at the relatively low sensation level of 20 dB above absolute threshold (20 dB SL). This low level should be sufficient to render distortion products inaudible but should nevertheless be sufficient for good pitch perception. For instance, Hoekstra (1979) showed that F0DLs for complex tones in noise approach an asymptotic value at around 20 dB above masked threshold.

B. Methods

The stimuli and procedure were the same as those used in experiment 2, with the following two differences: (1) there was no background noise present; (2) the three-tone complexes were presented at a level 20 dB above detection threshold in quiet. Detection thresholds in quiet were measured for three-component complexes, with the frequency of the middle component fixed at 2 kHz and the lowest harmonic number set to 6, 8, or 10 (corresponding to F0s of 285.71, 222.22, and 181.82 Hz). The overall level of the complex was varied adaptively, following a 3-down 1-up rule, which tracked thresholds corresponding to 79.4% correct. After thresholds had been estimated by taking the average of three adaptive runs for each subject for each of the three test conditions, the level of the test stimuli was set to 20 dB above the estimated threshold value for each subject individually. Five normal-hearing listeners participated in this experiment (aged between 18 and 22 yr). All of these subjects had also taken part in at least one of the previous experiments.

C. Results and discussion

The results are shown in Fig. 5. Despite the lack of background noise and the lower absolute level, the pattern of results was very similar to that found in experiments 2 (Fig. 3) and 3 (Fig. 4). In this case, the cutoff F0DL was 3.92%, and the highest value of N for which the COS F0DL fell below the cutoff was again 6. At this value of N a paired t-test revealed no significant effect of phase [paired $t(4)=0.49$, one-tailed $p=0.325$]. Overall, the results from this experiment in the absence of background noise were consistent with those from experiments 2 and 3, suggesting that the lack of a phase effect when F0DLs are low cannot be ascribed to direct masking or interference by the noise. A parsimonious interpretation of the results from all five experiments so far is that distortion products can affect F0DLs when audible (experiments 1 and 1a); when distortion products are not audible, no effects of phase are observed in conditions producing low F0DLs.

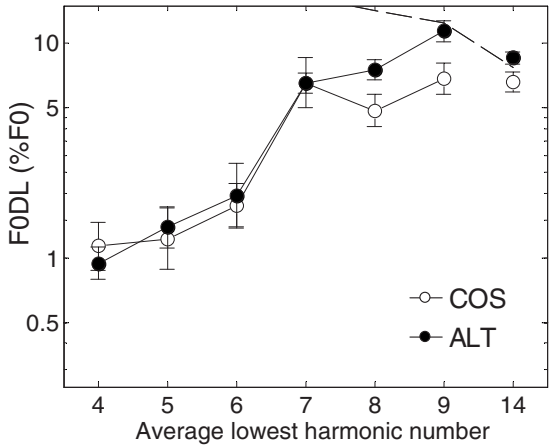

FIG. 5. As in Fig. 3, except that no background noise was present and that the complexes were presented at 20 dB SL.

All three experiments in which distortion products were deemed inaudible (experiments 2–4) yielded very similar patterns of results. The trends observed between and within each of three experiments were further studied using a mixed-model ANOVA, with experiment as a between-subjects variable and N and phase as within-subject variables.[2] The results of this analysis revealed a significant main effect of phase [$F(1,20)=24.73$, $p<0.0005$], a significant main effect of harmonic number [$F(5.38,107.76)=123.48$, $p<0.0005$], and a significant interaction between these two factors [$F(4.51,90.24)=5.02, p=0.001$]. *Post hoc* comparisons (paired t-tests) between COS and ALT thresholds pooled across all three experiments for each value of N showed a phase effect emerging at $N=8$ [$t(22)=5.25$, one-tailed $p<0.005$; for higher N's: $4.20<t(22)<14.66$, one-tailed $p<0.005$] but not below [for $4\leq N\leq 7$: $-2.00<t(22)<2.01$, one-tailed $p\geq 0.2$].[3] This pattern of results is consistent with the hypothesis that when distortion products are inaudible, phase effects are only observed in conditions where F0DLs are poor and are likely to be determined by temporal envelope cues. All three experiments showed a significant phase effect emerging at $N=8$, rather than at $N=7$, even though F0DLs were already high for $N=7$ (see Figs. 3–5). This outcome may be related to how resolvability affects pitch and phase effects differently: for tones to be unresolved, at least two must interact, but for a phase effect to be observed between tones that are not in an octave relationship, at least three components must interact. This might account for why a phase effect emerged at a value of N that was 1 higher than the value of N for which F0DLs became poor.

VI. EXPERIMENT 5: EFFECTS OF PHASE ON THE RELATIVE LEVEL OF DISTORTION PRODUCTS

A. Rationale

The results of the current study suggest that distortion products may play an important role in explaining the results

of Moore *et al.* (2006a). However, all the evidence presented so far is indirect in that it is inferred that the primary effect of the broadband noise (experiment 2), lowpass noise (experiment 3), and low-level stimuli (experiment 4) was to render distortion products inaudible. To explain the phase effects observed by Moore *et al.* (2006a) (and replicated here in experiment 1) at lower values of N, it must be assumed not only that distortion products were audible but that they were more audible (or had a greater effect on F0DLs) when the components were in COS phase than when they were in ALT phase. The results of Pressnitzer and Patterson (2001), using multitone complexes, suggest that this may indeed occur under certain conditions. They measured the distortion produced by harmonics 15–25 of a 100-Hz F0, with a level of 54 dB SPL per component. Using a beat-suppression technique, these authors estimated that a tone at the F0 had to be presented at between about 40 and 44 dB SPL to match the level of the distortion product when the complex was in COS phase, but when the complex was in ALT phase the level of the matching tone was found to be less than 35 dB SPL in one subject and was unmeasurable in the other subject. Although the level of their components was comparable to ours, the number of components and the N used were not, making direct predictions for our situation difficult. The stimuli of Buunen *et al.* (1974) were closer to those used in the present study. They measured distortion products for a three-component complex with an F0 of 200 Hz, centered at 2000 Hz, corresponding to our $N=9$ condition. Their stimuli were presented at a sensation level of 40 dB, and the lowest component was presented at a level 10 dB below that of the upper two components to maximize the relative level of the distortion products. They found clearly audible distortion products at the frequencies corresponding to one and two harmonics below N. Using a method of cancellation, they also found that the relative phase of the center component strongly affected the level of distortion products, as well as affecting the pitch strength of the F0. However, the relationship between the complex's phase and the level of the distortion products varied between the three subjects tested. Our final experiment attempted to estimate the relative levels of some distortion products in the presence of both the COS and ALT complexes. Our prediction was that the COS complex would produce higher-level distortion products than the ALT complex, thereby leading to a lower effective N in the COS than in the ALT case, even when the actual component frequencies were the same.

The technique used to provide an estimate of the relative levels of the distortion products involves presenting the three-tone complex along with an additional tone that was mistuned from the frequency of an expected distortion product by 4 Hz to produce an audible beating sensation with the distortion product, which should be maximal when the additional tone and the distortion product were at comparable effective levels. Listeners were asked to adjust the level of the additional tone to the level at which the beats were most prominent.

B. Methods

1. Subjects

Seven normal-hearing listeners participated in this experiment (ages ranged from 20 to 38). One of these listeners also took part in experiment 1.

2. Stimuli

Three-component complexes similar to those used in experiment 1 were used in this experiment. One difference was that the F0 of the complexes was fixed instead of roved across trials. The value of N was fixed at 8, and the F0 was 222.22 Hz, so that the frequency of the center harmonic was equal to 2000 Hz. The other stimulus difference with experiment 1 was that each complex lasted for 1150 ms, instead of 400 ms, to allow for multiple beat cycles. Each complex was accompanied by a "probe" pure tone with a frequency that was 4 Hz below the frequency of a potential distortion product. This probe tone was gated on 200 ms after the onset of the complex and off 200 ms before the offset of the complex. The total duration of the probe was therefore 750 ms (three cycles of the 4-Hz beat modulation), and it was gated on and off with 20-ms raised-cosine ramps. The distortion products tested were the three consecutive harmonic frequencies below the complex $(2f_1-f_2, 3f_1-2f_2, 4f_1-3f_2)$, as well as the F0 itself (the difference tone; f_2-f_1), where f_1 and f_2 denote the frequencies of the lowest and center harmonics in the complex, respectively. The 4-Hz deviation between the frequency of the probe tone and the frequency of the targeted distortion product was chosen based on informal pilot tests, which revealed that the depth of beats at 4 Hz was relatively easy to judge. No background noise was used in this experiment.

3. Procedure

Listeners were instructed to adjust the level of the probe tone until they found the level at which the 4-Hz beating sensation was most salient. The level of the probe tone could be adjusted after each stimulus presentation by three pairs of buttons on the computer screen. The upper, middle, and lower pairs of buttons adjusted the test-tone level by steps of 6, 3, and 1 dB, respectively. Listeners were instructed to try a wide range of levels on each run and to bracket the point of maximum saliency, first using largest step sizes and then the smaller ones. At the beginning of a match, the level of the probe tone was drawn randomly from a uniform discrete range including values between −25 and +25 dB around 50.2 dB SPL in 5-dB steps. The level of the probe tone was not allowed to exceed the limits of this 50-dB range. Each listener produced six matches in each condition.

C. Results and discussion

Beating was heard by subjects at all the test frequencies considered. The mean levels of the probe tones that were judged by subjects to produce the most salient beats are shown in Fig. 6. Overall, there was a small but significant trend for the level of the matching tone to be higher for the COS condition than for the ALT condition $[F(1,6)$

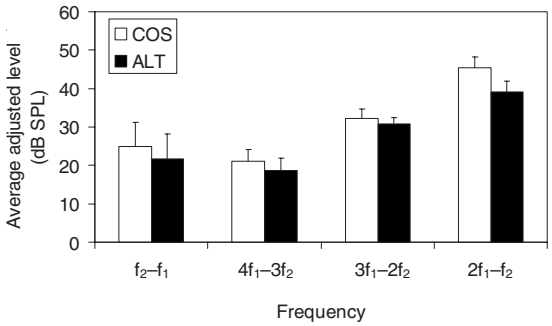

FIG. 6. Mean levels (in dB SPL) to which the matching probe tone was adjusted to produce the most salient beating sensation with the distortion products at different frequencies. Error bars represent ±1 standard error of the mean. See text for details of the different conditions.

$=96.67$, $p<0.0005$]. In the original experiment of Moore *et al.* (2006b), the background noise was set to 30 dB SPL/ERB_N, which would have resulted in masked thresholds of between 25 and 30 dB SPL. This suggests that only the $2f_1-f_2$ distortion product would have been reliably above masked threshold in the noise; no other average effective distortion product level fell above 33 dB SPL. Interestingly, the most audible ($2f_1-f_2$) distortion product also showed the largest mean difference between probe-tone levels in the COS and ALT conditions of about 6 dB (paired *t*-test: $t=4.29$, df=6, $p=0.005$).

The results suggest that at least the distortion product closest to the stimulus would have been audible in our experiment 1, which replicated that of Moore *et al.* (2006b). The higher level of the distortion product in the COS condition may have made it more salient and may therefore have lowered the effective value of *N* by 1 in the COS condition but not in the ALT condition. This in turn may have led to the effects of phase that were observed at intermediate values of *N* where the F0DLs were low.

VII. GENERAL DISCUSSION

Experiments 1 and 1a replicated the findings of Moore *et al.* (2006a) that F0DLs with three-tone harmonic complexes could be small, suggesting the use of TFS cues, and yet still be dependent on the component phase relationships, suggesting that the components were unresolved. However, experiments 2–4 showed that the results were different when distortion products were rendered inaudible, either by increasing the background noise level (experiment 2 and 3) or decreasing the overall stimulus level (experiment 4). Under these conditions, phase effects only emerged once F0DLs were high, implying the use of temporal envelope cues. The results from experiment 5 provided more direct evidence that the cubic distortion product just below the primary components would have been audible in the Moore *et al.* (2006a) experiment and may have been lower in amplitude in the ALT-phase than in the COS-phase conditions. The differences between the ALT and COS conditions found in their experiment (and our experiment 1) at intermediate values of *N* may have been due to the differential audibility of distortion rather than to differences in the TFS representations.

Overall, the results from the present study (experiments 2–4) are consistent with earlier studies using more harmonics (Houtsma and Smurzynski, 1990; Bernstein and Oxenham, 2006b; a) in showing that no phase effect is observed for conditions that produce small F0DLs. Based on these results, some of the conclusions from Moore *et al.* (2006a) require re-examination. As outlined in Sec. I, one rationale of the experiment of Moore *et al.* (2006a) was to distinguish between two interpretations of the earlier results of Moore and Moore (2003), involving the pitch of frequency-shifted harmonic complexes. Moore *et al.* (2006a) interpreted their finding of small F0DLs in conjunction with phase sensitivity as indicating that listeners had access to TFS within the waveform of unresolved harmonics. As phase sensitivity is not found when distortion products are rendered inaudible, the results of Moore *et al.* (2006a) can no longer be taken as evidence that listeners have access to TFS to code the F0 of unresolved harmonic tone complexes.

Another implication of the present results relates to studies of pitch perception and TFS processing in hearing-impaired listeners (e.g., Moore *et al.*, 2006b; Hopkins and Moore, 2007). These studies have shown that hearing-impaired listeners often do not exhibit low F0DLs for low or intermediate values of *N*. If, as suggested by Moore *et al.* (2006a), normal-hearing listeners can use TFS information from unresolved harmonics to code F0, poorer performance in hearing-impaired listeners might be interpreted as implying that they have a selective deficit in processing TFS. Similar claims have been made with regard to hearing-impaired listeners' ability to use TFS information in speech (e.g., Lorenzi *et al.*, 2006; Hopkins *et al.*, 2008). An alternative explanation is that the limited benefit of TFS information for hearing-impaired listeners relates to the well-known effect of broadened auditory filters, poorer frequency selectivity, and lower-amplitude (or absent) distortion products (Moore, 2007). For instance, Bernstein and Oxenham (2006b) found that the transition between good and poor F0DLs in hearing-impaired listeners corresponded well with other measures of frequency selectivity, suggesting that reduced frequency selectivity and fewer resolved harmonics may account for the poorer F0 discrimination associated with hearing impairment. Broader filters have been proposed as one reason for poorer TFS sensitivity in hearing-impaired listeners (Moore, 2008). However, given the lack of conclusive evidence that normal-hearing listeners use TFS to code F0 using unresolved harmonics, it may not be necessary to posit any deficits beyond frequency selectivity in order to explain the results found for hearing-impaired listeners in tests that have been designed so far to probe potential TFS deficits.

As mentioned in the discussion of experiment 2, the fact that the transition between good and poor F0DLs seems to occur when the average *N* is between 6 and 7 does not appear to be consistent with earlier studies, which found the transition to occur between *N* values of 9 and 12 (e.g., Houtsma and Smurzynski, 1990; Bernstein and Oxenham, 2003). Whether this is due to the number of harmonics in each complex or to the value of F0 remains to be determined. In either case, it presents a challenge to the view that the transition between good and poor F0DLs is intimately linked

to auditory filter bandwidths. Such questions have been raised before, but primarily in conjunction with the lower limit of pitch perception (e.g., Krumbholz *et al.*, 2000). This question leads to a more general note of caution regarding the definition of resolved and unresolved components. The present study used the rationale forwarded by Moore *et al.* (2006a) to distinguish between resolved and unresolved harmonics, as well as between temporal envelope and temporal fine structure. However, this approach should not be interpreted as implying that the distinction between resolved and unresolved harmonics, or between temporal envelope and fine structure, is always clear cut (Shackleton and Carlyon, 1994). For instance, it is possible that situations exist in which stimulus components may be sufficiently resolved for one purpose (such as estimating the frequencies of individual components) and yet sufficiently unresolved for another purpose (such as perceiving interactions between neighboring components). One example of such a situation is the perception of beats between two tones a semitone apart, where the individual frequencies can be heard, but where the interactions (beats) are also audible. Similarly, stimuli that are not spectrally resolved (in terms of producing large peaks in a spectral excitation pattern) may nevertheless be resolved via a temporal code that involves phase-locking to the component frequency (e.g., Sachs *et al.*, 1983). In summary, it is unlikely that resolvability is a binary variable, and caution should be used in generalizing across different measures of resolvability.

ACKNOWLEDGMENTS

This work was supported by a grant from the National Institutes of Health (Grant No. R01 DC 05216). We thank Brian Moore, Daniel Pressnitzer, one anonymous reviewer, and the associate editor, Richard Freyman, for numerous helpful comments on previous versions of this paper.

[1]For the purposes of analysis, the two subjects who participated in both experiments were treated as independent subjects in each experiment. However, the conclusions remained the same if the two subjects were excluded from experiment 1a to maintain completely independent samples (and more equal sample sizes) in each experiment.

[2]The design of this analysis was complicated by the fact that some of the listeners took part in more than one experiment. As listeners who had lower thresholds on average (compared to other listeners) in one experiment also tended to have lower thresholds in another experiment, the data were not uncorrelated across experiments. In order to overcome this problem, we subtracted from each (log-transformed) threshold measured in a given listener the mean of the (log-transformed) thresholds measured in this same listener across all experiments and conditions in which the listener took part. This transformation left the effects of phase and harmonic number within each listener unchanged, but reduced across-experiment correlations in the data. Following this transformation, no significant main effect of experiment [$F(2,20)=3.32$, $p=0.057$] or interactions with experiment and other factors were observed [experiment$\times N$ interaction: $F(10.78,107.76)=1.03$, $p=0.423$; experiment$\times$phase interaction: $F(2,20)=0.03$, $p=0.970$; three-way interaction: $F(9.02,90.24)=0.439$, $p=0.911$]. These conclusions remained unchanged when the ANOVA was performed directly on the measured thresholds, without first subtracting the mean from each listener's data. Here and in the main text, non-integer degrees of freedom in the reported F statistics reflect the application of the Huynh–Feldt correction.

Release from informational masking in children: Effect of multiple signal bursts

Lori J. Leibold[a] and Angela Yarnell Bonino
Department of Allied Health Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599

(Received 17 April 2008; revised 2 February 2009; accepted 4 February 2009)

This study examined the degree to which increasing the number of signal presentations provides children with a release from informational masking. Listeners were younger children (5–7 years), older children (8–10 years), and adults. Detection thresholds were measured for a sequence of repeating 50-ms bursts of a 1000-Hz pure-tone signal embedded in a sequence of 10- and 50-ms bursts of a random-frequency, two-tone masker. Masker bursts were played at an overall level of 60-dB sound pressure level in each interval of a two-interval, forced choice adaptive procedure. Performance was examined for conditions with two, four, five, and six signal bursts. Regardless of the number of signal bursts, thresholds for most children were higher than thresholds for most adults. Despite developmental effects in informational masking, however, masked threshold decreased with additional signal bursts by a similar amount for younger children, older children, and adults. The magnitude of masking release for both groups of children and for adults was inconsistent with absolute energy detection. Instead, increasing the number of signal bursts appears to aid children in the perceptual segregation of the fixed-frequency signal from the random-frequency masker as has been previously reported for adults [Kidd, G., *et al.* (2003). J. Acoust. Soc. Am. **114**, 2835–2845]. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3087435]

I. INTRODUCTION

A child's typical environment contains multiple sources of competing sounds. Each source generates acoustic waveforms consisting of individual frequency components that change over time. Many sound sources can be active at the same time and the child receives a mixture of overlapping waveforms from these multiple sources. In order to develop speech and language in this complex environment, the child must determine which frequency components were generated both sequentially and simultaneously from the same source. This process has been referred to in the literature as sound source segregation or sound source determination (e.g., Bregman, 1990; Yost, 1991).

Results from studies investigating children's speech perception in noise are consistent with the idea that the ability to perform sound source determination is immature during childhood. For example, children require a higher signal-to-noise ratio than adults to recognize speech in the presence of competing noise or speech maskers (e.g., Elliott *et al.*, 1979; Litovsky, 2005; Wightman and Kistler, 2005). Of particular interest to the study of sound source determination in children, these child-adult differences are pronounced for nonsensory or "perceptual" masking (Carhart *et al.*, 1969). Hall *et al.* (2002) observed larger developmental effects in speech recognition in the context of perceptual masking (i.e., spondee words presented in a two-talker masker) than in the context of "energetic" masking (i.e., words presented in speech-shaped noise). Note, however, that children's decreased performance on speech-in-noise tasks might also reflect their lack of experience using acoustic cues across different contexts. Moreover, the relation between sound source determination and auditory masking might be bidirectional for children. Increased masking might result in reduced sound source determination during childhood or vice versa.

Direct evidence supporting the hypothesis that infants and children have difficulty performing sound source determination is provided by studies of auditory stream segregation (Bregman, 1990). Auditory stream segregation refers to the ability to group incoming waveforms into separate auditory streams on the basis of acoustic cues that promote temporal coherence. For adults, these cues can include spatial separation, spectral separation, spectral profile, harmonicity, temporal onsets and offsets, and temporal modulations (e.g., Darwin and Carlyon, 1995; Yost, 1997). Results from several studies of auditory stream segregation during infancy indicate that this process is functional early in life (e.g., Winkler *et al.*, 2003) and that infants use many of the same acoustic cues that adults use to segregate auditory streams (Demany, 1982; Fassbender, 1993; McAdams and Bertoncini, 1997). Larger acoustic separations have been used for testing infants than for testing adults, however, and procedural modifications introduced to test infants limit direct comparisons with adult data. Thus, while the process of auditory stream segregation appears functional early in life, it is not clear how accurately this process operates as the child enters the preschool and school-aged years.

Recent data reported by Sussman *et al.* (2007) indicate that the ability to perform auditory stream segregation continues to develop well into childhood. School-aged children (5–11 years) and adults were presented with a sequence of

 0001-4966/2009/125(4)/2200/9/$25.00

alternating pure tones. The difference in frequency of the alternating tones was varied and listeners were asked to report whether they heard a single integrated auditory stream or two distinct streams. Compared to adults, children required a greater frequency difference between alternating tones before indicating they heard two separate streams. Sussman *et al.* (2007) suggested that the process of auditory stream segregation requires maturation and perceptual experience to fully develop.

We are unaware of other studies describing the efficiency and accuracy of sound source determination during childhood. Thus, it is not clear whether children's abilities to use cues in addition to frequency proximity also follow a prolonged course of development. This lack of information reflects, in part, how challenging it can be for young children to perform the conventional auditory streaming tasks. Interpreting data obtained from these studies is further complicated by the potential for differences in response bias across children and adults using conventional auditory streaming procedures. Differences in response bias can occur as a result of criterion placement and may be responsible for individual differences in the streaming percept across adult listeners for intermediate or ambiguous frequency separations (e.g., Rose and Moore, 1997). Furthermore, studies of complex auditory perception using single-interval tasks have reported developmental changes in response bias (e.g., Leibold and Werner, 2006). Thus, interpreting child-adult differences in auditory streaming is challenging. Observed developmental changes might reflect immaturity in auditory streaming mechanisms. Alternatively, these age effects might reflect differences in the underlying decision processes used by children and adults.

An alternative approach for examining the development of sound source determination is to examine whether children benefit from stimulus manipulations thought to aid in sound source determination by providing a release from "informational" masking (e.g., Watson *et al.*, 1975; Neff and Green, 1987; Kidd *et al.*, 1994). In this context, informational masking refers to masking produced by energy remote in frequency from the signal, that is, masking produced despite an adequate sensory-neural representation of the signal. For simultaneous masking of a pure-tone signal, these effects are largest when stimulus uncertainty is created by introducing random variations in the spectral content of a multi-tonal masker. For example, adults' thresholds for a fixed-frequency, pure-tone signal can be elevated by as much as 50 dB when the spectral content of a multi-tonal masker is varied on each presentation (e.g., Neff and Green, 1987). One advantage of using this approach is that measures of masking release can be obtained efficiently by estimating thresholds using multiple-interval, forced-choice adaptive procedures not likely to be influenced by the placement of the listener's response criterion (e.g., Marshall and Jesteadt, 1986).

The mechanisms responsible for informational masking are not fully understood, but a failure of sound source determination appears to be responsible for a substantial portion of the masking observed in these conditions (e.g., Kidd *et al.*, 1994, 2002; Neff, 1995; Durlach *et al.*, 2003). Evidence supporting this hypothesis is provided by studies that have manipulated stimulus properties thought to promote sound source determination, including spatial separation, asynchronous temporal onsets, and dissimilar temporal modulations (e.g., Darwin and Carlyon, 1995; Yost, 1997). A substantial release from informational masking is observed for most adult listeners when these cues are introduced (e.g., Kidd *et al.*, 1994; Neff, 1995; Oh and Lutfi, 1998; Arbogast *et al.*, 2002; Durlach *et al.*, 2003).

On average, children appear to be more susceptible to informational masking than adults (e.g., Allen and Wightman, 1995; Oh *et al.*, 2001; Wightman *et al.*, 2003). For example, Oh *et al.* (2001) found that the average threshold for detection of a 1000-Hz tone embedded in a random-frequency, multi-tonal masker was about 20 dB higher for children (4–16 years) than for adults. Given children's increased susceptibility to informational masking relative to adults and the mounting evidence that informational masking reflects difficulties performing sound source determination, identifying stimulus cues that benefit children's performance on these tasks has the potential to provide valuable information regarding the development of sound source determination. This approach has been used to examine whether informational masking in children can be reduced by presenting the signal and the masker to different ears (Wightman *et al.*, 2003; Hall *et al.*, 2005), asynchronous temporal onsets (Hall *et al.*, 2005; Leibold and Neff, 2007), spectro-temporal coherence (Hall *et al.*, 2005), spatial separation (Litovsky, 2005), and auditory-visual integration (Wightman *et al.*, 2006). As Hall *et al.* (2005) discussed, results from these studies suggest that the extent to which children benefit from stimulus cues that promote sound source determination for adults depends on the specific cue manipulated. For example, a smaller release from informational masking has been observed for children than for adults when the target signal and the masker are presented dichotically (Wightman *et al.*, 2003; Hall *et al.*, 2005). Both Wightman *et al.* (2003) and Hall *et al.* (2005) found that children receive limited benefit when a fixed-frequency pure-tone signal and a random-frequency multi-tonal masker are presented to opposite ears, a manipulation associated with a large masking release for adults. In contrast, informational masking can be effectively reduced for most children when the onset of a pure-tone signal is delayed relative to the onset of a multi-tonal masker. Children and adults receive a similar average masking release for signal-masker onset asynchronies of 120 ms (Hall *et al.*, 2005) or 100 ms (Leibold and Neff, 2007). Thus, whereas most children demonstrate substantial benefit for a temporal onset asynchrony cue, they demonstrate reduced efficiency for other stimulus cues such as contralateral presentation of the signal and masker. Discrepancies across studies indicate that the relative benefit or salience of stimulus cues that promote a release from informational masking changes with development. However, data remain limited and the benefit provided by several cues shown to aid adults' performance has not yet been determined for children. In addition, most developmental studies have examined performance across conditions with relatively large acoustic differences. Few developmental studies have parametrically varied

the strength of the grouping cue or examined the extent to which children benefit from smaller manipulations.

This study examined the degree to which children benefit from a potential spectro-temporal grouping cue, multiple presentations of a constant-frequency, pure-tone signal. A modified "multiple-burst different" informational masking paradigm (Kidd *et al.*, 1994) was used to parametrically examine child-adult differences in informational masking release for conditions with two, four, five, and six bursts of a 50-ms, 1000-Hz tone embedded in a sequence of random-frequency, two-tone masker bursts. Multiple presentations of the fixed-frequency signal bursts appear to contrast with the random-frequency masker bursts to form a coherent auditory stream and reduce masking for adults (Kidd *et al.*, 2003; Huang and Richards, 2006). Children, however, appear to listen less selectively than adults in complex listening conditions (e.g., Lutfi *et al.*, 2003) and may require more signal presentations than adults to form a coherent stream and perceptually segregate the signal from the masker.

II. METHODS

A. Listeners

Fifteen children (5–10 years) and eight adults (20–29 years) participated in all conditions. Two groups of children were studied: (1) seven younger children aged 5–7 years and (2) eight older children aged 8–10 years. Younger children had a mean age (years:months) of 6:6 (range=5:5–7:6), older children had a mean age of 9:5 (range=8:6–10:5), and adults had a mean age of 24:1 (range=20:0–29:5). Listeners were required to pass a hearing screening prior to testing (re: ANSI, 1996) and had no known history of chronic ear disease. Testing occurred in a single-walled, sound-treated room. Adults and older children completed testing in a 2-h visit. Younger children were typically tested in two 1-h visits. Regular breaks were provided during testing, after the completion of two to three conditions for children and between blocks for adults. Three additional children were tested, but were excluded from data analysis. One child (age 5) did not meet the training criteria, discussed below. A second child (age 5) adapted out of bounds for one condition and did not provide sufficient data to estimate a threshold. Data for a third child (age 7) were excluded because of unusually variable threshold estimates across test sessions. A closer examination of this child's adaptive tracks revealed inconsistent responses and high variability (>5 dB) of reversals.

B. Stimuli and conditions

Following the multiple-burst paradigm of Kidd *et al.* (1994), the masker was a sequence of 10- and 50-ms tone bursts (5-ms, $\cos^2$, rise/fall ramps). There was no temporal overlap between successive masker bursts, resulting in a total duration of 500 ms for each masker sample. Individual masker bursts within the sequence were comprised of two frequency components drawn randomly from a uniform distribution with a range of 300–3000 Hz, excluding 920–1080 Hz. The frequency range from 920 to 1080 Hz extends beyond the equivalent rectangular bandwidth centered on 1000 Hz (Glasberg and Moore, 1990) and was excluded to reduce energy-based masking. The overall level of each burst was 60-dB sound pressure level (SPL) (57 dB/component).

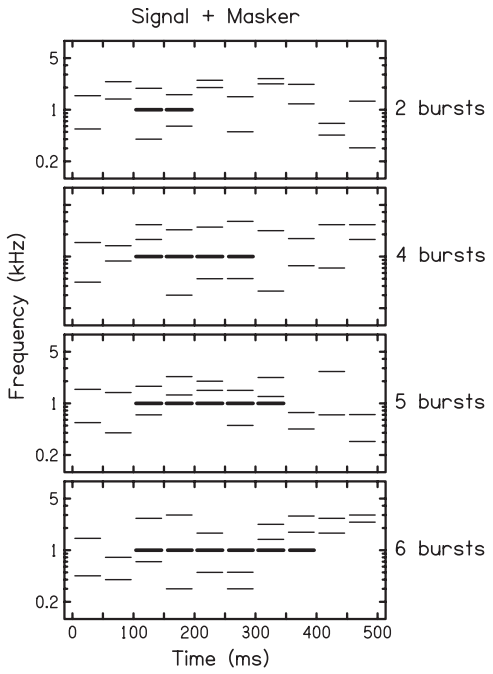

FIG. 1. Schematic representations of the stimuli and conditions are shown as spectrograms. The signal interval of a 2IFC trial with two, four, five, or six bursts of a 1000-Hz tone (bold) are illustrated. For all conditions, the masker consisted of ten bursts of two-component random-frequency maskers (light shading).

The signal was a sequence of 50-ms bursts of a 1000-Hz tone (5-ms, $\cos^2$, rise/fall ramps). Across conditions, the number of signal bursts was varied. Performance for conditions with two, four, five, and six bursts was examined in the presence of the sequential masker. The choice of conditions was based on data reported by Kidd *et al.* (2003) for trained adult listeners using similar conditions as well as pilot data collected from untrained adult and child listeners using the current stimuli. Performance was not assessed for a one-burst condition in the present study. This condition was not tested because both the data reported by Kidd *et al.* (2003) and the pilot data indicated that most children and some adults had difficulty detecting a single, 50-ms burst of the 1000-Hz tone presented in a random, multiple-burst masker. The signal bursts were turned on and off synchronously with the masker bursts, but the onset of the initial signal burst was delayed by 100 ms relative to the first masker burst. Thus, the onset of the first signal burst coincided with the onset of the third masker burst. In addition, a minimum of two masker bursts were played following the offset of the signal bursts. The expectation was that the 100-ms asynchronous onset and offset between the signal and masker bursts would aid in the perceptual segregation of the signal from the masker to a similar degree for both adults and children (Hall *et al.*, 2005; Leibold and Neff, 2007). Schematic representations of the stimuli for the signal-plus-masker interval of one two-interval, forced choice (2IFC) trial are provided in Fig. 1. Thresholds were also measured for the two-burst and six-burst signals in quiet.

Stimuli were played through a 24-bit digital-to-analog converter (Digital Audio Laboratories) at a sampling rate of 20 kHz. Stimuli were presented monaurally to the listener's left ear via Sennheiser HD-25 earphones. Twenty-five masker sequences were generated and stored. The computer randomly selected a different masker sample from this file on each presentation. The same 25 masker samples were used for all masker conditions.

C. Procedure

Prior to testing, listeners completed training for the two-burst signal presented in quiet and both the two-burst and six-burst signals embedded in the random masker sequence. Children sat in front of a computer monitor. Using a two-interval, forced-choice procedure, each trial consisted of two successive observation intervals (indicated by "1" and "2" on the computer monitor). The interstimulus interval was 500 ms. The signal was presented at a clearly audible level during training, based on pilot data. The initial training level was 80-dB SPL. The training level was increased to 90-dB SPL for children who had difficulty performing the task at the initial level. The signal occurred in either interval with equal *a priori* probability and children were instructed to verbally indicate which interval contained the signal. An experimenter sat inside the booth with the child, initiated trials, and entered responses. Correct responses were rewarded by an image presented on the monitor in a video game format. Adults were tested using the same procedure, but were alone in the booth, self-initiated trials, and entered responses directly. Training continued until the listener correctly responded to a minimum of four correct responses within five consecutive trials. As noted previously, one child (age 5) was unable to meet the training criteria.

Following training, thresholds for the 1000-Hz signal were measured with the two-interval, forced-choice procedure used for training, but combined with a two-down, one-up adaptive paradigm that estimated 70.7% correct on the psychometric function (Levitt, 1971). For the first testing block, the individual training level was used as the starting level of the adaptive track. For the second and subsequent testing blocks, the starting level was 10–15 dB above the initial threshold estimate, adjusted for individual listeners. The initial step size was 4 dB, followed by a step size of 2 dB starting with the third reversal. The maximum allowable signal level was 96-dB SPL. For masked conditions, the adaptive track was terminated after 12 reversals and threshold was determined by averaging the levels for the last 10 reversals. For quiet conditions, the adaptive track was terminated after eight reversals and threshold was determined by averaging the levels for the last six reversals.

The order of testing was randomized across all conditions within blocks for each listener. All listeners completed two blocks of testing. Additional blocks were completed if the first two threshold estimates varied by more than 5 dB. For younger children, additional blocks were run for 36% of quiet conditions and 54% of random two-tone conditions. For older children, additional blocks were run for 19% of quiet conditions and 50% of random two-tone conditions. For adults, additional blocks were run for 6% of quiet conditions and 44% of random two-tone conditions. The two threshold estimates with the best agreement were used to determine a listener's average threshold for each condition.

III. RESULTS

Individual threshold estimates for the two-burst and six-burst signals presented in quiet are provided in Table I. Figure 2 shows average quiet thresholds for younger children (open triangles), older children (open squares), and adults (filled circles) as a function of the number of signal bursts (2 versus 6). Error bars represent ± 1 standard error (SE) of the mean threshold across listeners within each age group. For both groups of children, the average threshold for the six-burst signal in quiet is about 2 dB lower than the average threshold for the two-burst signal in quiet. The average adult threshold for the six-burst signal in quiet is about 4 dB lower than the average adult threshold for the two-burst signal in quiet.

A repeated-measures analysis of variance (ANOVA) of threshold was consistent with the trends observed in Fig. 2. No significant differences in absolute threshold across the three age groups were observed [$F(2,20)=2.1$; $p=0.1$], indicating similar performance in quiet for younger children, older children, and adults. However, this analysis showed a significant effect of number of signal bursts [$F(1,20)=9.1$; $p=0.007$], indicating thresholds in quiet decreased as the number of signal bursts increased from 2 to 6. There was no interaction between age group and number of signal bursts ($p=0.7$). Thus, increasing the number of signal bursts in quiet did not affect adults' performance to a significantly greater degree than it affected children's performance.

Individual thresholds for bursts of the 1000-Hz signal presented in the multiple-burst masker are also provided in Table I. Figure 3 shows average masked threshold for younger children (open triangles), older children (open squares), and adults (filled circles) as function of the number of signal bursts. Error bars represent ± 1 SE of the mean threshold across listeners within each age group. For all conditions, average masked threshold for both groups of children was higher than the average masked threshold for adults. Moreover, average masked thresholds for younger children were consistently higher than average masked thresholds for older children.

Despite age differences in susceptibility to masking, masked threshold decreased as the number of signal bursts increased for all three age groups. The largest improvement in average masked threshold was observed as the number of signal bursts increased from 2 to 4. The average threshold improvement in the four-burst condition relative to the two-burst condition was 15.6 dB (SE=7.3) for younger children, 14.2 dB (SE=3.5) for older children, and 9.5 dB (SE=1.3) for adults. A smaller, but progressive, improvement in threshold was observed as the number of signal bursts increased from 4 to 6. The average threshold improvement in the six-burst condition relative to the four-burst condition was 8.7 dB (SE=1.7) for younger children, 7.8 dB (SE=2.7) for older children, and 5.3 dB (SE=2.7) for adults.

TABLE I. Thresholds in decibel SPL for younger children (5–7 years), older children (8–10 years), and adults for the signal bursts presented in quiet and presented in the random masker sequence. The age of each listener is given in years:months.

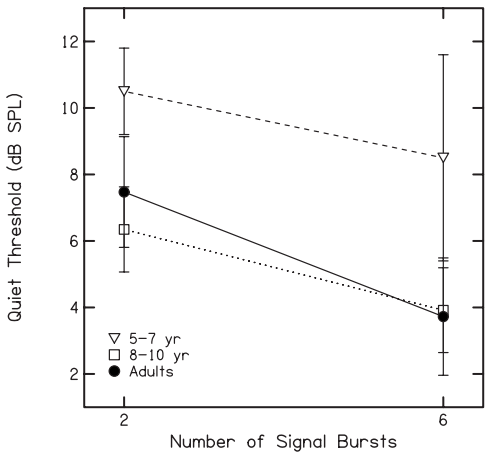

FIG. 2. Average quiet thresholds across listeners (with SEs) for each of the three age groups (open triangles for younger children, open squares for older children, and filled circles for adults) are presented for the two-burst and six-burst signals.

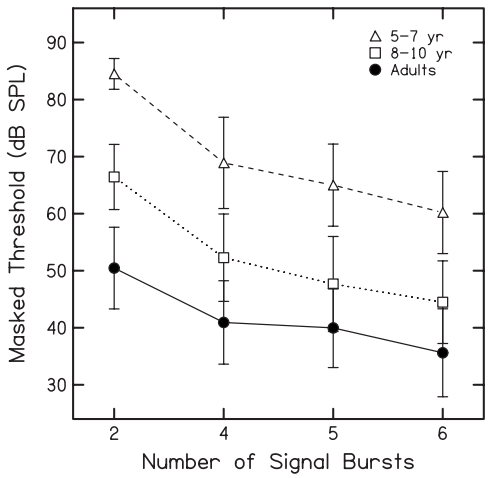

FIG. 3. Average masked thresholds across listeners (with SEs) for each of the three age groups (open triangles for younger children, open squares for older children, and filled circles for adults) are presented for the two-, four-, five-, and six-burst signals.

A repeated-measures ANOVA of threshold was performed with one between-subjects factor (age) and one within-subjects factor (number of signal bursts) to assess developmental effects in the amount of masking release associated with increasing the number of signal bursts. This analysis revealed a significant main effect of number of bursts [$F(3,60)=32.9$; $p<0.001$], indicating thresholds decreased as the number of bursts of the 1000-Hz signal increased. *Post hoc* pairwise comparisons (Bonferroni, using a criterion of $p<0.05$) indicated that thresholds were significantly higher in the two-burst condition than in the four-, five-, and six-burst conditions. Thresholds were also higher in the four-burst condition than in the six-burst condition. Thresholds were not significantly different across the four-burst and five-burst conditions ($p=0.06$) or across the five-burst and six-burst conditions ($p=0.2$). The main effect of age was also significant [$F(2,20)=4,4$; $p=0.03$], indicating developmental effects in susceptibility to masking for these conditions. *Post hoc* pairwise comparisons (Bonferroni, using a criterion of $p<0.05$) indicated that thresholds were significantly higher for younger children than for adults, but were not significantly different across older children and adults ($p=0.7$) or across older and younger children ($p=0.3$). No interaction between number of bursts and age was observed [$F(6,60)=0.6$; $p=0.7$], indicating that threshold decreased with increased signal bursts in a similar way for younger children, older children, and adults.

Considerable between-subjects variability in both amount of masking and masking release was observed for all three age groups, as shown by the error bars in Fig. 3 and the individual thresholds provided in Table I. Despite large individual differences between and within age groups, however, thresholds for all listeners decreased as the number of signal bursts increased. With the exception of one younger child, all listeners showed a masking release of 4 dB or greater as the number of signal bursts was increased from 2 to 4. The remaining listener (age 6:11) showed a masking release of 2 dB. All listeners, including the younger child (6:11) who showed a 2-dB improvement in threshold when the number of signal bursts increased from 2 to 4, showed a masking release as the number of signal bursts was increased from 2 to 6. Also note that the majority of listeners showed additional masking release as the number of signal bursts was increased from four to six bursts.

IV. DISCUSSION

A. Child-adult differences in susceptibility to informational masking

1. Group differences

The current results support the hypothesis that informational masking is greater for children than for adults. Thresholds for the detection of bursts of a 1000-Hz signal in the presence of a random-frequency masker sequence were elevated for all three age groups. However, younger children had significantly higher masked thresholds than adults. These results are in agreement with previous developmental studies of informational masking that have employed sequential multi-tonal maskers (Hall *et al.*, 2005), simultaneous multi-tonal maskers (e.g., Oh *et al.*, 2001; Wightman *et al.*, 2003), and speech maskers (e.g., Wightman and Kistler, 2005). The mechanisms responsible for these age-related changes in susceptibility to informational masking are not fully understood, but are not likely the consequence of immature sensory processing [reviewed by Werner (1996)]. Instead, children's increased susceptibility to informational masking appears to reflect developmental changes in nonsensory processes. For example, Lutfi *et al.* (2003) modeled children's responses in a pure-tone informational masking task, and their elevated thresholds suggest a reduced ability to attend selectively to the auditory filter containing the signal.

2. Individual differences

As in previous investigations of informational masking involving both children (e.g., Oh *et al.*, 2001) and adults (e.g., Neff and Dethlefs, 1995), a wide range of performance was observed within and across age groups. However, systematic differences in threshold variability were not observed across the three age groups. For example, the range of masked thresholds for the six-burst condition spanned a range of 47 dB for younger children and 53 dB for both older children and adults. In contrast, Hall *et al.* (2005) observed a smaller range of thresholds for adults (30 dB) than for children aged 4–9 years (50 dB) for an eight-burst signal embedded in a sequence of two-tone masker bursts with random spectra. Differences in methodology across studies make it difficult to determine the basis for this discrepancy. Note, however, that differences in threshold variability between the current data and Hall *et al.* (2005) reflect an increased range of threshold estimates for adults in the current study. A comparison of threshold estimates for children across the two studies indicates a similar range of performance.

B. Child-adult similarity in release from informational masking

The main purpose of this study was to determine whether there are developmental effects in informational masking release as the number of signal presentations increased. The results indicate this cue reduced masking for younger children (5–7 years), older children (8–10 years), and adults. Even with adults' lower thresholds in the baseline (two-burst) condition compared to younger children, the three age groups experienced similar release from masking as the number of signal bursts increased.

The pattern of results for untrained adult listeners in the current study is in general agreement with the pattern observed by Kidd *et al.* (2003) for trained adults. This agreement suggests that increasing the number of presentations of the signal, as opposed to the masker, is likely responsible for reducing informational masking using the multiple-burst different paradigm. Kidd *et al.* (2003) examined listeners' ability to detect a sequence of 60-ms, 1000-Hz signal bursts embedded in a masker consisting of 60-ms bursts of a random-frequency, eight-tone complex. In contrast to the current study in which the number of masker bursts was 10 for all conditions, Kidd *et al.* (2003) varied the number of masker bursts across conditions to match the number of sig-

nal bursts. In conditions with one, two, four, and eight bursts and an inter-burst interval of 0 ms, all listeners showed a masking release as the number of signal and masker bursts was increased. The current results corroborate these previous findings by confirming the effectiveness of providing listeners with a coherent signal across time for reducing informational masking (e.g., Kidd *et al.*, 2003; Huang and Richards, 2006). Inconsistent with the result of Kidd *et al.* (2003), however, the present study showed smaller reductions in threshold as the number of signal bursts increased. Whereas Kidd *et al.* (2003) found an average masking release of 24 dB as the number of masker bursts was increased from 2 to 4, an average masking release of 10 dB was observed here. Differences in stimuli are the most likely reason for this discrepancy. In addition to varying the number of both signal and masker bursts, Kidd *et al.* (2003) used masker bursts comprised of eight pure-tone components. Maskers with fewer components, such as the two-component maskers used in the current study, have been shown to produce less informational masking (e.g., Neff and Green, 1987) and thus, a reduced potential for masking release.

Increasing the number of presentations of a 1000-Hz signal was clearly an effective cue for children as well as adults. Despite considerable individual differences, children as young as 5 years of age were able to take advantage of the increased number of signal bursts. Though a direct comparison is not evident in the literature, Hall *et al.* (2005) also found that most children (5–10 years) benefited from stimulus cues believed to be related to spectro-temporal coherence. Inconsistent with the current results, however, Hall *et al.* (2005) observed a smaller average masking release for children than for adults. Perhaps the most important difference across the two studies is that Hall *et al.* (2005) assessed informational masking release related to manipulations made to the spectral properties of the masker. The current study examined informational masking release related to changes made to the temporal properties of the signal.

C. Relation between susceptibility to and release from informational masking

The finding that children's thresholds were generally higher than adults in the baseline (two-burst) condition complicates the interpretation of age differences in masking release. Increased susceptibility to informational masking in some children may have permitted larger reductions in threshold. Several observations are inconsistent with this explanation. First, children with the greatest release from masking did not have uniformly high thresholds in the baseline (two-burst) condition. In fact, the child (8:6) with the lowest threshold for the two-burst condition among all children showed a larger-than-average masking release (17 dB) as the number of signal bursts increased to four bursts. Second, regression analyses indicated that thresholds in the two-burst condition were not a significant predictor of the amount of masking release observed as the number of signal bursts was increased from two to four bursts for any age group (all p's >0.8). Third, a comparison of informational masking release among adults found no evidence of differences in masking release for the four adults with the lowest two-burst thresholds ($<$40-dB SPL) versus the four adults with the highest two-burst thresholds ($>$60-dB SPL). The average masking release for the four adults with the lowest thresholds was 10 dB. Similarly, the average masking release for the four adults with the highest thresholds was 9 dB. Together, these observations are inconsistent with the viewpoint that developmental effects in susceptibility to informational masking are responsible for the amount of benefit provided by increasing the number of signal presentations.

The average child-adult difference in threshold for the six-burst signal embedded in the random masker was 26 dB for younger children and 9 dB for older children. Thus, children's thresholds remain elevated compared to adults despite their ability to benefit from the increased number of signal bursts. The basis for children's increased susceptibility to informational masking relative to adults in the presence of an effective cue is unknown. However, this finding is consistent with previous studies that have examined developmental effects in susceptibility to and release from informational masking. For example, Leibold and Neff (2007) observed a similar effect of reducing masker-spectral variability and adding an onset/offset asynchrony cue for children and adults in the context of a simultaneous informational masking task. Nonetheless, Leibold and Neff (2007) reported that children's thresholds remained elevated compared to adults for conditions in which both of these grouping cues were available.

D. Energy detection versus perceptual segregation

One explanation for the observed masking release is that listeners combined or integrated stimulus energy across time to improve performance. It has been well documented that detection thresholds for a pure-tone signal presented in quiet or in broadband noise decrease as signal duration increases from about 10 to 200–300 ms [reviewed by Gerken *et al.* (1990)]. This phenomenon is typically referred to as temporal integration. Several models have been proposed to account for temporal integration, including models that assume that listeners integrate stimulus energy across 200–300 ms (e.g., Swets *et al.*, 1959; McKinley and Weber, 1994) and more recent models that assume that the listener's decision is based on information combined across multiple shorter "looks" or samples (Viemeister and Wakefield, 1991).

The current data for the signal presented in the random two-tone masker are inconsistent with energy-detector and multiple-looks models. For example, a decrease in threshold of approximately 10 dB/decade increase in signal duration is predicted using a simple energy-detector model that assumes linear integration. For the current stimuli, this prediction corresponds to an improvement in threshold of approximately 3 dB for the four-burst signal (200 ms) compared to the two-burst signal (100 ms). In contrast to the predicted improvement, the average observed masking releases were 16, 14, and 10 dB for younger children, older children, and adults, respectively. The discrepancy between predicted and observed performances for the random two-tone masker suggests that listeners are not basing their decisions on absolute energy detection. In addition, the average observed threshold

improvement in quiet across the six-burst and two-burst signals was about 2 dB for both groups of children and 4 dB for adults. Thus, whereas the observed threshold improvement was equal to (adults) or slightly less than (children) predicted for optimal energy detection in quiet, the magnitude of threshold improvement for all three age groups with increasing signal bursts was considerably greater than predicted in the presence of the random two-tone masker.

Previous work by Kidd *et al.* (2003) examined whether a multiple-looks model (Viemeister and Wakefield, 1991) could account for adults' performance on multiple-burst different conditions. Both the number of signal bursts and the silent interval between successive bursts (interburst interval) were manipulated. Consistent with the multiple-looks model, masking decreased as the number of bursts increased. However, several observations were inconsistent with the multiple-looks model. First, the observed magnitude of masking release exceeded the amount predicted by the model. Second, masking increased as the interburst interval increased. Third, the group-mean slope of the psychometric function increased as the number of signal bursts increased or as the interburst interval decreased. A similar increase in the slope of the psychometric function with reductions in informational masking has been observed by researchers using a simultaneous multi-tonal paradigm (e.g., Durlach *et al.*, 2005). Based on these observations, Kidd *et al.* (2003) suggested that increasing the number of bursts of the fixed-frequency signal contrasted with the random-frequency masker to provide an effective perceptual grouping cue. The magnitude of masking release and the discrepancy across quiet and masked conditions observed in the current study suggest that increasing the number of signal bursts strengthens perceptual coherence and reduces thresholds for children as well as for adults.

V. CONCLUSIONS

The results of the current study indicate that multiple presentations of a constant-frequency signal embedded in a random-frequency masker provide both children and adults with a robust cue for reducing informational masking. Although younger children were more susceptible to informational masking than adults, a similar decline in thresholds was observed as the number of signal bursts was increased for all age groups. Determining the relative importance of stimulus cues that reduce informational masking has the potential to provide insight into the mechanisms responsible for children's increased susceptibility to auditory masking. Further studies are needed to determine which cues are the most salient during development, how children integrate multiple cues to improve performance in the presence of competing sounds, and whether infants and children can benefit from similar acoustic cues in more natural environments.

Maximal azimuthal resolution needed in measurements of head-related transfer functions

Xiao-Li Zhong and Bo-Sun Xie[a)]
Physics Department, Acoustic Laboratory, South China University of Technology, Guangzhou 510641, China

(Received 23 March 2008; revised 2 February 2009; accepted 3 February 2009)

The head-related transfer function (HRTF) is a continuous function of sound source position. Measurement of the HRTF can only be undertaken at discrete positions in space, however. Determination of angular resolutions so as to reconstruct HRTFs at unmeasured positions has been an open problem. Azimuthal Fourier analysis was proposed to analyze the variation in the HRTF in each elevation plane. As a result, an azimuthal sampling theorem and a corresponding interpolation formula were derived. It was proved that the maximal azimuthal resolution of measurements is $360°/(2Q+1)$, where Q represents the highest order in the truncation of the azimuthal Fourier expansion of the HRTF. The maximal azimuthal resolutions for the HRTF with and without arrival time correction were investigated. Results show that the arrival time correction can reduce the burden of measurements, since a larger azimuthal resolution is possible without introducing obvious interpolation error. A psychoacoustic experiment was also conducted to evaluate the proposed theorem. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3087433]

I. INTRODUCTION

Head-related transfer functions (HRTFs) reflect the overall filtering effects caused by anatomical structures such as the head, torso, and pinna. Because HRTFs contain all primary sound localization cues (Blauert, 1997; Kulkarni and Colburn, 1998; Wenzel *et al.*, 1993), the nature and use of HRTFs are important for understanding binaural hearing and in the implementation of virtual auditory displays (Shinn-Cunningham, 1998; Xie, 2008).

Although calculation is a way to obtain HRTFs (Algazi *et al.* 2002; Katz, 2001), measurement remains a common approach. To date, measurements have been undertaken on artificial heads and human subjects by various research groups (Algazi *et al.*, 2001; Blauert *et al.*, 1998; Bovbjerg *et al.*, 2000; Gardner and Martin, 1995; Genuit and Xiang, 1995; Middlebrooks *et al.*, 1989; Møller *et al.*, 1995; Riederer, 1998; Wightman and Kistler, 1989; Xie *et al.*, 2007).

Naturally, HRTFs vary as a continuous function of sound source position. Only the HRTFs at discrete positions can be measured in practice, representing a sampling of the continuous three-dimensional space for sound source positions. Differing spatial resolutions have been used by different research groups. For example, in the horizontal plane, the azimuthal resolutions were in a range 0.9°–22.5° in the references above. In order to obtain HRTFs at unmeasured positions, a number of interpolation methods have been proposed (Biscainho *et al.*, 2002; Nishino *et al.*, 1999; Wenzel and Foster, 1993; Wightman *et al.*, 1992). In view of achieving good interpolation performance, measurement with a high spatial resolution is preferable. However, because dense measurement is time consuming and laborious, it is inconvenient to measure HRTFs with a very fine spatial resolution. Then, the problem of how to determine an appropriate spatial resolution in HRTF measurement arises.

Minnaar *et al.* (2005) analyzed the spatial resolutions needed in HRTF measurement by examining the audible error introduced by the linear interpolation of two neighboring measurements. They found that different spatial regions required different spatial resolutions. For example, in the horizontal plane, an azimuthal resolution of 16° was sufficient except for the lateral region where an azimuthal resolution of 8° was required. Since an audible criterion was used, the resulting spatial resolutions could not ensure the interpolation accuracy in mathematics.

Inspired by the reciprocal principle of acoustics, Ajdler *et al.* (2005) deduced an azimuthal sampling theorem in the horizontal plane from the theory of sound-field pickup, in which the maximal azimuthal resolution was directly related to the bandwidth of the HRTF. This theorem is only an approximation, however, since it was not derived from measured HRTFs and did not fully account for the complex sound wave diffraction introduced by the anatomical system.

According to the signal processing theory, the maximal azimuthal resolution needed to reconstruct a continuous signal is determined by the complexity of the signal itself. Analyzing the spatial variation of the HRTF is therefore a way to determine the spatial resolution of the HRTF. Preliminary work relating the spatial variation of the HRTF to its reconstruction was done by Evans *et al.* (1998), but no explicit discussion of the spatial resolution of the HRTF was given. Moreover, since Evans *et al.* (1998) expanded HRTFs by surface spherical harmonics, there are some limitations on the spatial resolution of the HRTF in order to estimate the expansion coefficients effectively using the Gauss–Legendre quadrature formula.

In the current study, the azimuthal variation of the HRTF is investigated using azimuthal Fourier analysis. As a result, an azimuthal sampling theorem of HRTF is obtained, which is similar to the famous Nyquist sampling theorem, and a corresponding interpolation formula is derived. Unlike the spherical-harmonic expansion, which deals with elevation and azimuth simultaneously, the azimuthal Fourier analysis of the HRTF focuses only on HRTF variation with azimuth in a given elevation plane. The resulting azimuthal sampling theorem allows different azimuthal resolutions in different elevation planes. The basic idea of the azimuthal Fourier analysis appeared in Zhong and Xie (2005), which analyzed the spatial variation of the HRTF from KEMAR. The present paper sets out a detailed exposition of the basic theory of the azimuthal Fourier analysis. Analyses of the HRTFs from KEMAR and humans under the original and the arrival time correction representation are elaborated. Finally, recommendations are given on the maximal azimuthal resolution for different elevations based on the statistical results of 52 human subjects.

II. FUNDAMENTALS

The center of the head is chosen as the origin of coordinates. The distance from a sound source to the origin is denoted by r. The sound source direction is specified by the azimuth θ from 0° to 360° and the elevation ϕ from –90° to 90°, where ϕ=0° and 90°, respectively, correspond to the horizontal and vertical plane. In the horizontal plane, θ=0° is the front and θ=90° is the right.

In the free field, HRTF is defined as

$$H(r,\theta,\phi,f)=\frac{P(r,\theta,\phi,f)}{P_0(r,f)}, \tag{1}$$

where P denotes the sound pressure at the left or the right ear caused by a sound source, and can be measured anywhere from the eardrum to the entrance of the ear canal; P_0 denotes the sound pressure at the origin with the head absent, and f is the frequency of sound waves. Generally, HRTF is a complicated function of the sound source position (including sound source direction and distance) and the frequency. In the far field, however, when the distance from the head center to the sound source exceeds 1.0–1.2 m, the HRTF is asymptotically independent of distance. Also, the HRTF is closely related to anatomical features which differ from person to person, so that the HRTF is individual-dependent. The counterpart of the HRTF in the time domain is called the head-related impulse response (HRIR), which is the inverse Fourier transform of the HRTF.

A. Azimuthal Fourier analysis and azimuthal sampling theorem

In the far field, the HRTF is a continuous function of azimuth with a period of 2π for a given elevation. It can therefore be expanded as an azimuthal Fourier series as

$$H(\theta,f)=\sum_{q=-\infty}^{+\infty} d_q(f)e^{iq\theta}, \quad d_q(f)=\frac{1}{2\pi}\int_0^{2\pi} H(\theta,f)e^{-iq\theta}d\theta, \tag{2}$$

where $H(\theta,f)$ denotes the azimuthal HRTF at a given elevation, $d_q(f)$ is the weight coefficient, and q the expansion order. In Eq. (2), the azimuthal HRTF is decomposed as a linear combination of infinite weighted azimuthal harmonics. If the azimuthal harmonic expansion in Eq. (2) is convergent, Eq. (2) can be truncated as

$$H(\theta,f)=\sum_{q=-Q}^{+Q} d_q(f)e^{iq\theta}, \tag{3}$$

where Q is the truncation order, above which the higher-order harmonics are neglected because their contribution is insignificant. The azimuthal HRTF then consists of $(2Q+1)$ weighted azimuthal harmonics, and is completely determined by their $(2Q+1)$ weight coefficients. By sampling the azimuthal HRTF from azimuth 0 to 2π at M positions with an azimuthal resolution $2\pi/M$, we have

$$H(\theta_m,f)=\sum_{q=-Q}^{+Q} d_q(f)e^{iq\theta_m}, \quad \theta_m=\frac{2\pi m}{M}, \quad m=0,1,\ldots,(M-1), \tag{4}$$

where θ_m is the measured azimuth, and $H(\theta_m,f)$ is the measured HRTF at azimuth θ_m. If the number of azimuthal measurements $M\geq(2Q+1)$, then $(2Q+1)$ weight coefficients can be obtained by resolving the M linear equations in Eq. (4) using the orthogonality and completeness properties of $\{\exp(iq\theta_m)\}$:

$$d_q(f)=\frac{1}{M}\sum_{m=0}^{M-1} H(\theta_m,f)e^{-iq\theta_m}, \quad |q|\leq Q,$$

$$d_q(f)=0, \tag{5}$$

$$Q<|q|\leq(M-1)/2 \quad \text{if } M \text{ is odd},$$

$$-(M/2)\leq q<-Q \quad \text{and} \quad Q<q\leq(M/2)-1 \quad \text{if } M \text{ is even}.$$

Substitution of Eq. (5) into Eq. (3) yields

$$H(\theta,f)=\frac{1}{M}\sum_{m=0}^{M-1} H(\theta_m,f)\frac{\sin\left[\left(Q+\frac{1}{2}\right)(\theta-\theta_m)\right]}{\sin\left(\frac{\theta-\theta_m}{2}\right)}. \tag{6}$$

Equation (6) allows the HRTFs at unmeasured azimuths to be reconstructed from the M measured HRTFs. Note that the derivation of Eqs. (5) and (6) supposes that the number of azimuthal measurements $M\geq(2Q+1)$. Therefore, $(2Q+1)$ is defined as the minimal number of azimuthal measurements (MNAM) for the HRTF, and correspondingly the maximal azimuthal resolution is 360°/MNAM.

In conclusion, for a given elevation, the azimuthal HRTF can be decomposed as a linear combination of

weighted azimuthal harmonics. When the number of azimuthal measurements is not less than the MNAM, or equivalently when the azimuthal resolution is not larger than the maximal azimuthal resolution 360°/MNAM, the HRTFs at unmeasured azimuths can be reconstructed from measured HRTFs at discrete azimuths using Eq. (6). This is the azimuthal sampling theorem of the HRTF, which is similar to the famous Nyquist theorem with respect to time.

Because the azimuthal variation of the HRTF is unlikely to be the same for different frequencies, the truncation order Q, and hence the MNAM, depends on frequency.

B. Determination of MNAM

In order to determine Q and then the MNAM, the relative power of the sth-order azimuthal harmonic term against the total power is defined as

$$\eta_s(f) = \frac{|d_s(f)|^2 + |d_{-s}(f)|^2}{\sum_{q=-\infty}^{+\infty} |d_q(f)|^2}, \quad s = 1,2,3,\ldots. \tag{7}$$

In Eq. (7), the denominator is an infinite sum over weight coefficients which should be calculated from the azimuthal HRTF, as shown in Eq. (2). Unfortunately, the azimuthal HRTF within the audible frequency range is not available, since only HRTFs at discrete positions can be obtained by measurements. However, if a HRTF database exists which contains sufficient measured HRTFs and satisfies the azimuthal sampling theorem of the HRTF, then the coefficients can be calculated by Eq. (5). Equation (7) can then be rewritten as

$$\eta_s(f) = \frac{|d_s(f)|^2 + |d_{-s}(f)|^2}{\sum_{q=-Q_1}^{+Q_2} |d_q(f)|^2}, \tag{8}$$

where (Q_1+Q_2+1) is the number of azimuthal measurements M. To evaluate the contribution of the preceding S-order azimuthal harmonic terms, the relative power ratio η is defined as

$$\eta = \frac{\sum_{q=-S}^{+S} |d_q(f)|^2}{\sum_{q=-Q_1}^{+Q_2} |d_q(f)|^2}, \quad \begin{array}{l} S = 1,2,\ldots,\min(Q_1,Q_2). \\ Q_1 = Q_2 = (M-1)/2 \ \text{ if } M \text{ is odd.} \\ Q_1 = M/2, Q_2 = (M/2)-1 \ \text{ if } M \text{ is even.} \end{array} \tag{9}$$

The steps for determining Q and hence the MNAM for each elevation are as follows.

(1) At each discrete frequency point whose value is determined by the frequency sampling rate, calculate η for $S=1,2,\ldots,\min\ (Q_1,\ Q_2)$ until $S=S_1$ when the η reaches a power criterion (such as 0.95) that is chosen according to the accuracy desired. Then, S_1 is regarded as the truncation order Q above which the contribution of higher-order terms is negligible. According to the azimuthal sampling theorem of the HRTF, $(2Q+1)=(2S_1+1)$ is the MNAM.

(2) If $S_1<\min(Q_1,Q_2)$, then $(2S_1+1)<2\ \min(Q_1,Q_2)+1 \leq (Q_1+Q_2+1)$, where the first term is the MNAM and the last term is the number of azimuthal measurements. In this case, because the MNAM is less than the number of azimuthal measurements, the number of azimuthal measurements is sufficient with some redundancy under the chosen power criterion. Otherwise, if $S_1=\min(Q_1,Q_2)$, which means the truncation rests on the harmonic term with the highest order that the HRTFs employed can provide, then it is difficult to judge whether the number of azimuthal measurements just suffices or not. In this case, the number of azimuthal measurements analyzed is regarded as insufficient.

(3) The MNAM calculated by the steps above is just for each discrete frequency point. For a given frequency range, such as the audible frequency range, the maximum among the MNAMs of the discrete frequency points included in the frequency range is chosen as the MNAM of the frequency range. In this paper, MNAM of the audible frequency range is denoted by $\text{MNAM}_{\text{audio}}$.

C. Arrival time correction representation of the HRTF

Section II A deals with the original HRTF, and Eq. (6) is the azimuthal interpolation equation for the original HRTF. Since the HRIR is the time domain version of the HRTF, Eq. (6) can also be regarded as an azimuthal interpolation equation for the original HRIR.

Each original HRIR contains a position-dependent onset delay, relating roughly to the arrival time of sound waves from the sound source to the ear. Some studies found that if the arrival time was corrected prior to interpolation, i.e., the arrival time for each position was made synchronous by shifting the onset time of the HRIR, then the interpolation performance of the HRIR or HRTF could be improved (Evans *et al.*, 1998; Matsumoto *et al.*, 2004). This motivates correction for the arrival time in the original HRTF in the azimuthal Fourier analysis.

There are several ways to determine the time displacement. In the work of Evans *et al.* (1998), the time displacement was chosen as a time segment from the beginning of the HRIR to four samples before the instant when the HRIR first exceeded an onset threshold of 0.015. An alternative method is used here. For a given elevation plane, the time displacement is chosen as the time value that maximizes the cross-correlation function between the HRIR at azimuth 0° and the HRIR at each azimuth θ_m. This is equivalent in the frequency domain to maximizing the cross-spectra function. Moreover, modifying the arrival time in the HRIR is equivalent to transforming the original HRTF to its time-corrected version H_τ as

$$H_\tau(\theta,f) = H(\theta,f)\exp[-j2\pi f\tau(\theta)], \tag{10}$$

where $\tau\ (\theta)$ is the time displacement. A positive time displacement means incorporating a time delay to the original

[a]Gardner and Martin (1995).

HRTF, whereas a negative value means incorporating a time advance.

Below are the steps for obtaining the interpolated HRTFs under the arrival time correction representation.

(1) At a given elevation, suppose there are M original HRTFs measured with an azimuthal resolution of $(360°/M)$, among which the first sampled azimuth is 0°. Then, M time displacements can be estimated by calculating the delay that maximizes the cross-spectra function between the HRTF at azimuth 0° and the HRTF at azimuth θ_m. Note the time displacement is zero for azimuth 0°. Next, as shown in Eq. (10), shifting of the original HRTFs according to the calculated time displacements yields the $H_\tau s$, which have the same onset time as in the original HRTF at azimuth 0°.
(2) As with the original HRTF, the azimuthal H_τ at a given elevation is also a periodic function of azimuth with a period of 2π, so that the methods proposed in Secs. II A and II B can also be applied. The MNAM for the azimuthal H_τ can be calculated and the H_τ at unmeasured azimuths can be obtained using Eq. (6).
(3) The methods in Secs. II A and II B can also be applied to the azimuthal function of time displacement τ in a given elevation for its periodicity. The MNAM for the time displacement can be calculated and the time displacements at unmeasured azimuths can be interpolated by

$$\tau(\theta) = \frac{1}{M}\sum_{m=0}^{M-1} \tau(\theta_m)\frac{\sin\left[\left(Q' + \frac{1}{2}\right)(\theta - \theta_m)\right]}{\sin\left(\frac{\theta - \theta_m}{2}\right)}, \tag{11}$$

where $\tau(\theta_m)$ is the measured time displacement obtained by step (1), and Q' is the truncation order of the azimuthal function of time displacement, which may be different from the truncation order of the azimuthal H_τ.
(4) For the same azimuth, add the interpolated time displacement in step (3) back to the corresponding interpolated H_τ in step (2) to obtain the overall HRTF under the arrival time correction representation.

As with the original HRTF, a power criterion is used to determine the truncation order of the azimuthal harmonics of the azimuthal H_τ in step (2). For the truncation of the azimuthal function of time displacement, a time criterion such that truncation error is less than 5 μs is used to ensure that the largest error of the interaural time difference does not exceed 10 μs.

For the arrival time correction representation of HRTF, the MNAM needed to reconstruct the overall HRTFs at unmeasured azimuths is determined by the larger one of the MNAM for the H_τ and the MNAM for the time displacement. It will be shown in Sec. III C that the final MNAM is always determined by the former, that is, the MNAM for the H_τ. In the following, the HRTFs under the original and the arrival time correction representation are denoted by $HRTF_{original}$ and $HRTF_{correction}$, respectively.

III. RESULTS FOR MNAM

A. HRTF database

Two sets of HRTF database are used.

(1) The HRTF database for KEMAR from the MIT media Laboratory (Gardner and Martin, 1995).

Since KEMAR is designed according to the mean anatomical size of the Western population, results from KEMAR HRTF are representative in a sense of the mean (Burkhard and Sachs, 1975). Moreover, the measurement error of KEMAR is small as KEMAR is not liable to movement during measurements. The far-field HRTF data from KEMAR with small pinna (DB-061) are therefore used, as shown in Table I. For each measured position, the database contains a 512-

TABLE II. The number of azimuthal measurements for the HRTF database containing 52 human subjects and calculated mean $MNAM_{audio}$ to reconstruct HRTFs up to 20 kHz. Corresponding standard deviations are in parentheses.

75°	24	15°	23 (±1.4)	14 (±3.6)

tap HRIR with a frequency sampling rate of 44.1 kHz, from which a 512-tap HRTF can be obtained by the discrete-time Fourier transform.

(2) HRTF database of human subjects(Xie *et al.*, 2007).

To obtain statistical results of human subjects, a HRTF database established recently by our laboratory was used, which contains HRTFs of 52 subjects, 26 male and 26 female. For each subject, the far-field HRTFs ($r=1.5$ m) were measured at 493 spatial positions, including eight elevation planes. Azimuthal resolutions are shown for each elevation plane in column 3 of Table II. For each measured position, a pair of 512-tap HRIRs for the left and right ears with a frequency sampling rate of 44.1 kHz was obtained. The method in Sec. II can be applied to either left-ear or right-ear HRTFs. For simplicity, only the data from the left ear are used in the following analysis.

B. MNAM for the $HRTF_{original}$

Figure 1(a) shows how the relative power contribution of each azimuthal harmonic of the original HRTF varies with frequency in the horizontal plane. Figure 1(b) is for the H_τ, which will be discussed in Part C. In Fig. 1(a), the relative contribution of lower-order azimuthal harmonics, which correspond to the smooth azimuthal variation of the HRTF, is significant at low frequencies when the wavelength is large. As a result, the truncation order is low and the MNAM is small. With increasing frequency, the interference of sound waves caused by the head and pinna becomes significant. As a result, the HRTF varies with azimuth rapidly at high frequencies, and the relative contribution of higher-order azimuthal harmonics increases. For example, the relative contributions of the 20th-order azimuthal harmonic are 3.2×10^{-7} at 172 Hz and 1.2×10^{-1} at 15.4 kHz. Therefore, the truncation order is likely to be high, so that the MNAM is large at high frequencies. Moreover, Fig. 1(a) shows that, at each frequency sampling point, the relative contribution of the azimuthal harmonics demonstrates a clear downward trend with increasing expansion order, verifying the hypothesis in Sec. II A that the azimuthal harmonic expansion of the HRTF is convergent.

The results for other elevation planes are similar, but the relative contribution of high-order azimuthal harmonics declines gradually as the elevation deviates from the horizontal plane. For example, the relative contributions of the 20th-order azimuthal harmonic at 15.4 kHz are 1.2×10^{-1}, 5.1×10^{-2}, and 2.3×10^{-3} for elevation 0°, 20°, and 50° in turn.

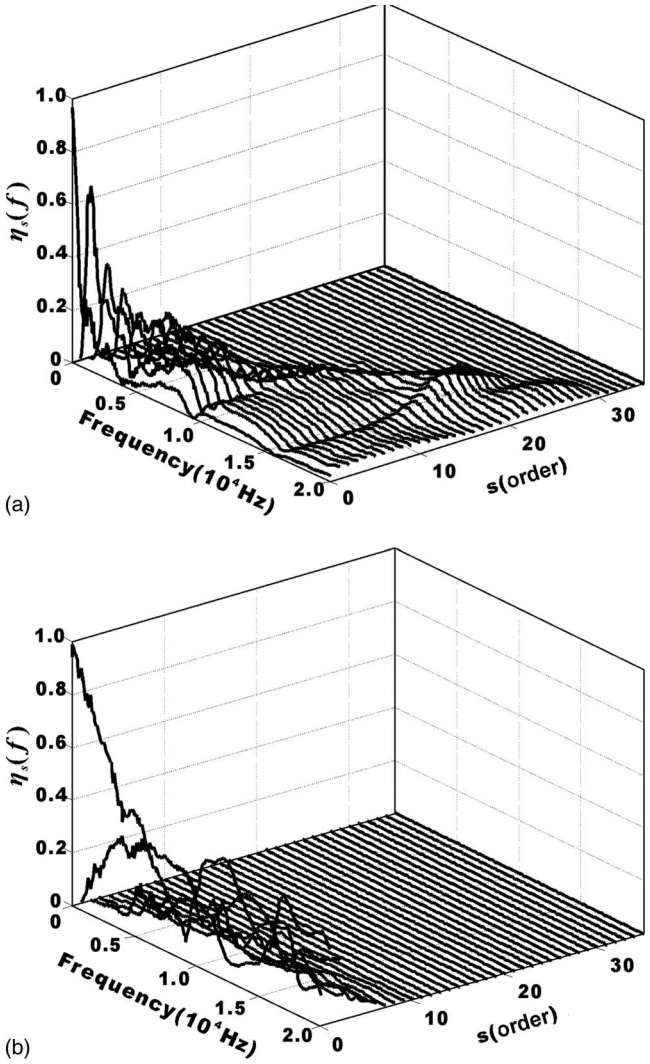

FIG. 1. In the horizontal plane, the relative contribution of each azimuthal harmonic of KEMAR is shown, with (a) for the $HRTF_{original}$ and (b) for the H_τ calculated from Eq. (8).

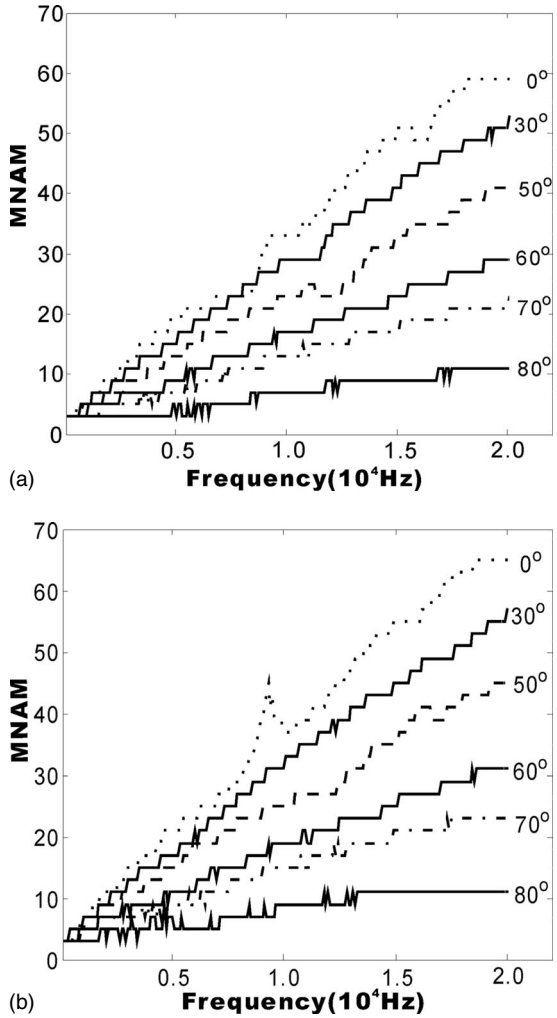

FIG. 2. Calculated MNAM of KEMAR for different elevation planes. The abscissa is frequency, and the ordinate is the MNAM of the power criterion (a) 0.95 and (b) 0.99. The MNAMs for elevations 10° and 20° (omitted) are very similar to that of elevation 0°.

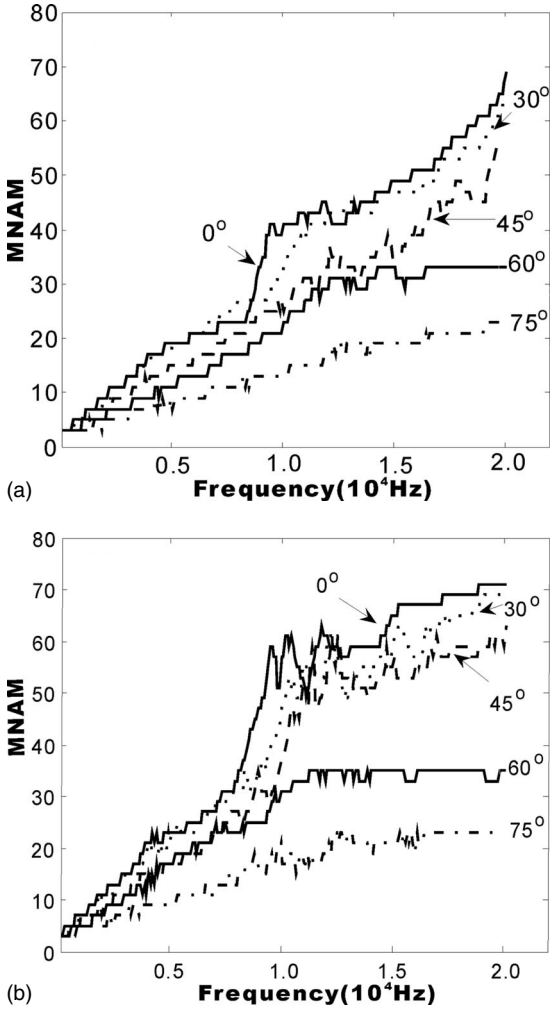

FIG. 3. Calculated MNAM for the human subject 23 in different elevation planes with the power criterion (a) 0.95 and (b) 0.99. The MNAM for elevation 15° is very similar to that of elevation 30°, and is omitted for clarity.

This is because the variation in the HRTF with azimuth smoothens gradually with elevation shifting from the horizontal plane.

Figure 2 shows the MNAM for KEMAR as a function of frequency and elevation. The features in this plot are as follows.

(1) Given an elevation plane and a frequency sampling point, the MNAM with criterion 0.99 in Fig. 2(b) is always larger than that with criterion 0.95 in Fig. 2(a), because the former is stricter than the latter in accuracy.
(2) Given an elevation plane, the MNAM of each frequency point increases stepwise with increasing frequency, although a few exceptions may exist. Therefore, the MNAM of a frequency range, which is the maximum among the MNAMs for all discrete frequency points in the range, is likely to be the MNAM of the high-limit frequency sampling point in that range.
(3) Given a frequency sampling point, the MNAM decreases gradually as elevation deviates from the horizontal plane. This is because the azimuthal variation of the HRTF smoothes gradually with elevation shifting from the horizontal plane.

The HRTF of the audible frequency range (up to 20 kHz) has been widely measured and employed. Therefore, the $\mathrm{MNAM}_{\mathrm{audio}}$ needed to reconstruct the HRTFs for KEMAR at unmeasured azimuths up to 20 kHz were calculated according to step (3) in Sec. II B. Results are listed in columns 4 and 5 of Table I. Comparison with the numbers of azimuthal measurements in column 2 of Table I shows that, for the criterion 0.99, the numbers of azimuthal measurements in the MIT database are sufficient except for elevations 50°, 70°, and 80°, while for the power criterion 0.95 only the numbers of azimuthal measurements for elevations 70° and 80° are likely to be insufficient.

The methods in Secs. II A and II B can also be implemented on human HRTFs. Figure 3 shows how the MNAM calculated from the left-ear HRTFs of a typical subject (No. 23 in the database) varies with elevation and frequency. Compared with Fig. 2, a similar tendency is observed, i.e., the MNAM in a given elevation increases with increasing frequency, and for a given frequency sampling point the MNAM decreases gradually with elevation deviating from the horizontal plane.

Calculations also indicate that the MNAM for humans is

TABLE III. Suggested azimuthal measurement number for human HRTF measurement with azimuthal resolutions in parentheses, which are determined with arrival time correction.

Elevation	Calculated mean $MNAM_{audio}$ and standard deviation with criterion 0.95	Suggested azimuthal measurement number needed to reconstruct HRTF up to 20 kHz with a confidence level of 95%	Suggested azimuthal measurement number needed to reconstruct HRTF up to 20 kHz according to conventional selection
−30°	37 (±11.3)	60 (6°)	72 (5°)
−15°	29 (±10.0)	60 (6°)	72 (5°)
0°	36 (±10.3)	60 (6°)	72 (5°)
15°	29 (±5.7)	40 (9°)	72 (5°)
30°	28 (±7.7)	45 (8°)	72 (5°)
45°	24 (±8.0)	40 (9°)	72 (5°)
60°	16 (±3.2)	24 (15°)	24 (15°)
75°	14 (±3.6)	24 (15°)	24 (15°)

always larger than that for KEMAR under the same conditions, including elevation, frequency point, and power criterion. This is because the azimuthal variation of human HRTFs is more complex than that of KEMAR, since humans have finer anatomical appearance and are liable to slight movements during measurements. In view of the relatively large error in human HRTF measurements, the criterion 0.95 is used in the following analysis of human HRTFs.

According to step (3) in Sec. II B, the mean $MNAM_{audio}$ and the standard deviations σ for 52 human subjects were calculated with criterion 0.95. The results are listed in column 4 of Table II, which shows that almost all the numbers of azimuthal measurements in column 2 are larger than the upper-limit values of the calculated mean $MNAM_{audio}$ at 95% confidence level (that is, the values of (mean+2σ)) except for a slight insufficiency at elevations 60° and 75°. Consequently, the numbers of azimuthal measurements used in our HRTF database are sufficient to reconstruct the HRTFs at unmeasured azimuths up to 20 kHz in almost all measured elevation planes.

C. MNAM for the $HRTF_{correction}$

In the horizontal plane, KEMAR HRTFs at 72 measured azimuths can be decomposed into 72H_τ and 72 time displacements according to step (1) in Sec. II C. As discussed in step (2) in Sec. II C, the spatial Fourier analysis in Sec. II A can also be applied to the azimuthal H_τ. The relative power contribution of each azimuthal harmonic of the azimuthal H_τ evaluated from Eq. (8) is shown in Fig. 1(b). Upon comparing Fig. 1(b) with Fig. 1(a), it is apparent that the arrival time correction smooths the spatial variation of the HRTF by decreasing the coefficients of high-order azimuthal harmonics. This explains why the arrival time correction improves the interpolation performance reported by Evans *et al.* (1998) and Matsumoto *et al.* (2004).

According to steps (2) and (3) in Sec. II C, the $MNAM_{audio}$ for KEMAR H_τ with criterions 0.99 and 0.95, and for corresponding time displacement, are listed in columns 6–8 of Table I, respectively. The data show that the $MNAM_{audio}$ for the H_τ is always larger than that for the time displacement in each elevation plane, except for elevations −30°, −20°, and 50° with criterion 0.95. Therefore, the $MNAM_{audio}$ for the $HRTF_{correction}$ is almost determined by the $MNAM_{audio}$ for the H_τ, as mentioned in Sec. II C. In Table I, comparison of the $MNAM_{audio}$ values for the $HRTF_{original}$ listed in columns 4 and 5 with those for the $HRTF_{correction}$ listed in columns 6 and 7 reveals that the latter are smaller. For example, in the horizontal plane, $MNAM_{audio}$ decreases from 65 for the $HRTF_{original}$ to 43 for the $HRTF_{correction}$ with criterion 0.99, and 59 for the $HRTF_{original}$ to 21 for the $HRTF_{correction}$ with criterion 0.95.

The arrival time correction is also applied to the HRTFs of 52 human subjects, and the mean $MNAM_{audio}$ (with standard deviation) is listed in column 5 of Table II. The mean $MNAM_{audio}$ for human $HRTF_{correction}$ is slightly larger than that for KEMAR due to the finer anatomical detail and larger measurement error of humans. As with KEMAR, the arrival time correction reduces the mean $MNAM_{audio}$ nearly by half. This suggests that the sampling positions needed in human HRTF measurement could be halved by using the arrival time correction.

D. Discussion

Calculations show that, for the same HRTF data of humans, the mean $MNAM_{audio}$ for the $HRTF_{correction}$ is about half of that for the $HRTF_{original}$. For the both representations, the overall HRTF including magnitude and phase can be reconstructed exactly, if the azimuthal sampling theorem of the HRTF is satisfied. The MNAM used in HRTF measurement should therefore be determined according to the results with the arrival time correction in view of experimental efficiency. For humans, the mean $MNAM_{audio}$ (up to 20 kHz) with the arrival time correction is listed in column 5 of Table II and rewritten in column 2 of Table III. To make practical measurement convenient and satisfy the sampling theorem, the suggested number of azimuthal measurements listed in column 3 of Table III is chosen as an integer that divides 360° exactly and is equal to or a little larger than the upper-limit value of the mean $MNAM_{audio}$ at 95% confidence level; the corresponding azimuthal resolution is also given. Since con-

TABLE IV. Conditions for the interpolation in the horizontal plane.

[a]Results for subject 23 are used to demonstrate the typical interpolation performance of humans. The reconstructed frequency range and the SDR_{mean} may vary slightly with subject.

ventional HRTF measurement is usually performed at intervals of multiples of 5°, an alternative suggestion is given in column 4 of Table III.

Evans *et al.* (1998) expanded measured HRTFs using surface spherical harmonics as basis functions. Because the surface spherical harmonics vary as a function of both azimuth and elevation, some limitations are imposed on sampling positions in HRTF measurements. In the work of Evans *et al.* (1998), to obtain the spherical-harmonic coefficients up to and including l-order from measured HRTFs at discrete positions exactly and with mathematical efficiency, measurements should be carried out at L $(L \geq l+1)$ specific elevations determined by the Gauss–Legendre quadrature, including some low elevations such as $-82.5°$ for which the measurement is difficult. Moreover, measurements at $2L$ equally-spaced azimuths are needed in each elevation plane measurement, which is difficult and inefficient, particularly at high elevation planes. Most HRTF databases available at present are unsuitable for the surface spherical-harmonic expansion. In contrast, for the azimuthal Fourier expansion of the HRTF, only uniform azimuthal measurements are needed at each elevation. However, only the HRTFs at unmeasured azimuths can be reconstructed by the azimuthal Fourier analysis, and other methods should be developed to reconstruct the HRTFs at unmeasured elevations.

Using the theory of sound-field pickup, Ajdler *et al.* (2005) deduced that the maximal azimuthal resolution for HRTF measurement in the horizontal plane was about 5° for the audible frequency range, or equivalently that $MNAM_{audio}$ was 72. In Tables I and II, the $MNAM_{audio}$ for KEMAR in the horizontal plane are 65 and 59 with criterions 0.99 and 0.95, respectively, and for human subjects it is 64 with criterion 0.95. It is encouraging that our result is consistent with that of Ajdler *et al.* (2005). However, the method proposed by Ajdler *et al.* (2005) is unable to solve the situation with the arrival time correction. Moreover, only the azimuthal sampling in the horizontal plane was discussed by Ajdler *et al.* (2005).

IV. INTERPOLATION PERFORMANCE AND ANALYSIS

A. Procedure

Validity of the azimuthal sampling theorem and the resulting interpolation formula Eq. (6) are evaluated using the HRTFs in the horizontal plane, where HRTF varies with azimuth most rapidly. As shown in Tables I and II, HRTFs were measured at 72 azimuthal positions with an azimuthal resolution of 5° in the horizontal plane. Those positions are divided into two subsets: a calculation subset serving as input data to the interpolation and a comparison subset that will be predicted based on interpolation. Thus, for each position in the comparison subset, HRTF obtained via interpolation will be compared to the measured HRTF.

Two kinds of division patterns are used.

(1) Pattern 1: The 36 positions from azimuth 0°–350° at an interval of 10° make up the calculation subset, and the remainder 36 positions make up the comparison subset.
(2) Pattern 2: The 24 positions from azimuth 0°–345° at an interval of 15° make up the calculation subset, and the remainder 48 positions make up the comparison subset.

The two kinds of division methods are used to simulate two kinds of the measurement numbers: 36 in pattern 1 and 24 in pattern 2.

According to the azimuthal sampling theorem, the HRTF of a frequency range can be reconstructed by interpolation when the number of azimuthal measurements is not less than the MNAM of that range. In practice, the number of azimuthal measurements is always selected as equal to or just a little larger than the MNAM of the frequency range, which is also the basic principle in selecting division patterns. The two possible cases which may arise in selecting division patterns are as follows.

(1) If the $MNAM_{audio}$ in Table IV is not larger than 36, the division pattern in which the number of azimuthal measurements (the number of positions in the calculation subset) is equal to or a little larger than the $MNAM_{audio}$ is selected. For example, in the horizontal plane, the $MNAM_{audio}$ for KEMAR $HRTF_{correction}$ is 21, and pattern 2 is used with the azimuthal measurement number of 24, whereas for subject 23, the $MNAM_{audio}$ for the $HRTF_{correction}$ is 31, and pattern 1 is used with the azimuthal measurement number of 36.
(2) Otherwise, if the $MNAM_{audio}$ in Table IV is larger than 36, then the "unknown" HRTFs up to 20 kHz in the comparison subset cannot be reconstructed by interpolation, because the azimuthal measurement number of 36 in pattern 1 is the densest uniform sampling condition that could be extracted from the 72 measured HRTFs. This is the case for KEMAR $HRTF_{original}$ shown in Table

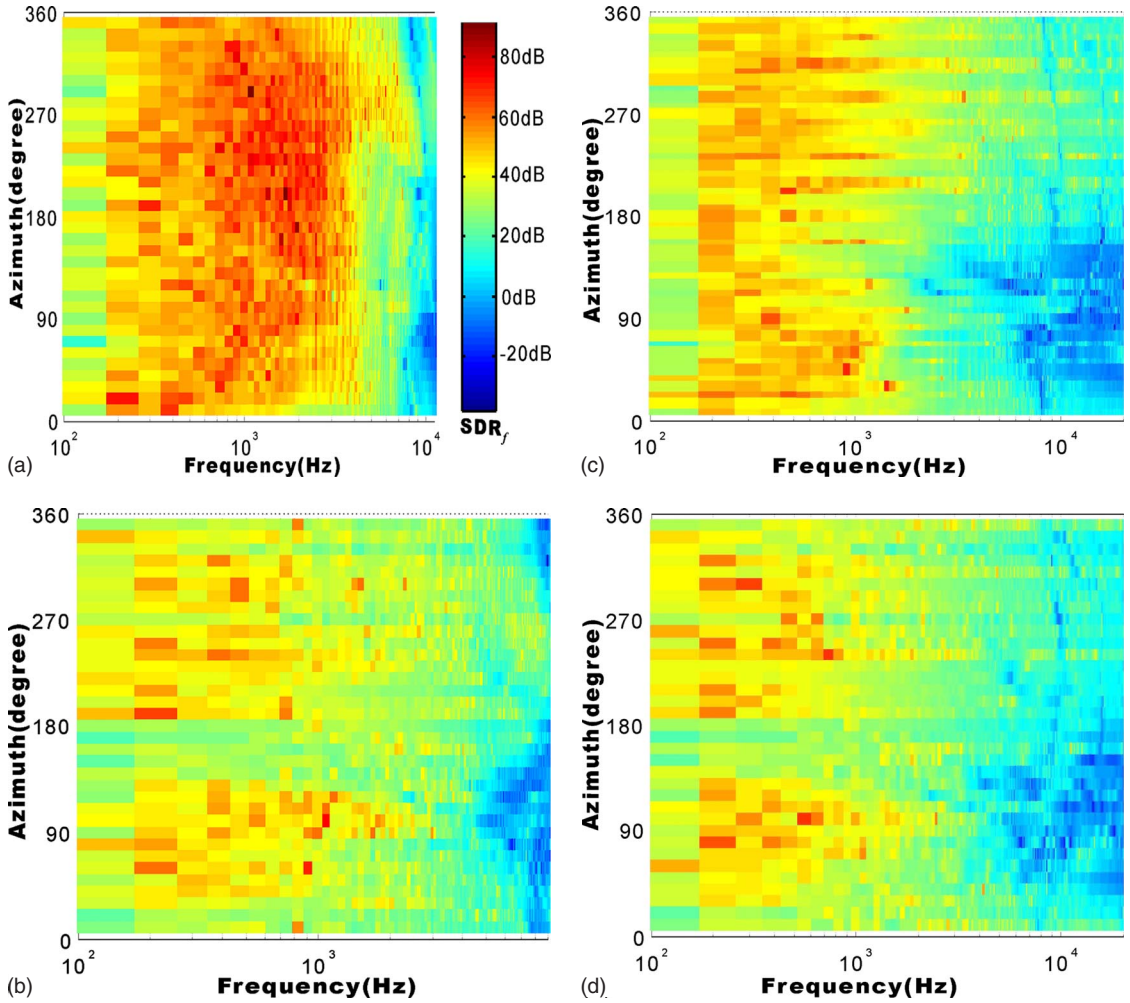

FIG. 4. (Color online) SDR_f varies with frequency and azimuthal position, where (a) is for the $HRTF_{original}$ of KEMAR with the reconstructed frequency up to 11 kHz, (b) is for the $HRTF_{original}$ of subject 23 with the reconstructed frequency up to 9 kHz, (c) is for the $HRTF_{correction}$ of KEMAR with the reconstructed frequency up to 20 kHz, and (d) is for the $HRTF_{correction}$ of subject 23 with the reconstructed frequency up to 20 kHz.

IV. From the MNAMs of KEMAR shown in Fig. 2(a), the MNAM of a frequency range up to 9 kHz is 24, whereas the MNAM of a frequency range up to 11 kHz is 36. Therefore, selecting pattern 1 with the azimuthal measurement number of 36 can yield a wider reconstructed frequency range than pattern 2 with the azimuthal measurement number of 24, according to the azimuthal sampling theorem. So pattern 1 is selected in this case with a reconstructed frequency range up to 11 kHz.

The selected pattern corresponding to each HRTF set and representation, and resulting reconstructed frequency range are shown in rows 4 and 5 of Table IV respectively.

To evaluate the azimuthal interpolation error quantitatively, the signal distortion ratio of each reconstructed frequency point is defined as SDR_f,

$$\mathrm{SDR}_f(\theta,f) = 10\log_{10}\left(\frac{|H(\theta,f)|^2}{|H(\theta,f)-\hat{H}(\theta,f)|^2}\right) \quad (\mathrm{dB}), \quad (12)$$

where $H(\theta,f)$ denotes the measured HRTF, and $\hat{H}(\theta,f)$ denotes the interpolated HRTF from Eq. (6). Since this work focuses on reconstructed HRTFs of a frequency range, SDR is defined as the average signal distortion ratio across the reconstructed frequency range,

$$\mathrm{SDR}(\theta) = 10\log_{10}\left(\frac{\sum_f |H(\theta,f)|^2}{\sum_f |H(\theta,f)-\hat{H}(\theta,f)|^2}\right) \quad (\mathrm{dB}). \quad (13)$$

B. Results

The SDR_f of KEMAR and subject 23 for both $HRTF_{original}$ and $HRTF_{correction}$ are illustrated in Figs. 4(a)–4(d). The general trend is that the SDR_f of each frequency point decreases with increasing frequency; that is, the interpolation error increases with increasing frequency. This result is consistent with other studies. (Minnaar *et al.*, 2005).

The broadband SDRs for the $HRTF_{original}$ of KEMAR and subject 23 are illustrated in Fig. 5(a) as a function of azimuth. In the figure, a common tendency is that the SDR is relatively low at azimuths 0°–180° contralateral to the left ear (the studied ear) and high at azimuths 180°–360° ipsilateral to the left ear. This phenomenon is due mainly to the head shadow effect, which deteriorates the signal-to-noise

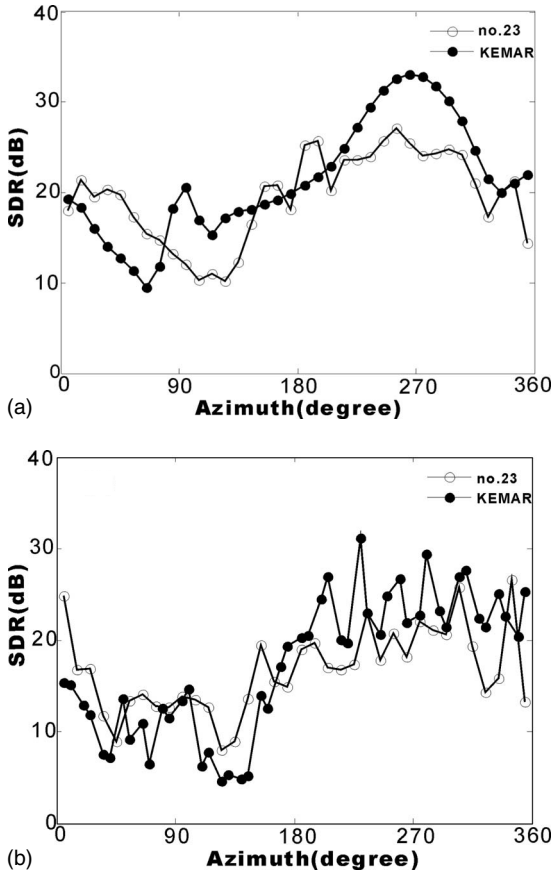

FIG. 5. SDR varies as a function of azimuth in the horizontal plane, with (a) for the $HRTF_{original}$ and (b) for the $HRTF_{correction}$. The filled circles represent the calculation points for KEMAR, and the bare circles represent the calculation points for subject 23.

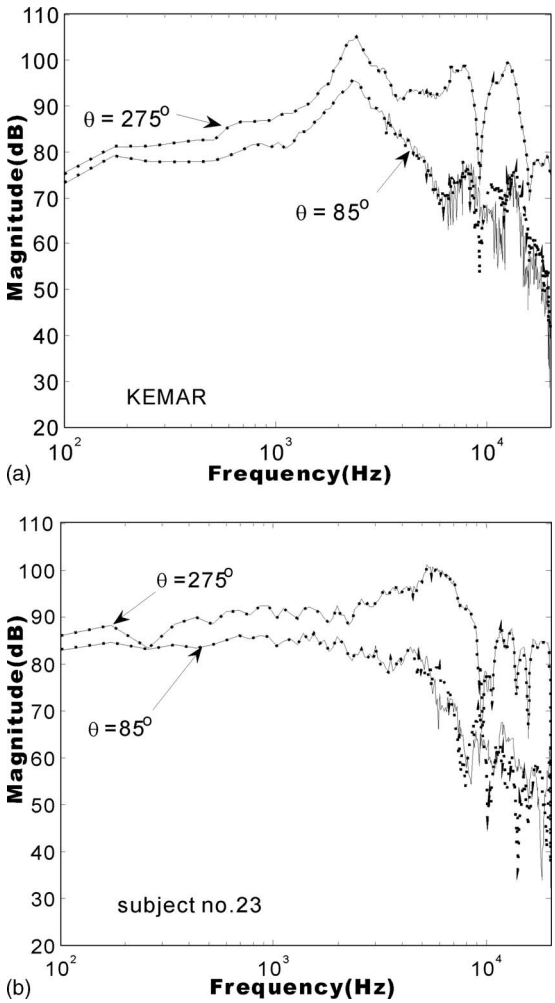

FIG. 6. Comparisons between the measured and interpolated HRTFs under the arrival time correction representation. Solid lines represent the magnitudes of the measured HRTFs and the dashed lines represent the magnitudes of the interpolated HRTFs.

ratio of the contralateral HRTFs. Moreover, the great detail in the contralateral HRTFs, caused by the interference of multi-path waves scattering across the head, would also add to the difficulty of reconstruction. Figure 5(b) is the SDR varying with azimuth in the horizontal plane for the $HRTF_{correction}$ of KEMAR and subject 23. As with the $HRTF_{original}$, the SDR for positions ipsilateral to the left ear is always larger than positions contralateral to the left ear.

The SDR_{mean} (averaging SDRs on azimuth) are shown in row 6 of Table IV. The SDR_{mean} for KEMAR $HRTF_{original}$ is 21.4 dB, and for subject 23 is 19.6 dB. The SDR_{mean}, however, decreases slightly by 3–4 dB with the arrival time correction. This reduction in SDR_{mean} is due to the fact that the interpolation result with the arrival time correction may suffer from the summation of the errors introduced in the process of interpolating the H_τ and the time displacement separately.

To demonstrate the interpolation performance more directly, the similarity between interpolated and measured $HRTF_{correction}$ in magnitude at two typical azimuths (275° and 85° in the horizontal plane) is shown in Fig. 6. In these figures, both for KEMAR and human subject 23, the interpolation performance at azimuth 275° is better than at azimuth 85°, which is consistent with the calculated SDRs in Fig. 5(b) and SDR_f in Figs. 4(c) and 4(d).

V. PSYCHOACOUSTIC EXPERIMENT

A. Method

The aim of this psychoacoustic experiment is to evaluate the validity of the azimuthal sampling theorem and the resulting interpolation formula through a series of auditory discrimination measurements. The task of the listener is to discriminate whether there are some differences between the stimuli filtered by the measured HRTF and that filtered by the interpolated HRTF for any reason perceived. Since the variation in the HRTF with azimuth is most complicated in the horizontal plane, six azimuths in the horizontal plane, i.e., 25°, 55°, 85°, 115°, 145°, and 175°, were chosen as intended positions in the experiment. As shown in row 4 of Table IV, pattern 1, with an azimuthal measurement number of 36, should be used in the interpolation of human HRTFs according to the azimuthal sampling theorem. The azimuthal measurement numbers of 24 and 18 were also used in this experiment with the same conditions, to demonstrate the interpolation performance when the sampling theorem is not satisfied.

Individualized HRTF (HRIR) data for each listener were used in the experiment. For each listener, the HRTFs may be

slightly left-right asymmetric (Zhong and Xie, 2007). Therefore, the interpolated HRTFs of the left and right ear were derived from the measured HRTFs of the left and right ears, respectively. First, a 5 s white noise, used as original mono stimulus, was convolved with the measured or interpolated HRTFs of the two ears, respectively, and then passed through a pair of low-pass filters whose band width was equal to the reconstructed frequency range. Finally, the resulting binaural signals were reproduced through a pair of Sennheiser HD 250 II headphone. Individualized headphone equalization was performed before rending the binaural stimuli to the headphone (Møller *et al.*, 1996).

The experiment was divided into two stages. The first stage was to evaluate the interpolation performance using 36, 24, and 18 azimuthal measurement numbers, respectively, under the original representation. The second stage was identical but under the arrival time correction representation. A three-interval, two-alternative forced-choice testing method was used in the experiment. In each condition [including the intended position, HRTF representation ($HRTF_{original}$ and $HRTF_{correction}$), azimuthal measurement number, and specific listener], there was a stimulus presentation consisting of three segments, with a 1 s interval between neighboring segments. The length of each segment was 5 s, with 1 s fading in at the beginning and 1 s fading out at the end. The first segment was the reference signal "A" filtered with the measured HRTF, and the second and third segments were either reference signal "A" or object signal "B" filtered with the interpolated HRTF with a random order. There were therefore two kinds of stimulus presentations, AAB and ABA. The listeners were asked to judge which segment of the second and the third was different from the first segment. Six listeners from the database with normal hearing participated in the experiment. Each listener heard 216 stimulus presentations in total, 3 kinds of azimuthal measurement number $\times 2$ representations of interpolated HRTF $\times 6$ intended positions $\times 6$ experiments. In a specific condition, there were 36 judgments for an intended position, 6 listeners $\times 6$ experiments.

B. Results

The proportions correct for six intended positions in the horizontal plane are shown in Fig. 7(a) for the $HRTF_{original}$ and Fig. 7(b) for the $HRTF_{correction}$. The 95% confidence limits for chance performance that were calculated from a binomial model are plotted as the two horizontal lines in the figures. For a significance level 0.05, the region bounded by the two solid lines on the graphs corresponds to a chance performance. That is, if the proportion correct is between 0.34 and 0.66, there is no audible difference between the measured and interpolated HRTFs. We note from Fig. 7(a) that the proportion correct of each position increases with the azimuthal measurement number decreasing from 36, 24 to 18 in turn. It is clear that, for all the positions, the proportions correct for the azimuthal measurement numbers of 18 and 24 exceed the upper confidence bound for chance performance except at azimuth 175°, whereas the proportions correct for the azimuthal measurement number of 36 are between the upper and the lower confidence bound for chance performance. In this experiment, since the reconstructed frequency range is determined by the azimuthal measurement number of 36, the azimuthal measurement numbers of 24 and 18 are insufficient to obtain the interpolated HRTFs exactly according to the azimuthal sampling theorem of the HRTF. As a result, only the azimuthal measurement number of 36 can ensure the interpolation performance in audibility for all positions. Similar results are found in Fig. 7(b) for the time arrival correction representation. Consistency between the theory and experimental result validates the azimuthal sampling theorem and the resulting interpolation formula.

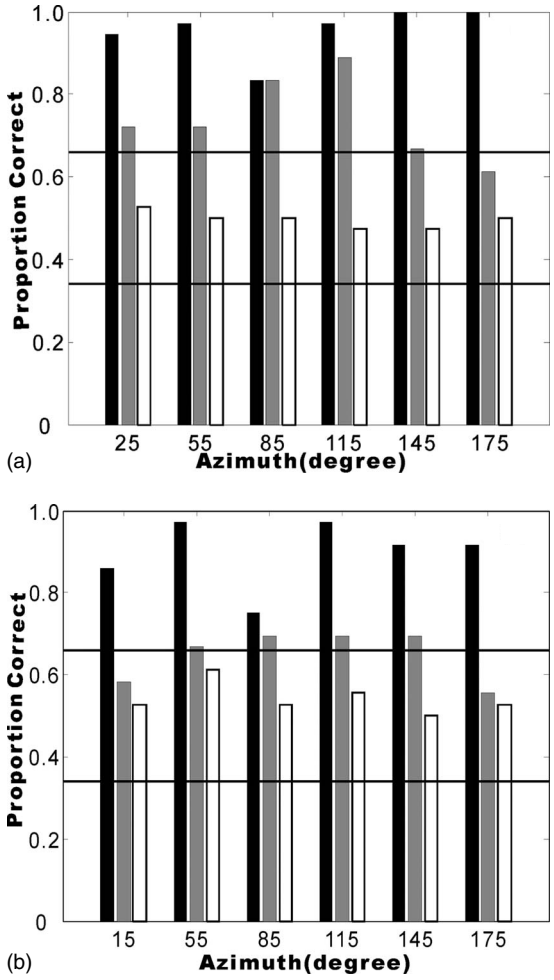

FIG. 7. Bars of proportion correct of judgments for six intended positions in the horizontal plane, with (a) for the $HRTF_{original}$ and (b) for the $HRTF_{correction}$. At each azimuth, the dark bar represents the proportion correct with an azimuthal measurement number of 18, the gray bar represents the proportion correct with an azimuthal measurement number of 24, and the bare bar represents the proportion correct with an azimuthal measurement number of 36. The upper and lower confidence bounds for chance performance are also shown as two horizontal lines.

VI. CONCLUSIONS

Azimuthal Fourier analysis of the HRTF in each elevation plane has been proposed, and an azimuthal sampling theorem for the HRTF and a corresponding interpolation formula deduced. Results show that the azimuthal variation of the HRTF is captured by the azimuthal harmonic coefficients of the HRTF, and if the harmonic expansion of the HRTF is

truncated at order Q according to a certain power criterion, then MNAM for the HRTF is $(2Q+1)$, or equivalently the maximal azimuthal resolution is $360°/(2Q+1)$. If the number of uniform azimuthal measurements in an elevation plane is not less than the MNAM, then the HRTFs at unmeasured azimuths can be reconstructed from measured HRTFs using the interpolation formula proposed above. The azimuthal sampling theorem for the HRTF and the interpolation formula reveal the relations among the spatial variation feature of the HRTF, the number of azimuthal measurements (or the azimuthal resolution), and the interpolation performance, both physically and mathematically.

HRTFs from KEMAR and 52 human subjects under the original and the arrival time correction representation were analyzed. Results show that at a given elevation the MNAM increases with increasing frequency, and at a given sampling point of frequency the MNAM decreases gradually as the elevation plane deviating from the horizontal plane. Moreover, the MNAM for humans is always larger than for KEMAR.

Arrival time correction to HRTF can dramatically reduce $\mathrm{MNAM}_{\mathrm{audio}}$ (the MNAM of the audible frequency range) without introducing obvious mathematical error in reconstruction. As a result, the statistical results of $\mathrm{MNAM}_{\mathrm{audio}}$ with the arrival time correction in HRTFs are proposed as a reference to determine the azimuthal measurement number of HRTF measurement in scientific research.

A psychoacoustic experiment was carried out to evaluate the interpolation performance with and without the arrival time correction in HRTFs. The results show that the interpolation is effective without introducing audible error.

The present results are useful to determine the MNAM needed in arbitrary elevation plane at arbitrary frequency. Only the azimuthal measurement of the HRTF has been investigated, and further work should be carried out on the elevation measurements of the HRTF.

Specificity of binaural perceptual learning for amplitude modulated tones: A comparison of two training methods

(Received 25 April 2008; revised 4 November 2008; accepted 23 January 2009)

The specificity of auditory perceptual learning has been taken as an indicator of the likely locus within the brain at which underlying neuronal changes occur. This study examined interaural level difference (ILD) discrimination learning with sinusoidally amplitude modulated (SAM) tones and whether training-induced threshold improvements generalize from one side of auditory space to the other and to an untrained carrier frequency. A novel, dual-staircase adaptive method was adopted that was designed to prevent participants from identifying the nature of the adaptive track. ILD thresholds obtained with this method were compared with a constant-stimulus technique using otherwise identical stimuli. Adaptive thresholds derived from psychometric functions were found to be biased compared to those obtained from reversals. Although adaptive and constant-stimulus procedures appeared to yield different temporal patterns of learning, no global differences were found between them in terms of training outcomes. These data show that ILD discrimination learning with SAM tones does generalize to an untrained carrier frequency but does not generalize across the midline. This implies that the neural substrate for binaural plasticity is found at a relatively high level of the auditory pathway where information is combined across frequency and where each side of auditory space is represented separately.

I. INTRODUCTION

The finding that sound localization performance can improve after perceptual training (for a review, see Wright and Zhang, 2006) is highly relevant for hearing impaired populations, for whom binaural cue values may have been altered as a result of either auditory deprivation or stimulation (Boothroyd, 1993; Philibert *et al.*, 2005; Silman *et al.*, 1984). An understanding of the potential extent and generality of perceptual learning is essential for developing optimal assessment and training strategies for these populations and others, including children with linguistic deficits (Constantinides *et al.*, 2003; Kujala *et al.*, 2001; McArthur and Bishop, 2001). To this end, two aspects of perceptual learning—the time-course over which it occurs and the potential for learning to transfer to other stimuli or tasks—are of crucial importance in determining the clinical utility of auditory plasticity.

The degree of transfer of perceptual learning to untrained tasks and stimuli can also provide valuable insights into the possible locus within the brain at which changes in neural circuitry take place and therefore guide subsequent physiological studies. For example, it has frequently been reported that training adult humans to perform visual discrimination tasks leads to improvements that are specific to the location on the visual receptor surface and for the orientation of the trained stimulus (reviewed by Gilbert *et al.*, 2001). This suggests the involvement of early stages in cortical visual processing, where neurons are orientation selective and have small receptive fields that are arranged in a precise, topographic order.

Some of the most dramatic demonstrations of the adaptive capabilities of the adult auditory system have come from studies in which auditory localization cues have been altered (Hofman *et al.*, 1998; Kacelnik *et al.*, 2006; Van Wanrooij and Van Opstal, 2005). However, training can also alter the discrimination of interaural level differences (ILDs) and interaural time differences (ITDs) by normal hearing listeners (Rowan and Lutman, 2007; Spierer *et al.*, 2007; Wright and Fitzgerald, 2001; Zhang and Wright, 2007). Wright and Fitzgerald (2001) found that training-induced improvements in ILD discrimination with pure tones generalized to an untrained standard stimulus location (ILD value), but only at the trained frequency, suggesting that the neural processing of localization cues was altered within frequency-specific channels. On the other hand, generalization across different types of stimuli was reported by Rowan and Lutman (2007), who found that ITD discrimination training with either pure tones or higher-frequency transposed tones led to reduced thresholds for both stimuli and for sinusoidally amplitude modulated (SAM) tones with the same modulation rate and carrier frequency as the transposed tones. This suggests that generalization of ILD learning to other stimulus frequencies might also be found if more complex stimuli, such as SAM tones, are used for training. We examined this question in the

[a]Author to whom correspondence should be addressed. Electronic mail: andrew.king@dpag.ox.ac.uk

present study, as well as the extent to which perceptual learning in a binaural discrimination task is specific for spatial location.

There is a growing body of evidence that intensive training can facilitate improvements in perceptual abilities in humans and animals with central auditory processing or peripheral deficits (Kacelnik *et al.*, 2006; Merzenich *et al.*, 1996; Tallal *et al.*, 1996; Zhou and Merzenich, 2008). Various psychophysical methods have been adopted for the study of perceptual learning. In order to maximize the benefits of training in clinical populations, it is important to compare the degree of learning provided by different methods. This issue seems to have been neglected with respect to transfer of auditory perceptual learning. Since the seminal paper of Levitt (1971), adaptive staircase methods (such as the transformed up-down procedure) have become increasingly widespread in the literature (reviewed by Leek, 2001). Compared with constant-stimulus methods, where the range of stimulus values covered by the underlying psychometric function must be chosen and fixed beforehand, staircase methods require fewer restrictive assumptions and target stimulus values efficiently around a specific threshold on the function based on the listener's previous performance.

The relative flexibility and efficiency of adaptive methods are offset by a number of disadvantages, not least the fact that attentive listeners may become aware of the algorithm being used and try to "second-guess" the strategy, which can lead to distraction from the task at hand, possibly affecting the observed threshold. One remedy that has been suggested to address this particular issue is to use one or more simultaneous staircases, each of which governs the stimulus selection in turn from one trial to the next (e.g., Rammsayer, 1992). Another disadvantage is that adaptive tracking techniques tend to focus rapidly on a predetermined threshold value, which can limit their ability to provide accurate information regarding the slope and shape of the underlying psychometric function. A related problem is the fact that adaptive procedures may not allow an observer sufficient exposure to the range of binaural cue values required for learning to occur (Trahiotis *et al.*, 1990), which could influence the observed time-course of learning or the degree of generalization seen. Finally, several simulation studies have shown that psychometric functions obtained from adaptive data can exhibit an inherent bias that causes the slope to be steeper than that of the underlying psychometric function, again potentially affecting threshold estimates (e.g., Leek *et al.*, 1992; O'Regan and Humbert, 1989; Schlauch and Rose, 1990). This bias appears to be a result of the serial dependency of trials in an adaptive sequence (Kaernbach, 2001) and is exacerbated by other factors, such as the type of staircase, the choice of step size and the number of trials performed (Dai, 1995; Saberi and Green, 1996; Leek *et al.*, 1992). However, obtaining a psychophysical measure of the absolute bias seen in adaptive methods is difficult, unless a full psychometric function is obtained simultaneously. Some studies have reported a "relative" bias between different adaptive methods (e.g., Rowan *et al.*, 2006), whereas others have found that thresholds obtained from adaptive psychometric functions are similar to those obtained from reversals (Amitay *et al.*, 2006) and to those obtained using a constant-stimulus technique (Dai, 1995).

In this study, we compare the relative impact of using a constant-stimulus versus an adaptive training strategy on the learning time-course and generalization pattern seen after ILD discrimination training with SAM tones. We also used these experiments to extend recent findings on the specificity of perceptual learning by examining whether or not training with stimuli containing binaural cues that favor one side of auditory space can enhance performance for stimuli either with a different carrier frequency or presented on the opposite side.

II. METHOD

A. Subjects

A total of 22 listeners took part in the first experiment, in which we compared adaptive and constant-stimulus algorithms for measuring ILD discrimination thresholds, and 31 in the second experiment, which examined the specificity of ILD learning. Seven listeners took part in both experiments, having completed the learning experiment first. All subjects were assessed before testing to ensure normal bilateral audiometric thresholds (i.e., within 20 dB of normal, from 125 Hz to 8 kHz). Ages were in the range 19–42, with a mean age of 24.5 years. All subjects were right-handed. Subjects were recruited through departmental emails and public notices, and received payment for their contribution. All subjects provided informed consent before participation in the study. Ethical approval was provided by the Central University Research Ethics Committee of the University of Oxford.

B. Apparatus

The software package MATLAB (Mathworks, Inc., r.14) was used for stimulus generation, response collection and data organization. Further analyses were conducted in S-PLUS (Insightful Corp, r. 6.2). Stimuli were passed to a Tucker-Davis Technologies (Alachua, FL) RM1 mobile processor for D/A conversion and presented to subjects over headphones (Sony MDR-V500, Tokyo, Japan). Subjects responded by clicking a mouse on one of two response alternatives presented on a flat-screen monitor, which was also used to cue each response period and to provide trial-by-trial feedback. All testing took place in a double-walled sound-attenuating chamber.

C. Stimuli

Prior to testing, head-related transfer functions for 4 and 0.5 kHz pure tones were measured from one of the authors using a similar procedure to that reported previously in the literature (Wightman and Kistler, 1989). From these measurements we estimated the ILD/ITD values associated with 4 and 0.5 kHz tones presented at approximately 5° (for all familiarization runs conducted before testing) and 30° (for the experiment proper) from the midline, and these values

TABLE I. Offset binaural cue values used (± indicates lateralization favoring right or left hemifield).

4 kHz	ILD offset	ITD offset
5°	±1.90 dB	±0.06 ms
30°	±11.42 dB	±0.34 ms
0.5 kHz	ILD offset	ITD offset
5°	±0.70 dB	±0.06 ms
30°	±4.23 dB	±0.36 ms

were used to offset the overall perceived position of stimulus presentation. These offset ITD and ILD values are presented in Table I.

On each trial, two sequential SAM tones, with a carrier frequency of 4 or 0.5 kHz, modulation depth of 100%, and a modulation rate of 80 Hz, were presented binaurally. These stimuli were presented with offset ITDs and ILDs appropriate for sound source directions at either 5° or 30° from the midline. However, while the ITD was held constant throughout the presentation of the stimulus pair, the ILD was varied by a small increment, ΔILD, between the two stimuli. Positive increments (larger ILD on the second stimulus presentation of the pair) gave the percept of the sound source shifting away from the midline, whereas negative increments produced a perceived shift toward the midline. The size of the increment was varied throughout the experiments, either adaptively using the staircase methods described below or chosen randomly from a constant-stimulus set, to determine the subjects' sensitivity to small ΔILDs. We wished to avoid the use of one fixed standard ILD as one of the stimuli in each trial, as this has been viewed as a potential source of the discrimination learning described in other studies (Karmarkar and Buonomano, 2003). The ILD of the first interval stimulus was therefore the offset value plus half the ΔILD and that of the second interval stimulus the offset value minus half the ΔILD, or vice versa, depending on the intended, pseudorandomly determined direction of the ILD shift. Thus, the ΔILDs presented to the subject straddled the offset ILD value appropriate for a sound source located at either approximately 5° or 30° from the midline.

Stimuli were generated digitally, with a sample rate of 48 kHz. Stimulus duration was 400 ms, with an interstimulus interval of 500 ms. The SAM tones were ramped on and off in phase with the stimulus envelope, giving rise/fall times of 6 ms. Stimulus intensity was calibrated such that the maximum sound level (offset ILD+0.5×ΔILD) to be presented to either ear would be 74 dB sound pressure level, and overall presentation level was pseudorandomized at attenuations of 0, −5, and −10 dB to prevent the subjects from using monaural level cues, rather than binaural level difference cues.

D. Procedure

Early pilot work using a single-staircase paradigm highlighted the issue of subjects becoming aware of the adaptive algorithm (Fig. 1), a problem that has been described in some other studies (e.g., Rammsayer, 1992). It appeared that,

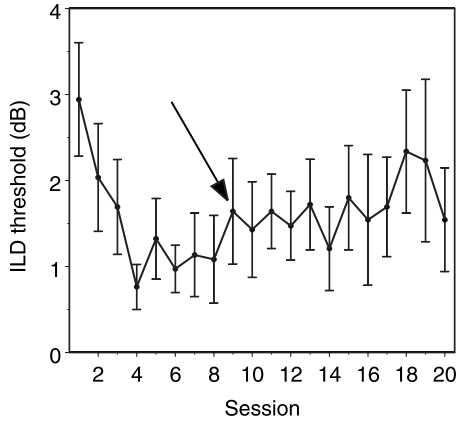

FIG. 1. Example of the confounding nature of awareness of the track in an adaptive staircase method for determining the effects of training on ILD discrimination thresholds. The learning curve represents data from one subject on a single-staircase 3D1U training paradigm. The arrow highlights the first session after the subject became aware of the adaptive algorithm. Errorbars represent one standard error of the reversal points in each session.

even though subjects were capable of performing the task, once they had discovered the algorithm they found it distracting. At times this led to elevated thresholds, because the subjects diverted their attention to trying to second-guess the algorithm, rather than focusing solely on the physical attributes of the stimulus. In the case of the subject represented in Fig. 1, the single-staircase adaptive tracks regularly reversed around stimulus values that were well above the true threshold, based on the performance achieved before the presentation strategy was detected. We therefore devised a similar algorithm that used two staircases running alternately on each consecutive trial. For trial n, stimulus placement was dependent not on the adaptive track pertaining to $n-1$ trials but to $n-2$ trials (see Fig. 2). This allowed for consecutive trials in which the ΔILD value presented was regularly different from one trial to the next and was not dependent on performance on the previous trial, thus reducing the effects of listener expectancy. Each staircase followed a 3-down, 1-up algorithm, with three correct answers leading to a decrease in absolute ΔILD value between the two stimuli and

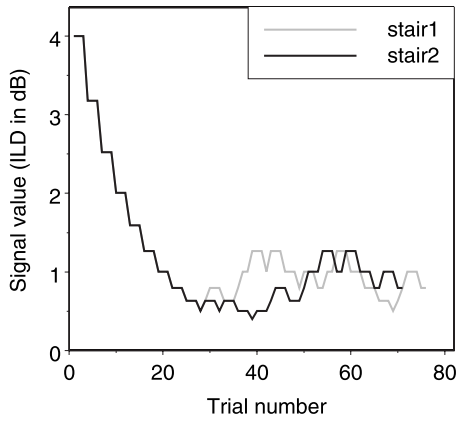

FIG. 2. Example of a dual-staircase run. The first staircase (stair 1) is denoted with a gray line, and the second with a black line (stair 2). In this example, the staircases diverge after around 30 trials.

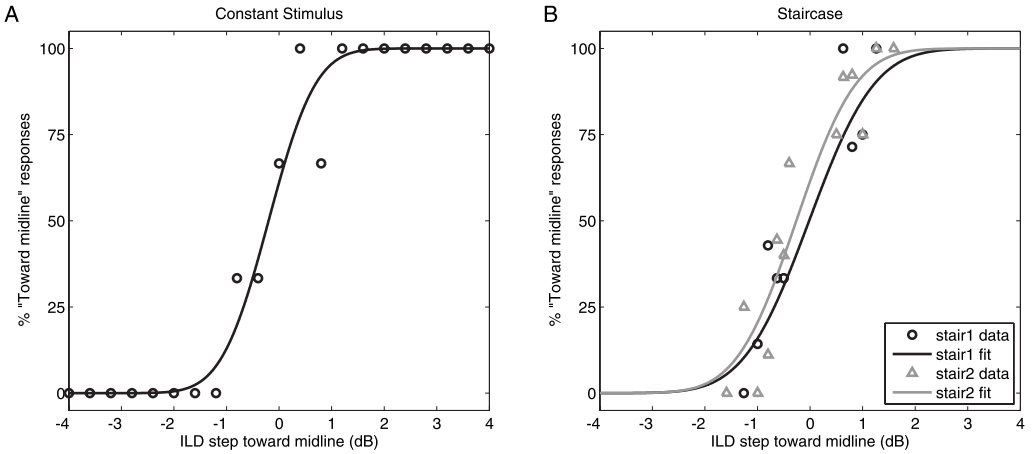

FIG. 3. Examples of psychometric functions fitted using probit analysis for the constant-stimulus method (A) and the dual-staircase method (B). In (B), the black line and circles represent the first staircase, and the gray line and triangles represent the second staircase.

one incorrect answer leading to an increase. For each staircase, this method targeted the 79.4% correct point on the psychometric function (Levitt, 1971).

Pilot data had indicated the presence of serious ceiling effects in untrained subjects (probably caused by the difficulty in performing an ILD discrimination task away from the midline, especially for SAM tones with a 0.5 kHz carrier), and adaptive tracks that frequently reached a ΔILD of 0 dB in highly trained subjects, thus preventing us from obtaining an accurate threshold. We therefore changed the step size logarithmically using a factor of 0.2057 (Saberi, 1995). This procedure results in psychometric functions that are parallel, so that thresholds depend on the performance of the subjects within the range of ILDs tested rather than on the underlying slope of the function. This also prevented the stimulus level from ever reaching zero, reducing the impact of floor effects on the estimated threshold. Logarithmic step sizes were considered to be unnecessary for the constant-stimulus technique, as the selection of stimulus values was predetermined, so that all subjects were exposed to the full range of stimulus values used to plot the psychometric function.

The starting ΔILD for the first run was 4 dB and the starting value for the next run was set two log-steps above the geometric mean of the reversal-derived thresholds from each staircase. A maximum ceiling ΔILD of 10.05 dB was applied, equivalent to four log-steps above the starting ΔILD. Subjects completed 13 reversals per staircase, after which the run was terminated. The constant-stimulus method presented randomized ΔILD values that ranged from 0 to 4 dB in 0.4 dB steps.

The listener's task was identical across experimental stages, groups, and stimulus algorithms. Two SAM tones were presented sequentially on each trial, as described above, differing only by a ΔILD that was determined by the experimental algorithm. In every condition, binaural cue values were displaced from the midline as described above by the introduction of the base ILD and ITD values, upon which the stimulus ILD values were superimposed. Subjects were required to indicate which of the two stimuli had been furthest from the midline.

For experiment 1, both constant-stimulus and adaptive thresholds were extracted by fitting psychometric functions to the data obtained in each run. For constant-stimulus thresholds, trials in which presentation of the most peripheral or lateral stimulus occurred in the first interval were denoted by positive ILD values and those in which it occurred in the second interval by negative values. Psychometric functions were then fitted to the data using probit analysis [Finney, 1971; see Fig. 3(A)]. Because we modeled the data based on the distribution of responses for which the more peripheral stimulus was perceived to have been presented first (i.e., "stimulus shifted toward midline" between the first and second intervals), threshold values equivalent to that yielded by the 3-down, 1-up adaptive method (79.4%) were obtained by taking the mean of the stimulus values yielding 79.4% and 20.6% correct on the fitted function.

For the adaptive method, psychometric functions were fitted to the data from both adaptive tracks in each run [see Fig. 3(B)], and then ILD threshold for each was determined as above. The threshold for a given run was defined as the arithmetic mean of these two values. We also extracted reversal-derived thresholds by taking the geometric mean of the final ten reversals in each staircase and by averaging the values obtained from the two interleaved staircases.

For experiment 2, thresholds were extracted as described above, but for the constant-stimulus data we used all of the data from a given session (six runs) to calculate the daily thresholds. Adaptive thresholds for a given session were defined as the mean of the thresholds obtained from all of the runs performed by the listener during that session.

E. Experimental organization and design

1. Threshold bias in the psychometric function

This experiment was intended to shed light upon the relative integrity of the data obtained from the dual-staircase and constant-stimulus methods, and to provide an indication of the effects of any slope or inherent methodological bias upon measured adaptive thresholds. Subjects performed one run with each method, with base binaural cue values that were offset to 5° left or right of the midline. Half the subjects

performed the constant-stimulus run followed by the adaptive run and vice versa. Because the number of trials in an adaptive run is known to contribute to the bias in the slope of the psychometric function (Kaernbach, 2001; Leek *et al.*, 1992), the number of trials in each constant-stimulus run was made roughly equivalent to the mean number of trials in the adaptive runs, for which the number of trials was variable. This ensured that any bias in thresholds obtained from psychometric functions that was due to differences between the methods could be more accurately assessed, and also ensured that each run lasted a similar length of time. Each constant-stimulus run contained 121 trials, with 11 presentations at each stimulus value. The mean number of trials in each adaptive run was 131.7.

2. Perceptual learning

Listeners were randomly assigned to either the constant-stimulus or dual-staircase algorithm, and also randomly assigned to be either a training subject or a control subject within that algorithm. The experiment was conducted in four phases. All subjects took part in a familiarization phase 2–3 days before the pre-test, designed to acquaint them with the task requirements and the stimuli as far as possible, without inducing binaural learning. To this end, listeners completed eight runs, each comprising 120 ILD discrimination trials in a session lasting 2–3 h, with base binaural cue values that were offset to 5° and a constant ΔILD of 4 dB. This allowed for learning of the task requirements with an easy cue value and at a relatively central position in auditory space, where binaural cue resolution should be well developed (Mills, 1960; Yost, 1974; Yost and Dye, 1988). Runs centered on ILD values corresponding to either 5° left or right of the midline were interleaved throughout this familiarization session, allowing subjects to become accustomed to switching sides during a session in preparation for the pre-test. Subjects were required to score 90% in at least two familiarization runs on each side before progressing to the pre-test.

During the pre-test phase (3–3.5 h), baseline ILD discrimination thresholds were obtained from each participant for each of three conditions: (1) 4 kHz SAM offset 30° to the left, (2) 4 kHz SAM offset 30° to the right, (3) 0.5 kHz SAM offset 30° to the left. Conditions were always run in that order to ensure that order effects were similar across subjects and groups. Before each condition was run, a short (30-trial) practice run was administered, with a 5° offset and ΔILD values of 4 dB.

After the pre-test, training subjects underwent 8 days of ILD discrimination training on condition 1 (4 kHz, 30° left). Training took place over the course of 9–10 days, and lasted for approximately 1 h/day. Control subjects did not participate in the training phase. The post-test phase was identical to the pre-test, and was completed by all subjects 11–14 days after the pre-test.

For the constant-stimulus method, 66 trials were completed in each run, with six presentations at each stimulus level. Six runs were completed in each session at all times. For the dual-staircase method, two runs of 13 reversals per staircase were completed per condition during the pre-test and post-test; during training, four runs were completed per session.

F. Analysis

Any fitted psychometric functions that were over-dispersed were excluded from the analysis (in the case of the bias experiment, this meant that a subject's entire dataset would need to be excluded). Over-dispersion is observed if the variance in a dataset is significantly higher than the variance assumed in the probit model. It can arise when the performance of the subject drifts considerably throughout the course of the run, e.g., as a result of wandering attention or fatigue. We therefore considered over-dispersion as diagnostic of potentially unreliable data, and excluded from further analysis runs for which the value of the deviance for the fitted function was greater than twice the number of degrees of freedom for error. If one of the pair of psychometric functions in an adaptive run was over-dispersed, then that entire run was rejected. Under these criteria, 4 subjects were dropped from the analysis for the bias experiment, leaving 18 subjects to be used in the analysis. Of the remaining data, the degrees of freedom for error for each constant-stimulus function was always 19 and the mean deviance was 20.37 (s.d. 6.74). The mean degrees of freedom for error for the adaptive functions was 11.33 (s.d. 4.17), and the mean deviance was 10.5 (s.d. 4.68).

In the learning experiment, we adopted one further exclusion criterion: a subject's innate inability to perform the task. Subjects whose average pre-test ILD thresholds were greater than two standard deviations above the mean threshold obtained by all (trained and control) listeners within a method were excluded from all analyses. On this basis, two subjects were excluded from the training experiment, leaving 29 subjects for the analysis. Because in the learning experiment the data from all six runs within a session were used to calculate our constant-stimulus thresholds, the data were well-described by the fitted psychometric functions, and exhibited no over-dispersion. The number of degrees of freedom for error was again always 19, and the mean deviance was 20.36 (s.d. 7.21), a value that is extremely close to that obtained in the bias experiment and is therefore indicative of good agreement between the two experiments in terms of goodness-of-fit. The mean standard error of threshold estimate per psychometric function was 0.14 dB in condition 1 (on average, 10.5% of threshold obtained for a given run), 0.33 dB in condition 2 (on average, 10.7% of threshold obtained), and 0.61 dB in condition 3 (on average, 16.5% of threshold obtained). For the adaptive method the total proportion of rejected functions was 9.74%. For the remaining functions the mean degrees of freedom was 10.22 (s.d. 2.9) and the mean deviance was 10.69 (s.d. 4.37). The mean standard error of threshold estimate per psychometric function was 0.38 dB in condition 1 (on average, 25.2% of threshold obtained for a given run), 0.59 dB in condition 2 (on average, 29.4% of threshold obtained), and 0.68 dB in condition 3 (on average, 26.6% of threshold obtained).

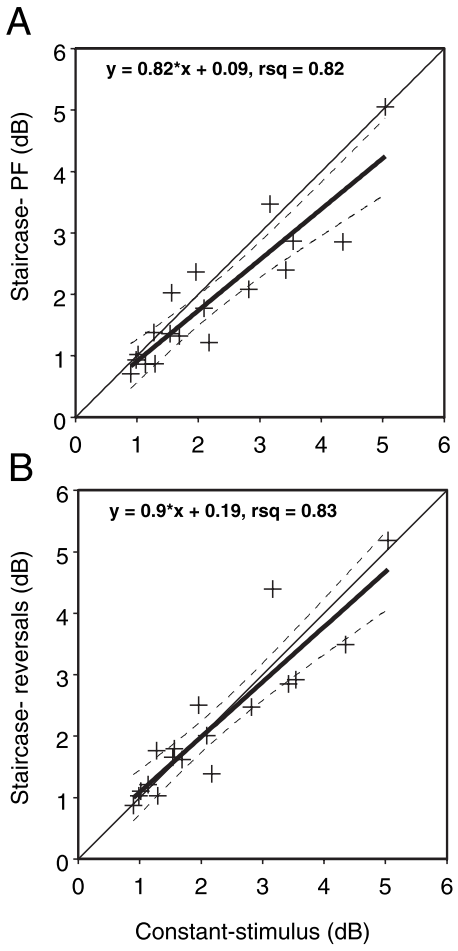

FIG. 4. Bias in the adaptive thresholds derived from psychometric functions (A) and reversals (B) as a function of corresponding constant-stimulus score. The fits are for the non-constrained linear regression models. The crosses indicate thresholds measured for a single subject. Dashed lines indicate 95% confidence intervals for the linear regression fits. In (A), the confidence intervals intersect and are mostly below the unity line, indicating that adaptive thresholds calculated from psychometric functions were generally biased low compared with corresponding constant-stimulus thresholds obtained from the same subjects. In (B), the unity line is completely encompassed by the confidence intervals, indicating that adaptive thresholds were relatively unbiased when calculated from reversals.

The extracted data were then subjected to statistical testing that was appropriate to the analysis in question.

III. RESULTS

A. Assessing the adaptive method

1. Threshold bias in the psychometric function

To assess the amount of bias in the adaptive thresholds, we computed the linear regression of constant-stimulus thresholds against thresholds obtained with the adaptive method (estimated either using reversals or probit fits, as described above). Figure 4 compares the thresholds obtained using the two estimation techniques with the corresponding constant-stimulus thresholds. Adaptive thresholds derived by fitting psychometric functions [Fig. 4(A)] tended to be slightly lower than those obtained from reversals [Fig. 4(B)]. However, for both estimation techniques, regression analysis showed that the intercepts were not significantly different from zero. We therefore constrained the regression intercept term for each to be 0. This yielded r^2 values of 0.96 for each estimation technique, indicating that the relationship between the scores obtained in the constant-stimulus runs and those calculated using either estimation technique from the adaptive data was highly consistent. We then tested the slopes of each of these functions to see if they were significantly different from 1. For the reversal-derived thresholds, this difference was not significant [$t(33)=0.76$, $p=0.45$]. However, the data derived using thresholds calculated from psychometric functions exhibited a slope that was significantly different from 1 [$t(33)=3.21$, $p<0.01$], indicating that, as measured threshold increased, these scores exhibited significant bias compared with the corresponding constant-stimulus scores.

To provide confirmation that the threshold bias described above persisted in the learning data, we also compared the adaptive thresholds derived from psychometric functions with those derived from reversals in the perceptual learning experiment. In the latter case, we collapsed the data across pre-test and post-test for all three experimental conditions. These data provided both a wide range of thresholds and experimental conditions for which this relationship could be compared. Outliers in the learning dataset were identified using a leverage test. If the leverage of any datapoint exceeded $2(p/n)$, where n is the number of observations and p is the number of parameters in the model (i.e., 2), that datapoint was excluded from the analysis (Hoaglin and Welsch, 1978).

Figure 5 compares the psychometric function- and reversal-derived thresholds obtained from both the bias investigation [Fig. 5(A); data derived from Fig. 4] and the learning experiment [Fig. 5(B)]. The regression parameters are almost identical to each other, suggesting that the difference between the two estimation techniques seen in Fig. 4 also applied to the learning data. Neither of the functions shown in Fig. 5 have intercepts that are significantly different from 0, so we constrained the intercepts for both to be the same and fitted models with differing slopes to the data obtained for each. These slopes did not differ significantly [$t(184)=1.88$, $p=0.06$]. These slopes did not differ significantly [$t(184)=1.88$, $p=0.06$]. It can be seen in Fig. 5(B) that the slope of the regression line for the learning dataset shows a small but clear tendency for thresholds derived from psychometric functions to be systematically (mean=8.4%) lower than those obtained from reversals, across the threshold range.

In order to investigate whether or not the psychometric function fitting technique was contributing to the bias observed in these data, we also fitted the pre-test and post-test learning data obtained from the adaptive and constant-stimulus methods using a logit function. Adaptive thresholds calculated using a probit function were, on average, 1.6 times larger than their logit-calculated counterparts, while constant-stimulus thresholds were 1.7 times larger when calculated using the probit function. Paired-sample t-tests showed that both the constant-stimulus thresholds [$t(83)=11.23$, $p<0.0001$] and the adaptive thresholds [$t(168)=13.44$, $p<0.0001$] were significantly lower when calculated using the logit function. To compare how much the choice of fitting technique affected each training method, we

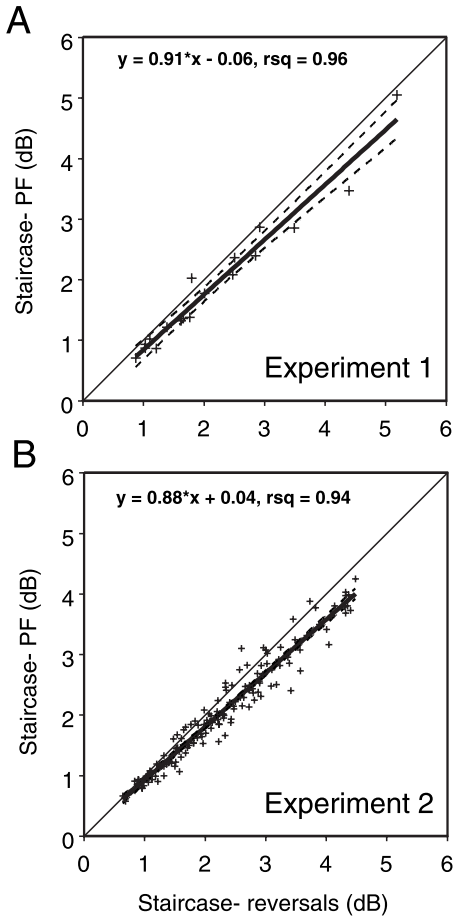

FIG. 5. Comparison of adaptive thresholds calculated from psychometric functions and from reversals for both the bias data (A) and the learning data (B). The dashed lines indicate 95% confidence intervals for the fitted functions; the confidence intervals for the learning data are so close to the function itself that they are only barely visible. For both sets of data, the fitted function lies mostly beneath the unity line, indicating that, when calculated from psychometric functions, the adaptive thresholds from both the bias investigation and the learning experiment exhibited similar degrees of bias compared with reversal-derived thresholds.

calculated difference scores for the thresholds from each fitting technique (probit-derived threshold–logit-derived threshold). A two-sample t-test indicated that the difference scores obtained for each training method were not significantly different from each other [$t(251)=0.42$, $p=0.64$].

These analyses imply that the particular fitting method chosen could significantly affect the amount of bias seen for both constant-stimulus and adaptive thresholds. The logit fits yielded lower thresholds, probably due to the relative "straightness" of the slope of the logit function, indicating that they would match the reversal-derived thresholds even less closely. Equivalent threshold differences were found for the two training methods with probit and logit fitting, suggesting that the choice of fitting method alone could not account for the bias we saw in the adaptive thresholds. Thus, the bias seen in experiment 1 is most likely caused by the adaptive method itself.

Because the reversal-derived thresholds more closely matched the constant-stimulus thresholds obtained in experiment 1 and therefore appeared to be free of bias, the adaptive learning thresholds obtained in experiment 2 were calculated from reversals only.

B. Perceptual learning

Across the training period, the overall mean number of trials for each adaptive staircase within a run was 62.5. The mean number of adaptive trials per subject on each day was 501, compared with the fixed value of 396 for the constant-stimulus method.

1. Time-course of learning in the trained condition

Figures 6(A) and 6(B) show the smoothed individual and group mean ILD learning curves for both methods in the trained condition. Subjects who did not show a numerical improvement in threshold between the pre-test and post-test ($n=1$ for each method) were excluded from further analyses and are not included in this figure. All other subjects showed a gradual, if variable, reduction in ILD thresholds across the training period. In order to characterize the rate of change in improvement for the two methods, we calculated the normalized percentage change in threshold [defined as (pre-test threshold−session×threshold)/pre-test threshold×100] across sessions for all subjects [Figs. 6(C) and 6(D)]. We then fitted linear models, either with or without a quadratic term, to the pooled group mean learning curves using least-squares regression. The constant-stimulus data [Fig. 6(C)] were well fitted by a model with no quadratic term ($r^2=0.9$, $t=8.32$, $p<0.0001$) and when a quadratic term was added it was found not to be significant ($t=1.08$, $p=0.31$), indicating that a linear trend best described the change in thresholds across sessions. The adaptive method, on the other hand, yielded data for which the simplest fit was obtained using a regression model that contained a quadratic term [Fig. 6(D); $r^2=0.9$, $t=2.78$, $p<0.05$].

Because in the adaptive method the number of trials varied from one run to the next, we also fitted the individual normalized learning curves from both techniques against the number of trials completed per session. Individually, the fitted models for the adaptive method were significantly better when they contained a quadratic term in five out of eight cases. In contrast, none of the constant-stimulus learning curves showed a significantly better fit when a quadratic term was included.

These data imply a dissociation between the two methods in terms of the rate of improvement in ILD discrimination performance during training, with the constant-stimulus method exhibiting a linear trend and the adaptive method yielding an improvement that was largely curvilinear. Comparison of Figs. 6(A) and 6(B) shows that the adaptive method generally produced thresholds that were slightly elevated compared to those measured with the constant-stimulus method. However, as can be seen from Figs. 6(C) and 6(D), the overall change in performance between the two methods was very similar.

2. Learning and generalization

The mean thresholds before and after training for each individual subject are shown as pre- vs post-threshold scatter plots in Fig. 7. Trained subjects are plotted in black, untrained controls in gray. Figure 7(A) shows the scores for stimuli with a 4 kHz carrier lateralized to the left, i.e., they

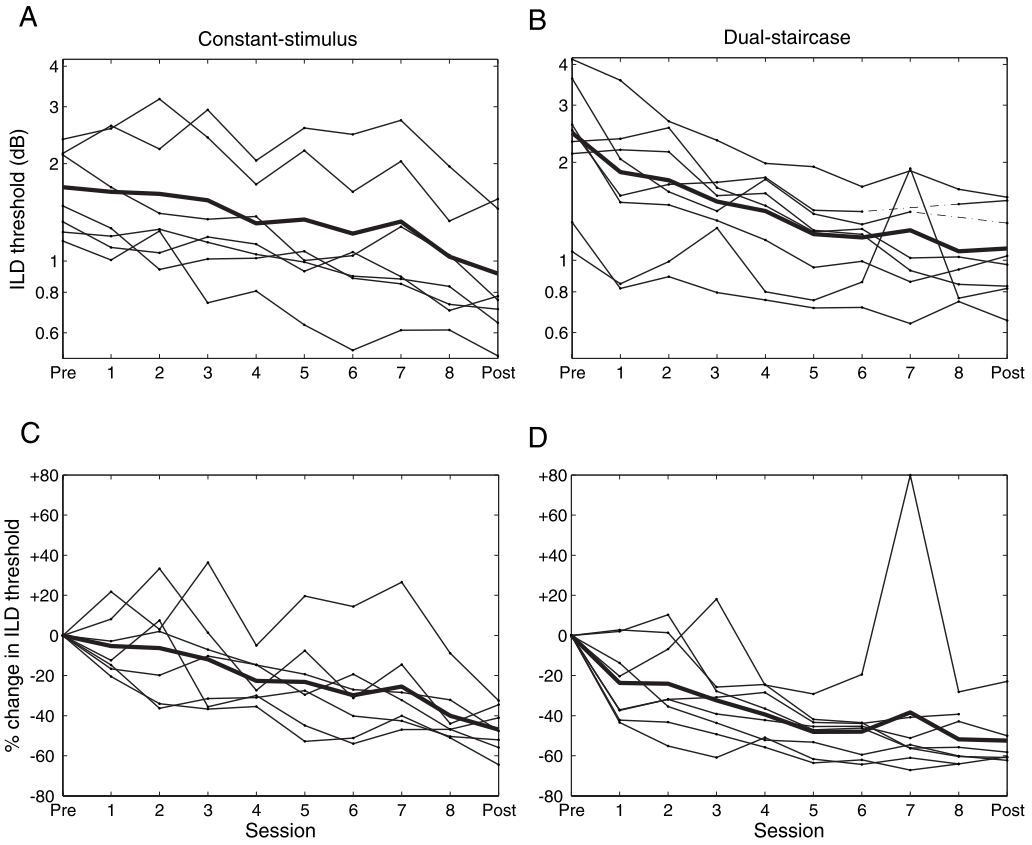

FIG. 6. Mean absolute [(A) and (B)] and normalized percentage change [(C) and (D)] thresholds for each training method as a function of training session. In panel (B) black dashed lines indicate days for which no data were available for a given subject. The thick black line in each plot indicates the group mean for that day. The relative curvature of the mean learning curve for the adaptive data [(B) and (D)] can clearly be seen.

illustrate performance on the trained stimulus condition. It is apparent that the clear majority of trained subjects exhibited improved thresholds after training (all but two of the black symbols lie well below the $x=y$ diagonal). In the "4 kHz right" condition, the datapoints for the trained cohort lie closer to, and are more evenly scattered around, the $x=y$ diagonal [Fig. 7(B)], indicating that any improvement gained by training on the left led to only small or no improvement on the right, i.e., there was little or no transfer to the opposite hemifield. By contrast, in the "0.5 kHz left" condition, we again observed that, in all but one case, the post-test threshold was smaller than the pre-test value [Fig. 7(C)], suggesting that training with a 4 kHz carrier SAM tone had led to improved performance even when tested with an untrained 0.5 kHz carrier SAM tone. In all three conditions, data from the untrained, control subjects are evenly spread around the $x=y$ diagonal, indicating no systematic difference between pre-test and post-test thresholds [Figs. 7(A)–7(C)].

t-tests revealed no significant differences between the methods at pre-test for all listeners in any condition, or for either trained or control listeners at post-test in any condition. In order to increase the power of our analysis, we therefore pooled the data from the two methods for each condition and calculated, for each subject, the normalized percentage threshold change relative to pre-test threshold, again defined as (pre-test threshold − post-test threshold)/pre-test threshold × 100. The observed mean percentage threshold changes were below zero for all groups and all conditions, but only the trained subjects in the "4 kHz left" [$t(16)=7.49$, $p<0.0001$] and the "0.5 kHz left" [$t(16)=3.12$, $p<0.01$] conditions had means that were significantly below zero (confirmed with sign tests; $p=0.002$ and $p=0.0003$, respectively). We saw the same pattern when this analysis was conducted using the absolute change in threshold [$t(16)=5.25$, $p<0.0001$, and $t(16)=4.42$, $p<0.001$ for these two conditions, respectively]. This finding was again confirmed with sign tests ($p=0.002$ for both analyses). Furthermore, t-tests indicated that, for the "4 kHz left" [$t(27)=4.18$, $p<0.001$] and the "0.5 kHz left" [$t(27)=2.2$, $p<0.05$] conditions, the mean percentage change in threshold was significantly greater in the trained cohort than in the untrained controls (confirmed using Wilcoxon rank-sum tests; $p=0.006$ and $p=0.0005$, respectively; see Fig. 8). Again, this pattern of generalization was observed when we analyzed the absolute change in threshold ["4 kHz left": $t(27)=2.81$, $p<0.01$; "0.5 kHz left": $t(27)=3.31$, $p<0.01$], and was confirmed using Wilcoxon rank-sum tests ($p=0.006$ and $p=0.002$, respectively). No significant differences were seen in the "4 kHz right" condition for these analyses.

The mean change in threshold in the trained "4 kHz left" condition was −0.95 dB, or a 46% improvement relative to the mean initial threshold. In the "0.5 kHz left" frequency-transfer condition, we observed a −1.32 dB mean change in threshold, corresponding to a 30% improvement. This change was not significantly different from that seen at "4

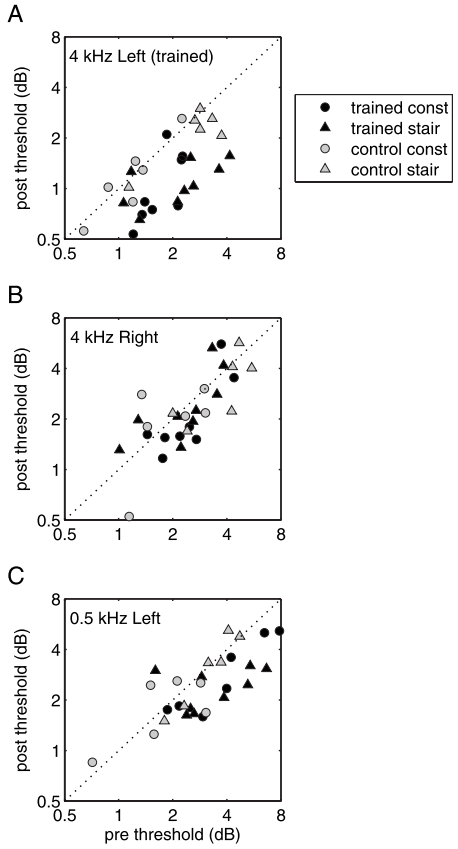

FIG. 7. Pre- and post-test thresholds for all subjects. Results in each of the stimulus conditions (4 or 0.5 kHz carrier, lateralized left or right) are shown in separate panels, as indicated. Subjects trained on the 4 kHz left condition are shown in black, and untrained controls in gray. Subjects trained with constant-level stimuli (const) are shown by the circles, and subjects trained using the adaptive staircase paradigm (stair) are plotted as triangles. In both the trained 4 kHz left and untrained 0.5 kHz left conditions, the trained subjects clearly tend to cluster below the unity line, indicating that post-test thresholds were lower than pre-test thresholds. In contrast, control listeners in all three conditions, as well as trained listeners in the 4 kHz right condition, exhibit thresholds that cluster around the unity line, indicating little change in thresholds between pre-test and post-test.

kHz left" [$t(16)=1.72$, $p=0.11$], indicating that the reduction in thresholds observed with a different carrier frequency was equivalent to that obtained with the trained stimulus.

We also compared the percentage change in threshold between trained and control listeners for each method. The adaptive method yielded significant differences between these groups for the trained "4 kHz left" condition [$t(13)=2.59$, $p<0.05$; confirmed with rank-sum test: $p=0.02$], but not the "0.5 kHz left" condition [$t(13)=1.12$, $p=0.14$]. However, when the absolute change in threshold was used for this analysis, the "4 kHz left" condition approached significance [$t(13)=1.67$, $p=0.06$] and the "0.5 kHz left" condition was significant [$t(13)=2.05$, $p<0.05$; confirmed with rank-sum test: $p=0.03$]. The constant-stimulus percentage change scores were significantly different between the trained and control groups for the "4 kHz left" condition [$t(12)=3.27$, $p<0.01$; confirmed with rank-sum test: $p=0.005$]. In the "0.5 kHz left" condition, a significant difference was also seen between groups [$t(12)=2.08$, $p<0.05$], although this was not confirmed with a rank-sum test ($p=0.1$). When we conducted this analysis using the absolute change in threshold, both the "4 kHz left" condition [$t(12)=3.42$, $p<0.01$; confirmed with rank-sum, $p=0.01$] and the "0.5 kHz left" condition [$t(12)=2.62$, $p<0.05$; confirmed with rank-sum, $p=0.02$] condition yielded significant differences between trained and control listeners. We attribute the apparent contradictions in some of these within-methods analyses to the relatively small sample sizes used in these tests, and the accompanying reduction in statistical power. For both methods, no significant differences were observed between trained and control listeners in the "4 kHz right" condition using any of the above analyses.

Together these results provide strong evidence that training with a 4 kHz SAM tone presented in the left hemifield led to significant improvements in ILD discrimination thresholds, and that these improvements transferred to an untrained carrier frequency presented in the same hemifield, but not to stimuli with the same carrier frequency presented in the opposite hemifield.

IV. DISCUSSION

In this study, we used SAM tones to investigate the time-course and specificity of learning on an ILD discrimination task. Thresholds were estimated using either a standard constant-stimulus method or a novel adaptive task. A methodological investigation was undertaken to compare adaptive thresholds obtained from fitted psychometric functions against those calculated by averaging the reversals in the adaptive track. A comparison was made with thresholds obtained from the same subjects using the constant-stimulus method, and adaptive thresholds were found to be unbiased only when they were calculated from reversals. We also observed differences in the rate of perceptual learning between the two behavioral methods across the training period. However, global learning outcomes in the trained condition were highly comparable in each case. ILD discrimination learning for SAM stimuli whose virtual position was lateralized to the left hemifield of auditory space did not generalize to the opposite hemifield, implying functional segregation of ILD processing for stimuli originating on opposite sides of the midline. However, perceptual transfer of ILD discrimination learning did occur for SAM stimuli presented to the same hemifield used for training, but with a different carrier frequency. Given that ILD learning does not generalize across frequency when pure tones are used (Wright and Fitzgerald, 2001), our results suggest that the amplitude envelope might be a more important cue for ILD discrimination learning than the fine-structure of the stimulus.

A. Methodological assessment

The threshold bias observed when behavioral thresholds were calculated from psychometric functions taken from the adaptive staircase data is consistent with the results of simulations by Leek *et al.* (1992). They found that slope bias in the adaptive psychometric function depends on its underlying true slope, such that, especially for shorter runs, shallower true slopes (and by implication in our analysis, higher thresholds) exhibit more bias than steeper ones (or lower thresholds). This phenomenon is potentially reflected in the

thresholds shown in Fig. 4(A), where it is clear that the higher the constant-stimulus threshold, the more biased is the corresponding adaptive threshold. This is problematic for studies of learning in general, in which the parameters of the psychometric function are likely to change over a period of time and therefore may exhibit more or less bias from one measurement to the next.

Based on the thresholds derived from reversals, the average bias in the adaptive thresholds derived from psychometric functions equated to 8.4% (Fig. 5). Rowan *et al.* (2006) indirectly assessed relative threshold bias for two adaptive methods (one of which was the 3-down, 1-up rule, and both of which are thought to exhibit bias) to be 6.5%. This value is less than that found in our study, as would be expected if the amount by which those adaptive thresholds were biased relative to the underlying psychometric function was within the range observed here.

In contrast to these results, Amitay *et al.* (2006) found little difference between adaptive thresholds obtained from psychometric functions or reversals. Furthermore, Dai (1995) reported that psychometric functions obtained using the constant-stimulus method and both 2-down, 1-up and 3-down, 1-up adaptive methods were equally accurate. However, this conclusion was based upon a comparison between the psychometric functions obtained from each method, and a "total" psychometric function computed by combining the functions derived from all three. If any inherent slope or threshold bias had been present in the adaptive data reported in that study, it may have also been present in the "total" psychometric function.

Simulations carried out by Saberi and Green (1996) indicate that bias in reversal-derived thresholds can be introduced by an inherent imbalance in the relative probabilities of the stimulus level increasing or decreasing at equal distances above or below the target threshold. However, the reversal-derived thresholds in our study showed good agreement with those derived from the constant-stimulus method. In light of this, it seems reasonable to suggest that adaptive thresholds obtained from short runs can be calculated from reversals without compromising the conclusions obtained to any significant degree.

B. Learning in the trained condition

Our results suggest that global learning outcomes for ILD discrimination in the trained condition were relatively unaffected by the choice of psychophysical training method used to induce and measure them. Nevertheless, the learning curves shown in Figs. 6(A) and 6(B) indicate slightly higher thresholds for the adaptive method than for the constant-stimulus method in the earlier training sessions. It is possible that in these sessions the adaptive method was not providing enough exposure to a sufficient range of stimulus levels for maximal learning to occur (e.g., Trahiotis *et al.*, 1990). The relative overall change in performance for the two methods did not, however, differ significantly and post-test thresholds were comparable between them.

The most striking difference between the methods is the temporal pattern of learning shown for each; the rather linear improvement seen for the constant-stimulus method contrasts with the exponential shape of the adaptive learning curve, which shows a large initial drop in threshold but appears to asymptote as training progressed. A similar nonlinear improvement in performance was also observed by Wright and Fitzgerald (2001) when ILD discrimination thresholds were measured using an adaptive staircase procedure. The rapid early improvement could reflect either task-specific or early perceptual learning (e.g., Hawkey *et al.*, 2004) (which seems unlikely, given that substantial familiarization with the task was provided before training began). Because an equivalent initial reduction in thresholds was not observed in the constant-stimulus data, it seems more likely that the overall shape of the adaptive learning curve was influenced by the combined strategies of (1) the logarithmically reducing step size and (2) starting ΔILD values for each run that were taken as two log-steps above the threshold obtained in the previous run. This could have caused large changes in measured threshold at the beginning of training, when the step size between successive stimulus levels was large, and progressively smaller changes, and therefore an asymptotic learning curve, as subjects became more expert with the task and the range of absolute stimulus levels to which they were exposed became smaller.

The thresholds obtained with the constant-stimulus method still appeared to be slowly improving after 8 days of training, suggesting that further ILD learning was possible for the stimuli used in this experiment. If that is the case, then the overall implication is that perceptual learning of ILD discrimination *per se* was relatively linear across time, with small but consistent changes in the degree of learning seen from day to day. Interestingly, the pre-test and post-test thresholds measured in the present study using either training method were lower than those reported by Wright and Fitzgerald (2001), who studied ILD learning with tonal stimuli. Thus, it appears that the use of SAM stimuli may confer an advantage over tonal stimuli for ILD discrimination learning, both in terms of absolute performance thresholds and potentially the degree of learning that is permitted by the underlying neural hardware.

C. Generalization to untrained conditions

Overall, our data do not offer any support for generalization of ILD discrimination learning from one hemifield to the other, implying that perceptual learning for highly lateralized stimuli may utilize perceptual hardware that is functionally separate. This finding is consistent with electrophysiological (e.g., Moore *et al.*, 1984; Brugge *et al.*, 1996; Mrsic-Flogel *et al.*, 2005; Campbell *et al.*, 2006; Harrington *et al.*, 2008) and behavioral studies (Kavanagh and Kelly, 1987; Kelly and Kavanagh, 1994; Malhotra *et al.*, 2004) in animals, and with psychophysical data in humans (Boehnke and Phillips, 1999), showing that each side of auditory space is represented largely contralaterally at higher levels of the auditory system. However, Zatorre and Penhune (2001) examined spatial hearing in human patients with unilateral temporal lobe lesions and found a dissociation in the pattern of localization deficit when the lesion occurred on the right side

of the brain compared with similar damage to the left. They reported that most of the individuals with right auditory cortex lesions were impaired in their ability to perform either a spatial localization or discrimination task in both left and right hemifields. If, as suggested by the results of this study, the right auditory cortex does represent both sides of space, we might expect transfer of ILD discrimination learning across the midline. However, the damaged regions in these patients were relatively large, possibly representing a more extensive region of space than those influenced by sound localization training. Accordingly, our data do not show transfer across the midline, implying that the underlying changes in ILD processing are found at a level of the auditory system where sounds are represented contralaterally.

In contrast to the lack of hemisphere transfer, we found that ILD discrimination learning for high-frequency complex stimuli did generalize to SAM tones with the same modulation rate but a much lower carrier frequency. The same result has been reported by Zhang and Wright (2005) but contrasts with the earlier demonstration by Wright and Fitzgerald (2001) of frequency-specific learning with pure tones. Generalization of perceptual learning is usually interpreted to be indicative of changes at higher loci in the sensory pathway, where information about the trained and generalized stimuli is shared (Gilbert *et al.*, 2001; Gilbert, 1994). Thus, while plasticity of ILD processing for tonal stimuli could potentially occur within any tonotopically-organized structure, beginning with the superior olivary complex where binaural cues are first computed (Yin, 2002), the lack of learning specificity for SAM tones implies the involvement of neurons that integrate information across different frequency channels. This does not mean, however, that binaural learning with more complex sounds, which are lateralized more accurately than pure tones (Bernstein and Trahiotis, 2002), is necessarily restricted to a level of the auditory pathway where frequency selectivity and tonotopicity are lost. Thus, electrophysiological recording studies have shown that neurons in both the inferior colliculus (Biebel and Langner, 2002) and primary auditory cortex (Schulze and Langner, 1999) can be driven by SAM tones with carrier frequencies that lie well outside the excitatory frequency response area defined with tonal stimuli. Although Li *et al.* (2006) found that such stimuli failed to activate inferior colliculus neurons, they did observe responses synchronized to the stimulus envelope when SAM tones with carrier frequencies beyond the excitatory response area were paired with pure tones at the neurons' characteristic frequency. The capacity of these neurons to detect the envelope of the stimulus across a wide range of carrier frequencies is consistent with the transfer of ILD discrimination learning to an untrained carrier frequency (Fig. 8).

Further insights into the neural substrate of auditory perceptual learning will require investigation of the physiological changes that take place as performance improves with training. Although electrophysiological recording studies in animals have so far focused mainly on plasticity of neuronal responses to non-spatial sound attributes, the results of an auditory evoked potential study in humans suggest that short-term training can alter the spatial representation in the auditory cortex (Spierer *et al.*, 2007). While adding to the growing body of evidence that perceptual improvements are associated with cortical plasticity (Dahmen and King, 2007), this does not rule out the possibility that these changes actually originate at a lower level, such as the inferior colliculus.

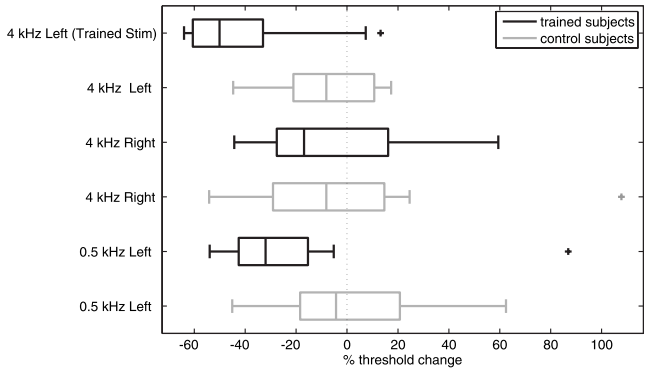

FIG. 8. Box plots showing distribution of threshold changes (post-test minus pre-test threshold expressed as % of pre-test score) for the trained and control cohorts in each of the stimulus configurations. It is clear that only the trained listeners in the 4 kHz left and 0.5 kHz left conditions showed a negative threshold change between pre-test and post-test.

D. Concluding remarks

Provided that thresholds are calculated from reversals in order to avoid adaptive bias, the effects of training on the measured thresholds were comparable for adaptive and constant-stimulus methods for determining ILD discrimination thresholds. Nevertheless, subtle but important differences persisted between the methods that implicate the influence of the adaptive algorithm upon the measured time-course of learning. Finally, the transfer of learning to low frequency ILD discrimination shows that exposure to stimuli with a periodically fluctuating envelope may allow such changes to occur across a wide range of frequencies, whereas the lack of transfer across the midline appears to restrict the site of plasticity to brain regions where spatial cues are represented contralaterally. In both cases, our findings are consistent with the physiological properties of auditory neurons in the midbrain and cortex.

A psychophysical evaluation of near-field head-related transfer functions synthesized using a distance variation function

Alan Kan,[a] Craig Jin,[b] and André van Schaik[c]
Computing and Audio Research Laboratory, School of Electrical and Information Engineering, University of Sydney, Sydney, New South Wales 2006, Australia

(Received 3 September 2008; revised 6 January 2009; accepted 20 January 2009)

A method for synthesizing near-field head-related transfer functions (HRTFs) from far-field HRTFs measured using an acoustic point-source of sound is presented. Near-field HRTFs are synthesized by applying an analytic function describing the change in the transfer function when the location of a sound source changes from the far-field to the near-field: the distance variation function (DVF). The DVF is calculated from a rigid sphere model and approximates the change in the frequency-dependent interaural level cues as a function of the change in sound source distance. Using a sound localization experiment, the fidelity of the near-field virtual auditory space (VAS) generated using this technique is compared to that obtained by simply adjusting the intensity of the VAS stimulus to simulate changes in distance. Results show improved distance perception for sounds at simulated distances of up to 60 cm using the DVF compared to simple intensity adjustment, while maintaining directional accuracy. The largest improvement for distance perception were for sound sources located to the side and within 40 cm. When intensity was removed as a cue for sound source distance from near-field sounds generated using the DVF, results showed some discrimination of sound source distances but, in general, distance perception accuracy was poor. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081395]

I. INTRODUCTION

A head-related transfer function (HRTF) or its time-domain representation, the head-related impulse response (HRIR) describes the change in the sound pressure from a point in the free-field to a listener's ear drum. A separate HRTF exists for each sound source position. Commonly, the HRTF is defined for a planar sound source; however, in this paper we will consider the HRTF for an acoustic point-source of sound. For an acoustic point-source of sound, HRTFs do not vary substantially for distances beyond 1 m since the incoming sound waves are approximately planar, but Brungart and Rabinowitz (1999) showed using acoustic measurements on a manikin that HRTFs can vary substantially for distances within 1 m. This variation is due to the curvature of the wavefront from the point-source of sound and its interaction with the subject's head, torso, and pinnae. Hence, it can be seen that the HRTFs within 1 m are dependent on the distance from the head due to the wavefront characteristics of the sound source.

For an acoustic point-source of sound located off the mid-sagittal plane, Brungart and Rabinowitz (1999) showed that the interaural level difference (ILD) increases as the distance to the head decreases, especially when the sound source is located within 0.5 m from the head. In particular, the low-frequency ILD (<500 Hz), which is usually small at sound source distances greater than 1 m, can be on the order of 20 dB for a sound source located at 0.12 m. Also, the HRTF for the contralateral ear shows increasing high-frequency attenuation with decreasing sound source distance. Results from human sound localization experiments conducted by Brungart *et al.* (1999) and Brungart (1999) suggest that the level differences in the HRTFs are a salient cue for distance localization for sound source distances within 1 m. From acoustic manikin measurements, Brungart and Rabinowitz (1999) also showed the existence of a shift in the spectral features of the HRTF, particularly at the high frequencies, as a function of distance, which is due to an "acoustic parallax" effect. This occurs when the angle between a sound source and the ear changes substantially when the sound source is moved closer to the head. The measurements also exhibit a small increase in the interaural time difference (ITD) at very close sound source distances (<0.25 m). However, Brungart and Rabinowitz (1999) argued that the small increase in ITD is likely to be insignificant and that the ILD in this region is the more dominant cue for sound source distance localization. To distinguish the region where the HRTFs exhibit significant variations with distance from the region where the HRTFs are relatively constant, the terms "near-field" and "far-field" will be used in this paper to refer to these two regions, respectively. A distance of 1 m is taken as the boundary between the two regions.

For the generation of virtual auditory space (VAS), it is common practice to acoustically measure HRIRs for a modest number of different sound source directions at a fixed radius of 1 to 2 m from the center of the listener's head. To estimate an HRIR for a sound source direction that has not been measured, numerous interpolation techniques have been proposed [for example, see Wenzel and Foster (1993); Har-

[c]Electronic mail: andre@ee.usyd.edu.au

tung *et al.* (1999); Carlile *et al.* (2000)]. VAS is generated by filtering sounds with HRIRs and presenting the filtered sounds over headphones [see Carlile (1996)]. Near-field VAS requires near-field HRIRs. However, Brungart (2002) highlighted a number of technical difficulties in recording near-field HRIRs on a human subject. First, it is difficult to obtain a small, broadband acoustic point-source which is necessary since the sound source needs to remain compact at relatively close measurement distances and to avoid sound reflections from the loudspeaker back into the microphones. Second, the subject's head position needs to be tightly constrained so that small head movements do not cause substantial angular errors in the recorded HRTFs. Third, an increased number of HRIR measurement points are needed to cover the variation in the HRTFs at the different distances which prolongs the measurement process and can be uncomfortable for the subject. Due to these technical difficulties, it has so far been difficult to obtain HRTFs measured on human subjects to accurately synthesize near-field sound sources in virtual auditory displays.

In this work, we present a new method for generating near-field VAS which involves synthesizing near-field HRIRs from far-field HRIRs. The near-field HRIRs are synthesized using analytical results obtained from a rigid sphere model. A rigid sphere is a reasonable first-order approximation of the human head and allows exact calculation of the pressure at the surface of the rigid sphere due to a stationary sound source in any direction and distance, at any frequency. By calculating, for a particular direction, the ratio of the pressure at the surface of the rigid sphere due to a far-field sound source to the pressure on the rigid sphere due to a near-field sound source for all frequencies of interest, a function can be obtained that describes the change in the transfer function of a sound from the far-field distance to the near-field distance. We call this function the distance variation function or DVF. A near-field HRTF is synthesized by combining the far-field HRTF, corresponding to the same direction, with the calculated DVF. The main advantage of the DVF method for synthesizing near-field VAS is that a near-field HRTF can be analytically calculated for any distance given a far-field HRTF. Since no near-field HRIRs need to be recorded, the technical difficulties with recording near-field HRIRs on a human subject are avoided.

A sound localization experiment was conducted to test the perceptual fidelity of the VAS generated using the HRTFs synthesized by the DVF method. The same experiment was also conducted with near-field sounds synthesized by simply adjusting the intensity of the VAS stimulus. The results of the experiments are presented and compared. In a further experiment, the intensity of the near-field sounds synthesized using the DVF method was held constant to investigate whether the remaining cues introduced by the DVF are salient for sound source distance perception.

II. METHODS

A. Calculation of the DVF

The DVF is calculated using a rigid sphere model. The function describing the pressure of a sinusoidal point-source of sound from any direction and distance in space to the surface of a rigid sphere was derived by Rabinowitz *et al.* (1993) and has been experimentally verified on a bowling ball by Duda and Martens (1998). The pressure at a point X on the surface of a rigid sphere of radius a due to a sinusoidal point-source of sound of angular frequency ω, at a distance r away from the center of the sphere, is given by

$$p(a,\omega,\theta,r) = -kr\sum_{m=0}^{\infty}(2m+1)\frac{h_m(kr)}{h'_m(ka)}P_m(\cos\theta)e^{-ikr}, \quad (1)$$

where $h_m(kr)$ is the spherical Hankel function of the first kind of order m and $h'_m(ka)$ is its first derivative at radius a, $k=\omega/c$ is the wavenumber, c is the speed of sound in air, $P_m(\lambda)$ is the Legendre polynomial of degree m, and θ is the angle between a vector from the center of the sphere to the point X on the surface of the sphere and a vector from the center of the sphere to the sound source. By evaluating Eq. (1) for all frequencies of interest, the transfer function at point X can be obtained for a particular source location. In our experiments, we calculated the transfer function for 256 frequency bins up to the Nyquist frequency.

To synthesize a near-field HRTF, the DVF for a sound source at a near-field distance d_n is calculated as the ratio of the pressure arising from a sound source at distance d_n to the pressure arising from a sound source at a distance d_f, where d_f is the distance at which the far-field HRTF was measured. In other words, we calculate

$$\mathrm{DVF} = \frac{p_n(a,\omega,\theta,d_n)}{p_f(a,\omega,\theta,d_f)} \quad (2)$$

using Eq. (1), for all frequencies of interest, where a is the radius of the listener's head and can be determined through measurement. In our experiment, the radius of the listener's head was estimated using the ITD model proposed by Kuhn (1977):

$$\mathrm{ITD} \approx \frac{3a}{c}\sin\theta_{\mathrm{inc}}, \quad (3)$$

where θ_{inc} is the angle of incidence of the sound source relative to the mid-sagittal axis. ITD values were obtained by cross-correlation of the measured left and right HRIRs below 5 kHz. To determine the angle θ to be used in Eq. (2), the positions of the ears were assumed to be at an angle of 100° on either side of the mid-sagittal plane on the audio-visual horizon for all subjects, in line with Duda and Martens (1998) and Blauert (1997). A separate DVF is calculated for each ear. To synthesize a near-field HRTF from a far-field HRTF, we calculate

$$\mathrm{HRTF}(d_n) = \mathrm{DVF} \times \mathrm{HRTF}(d_f). \quad (4)$$

To synthesize sounds at multiple locations and distances, a DVF needs to be calculated for every sound source distance and direction and for each ear.

B. HRIR measurement

The far-field HRIRs used in this experiment were recorded individually for each subject in an anechoic chamber

equipped with a loudspeaker (VIFA-D26TG-35) mounted on a robotic arm. The robotic arm can accurately position the loudspeaker to within a fraction of a degree, at any point on the surface of an imaginary sphere of 1 m radius except for positions greater than 45° below the audio-visual horizon. The subject was seated with his head in the center of the measurement sphere and aligned to the axes of the measurement system with the aid of a laser-alignment system. A chin-rest was provided and an electromagnetic sensor mounted on a headband worn by the subject monitored his head orientation during the measurement process. A light emitting diode (LED) display provided feedback to the subject with regard to the alignment of his head.

HRIRs were recorded using a "blocked-ear canal" technique, as described by Møller (1992), by placing miniature microphones (AuSim) at the entrance of the ear canal in both ears. Complementary Golay codes were used as stimuli and the HRIRs were obtained using the steps described by Zhou *et al.* (1992). In order to improve the signal-to-noise ratio, 16 repetitions of the Golay codes, each with a 1024 sample length, were recorded at each position. Tucker Davis Technology (TDT) system II hardware, interfaced with customized MATLAB software, was used to play and record the codes at an 80 kHz sampling rate. The stimulus duration at each recording position was just under 1 s. HRIRs were recorded for 393 different sound source directions, upwards of 45° below the audio-visual horizon and equally distributed around the subject's head.

After recording, a number of post-processing steps were applied to the HRIRs. First, the HRIRs were low-pass filtered at 16 kHz and resampled at 48 kHz. Second, since the HRIRs recorded with our system are at the limits of the noise floor for frequencies below 500 Hz, the recorded HRIRs were compensated below 500 Hz for each direction according to the frequency response derived from the rigid sphere model in Eq. (1) by replacing the HRTF magnitudes for frequencies below 500 Hz with those calculated by Eq. (1) and scaled relative to the level of the measured HRTF at 500 Hz. It should be noted that the HRIRs used in this experiment contain the transfer function of the measurement loudspeaker. Third, the magnitude response of the ear canal resonance up to 4 kHz, measured on a Brüel and Kjær Head and Torso Simulator (HATS) manikin (Type 4128), was also added to the HRIRs to compensate for the missing ear canal resonance caused by the blocked-ear recording and the use of in-ear tube phones for VAS presentation. The magnitude of the ear canal resonance was obtained from a blocked-ear recording made with the Ausim recording microphones on the HATS manikin and an open-ear recording made with the ear simulator microphones inside the HATS manikin. Assuming both the Ausim microphones and ear simulator microphones have a flat frequency response, the ear canal resonance can be obtained by subtracting the blocked-ear canal HRTF from the open-ear canal HRTF in the log-magnitude domain. The ear canal resonance obtained has a similar response as that presented in Hammershøi and Møller (1996) for the mean ratio of the pressure at the blocked-ear to the pressure at the ear-drum for 12 subjects, and was applied to the recorded far-field HRIRs as a minimum-phase filter.

C. Stimulus generation

A psychoacoustic experiment was conducted to test the perceptual fidelity of the VAS generated by the synthesized near-field sounds. White noise bursts, 400 ms in duration with 5 ms raised-cosine onset and offset ramps, were used as stimuli for the experiment. A different white noise burst was generated for each sound source location. In this experiment three conditions were tested, in which the near-field stimuli were generated by (1) filtering white noise bursts with near-field HRIRs synthesized by the DVF, henceforth referred to as the DVF-generated stimulus condition; (2) filtering white noise bursts with far-field HRIRs and scaling the intensity of the stimulus inversely proportional to the simulated sound source distance, henceforth referred to as the intensity-scaled stimulus condition; and (3) filtering white noise bursts with near-field HRIRs synthesized by the DVF but with constant intensity, henceforth referred to as the constant-intensity DVF-generated stimulus condition.

To generate stimuli for the DVF-generated stimulus condition, white noise bursts were convolved with near-field HRIRs synthesized by the DVF according to Eq. (2) and (4). A constant post-scaling factor was then applied to the stimuli to ensure that the stimuli at positions closest to the ears would be at a comfortable listening level.

In the intensity-scaled stimulus condition, we desired a scaling factor that would change the intensity of the stimuli with respect to the simulated distance and account for the fact that the distance between a sound source and the two ears can be substantially different when the source is located in the near-field and close to the interaural axis. For a real sound source, the intensity of the sound is inversely proportional to the distance, that is $I \propto 1/d$. To account for the different distances to the two ears, the intensity can be assumed to be approximately proportional to the mean of the two distances, that is,

$$I \propto \frac{1}{2}\left[\frac{1}{d_l} + \frac{1}{d_r}\right], \tag{5}$$

where I is the intensity and d_l and d_r are the distances between the sound source and the left and right ears, respectively. The scaling factor, S, can be defined as the ratio of the intensity level for a sound source at a near-field distance over the intensity level for a sound source at 1 m. Assuming the distance to the two ears are identical for a sound source at 1 m (e.g., along the mid-line), then

$$S = \frac{I_{\text{near field}}}{I_{1\text{ m}}} = \frac{50}{d_l} + \frac{50}{d_r}, \tag{6}$$

where d_l and d_r are in centimeters. The stimuli for the intensity-scaled stimulus condition were thus obtained by convolving white noise bursts with far-field HRIRs and scaling by the numerical factor S. An additional post-scaling factor was applied to the stimuli to ensure that a sound directly in front of the subject at a distance of 1 m would have the same root-mean-squared energy as a sound for the DVF-generated stimulus condition for the same position.

In the constant-intensity DVF-generated stimulus condition, near-field sounds were generated as described for the

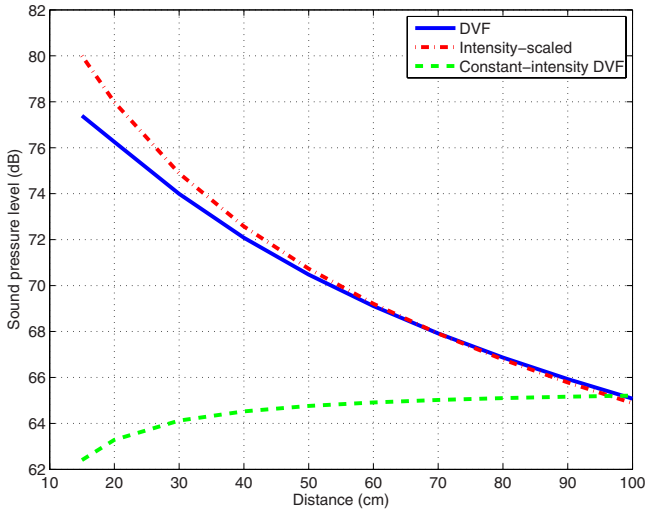

FIG. 1. (Color online) The stimulus level presented to the right ear for a sound source located directly in front of a subject at different simulated distances. Similar stimulus levels were presented to the left ear for the same sound source positions.

DVF-generated stimulus condition with an additional scaling factor of $1/S$ [refer to Eq. (6)] applied to the sounds to achieve approximately constant intensity for all simulated sound source distances. This condition was included to investigate the salience of the remaining cues introduced by the DVF for sound source distance perception when the intensity cue is absent.

Figure 1 shows the range of stimulus levels at the left and right ears for a sound source located directly in front of the subject at different simulated distances for the different conditions.

Near-field sounds were generated for 76 of the 393 HRIR measurement directions, in each of the following four distance ranges (in cm): [10–20], [25–35], [40–60], and [60–100]. Within each range, distances were normally distributed around the mean of each range. The 76 directions were equally spaced around the head between −40° and 40° elevation from the audio-visual horizon.

D. Experimental setup

A sound localization task was used for the experiment whereby the subjects indicated the perceived location of the near-field sounds by placing an electromagnetically-tracked sensor, mounted on the tip of a wand, at the perceived location. Brungart *et al.* (2000) found this method to be the least biased and more accurate than other types of response methods for indicating the perceived location of a sound. An electromagnetic tracking system (Polhemus Fastrak), with two sensors, was used to measure the perceived sound source location relative to the center of the listener's head. One of the sensors was mounted on the tip of the wand, and the other on a rigid headband worn by the listener. The transmitter of the electromagnetic tracking system was located about 50 cm behind the subject's head on a wooden pole, as shown in Fig. 2, and connected to a computer controlling the experiment from an adjacent room. A handheld pushbutton was given to the subject to trigger the computer and an LED display was used to provide head-orientation feedback to the listener prior to each stimulus presentation. Sounds were presented through in-ear tube phones (Etymotic Research ER-2) and played through an RME HDSP soundcard connected to the computer. The experiments were conducted in an ordinary room with no acoustical treatment. The room was lit during the experiment so that the subject could see the exact placement of the sensor at the end of the wand.

At the start of each trial the position of the center of the subject's head relative to the sensor on the headband was estimated by sequentially placing the sensor on the wand on the left and right ears and recording the sensor positions. The center of the head was then calculated as the midpoint between the recorded locations of the left and right ears. Prior to each stimulus presentation, the subject aligned his head to a prescribed starting position with the aid of an LED display [Fig. 2(a)]. The subject then pressed the handheld pushbutton causing the position of the sensor on the headband worn on the subject's head to be recorded by the computer to determine the current location of the center of the head and the stimulus to be played. The subject then responded by placing

FIG. 2. (Color online) The sound localization experiment setup. (a) shows the listener at the prescribed starting position and (b) shows the listener indicating the perceived sound source location

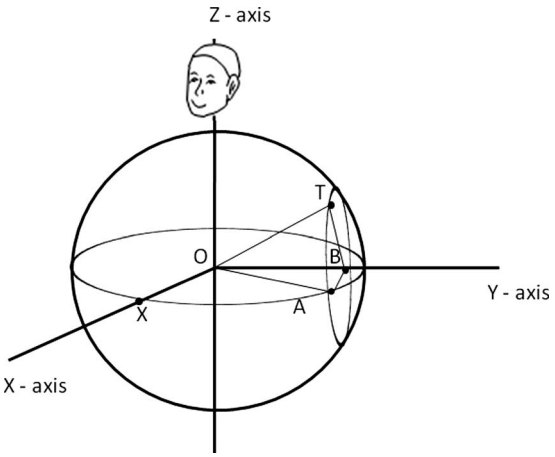

FIG. 3. The lateral-polar angle coordinate system. The lateral and polar angle related to point T are given by $\angle AOX$ and $\angle TBA$, respectively.

the sensor at the end of the wand at the perceived location, as shown in Fig. 2(b), and pressed the handheld pushbutton again. A reading was then taken from the sensor at the end of the wand to capture the perceived location. The perceived direction and distance of the sound stimulus were calculated relative to the location of the center of the subject's head prior to stimulus presentation. The subject then returned to the prescribed starting position for the next stimulus presentation.

In each test session, subjects would localize near-field sounds at each of the four distance ranges for 76 different directions. The stimuli for all directions and distances were presented in random order in each session. Subjects completed five sessions each for each stimulus condition described in Sec. II C. Since the different stimulus conditions were tested in separate sessions, subjects were aware of the method that had been applied to produce the stimuli during the test session. A total of five subjects participated in these experiments. The subjects were all male, between the ages of 26 and 37, and had normal hearing in both ears. All subjects had prior training and experience in human auditory localization experiments involving a head-pointing paradigm [see Carlile *et al.* (1997)] but no new training was given to the subjects for this new localization paradigm.

E. Analysis of results

The results of the psychoacoustic experiments will be presented in terms of direction and distance separately. The directional localization data will be presented using a lateral-polar angle coordinate system [see Fig. 3]. The lateral angle for a particular point T is defined as the horizontal angle away from the XZ-plane given by $\angle AOX$ in Fig. 3. Negative lateral angles (down to −90°) and positive lateral angles (up to 90°) define the left and right hemispheres, respectively. The polar angle corresponding to the point T is given by $\angle TBA$ in Fig. 3. Polar angles are defined with 0° representing the front, 90° representing directly above, 180° representing the back, and 270° representing directly below. The distance localization data will be presented with reference to the center of the head. Scatter plots will be used to display the data in terms of lateral angle, polar angle, and distance localization, where the target angle or distance is plotted against the response angle or distance. Perfect localization, that is, when the response location matches the target location, is indicated by circles along the diagonal from the bottom left to top right corner of the scatter plot. Mean differences between target and response locations across the localization data for all subjects will also be presented along with results from statistical significance tests. Kruskal–Wallis non-parametric analysis of variance (ANOVAs) and *post hoc* analyses (Tukey HSD) were conducted on the data within each condition, as well as across the conditions. An alpha value of 0.05 was used for significance testing. The corresponding non-parametric effect size was estimated by calculating Cliff's d, as described by Cliff (1993), where d estimates the fraction of the total number of samples where the samples in condition A are greater than the samples in condition B, minus the fraction of the total number of samples in condition B that are greater than the samples in condition A. That is, we calculate

$$d = \frac{1}{mn} \sum_i \sum_j d_{ij}, \tag{7}$$

where m and n are the number of samples in conditions A and B, respectively, and

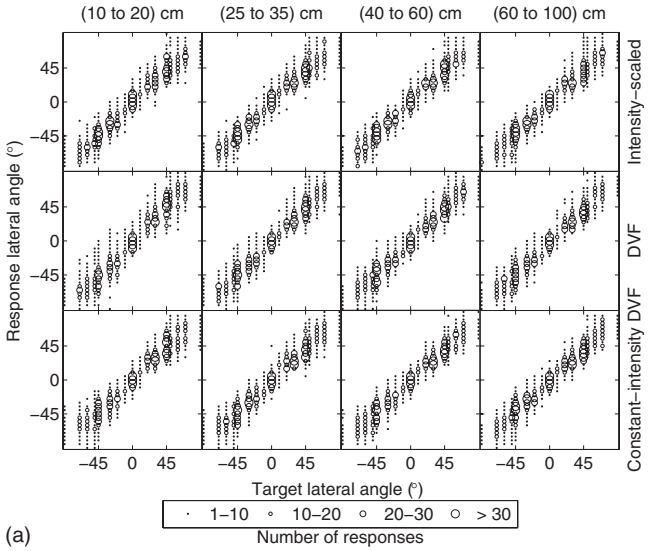
$$d_{ij} = \text{sign}(x_i - x_j), \tag{8}$$

where $i=1,2,\ldots,m$ and $j=1,2,\ldots,n$. Equation (8) compares a sample x_i from condition A with a sample x_j from condition B and assigns $d_{ij}=1$ if $x_i > x_j$, $d_{ij}=-1$ if $x_i < x_j$, and $d_{ij}=0$ if $x_i=x_j$.

III. RESULTS

A. Directional localization

The directional localization results in terms of lateral angle are presented in Fig. 4(a) for the three stimulus conditions. The lateral angle data have been rounded to the nearest 5° and the data for all the subjects have been grouped together since all subjects showed similar responses in each condition. Each column shows the localization data grouped into the different distance ranges and each row contains the results for the different conditions. The size of the circle indicates the number of responses in a particular angular region, as described by the legend at the bottom of the figure. In all stimulus conditions, the localization data show that the lateral angles of the responses were close to the target lateral angles at the different distance ranges implying that there were no major lateral angle localization errors in all stimulus conditions. Figure 4(b) shows the mean absolute difference between the target and response lateral angle for the different distance ranges for the three stimulus conditions. In all conditions there is a statistically significant increase in absolute lateral angle difference at the 10–20 cm distance range but the effect is small (Table I). Comparing across the conditions, there is a statistically significant increase in the absolute lateral angle difference in the two DVF stimulus conditions compared to the intensity-scaled stimulus condition [$\chi^2(2,7600)=17.64$, $p<0.005$] but again the effect is small ($d=0.08$).



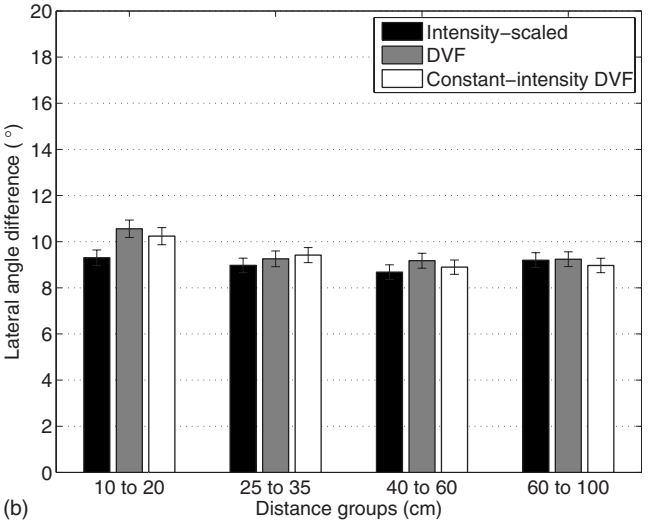


FIG. 4. (a) shows the directional localization results in terms of lateral angle. The data for the three stimulus conditions are shown in each row and are grouped into different distance ranges. (b) shows the mean absolute difference between the target and response lateral angle. The bars are grouped into different distance ranges and within each group, and the mean absolute angular difference is shown for the three stimulus conditions. The error bars indicate the 95% confidence interval of the mean.

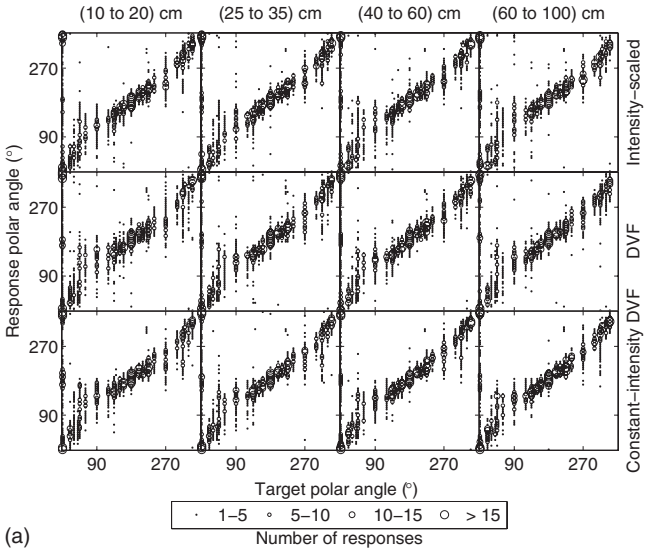

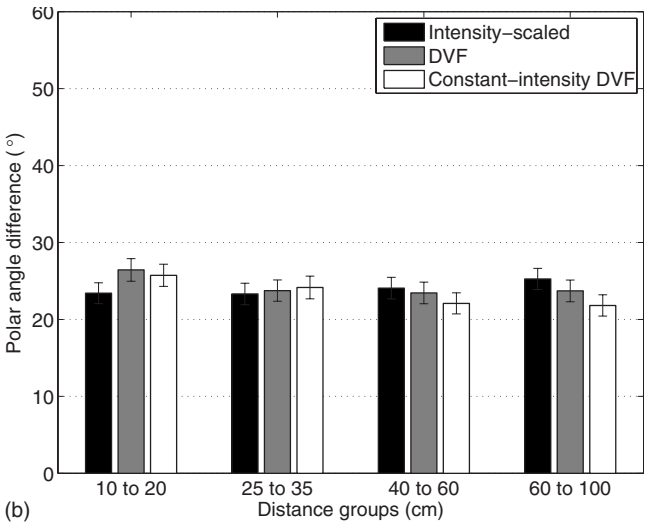

FIG. 5. (a) shows the directional localization results in terms of polar angle and (b) shows the mean absolute difference between the target and response polar angle. The data are shown in the same format as in Fig. 4.

The directional localization results in terms of polar angle are presented in Fig. 5(a), where the data are shown in a similar format as Fig. 4(a). The polar angles have been rounded to the nearest 10°. The data show that, in general, the polar angles of the responses were close to the target polar angles implying that there were no major polar angle localization errors in all stimulus conditions. Some of the localization differences between the target and response polar angles can be attributed to front-back confusions, where the lateral angle of the response is correct but the perceived direction is incorrectly placed in the wrong front-back hemisphere (Carlile *et al.*, 1997). In our analysis, a front-back confusion is identified when the response lateral angle is within 10° of the target lateral angle but the response is located in the wrong front-back hemisphere. The percentage of front-back errors for the different stimulus conditions are shown in Fig. 6. In all conditions, the percentage of front-back errors are of a similar order as free-field sound localization experiments using a head-pointing response paradigm reported elsewhere (Carlile *et al.*, 1997). The mean absolute difference between the target and response polar angle in each distance range for the three stimulus conditions is shown in Fig. 5(b), where front-back confusions have been removed. There are statistically significant increases in the

TABLE I. The results of a Kruskal–Wallis non-parametric ANOVA conducted on the absolute lateral angle differences across the distance ranges are shown for each stimulus condition. The table shows the χ^2, degrees of freedom (dof) and p-values. A *post hoc* analysis (Tukey HSD) revealed a statistically significant difference in localization performance between the 10–20 cm distance range and the other distance ranges in all stimulus conditions. The index measuring the size of this effect, d, is also shown in the table, and is small for all conditions.

Stimulus condition	χ^2	dof	p	d
Intensity-scaled	8.53	3	0.04	0.02
DVF	28.93	3	<0.005	0.08
Constant-intensity DVF	20.76	3	<0.005	0.06

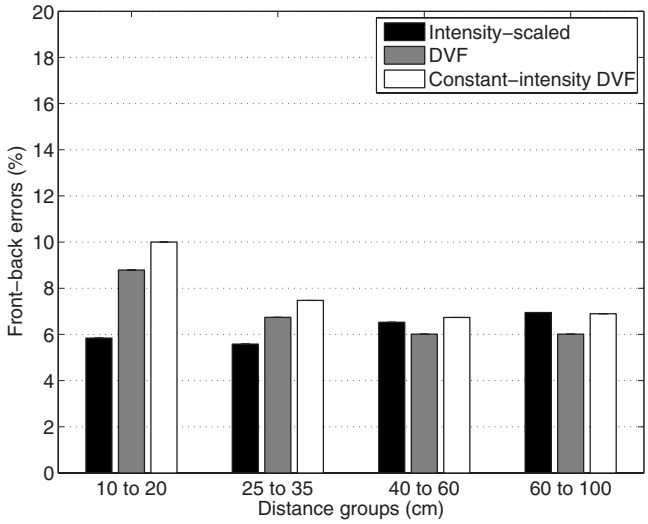

FIG. 6. The percentage front-back errors for the three stimulus conditions. The data are shown in the same format as in Fig. 4(b).

absolute polar angle difference between the target and response angle in the 10–20 cm distance range compared to the other distance ranges for the two DVF-generated stimulus conditions and in the 60–100 cm distance range for the constant-intensity stimulus condition though the effect is small (Table II). Comparing across the stimulus conditions, there are statistically significant differences in absolute polar angle localization performance at the different distance ranges but again the effect is small (Table III).

B. Distance perception

The perceived distances for the three stimulus conditions are shown in Fig. 7. Distances have been rounded to the nearest 5 cm. The data for both the left and right-hand sides have been grouped and divided into one of three azimuth regions shown in each column: front (0°–60°), side (60°–120°), and back (120°–180°), where 0° is directly in front. Each row shows the data for each stimulus condition. In all conditions, the localization data show a high degree of overestimation of the intended distance of the sound source indicated by the responses above the dashed line which indicates the theoretical responses for accurate distance perception. The mean perceived distance for all stimulus conditions separated into different distance ranges and azimuth regions

TABLE II. The results of a Kruskal–Wallis non-parametric ANOVA conducted on the absolute polar angle differences across the distance ranges are shown for each stimulus condition. The table shows the χ^2, dof and p-values. A *post hoc* analysis (Tukey HSD) revealed a statistically significant difference in localization performance in the 10–20 cm distance range compared to the other distance ranges for the two DVF-generated stimulus conditions and in the 60–100 cm distance range for the constant-intensity stimulus condition. The index measuring the size of these effects, d, is also shown in the table, and is small for all conditions.

Stimulus condition	χ^2	dof	p	d
Intensity-scaled	25.33	3	<0.005	0.02
DVF	27.28	3	<0.005	0.06
Constant-intensity DVF	58.01	3	<0.005	0.09

TABLE III. The results of a Kruskal–Wallis non-parametric one-way ANOVA conducted on the absolute polar angle differences across the stimulus conditions are shown for each distance range. The table shows the χ^2, dof and p-values. A *post hoc* analysis (Tukey HSD) revealed a statistically significant difference in localization performance between the constant-intensity stimulus condition and the DVF-generated stimulus conditions. The index measuring the size of these effects, d, is also shown in the table, and is small for all conditions.

Distance range	χ^2	dof	p	d
10–20 cm	7.84	2	0.02	0.05
25–35 cm	0.03	2	0.099	na
40–60 cm	11.74	2	<0.005	0.04
60–100 cm	49.53	2	<0.005	0.07

is shown in Fig. 8(a). In the intensity-scaled and DVF-generated stimulus conditions, the mean perceived distance follows the expected trend; that is, at the further distance ranges the mean perceived distance was larger than the closer distance ranges. However, the mean perceived distance is generally outside the intended distance range. In the constant-intensity DVF-generated stimulus condition, the mean perceived distance only fits the expected trend when the stimulus was located toward the side region. In the front and back regions, subjects generally perceived the stimulus as being at 50 and 65 cm, respectively, for all target distance ranges. From Fig. 7, it can also be seen that subjects exhibited a high amount of variability in perceived distance accuracy indicated by the spread of responses. The mean difference between the target and response distance for the different distance ranges and azimuth groups is shown in Fig. 8(b), where a positive difference indicates overestimation of the simulated distance. It can be seen that in all conditions subjects tended to overestimate the intended sound source distance when the stimulus was within 60 cm with slightly

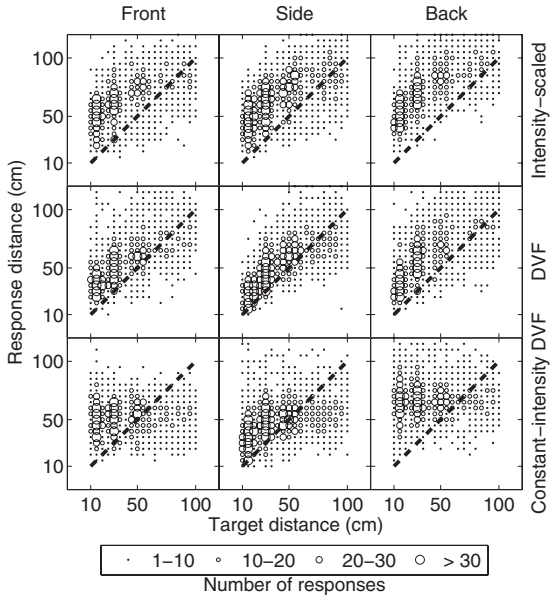

FIG. 7. The perceived distances are shown for the three stimulus conditions. Each column shows the data for one of three azimuth regions defined as front (0°–60°), side (60°–120°), and back (120°–180°), where 0° is directly in front. Each row shows the data for each stimulus condition. The dashed line indicates the theoretical responses for accurate distance perception.

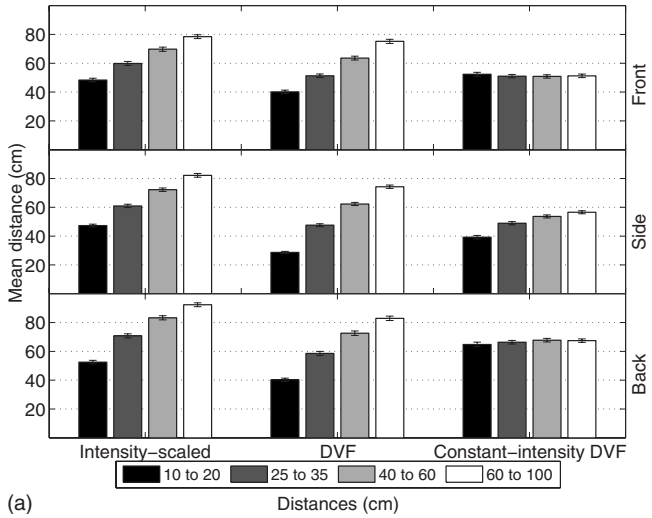

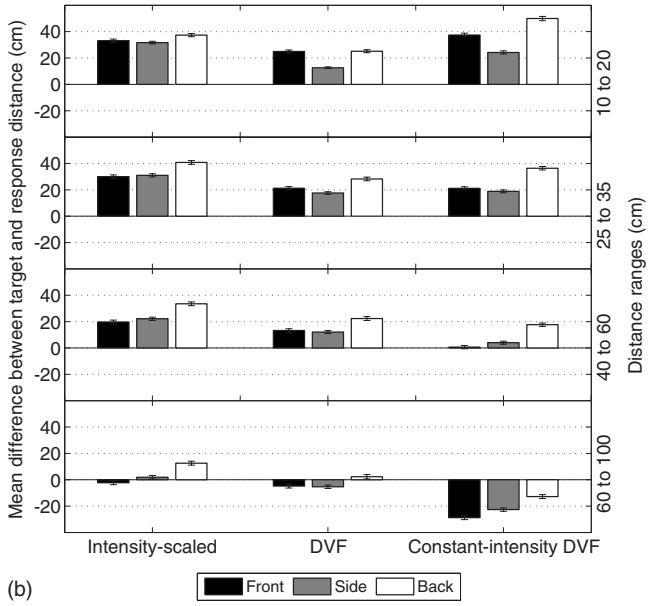

FIG. 8. (a) shows the mean perceived distance of each distance range for the three stimulus conditions. (b) shows the mean difference between the target and response distance, where the bars are grouped into the different azimuth regions and the results for the three stimulus conditions are shown within each group. The error bars indicate the 95% confidence interval of the mean.

greater overestimation occurring in the back region. The larger localization differences in the back region are probably due to the awkwardness of indicating perceived distances around the pole supporting the magnetic field transmitter of the sensor system, as well as the fact that the subject needs to turn his whole body first before indicating the perceived sound source location. Comparing the data for the front and side regions only, there is a statistically significant improvement in distance localization accuracy for sounds located to the side within 40 cm in the DVF-generated stimulus condition $[\chi^2(1,2650)=234.56,\ p<0.005]$, while there is no statistically significant improvement in the intensity-scaled stimulus condition in the same region $[\chi^2(1,2650)=0.84,\ p=0.36]$. In the constant-intensity DVF-generated stimulus condition, there is a statistically significant improvement in distance localization accuracy for sounds located to the side within the 10–20 cm distance range $[\chi^2(1,2650)=198.59,\ p<0.005]$. Comparing the DVF-generated stimulus condition and the intensity-scaled stimulus condition in Fig. 8(b), there is a noticeable improvement in distance perception for the DVF-generated stimulus condition for all azimuth regions when the sound source is located within 60 cm and calculation of the effect size index showed this improvement to be moderately large ($d=0.41$). The largest improvement in distance perception is in the side region within 40 cm of the subject ($d=0.61$).

IV. DISCUSSION

We conducted a psychoacoustic experiment to investigate the perceptual fidelity of near-field VAS generated using near-field HRTFs synthesized using the DVF method compared to that generated by simply scaling the intensity of the sound stimulus. A comparison of the distance perception from the DVF-generated stimulus condition and the intensity-scaled condition shows a statistically significant difference in localization performance in the side region between 60° and 120° and within 40 cm of the subject. In this region, subjects exhibited substantial overestimation of the sound source distance when intensity-scaled stimuli were used (on average, 35 cm from the intended sound source distance) compared to less than an average of 25 cm for the DVF-generated stimulus condition. This indicates that simply adjusting the intensity of the stimulus may not be enough to indicate to subjects that the sound stimulus is intended to be within 40 cm. Also, calculation of the effect size index showed that the improvement in distance perception using the DVF-generated stimulus over the intensity-scaled stimulus is large. The improvement in distance perception can be understood by studying the ILD introduced by the DVF. The ILD is calculated by taking the difference (in decibels) between the left and right DVFs for a particular sound source position. The magnitude of the ILD introduced by the DVF is shown as contour plots for different frequencies in Fig. 9. The DVF was calculated for a rigid sphere of 7 cm radius with "ears" located at ±100° azimuth from the mid-sagittal plane on the audio-visual horizon. Within each plot, the horizontal axis shows the distance between the sound source and the center of the head (on a logarithmic scale) and the vertical axis shows the lateral angle of the sound source. Areas of approximately equal ILD magnitude are indicated by color. A comparison of the ILD in the area of improved distance perception using the DVF-generated stimulus with that outside this region shows that the ILDs are greatest in the area between 60° and 120° within a distance of about 40 cm. Outside of this region, the ILDs are smaller. Hence, it would appear that the improvement in distance localization performance is related to the ILD introduced by the DVF. This ILD should approximate the true ILD of the near-field HRTF since the size of the rigid sphere used to calculate the DVF is similar in size to the subject's head.

In the case where intensity was removed as a cue for distance in the constant-intensity DVF-generated stimulus condition, it was observed that there was some distance discrimination in the side region and within the 10–20 cm distance range, though performance was poor. It would appear

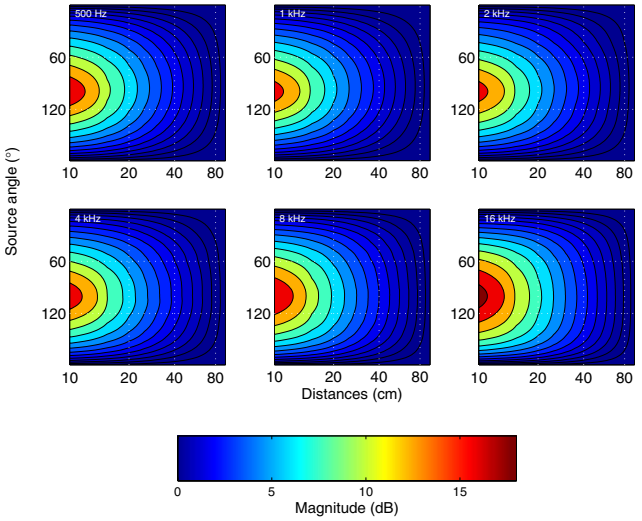

FIG. 9. (Color online) The ILD introduced by the DVF as a function of sound source distance and lateral angle is shown as contour plots for different frequencies. Distances are shown on a logarithmic scale. The ILD is calculated as the difference (in dB) between the left and right DVFs for a particular sound source position. The DVF was calculated for a rigid sphere of 7 cm radius with ears located at ±100° azimuth from the mid-sagittal plane on the audio-visual horizon. Color is used to indicate areas of approximately equal magnitude in the ILD.

that the ILD introduced by the DVF provides some cue for absolute distance discrimination but is not strongly salient. Hence, in using the DVF method to synthesize near-field HRTFs for generating VAS, the combination of intensity cues and ILD cues seem to be important for better distance perception.

Although there is an improvement in distance perception in the DVF-generated stimulus condition compared to the intensity-scaled stimulus condition, there is still a high degree of overestimation of the distance and variability for all subjects. However, a recent summary of human distance perception research by Zahorik *et al.* (2005) shows that it is quite common for listener's to underestimate distance of far-field sources and overestimate the distance of near-field sounds. They also show that there is often high variability in judgments of sound source distance. Hence, it is difficult to determine whether the overestimation and variability in distance perception are due to the generated VAS or due to the generally poor distance discrimination by humans.

It is also important to ensure that directional localization accuracy is not degraded by the synthesized near-field stimulus. In all conditions, there was a statistically significant difference in the mean difference between the target and response lateral and polar angles for different distance ranges. In particular, there was a statistically significant increase in the lateral and polar angle differences at the 10–20 cm distance range. However, calculation of the effect size index showed the effect of the differences in directional localization performance between the different distance ranges to be small for all conditions. It can be expected that directional localization errors would increase with decreasing sound source distance since a small error in the placement of the electromagnetic sensor to indicate the perceived location will translate into a larger angular difference at a close distance compared to a farther distance.

The advantage of the DVF technique is that it avoids the technical difficulties associated with measuring near-field HRIRs on human subjects which has hindered the development of high fidelity near-field VAS. There have been some other methods presented in the literature for generating near-field VAS without having to measure near-field HRIRs on human subjects. Martens and Yoshida (2000) presented a method for synthesizing near-field VAS using an approximation of the rigid sphere model. In their work a number of signal processing steps are applied to the stimulus to synthesize a sound source in the near-field. First, the ITD for the contralateral ear signal is adjusted for the intended near-field distance. Second, attenuation due to distance is applied to both the signals for both ears equally and an additional attenuation is applied to the contralateral ear signal to mimic the ILD in the near-field. Finally, a single-pole, single-zero filter that approximated the response of a rigid sphere is applied to model the frequency-dependent acoustical response of the head. Their method is based on the results of a simple psychoacoustic experiment that showed that the perceived distance of speech stimuli could be changed by manipulation of the ILD. However, the accuracy of the distance localization of the stimuli was not directly examined. It is also unclear whether directional localization accuracy would be affected by such adjustment of the ILD. The advantage of the DVF method over the method proposed by Martens and Yoshida (2000) is that the DVF is able to account for the ILD for sounds in the near-field, as well as low-frequency parallax effects of the HRTF. Since a human head and a rigid sphere of the same size have a similar low-frequency response, the DVF calculated from the rigid sphere model describes the change in the low frequencies of the HRTF as the sound source distance is changed from the far-field to the near-field. However, the DVF is unable to account for high-frequency parallax effects since pinnae are not modeled by the rigid sphere model. Although Møller *et al.* (1995) and Kim *et al.* (2001) suggested that it is possible to simulate a source in the near-field by choosing the appropriate far-field HRTF according to a simple parallax model, it is unclear that the high-frequency spectra of the HRTFs indeed do change in a manner that follows the simple parallax model they have presented and whether directional localization accuracy will be affected.

Brungart and Simpson (2001) conducted a psychoacoustic experiment to evaluate human sound localization performance of near-field VAS generated using near-field HRIRs measured on an acoustic manikin. They found that, in general, listener's could discriminate sound source distance but directional localization performance was not as accurate as that of nearby sounds in the free-field. This is not surprising since Wenzel *et al.* (1993) had previously shown that virtual sound stimuli generated using HRIRs recorded on a subject's own ears caused less directional localization errors than that generated using HRIRs measured on another person or a manikin. Brungart and Simpson (2001) investigation highlights the need for HRIRs measured on the subject for the generation of high fidelity near-field VAS. In our work, HR-

IRs measured on the individual subjects have been used to synthesize the near-field HRIRs and directional localization is preserved.

Duraiswami *et al.* (2004) presented a method for synthesizing near-field HRIRs from HRIRs measured in the far-field. By representing each measured HRTF as a series of multipole solutions to the Helmholtz wave equation and solving for the coefficients of the multipole solutions simultaneously, the HRTFs for any direction and distance from the head can theoretically be evaluated from the obtained coefficients. The major drawback of this technique is that close to 2000 far-field HRIRs need to be measured to accurately evaluate HRTFs up to 16 kHz. In our work, we have synthesized near-field HRIRs from far-field HRIRs measured on the subject using a rigid sphere model with the same radius as the head of the subject. Our method does not increase the number of far-field HRIRs that need to be measured to generate the near-field VAS.

V. CONCLUSION

We have presented a method for synthesizing near-field HRTFs using a rigid sphere model of the human head by calculating a DVF. The DVF approximates the ILD cues of the HRTF as a function of sound source distance. Using this method, the technical difficulties associated with measuring near-field HRTFs on human subjects are avoided. A human sound localization experiment was conducted to test the perceptual fidelity of the near-field VAS generated by this method as well as VAS generated by simply adjusting the intensity of the stimulus. Results show improved distance perception for sounds at simulated distances of up to 60 cm using the DVF compared to simple intensity adjustment, while maintaining directional accuracy, with the largest improvements for sound sources located to the side and within 40 cm. When intensity cues are removed from the DVF-generated stimulus, results still showed some discrimination of sound source distance but distance perception accuracy was poor.

(Received 29 September 2008; revised 27 January 2009; accepted 28 January 2009)

Wind noise can be a significant problem for hearing instrument users. This study examined the polar characteristics of flow noise at outputs of two behind-the-ear digital hearing aids, and a microphone mounted on the surface of a cylinder at flow velocities ranging from a gentle breeze (4.5 m/s) to a strong gale (22.5 m/s) . The hearing aids were programed in an anechoic chamber, and tested in a quiet wind tunnel for flow noise recordings. Flow noise levels were estimated by normalizing the overall gain of the hearing aids to 0 dB. The results indicated that the two hearing aids had similar flow noise characteristics: The noise level was generally the lowest when the microphone faced upstream, higher when the microphone faced downstream, and the highest for frontal and rearward incidence angles. Directional microphones often generated higher *flow* noise level than omnidirectional microphones but they could reduce far-field background noise, resulting in a lower *ambient* noise level than omnidirectional microphones. Data for the academic microphone-on-cylinder configuration suggested that both turbulence and flow impingement might have contributed to the generation of flow noise in the hearing aids. Clinical and engineering design applications are discussed. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3086268]

I. INTRODUCTION

Wind noise can be an annoyance for hearing instrument users, especially for those who enjoy outdoor activities. Excessive wind noise often results in complaints of poor sound quality and/or inability to communicate. A hearing instrument's ability to manage wind noise is reported to affect the satisfaction and the frequency of instrument usage (Kochkin, 2000, 2005).

Although wind noise has been a significant problem, there are only few reports on the characteristics and the management of wind noise in literature. Grenner *et al.* (2000) measured the level and spectra of wind noise at the output of four behind-the-ear hearing aids at 0° at a velocity of 7.0 m/s. They reported that wind noise had the highest amplitude at low frequencies, and that its characteristics differed among hearing aids. Thompson and Dillon (2002) measured the wind noise at the outputs of directional and omnidirectional microphones mounted on different styles of hearing aids and worn in the ears of a Knowles Electronic Mannequin for Acoustic Research (KEMAR) (Burkhard and Sachs, 1975). They concluded that directional microphones are, in general, noisier than omnidirectional microphones, and that wind noise is relatively lower at head angles of +90° and −90°.

Beard and Nepomuceno (2001) measured wind noise of an omnidirectional microphone and two directional microphones mounted on the faceplate of an in-the-ear hearing aid worn on a KEMAR in a wind tunnel. They also reported that directional microphones yielded higher wind noise levels. These studies, however, were limited to relatively low velocities (i.e., 5 m/s in Thompson and Dillon, 2002; and 2.1 and 5 m/s in Beard and Nepomuceno, 2001). Furthermore, no detailed analysis of the polar, spectral, or temporal characteristics of wind noise was reported.

The characteristics of wind noise in hearing aids can be affected by many factors such as venting, case/shell design, microphone location, signal processing algorithms, frequency response of the hearing aid, and wind velocity. In order to examine the cumulative effects of these factors on the characteristics of wind noise in users' ear canals, wind noise was recorded at the outputs of two commercially available behind-the-ear digital hearing aids. The goals were to investigate the effects of head angle and microphone type at three wind velocities [i.e., from a gentle (4.5 m/s) to a strong breeze (13.5 m/s)] and to examine the similarities and differences between the two behind-the-ear hearing aids. Measurements were also made on one of the hearing aids at higher wind velocities, ranging from a fresh gale (18.0 m/s) to a

c)Electronic mail: nick.mckibben@gmail.com

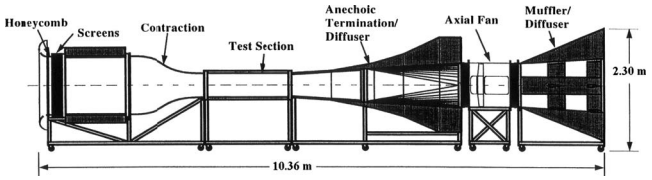

FIG. 1. Schematic of the wind tunnel.

strong gale (22.5 m/s). Additionally, as the aerodynamic pattern of a flow passing a cylindrical body is a well studied phenomenon, the wind noise recorded by a microphone mounted on the surface of a rigid cylinder was investigated to shed light on factors contributing to the generation of wind noise in hearing aids.

Note that "wind" normally refers to atmospheric air motion. The term "flow" is used hereafter to refer to the air flow generated in the wind tunnel. This is the first of a series of studies to examine the polar, spectral, and temporal characteristics of wind noise in hearing aids with directional and omnidirectional microphones.

II. METHODS

Each digital hearing aid was programed in an anechoic chamber when worn on KEMAR's right ear. The hearing aid and the KEMAR head were then transported to an acoustically treated wind tunnel located in a nearby facility. The noise at the hearing aid output was recorded for head angles from 0° to 360° in 10° increments. Measurements were made in the absence of a flow and at three flow velocities with the hearing aid programed to directional (DIR) and omnidirectional (OMNI) microphone modes. The KEMAR head was then transported back to the anechoic chamber and the hearing aid output in response to a 75 dB SPL pink noise was recorded with identical equipment and volume control settings as the wind tunnel measurements. This recorded noise was later used as the reference to estimate flow noise levels.

A. Wind tunnel characteristics

1. Construction

Figure 1 shows a simplified schematic of the wind tunnel. The Eiffel type wind tunnel had a closed, rectangular test section. A variable speed axial flow fan located downstream of the test section generated the flow. The Plexiglas test section walls were approximately 52.7 cm wide × 60.3 cm high × 121.9 cm long. A wire mesh screen was installed at the end of the test section to protect the fan against any debris.

Several wind tunnel features were designed to ensure a uniform flow in the test section: (1) a honeycomb flow straightener at the wind tunnel inlet, (2) several layers of wire mesh to break down large flow structures into fine-grained flow, and (3) a smooth contraction section to gradually accelerate the flow into the test section, ensuring a uniform velocity profile with thin boundary layers. The flow velocity uniformity at the entrance of the test section was within 1%, with velocity fluctuations less than approximately 3%. Two progressive diffuser sections were located downstream of the fan to minimize flow resistance and ensure a stable flow (Brown and Mongeau, 1995).

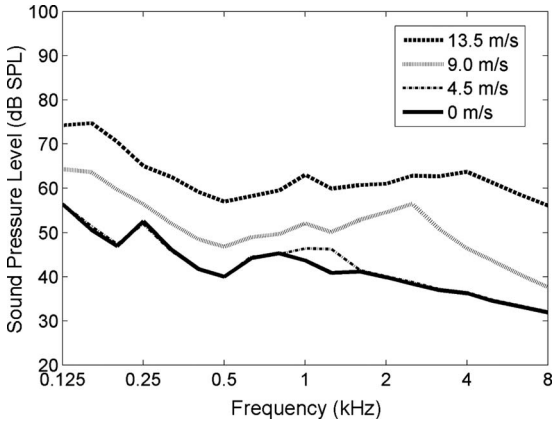

FIG. 2. One-third octave band ambient noise in the wind tunnel with no flow (0 m/s) and at three flow velocities. The flow noise was measured using a microphone with 1.27 cm diameter covered by an elliptical windscreen.

The wind tunnel was also treated to reduce acoustic noise in the test section. The inlet and diffuser sections were lined with sound absorbing materials in order to minimize acoustic noise from the fan and other aerodynamic noise sources. An additional muffler/diffuser was also implemented downstream of the axial fan section to reduce motor/fan noise and to reduce the noise in the surrounding area entering the wind tunnel. The ambient noise floor of the wind tunnel was measured using a microphone with 1.27 cm diameter (ER-11 in. microphone, Etymotic Research), which was protected with an ellipsoidal windscreen (B&K UA 0781). The ambient tunnel noise levels at 0, 4.5, 9.0, and 13.5 m/s were measured when the microphone was located approximately 30 cm upstream of the KEMAR head. The spectra of the ambient noise analyzed in one-third octave bands from 125 to 8000 Hz are shown in Fig. 2. Other details of the wind tunnel construction and flow characteristics are available in Brown and Mongeau (1995).

2. Flow velocity calibration

The flow velocity was altered by changing the fan rotational speed, and measured by using a Pitot tube. The Pitot tube was placed approximately 30 cm upstream from the location of the KEMAR head in the test section. The Pitot tube data were collected at fan speeds from 8.5 to 24.5 Hz in 4 Hz increments. Since fan speed and flow velocity data were linearly related, the desired fan speeds for target flow velocities were calculated using a linear regression equation. The fan speeds were determined to be 10.3, 19.3, and 28.2 Hz in order to obtain flow velocities of 4.5, 9.0, and 13.5 m/s, respectively. These velocities are equivalent to 10.0, 20.1, and 30.1 miles/hour, respectively. The Pitot tube was removed during flow noise measurements to reduce vortex shedding noise. These flow velocities yielded ratings of 3 (gentle breeze), 5 (fresh breeze), and 6 (strong breeze) on the 13-point Beaufort scale, respectively. The lowest flow velocity was estimated to be the average wind velocity on a normal non-windy day in the United States (National Climate

Data Center, 2006a). The highest wind velocity is the threshold for the National Weather Service to issue a wind advisory (National Climate Data Center, 2006b).

B. Hearing aid characteristics

Two behind-the-ear digital hearing aids were used, designated as BTE1 and BTE2. BTE1 had 14 signal processing channels and BTE2 had 16 channels, and they were made by two different manufacturers. Both hearing aids were worn on KEMAR's large pinnae on the right side and their outputs were coupled into KEMAR's ear canal via a No. 13 tubing (inner diameter of 1.9 mm) and an unvented skeleton earmold. Neither hearing aid had wind noise detection or a signal processing algorithm to manage wind noise.

1. Microphones

The directional microphones of both hearing aids had non-adaptive polar patterns and they utilized a dual microphone design in which the outputs of two omnidirectional microphones were processed to form one directional microphone. Both manufacturers reported that the directional microphones had hypercardioid patterns when measured in free field (Chung, 2004). When programed to the OMNI mode, the front microphone was active and the back microphone was disabled for both hearing aids.

2. Signal processing characteristics

Typical digital hearing aids often have several algorithms/limiters that can affect the input-output functions of the hearing aids: (1) a broadband input limiter to limit the overall level of the input; (2) an expansion algorithm to reduce low level noise, typically microphone noise and/or circuit noise below 35 dB SPL; (3) a wide dynamic range compression (WDRC) algorithm that has a linear region at low input level (e.g., $<$45 dB SPL), a compression region at low to high input levels (e.g., 45–90 dB SPL), and an output limiting region at high input levels (e.g., $>$90 dB SPL); and (4) a broadband output limiting algorithm to limit the overall level of the hearing aid output. The broadband input limiter could be an algorithm to limit the input signal or simply the upper limit imposed by the digital chip of the hearing aid. In addition, the expansion and WDRC algorithms are typically implemented in each frequency channel (i.e., narrowband), whereas the broadband input and output limiters usually act on the overall/summed signal.

In this study, both hearing aids had the expansion and WDRC algorithms in multiple channels. The compression region of the WDRC algorithms was linear. BTE1 had a broadband automatic gain control *output* limiting algorithm, which reduced the gain of the overall signal by changing the instantaneous gain (e.g., if the overall level would exceed the predetermined level by 5 dB at any time, the algorithm would reduce the gain of the overall signal by 5 dB). BTE2 had a broadband *input* compression limiting algorithm with a compression ratio of 8:1 (i.e., a change of 8 dB in the incoming signal resulted in a change of 1 dB at the output). All other signal processing features, such as feedback suppression and noise reduction algorithms, were disabled in both hearing aids.

3. Frequency response programming

The hearing aids were programed to be linear with relatively flat frequency responses when worn on KEMAR (i.e., relatively flat real-ear aided frequency responses). Pink noise was played from computer 1 and then fed to a powered loudspeaker (Mackie HR824) in an anechoic chamber. The overall sound pressure level of the pink noise was 70 dB SPL measured 1 m from the loudspeaker using a Type I sound level meter (Quest Precision 1200). The Mackie loudspeaker had a flat frequency response from 39 to 20 000 Hz ($\pm$1.5 dB) and a maximum output of 100 dB SPL. The KEMAR head was placed on a tripod with the ears at the same height as the center of the loudspeaker diaphragm.

The hearing aid output was recorded using a microphone with 1.27 cm diameter (ER-11) placed in the medial opening of a Zwislocki coupler. The signal was then fed to an external sound card (Sound Blaster Extigy) and analyzed simultaneously using SPECTRAPLUS software (Pioneer Hill Software) in another computer (computer 2, Dell D600). One-third octave band levels for pink noise (i.e., equal levels from 1 to 8000 Hz) were displayed on the computer screen. The frequency response of the hearing aid was adjusted to match that of the pink noise as much as possible. Hearing aid adjustments were accomplished using the NOAH programming software (Himsa) via a HIPRO programming interface and computer 2. The NOAH software and HIPRO interface are platforms that can program hearing aids from multiple manufacturers.

For each hearing aid, the OMNI frequency response was programed first. The frequency response of DIR was then adjusted to be as close to that of OMNI as possible. The low-frequency region of DIR was compensated to offset the inherent first-order high-pass-filter effects of directional microphones. If a match in frequency response was not possible, the OMNI frequency response was adjusted again so that the frequency response disparity between OMNI and DIR of the same hearing aid or across the hearing aids was minimal. This match was intended to minimize the effects of frequency response on flow noise measurements so that the levels obtained could be compared without additional signal processing or level adjustment.

The frequency responses of BTE1 OMNI and DIR modes were matched within 2.2 dB in one-third octave bands from 100 to 8000 Hz and that of BTE2 were matched within 3.7 dB (Fig. 3). Notice that BTE2 OMNI had a relatively higher level than BTE2 DIR below 250 Hz and relatively lower level between 250 and 1000 Hz. This pattern had also been noticed in other hearing aids and the disparity could not be eliminated (i.e., reducing the gain of OMNI at the lowest frequency would reduce the difference below 250 Hz but increase the difference between 250 and 1000 Hz). Attempts to adjust the frequency response of BTE2 DIR produced similar results. The frequency responses shown in Fig. 3 were obtained from attempts to minimize the differences at 125 and 500 Hz. The disparity was treated as intrinsic differences between the two microphone modes in real-life hear-

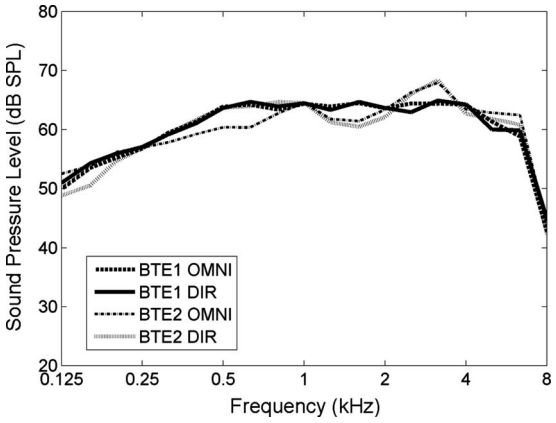

FIG. 3. Frequency responses of BTE1 and BTE2 in response to a 75 dB SPL pink noise presented at 0° azimuth in the anechoic chamber.

ing aid fitting and, therefore, no level adjustment was made in the flow noise level calculations. Overall, the differences between BTE1 and BTE2 for both OMNI and DIR were 3.7, 2.3, and 1.5 dB at 125, 500, and 2000 Hz one-third octave bands, respectively.

C. Flow noise measurements

After a hearing aid was programed in the anechoic chamber, the KEMAR head was transported to the wind tunnel for flow noise measurements. During transportation, the hearing aid was kept in KEMAR's ear and physical contact with other objects was avoided. This procedure ensured that the frequency responses used in the flow noise recordings were identical to those tested in the anechoic chamber.

1. BTE1 and BTE2

In the wind tunnel, the KEMAR head was mounted on a wooden rotating platform in the test section through a series of PVC pipe connections [Fig. 4(A)]. KEMAR's ears were placed at the center of the test section with respect to length, width, and height. The center reference notch on KEMAR's neck was set right above the 0° mark on the rotating platform, which was marked from 0° to 350° in 10° increments. A point equidistant to the side walls of the test section served as the reference for turning the KEMAR head. The angles reported in this study are variable head angles relative to a fixed flow direction.

The recording equipment used in flow noise measurements was identical to that used to program the hearing aid. To ensure optimal dynamic range, the maximum hearing aid overall output level was checked prior to flow noise recording. With the flow velocity at 13.5 m/s and the hearing aid set to DIR, the hearing aid output was monitored using ADOBE AUDITION 1.0 while the KEMAR head was rotated slowly from 0° to 360°. When the location corresponding to the highest flow noise output was identified, the recording level of the sound card was adjusted so that the hearing aid output peaked within 15 dB below the maximum amplitude level in AUDITION. This recording level was noted and maintained for all flow noise measurements.

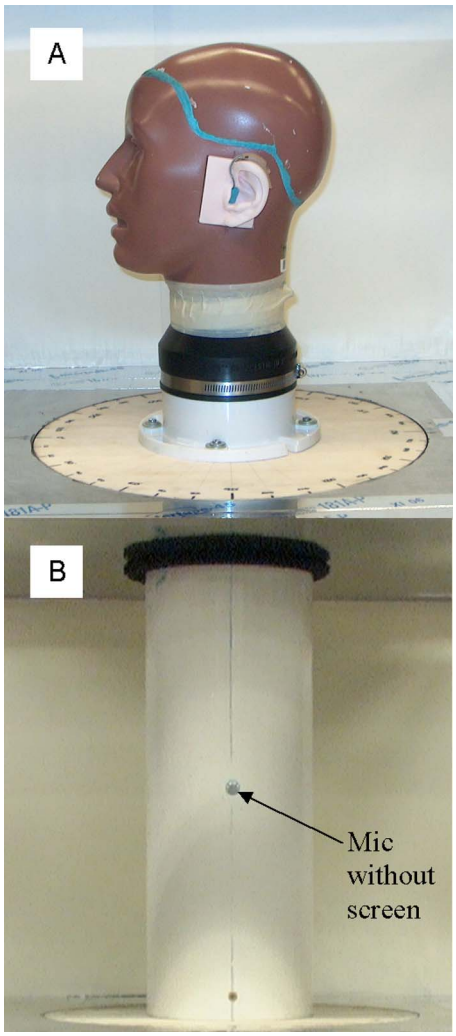

FIG. 4. (Color online) (A) KEMAR head on the rotating platform, and (B) a microphone mounted on a cylinder in the wind tunnel test section. (Note: Flow went from the left to right. A hearing aid worn on KEMAR's left ear and a microphone rotated to 270° are shown.)

Thirty-second recordings were made in 10° increments at four flow velocities, with the 0° angle repeated and recorded as 360° (i.e., 37 measurements per flow velocity). The hearing aid was later programed to OMNI and recordings were repeated for each flow velocity.

2. Repeatability and variability

Repeatability was verified by comparing the levels of consecutive recordings made using BTE2 DIR at each flow velocity, with identical equipment and hearing aid setup.

Variability was verified through repeated measurements using BTE1 OMNI at flow velocities of 4.5 and 13.5 m/s and BTE1 DIR at 0 and 9.0 m/s 14 days after the initial measurements. The hearing aid and earmold were taken off KEMAR's pinna and all the recording equipment was disassembled between the two measurements.

3. Left-right comparison

The flow noise at the outputs of BTE1 in DIR and OMNI modes was also recorded when BTE1 was worn on

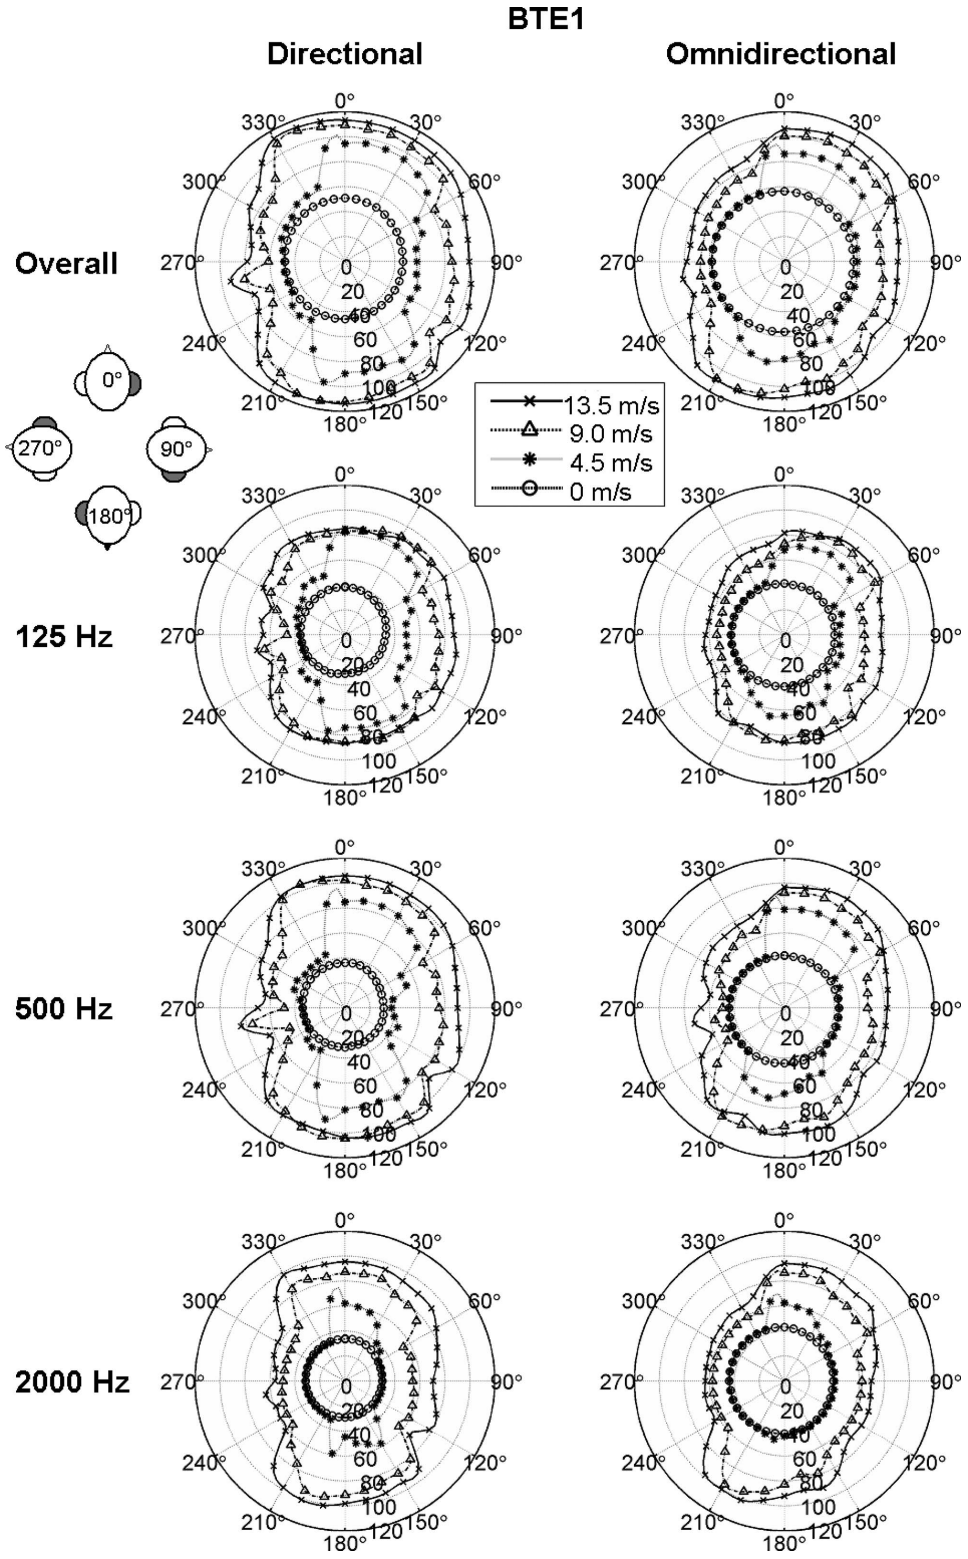

FIG. 5. Overall and one-third octave band levels of flow noise measured at the output of BTE1, which was set to the directional (DIR) and omnidirectional (OMNI) modes. The four aerial views of the KEMAR head with a darkened ear indicated the hearing aid locations when the head was turned at 0°, 90°, 180°, and 270°.

KEMAR's left ear (BTE1_Left). The frequency responses of BTE1_Left in DIR and OMNI modes matched those of BTE1 worn on KEMAR's right side within 1.9 dB from 100 to 6300 Hz, with most of the differences within 1 dB. The flow noise at the output of BTE1_Left was then compared with that of BTE1 in Fig. 5 in mirror images (i.e., flow noise at 60° and 90° recorded from BTE1 worn on the right was compared with the flow noise at 300° and 270° recorded from BTE1_Left, respectively).

Recordings were also made at 18.0 and 22.5 m/s (i.e., 40

and 50 miles/h, respectively) to examine the effects of the limiters in the hearing aid. The corresponding fan speeds were 37.2 and 46.1 Hz.

4. Flow around cylinder

The output of a 1.27 cm microphone (B&K 4936) mounted on a 15-cm diameter PVC cylinder was recorded at 0, 2.3, 4.5, 9.0, 13.5, and 18.5 m/s [Fig. 4(B)]. When the cylinder was set at 0° azimuth, the microphone was directly above the 90° mark on the platform (i.e., the microphone was on the right side of the cylinder). The microphone's protective grid was removed prior to mounting. The diaphragm of the microphone and the tack seal were flush with the surface of the cylinder. The microphone was located at the midspan of the cylinder, which extended over nearly the full height of the test section. Foam [black in Fig. 4(B)] was used to connect the top of the cylinder to the ceiling of the test section in order to ensure a good seal between the cylinder and the test section upper wall.

The microphone output was fed to a Quest Precision 1200 type I sound level meter via an angle-changing cable adaptor (B&K UA0122). Then the electrical output of the sound level meter was recorded using AUDITION. Other recording procedures were identical to those described above for hearing aids. The level range of the sound level meter was set to 70–140 dB SPL for recording flow noise at velocities of 4.5, 9.0, 13.5, and 18.5 m/s and to 30–100 dB SPL at flow velocities of 0 and 2.3 m/s.

D. Calibration of sound pressure levels

Immediately after each set of recordings was made, the KEMAR head and the recording equipment were transferred back to the anechoic chamber and a calibration noise was recorded.

1. Hearing aids

For each hearing aid, the output in response to a 75 dB SPL pink noise was recorded using identical hearing aid and recording equipment settings to those used in the wind tunnel recordings. This recorded noise served as the broadband 75 dB SPL calibration reference for the particular hearing aid. Adjustment of the hearing aid output in response to a 75 dB SPL pink noise input to 75 dB SPL essentially normalized the overall gain of the hearing aid to 0 dB, i.e., hearing aid output (assumed 75 dB SPL)=hearing aid input(75 dB SPL)+overall gain (0 dB).

This calibration procedure allowed the estimation of flow noise at the hearing aid input, and comparisons between flow noise levels among different hearing aids, but the estimated level depends on the frequency response of the hearing aid and on the gain at the particular frequency region. This disadvantage, however, was overcome by matching the frequency response described in the Hearing Aid Fitting section.

2. Flow around cylinder

The microphone was dismounted from the cylinder after making the flow noise measurements. Then the electrical output of the sound level meter in response to a 1000 Hz calibration tone at 94 dB SPL generated by a calibrator (Quest 211A) was recorded. The levels of this tone at the input ranges of 30–100 and 70–140 dB SPL served as the 94 dB references for the recordings made at the corresponding input ranges.

E. Data analysis

The overall and one-third octave band levels from 100 to 8000 Hz of the flow noise recordings were analyzed using MATLAB. The correlation coefficients and average differences between the levels in different data sets were analyzed. Correlation coefficients were used to infer similarities between the hearing aids' microphone sensitivity to flow noise at different head angles. They were calculated using the directivity data from 0° to 350°. High correlation coefficients suggested that flow noise levels in the two data sets rise and fall at corresponding head angles, although their magnitude might differ by a relatively constant number.

Average differences were calculated by subtracting the levels of one data set from the corresponding levels at the same head angles of another data set, taking the absolute values of the differences, and then calculating the mean of the differences. The average differences calculated using the absolute values of the differences were generally higher than simple differences because they treated levels lower or higher than the reference (i.e., negative and positive differences, respectively) as variations in the measurements.

In general, a high correlation coefficient with low average differences indicated that the polar patterns of the two data sets had similar trends/polar shapes and levels. A high correlation coefficient with high average differences indicated that the polar patterns of the two data sets had similar trends/shapes but their levels differed by an amount close to the average difference. A low correlation coefficient indicated that either the shapes of the polar patterns were grossly different or the levels in one data set were sometimes greater than the other set and other times vice versa.

III. RESULTS

The 125, 500, and 2000 Hz one-third octave band levels are reported along with overall levels to represent flow noise levels at very-low-, low-, and high-frequency regions, respectively. Note that the limiters in the hearing aid made the polar pattern look circular at high velocities, especially at frontal or rearward incidences. The actual level at the microphone output could be much higher.

Angles are reported in clockwise direction and the polar patterns are divided into four quadrants by ±45° oblique lines. Frontal incidence refers to angles between 320° and 40°, rearward incidence refers to angles between 130° and 220°, and right- or left-lateral incidence refers to angles between 230° and 310° or between 50° and 120°, respectively. In addition, hearing aid facing upstream generally refers to the angles between 230° and 310° when the hearing aid was worn on the right ear and angles between 50° and 120° when the hearing aid was on the left ear, and vice versa for hearing aid facing downstream.

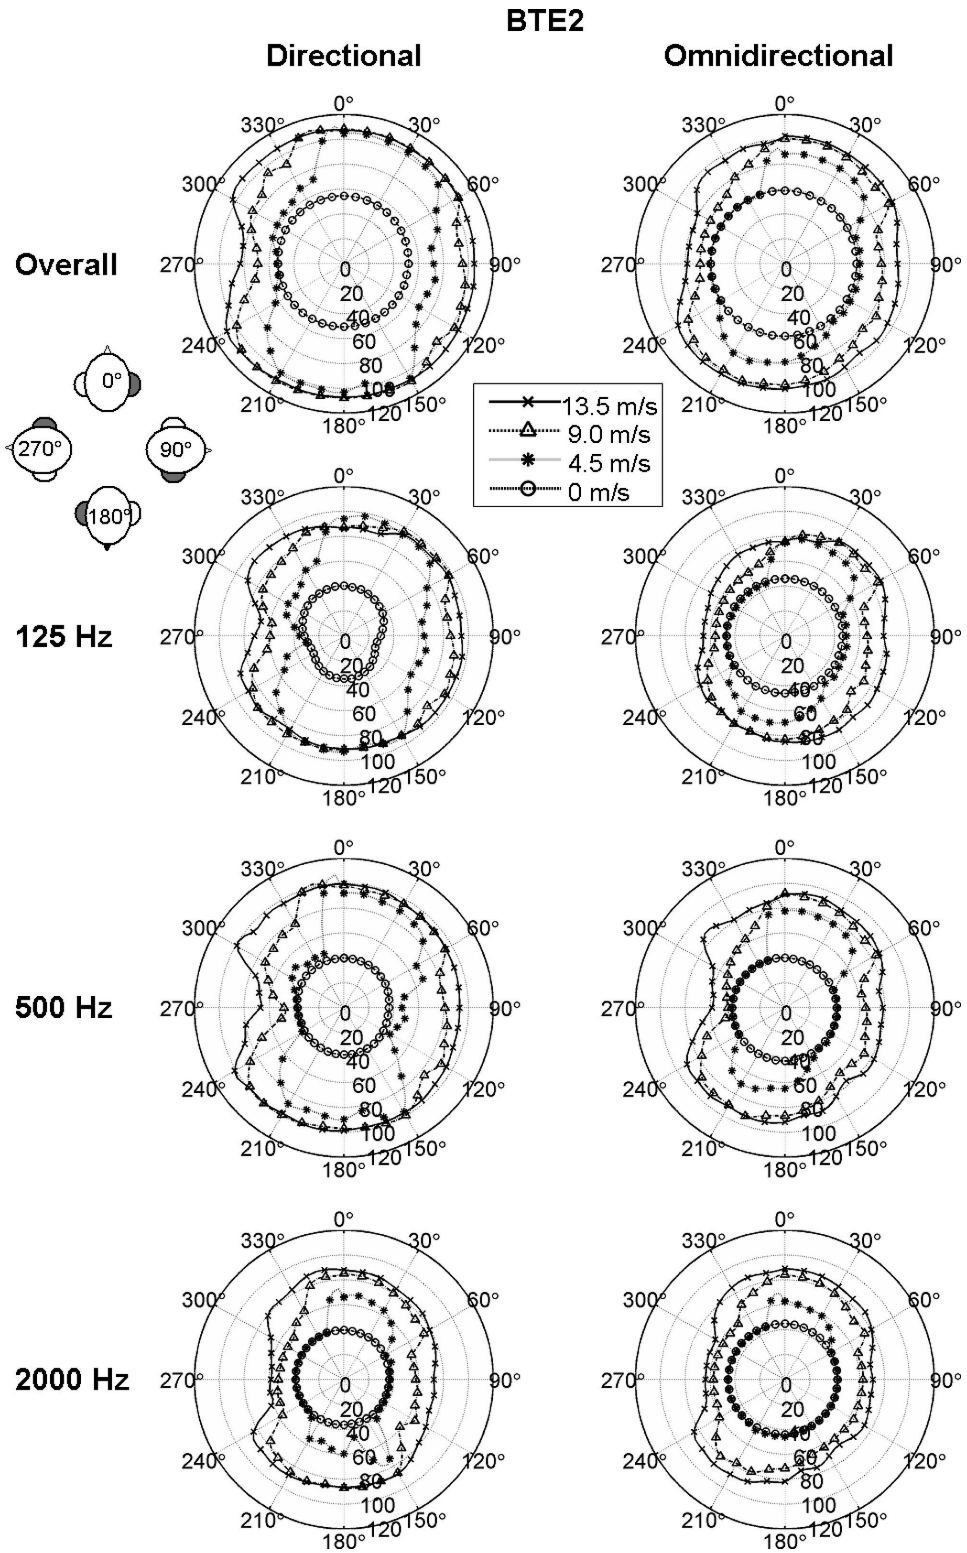

FIG. 6. Overall and one-third octave band levels of flow noise measured at the output of BTE2, which was set to the directional (DIR) and omnidirectional (OMNI) modes.

A. Flow noise responses

Figures 5 and 6 show the polar patterns of the noise levels at the outputs of BTE1 and BTE2 when both were worn on the right ear. Similar maximum values over several angles (e.g., BTE1 OMNI between 0° and 50° at 13.5 m/s in the overall level plot in Fig. 5) indicate that the hearing aid output has reached its maximum level as imposed by the input and/or output limiters in the signal path. Additionally, if the noise levels at 4.5 m/s were similar to those in the absence of a flow (i.e., ambient noise level at 0 m/s), it is likely that the flow noise was below the ambient noise level at this angle.

TABLE I. The correlation coefficients and average differences between BTE1 and BTE2 at three flow velocities when both hearing aids were worn on KEMAR's right ear. All correlation coefficients were statistically significant. The asterisks (*) mark the entries calculated from data set when overall levels reached the maximum output levels at least at three angles and the carets ($^\wedge$) mark the entries calculated from data set when flow noise levels fell below the ambient noise levels at least at three angles.

	Correlation coefficient			Average difference (dB)		
	4.5 m/s	9.0 m/s	13.5 m/s	4.5 m/s	9.0 m/s	13.5 m/s
			Overall level			
DIR	0.87$^\wedge$	0.78*	0.71*	12.6$^\wedge$	8.4*	6.7*
OMNI	0.93$^\wedge$	0.89	0.83*	2.8$^\wedge$	4.2	5.4*
			125 Hz third octave band level			
DIR	0.88$^\wedge$	0.84*	0.76*	14.5$^\wedge$	9.7*	6.7*
OMNI	0.92$^\wedge$	0.92	0.90*	5.3$^\wedge$	3.5	3.3*
			500 Hz third octave band level			
DIR	0.87$^\wedge$	0.75*	0.66*	9.2$^\wedge$	8.0*	7.1*
OMNI	0.93$^\wedge$	0.87	0.76*	3.9$^\wedge$	6.4	7.1*
			2000 Hz third octave band level			
DIR	0.88$^\wedge$	0.88*	0.81*	8.7$^\wedge$	5.2*	7.6*
OMNI	0.95$^\wedge$	0.82	0.72*	1.9$^\wedge$	4.2	6.9*

Table I summarizes the correlation coefficients and average differences between the two hearing aids. Coefficients calculated with levels below the ambient noise levels are marked with a #. Coefficients for which either or both hearing aids reached their maximum output level at more than three angles are marked with an *. All the correlation coefficients reported were statistically significant at $p < 0.01$ ($df = 34$).

Before the levels reached the maximum output levels (i.e., DIR at 4.5 m/s and OMNI at 4.5 and 9.0 m/s), the correlation coefficients between BTE1 and BTE2 were generally very high for corresponding microphone modes (between 0.82 and 0.95). This indicated similar BTE1 and BTE2 polar patterns, even though the flow noise fell below the ambient noise levels at some angles. The correlation coefficients for polar patterns calculated with data reaching the maximum output levels were somewhat lower (between 0.66 and 0.88). DIR at 13.5 m/s was generally the lowest, which was likely because the overall levels of BTE2 were limited to the same values at most angles but those of BTE1 showed level variations.

The average differences between BTE1 and BTE2 OMNI were between 1.9 and 7.1 dB, which were generally lower than the average difference between DIR (i.e., 5.2–14.5 dB), suggesting that DIR of different hearing aids had higher level variations than OMNI in wind noise.

1. Similarities between BTE1 and BTE2

In general, BTE1 and BTE2 polar patterns were similar (Figs. 5 and 6), which suggests that the two hearing aids were subjected to similar aerodynamic conditions due to similar microphone locations. Specifically, we observe the following:

(i) The polar patterns of the ambient tunnel noise levels at 0 m/s looked circular except that of BTE2 DIR at 125 Hz.

(ii) At high flow velocities, the flow noise level reached the maximum output level of the hearing aids (i.e., BTE1 DIR=114 dB, OMNI=109 dB; and BTE2 DIR=108 dB, OMNI=102 dB).

(iii) The flow noise levels were generally the lowest when the hearing aids were facing upstream. The flow noise levels at 4.5 m/s could drop below the ambient tunnel noise levels at 0 m/s at these angles.

(iv) The flow noise levels were generally the highest for frontal or rearward incidences. They were the highest between 350° and 60° and between 160° and 220° at 4.5 m/s. The difference between the lowest and highest overall levels within one 360° run could be as high as 53 dB (i.e., BTE2 DIR at 10 m/s). As the flow velocity increased, the flow noise level increased and the angles with high flow noise levels also broadened (e.g., the overall level of BTE1 DIR had high levels between 350° and 50° at 4.5 m/s and it had high levels between 330° and 50° at 9.0 m/s).

(v) When the hearing aids were facing downstream, the flow noise levels were generally higher than when the hearing aids were facing upstream and lower than the levels for frontal or rearward incidences.

2. Differences between BTE1 and BTE2

Several differences were also observed.

(i) As the maximum overall output level of BTE1 was slightly higher than that of BTE2, the overall levels of BTE2 DIR were limited to the maximum output level at most of the head angles (from 300° to 240° clock-

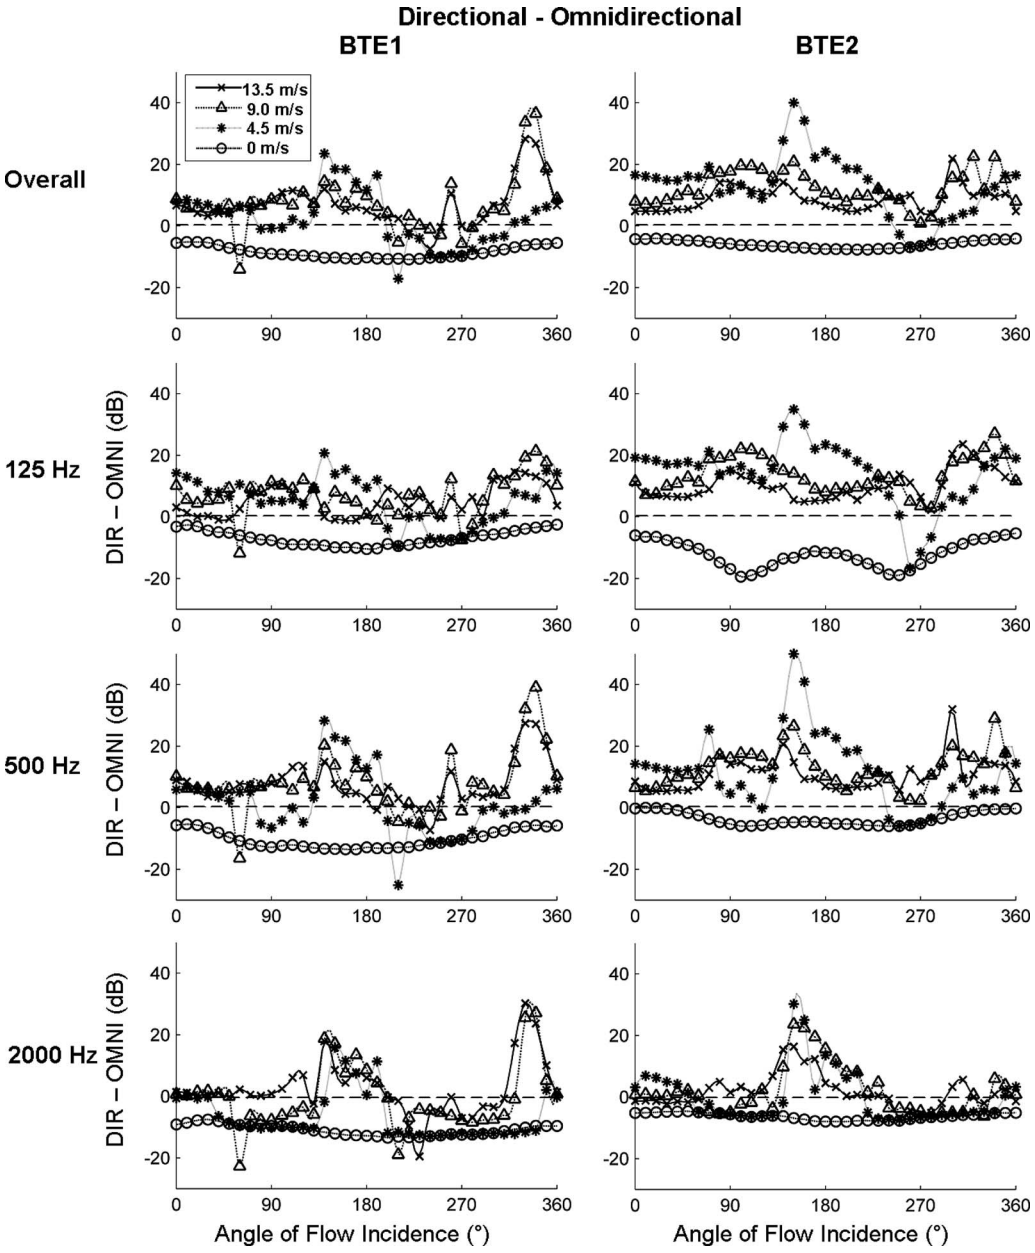

FIG. 7. Overall and one-third octave band level differences calculated by subtracting the noise level of the omnidirectional microphone (OMNI) from its corresponding directional microphone (DIR).

wise) whereas BTE1 DIR only reached its maximum output level at the frontal and rear incidence angles.

(ii) The overall plots of BTE1 DIR had a sudden level increase at 260° whereas BTE2 had a slight level increase between 300° and 310°.

(iii) In the 125 Hz plot between 0° and 10°, BTE1 DIR had similar levels from 4.5 to 13.5 m/s whereas BTE2 DIR yielded higher levels at 4.5 m/s than at 9.0 and 13.5 m/s.

B. DIR and OMNI comparison

The level differences of DIR minus OMNI for BTE1 and BTE2 are shown in Fig. 7. Table II also shows the correlation coefficients and average differences between the DIR and OMNI modes of the hearing aids. The data sets with the levels at three or less angles reaching the maximum output level generally had high to very high correlation coefficients (0.76–0.92), indicating that the polar patterns of DIR and OMNI had similar shapes. The exception is that the correlation coefficient at BTE2 at 4.5 m/s at 2000 Hz was slightly lower (i.e., 0.68). This was probably because the flow noise levels of BTE2 DIR were much higher than the ambient noise level at 0 m/s at the rearward incidence angles and showed level variations whereas those of BTE2 OMNI dropped below the ambient noise level at those angles and showed minimal level variations. Although similar observations are also noticed in BTE1 at 2000 Hz one-third octave band, the flow noise levels of BTE1 DIR for rearward incidence angles were relatively lower than those for BTE2 DIR. The correlation coefficient between BTE1 DIR and OMNI was, therefore, not lowered considerably.

The correlation coefficients were also high (between

TABLE II. The correlation coefficients and average differences between DIR and OMNI at three flow velocities when both BTE1 and BTE2 were worn on KEMAR's right ear. 			500 Hz third octave band level			
BTE1	0.87^	0.83	0.84*	8.0^	9.6	8.1*
BTE2	0.85^	0.90*	0.84*	13.2^	12.9*	10.9*
			2000 Hz third octave band level			
BTE1	0.76^	0.76	0.80*	9.1^	7.9	6.1*
BTE2	0.68^	0.82*	0.83*	6.8^	5.9*	3.8*

0.76 and 0.90) for data sets with levels limited at a greater number of angles (i.e., BTE1 at 13.5 m/s and BTE2 at 9.0 and 13.5 m/s). This could be because DIR and OMNI of the same hearing aid shared more commonalities in signal processing algorithm settings and physical characteristics.

The following observations were made for the DIR and OMNI modes of the two behind-the-ear hearing aids.

(i) In the absence of a flow (0 m/s), DIR generally had lower levels than OMNI (Figs. 5 and 6). This difference can also be seen as the negative lines in Fig. 7, which shows the difference of DIR minus OMNI.

(ii) DIR has higher levels than OMNI in most angles and flow velocities (i.e., positive values in Fig. 7). The average differences ranged from 3.8 to 16.3 dB (Table II), but they may be as high as 35–45 dB in some angles (Fig. 7).

(iii) DIR tended to reach the maximum overall levels at more angles and at lower flow velocities than OMNI (Figs. 5 and 6). The flow noise at angles between 300° and 350° and between 140° and 180° was always higher in DIR than in OMNI at flow velocities of 9.0 and 13.5 m/s.

(iv) In some angles, the flow noise of DIR was lower than that of OMNI (i.e., negative values in Fig. 7), especially at 2000 Hz. For angles at which the flow noise was equal to or below the ambient noise levels, the differences between DIR and OMNI at 4.5 m/s equaled those at 0 m/s (e.g., comparing the levels at 2000 Hz one-third octave band in Figs. 5 and 6 with Fig. 7 for angles around 270°).

(v) Although the output levels of both modes were programed to be as close as possible using pink noise during the fitting process, DIR tended to have a higher maximum overall level than OMNI for both BTE1 and BTE2 (i.e., the arc of similar values in the overall level plots had a higher level in DIR than in OMNI plots). One of the reasons could be because both of the omnidirectional microphones in DIR were saturated whereas only one omnidirectional microphone in OMNI was saturated.

C. Repeatability

Figure 8(A) shows overall levels of BTE2 DIR (Run2) recorded immediately after the BTE2 DIR (Run1, plots shown in Fig. 6). The correlation coefficients and average differences for the overall and one-third octave band levels between the two measurements are also tabulated in Table III.

The correlation coefficients between Run1 and Run2 of BTE2 DIR ranged between 0.93 and 1.0 and the average differences were within 2.3 dB at the overall and the one-third octave band levels at all flow velocities, indicating that the flow noise measurement was highly repeatable.

D. Variability

Figure 8(B) shows the Cartesian plot of the overall flow noise levels of BTE1 DIR measured 14 days apart at flow velocities of 9.0 and 0 m/s and Fig. 8(C) shows that of BTE1 OMNI measured at 13.5 and 4.5 m/s. Additionally, the correlation coefficients and average differences between Day 1 and Day 2 for overall and one-third octave band levels are shown in Table III.

The very high correlation coefficients (>0.92) and very low average differences (<4.0 dB) suggested that the flow noise measurements were highly repeatable within a 14-day period (Table III). Obvious differences were only seen at 210° for BTE1 OMNI and at 60°, 130°, 260°, and 330° for

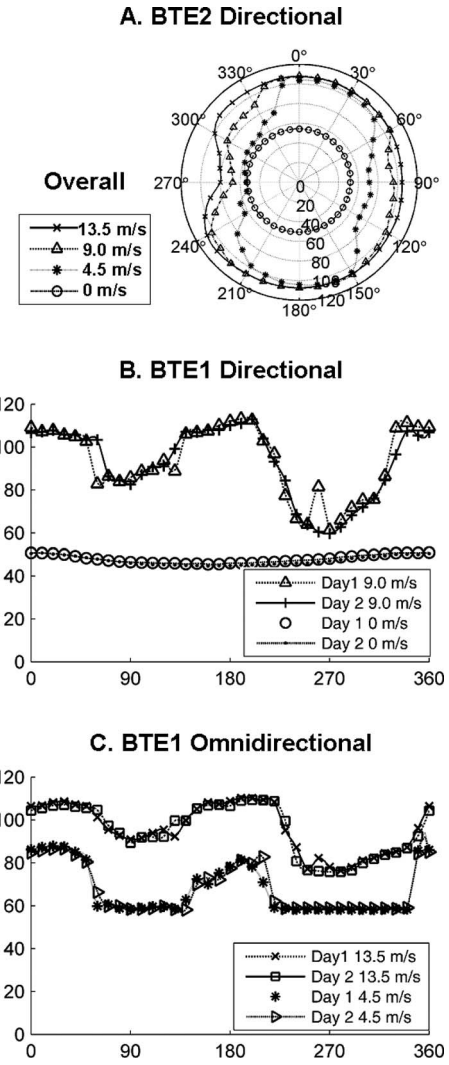

FIG. 8. (A) Overall of BTE2 DIR Run2 taken immediately after Run1 without dissembling the wind tunnel setup and the recording equipment. Overall levels of BTE1 (B) DIR and (C) OMNI taken 14 days apart.

BTE1 DIR. These differences were likely due to momentary fluctuations. Sometimes, the levels could shift by 10° at angles bordering a sharp change in flow pattern [e.g., 60° at 9.0 m/s in Fig. 8(B)].

E. Left vs right comparisons

Figure 9 shows the polar patterns of overall flow noise levels at the output of BTE1 when it was worn on KEMAR's left ear (BTE1_Left). The correlation coefficients and average differences between BTE1 and BTE1_Left were tabulated in Table III. They were calculated by inverting the flow noise levels recorded from 0°–350° to 350°–0° for the BTE1_Left data (i.e., mirror images).

Very high correlation coefficients (between 0.89 and 0.96) were found between the two sets of measurements, indicating that they had similar shapes when compared in mirror image. The average differences ranged between 2.3 and 5.5 dB, which were slightly higher than the repeated measures of BTE1 discussed above. This might be in part due to KEMAR's asymmetric facial features.

The measurements at 18.5 and 22.5 m/s indicated that flow noise at the hearing aid output was limited to its maximum output level at higher velocities, especially for frontal or rearward incidence. The flow noise levels when the hearing aid was facing upstream or downstream were consistently lower than those at other angles.

F. Flow around cylinder

Figure 10 shows flow noise recorded by the B&K microphone mounted on the cylinder at four flow velocities. Caution is needed in interpreting the measurement data. Flow noise levels cannot be directly compared with those recorded at the hearing aid output because KEMAR's cross section was oblong whereas the cylinder was circular with a relatively larger diameter. In addition, the size of the B&K microphone diaphragm was much larger than the hearing aid microphone diaphragm.

One prominent similarity between the hearing aid and cylinder measurements was that the lowest flow noise was recorded when the microphone was facing upstream. This was due to the presence of a large region of separated flow. Several differences, however, were also found.

(i) The highest levels for the cylinder measurement occurred when at angles that were close to 90° (i.e., the microphone diaphragm was facing downstream) at 4.5 m/s and between 20° and 170° at 9.0, 13.5, and 18.5 m/s. The highest levels for hearing aids, however, occurred when KEMAR was facing upstream or downstream (i.e., the hearing aid microphone was on the sides).

(ii) As flow noise increased, the levels of the cylinder measurements increased monotonically in most angles, suggesting that the cessation of level increase in the hearing aid measurements was indeed due to the limiters in the signal path imposing a maximum output level. The exceptions to the monotonic increase in levels were probably due to fluctuations in flow noise during the recording.

(iii) The overall and 125 Hz one-third octave band ambient tunnel noise levels at 0 m/s were generally higher in the cylinder than the hearing aid measurements. This was likely due to the relatively flat frequency response of the B&K microphone at low frequencies whereas those of hearing aids often have a roll-off below 200 Hz.

IV. DISCUSSION

In this study, we recorded flow noise at the output of two behind-the-ear digital hearing aids that did not have any wind noise management or cancellation algorithms. The following discuss in detail the factors that affected flow noise at the hearing aid output.

A. Level limiters

Recall that digital hearing aids may have several points in the signal path to limit the hearing aid output of high-level sounds. In this study, the effects of input and/or output level limiters could be observed in the polar patterns in several ways. First, flow noise at high velocity could saturate the

TABLE III. Correlation coefficients and average differences for BTE1 and BTE2 at three flow velocities. All the correlation coefficients were statistically significant ($p<0.01$).

BTE1 vs BTE1_wornL OMNI	0.97	0.91	0.93	2.3	3.8	4.6

microphone, resulting in digital distortions that could increase the level of high-frequency components at the hearing aid output. Second, the limiters in hearing aids could make the noise levels at two or more flow velocities similar (e.g., overall plots of BTE1_Left DIR at 13.5, 18.5, and 22.5 m/s). Third, the limiters could impose a limit on the maximum output level resulting in similar maximum values at high flow velocities, making the polar patterns at the frontal or rearward incidences look circular.

Fourth, the limiters could created a counter-intuitive phenomenon in the polar patterns—flow noise at lower flow velocities having a higher level than flow noise at higher velocities at low frequencies. For example, in the 125 Hz one-third octave band at angles between 0° and 10°, the levels of BTE2 DIR at 4.5 m/s were higher than those at 9.0 m/s (Fig. 6). Flow noise has a high level of low-frequency components at the microphone output. As the flow velocity increased, the high-frequency components of the flow noise increased. When the signal reached the broadband limiting algorithm, more gain reduction was provided to the signals recorded at a higher flow velocity than at a lower velocity. As the overall level was limited to the same/similar maximum output level, the levels of the low-frequency region for a signal with higher levels of high-frequency contents (i.e., flow noise at a higher velocity) was estimated to be lower than the levels of the low-frequency region for a signal with lower levels of high-frequency contents (i.e., flow noise at a lower velocity).

Another possibility was that when the microphone output reached the limiters implemented in different frequency channels (channel-limiters), the strong low-frequency components were limited by the limiters at low-frequency channels. As flow velocity was increased, the channel-limiter continued to act on the low-frequency components resulting in a relatively constant level at the low frequencies but allowing the high-frequency components to continue to increase in level. As the signal reached the broadband output limiter, flow noise generated at higher flow velocities incurred more gain reduction than that generated at lower flow velocities. The combination effect of the channel- and broadband-limiters resulted in lower low-frequency component levels at higher flow velocities than at lower flow velocities. Future studies are needed to study the flow noise patterns without the constraints of the limiters.

B. Influence of head angle

Flow noise levels recorded at frontal and rearward incidence angles were generally higher than those recorded when the hearing aid was facing downstream, which, in turn, was higher than when the hearing aid was facing upstream. These

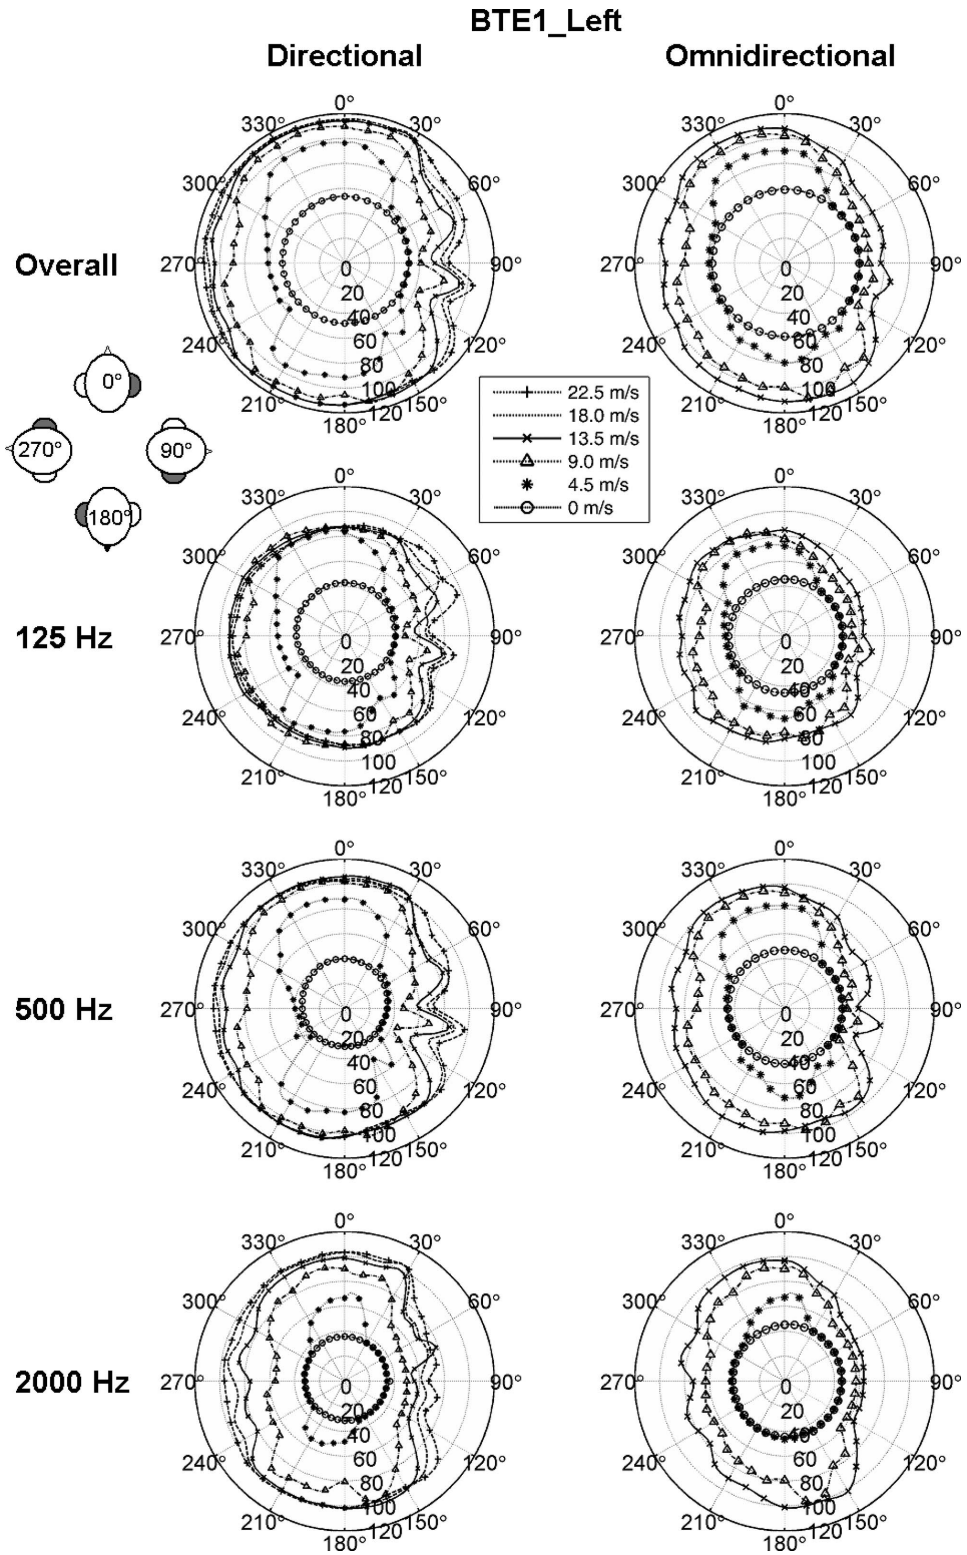

FIG. 9. Overall and one-third octave band levels of flow noise measured at the output of BTE1 from different head angles when it was worn on KEMAR's left ear.

results were consistent with those reported by Beard and Nepomuceno (2001) and Thompson and Dillon (2002). As the flow velocity increased, the noise level at frontal and rearward incidences reached the maximum output level first and then other angles followed. To shed light on the mechanisms of this head-angle-dependent phenomenon, we examined the aerodynamic patterns when a flow passes by a cylindrical body.

For a laminar flow around a cylindrical body, the flow accelerates and reaches a maximum velocity on the lateral sides of the cylinder (Fig. 11). An incompressible fluid is assumed at the relatively low flow velocities dealt with in this study. At a very low flow velocity [Fig. 11(A)], the flow pattern is characteristically laminar both upstream and downstream (i.e., the flow layers do not mix). The air bends outward on approaching the body, goes around it, and bends

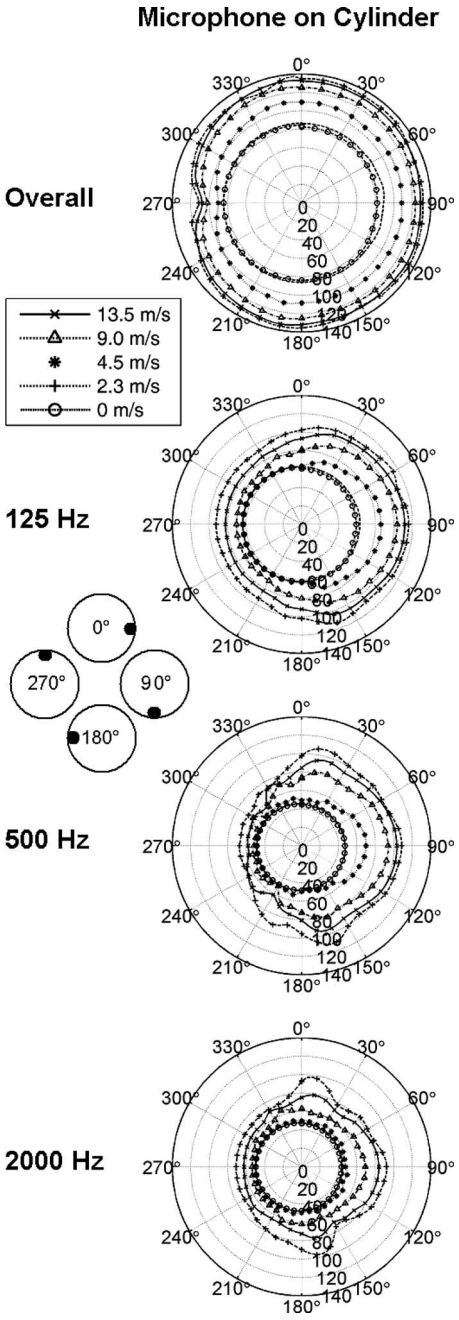

FIG. 10. Overall and one-third octave band levels of flow noise measured at the output of a B&K microphone when it was mounted on a cylinder with 15-cm diameter.

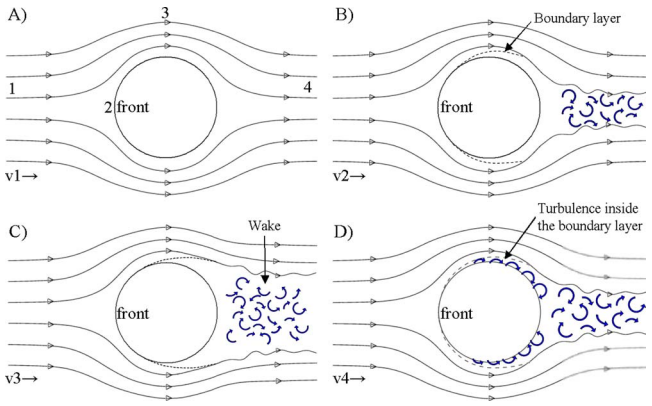

FIG. 11. (Color online) Aerodynamics of a flow passing a body at various flow velocities ($v1<v2<v3<v4$). (A) At a low flow velocity, $v1$, laminar flow is observed both upstream and downstream. Point 1: upstream flow; point 2: stagnation point; point 3: lateral side of the body; and point 4: downstream flow. (B) At a higher flow velocity, $v2$, the flow becomes turbulent in the wake. A thin boundary layer is formed around the sides of the body and vortices are formed in the wake. Note: The thickness of the boundary layer is exaggerated for clarity. (C) At flow velocity higher than $v2$, the wake becomes larger. (D) Above a certain critical velocity, $v4$, turbulence is formed inside the boundary layer and the size of the wake is reduced.

inward in the wake. Therefore, the flow velocity of the streamwise component on the lateral sides of the body (point 3) needs to be greater than that upstream (point 1) in order for the volumetric flow rate to be constant along the streamwise direction at the back of the body (point 4). In an idealized condition, a stagnation point is present at the center of the front surface (point 2). The flow velocity at this point is theoretically 0 m/s.

At higher flow velocities [Figs. 11(B) and 11(C)], viscosity causes flow velocity on the surface of the body to be still, forming a thin boundary layer. The streamlines beyond the boundary layer are free-flowing. The air flow velocity inside the boundary layer increases away from the surface of the body, but it is lower than the outer air streams. Beyond a certain point on the lateral sides of the cylinder, the air inside the boundary layer stops and reverses its flow direction as it encounters high pressure in the wake region. This flow reversal leads to the separation of air flow from the free-flowing stream and creates eddies in the wake. The size of the eddying wake increases with the flow velocity [i.e., the turbulent wake in Fig. 11(C) is greater than that in Fig. 11(B)]. Above a critical flow velocity [Fig. 11(D)], which depends on the size and surface characteristics of the body and the viscosity and density of the air, turbulence is formed inside the boundary layer. Above this velocity, the point of separation moves further downstream and the size of the wake is reduced (Anderson, 2005; Yip, 2007).

Relating the flow aerodynamics in Fig. 11 to the microphone-on-cylinder measurements in Fig. 10, it appeared that as the flow velocity increased from 0 to 2.3 m/s, the flow noise level at 125 Hz one-third octave band increased slightly when the microphone was facing downstream (i.e., between 60° and 120°) compared to facing upstream. The level increases were likely due to turbulent eddies in the wake of the cylinder. As the flow velocity increased to 4.5 m/s, flow noise levels in the 125 and 500 Hz one-third octave bands increased in level and spread to wider angles in the wake region, which was consistent with the increase in wake size as flow velocity increased [Figs. 11(B) and 11(C)]. As the flow velocity further increased to 9.0, 13.5, and 18.5 m/s, the flow noise level increased further in the wake and at all angles. Flow noise at higher frequencies also became prominent. Part of this level increase could be due to the increase in ambient tunnel noise level at higher flow velocities. Part of it would be due to the increase in small scale turbulence.

The unusual level increase at angles between 0° and 20° and between 160° and 180° at flow velocities of 9.0–18.5 m/s in the 500 and 2000 Hz one-third octave bands suggests

that factors other than turbulence might have contributed to the flow noise at the microphone output. From Fig. 11, the highest flow velocities are reached on the sides of the body. At the critical velocities, turbulent eddies were formed inside the boundary layer [Fig. 11(D)]. It was possible that the combination of high velocity and turbulence caused the sudden increase in flow noise levels. This interpretation is consistent with the observation that flow noise levels increased with the flow velocity. In the case of KEMAR, the flow might be tripped by the presence of the pinnae or other protuberances from the sides of the head, causing separation and increased generation of turbulence. Combined with the fact that the hearing aids were at the region with the highest flow velocity, the flow noise at frontal and rearward incidence angles, therefore, became much higher than the lateral incidence angles.

Consistent with the observation that the lowest flow noise levels were generated when the hearing aid microphone was facing upstream (Figs. 5 and 6), the lowest overall level for the microphone-on-cylinder measurement also occurred when the microphone was directly facing upstream (i.e., 270° in Fig. 10). This was likely because both flow velocity and turbulence were the lowest at the "stagnation" point. The increase in level could be partly due to the increase in ambient tunnel noise in the wind tunnel (Fig. 2) and partly due to the microphone was larger than an infinitely small point, which was assumed in an idealized case.

When the microphones were in the wake, flow noise levels at the hearing aid output were relatively lower than those at the corresponding angle recorded on the cylinder. This could partly be because KEMAR's head was oblong. The hearing aid microphone was, therefore, further away from the turbulence in the wake than the microphone mounted on the cylinder. Future studies utilizing flow visualization techniques are needed to study the relationship between anatomic structures, flow characteristics, and flow noise in hearing aids.

C. Influence of microphone type

1. No flow

In the absence of a flow (i.e., 0 m/s), the directional microphones of BTE1 and BTE2 provided more attenuation to far-field ambient tunnel noise and resulted in lower levels at the hearing aid outputs. This noise reduction effect is shown as the negative OMNI-DIR differences at 0 m/s in Fig. 7. The average amounts of attenuation in the overall, 125, 500, and 2000 Hz were 8.6, 7.0, 10.5, and 11.0 dB for BTE1, respectively, and 5.9, 12.2, 3.6, and 6.3 dB for BTE2, respectively.

The level variations at 0 m/s shown in Figs. 5 and 6 were likely a combination effect of the head shadow, the sensitivity/directivity pattern of the microphone, and the actions of the expansion algorithm. The polar patterns of OMNI were generally circular with slightly higher levels when the hearing aid was facing the wind tunnel inlet (i.e., around 270° in Figs. 5 and 6 and around 90° in Fig. 9). This suggested that the ambient noise was mainly from the inlet instead of the outlet side of the wind tunnel in the absence of a flow, and the head shadow effect resulted in lower ambient noise levels when the microphone was not facing the wind tunnel inlet.

On the other hand, the polar patterns of DIR showed relatively larger angle-to-angle level variations (Figs. 5 and 6). Similar to the data reported for OMNI, the levels of DIR at 270° were slightly higher than those at 90° due to the head shadow effect. In addition, the polar patterns for DIR showed a lower level for 180° compared to 0°, which was likely because DIR had lower sensitivity to sounds coming from the back. In general, the polar patterns of DIR measured in the wind tunnel lacked well defined nulls compared to those measured in anechoic chamber. Only BTE2 DIR at 125 Hz one-third octave band showed lower levels at the expected nulls of hypercardioid microphones (i.e., around 135° and 225°).

Previous studies suggested that directional microphones process sounds within and outside of the critical distance differentially (Leeuw and Dreschler, 1991; Ricketts and Hornsby, 2003). Directional microphones provide an equal amount of noise attenuation for sounds coming from the reverberant field (i.e., outside the critical distance). When signals are within the critical distance, however, they provide different amounts of attenuation to sounds coming from different directions and the amount of attenuation approaches the polar patterns measured in an anechoic chamber. Our results suggested that the sources of the ambient noise were in the reverberant field of the directional microphones at most frequency regions. The more distinct shape at 125 Hz for BTE2 DIR was speculated to be because the noise source was in the borderline of the critical distance at the 125 Hz one-third octave band.

Finally, Fig. 7 shows an unusually large amount of noise attenuation provided by DIR compared to OMNI. This was likely because the directional microphones attenuated the noise levels to below the expansion thresholds at the low-frequency channel of the hearing aids. As the expansion algorithms are designed to provide less gain to low-level signals than high-level signals, the noise at the DIR output was therefore reduced and yielded a very low level at the hearing aid output.

2. With flow

In the presence of a flow, DIR had a higher sensitivity to near-field flow variations and they generated higher flow noise levels than OMNI in most head angles (i.e., positive differences in Fig. 7). At some angles, the directional microphones were found to have lower outputs than the omnidirectional microphones (i.e., negative differences in Fig. 7). The following discusses several possible causes for such observations.

First, when there is a considerable change in flow noise between adjacent angles, OMNI may appear to have a higher flow noise level than DIR (e.g., at 60° of BTE1 in Fig. 5). The variability of BTE1 DIR in Fig. 8(B) shows that flow noise level at 60° varied from just over 80 dB SPL in Day 1 to over 110 dB SPL in Day 2. While this level difference seemed to be very large, this is likely a result of momentary fluctuations because the level at 60° had similar level as 70°

on Day 1 but it had similar level 50° on Day 2. When events like this happened in either DIR or OMNI measurements, DIR may appear to have lower flow noise levels than OMNI.

Second, when DIR reduced the ambient noise in the far field in the wind tunnel, DIR minus OMNI would yield a negative difference (Fig. 7). For example, BTE1 OMNI had a higher overall noise level than BTE1 DIR at 270° at 0 m/s in Fig. 5. As the flow noise at 4.5 m/s for both DIR and OMNI was lower than their corresponding ambient tunnel noise levels, the level recorded at the hearing aid output equaled the ambient noise level. The overall DIR-OMNI difference in Fig. 7, therefore, shows a negative difference at 270° because DIR reduced the ambient noise level.

Third, a negative DIR-OMNI difference could also be due to the attenuation of the wind tunnel ambient noise by DIR at higher flow velocities. For example, BTE1 DIR-OMNI difference at 2000 Hz is negative at 270° at 9.0 m/s in Fig. 7. Given that the BTE1 DIR-OMNI difference was −12 dB at 270° at 2000 Hz at 0 m/s, the flow noise of DIR needed to be at least 12 dB higher than that of OMNI in order to yield a positive DIR-OMNI difference. Our measurements, however, indicated that BTE1 OMNI and DIR were estimated to be 57 and 49.5 dB at 270° in the 2000 Hz plot at 9.0 m/s, respectively, resulting in a difference of −8.5 dB.

Fourth, the limiters that are responsible for setting the maximum output levels of the hearing aids can potentially diminish the DIR-OMNI difference or turn it negative. For example, the overall level of BTE2 between 0° and 50° exhibited a decrease in DIR-OMNI difference as the flow velocity increased from 4.5 and 13.5 m/s (Fig. 7). Figure 6 shows that the overall levels of BTE2 DIR were much higher than OMNI at 4.5 m/s (i.e., difference equaled 15–16 dB in Fig. 7). At 9.0 m/s, both BTE2 DIR and OMNI approached their maximum output level, resulting in lesser DIR-OMNI differences (i.e., 7–11 dB) than at 4.5 m/s. At 13.5 m/s, both BTE2 DIR and OMNI reached their own maximum output levels (Fig. 7) and the DIR-OMNI difference was reduced to the difference between the maximum output levels of DIR and OMNI (i.e., approximately 5 dB). Theoretically, if BTE2 DIR had the same or lower maximum output level than OMNI, the differences would have disappeared or become negative, respectively.

D. Summary and applications

By recording flow noise outputs from commercially available digital hearing aids and taking the standard signal processing algorithms into account, this study provided realistic flow noise data useful for clinical applications. The results indicated that both directional and omnidirectional microphones yielded the lowest flow noise levels when the microphones were facing directly upstream. Relatively low levels were also generated when the microphones were facing downstream. If unilateral hearing aid or cochlear implant users or users with a "good" and a "poor" ear want to conduct conversations in windy environments, it is advisable to position the "good" ear facing upstream and the "poor" ear facing downstream. For bilateral hearing instrument users including hearing protector users, it is best to position themselves so that one hearing aid faces upstream and the other faces downstream.

Our results also revealed that the limiters in the signal path can reduce the hearing aid output. Clinicians, therefore, can set a "wind noise program" with lower maximum output level and/or higher compression ratio for louder sounds to be used in environments where the hearing aid user does not need to converse much but may be bothered by wind noise (e.g., during jogging).

Besides the clinical applications, the results of this study also have several engineering implications. As mentioned before, an input limiter for digital hearing aids can simply be the upper limit of the dynamic range of the digital chip. When the overall sound pressure level of the incoming flow noise exceeded this level, digital distortions and unwanted noises were generated. It is, therefore, beneficial to use digital chips with higher input dynamic ranges to avoid or defer the digital distortions to a higher wind noise level/velocity.

In addition, an effective wind noise minimizing algorithm can be designed to take advantage of the voice detection and the limiting algorithms. When speech is not present, the thresholds of the output limiting algorithm can be lowered to reduce wind noise and increase comfort. When speech is present, the thresholds can be adjusted to allow speech clarity. For hearing aids with multichannel output limiting algorithms, the gain and/or the threshold of the output limiting algorithm for the low-frequency channel can also be lowered to reduce wind noise at low-frequency regions.

Further, although directional microphones generally yielded higher wind noise levels at the hearing aid output, engineering efforts can be applied to take advantage of their ability to reduce background noise in the far-field. An effective wind noise reduction algorithm can be implemented in conjunction with a multichannel automatic directional and omnidirectional microphone switching algorithm so that the hearing aid will always switch to the microphone mode with lesser output levels in each channel to reduce the overall noise level.

As wind noise is a rarely reported topic in literature, future studies are warranted in several areas: (1) the relationship among anatomic structures, flow characteristics, and flow noise in hearing aids; (2) the perceptual effects of wind noise on speech recognition and perceived sound quality for different hearing instrument users; (3) effects of signal processing algorithms; and (4) effect of physical modifications.

ACKNOWLEDGMENT

Many thanks are expressed to Paloma Mejia, Jong Beom Park, the Herrick Laboratories staff, and Dr. Kaibao Nie for their technical assistance. We also would like to thank Sonic Innovations for donating two behind-the-ear hearing aids for the study, and Michael Nilsson and Jennifer Grove for providing technical details on the hearing aids.

Improved fundamental frequency coding in cochlear implant signal processing

Matthias Milczynski,[a] Jan Wouters, and Astrid van Wieringen
ExpORL, K.U.Leuven, O & N 2 - Herestraat 49 bus 721, B-3000 Leuven, Belgium

(Received 6 August 2008; revised 28 January 2009; accepted 28 January 2009)

A new signal processing algorithm for improved pitch perception in cochlear implants is proposed. The algorithm realizes fundamental frequency (F0) coding by explicitly modulating the amplitude of the electrical stimulus. The proposed processing scheme is compared with the standard advanced combination encoder strategy in psychophysical music perception related tasks. Possible filter-bank and loudness cues between the strategies under study were minimized to predominantly focus on differences in temporal processing. The results demonstrate significant benefits provided by the new coding strategy for pitch ranking, melodic contour identification, and familiar melody identification.

I. INTRODUCTION

Pitch is an important perceptual property that is crucial for perception of musical melodies, gender discrimination in voice, prosody, and intonation of speech. In many cases, the fundamental frequency (F0) of a sound can be regarded as the physical counterpart of pitch. It is well known that cochlear implant (CI) recipients perform very poorly in pitch-related tasks and that this hampers music perception and appraisal. In Gfeller *et al.*, 2002 a familiar melody recognition test yielded significantly worse scores from CIs compared to normal hearing (NH) persons for both rhythmic and isochronous items. In the same study an average just noticeable difference in F0 (F0JND) of 7 semitones for a group of 46 CI users was determined. A control group of eight NH participants obtained considerably lower values (between one and two semitones). The high discrepancy in performance between CI and NH subjects was confirmed in other studies (Looi *et al.*, 2008; Fujita and Ito, 1999; Kong *et al.*, 2004). However, Nimmons *et al.* (2008) demonstrated that some CI subjects can achieve even smaller F0JNDs below one semitone.

In electrical hearing (EH) pitch can be mediated via temporal and place cues. Place cues refer to the place of stimulation along the basilar membrane. Expressed in terms of tonotopical organization, shifts from apex to base elicit a rise in pitch and vice versa. Temporal pitch can be transmitted either through variations of pulse rate (rate pitch) or envelope fluctuations of the stimulation pattern (envelope pitch), e.g., sinusoidal amplitude modulation (SAM) of current level at a fixed stimulation rate. In this case increasing the stimulation rate or modulation frequency, respectively, increases the perceived pitch. Furthermore, in the case of SAM pulse trains, an increase in modulation depth reinforces the periodicity information encoded by the modulation frequency and thus enhances the perceived pitch.

A large corpus of literature exists in which the potential of temporal pitch paradigms (and their possible interdependencies) was studied (Shannon, 1983; Townshend *et al.*, 1987; Pijl and Schwarz, 1995). McKay *et al.* (1994) showed that the pitch of SAM pulse trains (for carriers above 800 pps) can be matched with the pitch of unmodulated pulse trains presented at a stimulation rate similar to the modulation frequency. In other words, rate and envelope pitch can lead to a similar pitch percept. Both temporal pitch cues have a perceptual limit of about 300 Hz even though stimulation rate can elicit pitch percepts up to 1 kHz for some individuals (Shannon, 1983; Townshend *et al.*, 1987). At higher stimulation rates it is assumed that refractory properties of auditory nerve fibers become salient leading to an inconsistent pitch percept.

Nowadays, the commercially available processing strategies are based on the continuous interleaved sampling (CIS) (Wilson *et al.*, 1991) and advanced combination encoder (ACE) (Vandali *et al.*, 2000) processing schemes. For these algorithms an incoming signal is divided into a predefined number of frequency bands. This is accomplished by means of a filter bank with center frequencies usually spaced linearly below and logarithmically above 1 kHz. The envelope of each filter-bank channel is extracted either via half-wave rectification and lowpass filtering (CIS) or through magnitude response calculation and channel combinations (ACE). CIS and ACE differ mainly in the selection of valuable channels. In the CIS strategy usually all available electrodes are stimulated. In ACE, however, only a specified number of channels with maximal magnitudes are selected in every stimulation cycle. In subsequent processing steps the envelopes are subject to a nonlinear loudness growth function (LGF) and are finally used to modulate a fixed-rate electrical pulse train. Thus, the two pitch paradigms used in current processing strategies are place and envelope pitch. Processing schemes embedding variable stimulation rates such as F0F1F2 or MPEAK [see Loizou, 1998 for an excellent review] were predominantly represented in earlier commercial systems.

Several new experimental CI strategies targeting at improved F0 and/or music coding have been proposed in the present decade. Geurts and Wouters (2001) investigated the relevance of modulation depth in SAM pulse trains for modulation depth discrimination and F0JND of synthetic

vowels. A new processing strategy called F0CIS was implemented that allowed control over the modulation depth of temporal fluctuations. In the F0JND task no significant differences between F0CIS with increased modulation depth and the standard CIS scheme were demonstrated. Removal of temporal fluctuations (i.e., no available envelope pitch) resulted in the poorest performance.

Fearn (2001) developed a processing strategy with multiple channel stimulation rates. By employing an approach similar to the phase vocoder (Flanagan and Golden, 1966), instantaneous frequencies extracted from frequency bins of a digital fast fourier transform (FFT) filter bank were translated to stimulation rates in frequency channels below 1000 Hz. From the evaluation procedure no clear conclusion about the potential of the proposed strategy can be drawn (only two subjects were tested under different conditions).

A number of different experimental strategies were investigated by Vandali *et al.* (2005) and compared to the CIS and ACE strategies. In particular, the multichannel envelope modulation (MEM) strategy showed improvement in pitch ranking and no degradation in speech recognition (in quiet and in noise) as compared to ACE. Similar results for speech recognition were shown in a more recent study (Wong *et al.*, 2008). In their MEM approach envelope fluctuations, which inherently contain periodicity information, were extracted and additional control of modulation depth was provided. Modulation took place in phase across channels.

Green *et al.* (2004) proposed a coding strategy in which the filter-bank channel outputs of the CIS processing strategy were first lowpass filtered and then amplitude modulated at the F0 of the incoming sound with a sawtooth-shaped modulation. In a follow-up study (Green *et al.*, 2005) an improvement was demonstrated for a prosody identification task compared to the standard CIS strategy, but vowel recognition and formant frequency discrimination degraded with the new scheme. The authors concluded that the enhancement of temporal fluctuations might have an impact on spectral processing.

In a study by Laneau *et al.* (2006) the authors proposed a new coding strategy called F0mod that employed an enhanced coding of the envelope pitch cue. The strategy incorporated a F0 estimator into the processing framework of the ACE scheme. Filter-bank channels were amplitude modulated at the extracted F0. In a psychophysical evaluation significant advantages with F0mod over ACE were demonstrated in the scope of pitch ranking and melody recognition experiments.

In the present study we pursued the F0mod study, thereby focusing not only on implementation but also on psychophysical issues. Firstly, we aimed at a careful compensation of possible filter-bank cues that could have been an issue in the previous study due to the differences in spectral processing between ACE and F0mod. Secondly, in order to allow an even more systematic comparison between both schemes, possible differences in loudness were examined and eliminated in subsequent experimental procedures. Our hypothesis is that by minimizing spectral and loudness cues, differences between the strategies under study mainly result from their distinct temporal processing.

II. GENERAL METHODS

A. Modified F0mod strategy

We briefly review the most relevant components of the F0mod strategy as proposed in Laneau *et al.*, 2006, and the reader is kindly referred for further information not mentioned here. The strategy incorporated an autocorrelation-function-based F0 extractor into an ACE-like processing assembly. The channel outputs obtained from the filter bank were SAM at the estimated F0. The modulations were applied at full modulation depth (100% modulation) and in phase across channels. It was demonstrated in Laneau *et al.*, 2004 that these are optimal configurations for multichannel stimulation involving temporal cues. Moreover, the original F0mod algorithm from Laneau *et al.* (2006) introduced two modifications in spectral processing, as compared to ACE, namely, (1) a 512-bin FFT filter bank instead of a 128-FFT filter bank and (2) readjustment of the filter-bank center frequencies to allow for a better resolution in the low frequency range. The first modification was justified by the requirement that no temporal fluctuations in the filter-bank outputs should interfere with the amplitude modulations introduced by the F0 coding. The second modification was mainly motivated by outcomes from a study by Geurts and Wouters (2004) in which a filter bank with higher low frequency resolution could provide a better place pitch percept. In the evaluation procedure the original F0mod strategy was tested in comparison to standard ACE. CI subjects obtained statistically significant better scores with F0mod in pitch ranking of mu-

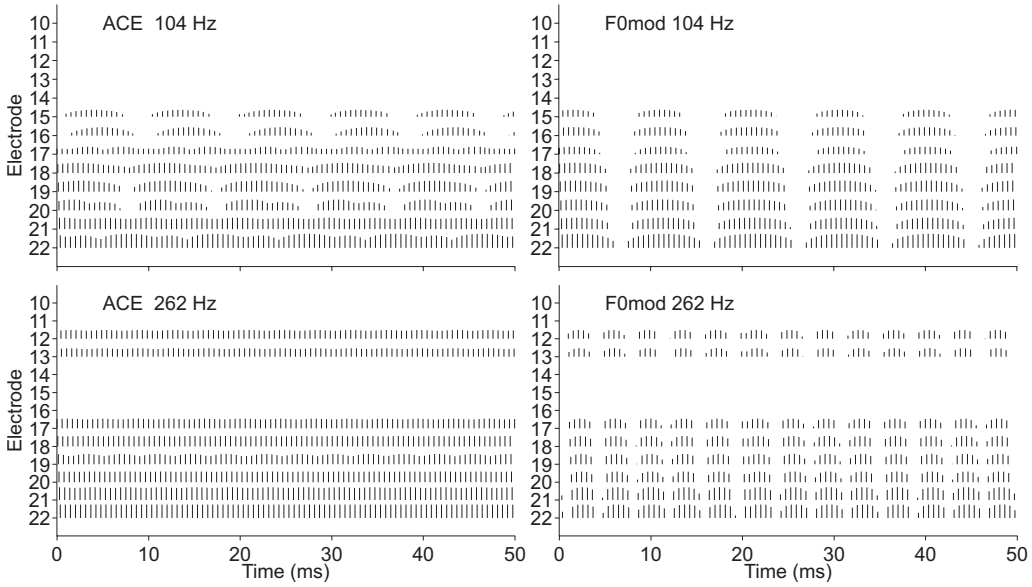

FIG. 2. Example electrodograms for harmonic complexes with F0's at G#2 (104 Hz) and C4 (262 Hz). The figures show stimulation patterns obtained with ACE and F0mod. Time is denoted on the *x*-axis of each figure and the electrode number (in base-to-apex order) on the *y*-axis. Strategy and F0 are given in the upper-left corner of each figure. Each electrodogram is truncated to 50 ms duration and to the range of active electrodes. The channel stimulation rate was 1800 pps in each example.

sical tones (for a limited frequency interval between 130 and 233 Hz) and in melody identification of isochronous items with F0mod. However, as explained above, not only enhanced temporal cues but also the modified spectral processing might have had an impact on the subjects' responses.

In order to minimize differences in spectral processing between ACE and F0mod a modified implementation is proposed here. In this implementation exactly the same filter bank as in the standard ACE scheme is used, i.e., a 128-bin FFT filter bank with the same crossover frequencies. The F0 estimation algorithm was enhanced by a voiced-unvoiced decision component. For voiced signals the envelopes of the filter-bank outputs were low pass filtered with a fourth order Butterworth filter (cutoff frequency at 60 Hz) and then amplitude modulated at the frequency of the extracted F0 (again at 100% modulation). Unvoiced sound segments were processed identically to ACE. The modified processing scheme is depicted in Fig. 1. If not otherwise stated the term F0mod will always refer to the new implementation.

In Fig. 2 stimulation patterns obtained from both strategies applied to two synthetic harmonic complexes (see also Sec. II C) at two different F0's are illustrated. Information regarding strategy and F0 (in hertz) is given in the upper-left corner of each electrodogram. The length of each segment was reduced to 50 ms and to the range of active electrodes for illustration purposes. The electrodograms clearly depict the similarities in peripheral information and the considerable differences in the temporal patterns between both schemes. In particular, temporal fluctuations that occur in ACE for the 104 Hz tone exhibit noticeable discrepancies in modulation depth, phase, and modulation shape. In contrast, the temporal information provided by F0mod is more regular with regard to these aspects. A striking difference in temporal processing between F0mod and ACE is also observed for the 262 Hz tone. In this case temporal information in ACE is almost completely absent, since this relatively high F0 exceeds the effective bandwidth of 250 Hz[1] of each FFT bin. In Fig. 3 average channel amplitudes are presented for the same two tones. The averaging was applied to each channel output of the LGF unit depicted in Fig. 1. Thereby, the amplitude values were mapped to the range [0, 1]. In general, larger average amplitudes are observed for ACE than for F0mod, in particular, for stimuli with higher F0's. This could result in possible loudness differences between ACE and F0mod, which will be addressed in Sec. III A.

B. Objectives of psychophysical tests

In the psychophysical evaluation we focused on music related tasks. The procedures were chosen under consideration of different aspects that are relevant to music perception. First of all, our evaluation test battery contained pitch ranking and familiar melody identification (FMI) of isochronous nursery songs. These two tests were also a part of the previous F0mod study and can be considered as standard procedures for the assessment of music perception in CIs (Nimmons *et al.*, 2008; Kasturi and Loizou, 2007; Kong *et al.*, 2004). These tests differ considerably in complexity with regard to perceptual dimensions. Pitch ranking demands a reasonable perception/comprehension of musical intervals and understanding of pitch. Indeed, it is not strictly related to perception of music since it can also be used for distinguishing between male and female voices. The FMI test bears a strong relation to music, but requires a certain degree of familiarity with the presented tunes. This is a critical issue since the ability to identify a musical piece is not only associated with perceptual abilities. The result will also depend on how well the particular item is represented internally (e.g., due to listening habits) and whether it can be connected to associative experiences (Peretz *et al.*, 2003). A further

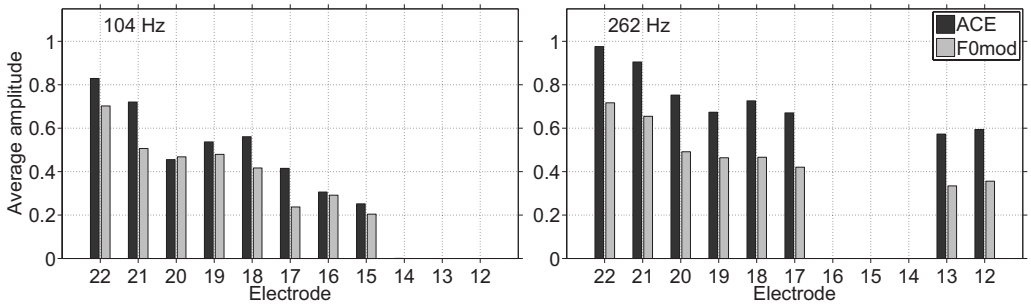

FIG. 3. Average amplitudes calculated from the electrodograms shown in Fig. 2. Note that the amplitude values at the output of the LGF are in the range between 0 and 1.

complication of the FMI test is that due to the modified rhythm the isochronous songs might become unfamiliar. In order to make a good compromise between both worlds we included the melodic contour identification (MCI) test (Galvin *et al.*, 2007) as part of the evaluation. The test addresses the perception of complex and music related stimuli but does not assume any familiarity with the stimuli. Thus purely musical abilities are accessed with the task. With these three tests (pitch ranking, MCI, and FMI) a composition of procedures is obtained with focus on different aspects of music perception at different levels of complexity.

C. Stimuli

The design of the stimuli in all procedures was identical to the synthetic harmonic complexes of the UW-CAMP test battery (Nimmons *et al.*, 2008). We used similar amplitude and phase information in the synthesis of the harmonic sounds. However, we did not apply the characteristic linear decay as was done in the UW-CAMP battery. The decay might influence the detection of envelope fluctuations perceptually since it is known that temporal modulation transfer functions (TMTFs) are level dependent in NH and EH (Shannon, 1992). For this reason we applied a 25 ms cosine ramp to the beginning and end of each sound with a 450 ms sustained part in between. The total duration of each stimulus was thus 500 ms. In this manner, a total number of 21 tones were generated with F0's ranging from 104 to 330 Hz, which is the range of most effective temporal pitch cues in CIs. Each complex stimulus contained 16 harmonics, meaning that the bandwidth of the stimuli ranged from 1500 (lowest F0 stimulus) to almost 5000 Hz (highest F0 stimulus).

The stimulus waveforms were all preprocessed in the nucleus MATLAB toolbox (NMT) developed by Cochlear Corp. This toolbox facilitates the conversion of digital waveforms into electrical stimulation patterns (i.e., electrodograms). The patterns are stored in a specific data structure that contains information about the active electrode, current level, stimulation mode, pulse width, phase gap, and time instance of stimulation for each cycle. The resulting data structure can be further used by particular software and hardware interfaces in order to be provided directly to a subject's implant (see also Sec. II D for details). The F0mod strategy was implemented in the framework of the NMT in which the standard ACE strategy is also available. Each electrical stimulus contained a channel stimulation rate of 1800 pps. This relatively high stimulation rate was necessary to allow a reasonable sampling of modulation frequencies above 250 Hz in F0mod (see also Wilson *et al.*, 1997). In each stimulation the maximal number of active channels was 8. The electrical pulses were biphasic with standard pulse width and phase gap values of 25 and 8 μs, respectively.

TABLE I. Details about CI subjects who participated in this study.

Subject	Age (yr)	Etiology	Duration of profound deafness (yr)	CI experience (yr)
S1	63	Progressive	>20	5
S2	60	Progressive	>30	7
S3	51	Unknown	6	12
S4	23	Meningitis	<1	5
S5	40	Progressive	<2	13

D. Setup

For all experimental procedures the APEX3 software (Francart *et al.*, 2008) served as the main platform for control, presentation of stimuli, and recording of the subjects' responses. The APEX3 framework also embeds the nucleus implant communicator (NIC) interface provided by Cochlear Corp. The interface facilitates direct streaming of the preprocessed electrodograms to a subject's implant. In doing so, the stimulation patterns, as described in Sec. III C, are sent directly to the internal part of the CI through a special clinical research processor. During each test session the subjects were presented with a graphical user interface. The possible answers for a particular task were represented by buttons, which had to be chosen by operating a mouse interface.

E. Subjects

Five postlingually deafened CI users participated in this study. Three subjects used the Nucleus Freedom speech processor and two subjects used the 3G speech processor. The strategy used by all subjects was ACE operating at 900 pps channel stimulation rate. The number of subjects varied per test. Subject S5 was not able to do the MCI test since he had a hard time understanding the task. Only three subjects (S1, S2, and S3) were familiar with the melodies used in the FMI test, so only those three subjects participated in that test. Table I provides details on the participating subjects.

III. EXPERIMENT 1: LOUDNESS BALANCING

A. Procedure

A loudness balancing procedure was conducted in order to equalize the loudness percept of all stimuli that were used in subsequent experiments. An adaptive 1-up, 1-down, 2-interval, 2-alternative-forced-choice (2I-2AFC) procedure was applied. The adaptive parameter of the procedure was the percentage of dynamic range (DR) to which the magnitudes of each channel were mapped. The parameter will be referred to as the DR mapping level (DRML). In this procedure, the DR is defined as the difference between most comfortable and threshold levels (or *T*-and *C*-levels) expressed in clinical current units. Mathematically, the DR mapping process for a channel n can be formulated as follows:

$$y_n = t_n + x_n(m/100)(c_n - t_n). \quad (1)$$

Thereby, x_n is the output of the LGF unit and the *T*- and *C*-levels are given by t_n and c_n. The DRML is represented by m that determines the percentage of DR to which the LGF output is mapped and which can obtain values between 0 and 100. Note that the DRML determines the peak amplitude of y_n. Figure 1 illustrates the DR mapping unit in the processing chain. In the test procedure, the subjects were presented with a fixed reference stimulus and a test stimulus in each trial in random order. They had to indicate the louder stimulus. The stimulus at 131 Hz F0 processed by ACE at a fixed DRML of 75% (thus $m=75$) served as the reference. In case the test stimulus was perceived as being louder its DRML was decreased; otherwise it was increased by a given amount Δm. The size of Δm was decreased from 10 to 2 throughout the experiment. After six reversals the procedure was terminated and the mean DRML was calculated from the last three reversals. Each test stimulus was played twice: once starting at $m=90$ and once at $m=60$. The mean of the two recorded DRMLs was taken as the final level at which the test stimulus was loudness balanced with the reference. Since the procedure is very time consuming the procedure was conducted for 11 tones ranging from 104 to 330 Hz, in steps of 1 whole tone, for both strategies. DRML values for intermediate tones were linearly interpolated.

The individual DRMLs (i.e., per tone and per subject) were used in all following experiments. Consequently, equal loudness was not only approached between strategies but also between stimuli within a strategy. Moreover, all tones were roved in loudness by adding a random value between −5% and +5% to the final DRML. Thus, the reference and test tokens in the pitch ranking test (see Sec. IV A) as well as contours and melodies in the MCI and FMI experiments (see Secs. V A and VI A), respectively, exhibited a different roving pattern in each trial. A similar loudness roving approach was applied by Nimmons *et al.* (2008) to acoustical stimuli. In the experiments described below none of the participating subjects reported apparent loudness effects.

B. Results

The results of the loudness balancing experiment averaged over five subjects are summarized in Fig. 4. Each marker represents the final DRML (y-axis) of a particular comparison stimulus for ACE and F0mod. The corresponding F0's (in hertz) are denoted on the x-axis. The dashed horizontal line highlights the DRML of the reference tone. There is a noticeable between-strategy difference in the progression of the loudness balance curves. In ACE DRMLs were adjusted to slightly higher values than the reference for F0's below 147 Hz but to progressively smaller values at higher F0's. A different trend is seen for F0mod. For F0's up to 165 Hz the loudness balance curve shows a steep positive slope starting at relative low DRMLs of about 55% and then approaching the DRML of the reference. At higher F0's the DRMLs were adjusted to values of about 80%. These results indicate that the loudness evoked by ACE stimuli increased with increasing F0 while the loudness of stimuli provided by F0mod decreased with increasing F0. A direct comparison of both strategies implies that at low F0's the F0mod stimuli are noticeably louder than in ACE but softer at higher F0's.

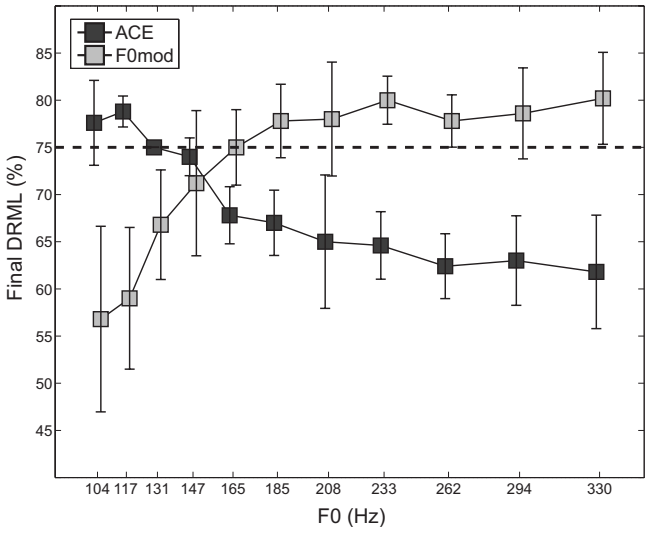

FIG. 4. Results loudness balancing. DRMLs (y-axis, see text for explanation of this parameter) obtained from the loudness balancing experiment averaged over five subjects are shown for ACE (dark gray markers) and F0mod (light gray squares). The particular tones are shown on the x-axis together with their corresponding F0's in hertz. The error bars indicate standard deviation and the dashed horizontal line highlights the DRML of the reference.

We performed a repeated measures ANOVA with two within-subject factors (strategy and F0) with the lower-bound adjustment for the degrees of freedom, on the final DRML values. The analysis revealed a significant effect of strategy ($p<0.05$). Moreover, the interaction between strategy and F0 was significant ($p<0.05$). The analysis also yielded a significant between-subject effect ($p<0.000\,001$).

C. Discussion

The results of experiment 1 demonstrated a significant difference in evoked loudness between both strategies under study. In both schemes the perceived loudness was frequency dependent. Since the spectral processing of ACE and F0mod was similar only differences in temporal processing could contribute to these outcomes. It is known from literature that temporal aspects influence the perceived loudness in EH. In Zeng and Shannon, 1995 the loudness of an AM stimulus

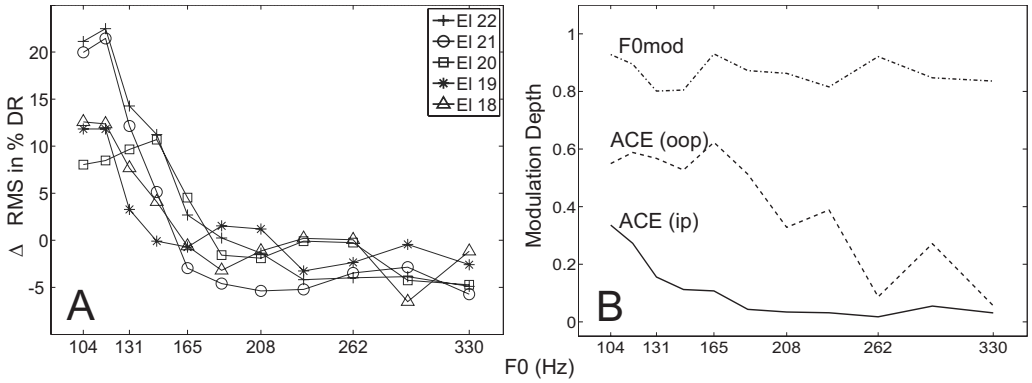

FIG. 5. (A) Differences in channel-rms values between ACE and F0mod expressed in % DR averaged over five subjects. The rms values were calculated from channel amplitudes (in microamperes) of electrodograms that yielded equal loudness in experiment III. Only those electrodes that were activated for each test stimulus were taken into account. (B) Modulation depth calculated from temporal information available in each electrodogram. For ACE the calculations were performed with [denoted by ACE (ip)] and without phase [dashed line denoted by ACE (oop)] information.

(modulation frequency was 100 Hz) was matched with a sinusoidal standard at 1 kHz in four Ineraid users. It was demonstrated that the slopes of the loudness balance functions decreased with increasing modulation depth indicating an increase in perceived loudness compared to an unmodulated stimulus. Moreover, the loudness difference between modulated and unmodulated signals was largest at high sensation levels. The authors concluded that either signal rms (low sensation levels) or signal peak (high sensation levels) determine the loudness percept. This was confirmed in a later study by Zhang and Zeng (1997) where Schroeder-phase harmonic complexes were balanced in loudness with zero-phase stimuli in three Ineraid users. In the same study an effect of modulation depth and modulation frequency on the loudness percept of SAM noise was shown in four NH subjects for relative low overall signal rms levels of up to 45 dB sound pressure level. Furthermore, it was reported by several authors (Cazals *et al.*, 1994; Chatterjee and Robert, 2001; Shannon, 1992) that TMTFs in EH are level dependent and dramatically decrease in slope (i.e., decrease in sensitivity) for modulation frequencies around 100 Hz and higher. These findings are relevant for our study. However, several differences that make a direct comparison somewhat more complicated should be pointed out. Firstly, in the above cited studies, only single electrodes were directly stimulated. In our study we use multichannel stimulation based on an entire implementation of a CI signal processing strategy. This means that we deal with by far more complex temporal and place characteristics of the electric stimulation pattern that vary not only across strategies but also across channels within a strategy. Secondly, the AM as implemented in our study was based on the following equation:

$$s(t) = \left[0.5 + 0.5 \sin\left(\frac{2\pi}{R}\sum_{i=0}^{t} F0(i)\right)\right] C_n(t),$$
$$n = 1 \cdots 22, \tag{2}$$

where $C_n(t)$ is the magnitude of filter-bank channel n at time t, $F0(i)$ is the extracted F0 at time i, R is the channel analysis rate (1778 Hz), and $s(t)$ is the resulting AM waveform. It is clear from Eq. (2) that the AM does not change the peak level of $C_n(t)$. Thirdly, we used pulsatile electric stimulation as opposed to analog stimuli used in Zeng and Shannon, 1995 and Zhang and Zeng, 1997. We suggest that this is the least critical issue concerning a comparison across studies since pulsatile and analog stimulations differ considerably in their physical properties but seem to evoke similar loudness percepts (see Zeng and Shannon, 1994).

We were interested in finding physical properties of the electric stimuli that would allow a reasonable interpretation of the perceptual results. Therefore, for each subject, we calculated the rms values in each channel of electrodograms that resulted from the loudness balance procedure. In each electrodogram we only considered those electrodes that were activated throughout the entire frequency range (i.e., in this case, electrodes 22–18). The rms values are first calculated from the channel amplitudes in μA and then expressed in % DR to allow a unified measure across subjects. In this case, the DR was calculated for each channel from its corresponding T- and C-levels in microamperes. The differences in channel-rms values between ACE and F0mod are shown in Fig. 5(A) for each of the selected electrodes. At low F0 stimuli (i.e., F0's in range 104–131 Hz) the channel-rms values of the selected electrodes are considerably higher in ACE than in F0mod. This is particularly true for the two lowest frequency electrodes 22 and 21. However, for F0's above 165 Hz the difference in channel-rms between both strategies decreased and was within 5%. The bias toward negative differences can be explained by the nonlinear relationship between microamperes and clinical current units that were used to express DR in the loudness balancing experiment. In other words, for this F0 region, the channel-rms values seem to be related to loudness. However, this measure cannot explain the high loudness discrepancy below 165 Hz. We speculate that in this case across-channel phase synchrony in AM and the subjects' frequency dependent modulation sensitivity have an effect on loudness.

Panel (B) of Fig. 5 shows modulation depths (range [0, 1]) calculated from the spectra of the channel amplitudes of each electrodogram [see Eq. (5) in Laneau *et al.*, 2004]. For ACE we also made a distinction between in-phase and out-of-phase modulations. From these measures it is obvious that ACE exhibits in-phase modulations in a limited frequency range at noticeably lower modulation depths than F0mod. It

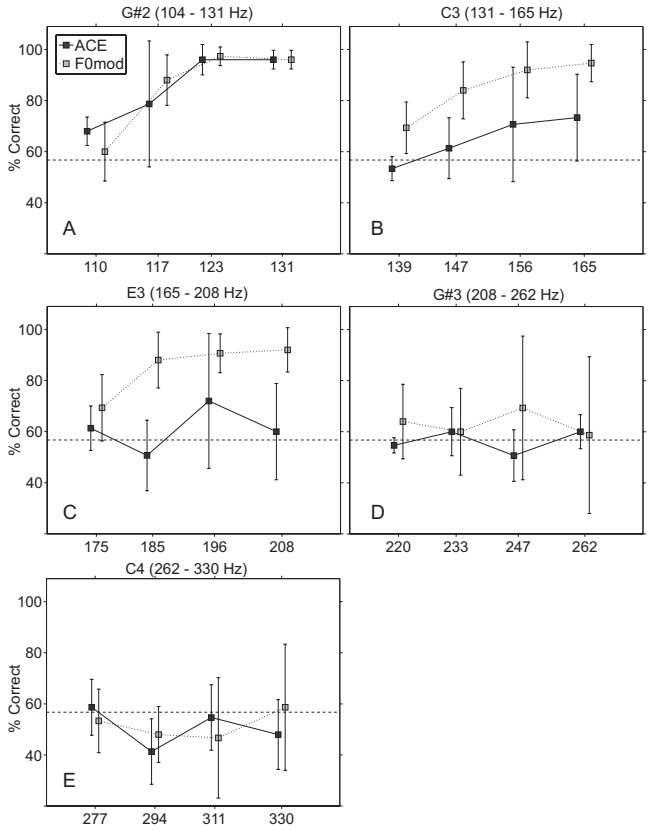

FIG. 6. Results pitch ranking. Panels (A)–(E) show the % correct scores (*y*-axis) for a particular frequency register (denoted by the title above each panel) averaged over five subjects. The F0's of the comparison tones (in hertz) are indicated on the *x*-axis. The reference note of the frequency register and the covered frequency range in hertz are denoted above each graph. The horizontal dashed line represents the level at which scores were significantly above chance level (with $p=0.05$ and chance level at 50%).

appears unlikely that in ACE these in-phase modulations could significantly contribute to a loudness percept. In contrast, F0mod contains in-phase modulations at full depth for the entire investigated frequency range. We assume that the only significant influence of these modulations was on loudness percept for F0's between 104 and 165 Hz. In summary, we propose that at low F0 stimuli mainly across-channel synchronized temporal fluctuations in the electric code contributed to the loudness percept for F0's between 104 and 165 Hz. At higher F0's the channel-rms levels essentially determined loudness. The implications of out-of-phase modulations on loudness remain unclear.

The demonstrated effects of the F0mod strategy on loudness could have a negative impact on speech perception. The different loudness percepts between ACE and F0mod could produce different consonant-vowel intensity ratios in both strategies. In F0mod, this might lead to less consonant enhancement (in case vowel and voiced consonants would appear equally loud) and consequently to degradation in consonant recognition (see also Kennedy *et al.*, 1998). We furthermore speculate that the evoked loudness is independent of modulating waveform since detection thresholds for, e.g., sinusoidally and sawtooth-shaped modulated pulse trains are similar as shown by Landsberger (2008). However, in order to overcome an eventual speech perception, deficit, subjects should be given sufficient time to get accustomed to the new processing scheme.

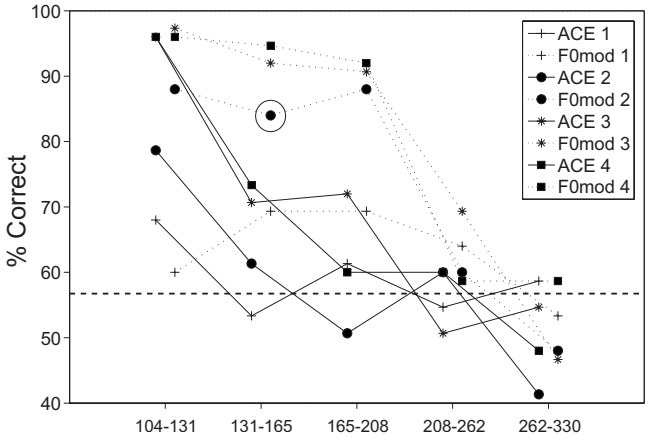

FIG. 7. Semitone-interval scores in which the pitch ranking results (experiment 2) were reorganized. The figure shows the % correct scores (*y*-axis) for particular intervals spanned by reference and comparison tones of each frequency register. Frequency registers are represented by their corresponding frequency range (in hertz) on the *x*-axis (compare with titles above each graph of Fig. 6). The parameters of this representation are strategy and interval (in semitones) and are denoted in the legend in the same order. Error bars were omitted for clarity. The circle exemplifies the % correct F0mod score for a two-semitone-interval spanned by reference and comparison tones in frequency range 131–165 Hz corresponding to frequency register C3. Note that semitone-interval scores representing the same interval and strategy are connected by a line.

IV. EXPERIMENT 2: PITCH RANKING

A. Procedure

Pitch ranking was conducted in a constant 2I-2AFC procedure. Upon each trial subjects were presented with a reference and a comparison tone in random order and had to indicate which was higher in pitch. A total of five frequency registers were created with reference F0's at 104, 131, 165, 208, and 262 Hz, respectively. Each register contained four comparison tones that were one, two, three, or four semitones higher in F0 than the reference. All frequency registers were tested separately in one block. Within a block each combination of reference and comparison tones was repeated 15 times resulting in a total of 60 trials (4 comparison tones $\times$ 15 repetitions) per block and thus per frequency register. No feedback on the subjects' responses was provided; likewise neither training nor practice sessions were presented.

B. Results

The pitch ranking results are shown in Fig. 6. Panels (A)–(E) depict the % correct scores for one particular frequency register represented by the corresponding reference note and frequency range (denoted above each graph). One filled square represents results averaged over responses from five subjects for one comparison tone (comparison tones are represented on the *x*-axis by their corresponding F0 in hertz). The dashed horizontal line in each graph shows the level at which a score significantly above chance is achieved (for $p=0.05$ and chance level at 50%). In Fig. 7 the pitch ranking results were reorganized into so called semitone-interval scores. Each marker shows the % correct score for a defined

interval spanned by reference and comparison stimuli from a given frequency register. Frequency registers are represented by their corresponding frequency range (in hertz) on the *x*-axis (compare with titles above each graph of Fig. 6). An example is given by the circle that represents the F0mod score for a two-semitone interval (i.e., the F0's were 131 and 147 Hz) in the frequency range 131–165 Hz corresponding to frequency register C3. In the figure legend the number following the strategy name denotes the interval in semitones. Note that each particular semitone-interval score (i.e., representing one interval and strategy) is connected by a line. This representation is particularly useful for an interpretation of the results of experiment 3 and will be referred to in Sec. V C.

A repeated measures ANOVA was performed on the scores taken from all registers with three within-subject factors (strategy, register, and comparison note). The analysis yielded significant effects for all factors ($p<0.05$). No other significant interaction effects were indicated. A pairwise comparison using the Bonferroni test showed that performance with F0mod was significantly better than with ACE ($p<0.05$). There was a significant between-subject effect ($p<0.0001$). A repeated measures ANOVA with two within-subject factors (strategy and comparison note) was applied to each frequency register separately. The analysis yielded a significant effect of strategy for registers C3 and E3. A pairwise comparison showed that indeed subjects performed significantly better with F0mod than with ACE ($p<0.01$) for these two F0 regions. The *p*-scores of the remaining results were not significant for both strategies.

C. Discussion

The results of experiment 2 demonstrated (1) equal performance with both strategies in register G#2, (2) a significantly better performance with F0mod in registers C3 and E3, (3) near chance level performance with both strategies in register G#3 with a small advantage for F0mod (average scores lie all significantly above chance level), and (4) overall low performance (i.e., not significantly above chance level in most instances) with both strategies in the last frequency register C4.

These outcomes can be best interpreted on the basis of three aspects that are relevant for perception of temporal pitch cues in EH, namely, (1) sensitivity to AM, (2) across-channel synchrony and depth of AMs, and (3) perceptual limit of temporal pitch cues. In frequency register G#2 the performance is equal in both strategies. In this frequency range, however, ACE exhibits in-phase modulations at considerably lower depths than in F0mod [see Fig. 5(B)]. This implies that at low F0's, where modulation sensitivity is highest, less modulation depth in AM synchronized channels than applied in F0mod is sufficient for pitch ranking. In frequency register C3, however, the scores with ACE drop compared to register G#2. This is probably due to the reduction in in-phase modulation depth for this strategy observed between 104 and 165 Hz. The out-of-phase modulation depth is almost constant in the same frequency range. The outcomes for ACE in register E3 can be explained in a similar way. Note that the performance with ACE in register C3 is more consistent (improved performance with increasing comparison F0) than in register E3. In contrast, the phase-synchronized AMs as provided by F0mod allow reliable pitch ranking between 104 and 208 Hz.

In the last two registers G#3 and C4, where the subjects exhibit least sensitivity to AM, temporal envelope cues become less important for pitch perception. In addition, in these registers, the generally accepted limit of temporal pitch cues, namely, 300 Hz, is approached. This means that in this case the subjects mainly relied on place pitch that probably could not contribute to a pitch percept alone within the limited frequency range of the above mentioned registers. However, in register G#3, the average scores with F0mod lie significantly above chance level showing that some subjects could indeed still use the temporal information to manage the task. This was confirmed by the individual scores of subjects S3–S5 who could clearly profit from F0mod compared to ACE especially for comparison F0's at 247 and 262 Hz (data not shown here).

Based on our results and previously reported findings (see also Sec. III C) we assume that with increasing F0 the subjects showed decreasing sensitivity to AM. In the F0mod strategy this diminishment could be compensated for F0 values up to 208 Hz by enhanced temporal cues, realized through across-channel synchrony in AMs applied at 100% modulation depth. The overall progression (between registers) of the pitch ranking scores together with modulation depth measures shown in Fig. 5 support the assumption that synchrony may be a more relevant property than modulation depth.

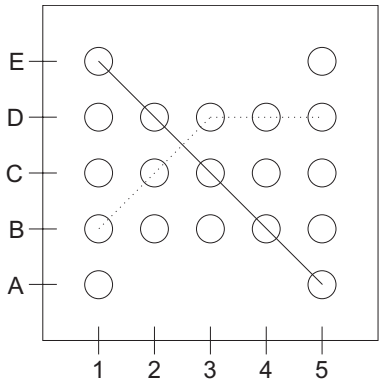
In Vandali *et al.*, 2005 several strategies that incorporate synchronized and enhanced envelope cues in a similar way to F0mod were compared with ACE. In a frequency range between 98 and 277 Hz, thus comparable to our study, significantly improved pitch ranking was demonstrated with the MEM, MDE2, and MDE3 strategies. The authors speculated that across-channel AM synchrony contributes more to an improved pitch percept than modulation depth. This in general agrees with our results. Furthermore, the authors also reported decreasing performance with increasing F0 another finding that is consistent with our study. It should be mentioned, however, that in the pitch ranking tests of the study by Vandali *et al.* (2005) the smallest interval between reference and comparison tones was half an octave. Thus, it remains unrevealed how well CI subjects would perform with their proposed strategies for smaller intervals that were assessed in our study.

V. EXPERIMENT 3: MELODIC CONTOUR IDENTIFICATION (MCI)

A. Procedure

The MCI test contained nine different melodic sequences of which each consisted of five tones. Every sequence was characterized by a specific F0 contour. The test was carried out in a constant 1I-9AFC procedure. In one trial the subjects were presented with one of the nine contours and were asked to indicate a corresponding visual counter-

Grp4	Grp3	Grp2	Grp1
262	208	165	131
208	175	147	123
165	147	131	117
131	123	117	110
104	104	104	104



Contour	Sequence
R	1A, 2B, 3C, 4D, 5E
FA	1E, 2D, 3C, 4B, 5A
FL	1C, 2C, 3C, 4C, 5C
RFA	1B, 2C, 3D, 4C, 5B
RFL	1B, 2C, 3D, 4D, 5D
FAFL	1D, 2C,3B, 4B, 5B
FAR	1D, 2C, 3B, 4C, 5D
FLR	1B, 2B, 3B, 4C, 5D
FLFA	1D, 2D, 3D, 4C, 5B

FIG. 8. Illustration of contours used in the MCI test. The contour matrix in the middle of the figure allows to navigate through the progression of each contour in time (horizontal locations 1, 2, 3, 4, and 5) and F0 (vertical locations A, B, C, D, and E). The table on the left contains the corresponding F0's (in hertz) of each contour tone for each interval group (denoted by Grp1–Grp4). These data are vertically aligned with the F0 locations in the contour matrix. For example, the point 4B corresponds to a F0 of 117 Hz in interval group 2 and a F0 of 131 Hz in interval group 4. The table on the right provides the sequence of contour matrix locations for each melodic contour. The following abbreviations were used: *R* (rising), FA (falling), FL (flat), RFA (rising-falling), RFL (rising-flat), FAR (falling-rising), FAFL (falling-flat), FLR (flat-rising), and FLFA (flat-falling). The solid and dashed lines in the contour matrix represent the FA and RFL contours, respectively.

part (Galvin *et al.*, 2007). We implemented four interval groups in which an interval of one, two, three or four semitones, respectively, separated two successive notes of one melodic contour. Each interval group was tested separately in one block, in which the order of contours was randomly chosen and each contour was repeated twice. Each block was repeated three times, yielding a total number of six presentations of one contour in one interval group. This resulted in 54 trials (9 contours $\times$ 6 repetitions) per interval group. Again, no feedback or training was provided. The particular tone sequences of each melodic contour and of each register can be derived using Fig. 8. The contour matrix in the middle of the figure allows to navigate through each contour in time (x-axis) and F0 (y-axis). The corresponding tones per register are given in the table on the left whose entries are aligned vertically with the y-axis of the contour matrix. The table on the right shows the sequence of tones for each contour as matrix locations. Two examples, FA and RFL, are depicted in the contour matrix (see caption of Fig. 8 for further explanation).

B. Results

In Fig. 9 the MCI test results representing averaged scores from subjects S1–S4 are shown. Panels (A)–(D) of Fig. 9 represent each interval group with bars indicating the % correct scores for one particular contour. The dashed line indicates the level at which scores were significantly above chance level (with $p=0.05$ and chance level at 11.1%). In Fig. 10 the scores for each interval group shown in Fig. 9 were averaged over the nine contours. In both figures the error bars indicate standard deviation.

A repeated measures ANOVA with three within subject factors (strategy, interval group, and contour) was performed on the scores taken from all interval groups. The analysis yielded a significant effect of strategy ($p<0.01$). The pairwise comparison showed a significantly better performance with F0mod. The between-subjects effect was significant ($p<0.01$). For each interval group a repeated measures ANOVA with two within-subject factors (strategy and contour) was performed. No statistically significant effect was indicated for any factor in interval groups 1 and 2. A statistically significant effect of strategy ($p<0.05$) was obtained in interval group 3 in which a pairwise comparison yielded a significantly better score obtained with F0mod. For the last interval group the better performance with F0mod approached significance ($p=0.055$).

We furthermore examined whether the subjects significantly improved their performance with one of the strategies across interval groups. We therefore performed a repeated measures ANOVA with two within-subject factors (interval group and contour) for each strategy. No significant effect for any of the factors was obtained for ACE. For F0mod the effect of interval group approached significance ($p=0.052$). A pairwise comparison yielded an improvement in performance from interval groups 1 to 4 that approached significance at the same p-level.

C. Discussion

In the MCI experiment we expected to observe an improved performance in higher interval groups as compared to lower ones since large intervals between successive tones require less pitch resolution for recognition. From Figs. 9 and 10 it is clear that performance with F0mod comes close to these expectations. The subjects consistently improved their scores with increasing interval group. Comparing interval groups 1–4 they, in fact, improved from 27% to 61% correct. In contrast, the progression of the scores obtained with ACE between interval groups is counterintuitive since the scores seem to decrease from the one-semitone (38% correct) to the three-semitone condition (20% correct). Though, in interval group 4 the performance with ACE was more accurate as compared to interval group 3 (improvement from 20% to 32% correct). Interestingly the results with ACE are insignificantly higher than with F0mod in the first interval group [see Figs. 10 and Fig. 9(a)].

We can carefully interpret the outcomes of the MCI task, in which recognition of intervals was crucial, using the semitone-interval scores shown in Fig. 7. The progressions

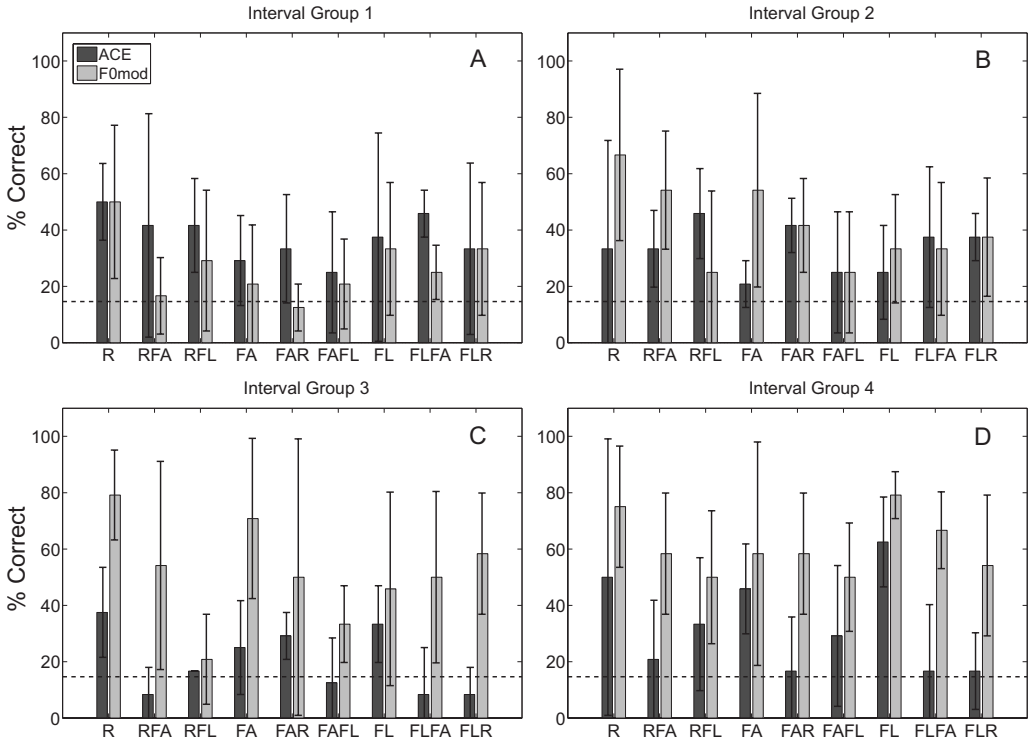


FIG. 9. Results MCI. The graphs in (a)–(d) for % correct scores (y-axis) for a particular interval group (denoted above each graph). Contours are denoted on the x-axis. The horizontal dashed line in each figure indicates the level of performance significantly above chance (for $p=0.05$ and chance level at 11.1%). Error bars indicate standard deviation.

of the semitone-interval curves of F0mod correspond with the average results of Fig. 10. First of all, an improvement is observed for this strategy between interval groups 1 and 2 (increase from 26.9% correct to 41.2% correct). The corresponding one- and two-semitone-interval scores also show an improvement by almost 30% (60% correct for one-semitone-interval score in frequency range 104–131 Hz, 88% and 84% correct for two-semitone-interval score in frequency range between 104 and 165 Hz). Moreover, an increase in performance is seen between interval groups 2 and 3 (improvement by 10%). This again agrees with the improvement between the two- and three-semitone-interval curves in the frequency range 104–208 Hz. Note also that these two curves show very little variance within this frequency range indicating that these two intervals could be perceived equally well throughout an entire melodic contour. Finally, the highest average scores with F0mod are obtained in interval group 4. The dramatic decrease in the corresponding four-semitone-interval scores from 208 Hz on had only little effect on the overall performance in this interval group since the only contours that spanned the entire frequency range between 104 and 262 Hz (thus from registers G#2 to G#3) were the R and FA contours. In fact, the average scores obtained for these contours are slightly lower than in interval group 3 [compare with panels (C) and (D) of Fig. 9].

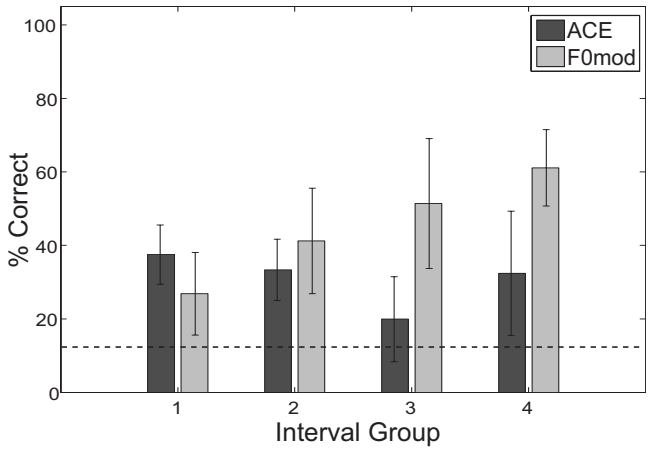

FIG. 10. Percent correct MCI scores (y-axis) averaged over four subjects and nine contours shown for each interval group (x-axis). Error bars indicate standard deviation.

The situation for ACE is somewhat different. The one-semitone-interval scores in frequency range 104–131 Hz for ACE amount to 69% correct. This could have led to the slightly better performance than F0mod in interval group 1. The two-semitone-interval scores for ACE, however, show a dramatic decrease from frequency range 104–131 Hz to 131–165 Hz (from 79% to 61%, respectively). This indicates that parts of the melodic contours falling between 104 and 131 Hz were more accurately recognized than parts falling between 131 and 165 Hz. An examination of the confusion matrices obtained with ACE for interval group 2 confirmed that this was indeed the case. The R contour, for instance, was eight times correctly identified but ten times confused with the RFL contour. Moreover the FA contour was 5 times correctly identified but 12 times confused with the FLFA contour. Similar confusions were observed in interval groups 3 and 4 for ACE. It remains, however, not entirely clear why the performance with ACE in interval group 3 was lower (even though not significantly) as compared to the remaining

registers. We speculate that up to interval group 3 temporal cues mainly mediated a pitch percept while for interval group 4 place cues prominently transmitted pitch information of higher F0's. As already discussed in Sec. IV C the temporal pitch cues in ACE systematically diminished from low to high F0's. For interval group 3 this would imply that as higher F0's were approached the subjects could neither reliably extract place nor temporal information with ACE.

In Galvin *et al.*, 2007 12 CI subjects were tested in the MCI task. In this study, among others, an interval group of five semitones was assessed. In many subjects consistently increasing scores with increasing interval group were observed. In contrast to this, in two subjects no considerable improvement was demonstrated between interval groups 2 and 5, one subject showed no improvement in performance between interval groups 2 and 4, and another subject could not improve noticeably between interval groups 3 and 5. Only one subject showed an inconsistent performance drop from interval group 3 to 4. However, in this test only frequency ranges above 220 Hz were tested. Furthermore, the study of Galvin *et al.* (2007) used stimuli containing only 3 harmonics, while our study used more complex stimuli containing energy in and up to the 16th harmonic. We assume that these are crucial differences to our study since harmonic complexes at higher F0's, with only a few harmonics, provide a distinct place pitch cue, which was also demonstrated by the study of Galvin *et al.* (2007).

VI. EXPERIMENT 4: FAMILIAR MELODY IDENTIFICATION (FMI)

A. Procedure

The FMI test contained two parts. In the first one the subjects were presented with 19 different titles of nursery songs well known to the Dutch–Flemish population. Thereby, they should indicate their familiarity with the title on a scale between 1 and 10 (1=not familiar, 10=familiar). The ten most familiar tunes were chosen. In the second part, one of the ten chosen familiar tunes was presented at random to the subjects in an isochronous version. Isochronous in this context means that rhythmical information was eliminated from the melodies by presenting each tone at equal duration and at equal time intervals. This approach prevents the subjects from using rhythm information as an additional cue. The subjects had to indicate the correct title of the song from a closed set of ten possible answers. Each melody was repeated twice within a block. One block was repeated three times yielding a total number of six presentations of each song. Again, as in the previous procedures, the subjects did not receive any feedback or training sessions. For more information about the song titles, the reader is referred to Laneau *et al.* 2006.

B. Results

The results of the FMI test are shown in Fig. 11 for each subject (S1–S3) and also for the group represented by the rightmost bars. Scores significantly above chance level are represented by the dashed horizontal line, and standard deviations are added to the group scores. A repeated measures ANOVA performed on the average scores did not indicate a significant effect of strategy. However, with F0mod, all subjects could obtain a score significantly above chance level, which was not the case for the ACE score of subject S3.

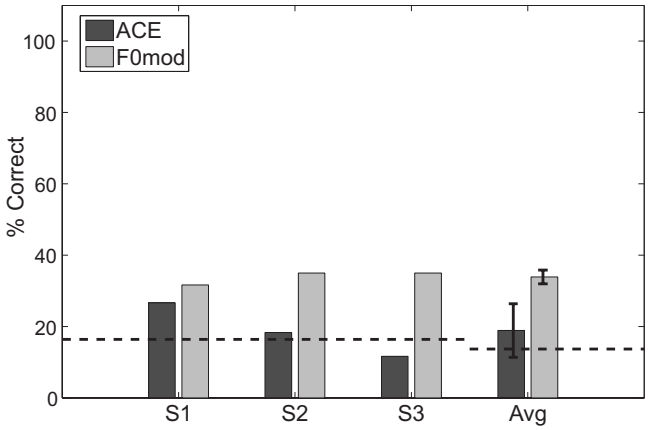

FIG. 11. Results FMI. The % correct scores (y-axis) are shown for each subject (denoted by S1–S3 on the x-axis). The two rightmost bars show scores averaged over the three participants. Note that the level at which performance was significantly above chance (dashed horizontal line, $p=0.05$ and chance level at 10%) is lower for the average scores.

C. Discussion

The results of the FMI task were modest. The subjects achieved scores between 31% and 35% with F0mod. The scores of two subjects (S2 and S3) were considerably smaller with ACE than with F0mod; in fact, subject S3 did not perform significantly above chance level with ACE. It is well known that in a FMI task with isochronous items CI users perform at chance level, which was shown, e.g., in Kong *et al.*, 2004 for four out of six CI subjects in a melody identification task. Overall low scores obtained by implanted subjects for recognition of isochronous melodies were also demonstrated in Gfeller *et al.*, 2002. This agrees with the results that were obtained for the ACE strategy in our study.

In general, in melody recognition tasks, CI subjects mainly rely on rhythmical cues rather than the melody itself. With F0mod the subjects could already obtain a baseline performance that was significantly above chance level. Note that the subjects did not have the opportunity to get accustomed to the sounds provided by F0mod. This means that with sufficient practice sessions eventually higher scores with F0mod could be demonstrated. This would imply that CI users would have better access to the melodic component of a familiar tune rather than to the rhythmic information alone. For the FMI tasks we should therefore gather data with more CI subjects over a longer term.

VII. CONCLUSIONS

In the present study we proposed an alternative implementation of a new coding strategy called F0mod originally developed in Laneau *et al.*, 2006. The strategy provides F0 information via amplitude fluctuations in each channel of the electrical stimulus thereby enhancing the envelope pitch cue. The new processing scheme was compared with ACE, nowadays the clinical standard strategy implemented in speech

processors of Cochlear Corporation. The evaluation was conducted in the scope of psychophysical tasks relevant to music perception. We carefully minimized possible differences in spectral processing as well as in evoked loudness percepts between the strategies under investigation. Thereby, we ensured that the strategies primarily differed in temporal processing. Significant improvements in pitch ranking, MCI, and FMI tests were demonstrated with the new F0mod scheme. The results indicate a potential benefit from consistently mediated envelope pitch cues, i.e., via amplitude modulations provided in phase across channels and at full modulation depth (i.e., 100% modulation). In particular, we also demonstrated that these cues significantly affect the loudness percept of a stimulus. This has to be taken into account in evaluation procedures and also when considering a real-time implementation.

ACKNOWLEDGMENTS

This research was carried out in the frame of the Institute for the Promotion of Innovation by Science and Technology in Flanders (IWT) Project No. 050445 and was partly sponsored by Cochlear Ltd. The authors thank the test subjects for their patient and enthusiastic participation to the experiments.

(Received 31 March 2008; revised 20 January 2009; accepted 21 January 2009)

Three dimensional large eddy simulations, microphone "pop" measurements, and high-speed videos of the airflow and lip opening associated with the syllable "pa" are presented. In the simulations, the mouth is represented by a narrow static ellipse with a back pressure dropping to 1/10th of its initial value within 60 ms of the release. The simulations show a jet penetration rate that falls within range of the pressure front of microphone pop. The simulations and high-speed video experiments were within 20% agreement after 40 ms, with the video experiments showing a slower penetration rate than the simulations during the first 40 ms. Kinematic measurements indicate that rapid changes in lip geometry during the first 40 ms underlie this discrepancy. These findings will be useful for microphone manufacturers, sound engineers, and researchers in speech aerodynamics modeling and articulatory speech synthesis. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081496]

I. INTRODUCTION

The release burst and aspiration or "pop" associated with voiceless aspirated plosive consonants (e.g., /p^h/, /t^h/, and /k^h/) in many languages is a potentially important cue in the perception of these sounds[1] and a well-known challenge for audio engineers and microphone manufacturers.[2,3] Plosive release burst and aspiration contains both sound and what has been termed pseudo-sound.[4,5] While sound waves propagate through air at the speed of sound ($c=\sqrt{\gamma P/\rho}$ for an ideal gas), pseudo-sounds are slower pressure fluctuations within the flow that are detectable by an ear or microphone. The present paper seeks to characterize the properties of flow (as opposed to sound) associated with English aspirated "p."

While a good deal is known about the properties of air flow from an orifice in industrial applications, there exist a number of problems peculiar to modeling oral aspiration in speech that have not been previously addressed, including properties of the orifice, flow description, and simulation type.

A. Orifice

During the production of the labial plosive "p" release, the lips constitute a highly complex orifice, being elastic and continuously changing in geometry and rigidity. During English and Japanese bilabial stop releases, Westbury and Hashi[6] used Westbury's x-ray micro-beam data to demonstrate that the lips accelerate away from each other after the release, reaching a maximum velocity of about 200 mm/s at 25 ms, and then decelerate until they reach an average opening of ~20 mm after ~200 ms. While this mouth opening time is quick, it is not negligible compared to the time scales under study. Pelorson *et al.*[7] argued for the importance of modeling changes in the lip opening over time, but presumably did not simulate it due to computational complexity. The rate of lip opening is likely to have a large effect on initial flow rate as air flows faster through constrictions in a tube. However, disturbances due to interaction between the flow and lips are expected to have little effect on the general flow.[8,9]

In an engineering setting there have been few studies of the effects of variable orifice geometry on the fluid mechanics. One such study, by Dabiri and Gharib,[10] considered the starting jet formed by a circular orifice of time-varying diameter. They studied the effects of changing nozzle diameter on the flow and found that a temporally increasing nozzle diameter causes the leading vortex ring to have the strongest vorticity at a larger radius from the centerline than for a constant nozzle diameter, but they did not measure jet penetration distance, which is a primary quantity of interest here.

During the production of "pa's," lip aperture geometry is

a)Electronic mail: dderrick@interchange.ubc.ca

 0001-4966/2009/125(4)/2272/10/$25.00

close to an ellipse,[7] and so there is the need to consider whether modeling the general elliptical shape of the mouth opening is important in simulating airflow after a bilabial release. Noncircular jets have been previously studied as a means of providing passive flow control. Research results, both numerical and experimental, show significant differences between circular and elliptical jets;[11,12] thus simulating the general shape of the lip opening is likely to be important for accurate simulations.

B. Flow description

After a bilabial stop release into a vowel, the pressure in the mouth drops asymptotically to approximately 1/10th of its initial value in the first 60 ms of the flow (similar to Fig. 4).[7,13,14] The pressure in the mouth is sufficiently great that the flow out of the mouth during an utterance such as "pa" is turbulent. In a turbulent flow a large range of scales is present, as opposed to the smaller range present in a smooth, laminar flow. One can confirm that a "pa" is turbulent by considering the Reynolds number, which is a dimensionless parameter important for characterizing flows:

$$\mathrm{Re} = \frac{\rho V D}{\mu}.$$

In this expression, ρ is the fluid density, V is the mean fluid velocity at the orifice, D is the orifice diameter, and μ is the dynamic viscosity. For a Reynolds number greater than 1000, round jets become turbulent a short distance from the nozzle.[15] D is approximated as 6.1 mm by finding the hydraulic diameter for the mouth (see Ref. 14 for similar hydraulic diameters), $V=20$ m/s as a conservative estimate, and using typical values of air of $\rho=1.2$ kg/m^3 and $\mu=1.8\times10^{-5}$ N s/m^2, the Re is ~8100, so this flow is turbulent.

Turbulent starting jets (the initiation of a continuous flow from an orifice) and puffs (in which flow at the orifice is cut off soon after initiation) have been heavily studied for other applications such as fuel injection, and are typically studied with round nozzles. Sangras *et al.*[9] (note correction[16]) provided a nice summary of starting jet and puff research. The leading edge of the burst follows the equation (dropping the virtual origin)

$$X = cT^n,$$

where $X=x/D$ is the non-dimensional distance, c is an experimentally determined constant, $T=tV/D$ is the non-dimensional time, and $n=1/2$ for starting jets and $n=1/4$ for puffs. Figure 1 shows the difference between a starting jet and a puff using the range of c reported in Ref. 9. The puff and starting jet penetration distances diverge significantly for $T\gtrsim100$. Using the characteristic diameter and velocity of a "pa" estimated above, puffs and jets would penetrate noticeably different distances after about 30 ms. Since there is a need to understand "pa" behavior to 100 ms or more, it is clearly necessary to model the actual transient pressure driving the flow.

Assuming the room temperature to be 22 °C and the air jet to be 37 °C (body temperature), then from the ideal gas law one finds the ratio $\rho_0/\rho_{\mathrm{jet}}=1.05$. Diez *et al.*[17] found the effects of buoyancy to be small for the temporal and spatial range considered in this study, and, while Diez *et al.* considered buoyant forces acting along the streamwise direction, in speech the buoyant force will be roughly perpendicular to the jet, presumably resulting in an even smaller effect on streamwise penetration. Temperature will also cause the jet viscosity to be ~5% higher than the surrounding air, but this difference should also produce negligible effects on a flow at this Re.

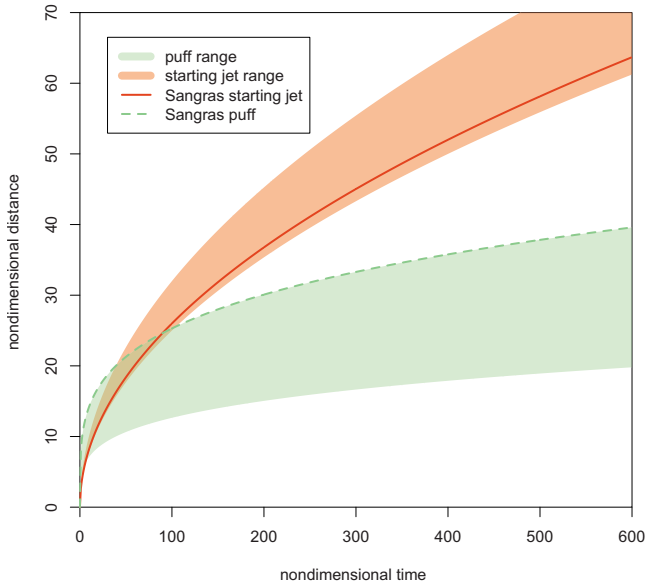

FIG. 1. (Color online) Starting puff and starting jet comparison.

C. Simulation type

One must consider whether the problem can be modeled in two dimensions, or if a more complex three dimensional (3D) model is required. If the domain is two dimensional (2D), then the mouth would have to be treated as a plane jet, as was done by Pelorson *et al.*[7] Although turbulence is a 3D flow, it is possible to consider a 2D Reynolds-averaged Navier–Stokes (RANS) turbulence model. However, Reichert and Biringen[18] and Stanley and Sarkan,[19] among others, reported significant inaccuracies in 2D simulations of plane jets. Finally, RANS models average the flow, but the turbulent fluctuations themselves are of interest to us; therefore a more sophisticated technique such as large eddy simulation (LES) is needed. Thus, both the geometry and the flow compel us to model plosive aspiration in three dimensions using LES.

D. Hypotheses

Based on the above discussion, it is proposed that to adequately simulate air flow from the mouth after the release of a bilabial stop into a vowel, one needs to take into account the known decrease in air pressure following the release. It is also hypothesized that the mouth can be adequately modeled as a 2D narrow ellipse. Computational limitations require a static geometry. The validity of this assumption must be compared with lip aperture over time from a high-speed video experiment. Due to the fact that the airflow throughout

most of the release is turbulent, it is necessary to resolve the turbulent properties, and because the lip aperture exists in 3D space, one needs a 3D LES to accurately model air flow after a bilabial release.

II. METHODS

These hypotheses were tested by comparing the results of two sets of experiments with simulations. The first experiment used a microphone located at varying distances from a participant repeating the syllable "pa" to record pressure fronts corresponding to microphone pops. The second experiment used high-speed video to record smoke particles. The microphone pops were compared to the simulation pressure front. The leading edge of the smoke particles recorded in the high-speed video was compared to the leading edge of the simulation particle front.

A. Microphone experiment

1. Data recording

For the microphone pop experiment, a single male participant was seated in a sound-proof room. Two microphones were placed in the room, one dummy microphone at 50 cm away from the mouth of the participant, and one SHURE SM58 set 5 cm away from the mouth of the participant. The cover of the microphone was removed to increase the effect of the pop on the recording, and the microphone was plugged into a Sound Devices USBPre microphone pre-amplifier plugged into a 1.42 Gbyte dual processor PowerMac G4 with 512 Mbytes of ram running Mac OSX 10.4.10 and recording with Audacity 3.3 at a sampling rate of 44 100 kHz. Both microphones were lined up and placed at exactly the mouth height of the participant.

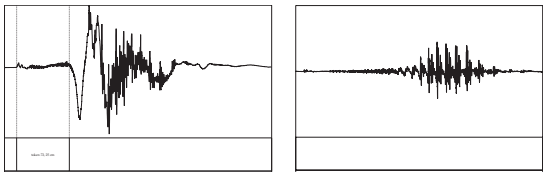
The participant wore a set of direct sound extreme isolation headphones plugged into the USBPre and set to monitor microphone input in real-time. The self-monitoring allowed the participant to adjust his speaking angle to make sure that microphone pops were being picked up by the Shure SM58 microphone, a particularly difficult task at distances past 20 cm.

The participant was handed a thin rigid tube to place in the corner of his mouth. The tube was attached to a SCICON Macquirer 516 airflow meter set to record the mouth pressure of the participant during the experiment. The airflow meter was attached to the same powerMac and using MACQUIRER 8.9.5.

The participant was asked to say the word "pa" 15 times while focusing on the dummy microphone set 50 cm away. The experiment was repeated with the microphone moved back at 5 cm increments from 5 to 40 cm away from the participant.

2. Data analysis

For each token the maximum air pressure just prior to the release burst of "pa" was recorded along with the difference in time from the onset of the sound of each "pa" and the beginning of a microphone pop. Airflow perturbations, or microphone pops, affect microphone output through the production of a very low frequency wave caused by the airflow, and high frequency aperiodic sound. To measure how long the airflow took to reach the microphone, the time between the onset of the release burst and the onset of the first significant low frequency perturbation that looks and sounds like microphone pop was used, as illustrated in token 75 in Fig. 2(a).



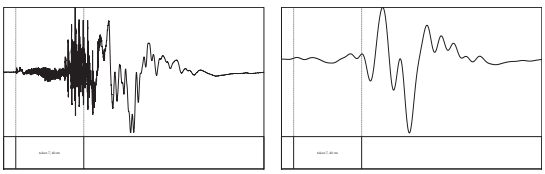
(a) 'pa' with pop (b) 'pa' without pop

FIG. 2. Sound waves from a "pa" with microphone pop and "pa" without microphone pop (183 ms clip).

However, these perturbations are difficult to isolate, particularly from a sound signal for distances from 20 to 40 cm due to overlap with the high amplitude vocalic portion of the sound wave. Fortunately, microphone pops are also associated with turbulence at higher frequencies. The high frequency aperiodic sound is hard to isolate in the waveform, but easy to detect by listening to the sound. Therefore each token was also examined by listening for the onset of pops using a set of high-quality Sennheiser HD650 headphones and a Total Bithead pre-amplifier. This turbulent sound helped isolate the onset of the microphone pop. For cases where neither listening nor examining the original wave worked, the original sound file was low-pass filtered using a band pass elliptic filter set from 30 to 100 Hz in MATLAB with 30 Hz skirts. These frequencies are produced in the sounds of speech, but microphone pops produce these frequencies at higher amplitude making the leading edge of the microphone pop easier to detect.

The time between the onset of the original sound wave and the onset of the first visibly larger peak was selected, but only when there was an obvious increase in the amplitude of these low frequency waves clustered together. This filtering method can reduce the accuracy of measurements because it excludes relevant frequencies that cannot be used because they overlap the fundamental frequency and first harmonic. However, in some cases the method was very helpful, as in token 7 shown in Fig. 3 where it is hard to see the onset of the pop in the unfiltered waveform, but easy to see in the low-pass filtered waveform.

If none of these three techniques produced a discernible result, the token was not used because the microphone did not record a loud enough pop to isolate.



(a) Unfiltered Sound Wave (b) Low Pass Filtered Sound

FIG. 3. Measurements from sound token 7, distance=40 cm, 437 ms clip.

The microphone pop timing corresponds to the leading pressure front recorded in the air puff simulation.

B. High-speed video experiments

Two sessions of high-speed video of the participant from the pop experiment saying the word "pa" while expelling white smoke were made. The smoke had a similar density as air, and was close to body temperature or approximately 37 °C at the time of expiration.

For the first round, digital videos of three productions of "pa" were captured using black foam board in the background and a standard tape measure pasted to the board for scale. The camera was placed approximately 460 cm away and focused on the tape measure such that the shot was 52.8 cm wide at the focal point. Bright sunlight was used to provide lighting. The participant then stood to the edge of the black bristol board such that their mouth opened just above the tape measure. The participant inhaled white smoke prior to the production of the "pa" so that the expelled air from the production of the "pa" would be visible during filming. Video was captured using a Bassler 504 kc high-speed color digital video camera with a Micro-Nikkor 70–180 mm telephoto zoom lens. The camera was plugged into an EPIX PIXCI CL3 SD frame grabber card with 1 Gbyte, of PC133 mHz memory in a P4 computer with 1 Gbyte of ram running Windows XP. Digital video was captured into the frame buffer using X-Cap Lite set to capture at 1024×768 resolution at 500 fps at maximum light gain and exported frame by frame into 1280×1024 32 bit tagged image file format (TIFF) files.

For the second round, digital video of 12 productions of "pa" was captured using black foam board background and meter sticks for scale. The camera was placed approximately 330 cm away and focused on the tape measure such that the shot was 53.0 cm wide at the focal point. A film light was placed facing the speaker to clearly illuminate the smoke particles. Video was captured using a Phantom v12 high-speed monochrome digital video camera with a Navitar 6.5 × lens. Digital video was transferred from the camera's built-in memory to 1280×800 resolution jpegs at 2000 fps.

1. Data analysis

For both rounds, the point of the opening of the mouth was captured using IMAGEJ's point capture utility, and the leading edge of the white smoke was recorded frame by frame for the first 150 ms of recorded time. The points were converted to distance in centimeters and analyzed statistically.

For both rounds, exact measurements of initial mouth pressure could not be made because the air flow apparatus would have interfered with the visual recording of air puff travel. However, the pressure can be inferred from Kenneth Stevens data on initial intra-oral air pressure during the production of aspirated stops at normal volume and the previous recordings of louder "pa's" during the microphone study which used the same subject (see Fig. 4 in Ref. 14).

For the second round, the rate of lip opening was also captured using IMAGEJ's point capture utility. The position of the top of the mucous membrane of the upper lip and the crease that intersects the mental protuberance and the skin below the lower lip were recorded frame by frame for 40 ms for each of the 12 recordings. These points provided stable landmarks for measuring the rate of lip opening. The points were converted to distance in millimeters and analyzed statistically.

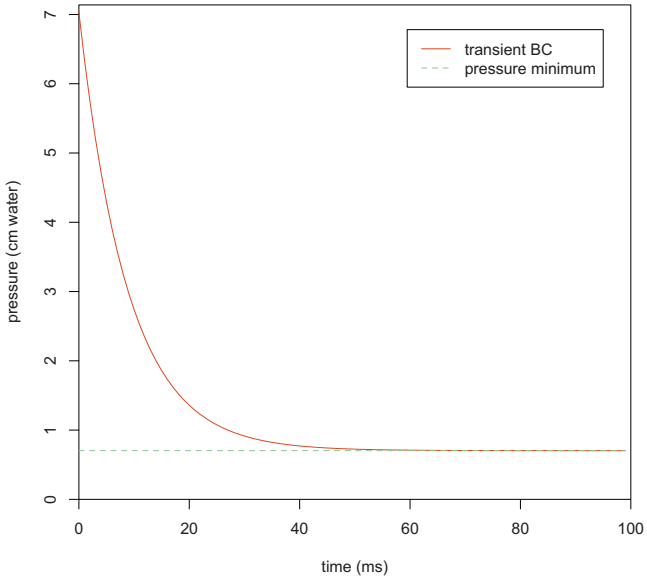


FIG. 4. (Color online) Transient boundary condition.

C. Numerical simulations

For the base numerical study, a domain of physical dimensions $350\times100\times100$ mm^3 which is meshed with 721 800, non-uniform, hexahedral control volumes was used. The mouth is shaped like a narrow ellipse in the $x=0$ plane, with $r_y=2$ mm and $r_z=15$ mm. A rough integration of upper and lower lip pellet velocities from the Westbury paper[6] shows that the lips have a y radius of 2 mm ~17 ms after they begin to separate.

Stevens[14] showed the intra-oral pressure quickly dropping after the release burst for "pa;" thus the mouth was modeled as a transient pressure inlet which quickly drops to 1/10th of its initial value, as shown in Fig. 4. In the simulation, the mouth lies in a plane that is modeled as a wall, while the rest of the boundaries are pressure outlets set to atmospheric pressure. The air is incompressible and initially still. Nitrogen particles were injected and tracked as a dye, thus defining the leading edge of the jet. An implicit bounded central differencing spatial discretization and an implicit second-order time discretization with a LES to model this turbulent flow were used. LES resolves the large eddies within the flow, but eddies smaller than the mesh scale are approximated by a turbulence model (in this case dynamic Smagorinsky[20]). The model was performed over 4000 time steps of size $\Delta t=0.025$ ms ($t_{\text{final}}=100$ ms). Using FLUENT as the solver, and running on three parallel processors, this process took ~6 days.

To explore the quality of the simulation methods and initial assumptions, numerous variations to this baseline

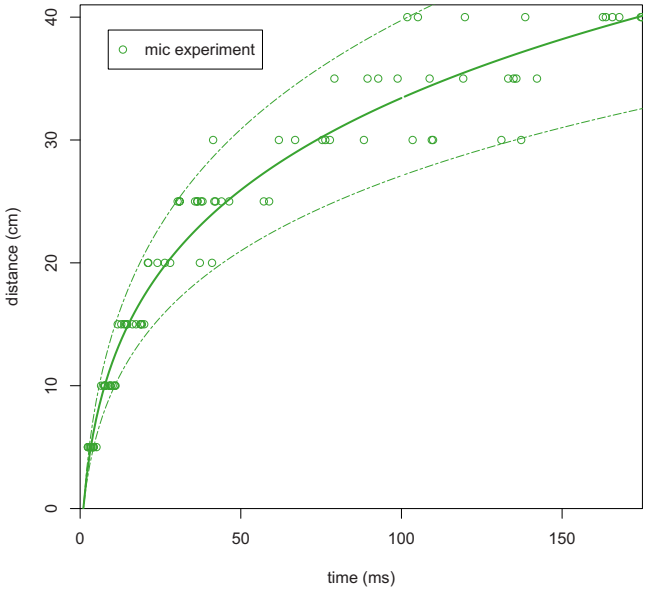

FIG. 5. (Color online) Experimental pressure fronts.

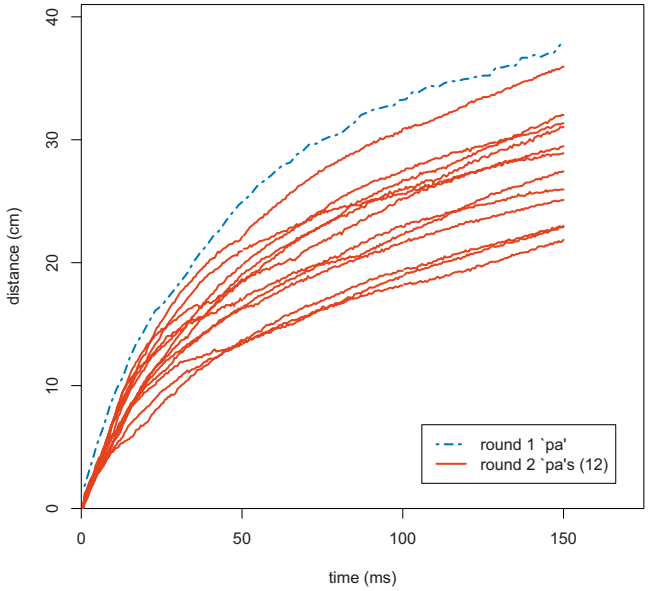

FIG. 6. (Color online) Leading smoke particle trails for pilot and second-round high-speed video experiment.

simulation were run; *Variation 1*: A grid refinement study was performed with the standard hexahedral mesh using a simulation with a medium mesh of 88 380 control volumes and a course mesh of 11 925 control volumes; *Variation 2*: A similar simulation replacing the mouth-shaped and time-varying inlet with a circular and constant velocity inlet, thus modeling a starting jet from a circular nozzle, was run in order to validate the numerical methods. See Ref. 21 for general discussion of verification and validation; *Variation 3*: A simulation with the starting inlet pressure three times higher than normal (24 cm/H_2O) yet falling to the same final value (0.703 cm/H_2O) was run to simulate a loud utterance: *Variation 4*: A simulation with a constant pressure inlet of 7.03 cm/H_2O (690 Pa), which is the same initial pressure of the baseline simulation was also run to test the importance of the transient pressure inlet; *Variation 5*: A simulation where the initial pressure was raised by 1 Pa was run. This slight change has little effect on the physics, but it does cause the numerics to change slightly, thus providing a second realization of the turbulent flow; *Variation 6*: A simulation was run where the inlet pressure condition was unchanged, but the initial domain was perturbed with small velocities, thus providing realistic disturbances in the air which are greater than machine zero. Some preliminary simulations in two dimensions, using LES and RANS were also conducted, but these soon proved to be inadequate.

III. RESULTS

The results of the microphone and high-speed video experiments, along with the numerical simulations, are described below.

A. Microphone experiment

Of 120 tokens recorded, 90 had discernible pops according to the standards described in Sec. II A. Individual measurements were highly variable, as seen in Fig. 5; the fit line is based on a loglinear quadratic fit with an assumed zero intercept. The fit line is highly significant, with an $F(2,88)=4386$, $p<0.001$ for each coefficient, and adjusted $R^2=98.9\%$. Linear, quadratic, cubic, and loglinear statistical models produced less significant results. As a result of trying to produce microphone pops in a microphone 50 cm away, the average intra-oral pressure was ~25 cm of water, or three times higher than normal, with high variability. This variability is largely a question of repeatability. It is almost impossible for a person to produce a repeatable mouth shape, initial air pressure, rate of decrease in air pressure, rate and degree of mouth opening, and orientation of the mouth to the microphone.

Many of these variables could not be measured and even initial mouth pressure could not be isolated from the other variables as no significant relationship was found between rate of air travel and intra-oral pressure prior to the release burst.

Nevertheless, the effect of many of these variables is known. Lower initial air pressure, faster rate of decrease in air pressure from the flow source, larger mouth opening, puff orientation away from the microphone, and perturbations in the air all decrease the rate of flow penetration. These effects combined can be quite significant.

B. High-speed video experiments

For the first round, three high-speed tokens were recorded, but only one was produced at a normal volume and voicing quality for an English "pa" syllable. This token was selected for comparison with the numerical simulations. For the second round of recordings, all 12 recordings were produced at a normal volume and voicing quality for an English "pa" syllable.

Results of measuring the leading edge of the smoke particles for each recording are shown in Fig. 6.

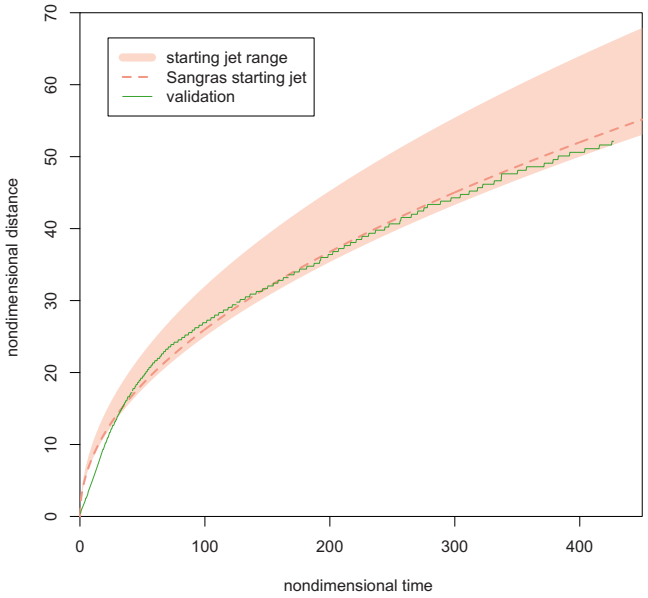

FIG. 7. (Color online) Numerical simulation validation: Starting jet range is defined by the constants reported in the summary of Sangras *et al.* (Ref. 9).

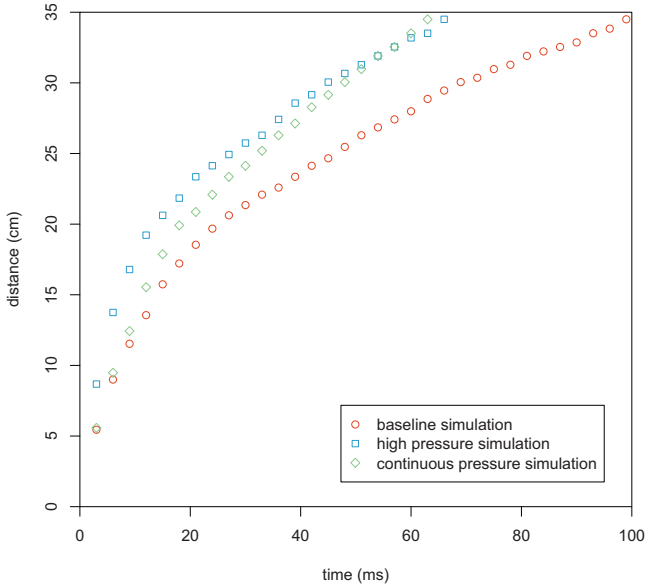

FIG. 9. (Color online) Comparison of leading particle front for baseline, high pressure onset, and continuous pressure simulation.

C. Numerical simulations

The validation study (variation 2) gives fine agreement with previous jet experiments described in the Introduction, as shown in Fig. 7. Figure 8 shows the grid refinement study (variation 1), along with the perturbed inlet simulation (variation 5) and the perturbed domain simulation (variation 6). The convergence is oscillatory, but outside of the asymptotic range. See Refs. 22 and 23 for discussion of oscillatory convergence and complications of LES verification, respectively. A comparison of the baseline numerical simulation, the simulation of the loud utterance (variation 3), and the constant inlet pressure simulation (variation 4) is presented in Fig. 9. As suggested in the Introduction, 2D simulations did not yield realistic results; generally they resulted in a jet penetration rate that was too fast. The loss of the 3D geometry caused the flow to be that of a plane jet rather than a jet from a nozzle. The loss of the 3D flow means that turbulence could not be truly modeled by LES, and the time-averaging of the RANS simulations removed flow details that are of interest. Use of 2D simulations was quickly dropped; therefore these results are not presented in detail here.

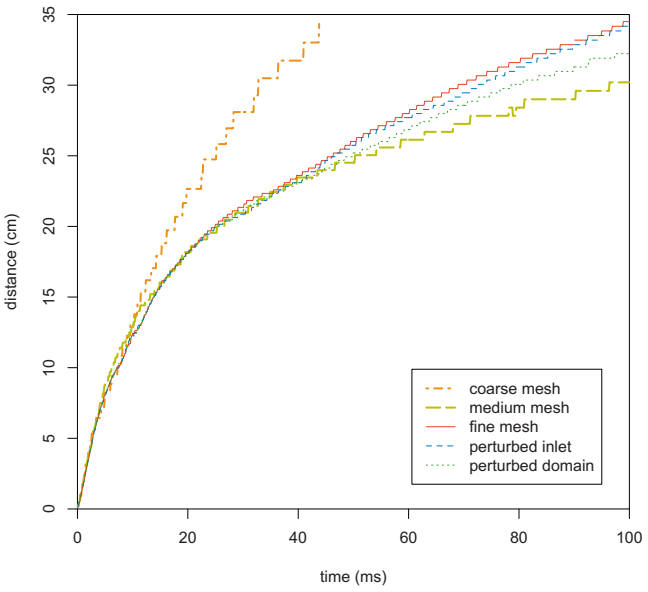

FIG. 8. (Color online) Simulation verification: Range represents confidence interval.

D. Comparison of simulation to microphone experiment

The simulation pressure front is defined as the distance at which the absolute value of the pressure reaches 1/10th of the maximum pressure for each time step. The simulation pressure front was compared to the results from the microphone experiment (Fig. 10). The green dots represent the mean measurements from the microphone experiment, the green line represents the loglinear quadratic fit, and the dashed green lines the 95% confidence interval. The simulation pressure front falls within the 95% confidence interval of the experiment.

E. Comparison of simulation to high-speed video experiment

A comparison graph between distance over time of the particle front from the high-speed video recordings and the numerical simulation appears in Fig. 11. The graph shows the loglinear quadratic fit lines for the pilot puff $[F(2,89)=1.125\times10^5,\ p<0.001,$ adjusted $R^2=99.9\%]$, second-round puff average $[F(3,3598)=7.479\times10^4,\ p<0.001,$ adjusted $R^2=97.7\%]$, and numerical simulation $[F(2,1208)=1.816\times10^6,\ p<0.001,$ adjusted $R^2=99.9\%]$. A comparison graph between the velocities over time of the particle front from the high-speed video recordings and the numerical simulation appears in Fig. 12. Note that the differences diminish dramatically after 40 ms, as shown in the inset within Fig.

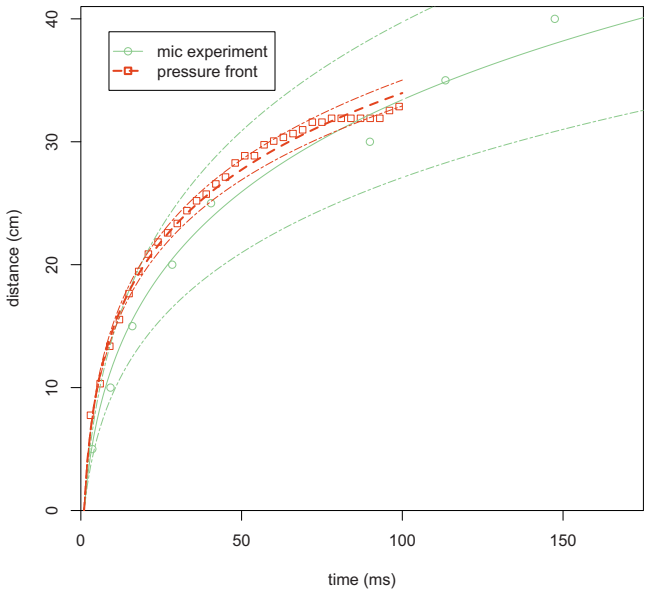

FIG. 10. (Color online) Average experimental and simulation pressure fronts.

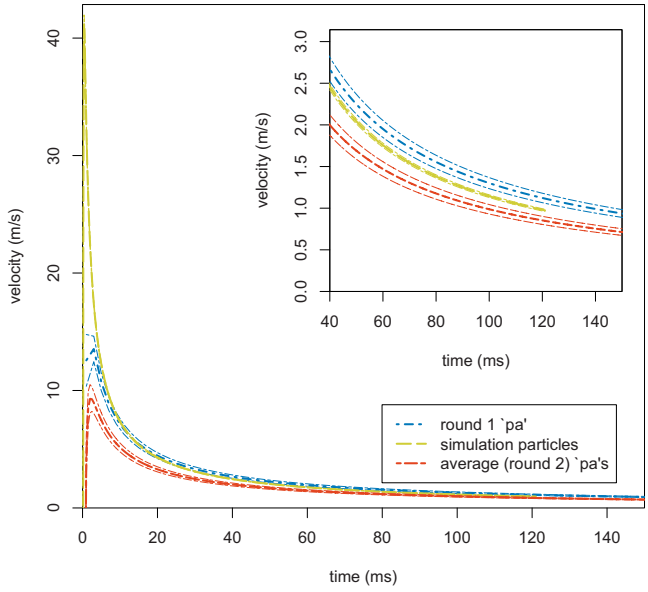

FIG. 12. (Color online) High-speed video particle front and simulation particle fronts (velocity).

12. There is a strong negative relationship between the rate of lip opening and leading particle edge distance traveled for the first 20 ms, diminishing after 30 ms and losing significance by 40 ms, as shown in Fig. 13. Both the significance and the *t*-value of the partial regression coefficient decrease over time as the leading edge of the puff moves away from the mouth opening. The results can be seen in Table I.

To illustrate the relationship between the smoke particle flow from high-speed film experiment and simulation results, a comparison of the video images from experiment round 1 and the baseline simulation is presented in Fig. 14. Round 1 video was selected to reduce the disparity between the images after time-alignment. Images were aligned such that the times at which the high-speed video's particle flow penetrates 5, 10, 15, 20, 25, 30, and 35 cm are matched with the same times in the simulation. Because frames are spaced 2 ms apart, the first frame with visible particle flow is assumed to occur ~1 ms after lip opening. This time-averaging, combined with the observation that the simulation flow rate matches closely, but not exactly with the high-speed video, creates distance alignment differences. As a result, the images do not align by particle front distance, and the differences can be seen in Table II. The velocity field instead of the particle field is shown because FLUENT does not export the particle data in a usable format and because the particle field can be inferred from the velocity field. In the high-speed video, most of the smoke is expelled in the first 30 ms, so the air expelled after that time is not as visible in the video frames. A graph of the simulated airflow velocity as a function of time in which each curve shows the velocity at a particular distance from the front of the orifice is shown in Fig. 15. The data are spatially averaged over a 1 cm radius in the *xz* plane and 2.1 ms in time. These lines reveal velocity oscillations around 100 Hz that were not smoothed out by the averaging. The oscillations are caused by large eddies in the flow that are resolved by the LESs, but which would not have been resolved with a RANS simulation.

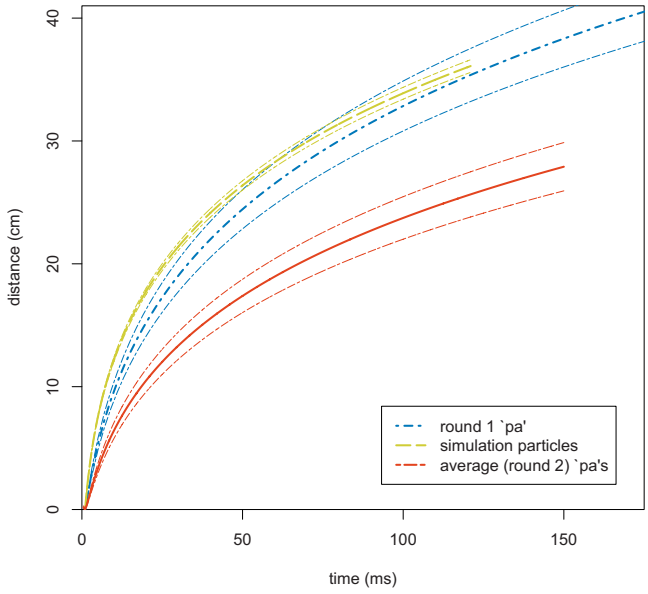

FIG. 11. (Color online) High-speed video particle front and simulation particle fronts (distance).

IV. DISCUSSION

These results show some significant discrepancies between the microphone experiment, the high-speed video experiment, and the simulations, but upon examination, these errors make sense in light of the assumptions and experimental methods used.

The microphone experiments were expected to show faster penetration than normal because the average intra-oral pressure was three times higher than normal, which was needed to attain good recordings. This impact, however, was not expected to be too large because velocity scales with the square root of pressure, as derived from Bernoulli's principle. Also, the air-pressure measurements showed that it

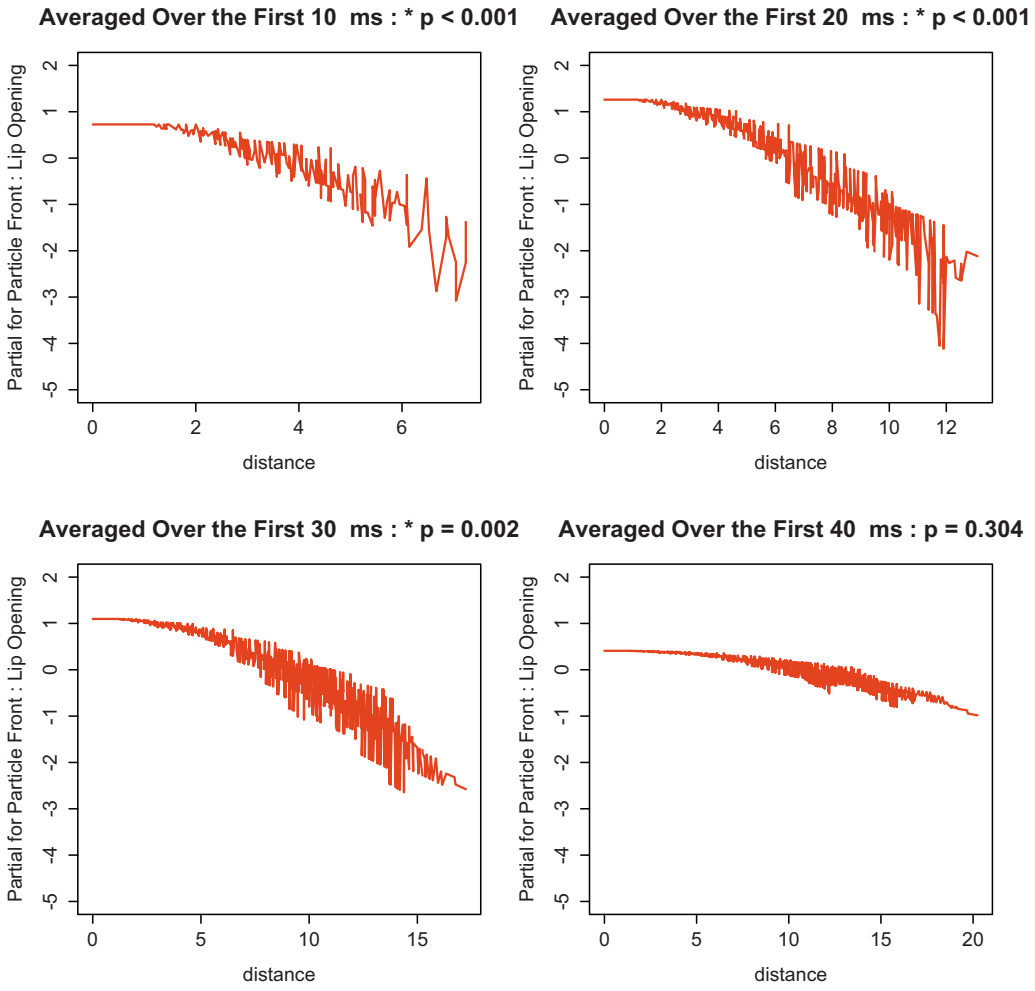

FIG. 13. (Color online) Negative partial regression between the width of lip opening and leading edge distance.

quickly fell to the normal level predicted in Stevens' book.[14] Therefore, the effect of the intra-oral air pressure would be less than one might expect, and the differences would be most significant at distances closest to the mouth.

The microphone experiment had a high variance due in part to the difficulty in capturing the microphone pops, especially at increasing microphone distances. Because of this high variance, the simulations fell within the range of results from the microphone experiment.

The high-speed video experiments, on the other hand, were captured at pressures reasonable for speech and were deemed trustworthy.

The measurements taken from the high-speed video were much more accurate than those taken from the microphone pop experiment as there were no visual artifacts interfering with visibility of the leading edge of the smoke comparable to the interference of the acoustic waves on the capture of microphone pops. Most of the variability in recorded results was seen in the rate of particle penetration during the first 40 ms, and could be largely attributed to the rate of lip opening during the first 20 ms. The faster the lips opened, the slower the initial penetration. Very tiny differences were significant.

TABLE I. Partial regressions of the interaction between the leading particle edge and lip opening averaged over 10, 20, 30, and 40 ms.

Coefficient	Time span (ms)	Estimate	Std. Err.	t	p
Puff travel	10	−1.69	0.34	−4.98	$*<0.001$
Distance	20	−0.81	0.18	−4.46	$*<0.001$
Lip opening	30	−0.36	0.11	−3.18	$*=0.002$
Width	40	−0.09	0.08	−1.03	0.304

The measured strong negative relationship between the rate of lip opening and the "pa" leading edge velocity was unexpected. Boundary layer effects would tend to produce a positive relationship between lip opening and "pa" velocity, so the negative relationship implies a more complex phenomenon, perhaps related to the geometry of the mouth behind the lips.

As discussed in the Introduction, there were a number of simplifying assumptions made for the simulation, particularly concerning the mouth. Not including the lips in the model means that the boundary layer effects were not modeled; these effects slow the jet. Also, Pelorson *et al.*[7] discussed the dominant role of viscous effects at the lips in the first milliseconds of a plosive, and Fujimura[24] also emphasized the rapidity of the change in the first 10 ms. Figure 12 shows that most of the simulation error occurs in the first 10–20 ms of the burst where the simulation velocity is much

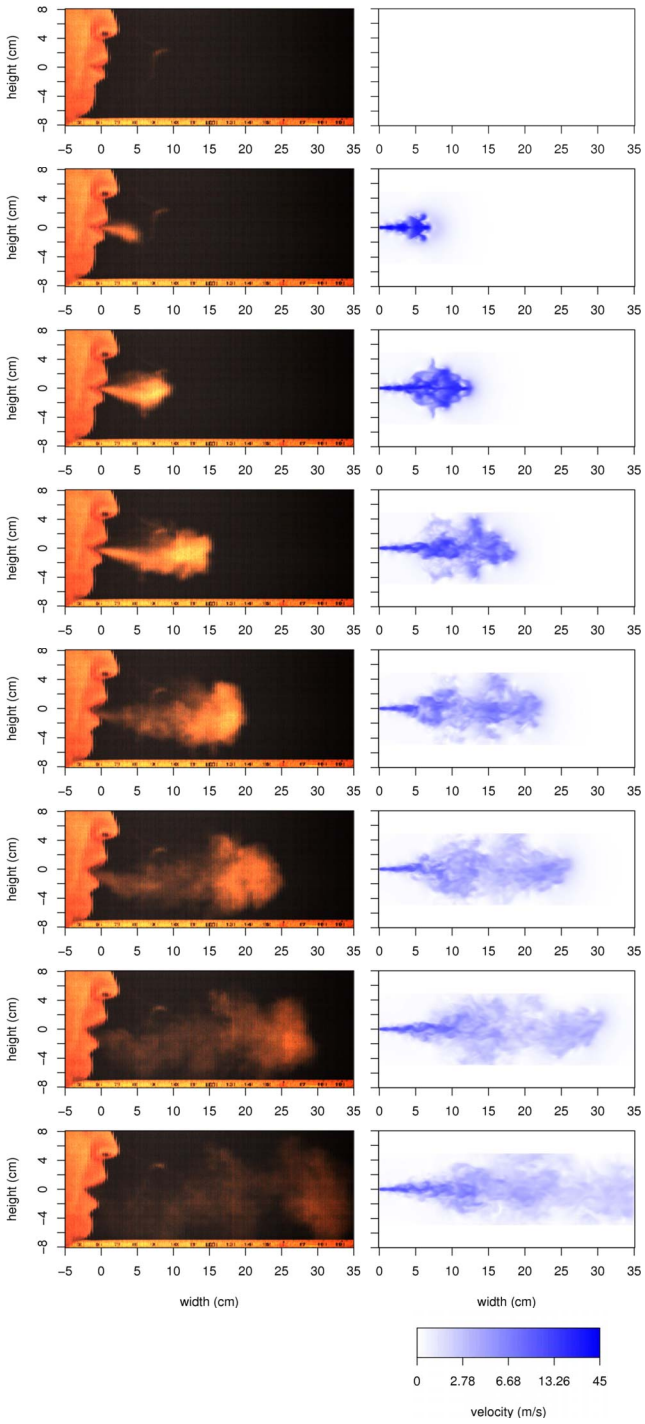

FIG. 14. (Color online) "Pa" on high-speed video (left) compared with numerical simulation velocity field (right). From top to bottom, the times (in milliseconds) of the image are 0, 5, 11, 21, 35, 51, 75, and 121.

higher than experiment, and the data in Fig. 13 and Table I confirm that the simulations suffer this error. This error largely accounts for the differences between the high-speed video experiment and the simulation.

A. Future work

The velocity data in this paper can be used to identify the maximum distance a perceiver can be positioned away from a speaker in order to detect puffs of air from labial plosives during their speech (though the minimum velocity at which skin receptors can detect air flow is as yet unknown), or as a basis for identifying the minimum distance a microphone needs to be from a speaker based on the microphone's sensitivity to air-flow velocity.

TABLE II. Time-alignment by distance for Fig. 14.

Time (ms)	Paticle distance (cm) by data source	
	High-speed video	Simulation
5	5.3	8.1
11	9.7	12.8
21	15.2	18.5
35	20.1	22.3
51	25.1	26.3
75	30.0	31.0
121	35.0	>34.8

While the simulations and the experiments match closely after 40 ms, the simulations predict faster airflow at the onset of the puff than that shown in the experiments. This difference was partially related to the fact that the mouth shape expands during the production of the "pa" syllable, but not in the simulation. Simulation of the change in oral aperture size would require changing the mesh throughout the simulation. This would be a challenging problem for further research. In addition, mesh and time step refinement may improve the quality of the simulations.

V. CONCLUSION

The results show that the hypotheses regarding the need for 3D LES with a mouth-shaped orifice and decreasing air pressure at the orifice are all reasonably valid for the accurate simulation of airflow after the release of an aspirated labial plosive. While the static elliptical orifice provided an adequate basis for simulation, the static and anatomically incorrect mouth shape contributed to the observed discrepan-

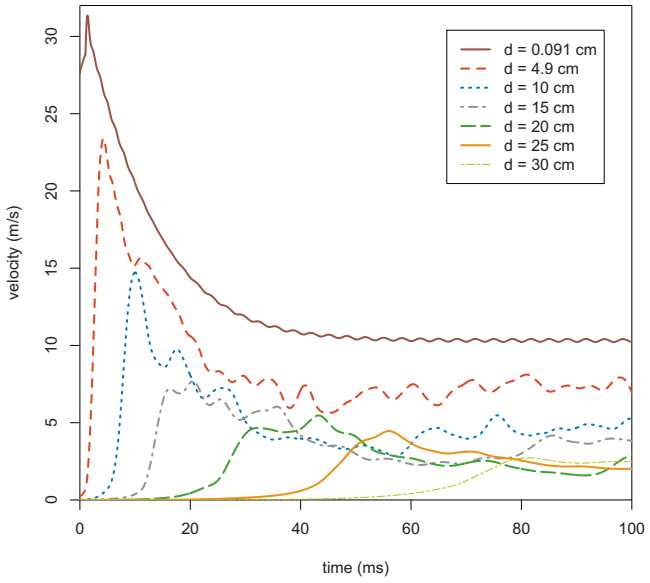

FIG. 15. (Color online) Airflow velocity over time based on the distance from orifice aperture.

cies in the results. Simulations involving a change in the orifice shape throughout the simulated time period, corresponding to known mouth shape changes in the production of labial plosives, may resolve this discrepancy.

By validating air-flow simulations to experimental data, it is possible to plot mean velocity in time as a function of downstream distance. This information can be used with experimental data to identify the distance away from the orifice or the time from the beginning of a speech release burst at which a person can perceive the airflow or a given microphone can pick up a pop.

These results provide the groundwork upon which future research in microphone manufacturing, sound engineering, speech perception research, and aerodynamic modeling of speech may be conducted.

(Received 25 April 2008; revised 29 January 2009; accepted 30 January 2009)

This study aimed to measure solid and liquid component parameters for canine vocal fold lamina propria tissue, as is consistent with the solid and liquid fraction parameters in the context of the biphasic theory. A liquid-displacement apparatus was developed and utilized to estimate volumes of small samples of tissue. Accuracy was determined by calibrations with an object of known mass and density (copper). The experimental apparatus was then used to determine the volume of eight tissue samples, followed by an apparently complete dehydration of the samples, yielding the dry or solid tissue. The mass and volume fractions of the liquid component were sufficiently higher than those of the solid component. These results represent preliminary experimental evidence for the biphasic composition (solid-liquid) of canine lamina propria tissue as predicted in the biphasic theory. This study presents an effective experimental method to estimate some of the biphasic model parameters, and may provide a valuable application in exploring the viscoelastic behaviors of vocal fold lamina propria tissue. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3086276]

I. INTRODUCTION

Vocal fold (VF) tissue is known to be a highly hydrated interstitial tissue. The level of VF tissue hydration plays an important role in vocal function (Verdolini *et al.*, 2002). Studies have shown that VF dehydration can lead to an increase in phonation threshold pressure and a decrease in vocal efficiency (Verdolini *et al.*, 1994; Jiang *et al.*, 2000). Classic viscoelastic models of VFs (Chan and Titze, 2000; Chan and Tayama, 2002), such as the quasi-linear model and the statistical network model, have been applied to study viscoelastic behaviors of the tissue. However, these models do not account for the liquid dynamics in the VF tissue. Clinically, dehydration contributing to dysphonia is associated with the loss of liquid components of the tissue. Without accounting for the liquid component in VF tissue, studies have not quantified the effects of liquid loss on the biomechanical properties of VF tissue.

A biphasic theory has been introduced to describe the effect of liquid components of the VF tissue (Zhang *et al.*, 2008). VF tissue can be described as a porous solid component (collagen, proteoglycan, and other structural components) that is swollen by interstitial liquid. Biphasic (liquid-solid) descriptions of tissue, which consider the interaction between the solid and liquid components of the tissue, show potential for explaining rheologic properties of VF lamina propria (LP). It predicts that the liquid component of the tissue is critical for shielding the extracellular solid matrix from extreme stressors, indicating that dehydration may decrease the stress support offered by the interstitial liquid. In addition, the liquid component is important in determining the stiffness, viscosity, and mass of the tissue (Chan and Tayama, 2002). In the biphasic theory, the liquid volume fraction was defined to describe the ratio of liquid volume to the total tissue volume. The liquid loss due to dehydration can be quantitatively measured by a decrease in the liquid volume fraction. Therefore, the direct measurement of the liquid and solid components is necessary for the application of the biphasic theory, a better understanding of the multiphasic composition of VF tissue and the effect of these parameters on biomechanical tissue properties. Despite these parameters' utility, liquid and solid volume fractions of laryngeal systems have not been measured in previous studies, although analogous parameters have been quantified in other biomedical systems, such as articular cartilage (Mow *et al.*, 1980, 1984).

The purpose of this study was to measure the individual contributions of the liquid and solid components to the total VF LP tissue's mass and volume. Due to the small tissue samples, we will apply a liquid-displacement apparatus to measure tissue volume. We will examine the accuracy of the experimental apparatus through measurements of copper samples, which has a known density and constant volume. Tissue volume measurement, in combination with the dry mass, allows for the calculation of the mass and volume fractions of the liquid and solid in the tissue. This information may lead to a better understanding of the biphasic description of VF LP tissue.

II. MATERIALS AND METHODS

A. Tissue sample preparation

Four larynges were harvested from healthy laboratory dogs, which yielded the eight tissue samples used in the experiment. Excision of the larynx was performed according to the procedure described by Jiang and Titze (1993). The excised larynges were placed in a 0.9% saline solution with a calculated density ρ_{sa} of 1.004 g/ml (McCutcheon *et al.*, 1993). The larynges were flash frozen in liquid nitrogen, stored in a freezer at −20 °C, and slowly unthawed in saline

 0001-4966/2009/125(4)/2282/6/$25.00

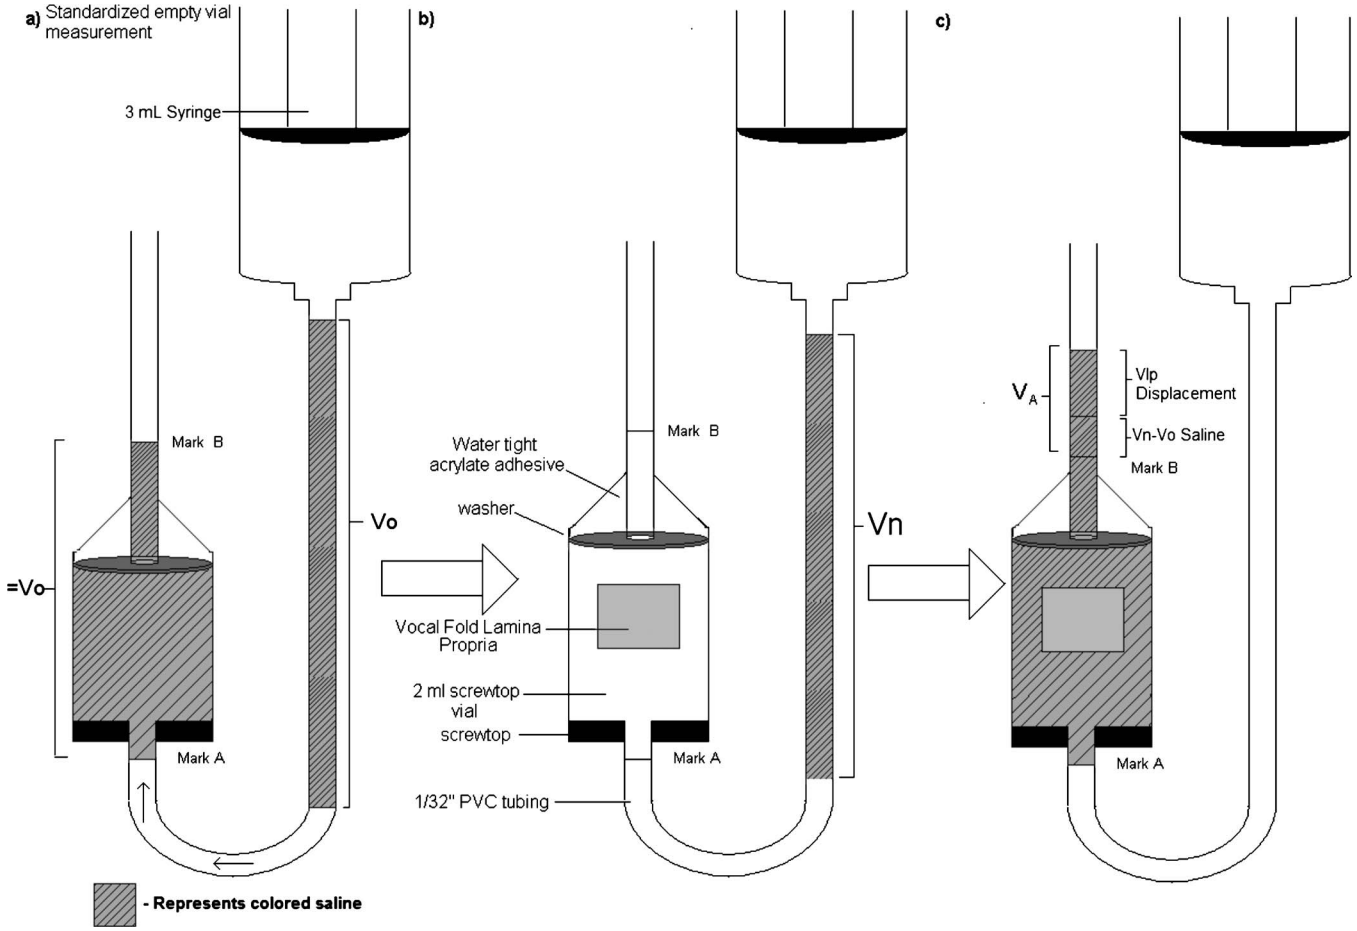

FIG. 1. Schematic of the liquid-displacement measurement process.

at about 4 °C a day before the experiment according to the Chan and Titze (2003) procedure which was found to minimize *postmortem* changes to VF tissue. A VF LP tissue was dissected out en block using a scalpel, with the anterior border 1 mm posterior to the anterior commissure, the posterior border 1 mm anterior to the arytenoid cartilage, the inferior border 5 mm inferior to the superior glottal edge, and the lateral border 5 mm lateral to the glottal edge. The thyroarytenoid muscle was then dissected away from the LP under a dissecting microscope using a scalpel. The epithelium was included in each sample in order to preserve the entire superficial lamina propria. The sample was then placed in a beaker containing 0.9% saline and allowed to equilibrate for 5–10 min before further handling.

B. Liquid-displacement method

Due to the small size of VF tissue, directly measuring tissue volume would bring sufficient errors. We applied the liquid-displacement method to measure the LP tissue volume V_{LP}. Figure 1 shows a schematic of this method, where the apparatus was assembled using approximately 2 m of 1/32 in. diameter clear PVC tubing, a 2 ml screw-top vial, a washer, silicone, and an acrylate adhesive. The screw-top vial was inverted and connected vertically downward (through the cap) to approximately 1.5 m of tubing in a U-bend shape. About 0.5 m of tubing was then run through the top of the vial using silicone adhesive for sealant. A washer was placed inside the vial, wedged against the chamber sides and below the silicone adhesive, preventing any volume changes in the chamber due to silicone compression.

Colored 0.9% saline solution was pushed via a 3 ml syringe (Terumo Supply, Elkton, MD) into the upper portion of the 1.5 m section of tubing and the height of this column was measured with an accuracy of 0.01 cm. 50 ml portions of saline had been colored using 1 drop of food dye to aid in measuring saline column height and identifying residual liquid remaining in the tubing. It was assumed that the small amount of dye used did not significantly affect the density or osmotic characteristics of the saline solution. Therefore, the density of the solution was calculated at 1.004 g/ml (McCutcheon *et al.*, 1993). Utilizing the known diameter of the tubing and the height of the water column, we were able to calculate the volume of this solution, V_0. The syringe was attached to the upper 1.5 m section throughout the procedure and facilitated the movement of the saline column along the tubing by "pushing" air into the system. This known volume was then pushed through the tubing so that it was approximately 1 cm below the vial, completely filling the vial, and a few centimeters above the vial. The tubing was continuously checked throughout the process to assure that the least amount of residual liquid possible was left behind in the tubing. According to the ratio of residue to total volume pushed through the tubing, it was estimated that far less than 1% of the original volume remained adhered to the inner

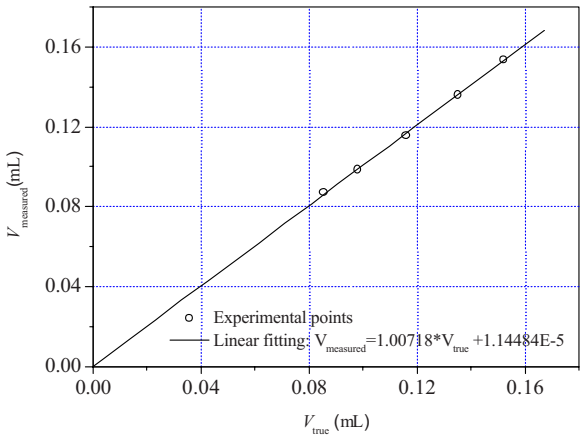

FIG. 2. (Color online) The relationship between the actual volume (V_{true}) and the experimentally measured volume ($V_{measured}$) of the five small copper samples.

tubing surface. The levels of solution below and above the vial were marked as marks A and B, respectively, and were considered to contain the known volume, V_0, between them. The fluid levels between marks A and B were measured to a ± 0.5 mm accuracy, which reflects an error value even less than that caused by the above saline-residue error. This volume was considered the "empty vial" volume since this part of liquid was taken out and was used to determine the volume of LP tissue in successive experiments, as shown in Fig. 1(a).

The tissue sample was then weighed on an electronic balance (SPE123, Ohaus Corporation, Pine Brook, NJ) accurate to 0.001 g, and immediately placed into the vial, soon to contain the new volume of saline, V_N. A new volume of liquid (V_N) was pumped into the upper 1.5 m of tubing, and the volume of this solution was calculated by measuring the height of the new column, and utilizing the known diameter of the tubing, as shown in Fig. 1(b). This volume was then pushed through the vial containing the excised LP tissue until the lower level of the fluid was exactly level with mark A. The liquid level above mark B was measured and used to compute V_A, or the volume of saline above mark B [Fig. 1(c)]. V_A includes the contribution from the tissue volume (V_{LP}) and the volume difference of $V_N - V_0$. From the measured V_0, V_A, and V_N, we can thus obtain the tissue sample volume V_{LP} by using the relationship

$$V_{LP} = V_0 + V_A - V_N. \quad (1)$$

In order to examine the accuracy of the volume measurement by liquid-displacement method, we used pieces of 99.99% pure copper with the density of 8.92 g/ml as test samples. Five small pieces of copper, all of which fit into the vial without restricting the flow of saline, were weighed with an accuracy of 0.001 g. From their mass and density, we calculated the volumes V_{true} of these copper pieces. The experimental volumes $V_{measured}$ of these copper pieces were measured using the liquid-displacement method. The volume measurement of each copper sample was repeated five times. Figure 2 shows the relationship between V_{true} and the averaged $V_{measured}$ of these copper pieces. The replicated volume measurements for all copper samples have the maximal error of 1.75% from their true values. The measured volumes V_{true} are a very close fit to a linear trend ($R=0.99964$), indicating a highly accurate volume measurement of small copper pieces.

C. Measurement of the volume and mass fractions of liquid and solid in VF lamina propria tissue

After measurement of the tissue volume V_{LP}, the mass of the tissue sample was measured on the electronic balance. The LP includes both liquid and solid components; therefore, its total hydrated mass was recorded as m_{LP}. The tissue density can be determined as $\rho_{LP}=m_{LP}/V_{LP}$. In order to completely dehydrate the tissue, the tissue samples were left in a vacuum oven (Isotemp Model 280A, Thermo Fisher Scientific, Waltham, MA) heated to 40 °C, and with the pressure lowered to approximately −15 mm Hg. The tissue was kept in the oven until it maintained a constant mass, which was denoted m_s or the dried solid component of the lamina propria. The difference between the total mass of the hydrated tissue and the dry solid component mass represents the loss of liquid from the tissue, allowing the mass of the liquid component to be computed as $m_l=m_{LP}-m_s$. We define the solid mass fraction ϕ_m^s as the fraction of the total mass represented by the solid mass and the liquid mass fraction ϕ_m^l as the fraction of the liquid mass of the total tissue mass. From the measured m_s and m_{LP}, we then can determine ϕ_m^s and ϕ_m^l as

$$\phi_m^s = \frac{m_s}{m_{LP}} \times 100\% \quad \text{and} \quad \phi_m^l = \frac{m_{LP} - m_s}{m_{LP}} \times 100\%. \quad (2)$$

Furthermore, the porous VF LP tissue was immersed in the physiological saline, which mimics the density and osmolarity of liquid in the tissue. The physiological saline as a bathing solution is considered to be isotonic to the tissue, thus preventing a net osmotic diffusion of water into or out of the tissue. Since the tissue can be viewed as in equilibrium with the saline, we can assume that the liquid density ρ_f sufficiently approached the density 1.004 g/ml of the saline solution. We then can obtain the liquid volume as $V_l=(m_{LP}-m_s)/\rho_f$. The difference between the total volume and the fluid volume gives the solid volume as $V_s=V_{LP}-V_l$. Similarly, we define the solid volume fraction ϕ_V^s as the fraction of solid volume versus total volume and the liquid volume fraction ϕ_V^l as the percent of the total volume occupied by the liquid phase. Thus, from the measured m_s, m_{LP}, and the total volume V_{LG} of the lamina propria, we can determine ϕ_V^s and ϕ_V^l as

$$\phi_V^s = \frac{V_{LP} - (m_{LP} - m_s)/\rho_f}{V_{LP}} \times 100\% \quad \text{and}$$

$$\phi_V^l = \frac{m_{LP} - m_s}{\rho_f V_{LP}} \times 100\%. \quad (3)$$

Clearly, these parameters are defined such that $\phi_m^l + \phi_m^s = 1$ and $\phi_V^l + \phi_V^s = 1$. During the experiment, the volume measurement was repeated on each tissue sample three times to ensure consistency in computing these parameters. The average variation of these measurements was 2.85% of the total tis-

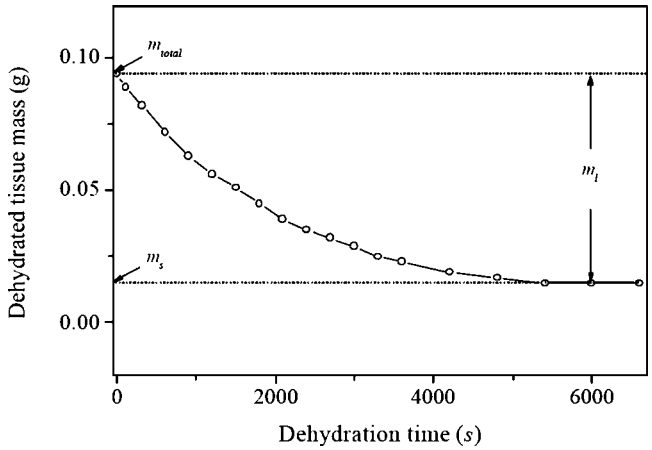

FIG. 3. The estimated solid and liquid masses of a VF LP tissue during dehydration.

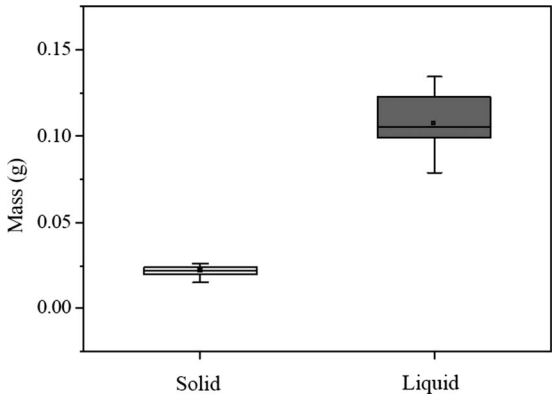

FIG. 5. The distributions of the solid and liquid masses from eight tissue data pieces excised from four larynges, where the line inside the box marks the median, and the upper and lower lines show maximum and minimum values. Error bars represent 10th and 90th percentiles.

sue volume. The masses (m_l, m_l) and volumes (V_s, V_l) of the eight VF LP samples from four excised larynges were measured in order to compare the results of liquid and solid components for each parameter.

III. RESULTS

Figure 3 shows the typical results of the solid and liquid masses of a VF LP tissue. Before dehydration, using the electronic balance and liquid-displacement method, the total mass m_{LP} and volume V_{LP} of the LP tissue were measured as 0.094 g and 0.090 m, respectively. The tissue density ρ_{LP} can be estimated as 1.044 g/m. After a thorough dehydration of the tissue, its mass approached a constant, as shown in Fig. 4, and thus the solid and liquid masses can be obtained as m_s=0.015 g and m_l=0.079, respectively. The liquid and solid volumes were estimated as V_l=0.079 ml and V_s =0.011 ml, respectively. Figures 4(a) and 4(b) illustrate the tissue sample before and after the complete dehydration. It can be seen that the dehydration sufficiently decreased the tissue volume. Based on Eqs. (2) and (3), we can determine the solid and liquid fraction parameters of this tissue as ϕ_m^s =16.0%, ϕ_m^l=84.0%, ϕ_V^s=12.2%, and φ_V^l=87.8%.

Using the same procedure, we obtained the solid and liquid fraction parameters of all eight tissue samples harvested from the four larynges used for the experiment. Figure 5 shows the distribution of the solid mass m_s and the liquid mass m_l. Mean values of m_s and m_l were estimated as 0.023 g and 0.111 g. Figure 6 shows the distributions of the solid volume V_s and the liquid volume V_l. The liquid volume with the mean value 0.111 ml was sufficiently higher than the solid volume with the mean value of 0.017 ml. Based on Eqs. (2) and (3), the fraction parameters ϕ_m^s, ϕ_m^l, ϕ_V^s, and ϕ_V^l can be obtained, as summarized in Table I. The mean value of the liquid mass fraction ϕ_m^l was 83.0%, which is sufficiently higher than that of the solid mass fraction ϕ_m^s (17.0%). The liquid volume fraction ϕ_V^l of 86.7% was higher than the solid volume fraction ϕ_V^s of 13.3%.

IV. DISCUSSION

Past studies on articular cartilage have used the buoyancy (sink-float) procedure to measure the density of small tissue samples, which can be used to calculate volume (Lipshitz *et al.*, 1976). However, this procedure requires an equilibrated solution of specific concentration, *p*H, and temperature, making it difficult to control for the permeable nature of the VF tissue in varied osmotic environments. Since the tissue would need to be submerged in a solution for this sink-float procedure, there may be a net diffusion of water, making an accurate volume measurement difficult. Other

TABLE I. Comparisons of solid and liquid groups on mass and volume fractions from eight tissue data pieces excised from four larynges, where the parameter values are given for each group (mean ± standard deviation).

	Solid	Liquid
Mass fraction ϕ_m (%)	17.0 ± 0.92	83.0 ± 0.92
Volume fraction ϕ_V (%)	13.3 ± 1.46	86.7 ± 1.46

procedures used to measure large tissue volumes include ultrasound technology (Hornblower *et al.*, 2007) and magnetic resonance imaging (Steen *et al.*, 2007), but these require relatively expensive equipment, and may be inconvenient for the measurement of VF samples with a small volume. To overcome the limitations of these methods, we have applied a liquid-displacement method to directly measure the small tissue volume of LP tissue. The current apparatus (Fig. 1) provides an inexpensive and simple way to measure small tissue samples. Differing from the buoyancy procedure, the liquid-displacement method allows the properties of the tissue to be conserved in a physiologic solution. In addition, as shown in Fig. 2, the linear relation and small deviation between the actual V_{true} and measured V_{measured} copper volumes showed the accuracy of the liquid-displacement apparatus and methodology. The precision of the apparatus in measuring copper samples allowed us to take the volume measurements in samples as small as 0.085 ml.

We measured the mean density of eight LP tissue samples as 1.049 g/ml, which is close to the density of the vocalis muscle reported in investigations by Perlman *et al.* (1984). Such a close relationship between LP density and vocal muscle density has also been used in recent studies of ultrasonic measurement (Huang *et al.*, 2007) and computer modeling of VF tissue (Titze and Hunter, 2004; Jiang *et al.*, 2001; Alipour *et al.*, 2000). The relative density difference $|\rho_{\text{sa}}-\rho_{\text{LP}}|/\rho_{\text{LP}}$ between the saline solution and the LP tissue was less than 4%. This implies that errors in determining the liquid density ρ_f and other fraction parameters may be less than 4%. However, error values this small are much less than the differences between the liquid and solid fraction parameters, since the liquid fraction parameters are at least five times larger than the solid fraction parameters, as shown in Fig. 6.

Limitations in our study resided in the number and type of larynges used. Our preliminary estimations are based on eight tissue samples from four distinct larynges which is not a large enough data set. Yet these estimations are still of value since they indicate a substantial difference in the currently assumed liquid and volume fractions. However, a greater number of laryngeal measurements will be included in our future studies. Another limitation in our study is that our *in vitro* estimations may not be the best representation of the dynamic relationship between the fluid and solid phases of the *in vivo* laryngeal system.

The VF LP tissue can be thought of as a porous solid structure swollen by fluid. The solid structure is comprised of collagen, elastin, and proteoglycans. Collagen is a fibrous structural protein and elastin is the other main structural protein. Highly branched proteins, called proteoglycans, fill a large amount of the superficial layer juxtaposed with the other fibrous proteins. The fibrous units form a cohesive porous composite solid phase in VF lamina propria. VF solid structure allows for a large amount of liquid storage and permeable flow. For example, hyaluronic acid is one component that can attract and hold water within the LP forming large, space-filling aggregates. Tissue solid components interact with the liquid regulating its distribution and flow. Homogeneous, solid descriptions of the VF tissue have primarily been applied in previous lumped mass and continuum models (Titze and Hunter, 2004; Jiang *et al.*, 2001; Alipour *et al.*, 2000). These single phase solid models are inadequate in describing the intrinsic solid-liquid interaction in the VF tissue and phenomena such as tissue stress relaxation. The consideration of the liquid contribution in VF models may be important for better understanding the viscoelastic behavior of VF lamina propria.

We recently proposed a biphasic model of VF LP tissue to describe the solid-liquid interaction (Zhang *et al.*, 2008). The biphasic theory predicts the stress relaxation of the LP and the crucial role of the liquid in stress support. However, there is no published research on the solid-liquid ratio of VF tissue, so the solid and liquid volume fractions (ϕ_V^l=80% and ϕ_V^s=20%) from the articular cartilage system (Mow *et al.*, 1980, 1984) were used in that study. In this study, by developing an apparatus which allows the volume measures of solid and liquid components, we provided preliminary experimental measurements of the biphasic (solid-liquid) parameters of LP tissue. In Table I, the mean liquid volume fraction ϕ_V^l and solid volume fraction ϕ_V^s of eight tissue samples harvested from four larynges were estimated as 86.7% and 13.3%, respectively. The lower ϕ_V^l in articular cartilage may be associated with differences in solid component composition. The amount or distribution of solid phase components holding water in the tissue could relate to differences in articular and VF ϕ_V^l. Biomechanical properties of VF tissue are fundamental factors affecting VF vibration and voice production (Chan *et al.*, 2001). Our study investigated the biomechanical property of VF LP tissue by measuring its biphasic parameters, which may provide useful information for understanding the VF vibratory systems.

V. CONCLUSION

In this study, we have measured the liquid and solid component parameters in canine VF lamina propria. A volume displacement apparatus was used to determine the volume of the VF LP tissue. The volume measurement of small copper samples examined the accuracy of the experimental apparatus. Using eight LP tissue samples, we found that the mass and volume of the liquid component in VF LP tissue were sufficiently higher than those of the solid component. Average mass and volume fractions of the liquid component were estimated as 83.0% and 86.7%, respectively, which are sufficiently higher than 17% and 13.3% of the solid mass and volume fractions. Liquid represents the major composition of the VF LP tissue. The results showed preliminary experimental evidence for the biphasic property (solid-liquid) of LP tissue. The estimated biphasic parameters may serve as cru-

cial parameters for future theoretical as well as experimental investigations exploring the viscoelastic behaviors controlling the vibratory motion of VF LP tissue.

An articulatory investigation of lingual coarticulatory resistance and aggressiveness for consonants and vowels in Catalan

Daniel Recasens[a] and Aina Espinosa
Departament de Filologia Catalana, Universitat Autònoma de Barcelona, Bellaterra, Barcelona 08001, Spain and Laboratori de Fonètica, Institut d'Estudis Catalans, c/Carme 47, Barcelona 08001, Spain

(Received 31 May 2008; revised 3 February 2009; accepted 4 February 2009)

Lingual movement data for Catalan vowel-consonant-vowel sequences reveal differences in contextual coarticulatory variability in tongue position at the middle of the consonant for /p/ > /n/ > dark /l/ > /s/ > /ʃ/ > /ɲ/ and at vowel midpoint for /u/ > /a/ > /i/. The velar stop /k/ exhibits a high degree of contextual variability in the horizontal dimension but not in the vertical dimension. These differences in coarticulatory sensitivity are attributed to differences in articulatory constraint, e.g., palatality and frication cause a higher degree of resistance in the consonant than laterality. A higher degree of contextual variability for dark /l/ than expected appears to be associated with speaker-dependent differences in darkness degree. Contextual variability is greater at regions not involved in closure or constriction formation, e.g., at the tongue dorsum than at the tongue front for alveolars. Coarticulatory resistance and coarticulatory aggressiveness are positively correlated: Phonetic segments, which are especially resistant to coarticulatory effects from the adjacent segments, exert maximal coarticulation on them. Consequently, highly constrained segments such as alveolopalatal consonants turn out to affect tongue position for less constrained segments such as back vowels rather than vice versa.

I. INTRODUCTION

The concept of coarticulatory resistance in phonetic segments, i.e., the extent to which a phonetic segment blocks the coarticulatory influence of adjacent phonetic segments, has long attracted scholars in the field of speech production (Bladon and Al-Bamerni, 1976; Hardcastle and Hewlett, 1999). Coarticulatory resistance for a given consonant or vowel is a measure of its degree of articulatory variability as a function of phonetic context. According to the degree of articulatory constraint (DAC) model of coarticulation (Recasens *et al.*, 1997), coarticulatory resistance should increase with the degree of articulatory constraint, i.e., with the mechanico-inertial properties of the articulators and their involvement in the formation of a closure or constriction and with manner of articulation demands. Thus, for example, consonants produced at the alveolopalatal or palatal zone (e.g., /ɲ/) are expected to resist the coarticulatory influence of the adjacent vowels at the primary tongue dorsum (TD) articulator to a greater extent than alveolars (e.g., /n/) for the production of which this lingual region is not involved directly in closure formation. Moreover, the higher the degree of articulatory constraint, the greater the degree of coarticulatory aggressiveness, i.e., the strength of the coarticulatory effects exerted by the target segment on the neighboring phonetic segments (Farnetani, 1990; Fowler and Saltzman, 1993).

In view of literature accounts summarized below, this paper attempts to validate differences in coarticulatory resistance and aggressiveness for consonants and vowels with lingual movement data collected by means of electromagnetic midsagittal articulometry (EMA). Data will be reported for symmetrical vowel-consonant-vowel (VCV) sequences with the Catalan consonants /p, n, l, s, ʃ, ɲ, k/ and the vowels /i, a, u/. These seven consonants differ in place of articulation and in primary articulator: /p/ is bilabial; /n, l, s/ are alveolar and articulated with the tongue tip and/or the tongue blade; /ʃ, ɲ/ are usually produced at the alveolopalatal zone with the tongue blade and the tongue predorsum; and /k/ is dorsopalatovelar or dorsovelar depending on vowel context.

A. Coarticulatory resistance

1. Consonant- and vowel-dependent characteristics

The DAC model makes the following predictions regarding coarticulatory resistance for consonants and vowels.

(a) Lingual coarticulatory resistance is minimal for labials since the tongue does not intervene in the production of these consonants.
(b) Alveolopalatal stops produced with the tongue blade and dorsum (e.g., /ɲ/) are more constrained than alveolars articulated with the tip and/or blade (e.g., /n/). This ought to be so since the production of the former consonants involves a larger contact surface and a more sluggish articulator, i.e., the tongue dorsum, than the produc-

[a]Electronic mail: daniel.recasens@uab.es

tion of the latter, and fronting and raising the tongue dorsum blocks the coarticulatory activity of other tongue regions (Recasens, 1985).

(c) Manner requirements on the formation of a narrow central groove for the passage of airflow account for why lingual fricatives are highly constrained, and perhaps more so the alveolopalatal fricative /ʃ/ than the alveolar fricative /s/ for reasons mentioned in (b) (Tabain, 2001). The formation of lateral openings for the apicoalveolar lateral /l/ requires that the tongue predorsum occupies a relatively low position, thus rendering the tongue body configuration relatively constrained. Moreover, dark /l/ (which is the variety of /l/ typically found in Catalan) should be more constrained than clear /l/ since it involves additional predorsum lowering and postdorsum retraction (Recasens and Espinosa, 2005).

(d) Dorsovelars exhibit highly systematic differences in closure fronting as a function of front vs back vowels. In this case, vowel-consonant overlap yields a blended outcome showing distant closure location targets depending on the following vowel rather than a single place which adapts to vowel context to different degrees (Browman and Goldstein, 1989).

(e) The entire tongue body is highly constrained during the production of the palatal vowel /i/, much in the same way as for alveolopalatal consonants. Regarding back vowels, there may be a stronger linkage between the tongue predorsum and the primary articulator for lower pharyngeal /a/ (tongue root) than for velar /u/ (tongue postdorsum).

Vowel-dependent differences in degree of lingual coarticulation as a function of the contextual consonants are consistent with differences in articulatory constraint mentioned in (e), i.e., coarticulatory resistance varies for /i/ > /a/ > /u/ (Catalan: Recasens, 1985; German: Hoole and Kühnert, 1995; Scottish English: Zharkova, 2007). Moreover, in agreement with the consonant-dependent characteristics in degree of articulatory constraint indicated in (a)–(d), F2 data and tongue dorsum contact data for Catalan consonants obtained by means of electropalatography (EPG) reveal the existence of differences in degree of vowel coarticulation varying in the progression /p/ (minimal degree of articulatory constraint or DAC value)>/n/ (intermediate DAC value) >dark /l/, /s/, /ʃ/, and /ɲ/ (maximal DAC value), with /k/ showing more or less variability depending on fixed vowel context (Recasens *et al.*, 1997). Similar patterns of coarticulatory resistance to vowel-dependent effects have been reported for other languages. According to tongue front and back movement data for German consonants, vowel coarticulation is maximal for the labials /p, b, m, f, v/, minimal for the palatoalveolar /ʃ/, and intermediate for alveolars in the progression /d/, /n/, clear /l/ > /t/ > /s/, and for the velars /k, g/ (Hoole *et al.*, 1990). EMA data for American English /b, v, ð, d, z, ʒ, g/, show more variability in tongue body position for labials than for dentals and alveolars, least variability for palatoalveolars, and moderate or little variability for velars occurring mostly along the horizontal dimension (Fowler and Brancazio, 2000). Tongue body coarticulation for a subset of Scottish English consonants recorded with ultrasound indicate that coarticulatory variability is maximal for /p, f/, minimal for /k/, and intermediate for the alveolars /t, l, s, r/ with the rhotic being more variable than /t, l, s/ (Zharkova, 2007). Finally, F2 data for stops in Australian languages show differences in coarticulatory resistance for /c/ > /t/ > /p/, with /k/ exhibiting large degrees of vowel coarticulation (Butcher and Tabain, 2004). This cross-language scenario suggests that most consonants are specified for nearly invariant degrees of coarticulatory resistance (Fowler and Brancazio, 2000), and that this articulatory characteristic may account for spectral regularities across places of articulation such as locus equation slopes.

In the light of this literature survey, the present study will try to substantiate some relevant findings on coarticulatory resistance reported earlier and will address several new issues on the subject. Recasens *et al.* (1997) did not report any obvious differences in coarticulatory sensitivity among dark /l/, /s/, /ʃ/, and /ɲ/ presumably since the EPG technique provides little information about tongue dorsum position for consonants such as dark /l/ and /s/, which are produced with more or less tongue lowering. The research goal is then to investigate by means of EMA whether differences in manner of articulation for highly constrained consonants sharing the same place of articulation (i.e., between /s/ and dark /l/ and between /ʃ/ and /ɲ/) affect degree of coarticulatory resistance. Special attention will be paid to variability patterns in articulatory displacement for /ɲ/, which have not been explored in detail so far; indeed, studies that have used EMA data for uncovering information on coarticulatory resistance do not have the alveolopalatal nasal in their consonant inventories (English: Fowler and Brancazio, 2000; German; Hoole *et al.*, 1990).

Data reported in literature summarized above indicate that velars may be more or less sensitive to vowel coarticulatory effects at the tongue dorsum and, therefore, could be specified for higher or lower degree of articulatory constraint. Another research topic of the present study is to investigate tongue dorsum contextual variability for velars and whether coarticulation for these consonants occurs along the horizontal rather than the vertical dimension (Fowler and Brancazio, 2000).

2. Tongue regions and articulatory dimensions

While differences in coarticulatory resistance among vowels and consonants have been much explored, articulator-dependent differences in coarticulation have been neglected to a large extent. Regarding vowels, earlier work indicates more sensitivity at tongue regions not involved directly in constriction formation, namely, at the postdorsum than at the blade and mediodorsum for /i/ and at more anterior tongue regions than at the tongue back for /a, u/ (Perkell and Nelson, 1985; Kiritani *et al.*, 1977). As for consonants, Hoole *et al.* (1990) found vowel coarticulation for consonants to increase at lingual regions not involved in closure or constriction formation, i.e., at the tongue back for alveolars and at the tongue front for velars.

Information on the specific articulatory dimensions along which coarticulatory effects occur has been gathered

with EPG and EMA for vowels, but mostly with linguopalatal contact data, less so with articulatory movement data, in the case of consonants. As for vowels, coarticulatory effects on /i/ are mostly associated with consonants produced with a low tongue dorsum position, i.e., dark /l/ and to some extent /s/. Variability at the tongue dorsum surface occurs mostly vertically for /a/ presumably since this pharyngeal vowel allows for little room for backward tongue body movement, and antero-posteriorly for /u/, which has been attributed to contraction of the posterior genioglossus muscle (Perkell, 1990). Coarticulatory effects involve tongue front raising and stretching as a function of dentoalveolars and alveolopalatals for /a/ and /u/, and tongue dorsum raising as a function of velars in the case of the vowel /a/. Regarding consonants (Recasens, 1999), tongue dorsum contact effects occur mostly in vowel height and fronting (/i/ > /u/ > /a/) and, less so, in vowel fronting (/i/ > /a,u/) for dentals and alveolars, and, when available, in vowel height (/i,u/ > /a/) for (alveolo)palatals. On the other hand, tongue dorsum fronting for /k/ decreases in the progression /i/ > /a/ > /u/, thus suggesting that place of articulation for velars adapts continuously to vowel context. Alveolar and velar consonants may also exhibit differences in tongue tip and blade fronting for /i/ > /a/ > /u/ or /i/ > /a,u/, with much backing for /u/ occurring perhaps in order to assist in lip rounding during the consonant so that the acoustic effect induced by front cavity enlargement is enhanced.

The present study will try to replicate earlier findings on lingual coarticulation at the tongue front and tongue dorsum for vowels and consonants using lingual movement data. Special attention will be paid to tongue articulator-dependent differences in coarticulation for alveolopalatals. In principle, alveolopalatals should exhibit an analogous behavior to velars though, in this particular case, the fact that maximal articulatory constraint takes place at a more anterior portion of the primary dorsal articulator is prone to cause little coarticulation at most or all lingual regions.

B. Coarticulatory aggressiveness

This investigation will also explore whether there is a direct relationship between coarticulatory resistance and coarticulatory aggressiveness, i.e., whether those sounds that are most resistant should be most aggressive and those that are least resistant should barely influence the adjacent phonetic segments. Systematic surveys of this relationship have not been carried out so far with articulatory movement data. Regarding V-to-C coarticulation, the expected trend is for coarticulatory aggressiveness to be greater for /i/ than for /a, u/. On the other hand, C-to-V coarticulatory effects ought to increase with the degree of coarticulatory resistance and, therefore, with the degree of articulatory constraint for the consonant in the progression alveolopalatals > alveolars > labials, with consonants of different manners of articulation within each place category exerting different degrees of coarticulation as well.

The coarticulatory outcome is especially relevant in strings of consonants and vowels involving antagonistic articulatory configurations. In sequences of phonetic segments specified for different degree of articulatory constraint, highly constrained consonants involving a high and front tongue body position (alveolopalatals) should affect vowels leaving a low tongue front relatively free to coarticulate (/a, u/), while the opposite, i.e., tongue dorsum lowering from back vowels on alveolopalatal consonants, ought to be less prone to occur. In sequences composed of highly constrained segments, stricter requirements on consonants than on vowels to achieve a closure or constriction ought to result into more prominent C-to-V than V-to-C effects. Therefore, the prediction is for consonants that are articulated with a relatively low tongue dorsum position such as dark /l/ and /s/ to exert tongue dorsum lowering effects on /i/, rather than /i/ to exert tongue dorsum raising effects on dark /l/ and /s/.

II. METHOD

Three male speakers of Eastern Catalan of 40–50 years of age (D. Recasens, J. Pi, and J. Cererols) read symmetrical VCV combinations with the consonants /p, n, l, s, ʃ, ɲ, k/ and the vowels /i, a, u/. As pointed out in the Introduction, /l/ is generally dark, and /ɲ/ is alveolopalatal, in this Catalan dialect. All VCV sequences were embedded in the meaningful sentence [ˈgraβə pVCVp əˈβans] ("He records pVCVp earlier") and, therefore, were preceded and followed by the phonetic segments [p] and [ə], which are largely unspecified for tongue position. Speakers were instructed to pronounce all target [pVCVp] sequences ten times each with a similar degree of prominence on the first and second syllables. The same or a similar speech material produced by the same speakers was used in previous EMA and EPG investigations (Recasens, 2002; Recasens *et al.*, 1997).

Articulatory movement data were collected by means of a Carstens articulograph system AG-100. The system is composed of a head mount with three magnetic transmitter coils and several small transducer coils attached to the articulatory structures. In the present experiment, coils were placed at roughly equidistant positions on the tongue tip (TT), tongue blade (TL), and tongue dorsum (TD), as well as on the lower incisors (jaw) and on the upper lip and lower lip. The TT coil was placed about 1 cm from the apex of the tongue, and cross-speaker distance ranges between coils were 1.5–2.3 cm (TL-TT) and 1.4–1.9 cm (TD-TL). Palate traces were recorded for each speaker. Coils were also attached to the bridge of the nose and upper incisors for head movement correction. Figure 1 presents sensor locations relative to the hard palate for each speaker.

Movement and acoustic data were digitized at a sampling rate of 250 Hz for movement and at 10 kHz for speech. The kinematic data were corrected for head movement, rotated to the corresponding occlusal plane, extracted into *X* and *Y* articulatory channels, and smoothed by a finite impulse response low pass filter using a Kaiser window with a cut-off frequency of 25 Hz.

Segmentation of the VCV sequences involved identifying five temporal points on the acoustic waveform with the help of spectrographic displays, namely, V1 onset, C onset, closure offset (just for the two stops /p/ and /k/), V2 onset, and V2 offset. V1 onset was taken to occur at the onset of the

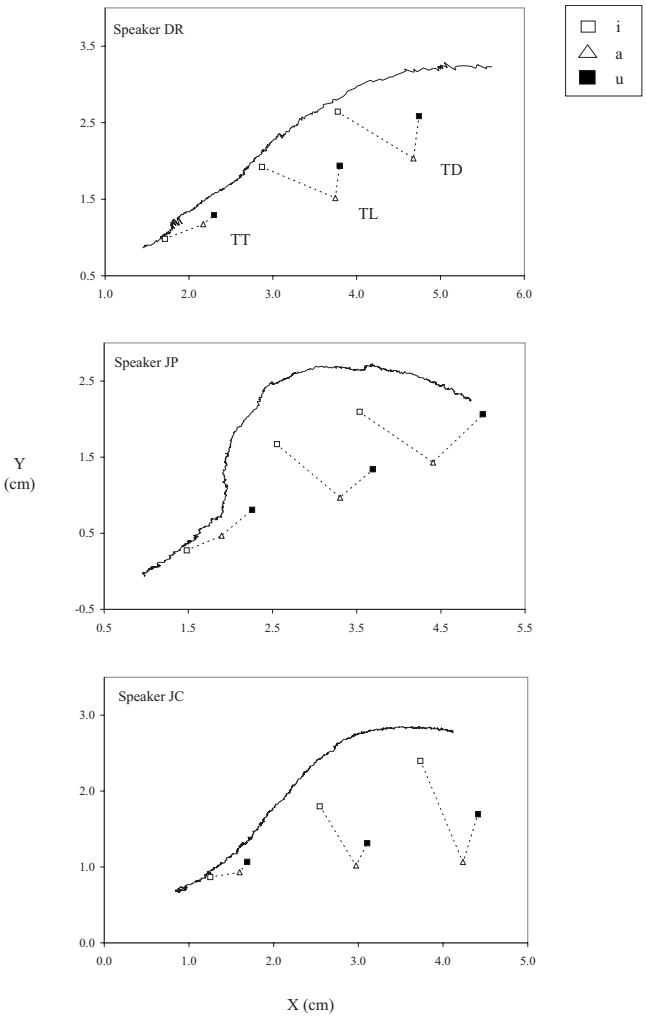

FIG. 1. TT, TL, and TD positions at consonant midpoint for /ini, ana, unu/ with palate trace. Data correspond to the speakers: D. Recasens (DR), J. Pi (JP), and J. Cererols (JC).

first pitch pulse following the burst for the first /p/, and V2 acoustic offset at the offset of vowel formant structure before closure onset for the second /p/. The onset of the intervocalic consonant occurred at the end of the V1 formant structure, which coincides with the onset of the acoustic closure for /p, k/, the frication noise for /s, ʃ/, and the low intensity formants for /n, l, ɲ/. Closure offset for /p, k/ takes place at the onset of the stop burst frication noise. V2 onset was set at the first vowel pitch pulse after the burst of a stop, the frication noise of a fricative, and the low intensity formant period of a nasal or a lateral.

Measurement points were selected according to an acoustic criterion rather than to an articulatory one since articulatory displacement maxima for the consonant and the two vowels were hard or impossible to detect in VCV sequences involving little movement (e.g., /iʃi/ and /iɲi/). Coarticulation was analyzed at two temporal points, i.e., at consonant midpoint for measuring V-to-C coarticulation and at vowel midpoint for measuring C-to-V coarticulation. Consonant midpoint was taken to occur at the midpoint of the period between C onset and closure offset for the stops /p, k/ and between C onset and V2 onset for the other consonants. Vowel midpoint was halfway between the onset and offset of voicing for the vowel. In order to render the vowel measures comparable across sequences with consonants of different manners of articulation, the 10–40 ms stop burst for unaspirated stops were not considered part of the vowel (see also Peterson and Lehiste, 1960 and Stevens, 1998, p. 258). Movement data for consonants and vowels were processed separately for each pellet and for the *X* and *Y* dimensions of articulatory displacement at the temporal points just mentioned.

A measure of coarticulatory resistance was calculated for each consonant and vowel, and for each speaker. Coarticulatory resistance for consonants was obtained at C midpoint by computing the centroid or grand mean across all three vowel contexts, and then averaging the Euclidean distances between the (x,y) position values for each vowel context and the centroid. Coarticulatory resistance for vowels was obtained at the midpoints of V1 and V2 by calculating the centroid or grand mean across all seven consonant contexts, and averaging the Euclidean distances between the (x,y) position values for each consonant context and the centroid. In both cases, the higher the degree of coarticulatory resistance, the smaller the contextual dispersion from the centroid. Data on coarticulatory resistance for vowels will be provided mostly for V1 since differences in coarticulatory resistance among vowels were found to be better defined at V1 midpoint than at V2 midpoint.

In order to find out whether variability was greater along the *X* or *Y* dimension, we also calculated the size of the contextual ranges in *X* and *Y* articulatory positions for each consonant and vowel, and for each speaker. Contextual ranges for each consonant were calculated at C midpoint by subtracting the minimal from the maximal mean contextual values across tokens for the three sequences /iCi/, /aCa/, and /uCu/ (e.g., /ipi, apa, upu/ for /p/). Ranges for each vowel at V1 location were derived by applying the same procedure to all seven VCV sequences exhibiting the same vowel (e.g., /ipi, ini, ili, isi, iʃi, iɲi, iki/ for /i/). Two other variability measures, i.e., standard deviation and coefficient of variation, were also computed but will not be reported because they yielded essentially the same differences among consonants and vowels as the contextual ranges.

A measure of coarticulatory aggressiveness was calculated for each consonant at V1 midpoint, and for each vowel at C midpoint, on the data for each speaker using the same Euclidean distance method described above. Coarticulatory aggressiveness for consonants was determined by averaging the Euclidean distances between the (x,y) position values for each consonant in the three vowel contexts and the centroid. Coarticulatory aggressiveness for vowels was computed by averaging the Euclidean distances between the (x,y) position values for each vowel in the seven consonant contexts and the centroid. In both cases, the higher the degree of coarticulatory aggressiveness, the smaller the contextual dispersion from the centroid.

Differences in coarticulatory resistance and aggressiveness were evaluated statistically by running analyses of variance (ANOVAs) with repeated measures on the Euclidean distances with consonant as a factor (resistance and aggressiveness for consonants) and with vowel as a factor (resis-

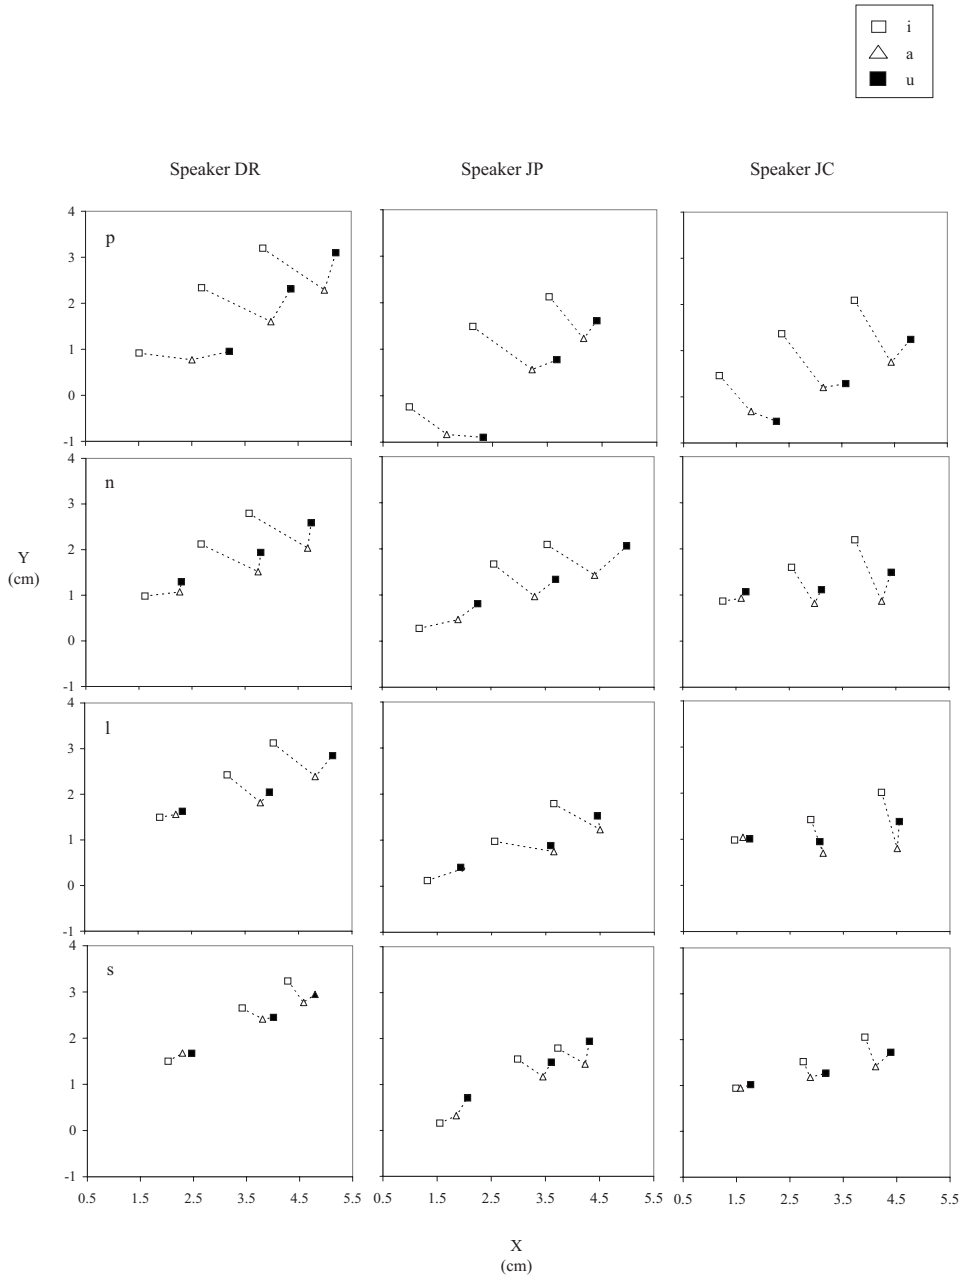

FIG. 2. (a) TT, TL, and TD positions for /p, n, l, s/ measured at consonant midpoint in the vowel contexts /i, a, u/. Data are given for all three speakers: D. Recasens (DR), J. Pi (JP), and J. Cererols (JC).

tance and aggressiveness for vowels). In order to elicit statistical differences in the V-to-C and C-to-V coarticulatory effects in articulatory position, ANOVAs with repeated measures were run separately on the *X* and *Y* lingual position values with vowel as a factor (V-to-C effects) and with consonant as a factor (C-to-V effects). Results for the significant C-to-V effects will be provided both at V1 and at V2 so as to achieve a more accurate description of the extent to which a given vowel is affected by different consonants. Levels of the vowel factor were i, a, and u and levels of the consonant factor were p, n, l, s, ʃ, ɲ, and k. Each speaker contributed one averaged score per condition. Huynh–Feldt corrected degrees of freedom were performed on the main effects. Given the small number of data entered in the ANOVAs, pairwise comparisons between levels of a given factor were carried out using Fischer least significant difference *post-hoc* tests. The degree of significance was set at $p < 0.05$.

III. RESULTS

A. Coarticulatory resistance

1. Consonants

According to Fig. 2, tongue tip position at closure or constriction location is highest for the alveolars /n, l, s/, and somewhat more retracted for /s/ than for the two other consonants; tongue blade and tongue dorsum position turns out to be higher for /s/ than for /n, l/. Bilabials, alveolopalatals, and velars are produced with the tongue tip down. Place of articulation for /ʃ/ and /ɲ/ occurs at the tongue blade and perhaps at the tongue dorsum, as indicated by the fact that

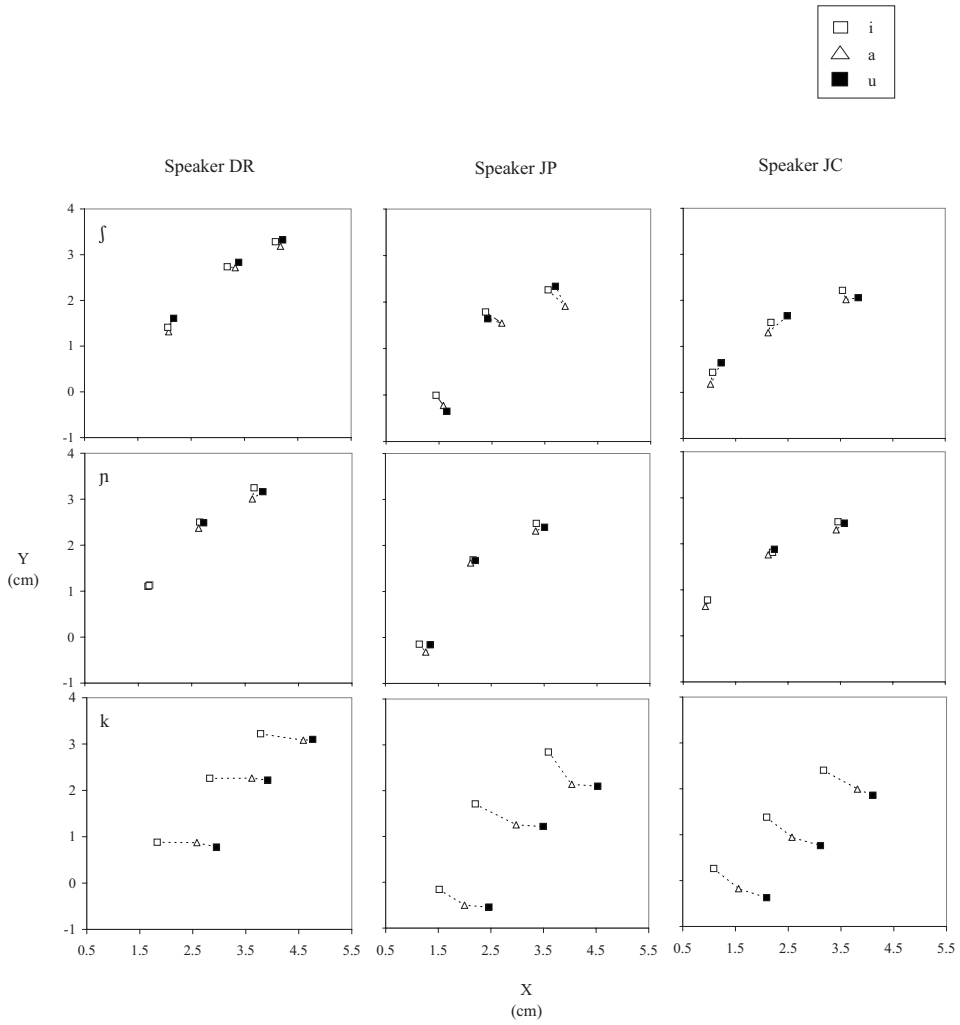

FIG. 2. (b) TT, TL, and TD positions for /ʃ, ɲ, k/ measured at consonant midpoint in the vowel contexts /i, a, u/. Data are given for all three speakers: D. Recasens (DR), J. Pi (JP), and J. Cererols (JC).

both articulators occupy the highest and anteriormost position in this case. The highest tongue position for /k/ is at the dorsal articulator.

ANOVAs on mean Euclidean distances yielded a significant effect of consonant for all articulators TT [$F(2.9,5.9)=21.39$, $p=0.001$], TL [$F(6,12)=46.00$, $p=0.000$], and TD [$F(1.9,3.9)=30.09$, $p=0.004$]. Consonant-dependent differences in coarticulatory sensitivity presented in Fig. 3 (top) turned out to be in accordance with data for Catalan reported in earlier EPG and acoustic studies. According to results from *post-hoc* tests, those differences vary in the progression /p/ > /n/ > /l,k/ > /s/ > /ʃ,ɲ/ especially for the TL and/or TD movement data. These consonant-dependent differences in coarticulatory sensitivity become apparent when the contextual position values for each consonant in Fig. 2 are taken into consideration: /p/ is most variable, /ʃ, ɲ/ are least variable, and, among alveolars, variability is maximal for /n/ and minimal for /s/. Considerable variability for /l/ appears to be related to speaker-dependent differences in tongue blade and dorsum positions mostly in the context of /i/ and, presumably, in darkness degree: Thus, the tongue body for the alveolar lateral occupies a higher position next to /i/ than to /a, u/ for some speakers (D. Recasens and J. Cererols) but less so or not at all for others (J. Pi); therefore, the consonant is less resistant to tongue dorsum raising effects induced by the high front vowel and thus, presumably clearer, for the two former speakers than for the latter. Speaker-dependent contextual differences for /l/ also occur along the *X* dimension.

Figure 3 (bottom) shows that the consonant-dependent differences in coarticulatory variability just referred to hold both along the *X* and *Y* dimensions. The only clear exception is /k/, which favors more *X* than *Y* movement and, therefore, is highly variable along the *X* dimension (as for /n/) and highly resistant along the *Y* dimension (as for /s/) (see also Fig. 2). The labial /p/ and the alveolars /n, l, s/ also exhibit a slightly greater degree of variability in the horizontal dimension than in the vertical dimension at the tongue tip and blade. Both dimensions of articulatory displacement show similar degrees of variability at all lingual regions for the alveolopalatals /ʃ, ɲ/.

Figure 3 (bottom) also reveals a decrease in contextual variability for TD > TL > TT in the case of the consonants /p, n, l, s/ along the *Y* dimension, and of /n, l/ and, to some extent, /s/ along the *X* dimension. It thus appears that the degree of coarticulation for front lingual consonants increases the more we depart from the primary articulator. The

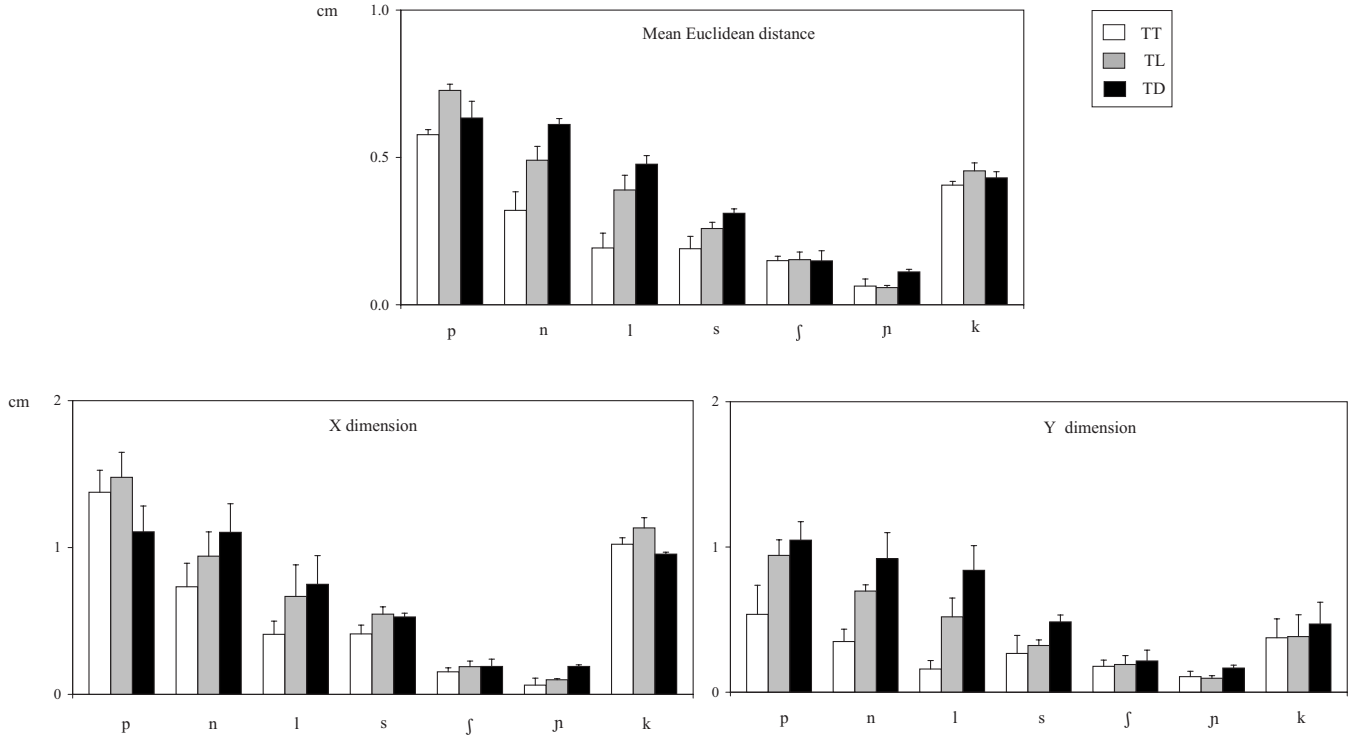

FIG. 3. Mean Euclidean distances in TT, TL, and TD positions (top), and ranges of tongue position values along the *X* and *Y* dimensions (bottom), for /p, n, l, s, ʃ, ɲ, k/ across vowel contexts measured at consonant midpoint. Data correspond to means and standard deviations across speakers.

lamino-predorsal and dorsal consonants /ʃ, ɲ, k/ exhibit no clear variability differences among lingual articulators (though they may also show a trend for the *X* and *Y* ranges for the tongue dorsum to exceed those for the tongue tip and blade).

According to Table I (see also Fig. 2), labials (/p/) and velars (/k/) allow significant vowel effects in horizontal displacement for /i/ > /a/ > /u/ at all or most pellets, which in the case of /k/ could be associated with three instead of two places of articulation. Moreover, labials also show significant tongue dorsum effects in vertical displacement as a function of high versus low vowels. *X* and *Y* vowel effects on the alveolopalatal consonants /ʃ, ɲ/ are negligible. As for alveolars, tongue fronting decreases in the progression /i/ > /a, u/ (/n/) and /i, a/ > /u/ (/s/), and tongue dorsum height in the progression /i, u/ > /a/ (/n, l/) and /i/ > /a/ (/s/). In a few cases, vowel-dependent differences in articulatory position for a given alveolar consonant fail to achieve significance because they may show up to different degrees or fail to occur depending on speaker, e.g., /i/ > /a, u/ for /p/ (TT*Y* and TL*Y*) and for /l/ (TL*Y*) (see Fig. 2).

TABLE I. Significant main vowel-dependent effects and *post-hoc* pairwise comparisons for /p, n, l, s, ʃ, ɲ, k/ as a function of tongue articulator and articulatory dimension (*, $p<0.05$; **, $p<0.01$; ***, $p<0.001$). *X* differences among contextual vowels proceed from most anterior to most posterior, and *Y* differences from highest to lowest.

2. Vowels

Tongue tip, blade, and dorsum position at V1 midpoint conform to the expected differences in anteriority for /i/ > /a/ > /u/ and in height for /i/ > /u/ > /a/. Thus, as shown in Fig. 4, the tongue dorsum is located between 3.5 and 4 cm behind the origin of the coordinate space at the upper incisors for /i/, between 4 and 4.5 cm for /a/, and between 4 and 5 cm for /u/. Moreover, according to the same figure, tongue dorsum height is about 2.5 cm for /i/, between 2 and 2.5 cm for /u/, and between 1.5 and 2 cm for /a/.

According to statistical tests run at V1 midpoint, differences in degree of consonant-dependent variability for vowels were highly significant at TT [$F(1.1, 2.3)=34.03$, $p=0.021$] and TL [$F(1, 2)=39.55$, $p=0.024$], and barely significant at TD [$F(1, 2)=13.42$, $p=0.067$]. *Post-hoc* tests reveal that those differences decrease in the progression /u/ > /a/ > /i/ at the tongue tip and blade and /u/ > /i/ at the tongue dorsum (see Fig. 5, top). Figure 4 shows indeed much less dispersion among consonant contexts for the high front vowel than for the two back vowels. All articulators exhibit similar degrees of contextual variability along the *X* and *Y*

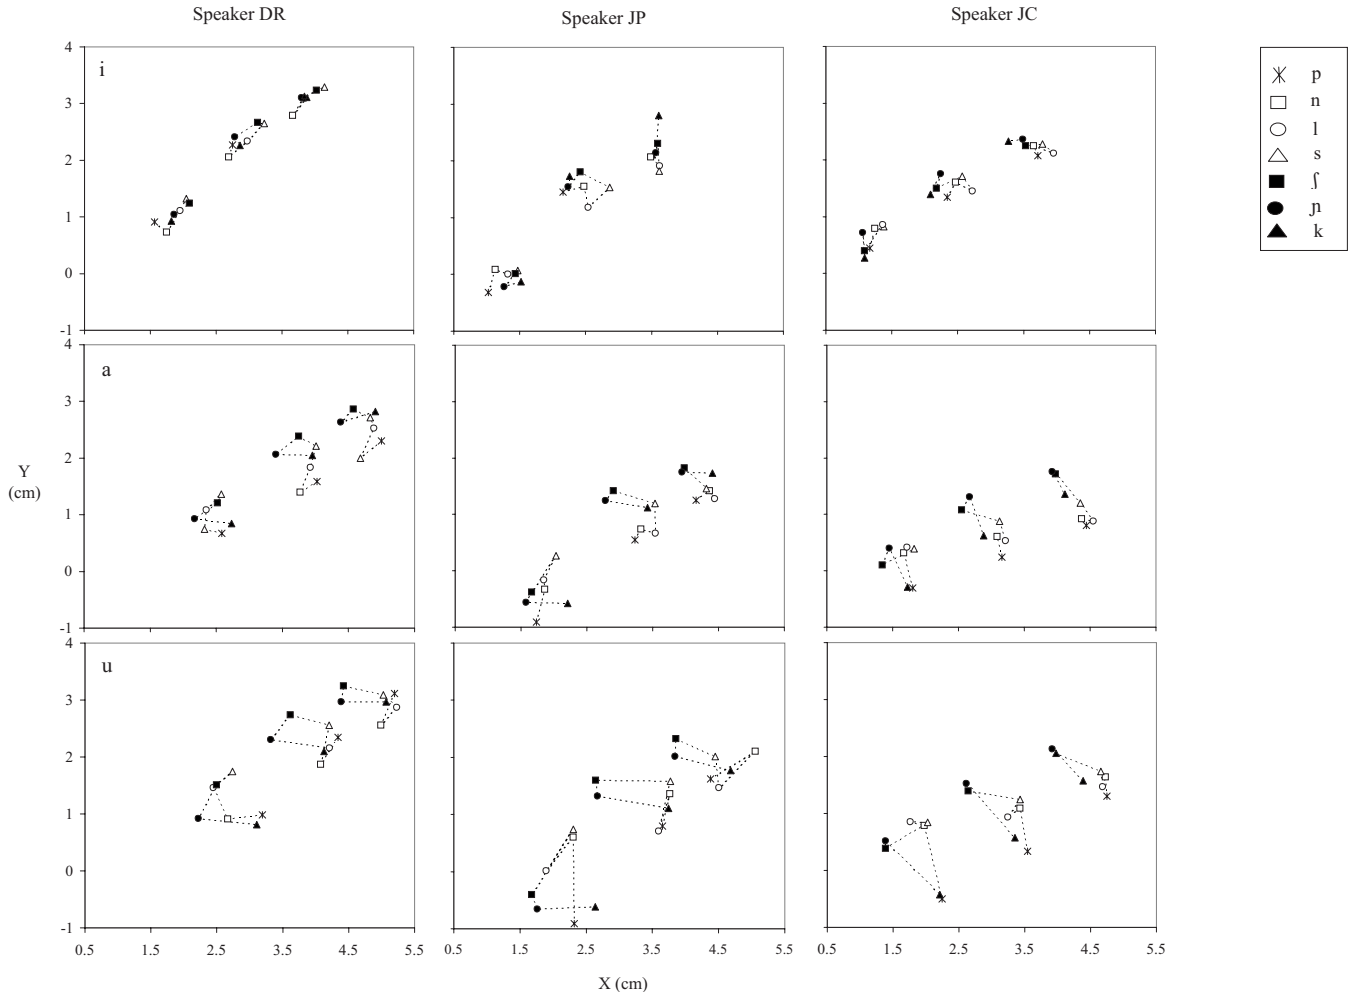

FIG. 4. TT, TL, and TD positions for /i, a, u/ measured at V1 midpoint as a function of contextual consonants of different place of articulation. Data are given for all three speakers: D. Recasens, J. Pi, and J. Cererols.

dimensions in the case of /i/ and some more variability in the *Y* dimension than in the *X* dimension for /a/ (Fig. 5, bottom). As for /u/, coarticulatory variability is especially large at the tongue tip along the *Y* dimension and slightly greater horizontally than vertically at the tongue blade and dorsum.

Table II provides information about the significant consonant effects at the two vowels' midpoint (see also Fig. 4). As indicated in the table caption, *X* and *Y* values for a given consonant appearing outside the panel always exceed those for the consonants that are paired with it and appear inside the panel. Consequently, for a given consonant pair, the consonant outside the panel may be considered to be responsible for significant C-to-V effects in the /a, u/ condition (since these effects involve tongue body raising and fronting), and the consonant inside the panel for significant C-to-V effects in the /i/ condition (since these effects involve tongue body lowering and backing). Effects on /i/ involve mostly tongue blade retraction as a function of /l, s/ (TL*X*) and tongue blade lowering as a function of /l/ (TL*Y*). Back vowels allow more considerable consonantal effects. Effects along the horizontal dimension occur on /u/ and, less so, on /a/, and involve fronting at the tongue blade and dorsum and, less so, at the tongue tip in the context of /ʃ, ɲ/, and at the tongue tip in the context of alveolars, mostly /l/. Effects along the vertical dimension are slightly larger on /a/ than on /u/, and involve raising at the tongue tip in the context of /l/, at the tongue blade next to /ɲ/, at the tongue blade and dorsum next to /k/, and at all articulators in the context of /s, ʃ/ (more so at tongue tip and blade in the case of /s/ and at tongue blade and dorsum in the case of /ʃ/).

B. Coarticulatory aggressiveness

ANOVAs on mean Euclidean distances yielded a significant consonant effect at V1 midpoint for all articulators TT [$F(1.6,3.3)=16.24$, $p=0.020$], TL [$F(6,12)=49.76$, $p=0.000$], and TD [$F(2.8,5.6)=20.75$, $p=0.002$]. Significant differences in coarticulatory variability take place for /p/ > /n/ > /l, s/ > /ʃ, ɲ/, with /k/ not differing significantly from /p, l, s/, and therefore resemble those reported at C midpoint (see Fig. 6, top). Indeed, consonants such as /p/ and /n/ exhibit larger differences in articulatory position across vowel contexts than consonants such as /ʃ/ and /ɲ/ and, therefore, the former can be considered to be less aggressive than the latter. A correlation analysis between mean Euclidean distances for consonants at V1 midpoint and at C midpoint yielded a high $\underline{r}$ value between the two measures (0.931),

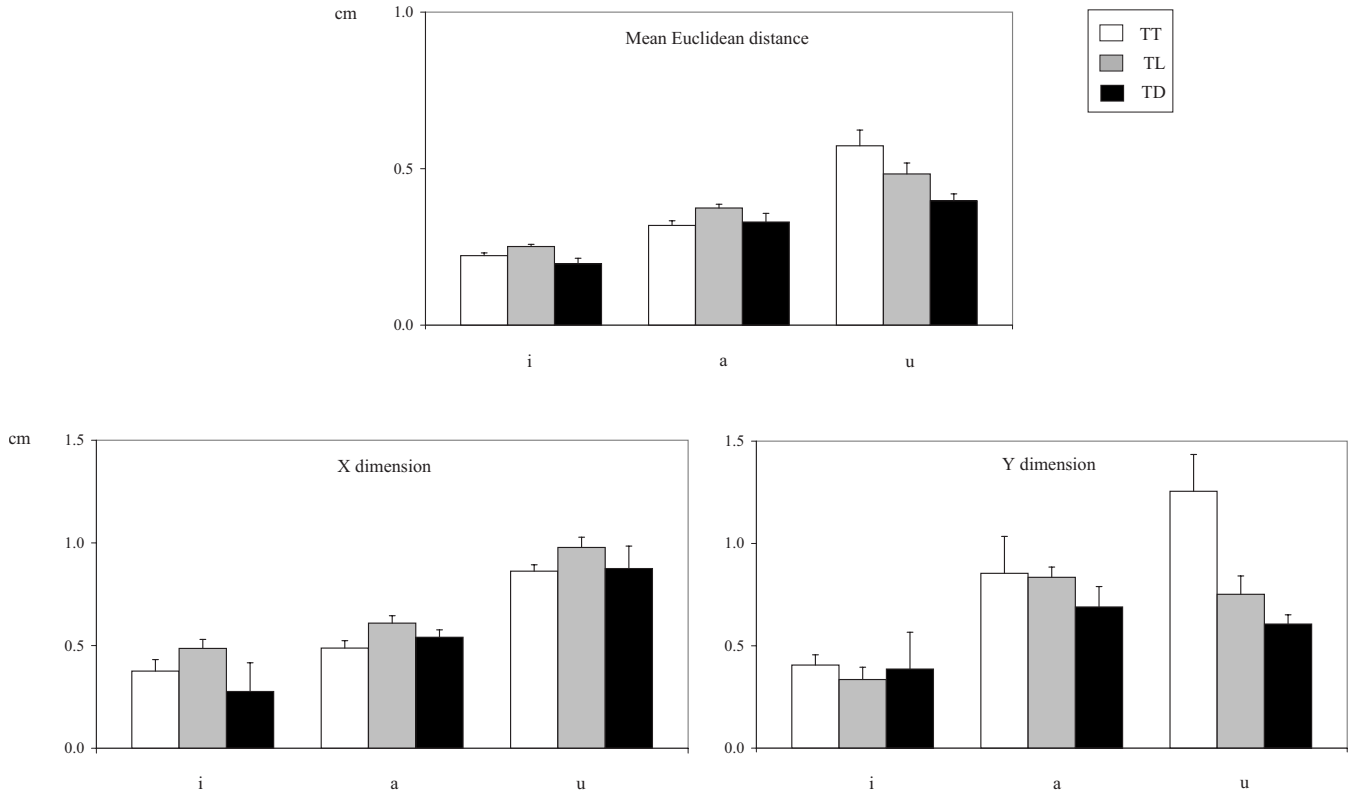

FIG. 5. Mean Euclidean distances in TT, TL, and TD positions (top), and ranges of tongue position values along the *X* and *Y* dimensions (bottom), for /i, a, u/ across consonant contexts measured at V1 midpoint. Data correspond to means and standard deviations across speakers.

thus proving that coarticulatory aggressiveness for consonants varies directly with coarticulatory resistance to vowel effects.

A similar scenario holds between coarticulatory aggressiveness and coarticulatory resistance for vowels. According to statistical tests run at C midpoint, the vowel factor turned out to be significant for TT [$F(1.8,3.6)=21.90$, $p=0.010$] and TL [$F(1.9,3.8)=38.60$, $p=0.003$], and barely significant for TD [$F(1,2)=21.48$, $p=0.043$]. *Post-hoc* tests reveal the existence of significant differences in coarticulatory variability for /a,u/ > /i/ at TL and TD (see Fig. 6, bottom). Given that /i/ exhibits less considerable consonant-dependent differences in articulatory position than /a, u/, it may be ascertained that the former vowel exerts greater V-to-C effects than the two latter ones. A correlation analysis between mean Euclidean distances for the three vowels at C midpoint and at V1 midpoint yields a high $\underline{r}$ value (0.873), meaning that coarticulatory aggressiveness and coarticulatory resistance for vowels are closely related.

The relative strength of the C-to-V and V-to-C effects in sequences of consonant and vowel segments produced with antagonistic articulatory actions depends on degree of articulatory constraint. Thus, as predicted, C-to-V effects from alveolopalatals on /a, u/ (Table II) are more prominent than V-to-C effects from /a, u/ on alveolopalatals (Table I). The coarticulation scenario in sequences of highly constrained segments conforms to some extent to our initial prediction that C-to-V effects should prevail onto V-to-C effects. Indeed, data show some tongue dorsum lowering and retraction effects from dark /l/ and /s/ on /i/ (Table II), and tongue dorsum raising and fronting effects from /i/ on /s/ but much less so on /l/ (Table I).

IV. DISCUSSION AND CONCLUSIONS

Patterns of contextual variability in tongue position for consonants and vowels (as well as individual V-to-C and C-to-V effects) reported in the present study confirm what appears to be a general principle of coarticulatory behavior, namely, that coarticulatory resistance and aggressiveness are indicative of degree of articulatory constraint and depend on the degree of involvement of a given articulatory region in closure and constriction formation and on manner requirements.

Differences in lingual variability for /p/ > /n/ > /l,k/ > /s/ > /ʃ,ɲ/ and /u/ > /a/ > /i/ are in agreement with the scale of degree of articulatory constraint proposed by the DAC model. They confirm previous accounts in that coarticulatory resistance decreases for alveolopalatals > alveolars > labials both along the horizontal and vertical directions of articulatory displacement (see below regarding the status of velars). In contrast with EPG data adduced by Recasens *et al.* (1997), a higher degree of coarticulatory resistance for alveolopalatals than for alveolars has been found to hold among the highly constrained consonants dark /l/, /s/, /ʃ/, and /ɲ/. These differences in coarticulatory sensitivity indicate that frication contributes more than laterality and possibly darkness to an increase in degree of articulatory constraint. Similar findings have been reported in studies measuring lingual coarticulatory resistance and variations in jaw-tongue tip cohesion induced by changes in vocal effort for German consonants, i.e., in this case variability was

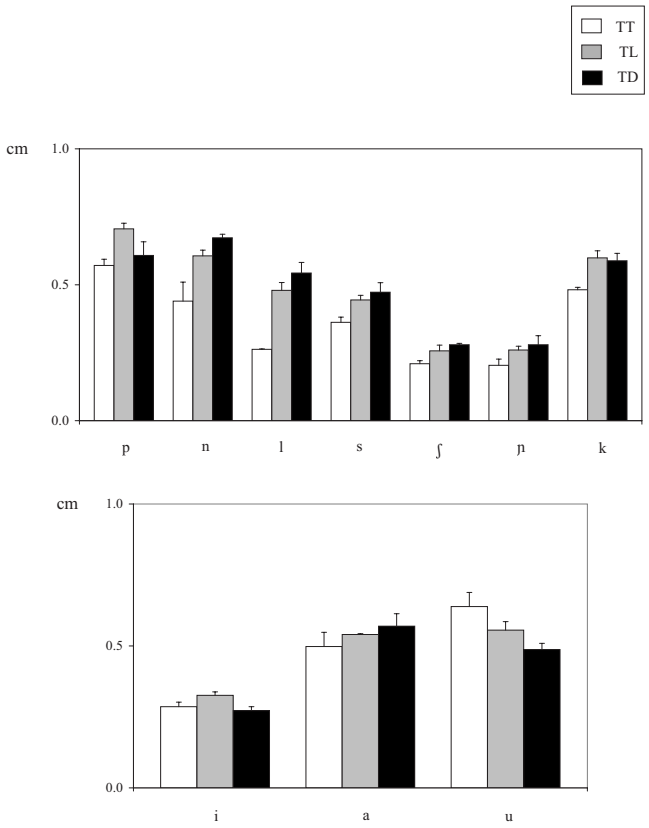

FIG. 6. Mean Euclidean distances in TT, TL, and TD positions for consonants across vowel contexts measured at V1 midpoint (top) and for vowels across consonant contexts measured at consonant midpoint (bottom). Data correspond to means and standard deviations across speakers.

found to be less for /s/ than for /l/ though the same for /l/ and /n/ perhaps since /l/ is clear in this language (Hoole *et al.*, 1990; Mooshammer *et al.*, 2006). In Scottish English, however, no differences in lingual coarticulatory resistance were found to occur between /l/ and /s/ (Zharkova, 2007).

The consonant /l/ turned out to be more variable than expected in the present study presumably in line with speaker-dependent differences in darkness degree. This appears to be in agreement with EPG and acoustic data reported in earlier studies for dark /l/ in Eastern Catalan (Recasens *et al.*, 1995) showing a high degree of speaker-dependent variability in the sequence /ili/ both regarding dorsopalatal contact size (between 10% and 35% of contact activation over the total amount of electrodes at the palatal zone) and F2 (between about 1250 and 1450 Hz). This finding suggests that certain articulatory properties are allowed to vary more than others, e.g., laterality and darkness than frication.

The special status of velars has been confirmed by the present investigation. Data from previous studies show that this consonant may be more or less variable depending on factors such as articulatory direction (Fowler and Brancazio, 2000), the transconsonantal vowel in asymmetrical VCV sequences (Recasens *et al.*, 1997), and language (Butcher and Tabain, 2004). In agreement with Fowler and Brancazio (2000), much contextual variability for velars has been found to take place along the horizontal dimension for /i/ > /a/ > /u/, which is in support of the notion that these consonants blend with the adjacent vowels. A high degree of coarticulatory resistance along the *Y* dimension is in accordance with minimal V-to-C coarticulatory effects on /k/ reported elsewhere (Zharkova, 2007).

As for vowels, fronting and raising the tongue body for /i/ appears to constrain all tongue regions to a large extent thus rendering this vowel more coarticulation resistant than back vowels. In agreement with previous studies, differences in coarticulatory resistance also hold for /a/ > /u/.

Whenever available, coarticulatory effects occur mostly at regions not participating in closure or constriction formation. Indeed, variability for /n, l, s/ was greater at the tongue dorsum where *X* and *Y* effects may take place as a function of front versus back and high versus low vowels, respectively, than at the tongue tip and blade where effects occur generally along the *X* dimension as a function of front versus back vowels. Regarding vowels, consonantal effects on /a, u/ take place mostly at the tongue tip and blade as a function of alveolopalatals and alveolars through variations in tongue height for /a/ and in tongue fronting for /u/, which is in accordance with a muscle-based account of variability for vowels (Perkell, 1990).

Trends in coarticulatory aggressiveness were found to be also consistent with the DAC model of coarticulation. Both for consonants and vowels, phonetic segments which were more resistant turned out to be more aggressive as well. Specific coarticulatory effects between segments involving antagonistic articulatory positions were in agreement with this general principle: More constrained alveolopalatals resist the lowering and backing influence of less constrained /a, u/ while exerting maximal coarticulation on these vowels. In consonant-vowel sequences composed of two highly constrained and antagonistic segments, e.g., dark /l/ or /s/ and /i/, the consonant appears to prevail onto the vowel rather than the other way around, which is in line with the articulatory demands for the two sound classes. In any case, the degree of V-to-C coarticulation exerted from /i/ on the consonant appears to be hard to evaluate since it depends heavily on the exact degree of darkness (for /l/) and frication (for /s/), which may vary according to speaker and other factors.

In summary, consonants and vowels may be differentiated quite successfully in terms of coarticulatory resistance, which falls naturally from the production demands involved. Moreover, a direct relationship appears to hold between coarticulatory resistance and coarticulatory aggressiveness. This scenario suggests that the coarticulatory resistance scale is a valid criterion of consonant and vowel classification and provides valuable information about the planning mechanisms used by speakers in speech production.

The present research points to several issues for further analysis. It remains unclear why phonetic segments in VCV sequences are more variable if produced with a low tongue dorsum than with a high dorsum. This finding suggests that production requirements for these sequences differ from those for consonant clusters where manner demands for low tongue dorsum consonants overcome consonants articulated with a high tongue dorsum position (Recasens and Pallarès, 2001). It may be that articulatory control on certain production mechanisms is greater in consonant clusters than in CV and VC sequences because consonants are required to configure the articulatory structures more precisely than vowels for the implementation of specific manners of articulation. In consonant clusters, the integrity of the consonant appears to be affected to a larger extent by deviations in tongue dorsum position induced in dark /l/, the apical trill /r/, and /s/ than in alveolopalatals even though the tongue dorsum is the primary articulator of the latter but not of the former group of consonants.

(Received 18 January 2008; revised 21 January 2009; accepted 22 January 2009)

The effect of stimulus timing on vocal responses to pitch-shifted feedback was investigated in different intonation patterns during Mandarin speech production. While speaking a four-word sentence consisting of the high-level tone, where the fundamental frequency (F_0) of the final word was either increased (question intonation) or slightly falling (statement intonation), pitch-shift stimuli ($\pm$100 cents, 200 ms duration) were presented at three different times (160, 240, or 340 ms) after vocal onset. Results showed that in the question intonation, response magnitudes (16 cents) were significantly reduced for the 340 ms condition compared to the 160 (26 cents) or 240 (23 cents) ms conditions. No significant differences were found, however, as a function of stimulus timing in the statement intonation. These findings demonstrate that a planned change in F_0 can cause a modulation in the reflexive response to a perturbation in voice pitch feedback and that there is a critical time period during which the response mechanisms are most sensitive to the planning process. These findings suggest an approach for the study of mechanisms involved in the timing of successive words during speech. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081523]

I. INTRODUCTION

In speech the role of voice fundamental frequency (F_0) is to convey various meanings in addition to those conveyed by consonants and vowels. Recent research on intonation has shown that F_0 can be used to encode two or more communicative meanings simultaneously (Eady and Cooper, 1986; Pierrehumbert and Hirschberg, 1990; Xu, 1999; Liu and Xu, 2005). It has been found that Mandarin speakers express lexical tone, focus, and question intonation by controlling F_0 in different ways (Xu, 1999; Liu and Xu, 2005). Tone is expressed by making F_0 approach a specific trajectory during the syllable, focus is encoded by expanding the pitch range of focused words and compressing the pitch range of post-focused words, and question is expressed by increasingly raising F_0 toward the end of the utterance. Similarly, simultaneous control of F_0 by lexical, focal, and intonational functions has been found in non-tonal languages such as English (Xu and Xu, 2005; Liu and Xu, 2007).

Important as it is to speech, little is known about neural mechanisms controlling voice F_0. Recent attempts to model this system provide a theoretical rationale on how the nervous system might accomplish this task (Hain *et al.*, 2000). An important component of such models is the role of sensory feedback in the control process. Experimental studies have demonstrated that if voice auditory feedback is missing, masked, or altered, voice F_0 control is diminished (Elliott and Niemoeller, 1970; Svirsky *et al.*, 1992; Mürbe *et al.*, 2002). The role of auditory feedback in voice control during speech development is particularly important, and deafness during language acquisition severely affects the quality of a child's articulation (Oller and Eilers, 1988). While the voice is not affected immediately if hearing loss occurs after mastering speech skills, there is a slow reduction in F_0 control (Angelocci *et al.*, 1964; Binnie *et al.*, 1982; Leder *et al.*, 1987; Waldstein, 1990; Lane *et al.*, 1997). It has also been shown that changes in kinesthetic feedback through anesthetization procedures reduce fine control of voice F_0 in pitch-masking tasks (Mallard *et al.*, 1978; Sundberg *et al.*, 1995). Recently, Larson *et al.* (2008) reported that voice responses to pitch perturbations were larger when the vocal fold mucosa was anesthetized than during normal kinesthesia, which could be due to the involvement of both kinesthesia and auditory feedback control of voice F_0. In addition, it has been demonstrated that auditory feedback plays an important role in voice control in birds and mammals. For example, presenting electronically pitch-shifted voice feedback to horseshoe bat elicits compensatory changes in call frequency (Metzner, 1996), and the Lombard effect has been demonstrated in monkeys (Sinnott *et al.*, 1975). All of these studies

point to the importance of auditory feedback for on-line control of speech and vocal communication in general (Smotherman, 2007).

In addition to feedback models of voice F_0 control, it has also been suggested that speech and F_0 are controlled by "internal models" (Wolpert *et al.*, 1995; Perkell *et al.*, 1997; Kawato, 1999) that represent the relation between motor commands and their acoustic output. The development and maintenance of such internal models may depend on sensory feedback (Wolpert *et al.*, 1998; Jones and Munhall, 2000). That is, the neural system learns how to generate motor commands that can produce the desired acoustic output and to continuously fine-tune the internal representation of such motor-acoustic relations. Jones and Munhall (2000, 2002) showed that both English and Mandarin speakers compensated for pitch-shifted voice feedback to maintain their habitual pitch targets when their voice auditory pitch feedback was slowly shifted up or down without their awareness, indicating that auditory feedback is used in calibrating the internal model for the control of F_0. When the pitch-shifted voice feedback was then suddenly removed, there was a negative aftereffect, which further supported the contention that the feedback had temporarily altered the internal model.

Others have also used the pitch-shift perturbation technique for the study of the role that auditory feedback plays in control of voice F_0. When voice pitch feedback is unexpectedly either increased or decreased during vowel phonation or speech production, subjects compensate for the perturbation with voice F_0 responses that change in a direction opposite to that of the perturbation as if to nullify an unplanned deviation in F_0 (Elman, 1981; Kawahara, 1995; Burnett *et al.*, 1998; Hain *et al.*, 2000; Natke and Kalveram, 2001; Jones and Munhall, 2002). These compensatory responses have been interpreted as support for the idea that auditory feedback can be used online to help stabilize voice F_0. Other studies have shown that voice F_0 responses to perturbations in voice pitch feedback may also be observed during speech (Donath *et al.*, 2002; Jones and Munhall, 2002; Xu *et al.*, 2004; Chen *et al.*, 2007). Moreover, such responses occur rapidly enough to correct for errors within the same syllable (Xu *et al.*, 2004) or subsequent syllables (Donath *et al.*, 2002; Xu *et al.*, 2004).

Recently, several studies of pitch-shifted voice feedback demonstrated that voice F_0 responses to pitch perturbations could be modulated according to the demands of the vocal task during either vowel phonation (Liu and Larson, 2007) or speech production (Natke *et al.*, 2003; Xu *et al.*, 2004). Task-dependent modulation of such responses was tested more directly in a study where English speakers either spoke a phrase or produced vowel phonations (Chen *et al.*, 2007). During speech production, vocal responses to downward pitch-shift stimuli presented before a rising F_0 contour were larger than to upward stimuli. Furthermore, overall responses to pitch perturbations during speech production were larger than those during vowel phonations. The larger responses to the downward stimuli during speech may indicate that the system recognized that the downward stimuli were in the wrong direction to the planned upward F_0 contour, and a corrective response was needed. Implicit in this assumption is the idea that the F_0 level existing prior to a planned change in F_0 is known or can be predicted from the present F_0 level. If the actual F_0 level at the time of implementation of the change deviates from the predicted level, a response would be generated to correct for the error and to complete the planned change accurately. Thus the system controlling voice F_0 evidently takes into consideration the present F_0 level while planning for future changes in F_0. If the system plans ahead for future changes in F_0, there must be a time period during which this planning takes place.

The present study was designed to determine the boundaries of the temporal window during which planning for a subsequent change in F_0 takes place. Results from the study of Chen *et al.* (2007) suggest that the system is more sensitive to pitch-shift stimuli before a planned change in F_0 takes place. Therefore, measurement of response magnitudes to pitch-shift stimuli presented at different times before a planned change in F_0 may reveal the temporal boundaries of these periods of increased sensitivity to pitch-shift stimuli. In the present study, Mandarin subjects spoke a phrase that contained different intonation patterns while hearing perturbations in their voice pitch feedback. Pitch-shift stimuli were presented at three different times prior to a planned change in F_0 to test the hypothesis that response magnitude or latency would be modulated according to the timing of stimulus presentation in relation to the planned F_0 trajectory.

II. METHODS

A. Subjects

Ten native speakers of Mandarin (3 males and 7 females) between the ages of 24 and 30 were recruited. All subjects reported normal hearing, and none reported a history of speech or language problems or neurological disorder. All subjects signed informed consent approved by the Northwestern University Institutional Review Board and were paid for their participation.

B. Apparatus

Subjects were seated in a sound-treated room. They wore Sennheiser headphones with attached microphone (model HMD 280). The voice signal from the microphone was amplified with a Mackie mixer (model 1202), shifted in pitch with an Eventide Eclipse Harmonizer (H3000, SE), mixed with a 40 dB SPL pink masking noise (Goldline model PN2; spectral frequencies of 1–5000 Hz) through another Mackie mixer (model 1202-VLZ), and further amplified to 10 dB greater at the headphones than at the microphone with a Crown D75 amplifier and HP 350 dB attenuators. This 10 dB gain in feedback over the voice was used to reduce the chances that the subjects heard their nonshifted bone-conducted signal during vocalization. MIDI software (MAX/MSP, Version 4.5 by Cycling'74) on a laboratory computer was used to control the harmonizer and to generate control (TTL) pulses. A Brüel & Kjær sound level meter (model 2250) and in-ear microphones (model 4100) were used to make acoustic calibrations prior to testing any of the subjects. Subjects monitored their voice loudness from a Dorrough loudness monitor (model 40-A), providing a vi-

sual feedback reference of their voice amplitude. Digitization of the voice output signal, feedback, and control pulses were performed at 10 kHz (12 bits), low-pass filtered at 5 kHz through POWERLAB (model ML880, AD Instruments), and recorded on a computer using CHART software (AD Instruments).

C. Procedures

Subjects were instructed, upon hearing one of two prerecorded speech samples (male voice, ≈80 dB SPL) over the headphones, to repeat them with the same exact inflection pattern within 1 s. The Mandarin sentences consisted of four syllables, "mao1 mi1 mo1 ma1" (kitty touches mom), in which the numeral 1 represents the high-level tone. The pitch on the final syllable "…ma1" was raised in the question intonation and held constant in the statement intonation. The MIDI program, triggered by the onset of the subject's voice, delivered a signal to the harmonizer that modulated the voice pitch feedback of the subject's voice. The variability in the timing of the MIDI output from the onset of the pulse from the vocal detection circuit was about 25 ms. In each block of 60 trials, the model presented to the subjects on each trial had the same intonation pattern, and the stimulus timing was held constant at one of the three values. On each trial, the voice pitch feedback was either shifted up (increasing), down (decreasing), or not changed (control trials). The sequence of stimuli was randomized so that subjects could not predict which type of stimulus would occur on any given trial. Thus the subjects received 20 increases in pitch feedback, 20 decreases, and 20 control trials for each condition. Across six blocks (three stimulus timings by two intonation patterns) of 60 trials each, the stimulus magnitude was fixed at ±100 cents (200 ms duration), but the timing was varied at 160 ms, 240 ms and 340 after vocal onset in the question and the statement intonations, as shown in Fig. 1. Table I lists the averaged timing values of pitch perturbations for three stimuli in the question and statement intonation. During any block of the trials, the stimulus timing was held constant at one of the three delay times. Because of the natural variations in speaking rate, we attempted to keep speaking rate constant by having the subjects repeat a model, even though it was recognized that variation in timing would still occur. We also judged that attempting to measure the syllable durations for each subject would be impractical because here again, rates and syllable durations would vary. We therefore concluded that selecting a single set of delay times was the best compromise between experimental design and variations in production both within and across subjects.

TABLE I. Averaged timing values in milliseconds (SD) of stimuli relative to the onset of syllables 1–4 as a function of intonation, in which positive and negative values, respectively, indicate the presentation of pitch perturbation after and before the utterance of the syllable.

Stimulus (ms)	Intonation	Syllable 1	Syllable 2	Syllable 3	Syllable 4
160	Question	212 (26)	43 (31)	−150 (30)	−369 (38)
	Statement	204 (9)	13 (20)	−207 (28)	−438 (44)
240	Question	292 (25)	128 (22)	−69 (21)	−318 (85)
	Statement	282 (13)	87 (22)	−134 (37)	−381 (43)
340	Question	388 (17)	217 (20)	−39 (14)	−288 (24)
	Statement	387 (19)	196 (16)	−36 (18)	−279 (42)

For data analysis, the voice signal was processed in PRAAT (Boersma, 2001) using an autocorrelation method to produce a train of pulses corresponding to the fundamental period of the voice waveform. This pulse train was then converted into an F_0 analog wave in IGOR PRO (Wavemetrics, Inc., Lake Oswego, OR). An operator manually marked the beginning and end points of the F_0 wave for each sentence according to the voice waveform, and then all the vocalizations in a block were time-normalized (linear interpolation) to reduce temporal variability and enhance the averaging procedures. An average of voice F_0 response was calculated by triggering the averaging computer on the TTL control pulse separately for each condition (phrase type, stimulus onset delay, and stimulus direction), summating all trials and dividing by N to produce an average F_0 response for that particular condition. A "difference wave" was then calculated by subtracting the average control wave from the average test waves derived from the increasing or decreasing pitch-shift stimulus. A point-by-point series of t-tests was run between all control and all test trials for a given condition and subject (Xu *et al.*, 2004). Valid responses were defined by significant t-tests ($p=0.02$) beginning at least 60 ms after the stimulus onset and lasting at least 50 ms. Response latencies were defined as the point where the p values of significant differences decreased below 0.02 and remained decreased for at least 50 ms. Response measurements were made during

the 200 ms period of the stimulus because in the 340 ms condition, the intonated rise in F_0 often began near the end of the 200 ms making it difficult to measure the response. Response magnitudes were measured from the difference wave at the time indicated by the most significant p value within the above-defined measurement window. Statistical analyses were performed on response latency and magnitude using repeated-measures ANOVAs (SPSS, Version 16.0). Assumptions of compound symmetry and circularity for a repeated-measures ANOVA were met. For statistical analysis, non-responses were replaced by the mean value calculated from the measured data from other subjects for that condition.

III. RESULTS

From ten subjects across three stimulus timings, two stimulus directions, and two intonation patterns, there were 120 possible responses ($10\times3\times2\times2$). Tables II–IV list the numbers of opposing (the voice response change was in the opposite direction to the stimulus), "following" (response and stimulus changes in the same direction), and non-responses across stimulus direction, stimulus timing, and intonation pattern, respectively. 88% of the responses "opposed" the stimulus direction. Only 8 out of 120 responses did not meet our criteria of valid response (see Sec. II C) and were declared to be non-responses. The number of valid responses did not vary greatly across the experimental conditions.

Figures 2 and 3 illustrate average responses from representative subjects to pitch-shifted stimuli (thick black lines with error bars) superimposed on average control curves (thin black lines with error bars) across three stimulus timings in the question and statement intonations, respectively. Responses to the upward stimuli are illustrated on the left and downward stimuli on the right. The square brackets at the bottom of these figures indicate the time and direction of the stimulus. The major increase in traces in Fig. 2 coincides with the onset of the fourth syllable. The separation between the control (thin lines) and test (thick lines) wave that begins during the stimulus is the response to the perturbation. Compensatory vocal responses were produced across all experimental conditions in Figs. 2 and 3, except for the upward response for the 340 ms timing in the question intonation (bottom left in Fig. 2) that is a following response. In Fig. 2 (question intonation), it appears that response magnitudes for the responses in the 340 ms timing condition (right) are smaller than those for the 160 and 240 timing conditions. All the responses started before the rising of the F_0 contour of the last syllable. In Fig. 3 (statement intonation), there are no obvious differences in response magnitude across the three stimulus timing conditions.

Figures 4 and 5 show box plots of response magnitudes and latencies as a function of stimulus timing and direction in the question and statement intonations, respectively. Values of response magnitude and latency across stimulus tim-

Box plot definitions: middle line is median, top and bottom of boxes are 75th and 25th percentiles, and whiskers extend to limits of main body of data defined as high hinge +1.5 (high hinge—low hinge) and low hinge −1.5 (high hinge—low hinge).

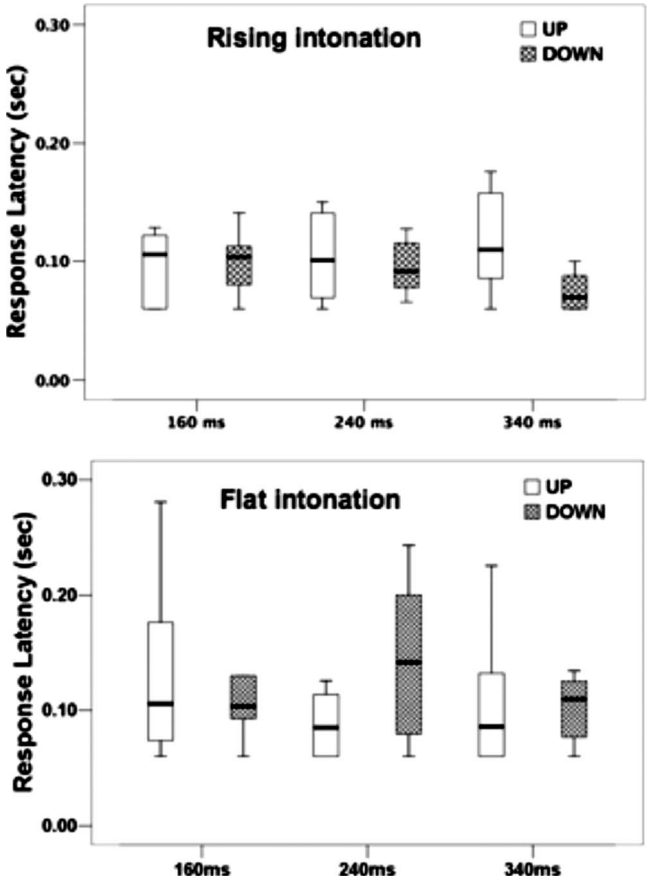

FIG. 5. Box plots illustrating the response latency as a function of stimulus timing and stimulus direction in the rising and the flat intonations.

ing and intonation pattern are shown in Tables V and VI. Three-way repeated-measures ANOVAs (stimulus direction, stimulus timing, and intonation pattern) performed on the response magnitude revealed significant main effects for stimulus timing $[F(2,18)=6.979, p=0.006]$ but not for stimulus direction $[F(1,9)=2.083, p=0.183]$ or intonation pattern $[F(1,9)=0.008, p=0.993]$. A significant interaction effect was found between intonation pattern and stimulus timing $[F(2,18)=6.826, p=0.006]$. In order to determine the effect of stimulus timing on vocal responses in the different intonations, two-way repeated-measures ANOVAs were performed on the response magnitude and latencies for the rising and the flat intonation patterns. The results indicated significant main effects across stimulus timing in the rising $[F(2,18)=9.913, p=0.001]$ but not in the flat pattern $[F(2,18)=1.276, p=0.303]$. No significant main effects were found for stimulus direction in the question $[F(1,9)=0.286, p=0.625]$ or the statement condition $[F(1,9)=7.028, p=0.250]$, and there were no interaction effects between stimulus direction and stimulus timing for the intonation patterns [question: $F(2,18)=0.390, p=0.768$; statement: $F(2,18)=3.236, p=0.180$]. *Post hoc Bonferroni* tests in the rising intonation indicated that the 160 ms (26 ± 7 cents) and 240 ms (23 ± 9 cents) conditions produced significantly larger response magnitudes than the 340 ms (16 ± 6 cents) condition ($p=0.001$ and $p=0.014$, respectively). In addition, three-way repeated-measures ANOVAs performed on the response latency revealed no significant main effects across all conditions.

IV. DISCUSSION

The purpose of the present study was to investigate the effect of timing of pitch-shifted voice feedback on the vocal response across two different intonation patterns during meaningful Mandarin speech. The findings indicated significantly larger response magnitudes for the 160 and 240 ms stimulus onset conditions than for the 340 ms condition in the question intonation, while no significant differences existed between 160 and 240 ms timing conditions. Furthermore, there was no effect of stimulus timing on the responses in the statement intonation.

It is now well known that perturbations in voice pitch feedback evoke compensatory changes in voice F_0 during sustained vowels, singing and speaking conditions (Elman, 1981; Kawahara, 1995; Burnett *et al.*, 1998; Hain *et al.*, 2000; Natke and Kalveram, 2001; Donath *et al.*, 2002; Jones and Munhall, 2002; Xu *et al.*, 2004; Chen *et al.*, 2007). The mechanisms of these responses are unknown but necessarily

involve detection of a change in voice pitch feedback, comparison of the feedback with an internal referent of the desired F_0, activation of neurons related to motor output, transmission delays in the central and peripheral nervous system, and contraction (or relaxation) of laryngeal muscles leading to a change in voice F_0. Question intonation in Mandarin involves a large increase in F_0 at the utterance-final position (Ho, 1977; Lin, 2004; Liu and Xu, 2005), although smaller F_0 increases also occur before the final syllable (Yuan *et al.*, 2002; Liu and Xu, 2005; Ni *et al.*, 2006). For statements, it has been found that there is an F_0 decline over the course of an utterance in Mandarin (Xu, 1999; Shih, 2000), but the declination is very slight if the utterance consists of only the high-level tone (Xu, 1999). These patterns are also found in the utterances produced by our subjects. Large F_0 differences occurred at the utterance-final position between questions (288 Hz) and statements (241 Hz), $[F(1,9)=51.593, p=0.000]$ for this mix of male and female subjects. Smaller F_0 differences also occurred in the first syllable, 257 Hz in questions and 240 Hz in statements $[F(1,9)=5.753, p=0.040]$.

When a speaker plans on increasing voice F_0 at the end of an utterance in a question, as is the case in the present study, there must be a planning process that is aware of the current F_0 level and the correct time to contract muscles to change F_0. The observations of the present study suggest that there is a time-dependent interaction between responses to pitch perturbations and mechanisms involved in planning a question intonation in Mandarin speech. The interaction is time-dependent because only responses to the 340 ms stimuli, not responses to stimuli that occurred earlier, were affected. The interaction is related to the planning of the increase in F_0 because the reduction in response magnitude only occurred with the question intonation condition, not the statement intonation condition.

Further observations suggest the dimensions of the time window during which planning for the F_0 contour may take place. With the 340 ms stimulus onset time, the response began about 100 ms following the stimulus onset and about 100 ms before the rising F_0 contour of the fourth syllable. The decrement in response magnitude was not observed for the 160 or 240 ms conditions with the rising intonation (question). Therefore, the reduction in the response is related to the rising intonation on the last syllable. Moreover, the time period when the interaction between the pitch-shift stimulus and the decrement in response magnitude occurred must be between the stimulus onset, 200 ms before the rising intonation, and the beginning of the response, 100 ms before the rising intonation. It is therefore suggested that there is a time window of 100 ms duration (between 200 and 100 ms before a planned increase in F_0 contour) during which auditory feedback may interact with the central planning mechanisms.

It is next instructive to consider the reasons for this interaction. One explanation for the reduction in response magnitudes observed for the 340 ms condition with the rising F_0 contour may relate to the pattern of voice F_0 regulation in question intonation. When a sentence is spoken as a question with either final or neutral focus, F_0 starts to rise exponentially from the start of the last word (Liu and Xu, 2005). In the present study, the final word is the syllable /ma/ for "mother." In other words, the F_0 of /ma/ is controlled by a lexical function as well as an intonation function. Such dual control presumably requires greater amounts of neural resources than when only a single function is involved. This control may have depleted some of the neural resources needed to monitor sensory, including auditory feedback.

Another possible explanation for these results is that the auditory perturbation interacted with mechanisms that were involved in elevating F_0 at the end of the sentence. One type of interaction may be that the mechanisms responsible for the voluntary increase in F_0 caused a reduction in sensitivity to the perturbation so that the response to the perturbation would not interfere with the planned increase in F_0. It is also possible that there was active attenuation of the responding mechanisms, again possibly to avoid interference with the planned rise in F_0. Regardless of the exact mechanisms and the reasons for the response reduction, the results suggest that there is a time window (100–200 ms) before a rise in F_0 during which a response to an auditory perturbation may interact with speech planning mechanisms.

Another interpretation of the data relates to the method of measurement of the responses. Due to the fact that for the question intonation condition, there was a rising intonation on the fourth syllable and the need to make response measurement conditions consistent across all conditions, it was necessary to limit the time window for measurement of responses in all conditions to the 200 ms stimulus window. If it had been possible to extend the measurement window out further in time, response magnitudes may have been the same in all timing conditions. Nevertheless, the fact that the responses in the 340 ms condition were smaller than those for the 160 and 240 ms conditions within a 200 ms time period following the stimulus indicates that response-generating mechanisms behaved differently in the 340 ms condition compared with the other timing conditions.

A. Comparison with other studies

The effect of stimulus timing on the response during the production of bi-tonal Mandarin phrase was also investigated by Xu *et al.* (2004). The disyllabic nonsense phrases /ma ma/ with different tonal patterns (high-high, high-rising, and high-falling) were tested with stimuli of 100 and 250 ms delays after the onset of the voice. The results indicated no effect of stimulus timing on the response magnitude or the latency. This finding is in contrast to the present study and may be explained by the fact that only tonal changes were manipulated in the study of Xu *et al.*, without intonation

changes, which may require a different response mechanism during the dynamic control of voice F_0. Another explanation is that a nonsense phrase was used in the study of Xu *et al.* (meaningful words in a nonsense phrase), and meaningful speech was tested in the present study. In the present study, however, data in the statement intonation indicated no effect of stimulus timing on the response, which is comparable with the findings of Xu *et al.* in the high-high (/ma ma/) condition.

In comparing this study with previous pitch shift experiments, the variability in speech style (meaningful speech vs nonsense speech) may contribute to the variability in response magnitudes and latencies. For example, during nonsense speech, vocal response magnitudes of 47 cents (Natke *et al.*, 2003) were reported for 100 cents stimuli, and magnitudes of 50 cents (static tone) and 85 cents (dynamic tone) were reported for 200 cents stimuli (Xu *et al.*, 2004). These values are larger than the overall response magnitudes during meaningful speech of 22 cents in the present study (see Table V). The smaller magnitude responses reported for meaningful speech compared to nonsense speech in these studies may be partially explained by findings from the present study that intonation pattern and stimulus timing can modulate response magnitudes. It should come as no surprise, therefore, if responses to pitch-shifted feedback during some specific types of speech production conditions may be smaller than those in nonsense speech.

One problem with the interpretation of the data in the present study comes from a comparison of the present results with those reported by Chen *et al.* (2007). In that study, responses to 200 cents downward stimuli that were presented prior to a rise in F_0 during English speech were larger than those to upward stimuli. In the present study, there was no difference in magnitude of responses between upward and downward stimuli in any of the timing conditions. The 340 ms condition was most similar to that tested in the study of Chen *et al.*, and it is surprising that in the present study responses to the downward stimuli were not larger than those to the upward stimuli, as they were in the study of Chen *et al.* Two factors may explain this. First, although the rise in F_0 at the end of the phrase was a supra-segmental adjustment in both studies, the Mandarin language background of the subjects in the present study may have predisposed them to respond differently than the English speakers in the study of Chen *et al.* A recent finding has shown that speakers of English produce a much larger final rise in question intonation than do speakers of Mandarin (Liu and Xu, 2007). Second, the effect of the increase in response magnitude in the study of Chen *et al.* was only seen with 200 cents stimuli, not 100 cents stimuli as used in the present study. That is, the stimulus magnitude in the present study may have been too small to evoke the directional difference in the auditory system, causing no significant differences between the responses as a function of stimulus direction.

With respect to response latency, mean values of 211 ms (Jones and Munhall, 2002), 165 ms (Xu *et al.*, 2004), and 150 ms (Natke *et al.*, 2003) were reported for nonsense speech, while 122 ms (Chen *et al.*, 2007) and 109 ms (see Table VI) were observed in the present study during meaningful speech. One explanation for these differences may be that they are attributable to methodologies. Jones and Munhall used a value of 2 standard deviations (SDs) above or below the pre-stimulus mean to define the onset of a response. Natke *et al.* used the Castellan change-point test to define the "change point" in F_0 contours following a stimulus. The methods for measuring response latency in the present study are identical to those used in the studies of Xu *et al.* (2004) and Chen *et al.* (2007) and are hence more comparable to those studies.

Other than the methodological differences, the latency differences suggest that responses to pitch-shifted voice feedback may be faster during meaningful speech than during nonsense speech. This observation may be explained by considering that the target of natural speech is to communicate with listeners. Even though response magnitudes during meaningful speech may be smaller than those during nonsense speech in some conditions, it may be more important for communication effectiveness for subjects to correct for errors faster during meaningful speech than during nonsense speech, resulting in the shorter latencies during meaningful speech than during nonsense phrases.

V. CONCLUSION

In the present study, the effect of the stimulus timing on the pitch-shift reflex during Mandarin speech was investigated in different intonation patterns. The results revealed that stimulus timing is an important variable that can affect the magnitude of vocal responses to pitch perturbations when they occur in a question intonation. Responses to pitch perturbations that were presented just prior to a planned pitch increase were reduced in magnitude compared to stimuli that were presented earlier or to those that were presented when there was no planned F_0 change. The reduction in response magnitude to stimuli that are presented just before a planned increase in voice F_0 demonstrates a contrast to previous reports that showed an increase in response magnitude in some speaking conditions. In combination, these contrasting effects demonstrate that the audio-vocal system can regulate the vocal response depending on the specific task. The factors that appear to be responsible for these differing effects are the timing of the stimulus and whether or not a subsequent change in F_0 is planned. Future studies directed at defining the time window in which stimuli can lead to changes in response magnitude may help us to understand the timing of neural mechanisms involved in the control of temporal features of speech.

(Received 18 July 2007; revised 2 August 2008; accepted 20 October 2008)

Place assimilation can lead to neutralization of segmental contrasts. It is controversial, however, to what extent such neutralizations actually happen in natural speech. This study examines: (i) the degree to which regressive place assimilations occur in word final consonants in conversational German, and (ii) whether these assimilations are perceived as neutralized by listeners. The production analysis, based on spontaneous speech, shows that complete assimilations do take place in conversational speech and that there is a clear asymmetry between coronal versus labial and dorsal segments. Furthermore, function words show a higher degree of assimilation than lexical words. Two experiments examined the effects of assimilation on perception. A forced choice reaction time perception experiment, using nasal stimuli from the corpus, examined how fast and accurately listeners identified sounds in different segmental contexts. Results indicate that (a) with equal accuracy and speed, listeners identified original and assimilated [m]s; (b) unassimilated-/m/s were identified equally well across contexts, but not unassimilated-/n/s. A free transcription experiment reproduced these findings. An acoustic analysis provides further evidence that regressive place assimilation across word boundaries can result in absolute neutralization of place contrasts in running speech. The results support models predicting asymmetries between coronal versus labial and dorsal consonants. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3021438]

I. INTRODUCTION

Speech is variable—certainly across speakers and across dialects, but also within a single speaker depending on speech rate or style. Acoustic shapes of lexical items easily vary across contexts or sentence types. Within a model of discrete phonological entities, it is customary to assume that reductions, deletions, insertions, and assimilations are processes which modify or alter idealized lexical representation in running speech. A German word like *einverstanden* "agree-past participle" occurring 47 times in the Kiel corpus (IPDS, 1994) has 23 different variants in the database (for a complete list see Appendix A).[1]

There is no utterance in the database which exactly matches the canonical pronunciation (i.e., [ˈʔaɪnfɐˌʃtandən]), most cases exhibiting more than one deviation. Not only are there many types of variation, but the deviations from the norm are optional and need not be complete and may still be perceptible. Remnants of a deleted sound may still be present as in [ˈaɪnfɐˌʃtan̰n], [ˈaɪnfɐˌʃtanʔn], or [ˈaɪnfɐˌʃtan̰], where some segments have been deleted completely, or glottalization indicates that a stop (i.e., [d]) has been severely reduced.[2] Transcriptions of place assimilations suggest complete neutralization of a featural contrast, as in [ˈaɪmfɐˌʃtan̰n] where additionally to deletions, the [n] is assimilated to the labiality of [f].[3]

However, as in deletions, traces of the original [n] may still be found in the signal. For instance, Nolan (1992) argued that assimilations were more likely to be gradient than complete, and that target information was available in assimilated sequences (see also Gow, 2002; for voicing assimilation, see Snoeren *et al.*, 2006). Listeners are sensitive to these gradient assimilations in production and could identify residual alveolar gestures in 40% of the assimilated tokens (Nolan, 1992, p. 271). Gow's results also indicate that listeners use the information of the underlying place of articulation even in segments that auditorily sound as if they are completely assimilated (Gow, 2002; Dilley and Pitt, 2007; also Manuel, 1995; Snoeren *et al.*, 2006). Indeed, some researchers express doubt concerning the very existence of complete assimilation (Gow, 2002; see also Snoeren *et al.*, 2006).

However, in a recent extensive coverage of regressive assimilation of naturally spoken American English (Buckeye Corpus of Conversational Speech, Pitt *et al.*, 2006), Dilley and Pitt (2007) found that 9% of coronal (alveolar) word final stops and nasals were transcribed as assimilated to the place of articulation of the following consonant (labials and

a)Electronic mail: aditi.lahiri@ling-phil.ox.ac.uk

velars).[4] Acoustic measurements consisting of the change in F2 and amplitude of the preceding vowel showed that these frequently did not differ between the assimilated consonants and the canonical labials and velars. They conclude that "assimilation is often complete or nearly complete in spontaneous speech" (Dilley and Pitt, 2007, p. 2350). One must note, however, that the F2 values were gradient for both consonants labeled as assimilated, as well as those in an assimilatory context (i.e., followed by labials or velars) as compared to alveolars in a nonassimilatory context (i.e., followed by other alveolars). As the authors report, a possibility exists that the real number of assimilations is underestimated, since even some instances of those that were labeled as unassimilated could be actually assimilated because the labelers are always reasonably conservative.

Thus, in spite of the optional and gradient nature of fast speech processes, neutralization due to assimilation can be perceived as complete. Furthermore, such assimilations can even lead to orthographic changes. Orthography tends to be conservative and even if a pronunciation change has occurred, the spelling remains often unaltered. However, when the orthography changes (without formal institutional intervention such as the German *Rechtschreibreform*), one is reasonably sure that a change has really taken place. For instance, words with the negative prefix {in-} have been borrowed into English from Romance at different times. A word like *impossible* could be spelt earlier as ⟨inpossible⟩: *It es bot foli al pi talking, And als an inpossibile thing* **1300** *Cursor M.* 14761 (OED, 1989, p. 732). The ⟨n⟩ is now always pronounced as a labial and this place assimilation changing the [n] of {in-} to [m] when labial [p, b, m] follow is now also always reflected in spelling.[5] Listeners must have perceived the assimilation to lead to a change in the (conservative) orthography. A new formation like *input*, which is not made with the negative prefix, preserves the ⟨n⟩ in the spelling, although it is also pronounced with a [m].

Although there is little doubt that dictionary-like pronunciations are not the norm in connected speech and there is an increasing number of spoken language corpora which are used in publications, such as Snoeren and colleagues (2006) and Dilley and Pitt (2007), there is still a dearth of statistically reliable data as to what extent connected speech phenomena like assimilations actually occur in other languages and moreover, even less is known about how they are perceived by normal listeners and trained labelers. In this paper, we analyze normal running speech to quantify how often the contexts for assimilations arise, how frequently such assimilations are realized, and how they are perceived, focusing on German where there is no study as yet bringing together corpus analysis and the repercussions for perception. In the following sections we first discuss possible across-word assimilation phenomena in German and provide a complete analysis of such assimilations in the Kiel corpus. Our analysis is first divided into a section for function words and a separate section for lexical words. There is ample evidence that the phonological and phonetic behavior of these two word categories is different (e.g., Selkirk, 1984; Kaisse, 1985; Nespor and Vogel, 1986; Hall, 1999; Ogden, 1999; Philipps, 2001; Local, 2003; Kabak and Schiering, 2006; Bybee, 2007). For instance, function words in German are often drastically reduced (Hall, 1999). For English, it has been reported that /m/ in the function words "I'm" may assimilate to neighboring segments, whereas /m/ in content words such as "time" does not (Ogden, 1999; Local, 2003). We also examine whether function words behave differently when it comes to regressive place assimilation and compare the findings of the two sections. This analysis is followed by two perception experiments examining the ability of listeners to hear the altered sounds based on the Kiel transcriptions. We offer a proposal for modeling alterations by assimilations in a framework assuming underspecification, such as the Featurally Underspecified Lexicon model (FUL) (Lahiri and Reetz, 2002).

II. ASSIMILATIONS IN GERMAN

How inviolable are word final consonants? Such consonants are of course subject to change, either by progressive assimilation within a word or by regressive assimilation across words. Although progressive place assimilations are reported to be frequent within a word in German, cf. *geben* [gebən]>[gebm], regressive assimilation across words is more controversial (Wurzel, 1970; Dressler *et al.*, 1972; Benware, 1986; Hall, 1992; Wiese, 1996; but see Kohler, 1995). As Wiese (1996) states, when it is possible to pronounce two words as a single unit then regressive assimilation is more likely (cf. *man kommt* "one comes" pronounced as [maŋ kɔmt] versus no assimilation in *der Mann kommt* "the man comes" [man kɔmt]). More definite conclusions regarding regressive assimilations in German is difficult since in his words, "…first, there is little systematic study of such differences, and, second, at the tempo of fast speech, assimilation is certainly possible in the latter example" (Wiese, 1996, p. 221). Nonetheless, regressive assimilations across words are not unknown and the possibility is at least mentioned by most of these authors.[6]

Kohler, however, explicitly claims that regressive place assimilation takes place across word boundaries (Kohler, 1995, p. 206; see also Kohler, 1990) and cites several examples where such assimilations occur. One such example is *bunt machen* "to make colorful" [bʊnt maxŋ] being pronounced as [bʊmp maxŋ]. A study on the Viennese variety of German by Dressler and his colleagues also mentions the possibility of regressive place assimilation in fast speech (Dressler *et al.*, 1972).

Given that there is little systematic work on regressive assimilation across word boundaries in conversational German, we turned to the Kiel corpus for natural speech data. The Kiel corpus (IPDS, 1994) provides us with ideal data for examining minute phonetic variations in naturally spoken dialogues. The corpus makes available detailed phonetic transcriptions and hand labeled segmentation of the acoustic signal performed by trained phoneticians. Thus, we have rich material to study across-word variations as noted by phoneticians who used both the information in the signal as well as their own perception to make decisions concerning what was actually produced.

In what follows, we refer to the sequence of consonants across word boundaries as C_1 and C_2. The word final segment (C_1), which could assimilate, will be referred to as the target and the word initial segment of the following word (C_2) as the trigger as shown in (1). C_1 could be any stop, fricative or nasal in German, whereas C_2 could be any obstruent or nasal which may occur in that position. Word finally (target position), voiced stops and fricatives are devoiced regularly in German (*Auslautverhärtung*—final devoicing—see Kohler, 1995; Wiese, 1996; Hall, 2000, and references therein). Consequently, in production, there are no word-final voiced obstruents.[7]

(1) TARGET (C_1) and TRIGGER (C_2) in word sequences
$[\ldots C_1]_{\omega 1}[C_2 \ldots]_{\omega 2}$
| |
e.g., *Termin bleiben* ("appointment stick"
—stick to appointment)

The following issues are addressed in the analyses of the speech data: (a) How often do German speakers produce regressive assimilations across words? (b) Is there a particular place of articulation for C_1 which favors assimilation? For instance, are [coronal] sounds more likely to assimilate than [labial] ones? (c) Does the manner of articulation of C_1 matter for regressive assimilation? For example, do nasals assimilate more often than stops in running speech? (d) Does the place and manner of articulation of the C_2 trigger correlate with regressive assimilation? (e) Does the lexical status of the first word (function words versus lexical words) increase the probability of assimilation since function words are supposed to be less stable and more vulnerable to alterations?

Other than quantifying the number of assimilations in conversational speech, we also address the issue of completeness of these assimilations in perception. Two perception studies were conducted using selected material from the database. The first experiment used a forced choice phoneme identification task on fragments of words from selected dialogues. In a second experiment, subjects were asked to transcribe freely what they heard. Our goal was to observe how listeners would perceive segments labeled as assimilated in the speech corpus and whether there were any remnants of the original segment to affect the speed and accuracy of identification as compared to unchanged segments.

III. ANALYSIS OF SPONTANEOUS SPEECH

The Kiel corpus consists of about 4 h of dialogues of 42 (northern) German speakers (18 female, 24 male) who were engaged in an appointment-making task. They were each given a schedule with existing and sometimes conflicting appointments, and their task was to decide on future meetings. In order to ensure a high degree of natural speech, the speakers were ignorant of the schedule of their partners. The dialogues were recorded with the speakers placed in different sound-treated rooms communicating by headsets. As mentioned earlier, all dialogues were transcribed and labeled by trained phoneticians using visual scaleable spectrograms and oscillogram displays as well as auditory information (Kohler *et al.*, 1995, p. 33). Other than the phonetic transcription of what was actually pronounced, the corpus contains an orthographic text, along with its canonical phonetic transcription. The idealized canonical transcription denotes how utterances should be if they were spoken in accordance with a careful dictionary-like pronunciation. This allows a direct comparison of a canonical transcription with the actual—phonetically transcribed—pronunciation. The nature of the task and the fact that participants had to make very similar appointments restricted the vocabulary. For instance, dates, times, and days of the week occur very often. Nevertheless, since the speakers were unaware of the purpose of the recordings, the conversations were very natural.

A. Material and methods

Overall the *Kiel Corpus of Spontaneous Speech* consists of 1984 turns of dialogues by 42 speakers available in three CDs. All transcribed dialogs from the appointment-making task consisting minimally of two words, including the test dialogs, went into our analysis. The longest turn is about 54 s and the shortest ones are less than a second. An example of average length of one turn is given in (2) with (a) the orthographic transcription with our English translation, (b) the canonical transcription in IPA, and (c) the phonetic transcription as given in the Kiel corpus (omitting instances of nonspeech sounds such as clicking, smacking, etc.).

(2) Example of a dialogue in the Kiel corpus (utterance g071a006):

(a) Orthographic transcription *Das würde mir ganz ausgezeichnet passen. Machen wir das fest*? "That would be excellent for me. Can we confirm this?,"
(b) Canonical transcription (IPA transcription of the orthographic form) [das vʏɐdə mɪːɐ ˈgants ˈʔaʊsgəˌtsaɪçnət ˈpasən. ˈmaxən viːɐ das ˈfɛst?],
(c) IPA transcription of the actual pronunciation [das vʏɐd mɪːɐ ˈgants ˈãʊsgəˌtsaɪhnət ˈpasn. ˈmaxm viːɐ das ˈfɛst?].

We counted all possible contexts of regressive place assimilations of nasals and obstruents, and then summed up all cases where they actually occurred, even across sentence boundaries. This meant that instances where the C_1-target and C_2-trigger had the same place of articulation were ignored. For the analysis, utterances were excluded where technical problems led to incomplete speech signals, or where speakers produced false starts, or where there were intervening hesitational markers as *ähm* or *m(hm)* ("ahem, hm") like in *machen äh(m) wir*. Furthermore, to rule out possible confounds, we did not include utterances where a possibility of progressive place assimilation existed and thus target and trigger could not be identified unambiguously. For example, the assimilated [m] in a phrase like *haben wir* ("have we") [haːbən viːɐ] spoken as [haːbm viːɐ] has two potential triggers, the preceding labial [b] or the following labial [v], and was therefore not considered in our data set. We also excluded words where the last segment (C_1) was

TABLE I. Obstruents and nasals in German and their phonological place features.

Labial	*bilabial, labiodental*	[m, p, b, f, v, pf]
Coronal	*alveolar, palatoalveolar, palatal*	[n, t, d, s, ʃ, z, ç, ts, tʃ]
Dorsal	*velar*	[ŋ, k, g, x]

deleted to rule out all possible confounds connected to deletions. Thus, phrases like *und Mittwoch* ("and Wednesday") [ʊnt ˈmɪtvɔx] pronounced without word final [t] as [ʊn ˈmɪtvɔx] were not included.[8] All obstruents and nasals were treated as possible triggers (C_2). The phonological features of the consonants that were taken into account, both as target and trigger, are given in Table I.[9]

The segments [ŋ, tʃ, s, x] do not occur word initially in standard German, except in a handful of loanwords. Due to final devoicing, one expects the voiced consonants to be devoiced word finally, but this does not affect place assimilation.

B. Analysis

Function words behave differently than content words in many different ways (e.g., Selkirk, 1984; Kaisse, 1985; Nespor and Vogel, 1986; Hall, 1999; Ogden, 1999; Philipps, 2001; Local, 2003; Kabak and Schiering, 2006; Bybee, 2007). Therefore, we split up the following analysis into a section for function words, another section for content words, and then we compare the results. The issue of interest to us is whether function words behave differently concerning regressive place assimilation. Since there is considerable controversy concerning which words count as function words, we opted for the classification in the Kiel corpus (marked with a final "+" in their transcription).

1. Function words

An overview of the different kinds of function words occurring in the database is given in (3). The function words could be either trigger or target. However, we ignored the syntactic category of the second word in a sequence, since our main point of interest is on the words that undergo assimilation, therefore the lexical status of the trigger was of no relevance in our analysis.

(3) Examples for different function word categories in the Kiel corpus:

(a) Auxiliaries: *bin, hatte, gewesen, möchte* ("am, had, been, would like"),
(b) Determiners: *der, die, das, ein, eine* ("the.*masc*, the.*fem*, the.*neut*, a.*masc*, a.*fem*"),
(c) Pronouns: *ich, wir, Sie, Ihre, Ihnen*, ("I, we, you.*hon*, you.*hon.gen*, you.*hon.acc*")
(d) Prepositions: *in, am, bis*, ("in, at.*dat*, until/to'"),
(e) Demonstratives: *diesen, dieser, diesem* ("this-*case*"),
(f) Conjunctions: *und, aber, zwar* ("and, but, but/namely").

Overall, 4144 function words qualified as target (C_1) in a sequence of two consonants at word boundaries. Out of those, in 266 (6.4%) instances the target C_1 was transcribed in the corpus as having been pronounced with a different place of articulation from the canonical form, e.g., *ein Montag* [aɪm moːntax] instead of [aɪn moːntax]. Table II(a)–(c) show the data for all occurrences of targets and the corresponding triggers, with the numbers and percentages of assimilated segments.[10]

The results clearly indicate that although regressive place assimilations are not obligatory, they do occur across word boundaries of function words. In Table II(b) we see that 232 out of 2961 [coronal] sounds assimilate in place to the following segment, most of which were /n/. Out of a total of 1230 /n/ final function words, 225 or 18.3%, were labeled as assimilated; 168 out of 1036 (16.2%) words ending in /n/ assimilated to [m] and 57 out of 194 (29.4%) changed to [ŋ], when followed by [labial] or [dorsal] consonants, respectively. Out of a total of 200 function words ending in /t/, only 4 assimilated to [p] when a labial followed, and none assimilated before [dorsal] segments. Overall, 1021 function words ended in /s/, one of which was assimilated to a labial [f]. Finally, out of 510 /ç/ final function words, 2 assimilated to [f].

Turning to the [labial] final function words [Table II(a)], there were in all 724 of which 27 assimilated, all of which were /m/. There were 583 instances of /m/ final function words and 27 were labeled as having changed its place of articulation, 23 (i.e., 4.3%) to [n] when followed by a [coronal], 4 (9.3%) to /ŋ/ when followed by a [dorsal]. None of the 82 /p/ or 59 /f/ final function words assimilated. As for the [dorsal] final function words [Table II(c)], they all ended in /x/, and 7 out of 459 instances (1.5%) showed assimilation—six times to [f] when a [labial] followed, and one [s] when a [coronal] consonant followed.

From the data it also becomes evident that there are clear asymmetries in the patterns of assimilation. [Coronal] sounds assimilate more frequently (7.8%) than other places of articulation; cf. [dorsal] (1.5%) and [labial] (3.7%).[11] Another asymmetry concerns the manner of articulation of the targets that undergo assimilation. Nasal sounds are more prone to assimilation than stops, and fricatives assimilate the least.

The question we turn to now is whether these results are special to function words or whether they form a general pattern observable in connected speech.

2. Lexical words

For lexical words, we counted a total of 2916 possible environments for regressive place assimilation. As compared to function words, there were more C_1 [dorsal] segments. Of all possible environments, 127 (4.4%) assimilations were actually realized. An overview over the different targets and triggers is presented in Table III(a)–(c).

The data for lexical words follow a similar assimilation pattern to that of the function words. [Coronal] segments undergo regressive place assimilation in 121 cases, of which 97 were nasals [Table III(b)]. Among the nasals, 8 /n/ (7.4%) were realized as [ŋ]. The rest, i.e., 89 /n/ (9.4%) were produced as [m]. For lexical words, final [t]s accounted for 24 cases (4.5%) of regressive assimilations. Of the 24 instances

where [t] was assimilated, there was one utterance where [t] became [k] (1.8%), 23 cases showed assimilation to [p] (4.9%). No [coronal] fricative changed place of articulation. As for [labial] target segments, there occurred one assimilation: a word final [m] assimilated to [n] preceding a coronal stop [Table III(a)]. No other labial segment assimilated. [Dorsal] segments assimilated 5 times, all of them were [x]; 3 of them assimilated to [labial], 2 to [coronal] [Table III(c)].

Overall, the data of the lexical words also revealed two kinds of asymmetries. First, the nasal consonants assimilated more often than stops or fricatives. The second asymmetry concerns again the place of articulation of the target segment: [coronal] sounds undergo regressive place assimilation much more frequently (6.1%) than [labial] (1.3%) or [dorsal] (0.6%) segments.

C. Comparison of function and lexical words

The general pattern of assimilation was the same for lexical and function words although the latter underwent assimilation more frequently. Overall, we analyzed 7060 possible sequences for regressive place assimilation in the Kiel corpus of which 393 instances of assimilation occurred (see Table IV); i.e., 5.6% of the possible sequences were actually assimilated. Function words assimilated in 266 cases, whereas lexical words account for 127 instances. However, we should also note that function words occurred more often as targets in our sample than lexical words. We counted 4144 function words (58.7%) and 2916 lexical words (41.3%) as targets; hence, 6.4% of the function words and 4.4% of the lexical words assimilated. Nonetheless, function words show a significantly higher degree of regressive assimilation, as a *Chi-Square* test revealed ($\chi^2=13.9$, $p<0.001$).

Figure 1 depicts the relative percentage of assimilations depending on manner and place of articulation of C_1 in lexical and function words. For both function and lexical words, nasals are the most frequent to assimilate (350 out of 393—89.1%). Overall, stops assimilate in 28 (7.1%) cases and fri-

TABLE II. C_1 Targets and C_2 Triggers for all assimilated function words. The lightly shaded cells highlight assimilations. (a) Function words ending in a [labial]. (b) Function words ending in a [coronal]. (c) Function words ending in a [dorsal].

catives in 15 instances (3.8%). Of a total of 393 assimilated targets, overwhelmingly the [coronal] sounds (353 out of 393—89.8%) assimilate to the place of a following segment across word boundaries, whereas [labial] (7.1%) and [dorsal] (3.1%) segments usually do not. In general, coronal targets (C_1) by far outnumber the other places of articulation (4931 or 69.8%). The fewest number of targets are [labial] sounds

TABLE IV. Assimilation of function and lexical words combined.

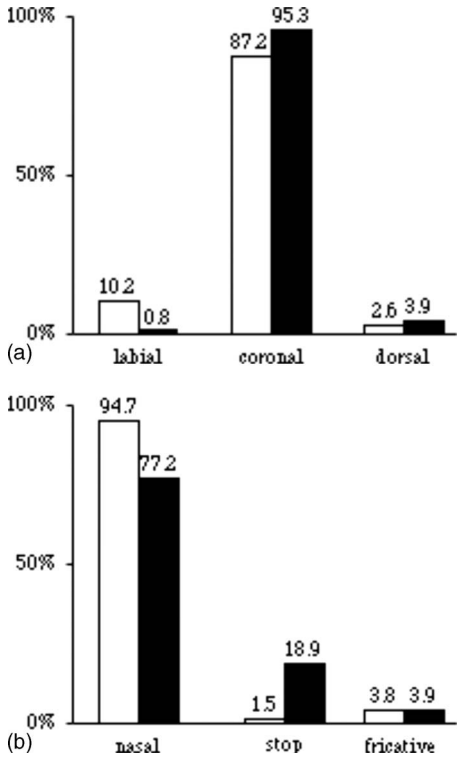

FIG. 1. Relative percentages of regressive place assimilations (based on the total number of assimilated sequences) across different place (a) and manner of articulation (b). Function words are represented by light bars, lexical words by dark bars.

(800 or 11.3%). The only [dorsal] segment—both in function words as well as lexical words—that assimilates is [x].

Note that the analysis did not differentiate between C_1 and C_2 sequences that were within one phrase or sequences that crossed phrase boundaries. Out of the 7060 items analyzed in the data, there were 1174 (16.6%) crossing either a period, a question mark, or a comma in the transcription. Of all 18 cases where C_1 and C_2 were separated by a question boundary, none showed assimilation. Concerning periods, there were overall 310 sequences in this category. There was one (out of 188) assimilation occurring in a [coronal]-[labial] context. Overall a comma separated 848 of the 1174 sequences. In this category, there were 13 assimilations. 10 (out of 319—3.1%) occurred in a [coronal]-[labial] context, 2 (out of 42—2.4%) showed an assimilation of [x] to [f] in front of [f], and two cases (out of 441 possible sequences—0.5%) had an assimilation of [x] to [s] in front of [z]. Thus, although phrase boundaries do impede assimilation, at least for commas, there are cases where assimilation even occurs across those boundaries.

To summarize, across word place assimilations in German is controversial. Some authors claim that such assimilations do not occur (cf. Wurzel, 1970; Vater, 1979; Wiese, 1996), while others assert the opposite (cf. Kohler, 1995). This controversy led us to systematically analyze assimilations across word boundaries in conversational German. The Kiel corpus data suggests that although such assimilations are not frequent, they do occur—overall, approximately 6% of possible assimilatory sequences did undergo a change in place of articulation. We analyzed function and lexical words separately since they are claimed to be different, and indeed, we found a significant difference in the number of assimilations between the two categories although the assimilation patterns were the same. Function words are more likely to assimilate than lexical words. Moreover, the data revealed clear asymmetries in the pattern of assimilations that actually occurred. One asymmetry concerns the place of articulation of the targets (C_1) undergoing assimilation: [coronal] sounds are more frequently assimilated than [dorsal] and [labial] consonants. A second asymmetry is that nasals assimilate more often than stops or fricatives.

The assimilation data we have analyzed and presented are based on the transcriptions of trained phoneticians who noted sequences where assimilation had occurred despite the fact that they had the orthographic as well as the canonical phonetic transcription that could have biased them to perceive the canonical sounds. Speech perception research suggests, however, that although some sounds might seem to be assimilated, there may still be residual cues for listeners to identify the underlying segments (cf. Gow, 2002). We therefore turn to the perception of naive listeners and compare them to the transcriptions of the trained phoneticians.

IV. IDENTIFICATION OF TRANSCRIBED PLACE OF ARTICULATION

The question we investigate next is: Do naive listeners (naive both with respect to the goal of the experiment as well as not having additional information from the context) perceive the assimilated and unassimilated segments from the Kiel dialogues in the same way as trained phoneticians who used speech analyses tools? We conducted two phoneme identification experiments—a forced choice and a free choice task—using material from the Kiel corpus. We opted to focus on nasals (/n/ and /m/) since the choice of assimilated segments was larger than for oral stops and we were able to take stimuli from several speakers thereby lessening speaker dependence (for details see Sec. IV A 1 below).

A. Experiment 1: Phoneme identification

A timed forced-choice identification task was chosen for the first experiment. Subjects had to decide whether the auditory stimuli included either a labial [m] or a coronal [n]. This method was chosen to determine the speed as well as the accuracy of the subjects' decision. Other studies have shown that assimilations can be only partial and that listeners are sensitive to residual cues left (cf. Nolan, 1992; Manuel, 1995; Gow, 2002). Manuel (1995), for example, found that in a sequence [nð] in *win those*, where the /ð/ became a nasal, the place of articulation was not that of a "real" [n], suggesting that some featural information was still available to the listener. Our focus was not just on the assimilated stimuli, but also stimuli that had been labeled as unchanged from the canonical—that is underlying /n/ or /m/ which were spoken and heard as [n] and [m]. The issue was whether the responses to the unchanged stimuli differed across varying contexts—vowel, labial, dorsal, coronal. The crucial conditions with a set of examples are listed in Table V. The segmental context from which the stimuli were extracted is

TABLE V. Examples of stimuli with the vowel [e:] for experiments 1 and 2. Column 1 gives the Kiel transcription. Column 2 provides the orthographic contexts from which the stimuli were extracted and column 3 gives the three conditions—unchanged unassimilated-/m/ and unassimilated-/n/, and assimilated.

Kiel corpus transcription	Example stimuli in orthography	Condition
		Unassimilated-/m/
[e:m]	…von d**em a**chtzehnten Juni?…	Vowel context /m/-vowel
[e:m]	…mit d**em B**ericht…	Labial context /m/-labial
[e:m]	…dann d**em D**ienstag…	Coronal context /m/-coronal
[e:m]	…und d**em g**anzen Kram…	Dorsal context /m/-dorsal
		Unassimilated-/n/
[e:n]	…Freitag, d**en e**rsten…	Vowel context /n/-vowel
[e:n]	…für d**en B**ericht…	Labial context /n/-labial
[e:n]	…in d**en d**eutschen…	Coronal context /n/-coronal
[e:n]	…d**en g**anzen Tag…	Dorsal context /n/-dorsal
		Assimilated
[e:m]	…über d**en B**ericht…	Labial context

double underlined. Since the coronal nasal assimilated most frequently, we only used conditions where /n/ was assimilated to [m].

Our predictions are the following. Most descriptions of assimilations suggest that coronal consonants are more vulnerable to variation in the context of consonants with other places of articulation (cf. Paradis and Prunet, 1991). Consequently, one could expect that labial and dorsal C_2 contexts would leave more acoustic traces in unassimilated-/n/ stimuli than coronal and dorsal C_2 segments influence unassimilated-/m/ stimuli. This would make it more difficult for listeners to come to a definite decision for the unassimilated-/n/ stimuli. Therefore, we expect slower reaction times (RTs) for unassimilated-/n/ in labial and dorsal contexts but no reaction time differences for those items in the vowel or homorganic consonantal context. Insofar as the difference between assimilated-/n/s and unassimilated-/m/s are concerned, we expect no difference in the speed of reaction, assuming that the assimilated-/n/s exhibit complete neutralization. However, whether the assimilated-/n/ items were equally well heard as [m] as the unassimilated-/m/s depends on whether the assimilation as perceived by the transcribers was reasonably complete. Thus, both the reaction time measures as well as percentage of [m] and [n] responses are vital.

1. Materials

The stimuli for the perception task consisted of a vowel-nasal (VN) sequence extracted from real words (CVN or VN), and were taken from 27 different speakers (13 female, 14 male) of the Kiel corpus. At most five items were taken from any given speaker. We thereby kept the segmental context as similar as possible and at the same time were able to make the perception task speaker-independent. The two vowels in the VN sequences we chose were transcribed as either a mid [eː] or a low [ɑ] vowel. The extracted sequences with [ɑ] form possible words: *an* [ɑn] "on, at.acc" and *am* [ɑm] "at.dat," whereas the [eːn] and [eːm] sequences do not. A set of sentences from which the [eː] sequences were extracted is given in Table V and corresponding [ɑm/ɑn] sequences are given in Appendix B.

We cut the VN-items at zero-crossings in order to avoid clicks at item boundaries using both visual as well as auditory information. The first identifiable glottal period was taken as the beginning of the vowel. However, when there was an extensive amount of coarticulation from the preceding segment (i.e., at the word onset), we cut off up to four glottal periods to ensure that the consonantal onset could no longer be perceived. The end of the nasal in the VN-items was determined when the amplitude of the waveform dropped markedly or at the beginning of the closure of the following consonant. Thus, the nasal itself was left untouched, but any contextual information in the following closure would have been removed.

For each vowel (i.e., [eː]/[ɑ]), we chose ten [coronal]#[labial] assimilated sequences (assimilated category), and 10 each of unassimilated [coronal] (unassimilated-/n/) and [labial] (unassimilated-/m/) items. This added up to 60 different stimuli. The unassimilated items were cut out of different contexts (see Table V and Appendix B); three preceded a [labial] consonant, three a [coronal] consonant, two a [dorsal] consonant, and two were originally followed by a vowel. The amplitude of the items was equalized.

2. Subjects and procedure

Overall, 18 undergraduates from the University of Konstanz with no reported hearing disorders served as subjects in the experiment and were paid for their participation. They were tested in groups of 5 or less and were given oral as well as written instructions. A push-button box with two buttons labeled [m] and [n] was placed in front of each subject. They were instructed to listen to the syllables presented over headphones and decide as quickly as possible whether the consonant was [m] or [n] and press the appropriate button with the index finger of their dominant hand. Before the test began,

TABLE VI. Least square means of reaction times for three main categories in all contexts for both [m] and [n] responses [% values are computed for each row by $N_x/(N_{\text{Response[m]}}+N_{\text{Response[n]}})$].

	Response [m]			Response [n]

/n/-vowel	77	21.9	538.6	275	78.1	536.8
Assimilated (labial context)	1534	87.5	545.8	219	12.5	580.0

the subjects familiarized themselves to the task with practice items, but were given no feedback about the "congruency" of their decisions.[12]

Each item occurred five times during the experiment, adding up to 300 items presented in a randomized order. The sequence of presentation was as follows. Each item was preceded by a warning tone of 300 ms followed by 200 ms of silence. After each test stimulus, there was a pause of 1500 ms where subjects had time to push the button and the next sequence began. Reaction time measurements began at the onset of the nasal segment. The stimuli were played from a SONY DAT recorder and presented over headphones (Sennheiser HD520II). In the setup, a central experimental hardware box connected the DAT recorder, the response boxes and a Macintosh computer, where the reaction times were recorded (Reetz and Kleinmann, 2003). A single experimental session lasted approximately 18 min excluding the practice items.

3. Results

The responses of all 18 subjects went into the reaction time analysis.[13] Responses faster than 200 ms and slower than 1000 ms were disregarded leading to the exclusion of 133 responses (2.5% of the data). None of the subjects showed an exceptionally high number of responses which were too slow or too fast. Reaction times as a dependent variable and the factors *subject* (as random), *response* ([m] or [n]),[14] *underlying* (unassimilated-/m/, unassimilated-/n/, assimilated), *context* (nested under *underlying*) (/n/-coronal, /n/-labial, /n/-dorsal, /n/-V, /m/-coronal, /m/-labial, /m/-dorsal, /m/-V, assimilated), *item* (nested under *underlying* and *context*), *response*×*context* (nested under underlying) and *underlying*×*response* as independent variables were entered into an analysis of variance (ANOVA) with REML estimation.[15] There was a main effect of *context* [$F(65\,181)=9.03$, $p<0.001$] and *response* [$F(15\,181)=15.37$, $p<0.001$], and the interaction of *context*×*response* was also significant [$F(65\,181)=4.70$, $p<0.001$]. *Speaker* and *repetition* were not significant factors in the ANOVA. They are therefore not reported. The least square means of the RT measures for both [m] and [n] responses for each *context* are given in Table VI.

Several pairwise posthoc comparisons were made for the critical conditions, the interpretations of which are summarized below with individual figures.

(i) Recall that based on the analysis of the Kiel corpora transcriptions, the expected congruent responses are [m], for the unassimilated-/m/ category and [n] for the unassimilated-/n/ category. The percentage congruent responses are revealing. For unassimilated-/m/ stimuli, 93% of the responses were [m], and only 7% were [n]. In contrast, for unassimilated-/n/ items, almost a quarter of the stimuli were identified as the opposite [m]—77% [n] versus 23% [m]. Obviously, listeners had more difficulty with the unassimilated-/n/ stimuli than with unassimilated-/m/ items. A *Chi-Square* analysis revealed a significant difference ($\chi^2=1773.63$, $p<0.001$). The reaction times also reflect the same pattern. If we consider the congruent responses, [m] for unassimilated-/m/ and [n] for the unassimilated-/n/, the reaction times across these categories (536 and 547 ms, respectively) are statistically different ($t=2.15, p<0.05$). There is a much larger difference between the reaction times for [m]- and [n]-responses to the unassimilated-/m/ stimuli (536 ms versus 580 ms, $t=2.97$, $p<0.05$). Likewise, there is a significant difference between the incongruent [m]-responses of unassimilated-/n/ and the [n]-responses of unassimilated-/m/ (547 ms versus 580 ms, $t=2.04$, $p<0.05$). The RT of [m] or [n] responses to the unassimilated-/n/ category are essentially identical. This suggests that it was more difficult for the listeners, and hence, they were slower, to give [n] responses to unassimilated-/m/ stimuli when they were uncertain.

(ii) Since there were four contexts, the next point to address is if any particular context is responsible for the worse identification of unassimilated-/n/ than

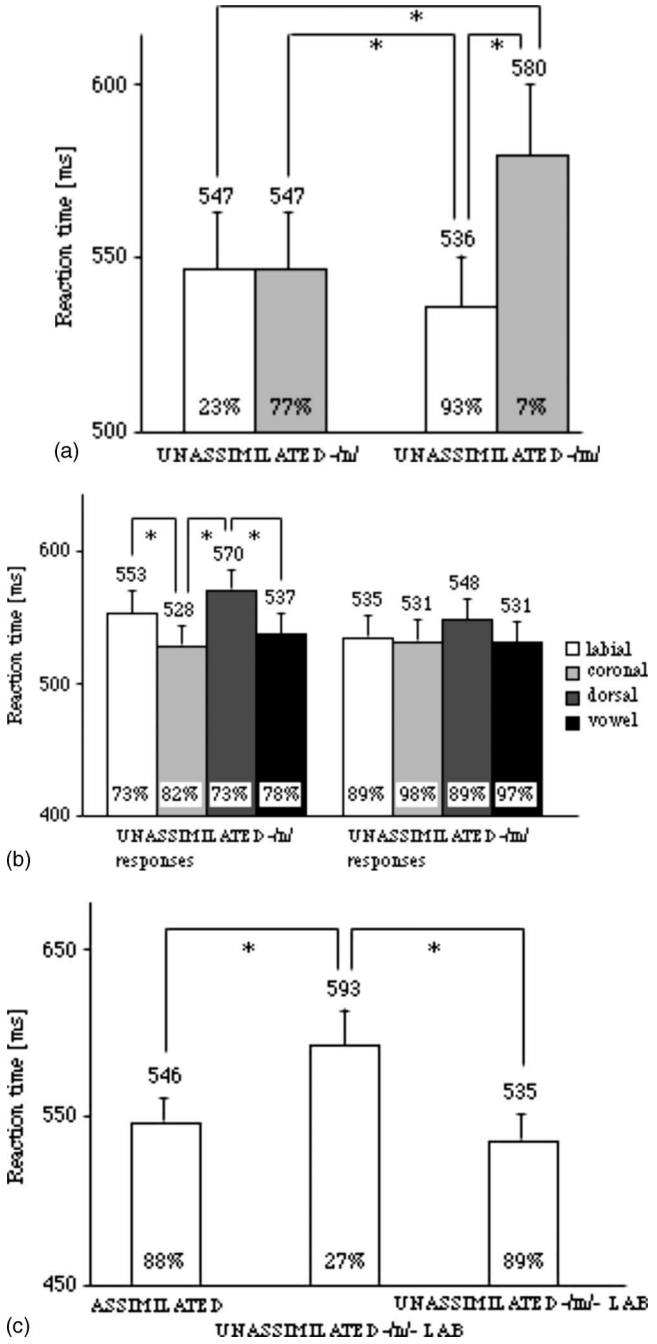

FIG. 2. (a) [m] and [n] responses to unassimilated-/n/ and unassimilated-/m/ stimuli in percent and with their reaction times as bars. Asterisks indicate significant differences in reaction times. White bars represent [m]-responses and gray bars show [n]-responses. (b) [n] responses to unassimilated-/n/ and [m] responses to unassimilated-/m/ stimuli differentiated by context. Percent of responses are given in numbers and the bars represent the reaction times with significant differences indicated by asterisks. (c) Percentages and reaction times for [m] responses to assimilated, unassimilated-/n/-labial, and unassimilated-/m/-labial stimuli. Asterisks indicate significant reaction time differences.

unassimilated-/m/ [see Fig. 2(b)]. With respect to percentage congruent responses, in all contexts more than 89% of the unassimilated-/m/ stimuli were congruently responded to as [m]. This was not so for the unassimilated-/n/ stimuli, where 27% of the responses were [m] in the labial and dorsal contexts. When an unassimilated-/n/ item was preceding another coronal or a vowel, the responses were more comparable to the unassimilated-/m/ stimuli, viz. around 80% [n] responses. To test whether parallel results are reflected in the reaction times, we ran pairwise comparisons across all four contexts—vowel, coronal, dorsal, labial [see Fig. 2(b)]. For the [m] responses to unassimilated-/m/, there were no significant differences in reaction across any of the contexts.

Thus, unassimilated-/m/ (extracted from *dem, am*, etc.) stimuli were heard and reacted to as [m] equally fast regardless of which context they had been extracted from. Would we find the same pattern for [n] responses to the unassimilated-/n/ category stimuli? Based in the corpus analysis, we know that /n/ is more vulnerable to coarticulation from following consonants with different places of articulation. There could therefore be a difference between the contexts dorsal, labial, on the one hand, versus coronal and vowel, on the other. In the former contexts, the /n/ may have more coarticulation cues of the place of articulation of the following dorsal or labial consonant, making it more difficult to label the unassimilated-/n/ as [n] in a reaction time task, whereas in the coronal context, the /n/ is in its ideal environment. The pairwise comparisons confirmed this prediction. The [n] responses to unassimilated-/n/ in coronal context differed significantly from the responses to unassimilated-/n/ in labial context ($t=-2.82$, $p<0.005$) as well as from the dorsal contexts ($t=-3.99$, $p<0.001$). Another significant difference emerged in the comparison of the [n]-responses to unassimilated-/n/ in the dorsal and the vowel contexts ($t=-2.91$, $p<0.005$). There were no further significant differences between any other contexts for the [n]-responses. Thus, the [n]-responses to unassimilated-/n/ in the coronal and vowel contexts, which are the most neutral contexts in terms of coarticulation, are significantly different from the labial and dorsal contexts, We can therefore conclude that the coarticulation cues from the (deleted) following labial and dorsal consonants were strong enough to slow down the subjects' [n] responses to these stimuli. Recall that these consonants had been labeled as [n] by phoneticians who had recourse to both visual and auditory cues and were under no time pressure.

In sum, the labial and dorsal contexts had a slowing down effect on the [n] responses for unassimilated-/n/ stimuli as compared to its homorganic coronal context. This effect is not observed for the unassimilated-/m/ stimuli in the coronal and dorsal contexts in comparison to its homorganic labial context. For the unassimilated-/m/ stimuli, the subjects' speed and their response were unaffected by the context of other places of articulation, from which we may deduce that there were less coarticulation cues which could confuse them. Thus, there was an asymmetry in the stimuli even where trained phoneticians had transcribed the sounds carefully.

(iii) The assimilated stimuli were always (by definition) extracted from a labial context. The crucial question

to gain further insight in how far the assimilations were produced completely is whether these stimuli differ from the unassimilated-/m/ stimuli in the same context. The unassimilated-/m/ stimuli in labial context can be seen as the most prototypically produced labial features without coarticulation and they are taken as clear examples of [m]. Since we found an effect of coarticulation of the labial context in the unassimilated-/n/ stimuli, we also take these for comparison. With respect to percent congruent responses, the [m] responses to the assimilated stimuli and the unassimilated-/m/-labial were almost identical—88% versus 89%. Further, there were no significant differences in reaction times in the [m] or [n] responses to these categories. From this we can conclude that subjects were equally fast in responding to the assimilated [m] and the canonical /m/ stimuli (e.g., [e:m] from *über de**n** **B**ericht* versus [e:m] from *mit de**m** **B**ericht*).

As for the reaction time of [m] responses to unassimilated-/n/-labial stimuli, these were different from the [m] responses to the other two categories (assimilated versus unassimilated-/n/-labial $t=-4.08$, $p<0.001$; unassimilated-/n/-labial versus unassimilated-/m/-labial $t=-4.64$, $p<0.001$), indicating that although there was sufficient coarticulation, these stimuli were different from those that were considered by the transcribers as real assimilated or canonical unassimilated-/m/ items. Crucially, there is no difference between the [m] responses in the assimilated and the unassimilated-/m/-labial categories ($t=-1.65$, $p<0.1$). Thus, for listeners, the assimilated stimuli were similar to the unassimilated-/m/-labial but not to the unassimilated-/n/-labial.

Recall that the task in experiment 1 was forced choice where subjects had to choose between [m] or [n] as possible responses. To determine in how far the forced choice task of experiment 1 created a possible bias in the subjects' responses, we ran a second experiment where the listeners were free to choose and write down what they heard.[16] Our hypothesis was that if we obtained the same pattern of results, then we could conclude that the context-dependent responses of unassimilated-/n/ stimuli was caused by the fact that the listeners were forced to choose between [m] or [n]. Further, we also wanted to examine the pattern of responses to the dorsal stimuli since in experiment 1 the listeners had no option of providing dorsal responses.

B. Experiment 2: Phoneme transcription task

1. Material and design

In order to analyze if possible confounds in the forced-choice task could have affected the results, we used a phoneme-identification task where subjects could write down in a booklet what fragment they heard. The stimuli were identical to experiment 1 except that there was a longer pause between two items (2500 ms instead of 1500 ms), sufficient for writing the syllables but not too much time to think about the stimuli. Each page in the booklet had space for ten items. Warning tones were added after every ten items, prompting subjects to turn to the next page of the booklet. This was done to ensure that if a subject missed an item, it was possible to correctly resume at the beginning of the next page. Thus, as in experiment 1, subjects listened to 300 stimuli.

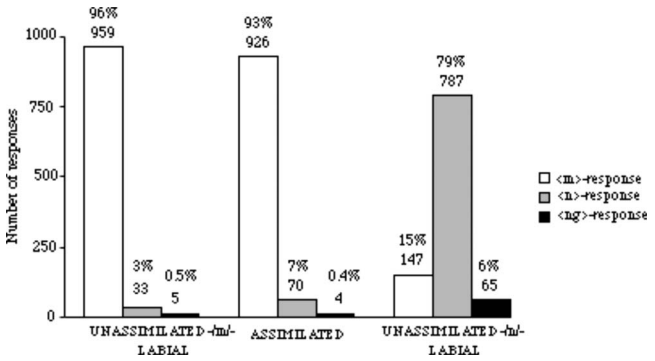

FIG. 3. Total number of responses and percentages within the three main categories.

2. Subjects and procedure

Ten students from the University of Konstanz served as subjects, and none had taken part in the earlier experiment. They were tested individually and were paid for their participation. The set up and equipment was the same as in experiment 1. Written instructions were given to the subjects prior to the experiment and they received the same practice items as before. They were asked to write down what they heard as quickly and accurately as possible. No instruction was given with reference to nasals, syllables or the "wordness" of the items. Given German orthography, if subjects heard nasals, we expected subjects to transcribe them using one of the three possible responses ⟨m⟩, ⟨n⟩, or ⟨ng⟩.

3. Results

In all, there was only one missing response and three were not a nasal. These four items were discarded (0.13%). The nasal responses were split up into the three main categories as above (labial, assimilated, and coronal), based on the original labeling in the Kiel corpus. A total of 2996 transcribed items went into the analysis. Across all categories subjects heard 2032 ⟨m⟩ (67.8%), 890 ⟨n⟩ (29.7%), and only 74 ⟨ng⟩ (2.5%), of which 41 (i.e., 55.4%) come from unassimilated-/n/ in a dorsal context.

Within the individual categories, the nasal segments were transcribed as follows (see Fig. 3). Unassimilated-/m/ segments were transcribed as ⟨m⟩ in 959 cases (96.2%), ⟨n⟩ in 33 instances (3.3%), and ⟨ng⟩ in 5 (0.5%) cases. Assimilated tokens were transcribed as ⟨m⟩ in 926 cases (92.6%), as ⟨n⟩ in 70 (7.0%) cases, as ⟨ng⟩ in four cases (0.4%). Unassimilated-/n/ were transcribed as ⟨n⟩ in 787 (78.8%) cases, ⟨m⟩ 147 times (14.7%), and ⟨ng⟩ in 65 (6.5%) instances.

Insofar as congruent responses are concerned, the percentage of [m] responses to assimilated and unassimilated-/m/ categories is far higher than the corresponding [n] responses to the unassimilated-/n/ category (93%, 96%, versus 79%).

4. Discussion

The free choice task was taken on to ensure that the incongruent responses in experiment 1 were not due to the fact that subjects were forced to choose between two nasals. In particular, we were concerned that the large number of ⟨m⟩ responses to unassimilated-/n/ stimuli was biased by the forced choice task. However, experiment 2 shows that this was not the case. First, there were only three non-nasal responses, and second, 97.6% of the entire responses were transcribed as ⟨m⟩ or ⟨n⟩.

In fact the pattern of results was the same as in experiment 1. On the whole, the unassimilated-/n/ stimuli were more difficult to identify congruently as ⟨n⟩ (79%) and were subject to context dependent responses, as compared to the unassimilated-/m/ or assimilated items, both of which were congruently identified as ⟨m⟩, 96% and 93%, respectively. As in experiment 1, the unassimilated-/n/ stimuli in the context of labial consonants were identified as ⟨m⟩ 15% of the time (experiment 1: 27%). In contrast, there were only 3% ⟨n⟩ responses to unassimilated-/m/ items. Overall, the accuracy of experiment 1 for [labial] and assimilated tokens was even higher in experiment 2, possibly due to the longer time subjects had for their decisions. The results for the assimilated category are very much the same as in experiment 1. They were largely perceived as [labial], indicating the completeness of assimilation. In general, this experiment replicates the same asymmetry we observed already in the identification task and the corpora analysis. One remaining issue is the acoustic differences between the different conditions, critically between the assimilated labial, the canonical unassimilated-/m/ against the unassimilated-/n/-coronal. Since the assimilated nasals did not differ in perception from the canonical unassimilated-/m/, one would conjecture that the acoustic differences would also be minimal.

C. Acoustic measurements

One important issue that has also been reflected in the literature on place assimilation is the question whether acoustic cues can be found that relate to listeners' decisions for [n] or [m] (e.g., Nolan, 1992; Gow, 2002; Dilley and Pitt, 2007). Following Dilley and Pitt's (2007) approach, we investigated the stimuli from the experiments. In their study, they compared assimilated segments with their underlying counterparts. Since their results are based on the variation in the F2 of the preceding vowel, we took the same measure and applied it to items from our perception test. We opted for the analysis of the most prototypical items. Therefore, we compared the assimilated items with unassimilated-/m/ stimuli in labial context and unassimilated-/n/ stimuli in coronal context. Since the number of items from the experiments was too small for calculating an ANOVA, we randomly selected additional items from the Kiel corpus.

There is one important difference between our stimuli compared to Dilley and Pitt's (2007): In our stimuli, the final consonant, in our case the nasal, was not deleted and acoustic information on place of articulation can also be extracted from the nasal segment, therefore, we also took F2 measurements at the midpoint of the nasal segment.

1. Method

We measured the difference in the F2 frequency values in hertz between the middle of the vowel and immediately before the beginning of the nasal murmur of all 20 assimilated items, six unassimilated-/m/-labial, and six unassimilated-/n/-coronal items that were used in the perception studies as an indication for the amount of possible assimilation. In order to base a statistical analysis on a more thorough database, we randomly added the measurements of four assimilated and 18 unassimilated-/m/-labial and 18 unassimilated-/n/-coronal items with the respective vowels. Overall, the measurements of 72 items were analyzed—36 for each vowel (i.e., [eː]/[ɑ]), 24 for each condition (i.e., assimilated, unassimilated-/m/-labial, and unassimilated-/n/-coronal). As in Dilley and Pitt, a mixture of automatic and hand taken measurements was performed (Dilley and Pitt, 2007). Formant values were taken form the estimation provided by PRAAT (Vers. 4.6.04, Boersma & Weening) and wide-band spectrograms. In case that the estimated formant values differed from the spectrograms we followed the spectrograms readings. Dilley and Pitt could measure only the difference between midpoint and endpoint of vowels to gain information about the place of articulation of the upcoming segments, since their items included cases where the consonant in question had been deleted. Since the nasal consonant was never deleted in our case, we were able to measure the F2 frequency in the midpoint of the nasal segments (F2 measurements on the nasal differ for labial and coronal nasal consonants, cf. Stevens, 1998, pp. 487–507). The F2 values at the midpoint of the nasals were measured the same way as in the vowels.

2. Results

F2 differences in the midpoint and endpoint of preceding vowels were subject to an ANOVA with *condition* (assimilated, unassimilated-/m/-labial, and unassimilated-/n/-coronal) and *vowel* as independent variable, as well as the interaction of the two factors (*vowel*×*condition*). Post-hoc tests were performed for the contrasts between the *conditions*. Figure 4(a) summarizes the results for the F2 differences.

As for the F2 difference analysis, there was a main effect of both *condition* [$F(2,66)=10.7106$, $p<0.002$] and *vowel* [$F(1,66)=3.3052$, $p<0.05$], but no significant interaction. A post hoc test revealed that unassimilated-/n/-coronal items were significantly different from assimilated ($t=-2.317$, $p<0.05$) and unassimilated-/m/-labial ($t=2.1242$, $p<0.05$) items, but the latter two were not significantly different from each other.

For the F2 measurements taken at the midpoint of the nasal consonants [see Fig. 4(b)] we used the same ANOVA design and gained the following results: There was a main effect of *condition* [$F(2,66)=5.1775$, $p<0.01$], but no effect of *vowel*, and no interaction. A post-hoc test showed that

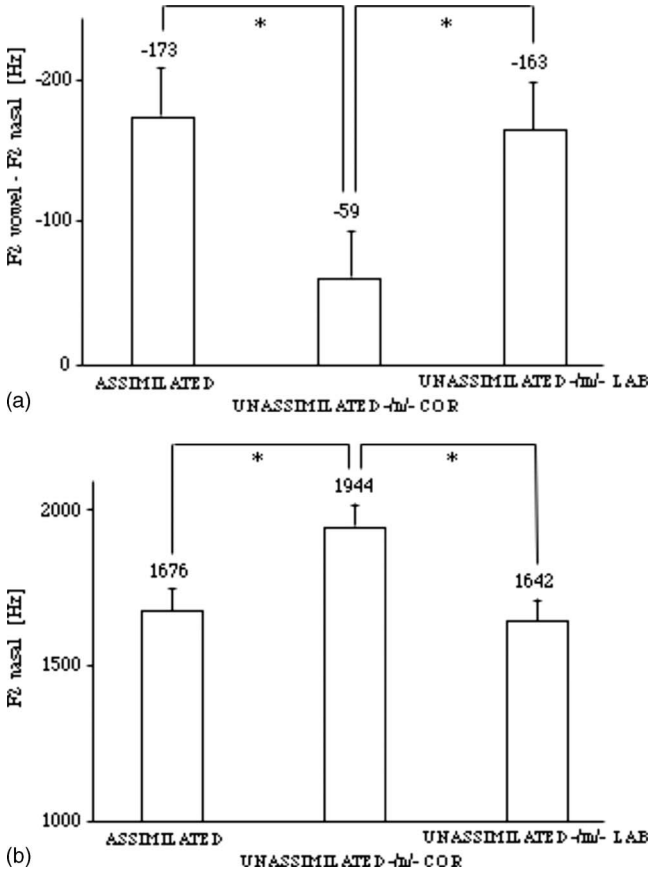

FIG. 4. (a) Differences between F2-frequency measures at the middle and at the end of the vowel in hertz. Significant differences between these difference values are marked by asterisks. (b) Least square means of F2-frequencies at nasal midpoints for the investigated conditions, significant differences are indicated with asterisks.

unassimilated-/n/-coronal items were significantly different from assimilated ($t=-2.605$, $p<0.02$) and unassimilated-/m/-labial ($t=2.9385$, $p<0.005$) items, but the latter two were not significantly different from each other. Figure 4(b) depicts the least square means of the nasal F2 measurements.

3. Discussion

The F2 differences between vowel and nasals and the F2 measurements on the nasals correspond to our perception results. There is no significant difference between the F2 of the assimilated coronals and the canonical unassimilated-/m/. Nor does the nasal F2 differ in these two categories. Corresponding to the perception results, there is a significant difference both in the F2 of the nasal and the F2 difference for the assimilated and unassimilated-/m/-labial nasals on the one hand and the unassimilated-/n/-coronal on the other. The results indicate that subjects take these acoustic cues as basis for their decision when deciding on whether they heard [m] or [n].

V. GENERAL DISCUSSION

The focus of this paper was to investigate the extent to which regressive place assimilations across words exist in conversational German and how listeners perceive them. Analyzing the Kiel corpus of spontaneous speech (IPDS, 1994; 42 speakers, approximately 4 h of recordings) we found that place assimilation does occur across words in German in approximately 6% of all possible sequences of consonants differing in place of articulation (cf. Sec. III C). This is slightly less than the percentage of assimilation reported by Dilley and Pitt (2007) for American English. We based our conclusions on the transcriptions made by trained phoneticians who had recourse to the speech signal as well as the context. Function words were more likely to assimilate than lexical words. Moreover, there was an asymmetry in the direction of assimilation. According to the transcriptions, coronal sounds [t, s, ʃ, ç, n] were more likely to assimilate than labial [p, f, m] or dorsals [k, x, ŋ] (see Table IV). A further asymmetry concerned the manner of articulation of consonants which were more likely to assimilate; nasal consonants were far more likely to assimilate than obstruents.

Exploiting the asymmetries, we ran two perception experiments (forced choice and free choice) to test how fast and accurately naive listeners' responses would correlate with the transcriptions. The two perception experiments using stimuli (from 27 speakers) labeled in the corpora as assimilated (/n/>[m]) or unassimilated (unassimilated-/n/, unassimilated-/m/), showed that the Kiel transcription is very accurate concerning regressive place assimilations. There is a high correlation between the phoneticians' transcriptions and the listeners' judgments. Thus, when the subjects had to decide whether they heard a [coronal] or a [labial] nasal in a VN-syllable without additional information from context, they were very accurate for the assimilated and the unassimilated-/m/ stimuli. The assimilated sounds were overwhelmingly transcribed as [m] both in a speeded forced choice task ([m] or [n]) as well as in a free identification task. In the identical labial context, the reaction times for unassimilated-/m/ and assimilated also did not differ [see Fig. 2(c)]. That is, subjects were equally fast in making an [m] response to stimuli which were really /m/ and those that had been labeled as assimilated from /n/ to [m] in a labial context.

The only nonequivalence between the transcriptions and the listeners' responses was the unassimilated-/n/ category in the context of labial or dorsal segments. If at all, the transcribers were conservative in their judgments of which sounds assimilated as is indicated by the high amount of variation in the /n/-category. As compared to unassimilated-/m/ which was congruently identified as [m] 93% of the time in experiment 1, only 77% of the unassimilated-/n/ stimuli were identified as [n]. The same pattern shows in experiment 2: 79% [n] responses to unassimilated-/n/ stimuli as compared to 96% [m] responses to unassimilated-/m/ stimuli and 93% [m] responses to the assimilated stimuli. The reaction times in experiment 1 also correspond to the accuracy data. The differences in the RT of congruent and incongruent responses of unassimilated-/m/ and unassimilated-/n/ responses are revealing. First, the incongruent [n] responses to unassimilated-/m/ stimuli are significantly slower than the corresponding incongruent [m] responses to unassimilated-/n/ stimuli, indicating that the former were less transparent for the listeners. Second, there is a stronger context effect for the unassimilated-/n/ stimuli

than for the unassimilated-/m/ stimuli. For the latter, there were no differences in reaction to the congruent [m] responses. However, the reaction times for the congruent [n] responses to the unassimilated-/n/ stimuli differed by context. For instance, in the neutral vowel and identical coronal contexts, the reaction times were much faster than in the labial and dorsal contexts. One could argue that coarticulation effects of the following deleted segments cause the incongruent responses, but this does not explain the asymmetry between unassimilated-/m/ and unassimilated-/n/ stimuli. That is, the coarticulation effects on the unassimilated-/n/ stimuli were presumably strong enough for listeners to respond to them with [m] as fast as they responded to the unassimilated-/n/ stimuli in their ideal coronal context. Almost a quarter of the unassimilated-/n/ stimuli were incongruently identified as [m] in both experiments. We see this as an indication that the transcribers of the Kiel corpus were "conservative" and labeled the unassimilated-/n/-labial as [n] rather than [m]. Since experiment 2 used a free-choice task, and the results were essentially the same to experiment 1, it is unlikely that subjects were forced to choose ⟨n⟩ as an answer as substitute for any other perceived segment.

We further investigated the acoustic patterns across the stimuli used in the perception experiments (Sec. IV C). Since our stimuli consisted of vowel-plus-nasal syllables, following Dilley and Pitt (2007) we took the F2 measures of the middle and end of the vowel, we also examined F2 at the nasal midpoint. Corresponding to the perception results, we found that the change in the F2 from the middle to the end of the vowel did not significantly differ between the unassimilated-/m/ and assimilated consonants. Similarly, the nasal formant measure did not differ between these categories indicating that the assimilated tokens shared these acoustic categories with the canonical /m/.

Both the perception results and acoustic analysis of the stimuli suggest that segments labeled as assimilated by the transcribers are indeed recognized not as tokens of the underlying words, but as perfect instances of the changed sound, i.e., complete assimilations do occur in running speech (/*n*/ > [*m*] in a labial context). Actually, some assimilated tokens are judged by subjects in our experiments to be [m] 100% of the time. Clearly however, there exists gradience in the assimilation as we have seen in the response to the unassimilated-/n/-labial stimuli. Although transcribers labeled them as [n] they were often perceived as [m]. Gradualness of assimilation is most important for the [coronal]-category where we see the greatest amount of (response) variation.

The asymmetry between coronal versus dorsal and labials both in production analysis (coronal consonants assimilate more than the others) and in perception (coronals vary most in perception) has been frequently noted in the literature (cf. Lahiri and Evers, 1991; Paradis and Prunet, 1991; Ghini, 2001). The unmarkedness and asymmetry of coronals are tackled by markedness rules or other phonological principles (cf. Clements, 2001) or built into a recognition model with underspecification as in FUL (Lahiri and Reetz, 2002).

The results of the corpus study as well as the two experiments are fully compatible with the FUL model of speech perception (Lahiri and Reetz, 2002). The model assumes that segments can be specified with a [labial] or [dorsal] feature for place of articulation, but do not possess a [coronal] feature, that is, they are underspecified. Evidence for underspecification has been presented in different languages and for different phonological processes (among others, Lahiri and Evers, 1991; Lahiri and Marslen-Wilson, 1991; Ghini, 2001, Wheeldon and Waksler, 2004; Scharinger, 2006; cf. also Paradis and Prunet, 1991). Segments specified for features [labial] or [dorsal] lead to corresponding labial and dorsal places of articulation in production. Segments which are underspecified for place of articulation are produced by the default feature [coronal]. Moreover, since these are underlyingly not specified for place of articulation, they can assimilate more easily to the place of articulation of neighboring [labial] and [dorsal] segments, but not *vice versa*. There can be instances where segments are produced in-between two categories due to overlapping gestures. FUL predicts that if this assimilation takes place before the default production rule applies, assimilation can lead to a complete neutralization of the place of articulation contrast. This is what we find in the corpus study, namely assimilations almost exclusively occur with [coronal] segments that assimilate to either [labial] or [dorsal] place of articulation, but not the other way around.

The model can also explain the finding that in general, RTs are slower for coronals than for labials. During recognition, features are extracted from the speech signal and matched directly onto lexical representations. However, for [coronal] sounds, there is no feature in the lexical representation that can be matched. Therefore, a nonmismatch condition arises. On the other hand, [labial] features can be matched onto a labial feature in a lexicon. Although there is no direct claim that nonmismatch conditions are always slower than matching conditions, the results are not unexpected from a theoretical point of view. However, there need to be more studies in order to exactly determine in how far there is a time advantage for matching versus nonmismatching conditions.

This was a first attempt to examine the perceptual consequences of such assimilations in conversational speech and it appears that if a coronal consonant is assimilated to the following consonant, it is perceived as such even when presented without any context. Further studies are necessary to see if this pattern or results hold for other languages as well.

ACKNOWLEDGMENTS

This work was in part supported by the Deutsche Forschungsgesellschaft (SFB 471, SPP 1234, and the Leibniz Preis awarded to A.L.) and the Ministry of Science, Research, and the Arts of Baden-Württemberg. We also wish to thank our anonymous reviewers for their very useful comments and suggestions.

[1]We ignored the "–h" symbol in the Kiel transcriptions since it has many phonetic correlates (e.g., aspiration, release) which are not relevant here. We translated the SAMPA transcription of the Kiel corpus into standard IPA transcription.

[2]We did not treat glottalization as instance of complete deletion, rather as some remnant of a severely reduced segment to keep the two processes apart.

[3]Neutralizations occur when speakers eliminate contrastive featural contrasts of segments in speech production. For instance, when they produce a segment such as /n/—underlyingly [coronal]—as a [labial] [m] due to a complete assimilation to the place of articulation of an upcoming [labial] segment, such as [b]. Complete means that the resulting [m] (underlyingly [n]) is not different from an underlying /m/ being produced as [m].

[4]Regressive assimilation occurs when in a sequence of two segments S_1 and S_2, S_1 assimilates in some feature(s) to S_2. Progressive assimilation occurs, when S_2 assimilates to S_1.

[5]Throughout this paper, we use the following convention for the description of letters and sounds. The sign ⟨ ⟩ is used to refer to orthography, [ ] indicates phonetic transcription, / / is used for underlying segments, and { } encloses morphemes.

[6]Along with Wiese (1996), Benware (1986) sees the "phonological word" as the only domain where regressive place assimilation can occur. He cites Kallmeyer (1981) for a case of regressive place assimilation in *kaputt gegangen* "has broken down," where the final /t/ of *kaputt* "ruined" is pronounced with a [k]. The phrase *kaputt gehen* consisting of two words is interpreted as a single phonological word in the sense that they form a very close unit, different from usual words in a phrase (Benware, 1986, p. 129).

[7]Since final devoicing affects all places of articulation, we did not differentiate between voiced versus voiceless segments.

[8]If there is a deletion and no assimilation on the preceding segment, it is not clear, whether the deleted segment itself was assimilated. If the preceding segment assimilates, it is not clear, whether the deleted segment triggered the assimilation, or the first segment of the upcoming word.

[9]The features are based on Lahiri and Reetz (2002). Palatals are assumed to be [coronal], as in many phonological accounts (e.g., Lahiri and Evers, 1991; Clements and Hume, 1995; Kenstowicz, 1994; for a different view, see for example Hall, 2000). The segments [x, ç] are assumed to be underlyingly placeless since the place of articulation of the preceding vowel determines the place of articulation of the fricative—[coronal] after front vowels, [dorsal] after back vowels. For sake of simplicity, we refer to the underlying fricatives as /x/ or /ç/.

[10]The fricative [x] is the only [dorsal] consonant function words end with. Due to final devoicing, only voiceless obstruents occur in C_1 target position.

[11]Almost all the cases of /m/ assimilating to /n/ could also be analyzed as being a wrong case-marking, a phenomenon that is well known for many German speakers (Bayer and Brandner, 2004; Schiering, 2005); *den* "the-*.accusative*" instead of *dem* "the.*dative*," etc. However, here we treated them as any other case of assimilation.

[12]We use the term congruent for responses where the transcription of the corpus was the same as the subjects' decision and incongruent for the opposite case.

[13]The analysis was carried out using SAS statistic software JMP, version 5.0.1.2.

[14]Since we were interested in the influence of the response on the reaction time, the responses are treated as a factor.

[15]The residual maximum likelihood (REML) estimation does not substitute missing values with estimated means and does not need synthetic denominators; rather the individual factors are tested against the whole model. This method is more conservative than the traditional expected mean squares estimation. Not significant results did not reach the 5% level.

[16]Subjects had only two possible response buttons, i.e., [n] or [m] to choose from in experiment 1. As can be seen, especially unassimilated-/n/ items in labial context produced a high amount of incongruent responses. This is arguably due to coarticulatory cues. For items in dorsal context, one could also expect coarticulatory cues influencing subjects' responses. However, it is not clear, how subjects would react in this situation, since there was no possibility to indicate "something else." In order to examine the nature of incongruent responses further, we opted for a free transcription task, where subjects could write what they heard without being restricted to two responses, in fact without being restricted to a nasal response at all.

Estimating vowel formant discrimination thresholds using a single-interval classification task[a)]

Eric Oglesbee[b)] and Diane Kewley-Port
Department of Linguistics and Department of Speech and Hearing Sciences, Indiana University, Bloomington, Indiana 47405

(Received 9 September 2008; revised 28 January 2009; accepted 29 January 2009)

Previous research estimating vowel formant discrimination thresholds in words and sentences has often employed a modified two-alternative-forced-choice (2AFC) task with adaptive tracking. Although this approach has produced stable data, the length and number of experimental sessions, as well as the unnaturalness of the task, limit generalizations of results to ordinary speech communication. In this exploratory study, a typical identification task was used to estimate vowel formant discrimination thresholds. Specifically, a signal detection theory approach was used to develop a method to estimate vowel formant discrimination thresholds from a quicker, more natural single-interval classification task. In experiment 1 "classification thresholds" for words in isolation and embedded in sentences were compared to previously collected 2AFC data. Experiment 2 used a within-subjects design to compare thresholds estimated from both classification and 2AFC tasks. Due to instabilities observed in the experiment 1 sentence data, experiment 2 examined only isolated words. Results from these experiments show that for isolated words, thresholds estimated using the classification procedure are comparable to those estimated using the 2AFC task. These results, as well as an analysis of several aspects of the classification procedure, support the viability of this new approach for estimating discrimination thresholds for speech stimuli.

I. INTRODUCTION

Previous work on examining vowel formant discrimination has often employed a modified two-alternative-forced-choice (2AFC) task with an adaptive tracking procedure (Kewley-Port and Watson, 1994; Kewley-Port *et al.*, 1996; Kewley-Port and Zheng, 1999; Kewley-Port, 2001; Liu and Kewley-Port, 2004b). Establishing thresholds for discriminating formants is important for determining the baseline ability of the auditory system to process small differences between vowels. Results of this research have shown how formant thresholds change when variables such as linguistic context, fundamental frequency, and hearing status were manipulated using a 2AFC task. While this modified 2AFC adaptive tracking task has been successful in estimating stable vowel formant thresholds, repeated stimulus presentations are quite unnatural compared to the single presentation of utterances that occurs in normal communication. Also, the number of trials necessary to obtain stable thresholds is rather large, and consequently listeners have to participate in multiple experimental sessions over the course of several days. Given these drawbacks, the purpose of the current study was to develop a method that used a linguistic labeling task to estimate vowel formant thresholds comparable to those estimated using a modified 2AFC adaptive tracking paradigm.

Although it is a worthy goal to improve experimental procedures for measuring discrimination for any listener, a particular goal in our laboratory has been to understand vowel processing abilities first in young normal hearing (YNH) listeners and then to determine how age, hearing impairment, or first language might degrade those abilities. Because the unnatural 2AFC task might limit generalizing laboratory results to more ordinary communication by elderly hearing-impaired (EHI) or second language (L2) learners of English, we were motivated to develop more natural methods for obtaining thresholds. Reviewing some of our research to date, several studies have used 2AFC procedures to document how the ability to process isolated vowels degrades with typical high-frequency sloping hearing loss. In the first study, Coughlin *et al.* (1998) examined isolated steady-state vowels and found that vowel formant discrimination abilities for low-frequency formants (F1) were the same between EHI listeners and YNH listeners, but that thresholds were significantly elevated for high-frequency formants (F2). In an effort to relate these thresholds to the identification of vowels, moderate correlations were found between the F2 thresholds and vowel identification by EHI listeners, indicating that there is a relationship between reduced ability to correctly identify vowels and poorer discrimination ability.

In two follow-up studies also using isolated steady-state vowels, Richie *et al.* (2003) and Richie and Kewley-Port (2005) reported similar results for young hearing-impaired

listeners. Given that such vowel stimuli are far different from those found in fluent sentences, new synthesis techniques using STRAIGHT (Kawahara *et al.*, 1999) were employed by Liu and Kewley-Port (2004b, 2007) to generate nearly natural vowel stimuli for three nine-word sentences. Their study of EHI listeners examined vowel formant discrimination for words in the sentences, as well as computer edited versions that presented only the word or only the isolated vowel from the word. Their results demonstrated a 100% elevation in F2 formant thresholds for EHI compared to YNH listeners for syllables and sentences. Encouraging results using the nearly natural speech stimuli from STRAIGHT led us to another set of experiments examining the relation between vowel thresholds and identification of vowels, this time with L2 learners of American English (AE). Listeners from three L2 languages with different vowel systems heard AE words. Preliminary results reported by Kewley-Port *et al.* (2005) showed little difference between the abilities of L2 and AE listeners to discriminate vowel formants. This is an important outcome, suggesting that more peripheral level processing abilities for vowels are not compromised by one's first language. However, outcomes of these L2 experiments, as well as those with EHI listeners, would be much stronger if the experimental tasks were more ecologically valid. The present study had the ambitious goal of designing more natural experimental procedures that could be used with many listener populations to determine the just noticeable differences in vowel spectra from a simple identification task [i.e., listen to a word (sentence) once and indicate what word was heard]. It should be noted that since the task we have chosen is an identification/classification approach for threshold estimation, it might not be appropriate for populations where large variability has made connecting identification performance to discrimination performance problematic (e.g., cochlear implant users; Iverson, 2003).

The task chosen for this study is a single-interval standard classification task using a continuum of stimuli that vary in one speech parameter, here the frequency of one vowel formant. Classification tasks (also called "labeling" or "identification" tasks) have long been used to examine the relation between category boundaries and discrimination in speech continua [e.g., voice onset time (VOT) continua from /ba/-/pa/, Lisker and Abramson, 1970]. Specifically, the prediction of discrimination performance from a classification task is at the core of research and theory concerning categorical perception (Harnad, 1987). However, there are clear differences between the goals of the current study and those related to categorical perception. For example, categorical perception is concerned with how discrimination performance changes along a classification continuum, especially at the boundary between categories (Repp, 1984), whereas the current study examines discrimination near a category center. Therefore, although the current study examines discrimination using a classification task, our interest is in determining the just noticeable difference between stimuli in contrast to the categorical perception literature that examines the nature of phonetic categories.

Some categorical perception studies have examined how details of the discrimination task alter the observed discrimination function and, therefore, the relationship between discrimination and predictions from the classification task. For example, if the stimulus properties are more steady state (vowel-like) versus rapidly changing (consonant-like), observed discrimination functions are more uniform and performance exceeds predicted discrimination (Pisoni, 1973; Mirman *et al.*, 2004). Also, changes in the discrimination trials from ABX to more sensitive tasks that use less working memory, such as the 4IAX (Pisoni, 1975) or 4I2AFC (Gerrits and Schouten, 2004) tasks, tend to flatten the discrimination function. While some of these issues are certainly related to the present experiments, these tasks all use two or more presentations of the stimuli per trial to measure discrimination. This contrasts with our goal of estimating discrimination thresholds using a single presentation of a stimulus by referencing the underlying psychometric function.

In the current study, principles from "Thurstonian scaling," as implemented in signal detection theory (SDT) (Macmillan and Creelman, 2005, p. 155), are used to find a point on a classification psychometric where thresholds comparable to those found in a 2AFC task can be estimated. Previously established theoretical relationships between performances on a 2AFC adaptive tracking task using a two-down-one-up (2D1U) rule (Levitt, 1971) and a two-category classification task (two-category classification is functionally equivalent to a yes/no decision) are used to provide a range of sensible cumulative d' values for estimating an empirical threshold from the classification psychometric. Thus, two types of experimental tasks were employed in the present study. In experiments 1 and 2 listeners participated in a single-interval classification task. In this task, a stimulus was presented, and listeners categorized the stimulus as one of two response categories (possible response sets were *bid/bed*, *cut/cot*, and *hack/hawk* in the experiments reported here). In experiment 2, the same listeners also used a modified 2AFC adaptive tracking task. This modified 2AFC adaptive tracking task had the same format as the one used in the previous discrimination studies cited earlier, in particular, Kewley-Port and Watson (1994). On each trial listeners heard three stimuli. The first stimulus presented on each trial was always the "standard." The second and third intervals contained the standard and test stimuli played in random order. Consequently, the possible stimulus sequences were ⟨STS⟩ and ⟨SST⟩, where "S" was a fixed standard for each formant continuum and "T" was the test stimulus. Listeners were asked to decide if the second or third interval contained the test stimulus. Using the typical 2D1U adaptive tracking rule, stable performance was obtained after a large number of trials (here 504 per formant) to measure thresholds from mean reversals.

To generate more natural speech stimuli for the classification task, stimuli were synthesized by using STRAIGHT (Kawahara *et al.*, 1999). STRAIGHT is a powerful speech analysis routine implemented in MATLAB that allows experimenters to manipulate amplitude, fundamental frequency, temporal relationships, and spectral characteristics of natural speech tokens. Although many of our earlier vowel threshold

	F1 (Hz)	F2 (Hz)	F3 (Hz)	Midpoint F0 (Hz)	Duration (ms)
bid	345	2196	2961	183	200
bed	485	1927	2918	162	206
cut	668	1561	2692	160	91
cot	829	1432	2616	157	171
hack	818	1906	2530	161	190
hawk	700	1055	2643	162	190

experiments used more controlled vowels (albeit unnatural sounding) created with the KLTSYN synthesizer (Klatt, 1980), Liu and Kewley-Port (2004a) showed that formant thresholds were very similar when estimated using STRAIGHT-synthesized as compared to formant-synthesized speech for analogous vowel stimuli.

In experiment 1, formant discrimination thresholds for vowels in both isolated words and in sentences were estimated using a classification task and then compared to previously collected 2AFC data (Liu and Kewley-Port, 2004b). As a follow-up, experiment 2 implemented a within-subjects design to estimate these thresholds using both a classification and a 2AFC task. Because unstable data were obtained from the sentence stimuli in experiment 1, only isolated words were examined in experiment 2. The isolated word results from the two experiments indicate that there are common processing mechanisms underlying vowel discrimination and classification that allow vowel discrimination performance to be predicted from classification performance. Furthermore, we present an analysis of the relationship between classification function parameters and estimated thresholds for a particular d' criterion, along with some suggested guidelines for implementing the proposed formant discrimination threshold estimation method.

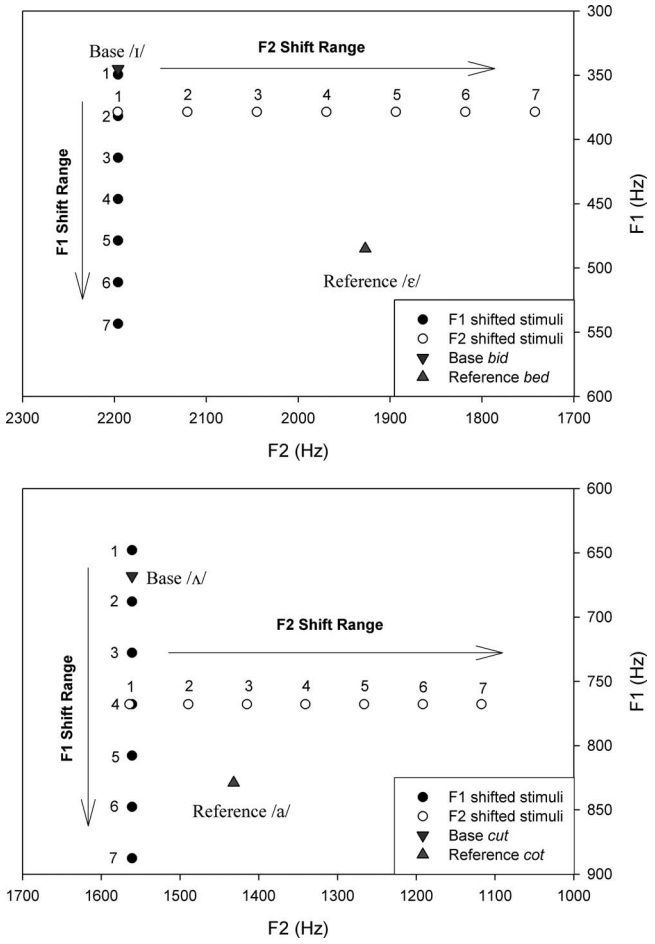

FIG. 1. F1 and F2 values for the four continua used in the forced choice classification (or labeling) tasks in experiments 1 and 2. *Bid/bed* continua are shown in the top panel; *cut/cot* continua are shown in the bottom panel. F1 and F2 shifted continua are indicated by closed and open circles, respectively. Formant values for base stimuli are shown with a downward pointing triangle. Reference stimuli for shifted end points are shown with an upward pointing triangle. Note that for the F2 continua, F1 was first shifted to an intermediate position between the base and reference stimuli.

II. EXPERIMENT 1

A. Method

1. Stimuli

The English vowels /ɪ/, /ɛ/, /ʌ/, and /a/ were chosen for investigation. These vowels were examined in several previous discrimination studies (Kewley-Port and Watson, 1994; Kewley-Port *et al.*, 1996; Kewley-Port and Zheng, 1999; Kewley-Port, 2001; Liu and Kewley-Port, 2004b) that used stimuli generated with either the Klatt (1980) synthesizer or STRAIGHT (Kawahara *et al.*, 1999). In this experiment, using STRAIGHT, four seven-step continua were resynthesized from words taken from recordings of a female speaker who read a list of nine-word sentences that had been designed to have relatively neutral prosody. The speaker for this study was the same one used as a model for synthesis in the studies listed above. The sentences were constructed such that the second, fifth, and eighth word positions within the sentence were filled with combinations of words taken from the minimal pairs *bid/bed*, *cut/cot*, and *hack/hawk*. Listening and acoustic analysis were used to select one prosodically neutral production for each word. Table I contains formant, F0, and vowel duration information for the six selected words. The words *bid* and *cut* were used as base stimuli for resynthesis, while *bed* and *cot* were used as reference stimuli for developing classification continua. *Hack* and *hawk* were used as fillers in the test sentences.

Figure 1 contains a graphical representation of the parameters modified in STRAIGHT across the four classification continua. In each continuum, as in the previous vowel formant discrimination studies cited earlier, a single formant was shifted in equal steps in hertz, while all other acoustic properties were held constant. The direction and magnitude of the formant shifts were determined by informal listening such that the base stimuli *bid* and *cut* would be well-identified as *bed* and *cot*, respectively, for the maximum shift. One strategy was to shift formants to more extreme values than observed in the reference stimuli. Also, to obtain high quality F2 stimuli, F1 was shifted to a somewhat ambiguous value before F2 was shifted. Because the original *bid* token had a relatively high F0, *bid/bed* tokens had F0 lowered by 10% in STRAIGHT's F0 resynthesis routine. To neutralize the duration difference between *cut* and *cot*, duration was lengthened by 20% for the base *cut* stimulus.

The procedure for shifting formant frequencies was a very similar version of the routine employed by Liu and Kewley-Port (2004b). First, a matrix in MATLAB representing the spectrogram (row=frequency; column=time; matrix entry=amplitude) of the base word was obtained by STRAIGHT (Kawahara *et al.*, 1999). Second, to shift a formant peak, the temporal onset and offset of the formant (including transitions) were visually identified. Third, in each time frame (i.e., one spectrum), the bottom of the valleys on either side of the formant peak was selected. Amplitude in the valley opposite of where the formant was shifted was adjusted to be a constant level that was equal to the bottom of the valley, while the shifted peak replaced the remaining spectral values. In most cases, the shift did not result in changes to other formants. A rule was employed where the shifted and original amplitude values were compared, and whichever was larger was retained. This resulted in formants being smoothly merged with one another when shifted to close proximity. Thus, details in the formant peaks were preserved in this procedure, with the valleys only somewhat changed. At last, this modified matrix was reloaded into STRAIGHT, and when necessary, other acoustic modifications such as F0 lowering and temporal expansion were simultaneously implemented [for more details on formant-peak shifting, see Liu and Kewley-Port (2004a) and their Fig. 1].

Sentence stimuli were created by digitally inserting words into the low-predictability sentence frame "Write _____ along with _____ but not _____ please," which was the same frame that was used to elicit the words during recording. Depending on the continuum that was being tested (*bid/bed* or *cut/cot*), the other positions were filled with a word from the pair *hack/hawk* and either *bid/bed* or *cut/cot*. All non-shifted words in the sentence were processed by STRAIGHT with no parameter changes such that the acoustic quality introduced by the STRAIGHT resynthesis was similar for all words tested.

2. Listeners

Indiana University students with normal speech and hearing by self report were paid for their participation in the present study. Of the 35 students tested, data from three listeners (two *bid/bed* F2 and one *cut/cot* F2) were excluded because the listeners had near chance identification of the isolated word end-point stimuli.

3. Procedures

Stimuli were presented to the right ears of listeners, who were seated in a sound-treated IAC booth, via TDH-39 earphones. Stimulus presentation was controlled by TDT System II modules including a 16-bit digital/analog converter, a programmable filter, and a headphone buffer. A low-pass filter with a cutoff frequency of 4500 Hz, and an attenuation level set by the calibration procedure, was loaded into the programmable filter. The standard vowel /ɛ/ was iterated for a duration of 3 s and used for calibration. The sound pressure level (SPL) for the test stimuli measured in a NBS-9A 6-c[3] coupler by a Larson-Davis sound meter (model 2800) using the linear setting was adjusted to be 70 dB SPL, with variation between stimuli from the same continuum less than 1.1 dB SPL.

Listeners were randomly assigned to four groups containing eight listeners each. Each group was exposed to stimuli from only one of the generated continua in both word and sentence conditions (i.e., either F1 shifted *bid/bed*, F1 shifted *cut/cot*, F2 shifted *bid/bed*, or F2 shifted *cut/cot*). Four types of blocks were run: word familiarization, word classification, sentence familiarization, and sentence classification. In each of these tasks, listeners were asked to indicate what word they heard. For isolated words, the possibilities were either *bid/bed* or *cut/cot*, depending on experimental group. For sentences, there were three words identified from the pairs *bid/bed*, *cut/cot*, and *hack/hawk* in each sentence. In the word familiarization blocks, listeners were exposed to the continuum end points in an alternating fashion for 12 trials with feedback for the correct response. In sentence familiarization, listeners heard the nine-word sentence, after which six response buttons appeared containing the words *hack*, *hawk*, *cut*, *cot*, *bid*, and *bed*. The order of presentation of the buttons matched the order of presentation of the word pairs in the sentence. Six sentences with continuum end points were used in the familiarization with feedback provided by the experimenter. The word and sentence classification blocks were similar to their familiarization counterparts, except that all seven stimuli from the continuum were presented multiple times in a random order, without feedback. In the word classification blocks, each stimulus was played nine times, resulting in 63 trials per block. The sentence classification blocks presented each stimulus twice in each sentence position, resulting in 42 trials per block.

Each subject participated in a single experimental session using a fixed protocol of block order. The number of blocks to approximate stable classification performance was determined from pilot experiments. Thus, altogether, four word familiarization, one sentence familiarization, four word classification, and six sentence classification blocks were presented. The session lasted for a total of 75–90 min, depending on a listener's response latency. The last two word classification blocks and last three sentence classification blocks were used for analysis.

B. Results

1. Raw labeling functions

The results for each subject were calculated as the proportion of *bed* or *cot* responses obtained over the 18 presentations of each stimulus. Figures 2 and 3 display a representative set of raw labeling functions for four of the eight conditions. Figure 2 displays data from the *bid/bed* continuum for both F1 and F2 in the word condition. The reasonably consistent performance across listeners exhibited in Fig. 2 are representative of behaviors also observed for *bid/bed* (F1 and F2) in the sentence condition and *cut/cot* (F1 and F2) in the word condition. Listener performance for *cut/cot* (F1 and F2) in the sentence condition was much less consistent than the other conditions and is illustrated in Fig. 3. In general, raw labeling functions were more consistent

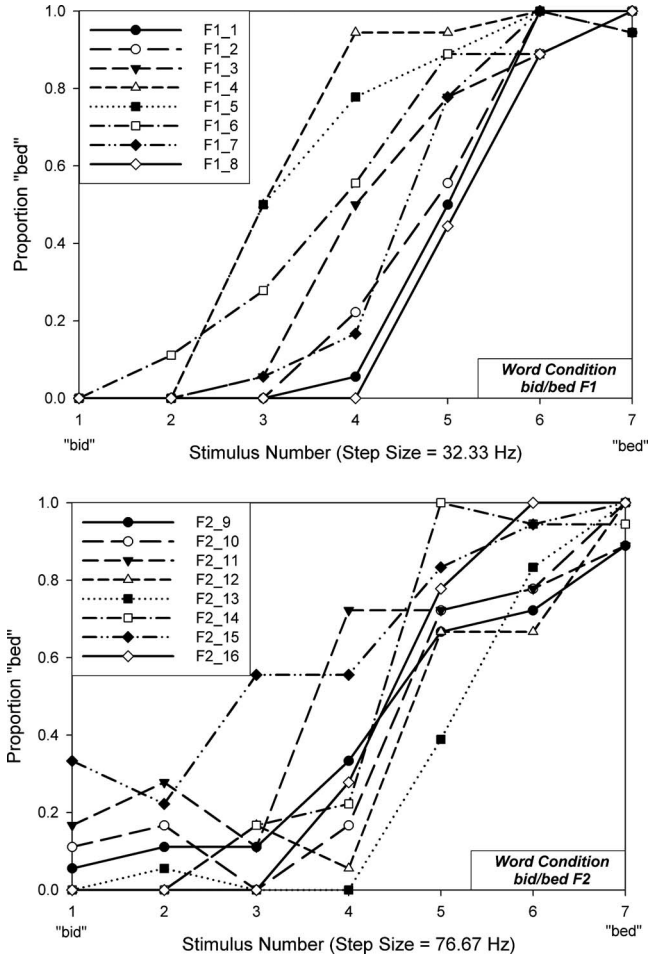

FIG. 2. Raw identification functions for *bid/bed* F1 and F2 stimuli in the word condition (18 judgments per stimulus). Each curve corresponds to a unique listener, numbered 1–16, with an additional identifier (F1 or F2) indicating which experimental group they belonged to. Each continuum contained seven stimuli that were randomized and presented to listeners for identification. The top panel contains results for F1 shifted stimuli; the bottom panel contains results for F2 stimuli. In both panels, stimuli 1 and 7 correspond to the most *bid*- and *bed*-like stimuli, respectively. Stimulus numbers correspond to their respective continua in the top panel of Fig. 1 (i.e., stimulus numbers in the top panel of Fig. 2 correspond to the F1 shift range of the top panel in Fig. 1). Below each panel, the shifted formant peak difference between stimulus steps is given in Hz.

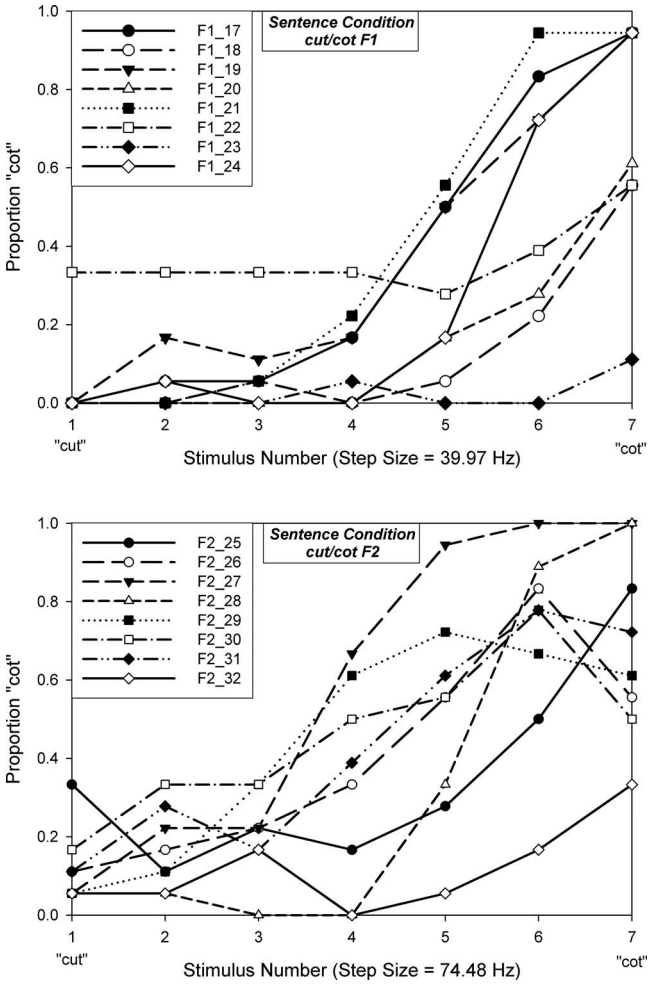

FIG. 3. Raw identification functions for *cut/cot* F1 and F2 stimuli in the sentence condition (18 judgments per stimulus). Each curve corresponds to a unique listener, numbered 17–32, with an additional identifier (F1 or F2) indicating which experimental group they belonged to. Each continuum contained seven stimuli that were randomized and presented to listeners for identification. The top panel contains results for F1 shifted stimuli; the bottom panel contains results for F2 stimuli. In both panels, stimuli 1 and 7 correspond to the most *cut*- and *cot*-like stimuli, respectively. Stimulus numbers correspond to their respective continua in the bottom panel of Fig. 1 (i.e., stimulus numbers in the top panel of Fig. 3 correspond to the F1 shift range of the bottom panel in Fig. 1). Below each panel, the shifted formant peak difference between stimulus steps is given in Hz.

and categorical for the word condition with F1 shifted formants compared to the sentence condition with F2 shifted formants.

2. Threshold calculation method

For discrimination, the concept of a "threshold" is the smallest amount of difference between two sounds that can be reliably detected. In most previous experiments reported by Kewley-Port and her colleagues (Kewley-Port and Watson, 1994; Liu and Kewley-Port, 2004b), vowel formant thresholds were measured as ΔF in hertz using a 2D1U rule in a modified 2AFC adaptive tracking paradigm. These 2AFC thresholds were calculated from average reversals along a stimulus continuum. Mathematically, this corresponds to the 70.7% correct point on a psychometric function plotted between 50% chance and 100% (Levitt, 1971).

In this paper, the term "classification threshold" is used to indicate estimations of discrimination thresholds obtained from the classification task. A difference between thresholds obtained from 2AFC adaptive tracking and classification tasks is that the psychometric function ranges from 50%–100% in a 2AFC task as compared to 0%–100% in a classification task. The goal of the present research was to establish a method to calculate a classification threshold that corresponds well to the 70.7% threshold criterion in a 2AFC discrimination task. This was approached using a SDT implementation of Thurstonian scaling for one-dimensional classification tasks (Macmillan and Creelman, 2005, pp. 114–119). In this approach, a threshold criterion in terms of cumulative d' (measured from a classification continuum end point) is selected. Then, an empirical threshold is calculated by locating the point on the classification psychometric that corresponds to the chosen cumulative d' criterion. In prin-

ciple, the choice of the criterion used to calculate the empirical threshold is arbitrary, although the threshold criteria used in the current experiments were selected with the goal of obtaining results comparable to previously reported vowel formant discrimination thresholds for YNH listeners (Liu and Kewley-Port, 2004b).

The following method was used in the current experiments for deriving an estimation of a discrimination threshold from a two-category classification task (i.e., a classification threshold). It should be noted that this method assumes that the end points of the classification continua were well-identified by a majority of listeners. First, using a least-squares method, a logistic function [see Eq. (1)] was fit to the labeling data,

$$p(s) = 1/(1 + e^{((A-s)/K)}), \quad (1)$$

where A and K are model parameters representing the 50% point and slope of the function, respectively, and s is the stimulus number (in the current experiment s ranged from 1 to 7). Next, the value for $s_{\text{threshold}}$ resulting in $z(p(s)) - z(p(1)) = D$ is determined, where z is the inverse of the normal distribution function and D is the d' value chosen for estimating the empirical threshold (a discussion of the D used in the current experiments appears below). Using the known step size in hertz between stimuli and assuming that the range for s begins at 1, ΔF is calculated using

$$\Delta F = (s_{\text{threshold}} - 1) \times \text{step size} \quad (2)$$

This value, ΔF, is the classification threshold calculated separately for each listener in each condition.

Because the choice of the cumulative d' criterion (i.e., D) associated with a threshold in a one-dimensional classification task is arbitrary, choosing D depends on the goals of the experiment. In the current experiments, the goal was to have the classification thresholds be comparable to those measured in a modified 2AFC adaptive tracking task. Two options presented themselves. One possibility was to collect classification data and then in a *post hoc* analysis determine a value for D which would maximize the correspondence in performance between two tasks. Given the relatively small amount of previous data available, this approach was not pursued. Therefore, we chose a second option, which was to use previously established mathematical relationships between our types of tasks (Macmillan and Creelman, 2005) in an effort to derive a set of candidate values for D and to then determine which of these D-values produced the best overall correspondence between the two tasks. In particular, d' conversions between 2AFC, yes/no, and "reminder" discrimination tasks were selected.

Because a traditional 2AFC adaptive tracking paradigm using a 2D1U rule estimates thresholds at the 70.7% level on the psychometric function, the d' between the 50% chance and 70.7% threshold level was used as the "basic" choice for D [$D_{\text{basic}} = z(0.71) - z(0.5) = 0.553$]. However, SDT also derives a relationship between 2AFC and yes/no tasks (we note that our two-category classification task is functionally equivalent to a yes/no task; i.e., a *bid/bed* decision could be interpreted as either *bid* or *not bid*). In a 2AFC task, d' is $\sqrt{2}$ times that of a yes/no task (Macmillan and Creelman, 2005, pp. 166–168). Thus a second possible cumulative d' criterion is $D_{\text{Y/N}}$, where $D_{\text{Y/N}} = D_{\text{basic}} \times 1/\sqrt{2} = 0.391$. A third possibility also presents itself. Experiment 2 used a modified 2AFC task, with the standard stimulus appearing in the first interval on every trial (⟨STS⟩ and ⟨SST⟩ were the only possible stimulus sequences). One plausible strategy for listeners would be to ignore the third interval and simply attend to the stimuli in the first and second intervals, respectively, since these two intervals contain enough information to make the discrimination decision (⟨ST⟩=test stimulus in the second interval; ⟨SS⟩=test stimulus in the third interval). This strategy is equivalent to interpreting the modified 2AFC task as a "reminder paradigm," where if the listener uses a "differencing" strategy as defined by Macmillan and Creelman (2005), pp. 180–181, the d' for the 2AFC task would be $1/\sqrt{2}$ times that of a reminder task. Thus the third cumulative d' criterion is $D_{\text{remind}} = D_{\text{basic}} \times \sqrt{2} = 0.783$. Analysis of which of these D (D_{basic}, $D_{\text{Y/N}}$, and D_{remind}) result in the best fit to 2AFC thresholds is deferred to experiment 2 where a within-subjects comparison was possible. Given that the outcome of that analysis demonstrated that $D_{\text{remind}} = 0.783$ had the best match, classification thresholds in experiment 1 are reported using this cumulative d' criterion.

It is important to note that the possible relationships between the classification and modified 2AFC tasks were used only as a guide in selecting D. The d' relationship between 2AFC, Y/N, and reminder tasks discussed by Macmillan and Creelman (2005) is in the context of discrimination experiments using identical stimulus sets. More specifically, our experiments differ in two fundamental aspects:

(1) One of our tasks was a two-category *classification* task.
(2) The tasks being compared have different stimulus sets.

Because of these two major differences, it is not clear that previously established relationships between d' in these tasks should hold in our application. We argue, however, that because the current study is exploratory in nature, the above conversion factors suggest a reasonable range for possible values of D.

3. Thresholds for words and sentences

Logistic functions were fit to all raw data functions, and ΔF thresholds [see Eqs. (1) and (2)] were calculated for $D = 0.783$ in Excel using the method described above. Calculated threshold averages and standard deviations for each formant in both the word and sentence conditions are given in Table II. Given the small number of listeners, as well as the unequal variance for word and sentence conditions, a nonparametric sign test (two-tailed) was used to examine separately for each formant whether the word and sentence thresholds within subjects were significantly different. Differences were not found for *bid/bed* F1 ($p < 0.29$) or F2 ($p < 0.73$); however, a statistically significant difference was observed for *cut/cot* F1 ($p < 0.01$) and F2 ($p < 0.01$). For both *cut/cot* F1 and F2, every subject had a higher threshold in the sentence task as compared to the word task. As expected, thresholds for words in sentences were equal to or greater than those for words in isolation.

TABLE II. Formant frequencies, thresholds, and standard deviation of ΔF (Hz) estimated using a classification task for four formants in two phonetic contexts: words and sentences.

	/ɪ/-F1		/ʌ/-F1		/ʌ/-F2		/ɪ/-F2	
Formant frequency	349		648		1564		2196	
	M	s.d.	*M*	s.d.	*M*	s.d.	*M*	s.d.
Word	34.8	6.3	45.4	9.5	73.8	25.1	107.7	29.9
Sentence	38.7	20.9	98.8	68.8	193.7	84.0	137.6	71.8

C. Discussion of experiment 1

1. Comparison to previous research using 2AFC adaptive tracking procedures

One goal for experiment 1 was to develop a method for estimating formant thresholds using a classification task, such that the estimated thresholds would be equivalent to those calculated using a 2AFC paradigm. The previous report of Liu and Kewley-Port (2004b) who determined F1 and F2 formant thresholds based on a 2AFC paradigm for the vowels /ɪ/ and /ʌ/ in /bVd/ contexts, both in isolation and in sentences, was influential in the design of the present experiment. Figure 4 contains individual listener thresholds from the syllable condition of that experiment, as well as the results of the word condition from experiment 1 (additional data from experiment 2 will be discussed later). Thresholds are very similar between Liu and Kewley-Port (2004b) and experiment 1, even though in the current experiment a /kVt/ context was used instead of /bVd/ for testing /ʌ/. Given that the number of listeners per formant was relatively small for the two experiments ($n=4$ and $n=8$) and that the number of listeners was quite different between the experiments, a nonparametric two-tailed Mann–Whitney *U*-test was used to test for differences between the 2AFC and classification data. In the word condition, thresholds for /ɪ/-F1 were found to be significantly different ($U=0, p<0.01$): every threshold estimated from the classification task was lower than those observed in the previous 2AFC data. No statistical differences were found for /ʌ/-F1 ($U=11, p=0.460$), /ʌ/-F2 ($U=13, p=0.682$), and /ɪ/-F2 ($U=15, p=0.934$).

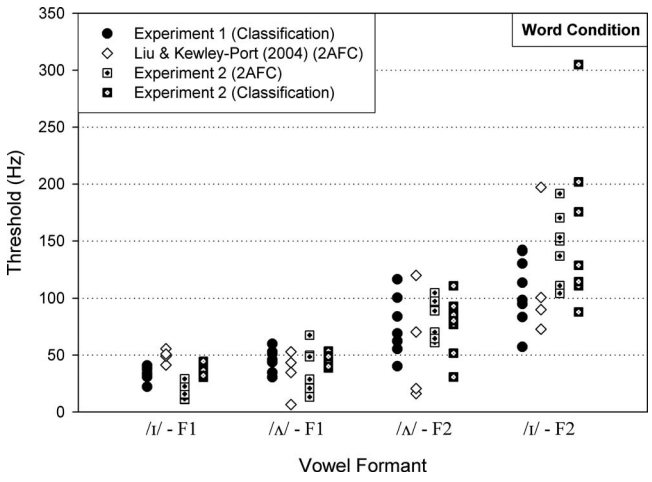

FIG. 4. ΔF for F1 and F2 of the vowels /ɪ/ and /ʌ/ estimated in isolated words. Vowel formants are shown from left to right in order of increasing frequency. Thresholds from individual listeners were estimated using a classification task (experiments 1 and 2) and a 2AFC paradigm (Liu and Kewley-Port, 2004b and experiment 2).

Unfortunately, however, in the sentence condition, thresholds for /ɪ/-F1 and /ʌ/-F1 from the two studies were significantly different ($U=4$, $p<0.05$ for each comparison). While no statistical differences were observed for /ʌ/-F2 ($U=6, p=0.110$) and /ɪ/-F2 ($U=16, p=1$), the range of values obtained in the classification task for /ʌ/-F2 was substantially greater than what was observed in the 2AFC experiment. In general, thresholds obtained from the classification task in the word condition appeared to match the previous 2AFC data better than those estimated from the sentence condition.

2. Positional effects within sentences

Differences in end-point categorization performance and estimated thresholds (Table II) between the word and sentence conditions using *cut/cot* stimuli seemed to indicate that some property of the sentence frame influenced categorization responses and, consequently, estimated thresholds. This contrasts with Liu and Kewley-Port (2004b) where no significant difference in performance was found between the word and sentence conditions. However, in the current study, striking differences for some individual listeners were observed.

Based on the results of Liu and Kewley-Port (2004b) where differences in word position did not significantly affect formant thresholds, by design our identification functions in the sentence condition were originally pooled across the three positions in the sentence frame. However, given the apparent differences between word and sentence conditions in this experiment, the sentence data were further analyzed by sentence position. This analysis using data from the last five of the six sentence blocks revealed one extreme example of position effects (listener F1_22). When *cut/cot* stimuli were placed in the final sentence position, F1_22 exhibited a complete reversal in the identification function. Stimuli that were identified as *cut* in initial and medial sentence positions were labeled as *cot* when presented in the final sentence position, and vice-versa.

Although F1_22 represents the most dramatic case observed among all participants, a visual inspection of the raw position functions across all listeners suggests that stimulus location within sentences had at least a moderate effect on the identification functions of 19 of the other 31 participants. It has been shown that the phonetic content of immediately

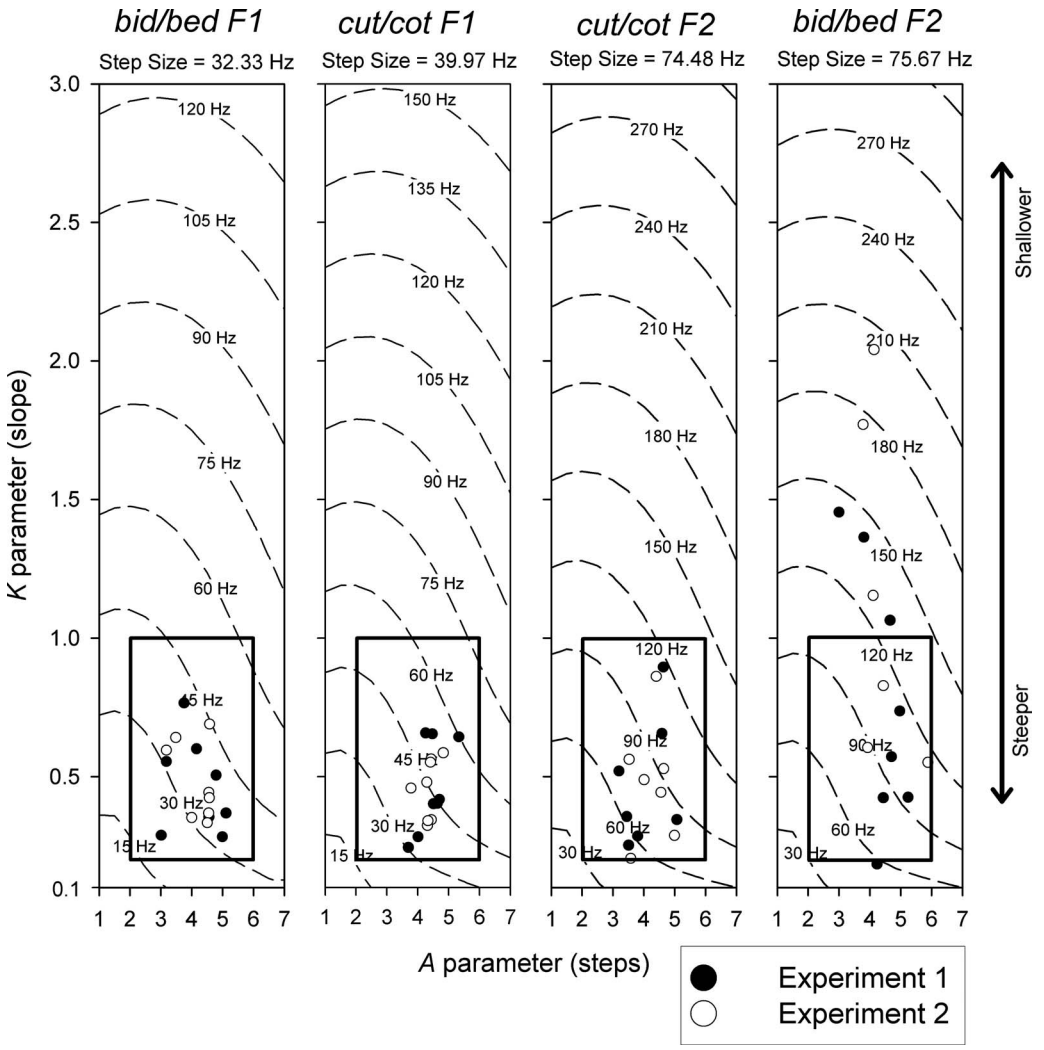

FIG. 5. Contour plots of estimated thresholds as a function of fitted logistic parameters and step size in Hz between stimuli in a classification task using a seven-step continuum. The step at which the fitted logistic reaches the 50% level (A parameter) is plotted on the horizontal axis, and the slope of the fitted logistic (K parameter) is plotted on the vertical axis. Each panel contains contours calculated from (A,K) parameter pairs. Contour lines are labeled with the estimated thresholds based on stimulus step sizes in Hz (shown above each panel) used in experiments 1 and 2. The black boxes in the figure indicates target ranges for (A,K) pairs for obtaining well-behaved threshold functions. Observed (A,K) parameter pairs from experiments 1 (filled circles) and 2 (empty circles) are shown.

adjacent segments can shift vowel perception (Holt *et al.*, 2000). In our results we see a long-distance effect where segments in neighboring words appear to substantially influence categorization. We hypothesize that the likely source of interference is the naturally produced vowel /a/ in the word *not* that appears before the final test position in the frame sentence; however, pursuing this question is beyond the scope of this paper. Consequently, estimating discrimination thresholds using the sentence classification task we designed does not appear to be a viable approach at this time. However, it should be noted that these context effects are not applicable to the isolated word stimuli.

3. Properties of classification threshold estimation procedure

In this section, a preliminary analysis of the general properties of the classification threshold estimation procedure is presented, with design elements and results from the word condition of experiment 1 used to illustrate these general properties. Basic guidelines for designing classification experiments that obtain reliable, stable thresholds are discussed, as well as the generalizability of the procedure. Finally, the success of experiment 1 is evaluated in light of this analysis.

a. General properties Based on the description of the threshold estimation method in Sec. II B 2 of experiment 1, there are three primary factors that affect values calculated for classification thresholds: parameters of the fitted identification function, cumulative d' criterion (D), and step size between stimuli. In the following analysis, the parameters of the logistic function [Eq. (1)] fit in experiment 1 are discussed. These parameters are easily interpretable; namely, A is the 50% point of the function and K is a measure of slope (values close to zero result in steep slopes). It should be noted that the threshold estimation method is general enough that other functions (e.g., Weibull) could be fit to the classification data.

Using the design parameters of experiment 1 (seven-step continua), Fig. 5 contains contour plots of estimated thresh-

olds for $D=D_{remind}=0.783$ as a function of logistic parameters (A parameter on horizontal axis and K parameter on vertical axis) and step size (different panels). Dashed contour lines at 15 and 30 Hz intervals for F1 and F2, respectively, show estimated thresholds. Filled circles mark the thresholds observed in the word condition of experiment 1.

Although these contour plots were created using a specific set experimental parameters, two general observations concerning the threshold estimation method can be made. First, in some regions of the contour plots there is a nonlinear relationship between logistic parameters and estimated thresholds. In particular, when the 50% point of the psychometric occurs early in the function ($A<2$), or when the slope is extremely steep ($K<0.1$) or shallow ($K>2$), the relatively flat portions of the contours indicate that the location of the 50% point has little to no effect on the estimated threshold.

Second, for fixed values of A and K, increasing step size results in specific threshold contours being shifted downward in the $A\times K$ space. For example, the threshold contours in panels 1 (*bid/bed* F1) and 4 (*bid/bed* F2) in Fig. 5 were calculated using step sizes of 32.33 and 75.67 Hz, respectively. Comparing panel 1 to panel 4, the location of the 60 Hz contour line is shifted downward substantially. Note that although this apparently is a strong effect, the experimenter still has a wide range of choices for step size. SDT presumes there is a fixed underlying probability distribution for perceiving stimuli along a continuum. Thus, assuming listener bias remains constant, a reasonable hypothesis is that listener responses will adjust to different step sizes, resulting in sets of logistic parameters that give comparable thresholds using our method. While research is needed in order to verify this hypothesis, the following example demonstrates that the hypothesis is reasonable. Suppose two continua testing the same formant were created from the same initial vowel with step sizes of 32.33 and 39.97 Hz respectively (these are the same step sizes for the *bid/bed* and *cut/cot* F1 panels in Fig. 5). All things being equal, if the same listener were tested on both continua with different step sizes, the slope of the psychometric function for the continuum with a step size of 39.97 Hz should be steeper than the continuum with a step size of 32.33 Hz. Also, because the continua had the same initial vowel, the 50% level of the continuum with the 39.97 Hz steps should be shifted leftward. Thus, the resulting thresholds should be nearly the same even when the physical step size differs.

b. Guidelines for experimental design The threshold contours in Fig. 5 have implications for experimental designs using the new threshold estimation method. Although the contour plots span a large range of A and K parameters, it appears that the range of parameters that should be considered acceptable is much smaller due to the nonlinearities in the threshold contours. In the case of a seven-step stimulus continuum as was used in experiment 1, the black box ($2\leq A\leq 6$; $0.2\leq K\leq 1$) in Fig. 5 represents the set of (A,K) parameter pairs that result in well-behaved threshold contours. This region also corresponds to the set of (A,K) parameter pairs that one would expect from a well-designed two-category identification task. Thus, the black box in Fig. 5 can be used as a *post hoc* evaluation for the appropriateness of classification thresholds estimated from a seven-step continuum.

c. Generalizability Although the above analysis and plots in Fig. 5 illustrate results from a seven-step continuum, preliminary examination of the threshold contour space suggest that the threshold estimation method may be applicable to continua containing 5–20 stimuli. In these cases, the range of A parameters contained within the black box would need to be adjusted; however, the K range should remain fixed. Also, the nature of the classification task suggests that the proposed estimation method may be used for estimating thresholds from any type of stimulus continuum that is designed to span two distinct categories, not just speech. For example, in vision research, thresholds for color categories could be examined. Obviously, further research is needed to examine either the effect of different numbers of steps or the application of the method to other stimuli.

One inherent limitation imposed by using any classification task is that only primary acoustic cues for a contrast can be studied in isolation (e.g., F1 or a complex cue such as VOT). This requirement arises out of the fact that different levels of the cue chosen for study must be capable of causing listener's judgments of category membership to shift reliably. Consequently, this method would not be appropriate for estimating F3 or F4 discrimination thresholds. However, the method would still be applicable if one wanted to pursue "multidimensional discrimination thresholds" where multiple primary and secondary cues are covaried in a single classification continuum, as is typical with complex cues such as VOT. Thus a future study of thresholds for vowels where F1 and F2 covary is in line with our goal of developing a more ecologically valid approach to formant discrimination.

d. Relation to traditional classification measures and predictions of discrimination from classification With respect to classification tasks, the 50% point on the psychometric function is typically the focus of study; however, the proposed threshold estimation method instead focuses on the end points of the psychometric. In order to test whether or not the thresholds estimated in experiment 1 are substantially different from the 50% point, a correlational analysis between estimated thresholds and the location of the 50% point was performed. First, a bark scale transform was applied to the data so that all four formants could be included in the same analysis (Kewley-Port and Zheng, 1998). A very small correlation was found ($r=-0.107$), indicating that classification thresholds are not directly related to the more traditional 50% boundary.

With respect to predicting discrimination performance from a classification task, the slopes of psychometric functions have previously been related to peaks in ABX discrimination functions (Repp, 1984). We note that the current approach incorporates more information in the determination of a discrimination threshold than previous approaches, because it takes into account both the slope of the psychometric *and* the location of the 50% crossover point. Below, in experiment 2, it is demonstrated that these two traditional measures of boundary performance (psychometric slope and 50% crossover point) can be successfully used to estimate within-category (i.e., non-boundary) discrimination thresholds.

TABLE III. Shifted formant step sizes for 2AFC stimuli in experiment 2.

	/ɪ/-F1	/ʌ/-F1	/ʌ/-F2	/ɪ/-F2
Base formant frequency (Hz)	349	648	1564	2196
Step size (Hz)	2.97	5.51	12.51	18.89
% of base frequency	0.85%	0.85%	0.80%	0.86%

e. Evaluation of experiment 1 In the four panels of Fig. 5 the (A,K) parameter pairs obtained for all listeners from the word condition of experiment 1 are plotted with filled circles. For three of the listener groups (*bid/bed* F1, *cut/cot* F1, and *cut/cot* F2), all of the data points fall within the black box discussed above; however, three of the *bid/bed* F2 listeners fall outside the black box, suggesting that the *bid/bed* F2 stimuli were not as well-designed as the others. Overall though, even with the *bid/bed* F2 difficulties, experiment 1 appears to have been well-designed with respect to the properties of the threshold estimation method.

III. EXPERIMENT 2

Given that classification thresholds for words (but not sentences) appear reliable, the purpose of experiment 2 was to directly compare, using a within-subjects design, formant thresholds estimated from a classification task with those calculated using a modified 2AFC adaptive tracking procedure. The motivation for using a within-subjects design was threefold. First, the within-subjects design permitted an evaluation of the three cumulative d' criteria discussed earlier (D_{basic}, $D_{\text{Y/N}}$, and D_{remind}). Second, lingering questions remained concerning the comparability of thresholds estimated using the two methods given the numerous differences in experimental variables between Liu and Kewley-Port (2004b) and experiment 1 (i.e., number of subjects, base stimuli for resynthesis, etc.). Third, because of the large variability observed in experiment 1, we wanted to examine the degree to which performance on the two tasks corresponded within individual listeners.

A. Method

1. Stimuli

For the classification portion of experiment 2, the continua developed in experiment 1 were used, allowing for replication of the results from experiment 1. The continua used in experiment 1 needed to be changed for use in a 2AFC adaptive tracking task because the step size between stimuli was too large. Therefore, four modified formant shifted continua were created for the 2AFC task using the same formant shifting methods employed in experiment 1. Similar to Liu and Kewley-Port (2004b), each continuum contained 15 stimuli (including the standard), and step sizes between stimuli were kept between 0.7% and 1% of the formant frequency of the standard stimulus. For each continuum, the standard was identical to the initial point of the corresponding continuum in the classification task. The specific step sizes for each 2AFC continuum were chosen such that some of the points from the classification continuum would be contained in the 2AFC continuum. Table III contains the formant frequencies for each standard, as well as the step sizes for each continuum.

2. Listeners

Eleven Indiana University students with normal speech and hearing by self report were paid for their participation in the present study. Three listeners did not finish the study due to scheduling difficulties and personal choice. Consequently, their data were excluded.

3. Procedure

Each listener participated in five experimental sessions that were completed within three weeks of the initial session. The first two sessions contained classification blocks, and the last three sessions contained 2AFC blocks. Calibration procedures were the same for experiment 2 as experiment 1.

a. Classification task In experiment 1, listeners were exposed to only one of the four stimulus continua. However, in experiment 2, each listener made classification judgments on all four word continua. For each continuum, two word familiarization and four word classification blocks described in experiment 1 were presented in a fixed order. Two continua were assigned in a quasi-random way for each experimental session. Two blocks with the same target words could not occur on the same test day (i.e., *bid/bed* F1 and F2 could not be presented on the same day). Also, each day had to contain one set of F1 blocks and one set of F2 blocks. With these restrictions, a unique continuum ordering was possible for each of the eight listeners.

Each experimental session during the classification portion of the experiment lasted for 0.5–0.75 h (depending on a listener's response latency). Data for estimating thresholds were typically taken from the last two blocks; however, in cases where one of the last two blocks was substantially different than the other, an earlier similar block was used for analysis.

b. 2AFC task The trials for the four vowel formants (F1 and F2 for both /ɪ/ and /ʌ/) were randomly presented within each block (i.e., under medium stimulus uncertainty). The modified 2AFC paradigm of Kewley-Port and Watson (1994) that was described in Sec. I was employed. Each experimental session lasted for 0.75–1 h with 96 trials in each block. Seven blocks per session were administered for three experimental sessions ($N=21$ blocks). ΔF for each listener was averaged from the mean reversals over the last four blocks in which performance was judged as stable by visual inspection.

B. Results

1. Effect of different cumulative d′ criteria

Figure 6 provides an illustration of the effect of the three cumulative d' criteria ($D_{\text{basic}}=0.553$, $D_{\text{Y/N}}=0.391$, and $D_{\text{remind}}=0.783$) discussed earlier on average classification thresholds. In order to quantify the best match for these three values of D, the 2AFC results were used as the expected value, and sums of squares of the differences were calculated across the four formants. For the F1 stimuli, D_{basic} was the best fit, while D_{remind} was the closest match for the F2 stimuli. Summing the squared differences across all four formants, D_{remind} provided the best overall match and therefore

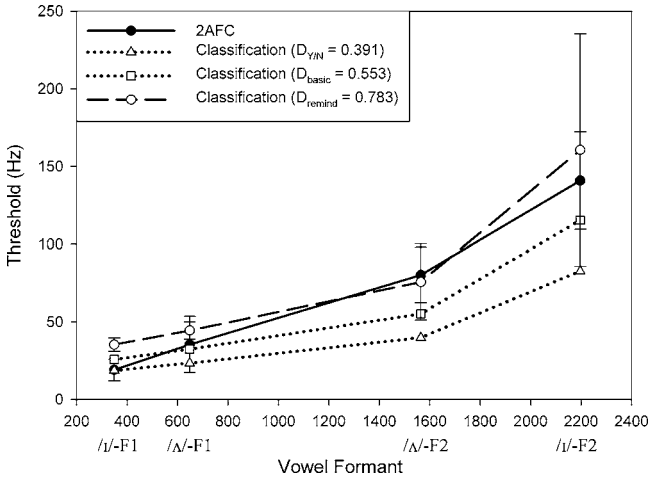

FIG. 6. Average thresholds for /ɪ/-F1 and /ɪ/-F2, and /ʌ/-F1 and /ʌ/-F2, estimated using classification and 2AFC tasks (formant frequency in Hz shown on horizontal axis). Error bars indicating one standard deviation are shown for the 2AFC thresholds, as well as the thresholds estimated using a d' criterion of 0.783 in the classification task. Mean thresholds for d' criteria of 0.391 and 0.553 are shown without error bars.

was used for reporting classification thresholds in experiments 1 and 2. Although this analysis is limited in scope, note that the values of D selected for the current study appear to bracket a reasonable range of values.

2. Classification and 2AFC tasks

In the classification task, raw labeling functions were similar to those observed in experiment 1. Individual thresholds for ΔF were estimated from logistic functions, as described in experiment 1, and are displayed in Fig. 4 (squares) and Table IV.

The average thresholds for the classification and 2AFC tasks were remarkably similar (Fig. 6 and Table IV). Using a repeated measures analysis of variance, a significant main effect for formant was found $[F(3,18)=55.232, p<0.001]$, but not for task $[F(1,6)=0.838, p=0.395]$ or for the task $\times$formant interaction $[F(3,18)=0.290, p=0.832]$. This significant effect of formant is consistent with previous observations that ΔF increases as formant frequency increases (Kewley-Port and Watson, 1994). The non-significant effect of task indicated that the null hypothesis of no difference between the tasks could not be rejected.

3. Threshold estimates within individual listeners

The similarity of the group results does not indicate the relation between classification and 2AFC thresholds within individual listeners. To determine whether the quicker, more natural classification task taps into the same underlying discrimination process as a 2AFC task, several analyses were performed.

First, a Spearman rank order correlation coefficient was used to determine if performance for listeners was ordered from best to worst similarly in the two tasks. Data for /ʌ/-F1 and /ɪ/-F1 conditions were excluded because variability in thresholds for the classification task appeared too small (s.d. $\leq$ 5.5 Hz, Table IV, Fig. 4) for correlations to be meaningful. Correlation coefficients for both /ʌ/-F2 ($N=8, \rho=-0.0238$) and /ɪ/-F2 ($N=7, \rho=0.2143$) indicate that the order of listener performance was not similar across the two tasks. The second way of comparing performance on the two tasks used a two-tailed correlated t-test to evaluate the similarities in individual performance in the F2 conditions. The differences in threshold estimates were not significant for either /ʌ/-F2 ($p=0.717$) or /ɪ/-F2 ($p=0.621$). Taken together, thresholds for individual listeners are generally similar between the two tasks but are not close enough to preserve order from best to worst performance.

Additional analyses of data from all four formants were made after a bark transform removed the effect of the increase in formant frequency on thresholds (Kewley-Port and Zheng, 1998). The bark transformed signed difference between 2AFC and classification thresholds was chosen as the dependent variable for the analyses in order to preserve whether classification thresholds either under- or overestimated the standard 2AFC thresholds, where zero indicates no difference. The average difference between the tasks was −0.063 barks (s.d.=0.163), indicating that individual thresholds were on average slightly lower for the 2AFC than the classification task as hypothesized. While −0.063 barks is small in relation to the 0.10 bark threshold for vowels tested under optimal listening conditions (Kewley-Port and Zheng, 1999; Liu and Kewley-Port, 2004b), the standard deviation of 0.163 is somewhat high.

Overall, there are several ways in which the 2AFC and classification thresholds were comparable. The group thresholds were very similar, with a tendency for classification thresholds to be higher. Although some listeners performed similarly on the two tasks, generally, individual listener thresholds were not ordered similarly from best to worst in the two tasks. Apparently listeners in the two procedures were influenced by separate factors that can result in large differences in individual performance. Thus while classification thresholds cannot be considered a substitute for 2AFC thresholds, it is reasonable to suggest that they would be useful as a performance measure in studies of individual dif-

TABLE IV. Means and standard deviations for classification and 2AFC thresholds estimated in experiment 2.

	/ɪ/-F1		/ʌ/-F1		/ʌ/-F2		/ɪ/-F2	
Formant frequency	349		648		1564		2196

ferences, because for a given individual, classification thresholds were shown to be reliable in their own right (see next section).

C. Discussion of experiment 2

1. Reliability of word classification thresholds in experiments 1 and 2

Although some of the details of the experiment 2 protocol were different than experiment 1, the word stimuli that were used for the classification portion were identical to those used in the word condition of experiment 1. Therefore, the reliability of thresholds shown in Fig. 4 can be examined between listener groups. Using two-tailed *t*-tests assuming equal variance ($N=8$), no statistically significant differences were found between experiments 1 and 2 for any of the formants: *bid/bed* F1 ($p=0.811$), *cut/cot* F1 ($p=0.813$), *cut/cot* F2 ($p=0.877$), and *bid/bed* F2 ($p=0.088$). We note that variance was high and thresholds were not as stable for /ɪ/-F2. Overall, classification thresholds for words appear reliable across the two different experimental groups.

2. Comparison of 2AFC thresholds with previous research

Given the difference in number of listeners per vowel formant between experiment 2 ($N=8$) and Liu and Kewley-Port (2004b) ($N=4$), a non-parametric two-tailed Mann–Whitney *U*-test was used to compare 2AFC thresholds obtained across experiments. No significant difference was found for /ʌ/-F1 ($U=15, p=0.934$), /ʌ/-F2 ($U=12, p=0.570$), and /ɪ/-F2 ($U=8, p=0.214$); however, a significant difference was found for /ɪ/-F1 ($U=0, p=0.004$). In the case of /ɪ/-F1, the thresholds estimated in experiment 2 ($M=19.1$ Hz, s.d.$=6.8$) were less than half the size of those observed in Liu and Kewley-Port (2004b) ($M=49.2$ Hz, s.d.$=5.9$) (see Fig. 4). A likely source of the threshold difference was that even though the same speaker was used for stimulus resynthesis, different recordings were used as base stimuli in the two experiments. Acoustic analysis showed that the base tokens for /ɪ/ were comparable between the two experiments in all ways except one: the difference in intensity between F1 and F2 (18.2 dB) for the experiment 2 /ɪ/ base stimulus was greater than the difference between F1 and F2 (13.9 dB) in the /ɪ/ base stimulus used in Liu and Kewley-Port (2004b). It is hypothesized that the greater prominence of F1 relative to F2 in experiment 2 made F1 of /ɪ/ in the current experiment more salient, and therefore thresholds were lower. Also, the lower relative intensity of F2 may have contributed to the difficulty of developing well-identified /ɪ/-F2 classification stimuli.

IV. SUMMARY AND CONCLUSIONS

A novel method for estimating discrimination thresholds from a classification task that are comparable to those obtained using a modified 2AFC adaptive tracking task was proposed using principles of Thurstonian scaling as implemented in SDT. In experiment 1, this method was tested using words both in isolation and in sentence context. F1 and F2 thresholds for two vowel continua (/ɪ/ to /ɛ/ and /ʌ/ to /a/) in a classification task were examined, and results showed the following:

- For isolated words, classification thresholds for three of the four formants tested were statistically similar to those from an earlier 2AFC task (Liu and Kewley-Port, 2004b).
- In the sentence context, only two of the four classification thresholds were statistically similar to thresholds reported from a 2AFC task (Liu and Kewley-Port, 2004b).
- The sentence context exhibited strong effects on vowel classification, especially for the /ʌ/-/a/ continua.

The implication of this final point is that while the goal of developing more natural methods for estimating discrimination performance in isolated words was met, an extension of these methods to sentences was not successful. However, in light of the promising results for classification thresholds for words, an analysis of the properties of the threshold estimation method was presented, and general guidelines for the use of this method were proposed. The simpler, more natural classification task, together with reasonably natural word length stimuli, should provide ecologically valid methods for examining vowel perception in general. It may be particularly useful for use with EHI and L2 listeners, although this should be experimentally established first.

In experiment 2, the goal was to further explore the relationship between thresholds estimated from classification and 2AFC adaptive tracking tasks by using a within-subjects design. Given the strong effect the sentence context had in experiment 1, the scope of experiment 2 was restricted to vowel classification in isolated words. The same stimuli from experiment 1 were used for the classification task in experiment 2, and continua for the 2AFC task had additional stimuli resulting in smaller steps between the stimuli used in experiment 1. Results from experiment 2 showed the following:

- The best match between thresholds estimated using the two tasks was found using a cumulative d' criterion (D) of 0.783, which corresponded to interpreting the modified 2AFC task as a "reminder design" in which listeners employed a differencing strategy.
- Thresholds were reliable across different groups of listeners; i.e., thresholds estimated in experiment 2 were comparable to those observed in experiment 1.
- At the group level, no statistical differences were observed between thresholds estimated using the two tasks.
- At the individual level, thresholds estimated using the two tasks were not significantly different; however, rank order correlation results suggested that individual differences between listeners influenced performance on the two tasks.
- Differences between thresholds reported in the current study and those reported in a previous study are probably related to differences in the acoustic properties of the base stimuli used to generate the continua in each study.

In summary, this study described a quicker, simpler threshold estimation method that appears to provide a reasonable approximation of thresholds estimated using a 2AFC

adaptive tracking task. Given that the proposed method is much more natural for speech stimuli and that the amount of listening time required to obtain stable thresholds is substantially less than a 2AFC task, estimating discrimination thresholds from a classification task appears to be a useful option.

Ideal binary time-frequency masking is a signal separation technique that retains mixture energy in time-frequency units where local signal-to-noise ratio exceeds a certain threshold and rejects mixture energy in other time-frequency units. Two experiments were designed to assess the effects of ideal binary masking on speech intelligibility of both normal-hearing (NH) and hearing-impaired (HI) listeners in different kinds of background interference. The results from Experiment 1 demonstrate that ideal binary masking leads to substantial reductions in speech-reception threshold for both NH and HI listeners, and the reduction is greater in a cafeteria background than in a speech-shaped noise. Furthermore, listeners with hearing loss benefit more than listeners with normal hearing, particularly for cafeteria noise, and ideal masking nearly equalizes the speech intelligibility performances of NH and HI listeners in noisy backgrounds. The results from Experiment 2 suggest that ideal binary masking in the low-frequency range yields larger intelligibility improvements than in the high-frequency range, especially for listeners with hearing loss. The findings from the two experiments have major implications for understanding speech perception in noise, computational auditory scene analysis, speech enhancement, and hearing aid design. I. INTRODUCTION

Human speech communication typically takes place in complex acoustic backgrounds with environmental sound sources, competing voices, and ambient noise. It is remarkable that human speech understanding remains robust in the presence of such interference. This perceptual ability is thought to involve the process of auditory scene analysis (Bregman, 1990), by which the auditory system first analyzes a noisy input into a collection of sensory elements in time and frequency, also known as segments (Wang and Brown, 2006), and then selectively groups segments into auditory streams which correspond to sound sources.

It is well known that listeners with hearing loss have greater difficulty in speech perception in background noise. A standard way to quantify speech intelligibility in noise is a speech-reception threshold (SRT), which is the mixture signal to noise ratio (SNR) required to achieve a certain intelligibility score, typically 50%. Hearing-impaired (HI) listeners need 3–6 dB higher SNR than normal-hearing (NH) listeners in order to perform at the same level in typical noisy backgrounds (Plomp, 1994; Alcantara *et al.*, 2003). For speech-shaped noise (SSN) which is a steady noise with a long-term spectrum matching that of natural speech, the SRT increase for HI listeners is from 2.5 to 7 dB (Plomp, 1994). For fluctuating noise or competing speech, the increase is considerably higher (Festen and Plomp, 1990; Hygge *et al.*, 1992; Eisenberg *et al.*, 1995; Peters *et al.*, 1998); for a single competing talker, the increase is as much as 10–15 dB (Carhart and Tillman, 1970; Festen and Plomp, 1990; Peters *et al.*, 1998). Note that, for typical speech materials, a 1 dB increase in SRT leads to a 7%–19% reduction in the percent correct score, and a 2–3 dB elevation creates a significant handicap for understanding speech in noisy listening conditions (Moore, 2007).

Although modern hearing aids improve the audibility and comfort of noisy speech, their ability to improve the intelligibility of noisy speech is unfortunately very limited (Dillon, 2001; Alcantara *et al.*, 2003). Extensive research has been made to develop noise reduction algorithms in order to close the SRT gap between HI and NH listeners. Monaural speech enhancement algorithms, such as Wiener filtering and spectral subtraction, perform statistical analysis of speech and noise and then estimate clean speech from noisy speech (Lim, 1983; Benesty *et al.*, 2005). Although these algorithms produce SNR improvements, they have not led to increased speech intelligibility for human subjects (Levitt, 2001;

 0001-4966/2009/125(4)/2336/12/$25.00

Moore, 2003b; Edwards, 2004). Attempts have also been made to directly enhance speech cues, especially formants which are spectral peaks of speech (Bunnell, 1990; Simpson *et al.*, 1990). This processing results in clearer formant structure; however, listening tests with both NH and HI listeners show little improvement in speech intelligibility (Baer *et al.*, 1993; Alcantara *et al.*, 1994; Dillon, 2001). Unlike monaural speech enhancement, beamforming (spatial filtering) with a microphone array has been demonstrated to achieve significant speech intelligibility improvements, particularly with large arrays (Kates and Weiss, 1996; Levitt, 2001; Schum, 2003). On the other hand, practical considerations of hearing aid design often limit the size of an array to two microphones, and the effectiveness of beamforming degrades in the presence of room reverberation (Greenberg and Zurek, 1992; Levitt, 2001; Ricketts and Hornsby, 2003). Additionally, to benefit from spatial filtering target speech and interfering sounds must originate from different directions.

Recent research in computational auditory scene analysis (CASA) has led to the notion of an ideal binary time-frequency mask as a performance upper bound to measure how well CASA algorithms perform (Wang and Brown, 2006). With a two-dimensional time-frequency (*T-F*) representation or decomposition of the mixture of target and interference, where elements in the representation are called *T-F* units, an ideal binary mask (IBM) is defined as a binary matrix within which 1 denotes that the target energy in the corresponding *T-F* unit exceeds the interference energy by a predefined threshold and 0 denotes otherwise. The threshold is called the local SNR criterion (*LC*), measured in decibels. More specifically, IBM is defined as

$$\mathrm{IBM}(t,f) = \begin{cases} 1 & \text{if } s(t,f) - n(t,f) > \mathrm{LC} \\ 0 & \text{otherwise,} \end{cases}$$

where $s(t,f)$ denotes the target energy within the unit of time t and frequency f and $n(t,f)$ the noise energy in the *T-F* unit, with both $s(t,f)$ and $n(t,f)$ measured in decibels. The mask is considered ideal because its construction requires access to the target and masker signals prior to mixing, and under certain conditions the IBM with $LC=0$ dB has the optimal SNR gain among all the binary masks (Wang, 2005; Li and Wang, 2009). As a separation technique, applying the IBM with $LC=0$ dB to the mixture input retains the *T-F* regions of the mixture where target energy is stronger than interference energy while removing the *T-F* regions where target energy is weaker than interference energy.

Varying *LC* results in different IBMs. Recently, Brungart *et al.* (2006) tested the effects of IBM with different *LC* values on speech mixtures with one target utterance and 1–3 competing utterances of the same talker, where the sound levels of all the utterances are set to be equal. Their experimental results show that, when $0\ \mathrm{dB} \geq LC \geq -12$ dB, IBM produces nearly perfect intelligibility scores, which are dramatically higher than in a control condition where speech mixtures are presented to listeners without processing. They suggest that the choice of $LC=-6$ dB, which lies near the center of the performance plateau, may be better than the commonly used 0 dB *LC* for intelligibility improvement. Furthermore, they attribute the intelligibility improvement to the removal of informational masking which occurs when the listener is unable to successfully extract or segregate acoustically detectable target information from the mixture. Anzalone *et al.* (2006) investigated the intelligibility improvements of a related version of IBM, defined by a comparison between target energy and a threshold rather than a comparison between target energy and interference energy. Using mixtures of speech and SSN, they found that IBM leads to substantial SRT reductions: more than 7 dB for NH listeners and more than 9 dB for HI listeners. In addition they reported that, while NH listeners benefit from ideal masking in both the low-frequency (LF) and high-frequency (HF) ranges, HI listeners benefit from ideal masking only at LFs (up to 1.5 kHz). Li and Loizou (2007) used the IBM to generate "glimpses," or *T-F* regions with stronger target energy, to study several factors that influence glimpsing of speech mixed with babble noise. Their results show that it is important to generate glimpses in the LF to mid-frequency range (up to 3 kHz) that includes the first and the second formant of speech, but not necessary to glimpse a whole utterance; high intelligibility is achieved when the listener can obtain glimpses in a majority of time frames. More recently, Li and Loizou (2008b) extended the findings of Brungart *et al.* (2006) to different types of background interference, including speech babble and modulated SSN. Moreover, they evaluated the impact of deviations from the IBM on intelligibility performance and found that there is a gradual drop as the amount of mask errors increases. A subsequent study by Li and Loizou (2008a) shows that NH listeners obtain significant intelligibility improvements from IBM processing with as few as 12 frequency channels, and IBM processing in the LF to mid-frequency range that includes the first and the second formant appears sufficient.

In this paper, we evaluate the effects of IBM processing on speech intelligibility with two kinds of background noise: SSN and cafeteria noise, using both NH and HI listeners. While SSN is commonly used in the literature, the cafeteria noise we use contains a conversation between two speakers in a cafeteria background and it resembles the kind of noise typically encountered in everyday life. Our study adopts the standard IBM definition with a comparison between target and interference and measures speech intelligibility by SRT at the 50% level. As suggested by the findings of Brungart *et al.* (2006), we set *LC* to −6 dB in IBM construction. Intrigued by the observation of Anzalone *et al.* (2006) that HI listeners derive little benefit from IBM in the HF range, we conduct an experiment to test whether ideal masking in the HF range is indeed not important for HI subjects. Unlike Anzalone *et al.* (2006) who applied a constant gain to compensate for the hearing loss of their HI subjects, we apply gain prescriptions to fit individual HI listeners.

In what follows, Sec. II details IBM processing. Section III describes an experiment that tests the effects of ideal masking on mixtures of speech with SSN or cafeteria noise. Section IV describes an experiment that compares the effects of ideal masking in LF, HF, and all-frequency (AF) ranges. Further discussion is given in Sec. V. Finally, Sec. VI concludes the paper.

II. IDEAL BINARY MASKING

The concept of IBM in CASA is directly motivated by the auditory masking phenomenon which, roughly speaking, refers to the perceptual effect that a louder sound renders a weaker sound inaudible within a critical band (Moore, 2003a). So keeping noise in *T-F* units with stronger target energy as done in the standard IBM definition with 0 dB *LC* should not reduce speech intelligibility, and this is indeed what was found by Drullman (1995). On the other hand, IBM processing removes all the *T-F* units with stronger interference energy as the target energy in these units is assumed to be masked by the interference. Removing these masker-dominated units also serves to remove informational masking, which is a dominant factor for reduced speech intelligibility in speech and other modulated maskers (Brungart, 2001). Hence IBM processing, as a form of ideal time-frequency segregation, is expected to yield larger speech intelligibility improvement in a modulated noise condition than in a steady noise condition (Brungart *et al.*, 2006).

Like earlier studies (Brungart *et al.*, 2006; Anzalone *et al.*, 2006), we use a gammatone filterbank to process a stimulus and then time windowing to produce a cochleagram which is a two-dimensional *T-F* presentation (Wang and Brown, 2006). Specifically, we use a 64-channel filterbank that is equally spaced on the equivalent rectangular bandwidth (ERB) rate scale with center frequencies distributed from 2 to 33 ERBs (corresponding to 55–7743 Hz). The bandwidth of each filter is 1 ERB. We note that this filterbank is similar to the one used in Anzalone *et al.* (2006) whereas Brungart *et al.* (2006) used a 128-channel filterbank covering the frequency range of 80–5000 Hz. The response of each filter is divided into 20 ms frames with a frame shift of 10 ms, hence generating a two-dimensional matrix of *T-F* units. The cochleagram of a stimulus is simply the two-dimensional graph of response energy within all the *T-F* units. For a given mixture of target signal and background noise, the IBM is calculated by comparing whether the local SNR within a *T-F* unit is greater than *LC*. As mentioned in Sec. I, we fix $LC=-6$ dB in this study as suggested by Brungart *et al.* (2006). Such a choice of negative *LC* retains certain *T-F* units where the target energy is weaker but not much weaker than the interference energy, in accordance with Drullman's observation that weaker speech energy below the noise level still makes some contribution to speech intelligibility (Drullman, 1995). Indeed, a pilot test with 0 dB *LC* indicates that SRT improvements are not as high as those produced with $LC=-6$ dB. More generally, in order to produce large auditory masking, the masker needs to be stronger than the masked signal (Moore, 2003a).

Given an IBM, the waveform output of IBM can be resynthesized from the mixture input by weighting the mixture cochleagram by the IBM and correcting phase shifts introduced during gammatone filtering (see Wang and Brown, 2006). Such an output can then be played to a listener as a stimulus in our experiments. Figure 1 illustrates IBM for a mixture of a speech utterance and a cafeteria background. The SNR of the mixture is 0 dB. Figure 1(a) shows the cochleagram of the target speech, Fig. 1(b) that of the background noise, and Fig. 1(c) that of the mixture. Figure 1(d) displays the IBM with $LC=-6$ dB, and Fig. 1(e) the cochleagram of the resynthesized result of ideal masking with the IBM in Fig. 1(d). The ideally masked mixture in Fig. 1(d) is clearly more similar to the target speech shown in Fig. 1(a) than the original mixture shown in Fig. 1(c) is. As a comparison, Fig. 1(f) shows the IBM with $LC=0$ dB, and Fig. 1(g) the cochleagram of the corresponding ideal masking output. With the increased *LC*, the IBM has fewer 1's and retains less mixture energy.

III. EXPERIMENT 1: EFFECTS OF IDEAL BINARY MASKING ON SPEECH-RECEPTION THRESHOLD

This experiment was designed to quantify the SRT effects of IBM for both NH and HI listeners. Sentences from the Dantale II corpus (Wagener *et al.*, 2003) were used as target speech, and tests were conducted with two different backgrounds: SSN and cafeteria noise.

A. Methods

1. Stimuli

The Dantale II corpus (Wagener *et al.*, 2003) comprises sentences recorded by a female Danish speaker. Each sentence has five words with a fixed grammar (name, verb, numeral, adjective, and object), for example, "Linda bought three lovely presents" (English translation). Each word in a sentence is randomly chosen from ten equally meaningful words. As a result, recognizing a subset of words in a sentence does not help with the recognition of the remaining words. There are a total of 15 test lists, and each list has ten sentences with no repeating word. There are a few seconds of silence between sentences within each list to allow a listener time to report what has been heard. Similar to the Swedish sentence test (Hagerman, 1982), the closed set corpus was designed for repeated use, and training effects are minimal after familiarization with a few lists (Wagener *et al.*, 2003). We use the speech-shaped noise included with the Dantale II corpus, which is produced by superimposing the speech material in the corpus. The cafeteria noise employed is a recorded conversation in Danish between a male and female speaker that took place in a cafeteria background (Vestergaard, 1998). To emphasize temporal modulation effects, the long-term spectrum of this noise was shaped to match that of the Dantale II speech material (Johannesson, 2006). Target speech and background noises are all digitized at 20 kHz sampling frequency.

A speech utterance and a background noise are first processed separately by a 64-channel gammatone filterbank (see Sec. II), which produces a flat frequency response within the frequency range of the filterbank. Filter responses are then windowed into 20 ms rectangular frames with a 50% overlap between consecutive frames, resulting in a two-dimensional cochleagram. This 100 Hz frame rate is frequently used in speech processing (Rabiner and Juang, 1993). For a given mixture of a Dantale II list and a background noise, the mixture SNR is calculated during the intervals that contain speech energy. To account for the forward masking of the continuously present noise that occurs between two consecu-

tive sentences (Moore, 2003a), a period of 100 ms is added before the onset of a sentence for mixture SNR calculation. For a mixture input with a specified SNR, IBM is constructed from the cochleagrams of the target speech and the background noise with *LC* fixed at −6 dB. The IBM is then used to resynthesize a waveform stimulus from the mixture cochleagram. Note that, as a result, the masker signals in between sentences are removed by IBM processing because during such intervals there is only masker energy.

As control conditions, mixtures of speech and background noise were also presented to listeners without segregation. To incorporate filtering effects and any distortions that might be introduced during cochleagram analysis and synthesis, a mixture in an unsegregated condition is processed through an all-1 binary mask or the IBM with the *LC* of negative infinity, therefore including all the *T-F* units in the resynthesis.

2. Listeners

A total of 12 NH listeners and a total of 12 listeners with sensorineural hearing loss participated in this experiment. All subjects were native Danish speakers. The NH listeners had hearing thresholds at or below 20 dB HL from 125 Hz to 8 kHz, and their ages ranged from 26 to 51 with the average age of 37. The NH listeners had little prior experience with auditory experiments, and were not informed of the purpose or design of the experiment.

The 12 HI listeners had a symmetric, mild-to-moderate, sloping hearing loss. The audiograms of these listeners are shown in Fig. 2. They had an age range from 33 to 80 with the average age of 67. All the HI listeners were experienced hearing aid wearers. The tests were performed with their hearing aids taken off, and compensation was applied to each HI subject individually. Specifically, a gain prescription was computed from an individual's audiogram using the NAL-RP procedure (Dillon, 2001), and then used to produce amplification with appropriate frequency-dependent shaping. The hearing losses in the left ear and the right ear were compensated for separately. The subjects had participated in Dantale II listening tasks before, but were not told of the purpose and design of this experiment.

3. Procedure

There are a total of four test conditions in this experiment: two ideal masking conditions with SSN and cafeteria noise and two control conditions with unsegregated mixtures. Three Dantale II lists with a total of 30 sentences were randomly selected from the corpus for each test condition. Subjects were instructed to repeat as many words as they could after listening to each stimulus that corresponded to one sentence, and they were not given any feedback as to whether their responses were correct or not. To familiarize them with the test procedure, subjects were given a training session at the beginning of the experiment by listening to and reporting on three lists of clean sentences. The order of the four conditions was randomized but balanced among the listeners (Beck and Zacharov, 2006). A subject test with the four conditions and a training session together took less than 1 h, and a short break was given roughly halfway through the test.

The Dantale II test employs an adaptive procedure in order to find the 50% SRT. The procedure is to present test sentences at SNR that is continuously adapted according to the number of correctly reported words in the previous sentence (Hansen and Ludvigsen, 2001). In a test condition with 30 sentences, the first 10 sentences are used to reach a steady 50% SRT level and the final SRT is determined by averaging the SNR levels for the last 20 sentences.

Speech and noise were both set to the same initial sound pressure level (SPL) for NH listeners. For HI listeners, the initial SPL of speech was set to 5 dB higher than the noise SPL in Experiment 1, and to the same SPL of noise in Experiment 2. In unsegregated conditions, the noise level was fixed while the speech level was adjusted during the adaptive procedure. In ideal masking conditions, as input SNR drops IBM becomes sparser with fewer 1's. To ensure that ideally masked stimuli remain audible at very low SNRs, the speech

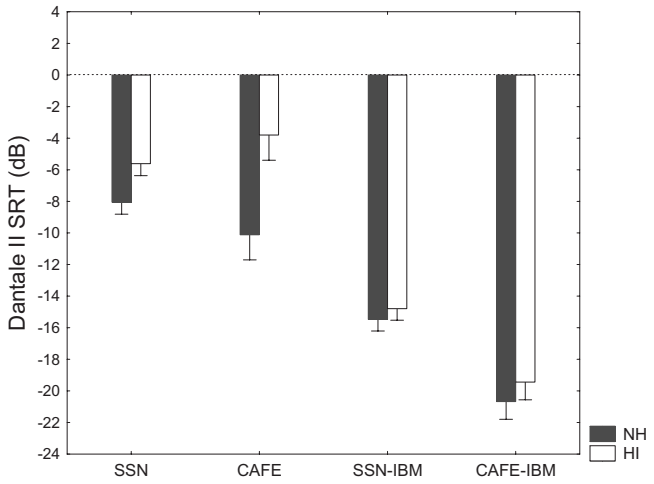

FIG. 3. SRTs for different conditions of Experiment 1 for NH and HI listeners. A more negative SRT corresponds to better performance. Error bars indicate 95% confidence intervals of the means.

level was fixed while the noise level was adjusted in all IBM conditions. As a result, with fewer retained *T-F* units their sound levels became higher even though the levels of the speech signals within these units were unchanged, and the loudness of a processed mixture was thus kept within a small range. This way of adjusting input SNR ensured that the stimuli in all four conditions were comfortably audible.

During a test, a subject was seated in a sound attenuating booth. Test stimuli were generated using the built-in sound card (SoundMAX) in a control computer (IBM ThinkCenter S50) and then presented diotically to a listener through headphones (Sennheiser HD 280 Pro). For HI listeners, an external amplifier (Behring Powerplay HA4000) was used to increase the sound level so that the stimuli within the test range were all audible and yet not uncomfortably loud. The amplification level was adjusted once for each HI listener before the test began.

4. Statistical analysis and power

During the planning phase of the study, the experiment was statistically powered to detect a within-subject between-condition difference of 1.0 dB on mean scores across conditions on the Dantale II test described subsequently for $p<0.05$ at 80% power. This required at least ten complete data sets per condition. Analysis of variance (ANOVA) was performed on all of the data from NH and HI subjects, with within-subject factors of type of processing (IBM or unsegregated) and of type of noise (SSN or cafeteria noise), and a between-subject factor of subject type (NH and HI). *Post hoc* tests were the Bonferroni test and/or the Fisher least-significant-difference (LSD) test, applied where appropriate. The Bonferroni test was used as the most conservative test to indicate differences between means, while the Fisher LSD test was used as the most conservative test for a null result. All statistics were performed using STATISTICA version 7 (StatSoft, 2007).

B. Results and discussion

Figure 3 shows the SRT results of all four test conditions: SSN, CAFE, SSN-IBM, and CAFE-IBM, for both NH and HI listeners. For NH listeners, the mean SRT for unsegregated mixtures with SSN (SSN) is −8.15 dB, for unsegregated mixtures with cafeteria noise (CAFE) is −10.25 dB, for ideal masking with SSN (SSN-IBM) is −15.56 dB, and for ideal masking with cafeteria noise (CAFE-IBM) is −20.70 dB. The ANOVA for NH subjects showed that the main effects of processing type and noise type were significant [$F(1,11)=606.1$, $p<0.001$, and $F(1,11)=78.1$, $p<0.001$, respectively], and there was also a significant interaction between processing type and noise type [$F(1,11)=32.3$, $p<0.001$]. The Bonferroni *post hoc* tests indicated that all means were significantly different [$p<0.005$] from one another. The results show that ideal masking leads to lower (better) SRT compared to unsegregated mixtures regardless of background noise, that the cafeteria background yields a lower SRT than the SSN, and that ideal masking has a greater effect on the cafeteria background. The SRT for the unsegregated SSN condition is comparable to the reference level of −8.43 dB for the Dantale II task (Wagener *et al.*, 2003). The lower SRT for the cafeteria background is consistent with previous studies showing that NH listeners exhibit higher intelligibility in fluctuating backgrounds (Festen and Plomp, 1990; Peters *et al.*, 1998).

For the SSN background, IBM produces an average SRT improvement of 7.4 dB. This level of improvement is consistent with what was found by Anzalone *et al.* (2006) using the HINT test (Nilsson *et al.*, 1994), but higher than the 5 dB improvement reported by Brungart *et al.* (2006) using the CRM task (Bolia *et al.*, 2000). The main difference between our experiment and Brungart *et al.* (2006) lies in different *LC* values: their test uses 0 dB *LC* whereas *LC* is set to −6 dB in our study. As reported in Brungart *et al.* (2006) the choice of $LC=-6$ dB seems better than $LC=0$ dB in terms of speech intelligibility (see also Sec. II).

For the cafeteria background, ideal masking lowers SRT by 10.5 dB on average, which represents a larger gain than for the SSN background. Unlike SSN, the cafeteria background contains significant spectral and temporal modulations which contribute to better intelligibility in the unsegregated condition. We stress that the larger SRT improvement for this background is achieved on top of the better performance of listening to unsegregated mixtures.

For HI listeners, the mean SRTs are −5.61, −3.80, −14.79, and −19.44 dB for the SSN, CAFE, SSN-IBM, and SSN-CAFE conditions, respectively. The ANOVA where both NH and HI subjects were included showed that the main effects of subject type, processing type, and noise type were significant [$F(1,22)=17.2$, $p<0.001$; $F(1,22)=1959.0$, $p<0.001$; and $F(1,22)=100.6$, $p<0.001$, respectively], and there were also significant interaction effects between-subject type and processing type, subject type and noise type, and processing type and noise type [$F(1,22)=49.9$, $p<0.001$; $F(1,22)=19.2$, $p<0.001$; and $F(1,22)=163.9$, $p<0.001$ respectively], as well as a three-way interaction between subject type, processing type, and noise type [$F(1,11)=19.7$, $p<0.001$]. The Bonferroni as well as the Fisher LSD *post hoc* tests on the three-way interaction indicated that all means were significantly different ($p<0.006$)

except for the SSN-IBM and CAFE-IBM conditions where the differences between NH and HI listeners were insignificant ($p > 0.05$). The *post hoc* results show that ideal masking produces lower SRT compared to unsegregated mixtures regardless of noise type, and has a greater effect for the cafeteria background. No difference, however, was revealed between the NH subjects and the HI subjects in the two IBM conditions by either the more conservative Bonferroni test or the less conservative Fisher LSD test. The elevated levels of SRT in the two unsegregated conditions show that HI listeners perform worse in speech recognition in noisy environments, and the levels of SRT increment, 2.5 dB for the SSN condition and 6.5 dB for the CAFE condition, are broadly compatible with previous findings of HI listeners' increased difficulty in speech understanding in noise (see Sec. I). IBM lowers SRT substantially. The SRT gain resulting from ideal masking is 9.2 dB for the SSN background, and this level of improvement is compatible with that reported in Anzalone *et al.* (2006). For the cafeteria background, ideal masking produces a very large SRT improvement of 15.6 dB.

By comparing NH and HI results in Fig. 3, it is clear that HI listeners benefit from ideal masking even more than NH listeners, particularly for the cafeteria background. The results suggest that, after IBM processing, the intelligibility performance is comparable for HI and NH listeners in both SSN and cafeteria backgrounds. It is remarkable that the speech intelligibility of HI listeners becomes statistically indistinguishable from that of NH listeners after ideal masking.

IV. EXPERIMENT 2: EFFECTS OF BAND-LIMITED IDEAL BINARY MASKING ON SPEECH-RECEPTION THRESHOLD

The results of Experiment 1 show large SRT improvements resulting from IBM processing. As mentioned in Sec. I, a main finding reported by Anzalone *et al.* (2006) is that, while NH listeners benefit from IBM in both the LF and HF ranges, HI listeners benefit from ideal masking only in the LF range. This finding is significant because it suggests that, to alleviate the hearing loss of HI listeners, one need not worry about performing *T-F* masking in the HF range; speech segregation at HFs tends to be more difficult than at LFs (Wang and Brown, 2006). Although their interpretation based on the upward spread of masking is reasonable, the fact that they apply constant amplification with no spectral shaping to compensate for the sloping hearing loss of their subjects may suggest a simpler interpretation: the lack of the IBM benefit in the HF range may be partially accounted for by the potentially less compensated hearing loss at HFs. Experiment 2 was primarily designed to assess the importance of IBM processing at HFs for HI listeners as compared to NH listeners. In this experiment, we compensated for the hearing loss of individual listeners based on their audiograms. We compare the intelligibility performance in three setups: IBM in the LF range only, ideal masking in the HF range only, and ideal masking in the AF range. Both SSN and cafeteria backgrounds are used. Consequently, there are a total of six test conditions in this experiment.

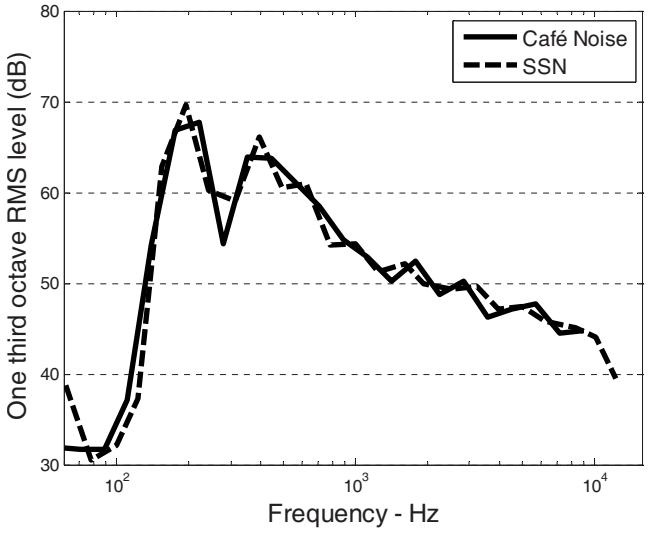

FIG. 4. Long-term spectrum of the SSN in Dantale II (redrawn from Wagener *et al.*, 2003). The spectrum is expressed as root mean square levels in one-third octave bands. Also shown is the long-term spectrum of the cafeteria noise.

A. Methods

1. Stimuli

As in Experiment 1, Dantale II sentences were used as target speech, and SSN and cafeteria noise were used as two different backgrounds. The IBM processing in the AF condition was the same as in Experiment 1. For the LF condition, the same IBM processing as in Experiment 1 was used in the lower 32 frequency channels while an all-1 mask was applied to the higher 32 frequency channels. This way of processing produces no segregation in the HF range. In the HF condition, the reverse was done: IBM was applied to the higher 32 channels while an all-1 mask was applied to the lower 32 channels (hence no segregation in the LF range). This equal division of the 64-channel gammatone filterbank yields a frequency separation boundary approximately at 1.35 kHz. Note that this boundary separating LF and HF ranges is a little lower than the 1.5 kHz boundary used in Anzalone *et al.* (2006). Our choice was partly motivated by the consideration that both the speech material and the SSN in the Dantale II corpus have energy distribution heavily tilted toward LFs so that IBM processing below 1 kHz likely removes significantly more noise than IBM processing above 1 kHz. The long-term spectrum of the SSN (Wagener *et al.*, 2003) is shown in Fig. 4, along with the long-term spectrum of the cafeteria noise. With the 1.5 kHz boundary, the NH results from Anzalone *et al.* (2006) show that the SRT in their LF condition is a little lower than the SRT in their HF condition.

2. Listeners

12 NH listeners and 12 HI listeners participated in this experiment. The pool of NH listeners was the same as that participated in Experiment 1 except for one. This substitution lowered the average age from 37 to 36 without altering the age range. The pool of HI listeners also remained the same as in Experiment 1 except for one. This substitution (see Fig.

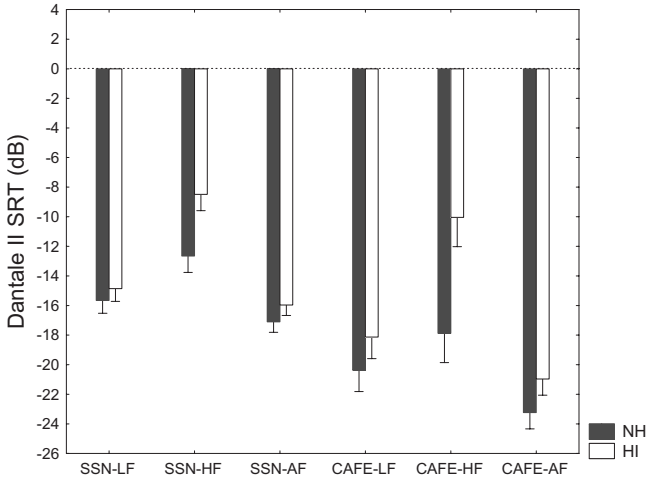

FIG. 5. SRTs for different conditions of Experiment 2 for NH and HI listeners. Error bars indicate 95% confidence intervals of the means.

2), plus a listener whose birthday occurred between the two experiments, changed the average age from 67 to 66 without changing the age range. Again, subjects were naïve to the purpose and design of the experiment. NH listeners were familiar with the Dantale II sentences by virtue of participating in Experiment 1, and as noted in Sec. III A 2, HI listeners had experience listening to Dantale II sentences prior to Experiment 1. Due to the limited number of test lists (15) available in the Dantale II corpus, the same lists used in Experiment 1 were also employed in Experiment 2. It is worth mentioning that the corpus was designed for repeated usage (Wagener *et al.*, 2003; see also Sec. III A 1).

3. Procedure and statistical analysis

The procedure of this experiment is the same as in Experiment 1 except for the following. To vary the input SNR, the noise level was adjusted while the speech level was fixed as in the ideal masking conditions of Experiment 1. In the LF and HF conditions, there is no segregation in half of the frequency channels. As the input SNR decreases in the negative range, the sound level of a stimulus in these conditions is dominated by the background noise in the unsegregated frequency range and hence becomes increasingly louder. To ensure that LF and HF stimuli are not too loud for NH listeners who have very low SRTs, the speech level was fixed at a lower volume than in Experiment 1. Despite this change of sound level, all test stimuli were still comfortably audible for NH listeners. Note that this change did not impact HI listeners as the amount of amplification was individually set for them. ANOVA was performed similarly on all the data from NH and HI subjects as in Experiment 1, with within-subject factors of type of processing (LF, HF, or AF) and of type of noise (SSN or CAFE), and a between-subject factor of subject type (NH or HI).

B. Results and discussion

Figure 5 shows the SRT results of all six test conditions in Experiment 2: SSN-LF, SSN-HF, SSN-AF, CAFE-LF, CAFE-HF, and CAFE-AF, for both NH and HI listeners. The ANOVA for NH subjects showed that the main effects of processing type and noise type were significant [$F(2,22)=255.5$, $p<0.001$, and $F(1,11)=231.2$, $p<0.001$, respectively], and there was also a significant interaction between processing type and noise type [$F(2,22)=4.4$, $p<0.05$]. The Bonferroni tests indicated that all NH means were significantly different ($p<0.006$) from one another, except between the SSN-AF and the CAFE-HF condition. For the SSN background, the mean SRT is −15.66 dB in the LF condition, −12.65 dB in the HF condition, and −17.10 dB in the AF condition. The results show that NH listeners perform better when IBM processing is applied in the LF range than in the HF range, and the difference in SRT is approximately 3 dB. This SRT difference is larger than the SRT difference of slightly more than 1 dB reported by Anzalone *et al.* (2006), despite the fact that the boundary separating LFs and HFs is 1.35 kHz in our processing and 1.5 kHz in their processing. Even with the lower frequency boundary we find that, with the same input SNR, the HF condition leaves more noise than the LF condition since the noise energy is distributed mostly in the LF range (see Fig. 4). The discrepancy is likely due to different ways of IBM processing used in the two studies. The AF condition yields the lowest SRT, which is about 1.6 dB lower than in the LF condition.

For the cafeteria background, the mean SRT is −20.37 dB in the LF condition, −17.88 dB in the HF condition, and −23.24 dB in the AF condition. Clearly NH subjects perform better in this background than in SSN, consistent with the results of Experiment 1. Again, NH listeners benefit more from IBM processing at LFs than at HFs and the relative benefit is 2.5 dB. The AF condition also gives the lowest SRT, which is about 2.9 dB lower than in the LF condition. That NH subjects performed better in the AF condition than in the LF condition for both the SSN and cafeteria backgrounds suggest that they do benefit from IBM in the HF range, even though the benefit is not as high as from the LF range.

The ANOVA where both HI and NH subjects were included showed that the main effects of subject type, processing type, and noise type were significant [$F(1,22)=19.1$, $p<0.001$; $F(2,44)=255.4$, $p<0.001$; and $F(1,22)=317.2$, $p<0.001$, respectively], and there were also significant interaction effects between subject type and processing type, subject type and noise type, and processing type and noise type [$F(2,44)=31.2$, $p<0.001$; $F(1,22)=18.3$, $p<0.001$; and $F(2,44)=14.2$, $p<0.001$, respectively], as well as a three-way interaction between subject type, processing type, and noise type [$F(2,44)=5.4$, $p<0.01$]. Table I shows the Fisher LSD *post hoc* tests. As seen in the table, all conditions were significantly different ($p<0.05$) from one another within the NH subjects (conditions {1}–{6} contrasted against each other) and within the HI subjects (conditions {7}–{12} contrasted against each other). However, the differences between NH and HI were insignificant for the conditions of SSN-LF and SSN-AF.

For HI listeners, the mean SRTs for the SSN background are −14.85, −8.49, and −15.96 dB for the LF, HF, and AF conditions, respectively. The SRT advantage of the LF condition over the HF condition is 6.4 dB, whereas the advantage of the AF condition over the LF condition is only

TABLE I. Fisher LSD *post hoc* significance tests for the three-way interaction of subject type, processing type, and noise type. Significance levels above $p > 0.05$ are given in boldface.

1.1 dB. These data are generally comparable with those in Anzalone *et al.* (2006). The results suggest that HI listeners derive considerably more benefit from ideal masking at LFs than at HFs, and the SRT difference is much larger than for NH listeners (see Fig. 5). Although part of the larger gap may be caused by a larger SRT gain (9.2 dB) in HI listeners than that (7.4 dB) in NH listeners due to IBM processing, the fact that the relative advantage of the AF condition over the LF condition for HI listeners is even a little smaller than for NH listeners (1.1 dB versus 1.6 dB) strongly indicates that IBM processing in LF is to a greater extent responsible for the SRT improvement of ideal masking in HI listeners than in NH listeners. In other words, almost all the benefit of IBM can be obtained by IBM only in the LF range. This, of course, is not to say that ideal masking in HF does not improve speech intelligibility compared to no segregation. As illustrated in Fig. 3, IBM processing at all frequencies results in a 9.2 dB SRT improvement compared to no segregation, and the AF condition produces a 7.5 dB relative advantage over the HF condition. This comparison suggests that ideal masking at HFs produces some improvement in speech intelligibility.

For the cafeteria background, the SRTs in the LF, HF, and AF conditions are −18.13, −10.05, and −20.96 dB, respectively (see Fig. 5). The SRT advantage of LF processing over HF processing is 8.1 dB and that of AF over LF is 2.8 dB. These results show a similar pattern as for the SSN background, even though the SRT difference of 2.8 dB between the LF and AF conditions clearly reaches statistical significance (see Table I), and HF processing yields a significant SRT improvement over no segregation as suggested by comparing with the data in Experiment 1. The use of the fluctuating cafeteria background reinforces the conclusion that ideal masking in LF produces a much stronger benefit than that in HF, and this effect is greater in HI listeners than in NH listeners.

The two AF conditions for the SSN and cafeteria backgrounds are the same as the corresponding ideal masking conditions in Experiment 1. The NH performances in Experiment 2 are somewhat better than in Experiment 1. A comparison between Fig. 5 and Fig. 3 shows that the discrepancies are 1.5 dB for SSN and 2.5 dB for cafeteria noise. The only difference in stimuli is the sound level; as pointed out in Sec. IV A 3, the sound level is softer in Experiment 2 than in Experiment 1. For example, at the input SNR of −10 dB, the sound level in Experiment 1 is about 63 dB(A) SPL for the SSN background and 75 dB(A) for the cafeteria background, while the corresponding levels in Experiment 2 are 51 and 51 dB(A), respectively. Studies suggest that softer sound can produce better recognition under certain conditions (Hagerman, 1982; Studebaker *et al.*, 1999). To examine whether the sound volume was a factor in the performance differences, we performed a follow-up experiment with the same pool of the NH listeners who participated in Experiment 2. The follow-up experiment was to simply check subjects' percent correct scores at the sound levels used in the two experiments when the input SNR was fixed at one of the SRTs (alternating between subjects) already obtained in the experiments. The cafeteria background noise was used. The scores are 50.6% with the louder level of Experiment 1 and 58.6% with the softer level of Experiment 2. The 8% difference is statistically significant $[t(11)=3.31,\ p<0.01]$, but unlikely large enough to explain the 2.5 dB SRT difference. Perhaps more important is a learning effect. Unlike HI listeners who were experienced with the Dantale II task, NH listeners used in this investigation had little prior experience with auditory experiments before participating in Experiment 1. When they participated in the second experiment, the familiarity with the Dantale II task acquired during Experiment 1 likely contributed to their better performance. In the predecessor to Dantale II—the Hageman sentence test—Hagerman and Kinnefors (1995) found a training effect of about 0.07 dB per ten sentences, which may explain the differences between Experiments 1 and 2. This interpretation is consistent with the observation that the corresponding performance differences between Experiment 1 and Experiment 2 are smaller for HI listeners; one-third of the mean performance differences is accounted for by the replacement of one HI listener from Experiment 1 to Experiment 2 (see Sec. IV A 2).

V. GENERAL DISCUSSION

The robustness of speech recognition in noise by NH listeners is commonly attributed to the perceptual process of glimpsing, or "listening in the dips," which detects and gathers *T-F* regions of a sound mixture where target speech is relatively stronger compared to interference (Miller and Licklider, 1950; Howard-Jones and Rosen, 1993; Assmann and Summerfield, 2004; Li and Loizou, 2007). As glimpsing involves grouping, this account is closely related to the ASA account that applies to both speech and nonspeech signals (Bregman, 1990). Poorer performance of listeners with hearing loss in fluctuating backgrounds is generally explained as their inability to take advantage of temporal and spectral dips, perhaps caused by reduced frequency selectivity and temporal resolution (Moore, 2007). IBM could be understood as producing glimpses or performing ASA for the listener. The fact that ideal masking also improves intelligibility of NH listeners suggests that even listeners without hearing loss can fail to make full use of the speech information available in a noisy input. The less-than-ideal performance in noisy environments is probably caused by the failure in detecting a glimpse—a *T-F* region with relatively strong target energy—or grouping detected glimpses. This failure becomes more acute with hearing loss. Because ideal masking does an "ideal" job of glimpsing for the auditory system, it helps to nearly equalize the performances of HI and NH listeners (see Fig. 3).

The results of Experiment 1 demonstrate that listeners with or without hearing loss benefit more from IBM processing in the cafeteria background than in the SSN background. The cafeteria background has temporal and spectral modulations, and as a result the amount of informational masking caused by target-masker similarity is expected to be higher than that in SSN. Indeed, some listeners voluntarily commented after the experiment that the conversation in the background distracted their attention, making it harder to concentrate on target utterances. The larger SRT improvement observed for the cafeteria background is thus consistent with the interpretation that ideal masking removes or largely attenuates informational masking (Brungart *et al.*, 2006). In a situation extremely conducive to informational masking, namely, the mixtures of speech utterances of the same talker, Brungart *et al.* (2006) found that the effect of ideal masking is tantamount to a 22–25 dB improvement in input SNR. The 10.5 dB SRT improvement obtained through ideal masking in the cafeteria background, although greater than that obtained in the SSN background, is much smaller than that obtained in mixtures of same-talker utterances. The improvement is also smaller than those obtained in mixtures of different-talker utterances (Chang, 2004), although the gap is not quite as big as in same-talker mixtures. One can therefore expect even larger SRT improvements when interference is one or several competing talkers, a kind of background that produces very large performance gaps between NH and HI listeners as reviewed in Sec. I.

The results of Experiment 2 are on the whole consistent with the related findings of Anzalone *et al.* (2006) even though we used individual gain prescriptions to compensate for listeners' hearing loss. The results are also qualitatively consistent with the findings of Li and Loizou (2007) illustrating that glimpses in the LF to mid-frequency range are more beneficial for speech intelligibility than those in the HF range. However, a few differences between our results and the results of Anzalone *et al.* (2006) are worth noting. First, although considerably smaller than LF processing, there is a benefit from ideal masking in the HF range for HI listeners in our study whereas their study did not show a significant benefit. A possible reason is the individual gain prescription employed in our study that makes segregated speech relatively louder in the HF range than the constant gain applied in their study. Second, we find a relatively greater LF benefit in NH listeners than in their study. The main reason, we believe, is that LF processing removes more background noise than HF processing for a given input SNR. With negative input SNRs (see Fig. 5), the residual noise in the HF condition is in the LF range while that in the LF condition is in the HF range, and the background noises used in our experiments have energy distributed mostly in the LF range, as shown in Fig. 4. This explanation, not considered by Anzalone *et al.*, gives a partial account for the larger LF benefit for listeners with hearing loss. The large SRT gap between LF and HF processing for HI listeners (see Fig. 5), however, cannot be fully explained this way as the gap is substantially larger—to the extent that the SRT performance in LF processing is almost the same as in AF processing. Another likely reason is upward spread of masking (Anzalone *et al.*, 2006) which listeners with sensorineural hearing loss are especially susceptible to (Jerger *et al.*, 1960; Gagne, 1988; Klein *et al.*, 1990). Upward spread of masking is a more prominent factor in the HF condition because of no segregation in the LF range. Also, with more hearing loss at HFs (see Fig. 2), HI listeners are less able to utilize audible HF speech information in recognition compared to NH listeners (Dubno *et al.*, 1989; Ching *et al.*, 1998; Hogan and Turner, 1998). This could also contribute to a steeper performance decline of HF processing relative to AF processing for HI listeners than for NH listeners.

Despite different definitions of IBM, the SRT improvements observed in our study and in Anzalone *et al.* (2006) are very close for the SSN background. It is all the more remarkable considering that their IBM is generated on a sample-by-sample basis while ours is generated on a frame-by-frame basis, which has a drastically lower temporal resolution, and that, in their experiments, IBM-determined gains take the values of 1 and 0.2 while the gains take the values of 1 and 0 in our experiments. The use of two-valued gains is a key similarity between the studies. The most important difference is, of course, that our definition is based on a comparison between target and interference energy and theirs is between target energy and a fixed threshold. The local SNR based IBM is arguably easier to estimate computationally, as many speech segregation algorithms compute binary time-frequency masks by exploring local SNR explicitly or implicitly (Divenyi, 2005; Wang and Brown, 2006). Also, there is little basis in a noisy signal to identify those *T-F* regions of significant target energy where interference is much stronger.

The results from our experiments have major implications for CASA and speech enhancement research aiming to improve speech intelligibility in noisy environments. In addition to affirming the general effectiveness of IBM as a computational goal, our data provide direct evidence that a choice of *LC* at −6 dB for IBM construction, first suggested by Brungart *et al.* (2006), is effective for improving human speech recognition. A comparison between the data of Brungart *et al.* (2006) and ours for the SSN background indicates that the IBM with −6 dB *LC* yields larger SRT improvement than commonly used 0 dB *LC*. Compared to 0 dB *LC*, the choice of −6 dB *LC* retains those *T-F* units where local SNR falls between 0 and −6 dB in ideal masking (see Fig. 1). From the standpoint of SNR, such inclusion will lower the overall SNR of the segregated signal. In other words, if the objective is to improve the SNR of the output signal, the choice of −6 dB *LC* is a poorer one compared to that of 0 dB *LC*. This discussion casts further doubt on the suitability of traditional SNR as a performance metric to evaluate sound separation systems, and at the same time, could shed light on why monaural speech enhancement algorithms often improve SNR but not speech intelligibility (see Sec. I). Another strong implication of our results (see also Anzalone *et al.*, 2006) is that performing speech separation in the LF range is a great deal more important than in the HF range, particularly for improving speech intelligibility of HI listeners.

Our results point to a very promising direction for hearing aid design to improve speech intelligibility in noise of listeners with hearing loss, that is, by designing hearing aids that function in similar ways to IBM. IBM processing improves SRT by a large margin, and HI listeners derive larger benefit than NH listeners. Equally important, the profile of improvement with respect to different kinds of background noise seems to match that of typical hearing impairment. We consider it a highly significant result that ideal masking almost equalizes the intelligibility performances of HI and NH listeners (see Fig. 3). Of course, facing a noisy input IBM cannot be directly constructed and algorithms must be developed to estimate IBM. Encouraging effort has been made in CASA with the explicit goal of IBM estimation (Wang and Brown, 2006), and in limited conditions high-quality estimates are obtainable (see, e.g., Roman *et al.*, 2003). However, computing binary masks close to the IBM in unconstrained acoustic environments remains a major challenge. On the other hand, the extent of intelligibility gain for HI listeners produced by IBM processing much more than fills the SRT gap from NH listeners; Experiment 1 shows a gap of 2.5 dB for the SSN background and a gap of 6.5 dB for the cafeteria background while the ideal masking improvements for HI listeners are 9.2 and 13.8 dB for the two backgrounds, respectively. Hence, perfect IBM estimation is not necessary to bring the performance of HI listeners to the same level as that of NH listeners.

VI. CONCLUSION

The present study was designed to evaluate the impact of IBM on speech intelligibility in noisy backgrounds for both NH and HI listeners. Two experiments were conducted and the main results are summarized below.

- For NH listeners, IBM processing resulted in 7.4 dB SRT reduction for SSN and 10.5 dB reduction for cafeteria noise.
- For HI listeners, IBM processing resulted in 9.2 dB SRT reduction for SSN and 15.6 dB reduction for cafeteria noise.
- After IBM processing, the intelligibility performances for HI listeners and NH listeners were comparable.
- For NH listeners, IBM processing at LFs produced greater SRT reduction than at HFs. The differences were 3 dB for SSN and 2.5 dB for cafeteria noise.
- For HI listeners, IBM processing at LFs produced greater SRT reduction than at HFs. The differences were 5.5 dB for SSN and almost 8 dB for cafeteria noise.

ACKNOWLEDGMENTS

We thank the Associate Editor Ken Grant, and two anonymous reviewers for their helpful comments. The work was conducted while D.W. was a visiting scholar at Oticon A/S. The authors are grateful to M. Schlaikjer, L. Bramsløw, and M. Hartvig, for their assistance in the experiments, and Y. Li for his assistance in figure preparation. Perception of allophonic cues to English word boundaries by Japanese second language learners of English

Kikuyo Ito[a] and Winifred Strange
Ph.D. Program in Speech-Language-Hearing Sciences, City University of New York—Graduate School and University Center, 365 Fifth Avenue, New York, New York 10016-4309

(Received 30 April 2008; revised 10 December 2008; accepted 23 January 2009)

Perception of stop aspiration and glottal stop allophonic cues for word juncture in English by Japanese second language (L2) learners of English was examined, extending a study of Spanish L2 learners [Altenberg, E. P. (2005). Second Lang. Res. **21**, 325–358]. Thirty Japanese listeners ranging in length of residence (LOR) in the United States (2 weeks–12 years) were tested on 42 contrasting pairs (e.g., aspiration: *keeps talking* vs *keep stalking*, glottal stop: *a nice man* vs *an ice man*, and double cues: *grape in* vs *grey pin*). Phrases were presented in randomly ordered lists and subjects responded in a two-choice identification task followed by a phrase familiarity test. The Japanese listeners performed more poorly than an American English-speaking control group ($N=10$), especially on aspiration pairs. Aspiration pairs were differentiated significantly less well (73% correct) by Japanese listeners than were glottal stop pairs (91% correct) and double cue pairs (94% correct); response biases predicted from relative familiarity of phrases were evident only for aspiration pairs. Performance correlated with LOR and suggested that aspiration cues take more immersion experience to learn than glottal stop cues. The patterns of errors were similar, but not identical, to Altenberg's Spanish data.

I. INTRODUCTION

When processing running speech, listeners have to segment continuous streams of sound into recognizable units such as words and phrases. Identifying word/phrase boundaries is a necessary stage for auditory language processing because there are no reliable pauses between words in continuous speech. The process of word segmentation in speech seems to be so automatic and effortless for first language (L1) listeners that, more often than not, they are not even aware of doing it. On the other hand, everybody has experience of not being able to figure out where the words start and end when listening to unfamiliar foreign speech, and even with learning experience, correctly segmenting a stream of non-native speech into words and phrases often requires extensive exposure to the language and a considerable amount of practice.

Various kinds of information may be involved in the process of word segmentation: lexical/semantic cues (e.g., Gow and Gordon, 1995), syntactic/morphological cues (e.g., Sanders and Neville, 2000), phonotactic cues (e.g., McQueen, 1998), prosodic/rhythmic cues (e.g., Cutler and Norris, 1988), and allophonic acoustic-phonetic cues (e.g., Nakatani and Dukes, 1977). Native listeners are likely to utilize all these multiple cues available in natural speech for efficient word segmentation, and several cue-trading segmentation studies by native English listeners have been documented. For example, Gow and Gordon (1995) examined the interaction of acoustic-phonetic and lexical information on word segmentation and found that lexical contexts induced simultaneous access to words other than those intended by speakers (e.g., accessing *tulips* in addition to *two lips* when listening to *two lips*). Mattys *et al.* (2005) investigated how word stress cues interacted with conflicting other cues and found that stress information became a strong segmentation cue when acoustic-phonetic, phonotactic, or lexical information was not available. Their results also indicated that acoustic-phonetic and phonotactic information were secondary to lexical knowledge, suggesting that higher-order information outweighs sublexical cues. Mattys and Melhorn (2007) also examined the effects of sentential context, lexical knowledge, and acoustic-phonetic cues in connected speech and found compensatory mechanisms between them: The more ambiguous the acoustic-phonetic cues, the larger the effect of both sentential and lexical context on segmentation when listening to near-homophonous phrases (e.g., /plʌmpaɪ/for *plum pie* or *plump eye*). They also found that lexical effects reduced sensitivity to the acoustic-phonetic cues (e.g., favoring *scum pie* over **scump eye* even when it was acoustically more like **scump eye*), highlighting the graded, interactive, and flexible nature of multi-cue segmentation. The present study examined how non-native listeners process acoustic-phonetic segmentation cues present in L2 speech to perceive word boundaries when other types of cues are not available.

In a series of studies on the use of multiple segmentation cues, Sanders and co-workers compared strategies in segmenting English input used by monolingual native speakers of English (Sanders and Neville, 2000, 2003a) and by late L2 learners of English (Sanders *et al.*, 2002; Sanders and Neville, 2003b). The studies used behavioral as well as event-

[a]Electronic mail: kikuyoito@hotmail.com

related potential (ERP) measurements and focused on the interaction of lexical, syntactic, and stress-pattern cues. The behavioral results for English listeners confirmed that they exploited these cues in combination (Sanders and Neville, 2000) whereas native Japanese and native Spanish late learners did not use syntactic information to the same extent as native listeners did, although they exploited lexical information to a similar extent (Sanders *et al.*, 2002). The results also indicated that Japanese late learners as well as Japanese near monolinguals used the typical English stress cues for segmentation better than Spanish late learners did, suggesting that the extent to which a cue was used depended on the characteristics of their native languages. In the ERP experiments, native English listeners showed strong word-onset effects, suggesting that neither semantic nor syntactic information is necessary for word-onset identification (Sanders and Neville, 2003a). Japanese late learners' ERP data, on the other hand, only showed semantic processing effects without showing the word-onset effects nor the syntactic processing effects (Sanders and Neville, 2003b). These results indicated that non-native listeners were not processing the acoustic differences in the same way as native listeners.

While the research on the use of multiple segmentation cues has increasingly drawn attention recently, studies on individual segmentation cues have not been as well documented to date. The bulk of segmentation research dealing with individual cues has concentrated on examining the use of rhythmic information, especially in the area of cross-language research. (e.g., Mehler *et al.*, 1981; Cutler and Norris, 1988; Cutler and Butterfield, 1992; Otake *et al.*, 1993; Cutler *et al.*, 1986, 1992; Cutler and Otake, 1994; Bradley *et al.*, 1993; Goetry and Kolinsky, 2000). Although the research on rhythmic cues has made a significant contribution to our understanding of native and non-native word segmentation, studies on other individual cues have not been well explored yet. The present study contributes by investigating the use of allophonic acoustic-phonetic segmentation cues (*allophonic cues*, hereafter) for word juncture in American English (AE, hereafter): (a) presence/absence of aspirated voiceless stop consonants (aspirated in word-initial stops) and (b) presence/absence of glottal stops as cues to word onset (present before word-initial vowels).[1]

In studies on the use of allophonic segmentation cues by native listeners, researchers have found that the occurrence of allophones of the same phoneme can signal segmentation. Christie (1974) examined English listeners' perception of syllable boundaries by using synthetic stimuli and found that the aspiration of /t/ affected the perception of the boundary location whereas formant transitions had little or no effect on the boundary. Nakatani and Dukes (1977) examined English listeners' use of allophonic variations as segmentation cues, using spliced speech of near-homophonous phrases such as *no notion/known ocean* and *play taught/plate ought*. The authors found that glottal stops or laryngealization (creaky voice) at the onset of word-initial vowels, aspiration of voiceless stops, and syllable-initial vs -final /l/ and /r/ allophones were strong segmentation cues for AE listeners. They also found that duration differences of words caused by presence/absence of voiceless word-final consonants (e.g., *plate* in *plate ought* being longer than *play* in *play taught*) were not useful as a segmentation cue for native listeners. Church (1987) also argued from a computational linguistic viewpoint that the information provided by allophonic variations is useful for segmentation. He illustrated that the systematic distribution of allophonic variations, such as word-initial aspiration of stops, stop release, flapping, and palatalization in English, facilitates parsing speech segments by determining the location of syllables and stress.

Cross-language research on word segmentation dealing with allophonic cues is very limited. Altenberg (2005) investigated whether Spanish L2 learners of English could use English aspiration cues and glottal stop cues for segmentation in the same way as native listeners did, using an adapted version of the design by Nakatani and Dukes (1977). Participants were presented speech stimuli, such as *keeps talking* and *a nice man*, and were asked to indicate whether they heard *keep stalking* or *keeps talking*, and *a nice man* or *an ice man*. In these examples, the presence of aspiration in /t/ in *keeps talking*, which is absent in *stalking*, and the presence of glottal stop or creaky voice preceding *ice* in *an ice man*, which is absent in *nice*, provide strong segmentation cues for native speakers of English (Nakatani and Dukes, 1977; Altenberg, 2005). Altenberg (2005) found that Spanish listeners perceived the word boundaries significantly less accurately than English listeners did. She also found that Spanish listeners' performance on the aspiration pairs was significantly worse than that on the glottal stop pairs, while no differences were seen in the performance of native English speakers. Altenberg (2005) concluded that Spanish L2 learners of English were unable to fully use these allophonic cues available to native English listeners and suggested that various factors, including L1 transfer and markedness, may be responsible for greater ease or difficulty of utilizing particular L2 word segmentation cues. Further research is needed to see if the observed relative difficulties generalize to listeners of other languages and to explore the factors that may cause ease or difficulty in processing L2 allophonic segmentation cues.

The present study is an extension of the Altenberg study (2005) of aspiration and glottal stop segmentation cues. Japanese L2 learners of English served as experimental subjects with native English speakers as a control group. The distribution and the extent of aspiration of voiceless stops in Japanese are different from those in English and also different from those in Spanish. Japanese voiceless stops /p/, /t/, and /k/ are weakly aspirated in word-initial position but unaspirated elsewhere (Hattori, 1951; Vance, 1987). According to Homma (1980), the voice onset time (VOT) of Japanese word-initial /t/ is approximately 25 ms. Recently, Riney *et al.* (2007) measured VOT values of Japanese /p/, /t/, and /k/ produced in several consonant + vowel (CV) contexts and compared them with those of English /p/, /t/, and /k/ produced in equivalent conditions by monolingual AE speakers. The mean values of Japanese /p/, /t/, and /k/ were 30.0, 28.5, and 56.7 ms, respectively, whereas the corresponding AE VOT values were 78.2, 94.8, and 102.8 ms. As for the VOT values of Spanish initial voiceless stops, the Latin American Spanish data by Williams (1977) seem to be the closest approximation of the native VOT values for Alten-

berg's (2005) Spanish participants, who were primarily Dominicans, Mexicans, and Panamanians. In Williams' data (1977), the average VOT values of /p/, /t/, and /k/ in Guatemalan, Venezuelan, and Peruvian Spanish ranged from 9.8 to 15.2 ms, 10.3 to 20.6 ms, and 25.7 to 32.6 ms, respectively. Thus, since aspiration of voiceless stops in initial position appears to be longest in AE, shortest in Spanish, and of intermediate duration in Japanese, we can assume that allophonic differences between initial and non-initial voiceless stops are greatest for AE, least for Spanish, and intermediate for Japanese, assuming that values for noninitial stops are near zero VOT for all three languages.

Glottal stops in Japanese frequently occur in utterance-final position in emphatic speech (Bloch, 1950; Vance, 1987), and some researchers further argue that any utterance-final short vowel in Japanese is followed by a glottal stop (Kawakami, 1977; Vance, 1987). A glottal stop in Japanese generally appears before an utterance-initial vowel in emphatic speech (Vance, 1987) as well and it may appear even before a word-initial or phrase-initial vowel (Kawakami, 1977). Thus, in Japanese, glottal stops appear to assume a role as an utterance-, phrase-, or word-boundary marker. A glottal stop in Japanese can be realized as an allophonic variation of the moraic obstruent /Q/ (i.e., the first half of geminate consonants) as well. However, it cannot be confusable with the boundary-marking glottal stops because the moraic obstruent /Q/ cannot occur utterance finally nor immediately before a vowel. In Spanish, as with Japanese, a glottal stop can be inserted before a word-initial vowel, and after a word-final vowel in emphatic speech (Stockwell, *et al.*, 1956).

Thus, if ease or difficulty in using non-native segmentation cues is based on their use in the native language (i.e., L1 transfer), Japanese listeners in the present study would be expected to show better perception of aspiration cues than Spanish listeners (Altenberg, 2005), while showing similar performance on glottal stop cues. By examining the perception of Japanese listeners using the same lexical items as the Altenberg study (2005), the present study contributes new information on the use of allophonic cues for L2 word segmentation.

In this study a new native speaker of AE produced the materials, using the same instructions as were used in the original experiment. A control group of AE listeners was included to verify that the materials contained sufficient segmentation cues for natives to perform with near ceiling as did Altenberg's control group (2005). Detailed acoustic analysis was also conducted to document the multiple parameters that distinguished the stimulus pairs. Two additional testing procedures were added: (a) listeners' confidence ratings of their response choices, and (b) a follow-up familiarity rating test. The latter was used to establish whether the familiarity of members of the pairs differed systematically with respect to the presence/absence of aspiration/glottal stop cues to segmentation and to help in the interpretation of the results.[2]

The research questions in the present study were as follows.

(1) Is Japanese L2 listeners' use of English allophonic cues for word segmentation poorer than that of AE native listeners? It was expected that AE listeners would perform at ceiling, whereas Japanese listeners would perform significantly worse on both kinds of segmentation cues. However, in addition to group differences, establishing AE listeners' performance levels on the same materials allowed us to compare individual Japanese participants' performance against a native-speaker level of accuracy as a function of immersion experience.
(2) Are aspiration cues more difficult for Japanese listeners to utilize than glottal stop cues? Given the distribution of such cues in Japanese, we expected that performance on aspiration cues would be significantly poorer than performance on glottal stop cues. In addition, performance on presence vs absence of the cues was compared, given Altenberg's finding (2005) that the presence of aspiration and glottal stop cues provided more effective information than their absence.
(3) Does Japanese listeners' use of English allophonic cues improve with more experience in an English-speaking environment? Correlational analyses of immersion experience and performance on each type of segmentation cues were also employed to explore whether some cues take more immersion experience to learn than others.

II. METHODS

A. Participants

Thirty adult native speakers of Japanese living in the United States and a control group of ten adult native speakers of AE participated in the experiment. All participants passed a hearing screening (ANSI standards 25 dB HL at 500, 1 000, 2 000, and 4 000 Hz). Information about the Japanese participants, such as age, gender, length of residence (LOR) in English-speaking countries, which includes stays in the United States, Canada, United Kingdom, or Australia,[3] age of arrival (AOA) in English-speaking countries, and educational experience in English-speaking countries (immersion experience), was collected by means of a questionnaire. Since none of the Japanese participants came to English-speaking countries earlier than 15 years of age (AOA: 15–45 years of age), all Japanese participants were considered late learners of English. The information for the AE participants was also collected via a questionnaire. All AE participants had had experience in learning at least one of the following languages at school: Spanish, French, Italian, or Latin. None of them, however, had learned Japanese or any Asian languages in their lives. The age range and gender proportion of the AE group were matched to those of the Japanese group as closely as possible. Table I shows the information about the Japanese participants and the AE participants.

B. Stimulus materials

Eighty-four naturally produced stimuli that constitute forty-two stimulus pairs were recorded. The stimuli were identical to those used in the Altenberg (2005) study but were produced by a different speaker: a phonetically trained

TABLE I. Biographical information for AE participants and Japanese participants (age, gender, LOR, AOA, and immersion experience).

	American participants	Japanese participants
Sample size	10 (9 females, 1 male)	30 (26 females, 4 males)
Mean age (range)	31.2 years (26–38 yrs)	30.7 years (20–46 years)
Mean LOR[a] (range)		4.0 years (2 weeks–12 years)
Mean AOA[b] (range)		25.0 years (15–45 years)
Mean immersion experience[c] (range)		2.5 years (0–10 years)

[a]LOR=length of residence in English-speaking countries.
[b]AOA=age of arrival in English-speaking countries.
[c]Immersion experience=educational experience in English-speaking countries (includes experience at language school).

female native speaker of AE with a New York dialect. The stimuli were produced in the carrier phrase "Say__again." Following the procedure of the Altenberg study (2005), the speaker was instructed to speak naturally but at a slightly slower rate than usual to minimize the likelihood of listeners' performance errors (p. 336). Altenberg (2005) noted that care was taken to minimize the influence of lexical familiarity. The stimuli were selected from a larger set of 168 phrases (84 pairs) based on naturalness ratings by 7 native speakers of English "such that the naturalness rating of one member of the set (e.g., *keep stalking*) would be as close as possible to the naturalness rating of the other member of the set (e.g., *keeps talking*)" (p. 336). All stimuli were digitally recorded in a sound-attenuated room at 22.050 kHz, monaural, with 16 bit resolution, using a microphone (SHURE SM 48) fed through a preamplifier (Earthworks LAB 101) into the computer analog to digital sound card using SOUND FORGE 4.5 software.

The stimuli are subdivided into three types: 18 Aspiration stimulus pairs (36 phrases) in which presence or absence of aspiration of a voiceless-stop at a word boundary signals the boundary, 18 Glottal stop stimulus pairs (36 phrases) in which presence or absence of glottal stop or creaky voice signals the boundary, and 6 Double cue stimulus pairs (12 phrases) in which both presence or absence of aspiration and of glottal stop can be used as cues for segmentation.

Aspiration stimuli are further broken down into three groups: the stimuli that have a vowel before the /s/ at the juncture followed by a voiceless stop (VsC group; e.g., *loose tops/Lou stops*), the stimuli that have a consonant before the /s/ followed by a voiceless stop (CsC group; e.g., *keeps talking/keep stalking*), and the stimuli that have a consonant before the /s/ followed by a voiceless stop plus another consonant (CsCC group; e.g., *cook's prints/cook sprints*). Glottal stop stimuli are also broken down into three groups: the stimuli that have a nasal consonant at the juncture (Nasal group; e.g., *an itch/a niche*[4]), the stimuli that have an obstruent at the juncture (Obstruent group; e.g., *wife ill/why fill*), and the stimuli that have a liquid at the juncture (Liquid group; e.g., *I'll earn/I learn*). The stimuli with an aspiration cue are referred to as *Positive Aspiration stimuli* and those with a glottal stop cue as *Positive Glottal stop stimuli*. The stimuli without aspiration and those without glottal stop are referred to as *Negative Aspiration stimuli* and *Negative Glottal stop stimuli*, respectively. Double cue stimuli do not have subcategories. The items of each pair are either one of the following two types: *Aspiration-negative/Glottal-positive* (hereafter *Asp−/Glot+*) *stimuli*, which contain the glottal stop cue but no aspiration cue (e.g., *grape in*); or *Aspiration-positive/Glottal-negative* (hereafter *Asp+/Glot−*) *stimuli*, which contain the aspiration cue but no glottal stop cue (e.g., *grey pin*).

In addition to the 42 stimulus pairs, 6 extra stimulus pairs (12 stimuli) for familiarization trials were recorded by the same speaker. These stimulus pairs were taken from those used in Nakatani and Dukes, 1977, except for one stimulus pair (*ice cream/I scream*). All stimulus pairs, including those used in the familiarization trials, are presented in the Appendix.

C. Acoustic analysis

An acoustic analysis was carried out for all 84 items to detect any consistent acoustic cues that signal the word juncture in the stimuli, using the computer software MULTI-SPEECH. The critical area of the target phrase, including pre-boundary and post-boundary segments, was selected and displayed on the screen in waveforms and wideband spectrograms that were temporally aligned. The selected areas contained four to five phonemes (e.g., /ipstɔ/ in *keeps talking* and *keep stalking*). The analysis size of the spectrogram was set at 100 points (323.00 Hz) with a 0–5000 Hz display in Hamming window. The durations of distinct acoustic segments, such as silence period, frication, VOT, stop burst, and nasal murmur, were measured by placing cursors in reference to both waveform and spectrogram. Where successive segments were difficult to divide further, as in a sequence of an approximant and a vowel, it was treated as one unit to avoid inaccurate segmentation.

1. Aspiration stimuli

The left panel of Fig. 1 shows the durations of acoustic segments observed in Aspiration stimuli that were averaged across the subcategorized groups with positive and negative distinctions shown separately. The primary aspiration cue was quantified by measuring the duration of VOT, which was seen as noise between the onset of the stop burst and the first striation of the following vowel in the spectrogram. As predicted, the VOTs were distinctively longer in Positive (range 40–114 ms) stimuli than in Negative (range=0–53 ms)

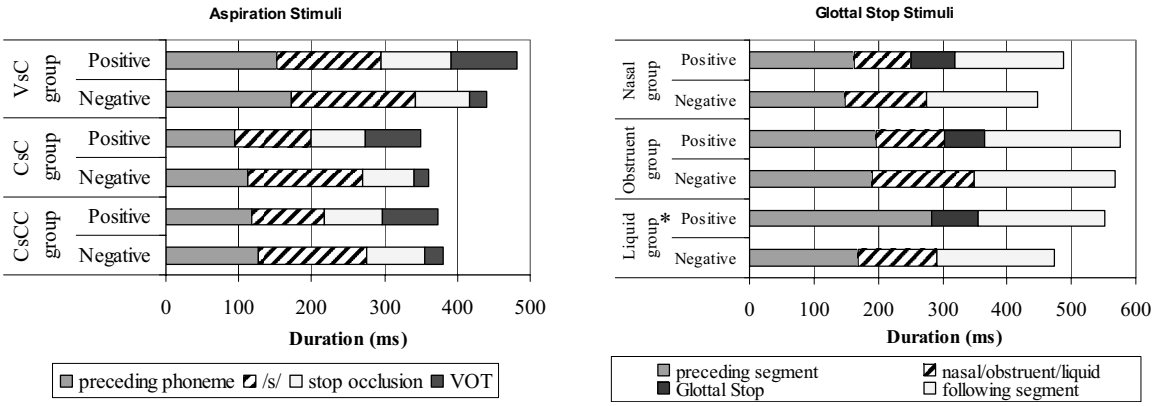

FIG. 1. Mean durations of acoustic segments: Aspiration stimuli (left panel) and Glottal stop stimuli (right panel). *In the positive stimuli of the Liquid group, the liquid segment was not distinguishable from the preceding segment. For this subgroup, preceding segment includes both the preceding segment as well as the liquid segment.

stimuli in all three subcategories, and the positive items were always longer than the negative counterparts (differences ranging from 22 to 95 ms). This difference was highly significant by a paired sample *t*-test (t [17]=12.17, $p<0.001$). In addition, the /s/ frication durations were noticeably shorter in the Positive than in the Negative stimuli (t [17]=5.92, $p<0.001$) and the preceding phonemes were slightly shorter in Positive stimuli than in Negative stimuli in all three subcategories (t [17]=2.46, $0.01<p<0.05$).

2. Glottal stop stimuli

The right panel of Fig. 1 shows the mean durations of acoustic segments in Glottal stop stimuli categorized in the same way as those in Aspiration stimuli. The most distinctive acoustic cue of Glottal stop stimuli, identified as glottal stop or creaky voice, was characterized by the silent gap or aperiodic sound preceding the word-initial vowel. None of the negative stimuli contained these cues. In Positive stimuli, there were two tokens, *an ice man* and *save amps*, that did not contain the glottal stop/creaky voice. They sounded potentially confusable with the negative counterparts, *a nice man* and *say vamps*, to the first author who was a native speaker of Japanese. However, two native speakers of AE judged them as the correct phrases and as sounding natural. Thus, these two tokens were kept as stimuli to see if native listeners were still able to correctly perceive them. The performance on these two tokens by the Japanese group and by the AE group is discussed in Sec. III B. Durational differences between positive and negative differences, including the two aberrant tokens, were statistically significant (t [17] =8.60, $p<0.001$).

It was also observed that the nasal murmurs in the Nasal group and the /f/ or /v/ frication in the Obstruent group were significantly shorter in Positive stimuli than in Negative stimuli (t [11]=3.15, $p<0.01$).[5] Furthermore, in the Liquid group, there was an obvious difference between Positive and Negative stimuli. While the liquid portion and the preceding vocalic part were distinguishable in spectrograms in negative stimuli (e.g., /l/ in *I learn*), they were not separable in the positive group (e.g., /l/ in *I'll earn*), due to their pronunciation as postvocalic allophones that are continuous with preceding vowel segments (vocalic [ɚ] and velarized [ɫ] in the above example). As a result, the "preceding segment" of positive stimuli in the Liquid group in the right panel of Fig. 1 includes the liquid part as well.

3. Double cue stimuli

As mentioned earlier, in Double cue stimuli, one type of item is characterized by the absence of aspiration and presence of glottal stop (*Asp−/Glot+ stimuli*), and the other by the presence of aspiration and absence of glottal stop (*Asp+/Glot− stimuli*). The acoustic analysis not only confirmed these acoustic characteristics but also suggested additional acoustic cues for word segmentation.

In Asp−/Glot+ stimuli, positive VOTs were not seen in either of the stimuli, and all stimuli contained silence or random noise that indicated glottal stop or creaky voice before the word-initial vowel with one exception, *light old*. In this particular token, there was a 108 ms of silence before the vowel, but the silence originated as a stop occlusion so it was not possible to judge whether a glottal stop was included in the silence or not. In addition to these expected acoustic cues, in Asp−/Glot+ stimuli with a bilabial or velar stop (i.e., *grape in, weep at, make art, like old*), 38–46 ms stop bursts were observed between the stop occlusion and the glottal stop/creaky voice, which can be a strong word juncture cue. In Asp+/Glot− stimuli, 105–122 ms VOTs, which were totally absent in Asp−/Glot+ stimuli, were observed, and no signs of glottal stop/creaky voice were seen. Additional possible juncture cues included shorter stop silences in Asp−/Glot+ stimuli (50–113 ms) than in Asp−/Glot+ stimuli (83–129 ms), except for the *light old/lie told* pair. Moreover, the segments preceding the stop occlusion in Asp −/Glot+ stimuli (117–339 ms) were always shorter than those in corresponding Asp−/Glot+ stimuli (152–410 ms).

4. Summary

Table II summarizes the acoustic cues confirmed by the acoustic analysis. The acoustic analysis revealed that the difference in VOT values was present as the most distinctive acoustic cue in Aspiration stimuli and further indicated that the duration of the /s/ frication, and possibly that of the preceding phoneme, may also signal the word juncture. For

TABLE II. Summary of acoustic cues for word juncture.

Stimulus type	Main cues	Secondary cues	Other cues
Aspiration stimuli			
Positive stimuli (e.g., *loose tops*)	Longer VOT	Shorter /s/ friction	Shorter preceding vocalic segment
Negative stimuli (e.g., *Lou stops*)	Shorter VOT	Longer /s/ frication	Longer preceding vocalic segment
Glottal stop stimuli			
Positive stimuli (e.g., *an itch, wife ill, seal of*)	Presence of glottal stop	• Shorter nasal murmur or /f/, /v/ frication • Post-vocalic /l/ or /r/	
Negative stimuli (e.g., *a niche, why fill, sea love*)	Absence of glottal stop	• Longer nasal murmur or /f/, /v/ frication • Pre-vocalic /l/ or /r/	
Double cue stimuli			
Asp−/Glot+ (e.g., *grape in*)	• Absence of +VOT • Presence of glottal stop	Stop burst of /p/ or /k/ (but not /t/)	• Shorter stop silence • Shorter preceding segment
Asp+/Glot− (e.g., *grey pin*)	• Presence of +VOT • Absence of glottal stop		• Longer stop silence • Longer preceding segment

Glottal stop stimuli, the clear difference of presence or absence of the glottal stop/creaky voice was the most reliable acoustic cue. The duration of the nasal murmur, or the /f/ or /v/ frication, was an additional cue for the word juncture. In the case of the Liquid group, the allophonic change of /r/ or /l/ suggested a strong cue for word juncture. For Double cue stimuli, the combination of the presence or absence of long VOT and glottal stop/creaky voice indicated strong juncture cues. In addition, the acoustic analysis suggested that the stop burst of /p/ or /k/ (but not /t/), the duration of the stop silence, and that of the preceding segment could also be juncture cues. The longer duration of frication, nasal murmur, and stop silence at word-initial position observed across all stimulus types correspond with the findings of the lengthening of word-initial consonants in early studies (e.g., Oller, 1973; Furgeron and Keating, 1997).

D. Procedures

The participants were tested individually in a sound-attenuated room in the Speech-Language-Hearing Sciences Department at the CUNY Graduate Center, using computer software, PARADIGM ID (written by Tagliaferri) in which participants responded by clicking on one of two response alternatives printed on the screen.[6] The experiment consisted of the main experiment and the familiarity questionnaire.

1. Main experiment

The stimuli were presented in random order, except that the members of each stimulus pair were separated by at least 15 other stimuli. The stimuli were presented binaurally through headphones (Telephonics TDH 39). The sound level was set in such a way that a 1000-Hz pure tone with the same amplitude as the median rms value of all stimuli was presented at 70 dB SPL. For each trial, the printed stimulus pair appeared on the computer screen approximately 1 s after the presentation of the auditory stimulus. One member of each stimulus pair on the screen always matched the auditory stimulus. Each pair was placed side by side and the position of the correct answer was randomized. Participants were informed by written instructions on the screen that they would hear two to three English words embedded in the sentence "Say__ again," and that they would be asked to click on one of the written alternatives that represented the speech stimulus. After choosing one member of the pair, they were asked to indicate how confident they were in their answer by clicking on one of the seven boxes corresponding to the seven levels of confidence rate (1=*not sure* to 7=*very confident*). They were specifically instructed that though some of the target phrases might sound awkward or unfamiliar, their choice should be based only on what they heard, not on the familiarity of the words. Participants responded to six sample stimulus pairs in the familiarization test before doing the main experiment.

2. Familiarity questionnaire

The main experiment was followed by the familiarity questionnaire that asked the participants whether one of each stimulus pair was more familiar than the other. The written stimulus pairs were presented on the screen without speech stimuli, and participants were asked to click on the member of the pair that was more familiar to them, or to click on *Same* when the two alternatives were equally familiar to them.

III. RESULTS

This section reports the results in the following order: (1) Japanese listeners' performance vs AE listeners as a group, (2) item analysis, and (3) correlation between Japanese listeners' LOR and performance. In the first part, the overall performance by the Japanese group, including their

TABLE III. Mean percent correct for each stimulus type (positive vs negative): japanese and AE subjects.

	American subjects (n=10)			Japanese subjects (n=30)		
Stimulus type	Mean	SD[a]	SE[b]	Mean	SD	SE
Aspiration (n=36) (e.g., Lou stops/loose tops)	95.8	4.4	1.46	73.1	9.4	1.74
Positive aspiration (n=18; e.g., loose tops)	98.3	3.7	1.25	73.5	15.5	2.88
Negative aspiration (n=18; e.g., Lou stops)	93.3	9.0	3.00	72.8	13.0	2.41
Glottal stop (n=36) (e.g., a niche/an itch)	96.9	1.6	0.53	91.3	6.2	1.15
Positive glottal stop (n=18; e.g., an itch)	98.9	2.3	0.78	95.9	7.0	1.30
Negative glottal stop (n=18; e.g., a niche)	95.0	3.2	1.05	86.7	11.5	2.13
Double cue (n=12) (e.g., grey pin/grape in)	99.2	2.6	0.88	93.6	7.8	1.45
Double cue (Asp−/Glot+) (n=6; e.g., grape in)	100.0	0.0	0.00	99.4	3.0	0.57
Double cue (Asp+/Glot−) (n=6; e.g., grey pin)	98.3	5.3	1.76	87.8	15.1	2.81
All stimuli (n=84)	96.8	2.1	0.70	83.8	5.7	1.06

[a]SD=standard deviation.
[b]SE=standard error.

performance on each stimulus type, is reported in relation to that of the AE group first, then the influence of the presence or absence of the acoustic cues (denoted as positive and negative) on the listeners' performance is reported. Furthermore, Japanese listeners' performance on the subcategories of each stimulus type with positive and negative distinctions is compared. The second part compares the most difficult items for Japanese listeners with those for AE listeners and also examines the performance on the items with irregular acoustic properties (e.g., the positive glottal stop items that do not contain glottal stop) by each language group. Furthermore, whether or not the confidence ratings showed close relations with the error rates of test items was investigated. In the third part, the correlation of the Japanese subjects' performance with their LOR in English-speaking countries is reported.

A. Comparisons of Japanese vs AE groups

1. Overall results and results on each stimulus type

The mean percentage of correct responses by Japanese and AE subjects for each stimulus type is presented in Table III. Nonparametric Median tests evaluated by chi-square were chosen for statistical analysis of the comparisons between the AE and Japanese groups because (a) the numbers of subjects in the two groups were different, and (b) the American group's performance showed ceiling effects. The AE group's performance was significantly higher overall than that of the Japanese group (χ^2 [1df]=12.06, $p<0.001$). Three separate Median tests were conducted to compare the performance on aspiration stimuli (χ^2 [1df]=12.06, $p<0.001$), on glottal stop stimuli (χ^2 [1df]=8.888, $p<0.01$), and on double cue stimuli (χ^2 [1df]=5.004, $p<0.05$). The AE group's performance was significantly better than that of the Japanese group for all three types of contrasts.

The data also show that the Japanese group was much less accurate on Aspiration stimuli (73.1%) than on Glottal stop stimuli (91.3%) or on Double cue stimuli (93.6%) while the AE group performed above 95% on all stimulus types. In addition, one can assume, from the Japanese group's rather high standard deviations (5.7–9.4) compared to those of the AE group (1.6–4.4), that Japanese subjects' performance was more variable than that of the AE group.

Since the AE group's performance was at or near ceiling on all stimulus types, within-group comparisons were performed only for the Japanese data. A nonparametric Friedman's test and Wilcoxon signed-ranks tests were chosen for examining differences in performance across stimulus types because of the unequal variances, skewed distributions, and ceiling effects seen in performance on Glottal stop and on Double cue stimuli. Friedman's test showed that Japanese listeners' performance differed significantly by stimulus types (χ^2 [2df]=46.41, $p<0.001$). Wilcoxon tests further revealed that their performance on Aspiration stimuli was significantly poorer than that on Glottal stop stimuli (z=4.62, $p<0.001$) and on Double cue stimuli (z=4.78, $p<0.01$), while the difference in performance on Glottal stop and Double cue stimuli did not reach significance (z=1.71, $p>0.05$).

2. Results on positive and negative stimuli

Table III also shows the mean percent correct responses by Japanese and AE subjects for Positive and Negative stimuli of each stimulus type. Since the AE group's performance was near ceiling on both Positive and Negative stimuli (though it appears to show slightly better perfor-

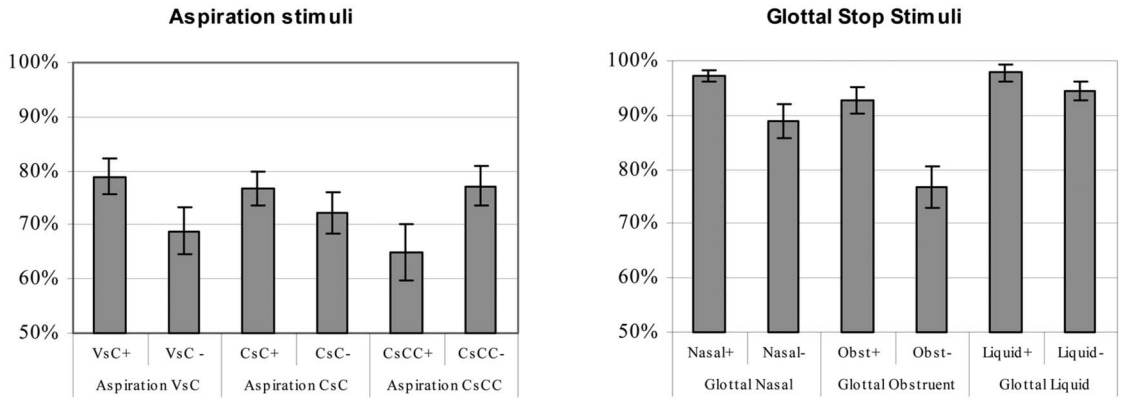

FIG. 2. Japanese listeners' mean percent correct: Aspiration stimuli (left panel) and Glottal stop stimuli (right panel). (Error bar = standard error.)

mance on Positive stimuli than Negative stimuli), statistical comparison between the performance on Positive and Negative stimuli was performed only for the Japanese data.

Wilcoxon signed-ranks tests revealed that Japanese listeners' performance on Positive and Negative stimuli did not differ significantly for Aspiration stimuli ($z=0.55$, $p>0.05$) whereas their performance did differ significantly for Glottal stop stimuli ($z=3.07$, $p<0.01$) and for Double cue stimuli ($z=3.30$, $p<0.01$). Regarding the perception of Glottal stop stimuli, Japanese listeners performed significantly better when the glottal stop cue was present than when it was absent. Their performance on Double cue stimuli also indicated that they performed better on the stimuli with a positive glottal stop cue without aspiration cue than on the stimuli with an aspiration cue but no glottal stop.

Figure 2 shows Japanese listeners' mean percentage of correct responses on subcategorized groups of Aspiration stimuli and Glottal stop stimuli. Here, again, the data for the subcategories of Glottal stop stimuli indicate that the negative stimuli of each subcategory, indicated by "−" in the graph, were always lower than the corresponding positive stimuli, indicated by "+" while those of Aspiration stimuli do not show obvious patterns of such tendencies.[7] Thus, Japanese listeners apparently did not utilize the presence/absence of aspiration cues effectively for word segmentation whereas they counted heavily on the presence of glottal stop cues as word juncture cues.

B. Item analysis

This section examines whether or not Japanese listeners and AE listeners made frequent errors on the same items and whether or not their confidence ratings reflected their difficulty in correctly perceiving the items. Figure 3 illustrates the relations between the error rate of each item and corresponding mean confidence rating by Japanese listeners (left panel) and by AE listeners (right panel) in scatter plots.

The items that were mistaken most by Japanese listeners were *keeps canning* (73.3% errors), *tops crawled* (60.0% errors), *keep stalking* (56.7% errors), and *Lou skis* (56.7% errors), and the items that were most error-inducing for AE listeners were *tea mat* (40% errors), *cook screams* (30% errors), *say vamps* (30% errors), and *cook sprints* (30% errors), showing no overlap of the most difficult items for the two groups. Furthermore, the error-prone items for Japanese listeners were all Aspiration stimuli whereas the error-prone items for AE listeners included both Glottal stop stimuli (*tea mat* and *say vamps*) and Aspiration stimuli (*cook screams* and *cook sprints*).

Although the error rates were not as high as for the items mentioned above, the Japanese group showed higher error rates on some of the items with irregular acoustic properties than on the other items in the same stimulus type. The AE group did not show such a tendency. The error rates of *an ice man* and *save amps*, which were categorized as Positive Glottal stop stimuli but did not have glottal stop/creaky voice, were 13.3% and 26.7%, respectively, for the Japanese group while the error rate for the rest of Positive Glottal stop stimuli was 1.7% on average. On the other hand, the AE group's error rate for *an ice man* was 0% and that for *save amps* was 10% (i.e., only one person answered incorrectly), showing no distinct difference from the mean error rate of the rest of Positive Glottal stop stimuli (0.6%). These results indicate the possibility that both Japanese and AE listeners were using acoustic cues other than glottal stop/creaky voice, although Japanese listeners were more disadvantaged by the lack of the glottal stop/creaky voice cue. For another irregular item *light old*, which was categorized into Double cue (Asp−/Glot+) stimuli but the glottal stop was not distinguishable from the stop silence, the error rate was 3.3% for the Japanese group and 0% for the AE group, showing no greater difficulty than the rest of Asp−/Glot+ stimuli by either the Japanese (6.1%) or by the AE (0%) group.

Spearman rank-order correlations were calculated to examine the relations between the confidence ratings and error rates for both Japanese and AE listeners.[8] The *rho* values were −0.778 for Japanese listeners and −0.377 for AE listen-

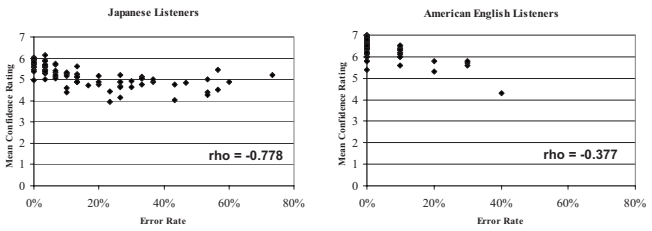

FIG. 3. Mean confidence rating and error rate by Japanese listeners (left panel) and by AE listeners (right panel).

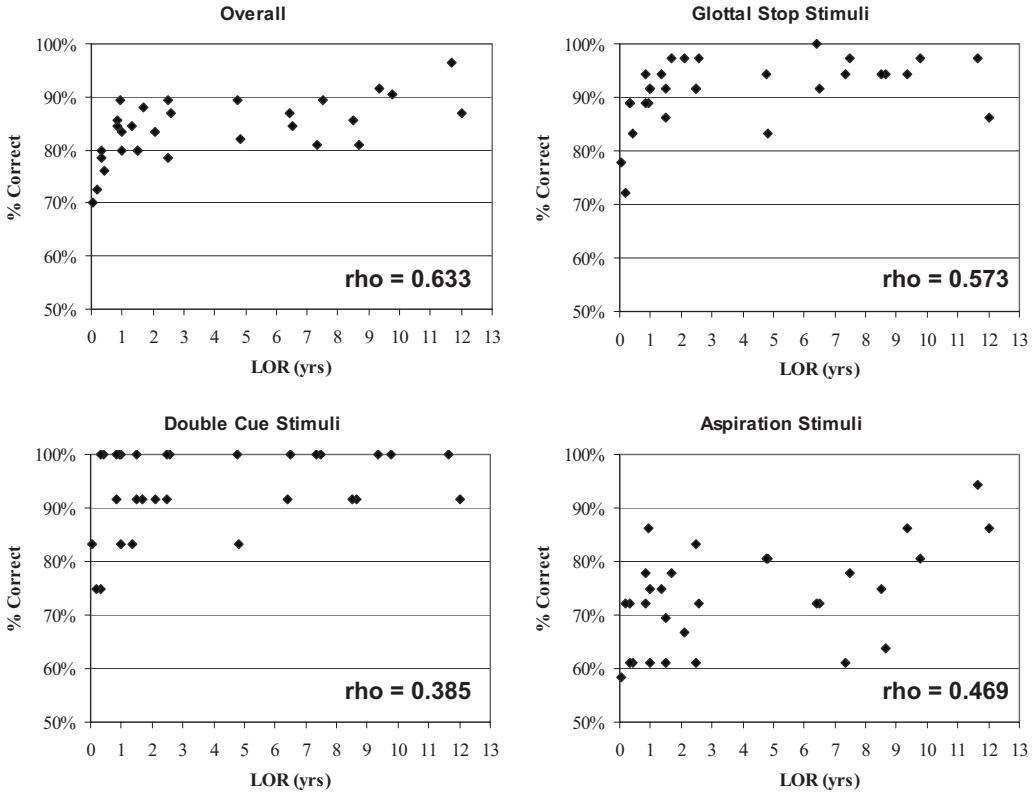

FIG. 4. Japanese listeners' LOR and performance: overall performance (top left panel), performance on Glottal stop stimuli (top right panel), on Double cue stimuli (bottom left panel), and on Aspiration stimuli (bottom right panel).

ers after the correction for tied ranks (Siegel and Castellan, 1988, p. 239). For the AE group, the correlation was limited by the large number of errorless scores (ceiling effects). For the Japanese group, the correlation was quite high, but the range in confidence ratings was limited, with relatively large variations across subjects in ratings for both easy and difficult items. The mean confidence ratings remained quite high even when more than half of the listeners answered incorrectly (see left panel of Fig. 3).

C. Correlation between Japanese listeners' LOR and performance

In order to investigate whether greater L2 experience was associated with listeners' better use of L2 acoustic-phonetic cues for word segmentation, Spearman rank-order correlations between Japanese listeners' LOR in English-speaking countries and their accuracy in the experiment were computed. Figure 4 illustrates the relation between their LOR and overall performance and those between LOR and performance on each of the three different stimulus types. All correlations were positive, although some were rather low, due to ceiling effects that restricted variability. Overall accuracy rates (top left panel) (rho=+0.633) increased rapidly over the first couple of years but flattened after that without reaching ceiling. However, performance seems to have increased again for participants with LOR of 9 years or greater. Performance on Glottal stop stimuli (top right panel) shows a similar tendency to that for overall performance (*rho*=+0.573), demonstrating a rapid increase in response accuracy in the first couple of years of LOR with rates near the ceiling after that. The correlations of LOR with performance on Double cue stimuli (bottom left panel) (*rho*=+0.385) and Aspiration stimuli (bottom right panel) (*rho*=+0.469) were lower than for overall performance and Glottal stop stimuli. Performance on Double cue stimuli showed ceiling effects because many subjects obtained perfect scores regardless of their LORs, although subjects with lower LOR varied more among themselves. For Aspiration stimuli, accuracy rates were widely distributed across LOR, although the subjects with more than 9 years of LOR tended to have higher scores than the rest of the subjects. Comparing these results with overall performance, it appears that the rapid overall improvement in the first few years of LOR is attributable to L2 listeners picking up on the glottal stop cue while the late improvement (i.e., the higher performance after 9 years of LOR) is due to their acquiring the ability to tap into the aspiration cue.

D. Effects of familiarity with phrases on Japanese listeners' performance

The results for the familiarity test for Aspiration stimulus pairs and Glottal stop stimulus pairs by Japanese listeners are summarized in Table IV. As can be seen, the numbers of more familiar items for Positive stimuli and for Negative stimuli in both Aspiration and Glottal stop stimuli were almost evenly distributed, showing no strong bias toward either Positive or Negative stimuli.

For Aspiration stimulus pairs, a tendency that may indicate response bias favoring more familiar items in perfor-

TABLE IV. Results of Japanese listeners' familiarity questionnaire.

Stimulus pair type	Familiarity answer	No. of pairs	No. of more familiar item better identified	Example (% correct in parentheses)
Aspiration stimulus pairs (18 pairs)	Positive item as more familiar	8	7/8 (87.5%)	*loose keys* vs *Lou skis* (90.0%) vs (43.3%)
	Negative item as more familiar	10	7/10 (70%)	*keep scanning* vs *keeps canning* (76.7%) vs (26.7%)
Glottal stop stimulus pairs (18 pairs)	Positive item as more familiar	10	9/10 (90%)	*grave at* vs *grey vat* (100%) vs (66.7%)
	Negative item as more familiar	8	0/8 (0%)	*we vend* vs *weave end* (80.0%) vs (93.3%)
Double cue stimulus pairs (6 pairs)	Asp−/Glot+ item as more familiar	3	2/3 (66.7%) (1 pair was both 100% correct)	*make art* vs *may cart* (100%) vs (73.3%)
	Asp+/Glot− item as more familiar	3	0/3 (0%)	*grey pin* vs *grape in* (73.3%) vs (100%)

mance was observed. The more familiar items tended to be better identified than their counterparts. Seven out of eight positive items and seven out of ten negative items that were chosen as more familiar had higher accuracy rates than the corresponding members of the pairs did. This means that Japanese listeners chose the more familiar items as the answers in the experiment significantly more often than their less familiar counterparts (14/18, significantly different from chance [$p<0.02$] by the binomial expansion). This tendency was not seen in Glottal stop stimulus pairs. In Glottal stop pairs, none of the more familiar negative items was identified more accurately than their positive counterparts while nine out of ten more familiar positive items were better identified than their negative counterparts. The better performance on Positive Glottal stop stimuli than on their negative counterparts, regardless of familiarity, indicates a lack of response bias for familiar items in identification of word onsets cued by glottal stops (9/18, not significantly different from chance). A similar pattern is seen in Double cue stimulus pairs. None of Asp+/Glot− items were better identified than their Asp−/Glot+ counterparts irrespective of their relative familiarity with their counterparts (2/6, not significantly different from chance). These results suggest that familiarity with words or phrases does not seriously affect how listeners segment speech when they can effectively use allophonic segmentation cues, but may affect segmentation when they cannot take advantage of the allophonic cues.

IV. DISCUSSION

This section summarizes the results of the study, offering answers to the three research questions presented in the Introduction, and then considers the limitations of the study and some directions for future studies.

A. Perceptual differences between Japanese and AE listeners

The results clearly indicated that Japanese L2 listeners, as a group, perceived English word boundaries more poorly than native AE listeners in many ways. First, Japanese listeners' overall performance was significantly worse than that of AE listeners, suggesting that Japanese listeners could not use the available cues as effectively as native listeners did. Second, Japanese listeners showed a significant difference in their performance on different stimulus types while AE listeners' performance was near ceiling on all stimulus types. Japanese performance on Aspiration stimuli was significantly worse than that on Glottal stop stimuli and on Double cue stimuli while the AE group's correct rates were consistently above 95%. Third, the items that were mistaken most by Japanese listeners and by AE listeners did not overlap. The four most error-prone items for Japanese listeners were all Aspiration stimuli, whereas those of AE listeners included both Glottal stop stimuli and Aspiration stimuli, implying different perceptual patterns by Japanese and AE listeners. Fourth, Japanese listeners seemed to have a poorer sense than AE listeners of how well they were able to perceive the word boundaries. The scatter plots of confidence ratings and correct performance showed that the Japanese listeners' confidence ratings did not decline much even when more than half of the listeners answered incorrectly, while the AE listeners' confidence ratings better reflected their error rates on the few items that were difficult. Finally, Japanese listeners seemed to be more disadvantaged than native AE listeners by the lack of the most distinctive acoustic cue for segmentation. Japanese listeners misperceived the word boundaries of the irregular Positive Glottal stop stimuli that did not have glottal stop/creaky voice more often than the stimuli with glottal stop/creaky voice present, while AE listeners did not show such a difference. These results suggest that when a reliable acoustic cue is absent, Japanese listeners are not capable of taking advantage of the remaining acoustic cues to the same extent as AE listeners. These results generally replicate those reported by Altenberg (2005) for Spanish late L2 learners of English on the same materials spoken by the different speaker.

B. Relative perceptual problems with different types of segmentation cues

Japanese listeners made significantly more errors on pairs differentiated by aspiration cues than they did on pairs differentiated by glottal stop cues. Furthermore, the data comparing Japanese listeners' performance on Positive and Negative stimuli within each stimulus type show that they performed significantly better when the glottal stop cues were present than when they were absent. However, the presence or absence of the aspiration cues did not significantly affect their performance. This pattern of results replicates those reported by Altenberg (2005) for Spanish L2 learners with the exception that her subjects showed better relative performance on both Positive Aspiration stimuli and Positive Glottal stop stimuli.

We can tentatively conclude that, independent of differences in the use of aspiration and glottal stops in the L1, aspiration cues (VOT and correlated duration parameters) are harder to learn by L2 learners than are glottal stop cues (and related parameters) for segmentation. In the course of discussing the cause of relative difficulty for Spanish listeners, Altenberg (2005) explored the concept of markedness as one of the possible factors. That is, "glottal stop insertion is less marked and hence easier to acquire than aspiration" (pp. 344–345). It has been observed by speech scientists that initiating phonation with a glottal stop (Borden *et al.*, 2003) and inserting a glottal stop at the boundary of abutting words ending and beginning with vowels (Kent and Read, 2002) are quite common by some speakers. Furthermore, glottal stop insertion at a word juncture preceding a word-initial vowel is commonly observed in many languages other than English, Japanese, and Spanish (e.g., Kohler, 1994; Rubach, 2000). Thus, it might have been the case that the less marked glottal insertion was learned more easily as a segmentation cue by Japanese listeners than the aspiration cue.

Another possible explanation may be related to the influence of the L1, or L1 transfer, as also suggested by Altenberg (2005). In comparing the pattern of relative difficulty across Japanese and Spanish listeners the two groups showed comparable performance on Glottal stop and Double cue stimuli, whereas Japanese listeners performed relatively better than Spanish listeners did on Aspiration stimuli (although worse than AE controls). This pattern of relative difficulty in utilizing aspiration cues corresponds to the extent of word-initial aspiration of voiceless stops in the three languages (AE > Japanese > Spanish), as discussed earlier. It has to be noted, however, that the data reported here and those of Altenberg (2005) are not completely suitable for comparison because of differences with regard to subject inclusion criteria. Altenberg (2005) tested college-level English as a second language students, whereas the present study included participants who ranged from those with almost no immersion experience to those with more than 10 years of immersion experience.

It is also useful to consider if constraints of L1 syllable structure affect Japanese listeners' L2 perception of word boundaries. Japanese syllable structure does not allow a consonant cluster within a syllable because the majority of Japanese syllables are CV syllables, with some exceptions of CVC syllables involving syllable-final moraic consonants (moraic final nasal and geminate consonants). If L1 syllable constraints influence the perception of L2 syllable patterns, therefore, one may predict that Japanese listeners would have more difficulty in segmenting words correctly as the consonant cluster at the word juncture in Aspiration stimuli became more complex. The results, however, did not show any obvious tendency. In the Aspiration stimuli, the consonant cluster at word juncture becomes more complex in the following order: VsC group, CsC group, and CsCC group. The mean accuracies on the above groups by Japanese listeners were 73.9%, 74.4%, and 71.1%, respectively, and did not differ from each other.[9]

Thus, the results regarding L1 transfer seem to be mixed. The relation between the degree of aspiration in L1 and that in L2 seems to suggest L1 transfer in perceiving L2 word boundaries whereas L1 syllable patterns do not seem to affect the perception of L2 syllable at word boundaries.

C. Relationship between immersion experience and use of allophonic cues

The positive relationships between Japanese listeners' performance and their LOR suggest that increased English experience does improve Japanese listeners' use of English allophonic cues. Their overall response accuracy increased as a function of their LOR, although it was not linearly related. A rapid difference in response accuracy across the first 1–3 years of LOR followed by a plateau was observed. Performance appeared to improve again after 9–10 years, although the sampling of participants with long LOR was limited. While Japanese listeners seem to learn to exploit glottal stop cues for English word segmentation within the first few years of residence, their mastery of aspiration cues may come much later. The pattern seen in the overall performance seems to reflect this "time lag" of learning different allophonic cues. These tendencies need to be followed up in future studies with larger numbers of participants with extensive immersion experience.

D. Other issues: Limitations and future studies

In addition to the findings related to the research questions, the present study suggested that familiarity with words or phrases may have affected Japanese listeners' responses in the experiment when they were not using the allophonic cues effectively. The results of the familiarity questionnaire revealed that for Aspiration stimuli, on which Japanese listeners performed significantly worse than the other types of stimuli, items that were chosen by Japanese listeners as more familiar had higher accuracy rates than the corresponding members of the pairs, indicating a response bias toward the familiar items. Since this tendency was not seen in Glottal stop stimuli, the results imply that familiarity with words or phrases affected performance only when Japanese listeners

could not fully use the acoustic-phonetic segmentation cues. This agrees with the finding reported by Mattys and Melhorn (2007) that lexical cues influence segmentation decisions when allophonic cues are ambiguous. Altenberg (2005) attempted to minimize lexical effects when constructing the stimuli; however, the present results suggest that it may not be possible to eliminate the effects of lexical bias completely from word segmentation studies of this kind. Future studies must take these effects into consideration when interpreting results.

As mentioned in the Introduction, cross-language research on L2 word segmentation is not extensive. There are fewer studies dealing with individual acoustic-phonetic cues than those examining rhythmic cues. The present study examined the use of only two of the many allophonic cues used in English word segmentation. Furthermore, the issue of coarticulatory effects across word boundaries, such as assimilation and deletion, which may cause significant changes in acoustic/phonetic properties of phonetic segments, has not been addressed sufficiently in L2 word segmentation studies, in spite of the fact that such coarticulatory variations commonly occur in connected speech. Future studies should examine these issues. In the process of L2 learning, non-native listeners must learn to perceive the distinctive segments (phoneme contrasts), the phonotactic patterns, and the allophonic variations of phonetic segments that serve as segmentation cues. Research on all aspects of L2 phonological learning will provide us with a better view of the problems associated with late language learning and guide our efforts to improve L2 language processing through intensive L2 training methods.

ACKNOWLEDGMENTS

We thank Evelyn Altenberg for her helpful comments and suggestions in preparing this manuscript. This research was supported in part by a grant to W.S. (NIH Grant No. DC00323).

APPENDIX: STIMULUS PAIRS USED IN THE EXPERIMENT [TAKEN FROM ALTENBERG (2005)]

ASPIRATION STIMULUS PAIRS

Positive stimuli	**Negative stimuli**
VsC group	
loose pills	Lou spills
loose tops	Lou stops
loose keys	Lou skis
lace peach	lay speech
lace table	lay stable
lace car	lay scar
CsC group	
keeps parking	keep sparking
keeps talking	keep stalking
keeps canning	keep scanning
chief's port	chief sport
chief's tar	chief star
chief's cool	chief school
CsCC group	
cook's prints	cook sprints
cook's truck	cook struck
cook's creams	cook screams
tops pry	top spry
tops trains	top strains
tops crawled	top scrawled

GLOTTAL STOP STIMULUS PAIRS

Positive stimuli	**Negative stimuli**
Nasal group	
seen either	see neither
an itch	a niche
an ice man	a nice man
seem able	see Mabel
team at	tea mat
claim annual	clay manual
Obstruent group	
wife ill	why fill
loaf ate	low fate
loaf ailing	low failing
grave at	grey vat
weave end	we vend
save amps	say vamps
Liquid group	
I'll earn	I learn
sail east	say least
seal of	see love
beer old	be rolled
cure ache	cue rake
beer ice	be rice

DOUBLE CUE STIMULUS PAIRS

Asp−/Glot+ Stimuli	**Asp+/Glot− Stimuli**
grape in	grey pin
weep at	we pat
light old	lie told
might owe	my toe
make art	may cart
like old	lie cold

Stimulus pairs used in the familiarization task [taken from Nakatani and Dukes (1977) except for *ice cream/I scream*]

ice cream/I scream	lawn chair/launch air
we'll own/we loan	stayed ill/stay dill
plate ought/play taught	no notion/known ocean

[1]Throughout this study, we will refer to these cues as aspiration cues and glottal stop cues, although an acoustic analysis of the stimuli revealed that there were other acoustic parameters that differentiated word-initial consonants and vowels.

[2]Although Altenberg (2005) selected the stimuli to minimize lexical influences on the experiment by using native speakers' naturalness rating, it cannot be ascertained whether L2 listeners' lexical bias contributed to the results. Altenberg (2005) reported that word frequency was not likely to affect the results by comparing the average frequency counts of words in

each stimulus type and the corresponding Spanish listeners' performance (pp. 348–349). In the present study, however, the familiarity test was designed for a more direct investigation of the possible correlation between participants' familiarity with words or phrases and their performance on the segmentation task.

[3]All Japanese participants were asked to report experience in staying in English-speaking countries only if it lasted for 1 month or longer, except for one participant who had come to the United States only 2 weeks before the test.

[4]Although it can also be pronounced as /niʃ/, the word *niche* was pronounced as /nɪtʃ/ in this experiment in order to make the phrase *a niche* nearly homophonous to the phrase *an itch*.

[5]The data for the Liquid group were not included in the statistic analysis because of the non-segmentability of the liquid portion in Positive stimuli.

[6]The original Altenberg experiment (2005) tested the participants in small groups in a quiet room with a fixed interval in which to respond on answer sheets.

[7]Wilcoxon signed-ranks tests showed that Japanese listeners' performance difference between Positive and Negative stimuli did not reach significance in any of subcategorized groups of Aspiration stimuli ($z=1.76$ for VsC group; $z=0.94$ for CsC group; $z=1.43$ for CsCC group).

[8]Because of the nonlinearity of the relationships, the non-parametric Spearman test that does not assume normal distribution or linearlity of the relationship was employed (Siegel and Castellan, 1988).

[9]Wilcoxon signed-ranks tests revealed that none of the Japanese listeners' performance differences between subcategorized groups of aspiration stimuli reached significance ($z=0.08$ for VsC vs CsC group; $z=1.09$ for VsC vs CsCC group; $z=1.13$ for CsC vs CsCC group).

Processing of fast speech by elderly listeners

Esther Janse[a)]
Utrecht Institute of Linguistics OTS and Max Planck Institute for Psycholinguistics Nijmegen, Janskerkhof 13, 3512 BL Utrecht, The Netherlands

(Received 8 April 2008; revised 21 January 2009; accepted 25 January 2009)

This study investigates the relative contributions of auditory and cognitive factors to the common finding that an increase in speech rate affects elderly listeners more than young listeners. Since a direct relation between non-auditory factors, such as age-related cognitive slowing, and fast speech performance has been difficult to demonstrate, the present study took an on-line, rather than off-line, approach and focused on processing time. Elderly and young listeners were presented with speech at two rates of time compression and were asked to detect pre-assigned target words as quickly as possible. A number of auditory and cognitive measures were entered in a statistical model as predictors of elderly participants' fast speech performance: hearing acuity, an information processing rate measure, and two measures of reading speed. The results showed that hearing loss played a primary role in explaining elderly listeners' increased difficulty with fast speech. However, non-auditory factors such as reading speed and the extent to which participants were affected by increased rate of presentation in a visual analog of the listening experiment also predicted fast speech performance differences among the elderly participants. These on-line results confirm that slowed information processing is indeed part of elderly listeners' problem keeping up with fast language. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3082117]

I. INTRODUCTION

When people age, listening to speech can become an effortful task. Frequent complaints of elderly listeners are that they have trouble listening to speech against a background of noise or competing speech, or that their interlocutors speak too fast, or do not articulate clearly enough. The high-frequency peripheral hearing loss typically found in a large sample of elderly people (Willott, 1991) can be held as the primary cause of the speech perception problems. Additional age-related causes are central auditory processing impairments and (general) cognitive decline (information processing speed or attentional problems). The central auditory problems have been reported to be caused by peripheral hearing loss: hearing loss can impair auditory functions as frequency and temporal resolution (Glasberg and Moore, 1986; Sommers and Humes, 1993; George *et al.*, 2007). Note, however, that there is also overlap between the "central auditory" and "cognitive" accounts (Jerger *et al.*, 1991). Either way, the central auditory account seems to be a bridge between whatever is received as auditory input and how it is processed. Humes (2005) noted, on the basis of data from a large group of elderly listeners, that performance on a battery of auditory processing measures was systematically related to individual differences in cognitive, rather than auditory, function. For recognition of time-compressed words, hearing loss accounted for the greatest part of the variance, but there was a significant correlation between (non-verbal) IQ and the ability to perceive time-compressed words as well. Similar relations between auditory processing impairments and higher cognitive-level impairments can be found in the domains of aphasia (Fink *et al.*, 2006) and dyslexia (Tallal, 1980; Wright *et al.*, 1997; Witton *et al.*, 1998, 2002; and Rosen, 2003 for an overview).

One approach to tease apart the relative contributions of age-related changes in hearing and cognitive factors to the increased problems elderly adults may have with speeded speech is to include several groups of listeners (Gordon-Salant and Fitzgibbons, 1993, 1995, 1999, 2001): young listeners with and without hearing loss and elderly listeners with and without hearing loss. In this way, the effects of aging and of hearing loss can be investigated separately. Younger adults with hearing loss also show substantial decrements in recognizing time-compressed speech compared to age-matched listeners with normal hearing. Gordon-Salant and Fitzgibbons (2001), Dubno *et al.* (1987), and Turner *et al.* (1997) attributed these problems to hearing impaired listeners' capacity to use brief acoustic cues. Nevertheless, Gordon-Salant and Fitzgibbons (1993, 2001) also showed that the problems in recognizing time-compressed speech that are attributed to age are independent of those attributed to hearing loss.

One other approach to evaluate the contribution of age-related hearing and cognitive factors to the increased problems elderly have with speeded speech is to speed up some parts of the signal more than others (Gordon-Salant and Fitzgibbons, 2001; Schneider *et al.*, 2005), or to allow listeners to "regain lost time" by introducing silent intervals at strategic points in the time-compressed speech material. In this latter way, listeners get time to catch up and process the information just presented at a high rate (Wingfield *et al.*, 1999). Even though allowing more time to catch up processing helped both elderly and young listeners, the elderly listeners, unlike the young, could not be brought back to base-

[a)]Electronic mail: E.Janse1@uu.nl

line (uncompressed) performance. These results could be taken to suggest that both auditory and cognitive factors contribute to elderly listeners' problems with fast speech. However, Schneider *et al.* (2005) argued for an auditory-only explanation, based on their results showing that the method of time compression matters. They referred to the findings of Gordon-Salant and Fitzgibbons (2001) that older adults find it especially difficult to deal with selective time compression of consonants because identification of consonants may depend on rapid formant transitions. Where most studies have used methods of time compression that involve removing speech segments without regard to their informational content, Schneider *et al.* (2005) used a selective method of time compression mainly affecting pauses or steady-state portions of vowels. This latter method of time compression thus presents the listener with a high rate of information content, while producing minimal acoustic distortion of the speech signal. If speech is speeded in such a selective way, elderly listeners are not affected more by an increase in rate than younger listeners (Schneider *et al.*, 2005). In this view then, an inability of the older adult's auditory system to cope with speed-induced stimulus degradation thus suffices to explain the problem, leaving little or no room for cognitive slowing.

Given the difficulty to pinpoint the role of central auditory processing problems, a third approach has tried to account for the age group × speed issue by investigating whether age-related cognitive slowing problems are modality-specific or not. In order to decide between central auditory and general cognitive explanations for elderly listeners' problems with fast speech, Humes *et al.* (2007) investigated whether cognitive processing is affected more in the auditory modality than in other modalities. Humes *et al.* (2007) compared speeded-speech performance to a visual text-based analog of their auditory test to investigate whether elderly participants were also more affected by increased presentation rate than younger participants when reading sentences. If amodal cognitive decline underlies performance on both reading and listening, performance should be strongly correlated because of this common underlying factor. Correlations across modalities had been found in people's ability to "fill up the gaps:" the results obtained with the text reception threshold test as an analog of the speech reception threshold test showed significant correlations between a participant's ability to identify auditory sentences in noise and written sentences masked by a bar pattern (Zekveld *et al.*, 2007; George *et al.*, 2007). As found by Zekveld *et al.* (2007), Humes *et al.* (2007) found correlations of performance for similar tasks across modalities. Importantly, however, with respect to presentation rate, Humes *et al.* (2007) found that older adults, regardless of hearing status, were more affected by the speeded speech than young adults, whereas there were no differences between groups regarding the effect of rate of visual presentation. This latter result agreed with results by Spehar *et al.* (2004) who found equal effects of speeding for older and younger adults in a test where words had to be identified on the basis of the visual signal only. The absence of a differential rate effect in reading for the elderly in Humes *et al.* (2007) is surprising given the claim that aging slows down the cumulative duration of all processes involved in visual word recognition (ranging from basic visual analysis of letter strings to activation of lexical presentations) with a factor of approximately 1.5 (Myerson *et al.*, 1992). Myerson *et al.* (1992) argued for this slowing factor on the basis of a meta-analysis of (visual) lexical decision studies. Since a similar performance ratio of older and younger adults had been found for naming studies (Balota and Duchek, 1988), Myerson *et al.* (1992) argued for general lexical slowing in aging. In other words, age not only affects sensory decoding of language (either in the auditory or visual domain) but also affects lexical activation patterns. Likewise, at the higher level of sentence comprehension, aging has been shown to delay semantic integration (Federmeier *et al.*, 2002, 2003). Nevertheless, studies on aging and speech perception have often focused on elderly listeners' greater use of sentence context as a means to compensate for their poorer hearing (Nittrouer and Boothroyd, 1990; Pichora-Fuller *et al.*, 1995; Sommers and Danielson, 1999). However, using context to fill up the gaps is a cognitive mechanism requiring mental resources (McCoy *et al.*, 2005). Thus, when we aim to investigate the *relative* contributions of hearing and cognitive factors to elderly adults' problem of keeping up with a fast rate of speech, allowing elderly participants unlimited time to come up with a response may blur our conception of why perceptual processing itself has become more effortful and on why (cognitive) repair strategies are necessary.

Summing up, the literature overview above shows that it has been relatively difficult to establish which factors determine one's ability to keep up with a fast speech rate. The role of (peripheral) auditory decline seems relatively clear: having to decode an impoverished speech signal requires more time and effort, which becomes all the more problematic when speech rate is fast. However, the direct relation between non-auditory factors, such as cognitive slowing, and fast speech performance has been much more difficult to demonstrate. In order to obtain a better understanding of elderly listeners' increased difficulty with time-compressed speech, the present study took an on-line approach. Rather than focusing on the outcome of the recognition process (in terms of recall or correct identification of sentences), the present study focuses on speech processing itself. Investigating just the result of speech processing might obscure which processes led to this result. Particularly if decreased information processing rate is one of the potential underlying causes, it makes sense to tap into speech processing as the speech signal unfolds and to look at processing time, in combination with the result of processing.

Therefore, in the present study, an on-line speech processing approach was chosen to investigate how quickly listeners would be able to detect target words in running speech. Elderly and young listeners were presented with fast speech at two rates of time compression and were asked to detect pre-assigned target words as quickly as possible. An age group × speed interaction was anticipated. The aim of the present study was to establish, within the group of elderly listeners, which factors (and to what extent) determine an individual elderly adult's ability to keep up with a fast speech rate. To this end, elderly listeners were recruited with

varying amounts of (age-induced) hearing loss. It was established how well individual hearing acuity and a number of non-auditory measures each predict elderly participants' word detection performance. The non-auditory measures involved a general measure of information processing speed [the digit symbol substitution (DSS) task] and two measures of the elderly participants' reading speed. Importantly, a number of studies have failed to find a link between elderly listeners' speech performance in taxing conditions and DSS score (Tun, 1998; Sommers and Danielson, 1999), thus challenging the impact of age-related general slowing on speech processing. This failure to find a relation might be due to the fact that most studies have used relatively short sentences (often from the revised sentence perception in noise materials) and have allowed listeners' unlimited response time to reproduce the presented sentence. The present focus on processing time may clarify whether general information processing speed, as measured by DSS performance, predicts fast speech performance in elderly participants.

Individual reading performance, as a measure of information processing rate specific to *language*, was expected to be a better predictor of fast speech performance than the more general DSS measure. If activation of lexical representations is slowed by age (due to general cognitive slowing), this should show up as a differential effect of increased rate of presentation on *reading* performance of the elderly participants as well (an age group × speed interaction in reading). Two complementary measures of individual reading speed were selected to investigate which measure was a better predictor of one's difficulty keeping up with fast speech rates: either self-preferred reading rate (in a self-paced reading experiment) or a measure of the effect of increased rate in a word detection study in which two fast reading rates were imposed on the participants. This latter word detection experiment was a visual analog of the word detection study with fast speech: similar compression rates were used in the two sensory modalities (listening and reading) to investigate whether there would be a shared underlying component in the effect of increased speed. In both reading studies (visual word detection and self-paced reading), presentation of sentences was done in a word-by-word fashion to make reading more like listening with respect to the transient nature of speech. Obviously, word-by-word reading is far from normal or typical reading where readers are able to look back and look ahead. Nevertheless, word-by-word reading resembles speech processing more than a more typical way of reading where all words are present at the same time.

The present study was set up to test the hypothesis that both auditory and non-auditory measures predict elderly listeners' relative difficulty with fast speech rates. Hearing acuity may be the most important one in determining individual difficulty in keeping up with fast rates of speech. However, measures of general cognitive slowing and of reading rate were also expected to be significant predictors of how well one can keep up with fast rates of speech. In other words, this on-line study was expected to show that non-auditory measures indeed contribute to elderly listeners' difficulty in keeping up with fast speech rates.

II. AUDITORY WORD DETECTION STUDY

A. Time compression

In line with many previous studies on fast speech and aging (Tun *et al.*, 1992; Gordon-Salant and Fitzgibbons, 1993, 1995, 1999, 2001; Vaughan and Letowski, 1997; Tun, 1998; Wingfield *et al.*, 1999; Schneider *et al.*, 2005), the present study focuses on artificially time-compressed speech, and not on naturally produced fast speech. The motivation for this choice is that artificial speeding leaves articulation clarity intact, whereas in naturally produced fast speech, higher rates are (almost inevitably) accompanied by greater slurring. Given that naturally produced fast speech was shown to be less intelligible than artificially time-compressed speech (Janse, 2004), and given the literature on "speaking clearly for the hard of hearing" (Picheny *et al.*, 1985, 1986, 1989; Uchanski *et al.*, 1996), artificially speeded speech was used to avoid further complication from slurred or unclear speech.

As mentioned in the Introduction, Schneider *et al.* (2005) attributed elderly listeners' problems with time-compressed speech mainly to their inability to cope with the acoustic artifacts of the time-compression technique used in most studies. They concluded this on the basis of a comparison between the sampling technique (in which short, e.g., 10-ms, segments are deleted periodically) and a more refined technique in which only steady-state portions of the signal were removed (i.e., pauses or gaps between words or portions of steady-state vowels). However, if no age differences are found with the more refined technique of time compression, this could be due either to the absence of acoustic artifacts in, e.g., consonant transitions (as argued by Schneider *et al.*, 2005) or by the non-linear (and thus less severe) way of speeding the sentence. Compressing pauses more than the remaining speech is a form of non-linear time compression that will always lead to better intelligibility than can be obtained with linear compression because the speech itself is less compressed (Janse, 2003, and compare the results obtained with time-compression algorithm Mach 1; Covell *et al.*, 1998). The results of the study of Schneider *et al.* (2005) do not rule out the possibility that an age × speed interaction may be found in terms of perceptual effort, or at more taxing time-compression rates.

The present study compares two methods of time compression: the sampling method as a rather crude method of deleting speech material that involves audible artifacts and the pitch-synchronous-overlap-add (PSOLA) method. PSOLA (Moulines and Charpentier, 1990), because of its high-quality time-scale manipulation, has become the technique incorporated in most speech editing programs (COOLEDIT, PRAAT, and AUDACITY). First, a pitch detection algorithm places markers at consecutive pitch periods (also in the unvoiced portions). The signal is decomposed into separate but overlapping (Hanning) windows, with window maxima at each pitch mark location. Window length is usually twice the length of one pitch period (yielding overlap in consecutive windows). Time compression is accomplished by deleting pitch periods. The crucial asset of PSOLA time compression is that in constructing the new waveform, the

speech signal of one descending window ramp is added to that of the next ascending window ramp (with, e.g., one intervening window deleted). This means that the information contained in the deleted pitch period is averaged across now overlapping windows, thus avoiding discontinuities and spectral jumps (cf. also Letowski and Poch, 1996 and Vaughan and Letowski, 1997) and thus avoiding nasty acoustic artifacts. Any acoustic distortion can be anticipated to be more detrimental the poorer the hearing level of the listener. Inclusion of these two methods of time compression provides a comparison of their perceptual consequences for elderly listeners. Importantly, time compression was applied linearly with both time-compression techniques: the two techniques differed in whether or not they involved audible discontinuities.

Two rates of time compression were chosen: 1.5 times the original rate (compression to 67%) and 2 times the original rate (compression to 50%). These two rates were chosen on the basis of the results of a pilot listening experiment with elderly listeners. Since this pilot group of listeners, having a mean age of 80 years, hardly thought the experimental task challenging when the materials were presented at 1.5 times the normal rate, and since mean age was expected to be lower for the elderly participants in the present experiment, the 1.5 times normal-rate condition formed the baseline condition against which the fastest rate (2 times normal rate) could be compared.

Time compression was achieved by applying either PSOLA or sampling compression to the original speech materials in the sound-editing software package PRAAT. The sampling version of the 1.5 times rate condition (67%) was made by deleting every third 10-s fragment. The sampling version of the 2 times normal-rate condition (50%) was achieved by deleting every other 10-ms fragment. The sampling method yielded an audibly discontinuous sound, due to waveform discontinuities and spectral jumps at points at which now adjacent fragments were joined.

B. Participants

The elderly participants were recruited via *Hoger Onderwijs Voor Ouderen* ("Higher Education for the Elderly"): an organization linked to several universities in the Netherlands that provides academic courses (on a variety of topics) for people of over 55 years of age. People who had subscribed for a course received an information letter in which they were asked to participate in the study. Given the academic level of the courses, the elderly group was a good match to the young (student) group in terms of education level.

There were 40 elderly participants, aged between 65 and 84, with a mean age of 70 (SE=0.7). Of the elderly participants, 18 held a university degree and 12 had finished a college of higher education (polytechnic). The 20 young participants were all students of Utrecht University (aged between 17 and 26, with a mean age of 21). All participants were native speakers of Dutch and they all received a small payment (students) or present (elderly) for their participation.

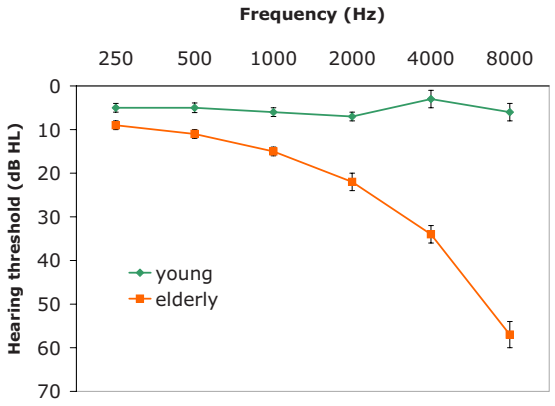

FIG. 1. (Color online) Mean pure-tone thresholds (better ear) for both age groups. Error bars reflect one standard error.

Some of the elderly participants had a hearing aid (only 4 out of 40). They were asked to remove it when participating in the listening experiment. Hearing levels of all participants were measured with a portable Maico ST20 audiometer in a silent booth of the Utrecht Institute of Linguistics Phonetics Laboratory. Figure 1 displays the mean threshold values (in decibels) measured in the better ear for both age groups.

Visual acuity was important in all studies because participants had to read target words from the computer screen (in both tested modalities). Obviously, visual acuity was particularly important in the two reading studies. Participants were asked to bring their glasses to the laboratory, if they had any, particularly the glasses they would use for looking at a computer screen. No further test was administered to measure participants' visual acuity. Large and easily legible fonts were used to minimize the chance that any subtle visual acuity differences affected the results. All participants also performed the DSS test (subpart of the Wechsler Adult Intelligence Test, 2004). Scores on the DSS test have been shown to exhibit strong correlations with measures involving perceptual speed or processing speed (Salthouse, 2000; Hoyer *et al.*, 2004). Mean substitution time needed per symbol was 1.83 s/symbol (SE=0.06) for the elderly and 1.35 s/symbol (SE=0.03) for the young participants. This should be corrected for motor speed (writing time), which was 0.93 s/symbol (SE=0.06) for the elderly and 0.71 s/symbol (SE =0.03) for the young participants. The corrected coding time (substitution time minus writing time) was then 0.90 s/symbol (SE=0.05) for the elderly and 0.64 s/symbol (SE =0.04) for the young participants.

Vocabulary knowledge of all participants was tested by way of the vocabulary subpart of the Groningen Intelligentie Test (Luteijn and van der Ploeg, 1983). Out of 20 multiple choice synonym questions, mean score correct was 18 (SE =0.2) for the elderly and 15 for the young (SE=0.4) participants. Better vocabulary scores for the elderly are often found in studies in which these two age groups are compared.

C. Material

The four conditions (two rates × two compression types) were distributed over 120 test sentences according to a Latin

square design. This design required four different stimulus lists to which the participants were randomly assigned.

The Dutch language material consisted of 120 disyllabic nouns as targets for detection: 60 with lexical stress on the initial and 60 with stress on the final syllable. The targets were embedded in sentences that varied from 7 to 15 words in length. The sentences were news bulletin sentences that were changed such that the noun would fit the sentence. The target words were possible but not fully predictable continuations of the sentence, e.g., *He did not pay enough attention to the traffic around him*, and *But there too the supply was increasingly more extensive and expensive* (target words underlined). The target's position in the sentence ranged from the second word in the sentence to the last word. Position in the sentence was not manipulated systematically. Additionally, the sentence materials comprised 60 overlap filler sentences in which the target had word-initial phoneme overlap with one of the words in the sentence (e.g., target being *cirkel* "circle" and sentence contains the word *circus*). There were also 40 miss filler sentences in which the target simply did not occur. One young male native speaker of Dutch read out all the materials at a normal speech rate (mean rate was 5.7 syllable/s). He was asked to place a sentence accent on the target word in the target sentences. The recording was made with an Audio-Technica AT 8410 microphone on a digital audio tape. All sentences were stored as separate files and downsampled to 32 kHz. Overall loudness of the audio files was equalized to 72 dB. Time compression was applied to the original recordings as discussed in Sec. II A.

D. Procedure

Testing was done in the Utrecht Institute of Linguistics Phonetics Laboratory in silent booths. Participants first performed the auditory word detection experiment. Then the diagnostic part was administered: the audiogram, the DSS test, and the vocabulary test. Then there was a short break after which they participated in the reading (word detection) experiment. Lastly, they performed the self-paced reading test.

In the auditory word detection study, the target words were presented visually in a large black font (Helvetica 80) on the computer screen 1200 ms before the auditory sentence started. The black target word was centered on the computer screen against a light gray background and remained on the screen during sentence presentation. Participants were instructed to respond as fast and as accurately as possible once they detected the pre-assigned visual target in the auditory sentence by pressing a button on the button box (with their dominant hand). Following sentence offset, participants still had 2 s to respond if they had not already done so, before the new visual target for the next sentence was presented. None of the participants reported feeling rushed by the pace of the experiment.

The auditory materials were presented binaurally over closed headphones (Beyer Dynamic DT 250) at a mean level of 81 dB SPL (for all listeners). Listeners were first presented with a practice part after which they could still ask questions if anything was unclear. They were then presented with the material, blocked by speech rate (first the sentences at 1.5 times the original rate, then the even faster sentences). Within each speech rate block, items made with either type of compression were presented in random order. Order of presentation of test and filler sentences was randomized for each participant.

As a check whether participants had actually paid attention to the content of the sentences, a sentence recognition test was administered to them immediately after the listening study. Participants were presented with a list of 16 sentences: 8 of which had been presented in the listening study and 8 similar sentences which had not been presented. They were asked to tick the sentences they thought they had just heard. Elderly participants on average correctly remembered 6.1 (SE=0.2) out of 8 sentences; the young participants had an average score of 5.75 (SE=0.2). The mean number of falsely recognized sentences was 0.58 (SE=0.1) out of 8 for the elderly and 0.20 (SE=0.1) for the young participants.

TABLE I. Correct word detection rates in the different conditions for both age groups.

	Compressed to 1.5×normal rate (67%)		Compressed to 2×normal rate (50%)	
	PSOLA	Sampling	PSOLA	Sampling
Young	99	100	99	98
Elderly	100	100	98	92

E. Results

The overall aim of the present study was to investigate, within a group of elderly listeners, which auditory and nonauditory measures determine one's ability to keep up with a fast speech rate. Before the results of the listening study will be related to background measures and performance in the reading experiments, the results of the listening study are presented and discussed as such for the two age groups to show that the increased speech rate indeed affected the elderly listeners more than the young listeners. Thus, an age group×rate interaction was anticipated. Furthermore, an age group×compression type interaction was anticipated: the type of time compression involving acoustic artifacts was expected to be more detrimental for the elderly listeners given their generally poorer hearing level.

A word detection response was counted as correct when the participant had pressed the button after target onset (and before the time out). Responses that were given within 200 ms from target onset were also excluded (for the young listeners this last criterion excluded 8 out of 2379 observations and 2 out of 4667 observations for the elderly listeners). In Table I, correct detection rates of both participant groups are given for the different test conditions.

Table I shows that correct detection rates were always higher than 92%. False response rates to the overlap fillers were 5% and 4% in the elderly listener group at the fast (1.5 times normal rate) and fastest rate of speech (2 times normal rate), respectively. False response rate to the filler sentences which did not contain a word related to the target (the miss

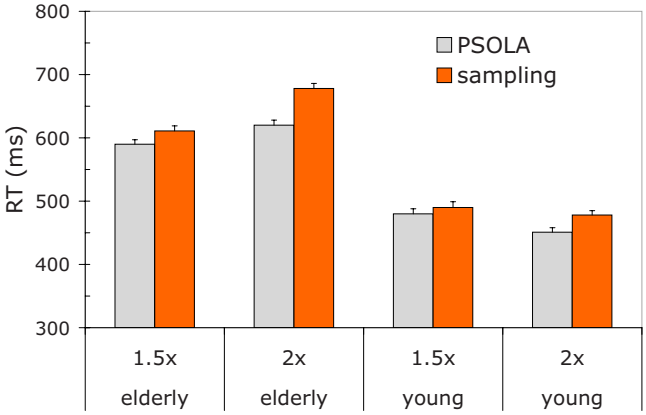

FIG. 2. (Color online) Mean response time (from target word onset) in the different rate conditions for both age groups. Error bars reflect standard errors.

condition) was 1% at both compression rates. False response rates for the young listeners were somewhat higher: 10% at both compression rates for the overlap fillers and 5% at both rates in the miss condition. These hit and false alarm rates indicate that the elderly listeners did not press the button randomly, nor did the younger listeners: collapsed over rates and conditions, d' (correct hits, relative to false alarms in overlap and miss conditions) for the elderly listeners was 3.73 and 4.50 for the young listeners.

Detection time was measured from target word onset. Mean average detection time in the different conditions is presented in Fig. 2.

The correct *RT* observations ($N=7036$) were logtransformed. Rather than by means of two analyses of variance, one having participants as a random effect and one with items as a random effect, mixed-effect modeling was used to analyze the data. The mixed-effect method allows one to acknowledge that multiple crossed random factors (participants and items) affect performance in psycholinguistic designs as the one used here (Pinheiro and Bates, 2000). Similar mixed-effect approaches were taken in acoustic measurement studies of speech corpus data in which speaker and item are multiple random factors (Pluymaekers *et al.*, 2005; Ernestus *et al.*, 2006; Quené, 2008). Mixed-effect modeling is argued to be superior to repeated measures or univariate analysis of variance (ANOVA) in a number of tutorial articles (Baayen *et al.*, 2002; Quené and van den Bergh, 2004, 2008; Baayen *et al.*, 2008).

The log *RT* data were analyzed here to test for the effects of age group, rate, compression type (PSOLA/sampling), and stress position and possible interactions between them. For all significant effects and interactions, estimated coefficients (β's), with standard errors for β in brackets, and p-values are reported.[1] The results showed a main effect of age group [estimated coefficient $=0.092(0.029)$, $p<0.001$]: the elderly participants were generally slower than the young. There was a main effect of rate [$\beta=-0.025(0.009)$, $p<0.005$], and more importantly, there was a significant age×rate interaction [$\beta=0.045(0.010)$, $p<0.001$]. As can be seen in Fig. 2, whereas the young listeners responded faster in the 2 times normal-rate condition than in the 1.5 times normal-rate condition, the reverse is true for the elderly. It is important to note that if one measures *RT*'s from target word *offset*, rather than from target *onset*, all participants have increased *RT*'s when speech rate is increased further (measured from target word offset, and collapsed over compression types, the young participants have a mean *RT* of 199 ms in the 1.5 times normal rate and 249 ms in the 2 times normal-rate condition, whereas the elderly participants go from 314 to 432 ms in the fastest condition). There was no overall effect of compression type [$\beta=0.003(0.009)$, *n.s.*]. However, there was a significant interaction between rate and compression type [$\beta=0.030(0.012)$, $p<0.05$]: the *RT* advantage of PSOLA over the sampling method was larger at the fastest (2 times original) rate than at the intermediate rate (1.5 times original). However, there was no interaction between age and compression type, nor a three-way interaction between age, compression type, and rate. Lastly, the effect of stress position of the target items was not significant overall, nor its interaction with age group [$\beta=-0.014(0.010)$, *n.s.*].

A very similar pattern of significant main effects and interactions was found when *RT* results were analyzed from target offset, rather than from target onset.

Accuracy of the responses in the different conditions was analyzed as well (note that accuracy was high overall). This was done with mixed-effect modeling for binomial data (responses being either correct or false). Quené and van den Bergh (2008) showed that mixed-effect logistic models provide a more conservative and appropriate method to analyze binomial data than the traditional practice of computing proportions correct over subjects or items. The effects of age group, rate, compression type, and stress position were tested and their interactions (estimated coefficients are reported, with their standard errors in brackets, and p-values). The mixed-effect model showed a significant effect of age group [the elderly having lower hit rates than the young: $\beta=-1.439(0.382)$, $p<0.001$]. The main effect of rate [$\beta=-1.954(0.503)$, $p<0.001$] was significant: detection accuracy was decreased at the fastest speech rate. There was no main effect of compression type [$\beta=0.160(0.673)$, *n.s.*], but the interaction between rate and compression type was significant [$\beta=-1.771(0.714)$, $p<0.05$]. Performance of both age groups was more affected by the acoustic artifact at the faster than at the intermediate (1.5 times normal) rate of speech. None of the other effects or interactions (including the interaction between age group and rate) was significant.

Thus, in the detection rate analysis and in the response time analysis, the effect of compression type was more disrupting at the faster rates, and this was found for both age groups.

The two reading studies will now be presented first, before the fast speech results are related to reading performance and to the background measures.

III. VISUAL WORD DETECTION STUDY

A. Participants

The participants in the two reading studies (visual word detection study and self-paced reading) were the same as

those who participated in the listening study. Due to technical failure during one test session, reading performance of 1 of the 40 elderly participants who had completed the listening experiment was not available. The results reported below are based on performance of 40 elderly listeners (thus, one replacement participant was included from the same elderly group).

B. Materials

One major complication in comparing rate in the auditory and visual modalities is that auditory presentation rate can always be related to "normal" or original speech rate: the rate at which the speaker uttered the sentence. In the visual modality, normal reading rate is up to each individual reader. On the basis of several studies on reading performance of elderly adults with sequential (word-by-word) presentation methods (Stine, 1990; Speranza *et al.*, 2000; Hartley *et al.*, 1994), normal presentation duration was estimated to be 400 ms per word. This estimation was on the safe side since this rate was to be speeded up.

The visual word detection study had an analogous set-up and similar sentence materials as the auditory word detection study. Sixty bisyllabic target words, always morphologically simplex nouns, were embedded in sentences in which they were not completely predictable from the sentence context. As in the listening experiment, half of the target items had initial stress; the other half had final stress. The sentence material was presented word-by-word: each individual word was displayed on the screen equally long. Given that normal reading rate was estimated to be 400 ms per word, the two rate conditions were made by speeding up presentation duration to 267 (67% rate condition) or 200 ms (50% rate condition) per word. Sentences were 8–19 words long. None of the words in the sentences had more than 12 letters. The two presentation rate conditions were distributed over the 60 test sentences according to a Latin square design. This design required two different stimulus lists to which participants were randomly assigned.

As in the auditory experiment, there were also filler trials: overlap fillers containing a noun that showed word-initial overlap with the target noun and miss fillers not containing a word that (partly) matched the target. The ratio of overlap and miss fillers to test sentences was identical to that in the auditory experiment: in addition to the 60 test sentences, there were 40 overlap trials and 26 miss trials.

C. Procedure

As in the auditory word detection experiment, participants were first presented with a visual target word, 1000 ms before the first word of the sentence was shown. The target word had a different font (Courier bold which has serifs; 50 point) and color (dark green) than the words of the sentence, and was in upper case, unlike the words of the sentence. This was done to make the target word as distinctly different as possible from the sentence such that participants would really have to read the sentence and not be able to detect the target word purely on the basis of superficial "image" matching. The sentence words were in a black Helvetica 50 point

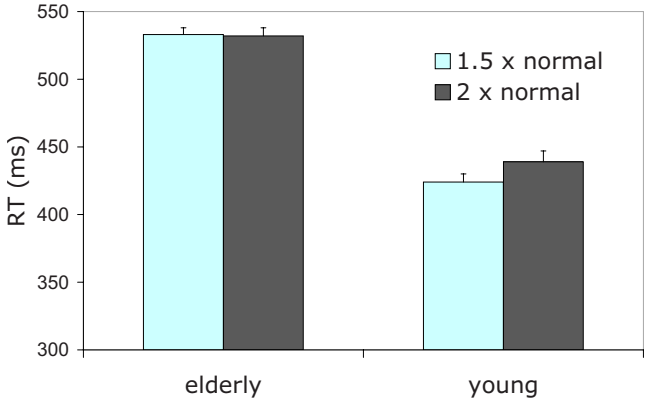

FIG. 3. (Color online) Mean response time in visual word detection experiment at both rates of presentation for both age groups (error bars reflect standard errors).

letter (this font has no serifs) on the screen: the words appeared in a white box against a light gray screen background. The target word remained on the screen during sentence presentation, clearly distinct from and under the box in which the words of the sentence were presented. Participants had 2 s following sentence offset to respond before the new visual target for the next sentence was presented. They were instructed to respond as fast and as accurately as possible once they detected the pre-assigned target in the sentence by pressing a button on the button box (with their dominant hand). They were informed that there would be sentences not containing the target word or with words similar to the target word. Participants were first presented with a practice part of eight sentences (containing both four test and four filler sentences in which the target would not appear: two misses and two with an overlapping word) after which they could still ask questions if anything was unclear. They were then presented with the material, blocked by speech rate (first the moderately fast sentences, then the faster sentences). Order of presentation of test and filler sentences was randomized for each participant.

D. Results

As in the auditory study, the increased rate of visual presentation was expected to have a more pronounced effect on the elderly than on the young participants. However, the two rates of visual presentation in the word detection study were hardly reported as challenging by the elderly participants. As in the listening study, response time was computed from target onset. Target detection times are given in Fig. 3 for both age groups and both presentation rates (1.5 and 2 times the normal rate, or compression to 67% and 50% of the normal duration, respectively). Correct detection rates were 99% for the elderly (at both presentation rates) and 100% for the young participants (at both rates).

The (correct) detection times ($N=3571$) were logtransformed and analyzed with linear mixed-effect models to test the effects of age group, presentation rate, and stress position of the target item. As in Sec. II E, estimated coefficients are reported, plus standard error for the estimate between brackets, and p-values. Elderly participants generally responded

more slowly than the young listeners [age group effect: $\beta = 0.099(0.024)$, $p < 0.001$], but there was no overall effect of rate of presentation [$\beta = 0.005(0.007)$, *n.s.*]. Responses to initially stressed items (word-initial stress being the default stress pattern in Dutch) were overall faster than to finally stressed items [main effect of stress position $\beta = 0.029(0.010)$, $p < 0.005$], and this effect was slightly more pronounced for the young than the elderly listeners [$\beta = -0.023(0.009)$, $p < 0.05$].

There was no specific hypothesis concerning the effect of stress position for the different age groups. Nevertheless, these reading results show that the elderly participants are less affected by stress position of the lexical item than the young participants. Increased exposure over the years to words that do not match the default stress pattern might explain this result.

The age group × presentation rate interaction was not significant [$\beta = 0.002(0.009)$, *n.s.*]: if anything, the elderly participants as a group seemed to show less influence of the increased presentation rate than the young (cf. Fig. 3). None of the other interactions reached significance.

IV. SELF-PACED READING

A. Participants

Participants were the same as those who participated in the auditory word detection study and in the visual word detection study (cf. Sec. III A).

B. Stimuli and procedure

In the self-paced reading experiment, participants were asked to read a short folk story (about a monkey) at their own preferred pace. With each press on a response button of a button box, the next word of the sentence would appear (or the first word of the next sentence). Even though each word disappeared before the next word was presented, the sentence was presented "from left to right:" each new word appeared in the position in which it would have been if the sentence had been presented as a whole at once. The dependent variable is reading time per word, or the pause between consecutive button presses. The words were presented in a white Helvetica font (size 30) against a black background (rectangle in which the sentence would fit). This sentence box was positioned just above the middle of the screen.

Participants received an oral instruction how to perform the task. By way of a practice set, the first sentence pair introduced the task to the participants once more: "You are going to read a short story now." "You decide what the tempo will be by pressing the button on the button box." If the participants had no more questions, they proceeded to the test part. The short story consisted of ten sentence pairs (the introductory practice sentence pair excluded), each of which consisted of two sentences. These sentences varied in length between 7 and 18 words.

C. Results

Overall slower (i.e., longer) reading times were expected for the elderly participants than for the young participants. In

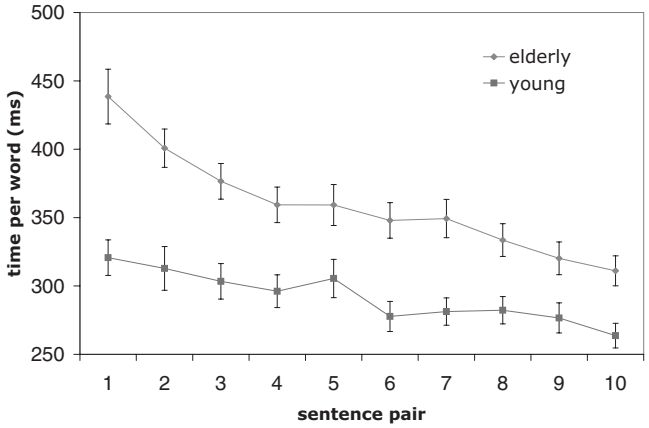

FIG. 4. Mean reading time per word per sentence pair for both age groups (error bars represent 1 SE).

Fig. 4 mean reading time per word is displayed for the two age groups as a function of sentence pair number. Because the story makes more and more sense toward the end, mean reading time per word shows a general downward trend. An ANOVA (by subjects) was carried out on these data because mixed-effect models (with both subjects and items as random factors) did not seem appropriate here. The (logtransformed) reading time per word data showed a main effect of age group [$F(1,58) = 4.85$, $p = 0.032$] and a main effect of sentence pair number [$F(9,49) = 43.07$, $p < 0.001$]. As Fig. 4 suggests, the interaction between age group and sentence pair is also significant [$F(9,49) = 6.21$, $p < 0.001$]: the difference in reading time between young and elderly listeners becomes smaller over the course of the short story.

The purpose of this self-paced reading experiment was to investigate a relationship between self-preferred reading rate and performance in the listening study. Therefore, each individual participant's reading pace to be entered as a predictor for fast speech performance was not computed over the entire story, but was restricted to the first two sentences because these set up a new semantic context frame. The later sentences introduce new content as well, but also refer back to concepts and persons introduced earlier. This fact that the first two sentences of the story introduce more new persons and concepts than later sentences makes them more similar to the sentence materials in the two word detection studies where every sentence is completely unrelated to the previous one and sets up its own new context. Mean reading time per word (computed over the first two sentence pairs) was 317 ms per word for the young adults (SE=10) and 419 ms for the elderly adults (SE=10, but note that 4 out of 160 observations were discarded because they were more than three SEs removed from the mean). An ANOVA on (logtransformed) reading times showed that this reading time difference between the age groups was significant [$F_1(1,58) = 13.67$, $p < 0.001$; $F_2(1,3) = 155.00$, $p = 0.001$]. Computed over the entire story, mean reading time per word was 292 ms for the young adults (SE=4) and 359 ms for the elderly adults (SE=4).

V. COMBINED RESULTS

The following three reading measures were considered potential predictors for fast speech performance: partici-

TABLE II. Correlation matrix with correlation coefficients (Pearson's) between all predictor pairs for the group of 39 elderly participants. Asterisk notation " * ": $p<0.05$.

	Hearing acuity	Age	Digit symbol	Vocab	Self-paced reading	log *RT* (visual word detection)	Rate effect (visual word detection)

Rate effect in visual word detection	0.35*	0.12	0.04	−0.16	0.15	0.34*	

pants' self-paced reading time (log time per word), overall target detection time (log) in the visual word detection study, and the effect of increased reading rate. Even though there was no overall effect of increased presentation rate in the visual word detection study, there were individual differences in the effect of presentation rate: the effect was computed for each of the elderly participants by dividing their mean (log) response time in the fastest presentation rate by their mean log *RT* in the slower presentation rate. As said, due to technical failure, this combination of reading and listening data applied to the data of 39 out of 40 elderly individuals. The other background measures were age, vocabulary score, hearing acuity, and corrected DSS score. For each listener, mean hearing loss in the better ear was computed by averaging pure-tone averages over 1, 2, and 4 kHz. Vocabulary performance was entered as the proportion of correct responses. Age was entered after subtraction of the minimum age of 65 years (because values of all other factors and predictors in the model are estimated for the minimum age value which would be far outside the actual age range if minimum age is not subtracted; cf. Snijders and Bosker, 1999 for the issue of centralization of predictor values). With respect to DSS test performance, each individual's corrected coding time (time required to recode one symbol) was entered.

Correlations among the different background measures were computed within the group of 39 elderly to address the issue of collinearity. If they are highly correlated, it does not make sense to consider them jointly in a multiple regression model of elderly participants' fast speech performance. Table II presents a correlation matrix with Pearson correlation coefficients between all predictor pairs (one asterisk denoting that $p<0.05$).

Given the weak (if any) correlations among these background measures, they were all entered into the analyses. The listening results were analyzed by using linear mixed-effect models with subject and item as crossed random effects (Pinheiro and Bates, 2000; Quené and van den Bergh, 2004; Bates and Sarkar, 2005). An additional advantage of mixed-effect models, over the advantage that multiple random effects can be considered in one analysis, is that both categorical and discrete predictors can be included in a single model (e.g., a manipulated factor, such as compression type, and individual characteristics, such as hearing acuity). Several models were fitted to the binomial detection accuracy data (using logistic regression, valid correct and incorrect responses made up 4678 observations), and several models were fitted to the detection time data (correct responses only, $N=4549$). It is important to note that in linear mixed-effect models, the order in which the predictors are entered does not influence their predictive value. The models evaluate whether coefficients are significantly different from zero in a model that contains all other predictors.

A. Detection rate

In Table III, an overview is given of four tested models. Model 0 is the simplest linear mixed-effect model which only contains as fixed factors the manipulated factors compression rate, compression type, and their interaction, and takes participant and item as random effects (as will be the case in all later models as well). In model 1, hearing acuity is added to the fixed part see how its inclusion improves the previous model. In model 2, self-paced reading time is added to model 1, and lastly, digit symbol coding time is added to the previous model in model 3. Table III also contains an evaluation of the four consecutive models in terms of goodness of fit. This is done by the likelihood ratio test, rather than by a computation of R^2 for each of the models because in mixed-effect models different sources of variation are modeled jointly (fixed and random effects). If R^2 were to be computed, it would not only cover the variance explained by the fixed effects (as is normally the case in multiple regression analysis, e.g., Jerger *et al.*, 1991) but also that of the random effects. Table III also shows how inclusion of the background measure predictors in the later, more complex models leaves less and less random between-subject variance (relative to model 0).

The log likelihood ratio test takes log likelihood, a measure of the model's goodness of fit, for the simpler model (containing less predictors) and compares it with the log likelihood for the more complex model with more parameters. The difference between the two log likelihoods, multiplied by 2, follows a chi-square distribution with the difference in number of parameter as number of degrees of freedom. In other words, the output of this likelihood ratio test determines whether inclusion of more parameters is justified. In Table III, each later model is evaluated relative to the previous model, and each model has a better fit than the previous one. Asterisks denote which of the coefficients are significant within that model.

This model comparison shows that model 3 contains

TABLE III. Comparison of several mixed-effect models of the accuracy data: estimated parameters (β coefficients) for the fixed part, variance of the two random effects, and evaluation characteristics (significant codes: " *** ": $p<0.001$, " ** ": $p<0.01$, " * ": $p<0.05$, and " . ": $p<0.1$).

		Model 0	Model 1	Model 2	Model 3

	SPR (log reading time)			−3.23*	−4.27*
	Digit symbol coding time				−1.05*
Random	Participant variance	1.06	0.50	0.38	0.27
	Item variance	5.43	5.46	5.54	5.59
Evaluation	Log likelihood	−413.08	−404.46	−401.55	−399.37
	Chi-square (compared to previous model)		17.242	5.84	4.35
	p-deviance (compared to previous model)		<0.001	<0.05	<0.05

predictor values that show significant effects over and above the manipulated factors. The other background measures (age, vocabulary score, mean log *RT* in reading, and the rate effect in reading) turned out not to predict fast speech performance.[2] Interaction terms between design factors and predictor variables were also added, but this did not improve the model.

Thus, the model with the best fit, model 3, showed the following effects (as in previous discussions of linear mixed-effect results for binomial data, estimated coefficients are reported plus their standard errors, and significance levels). Compression rate had a significant main effect on detection rate [estimated coefficient (henceforth β) is negative, meaning that the higher the speech rate, the lower the detection rate, compared to 1: $\beta=-2.270(0.604)$, $p<0.001$], but the main effect of compression type was not significant [$\beta=-0.250(0.750)$, *n.s.*]. The interaction between compression rate and compression type approached significance [$\beta=-1.477(0.797)$, $p=0.064$]. Hearing acuity [pure tone average (PTA)] significantly influenced detection rate: the more hearing loss, the lower the detection rate [$\beta=-0.067(0.012)$, $p<0.001$]. In addition, mean reading time per word (logtransformed, self-paced reading test) significantly influenced detection rate: the longer the reading time per word, the lower the detection rate [$\beta=-4.270(1.339)$, $p<0.01$].[3] Lastly, performance in the DSS test (as a measure of information processing rate) also significantly influenced performance: the longer one took to recode a digit to a symbol, the lower the detection rate [$\beta=-1.050(0.471)$, $p<0.05$]. Thus, hearing acuity, self-preferred reading rate, and information processing rate (in this order of relative importance) predicted success of target detection in fast speech.

B. Response time

Several linear mixed-effect models were fitted to the log *RT* data of the fast speech study (4547 observations). The following measures did not predict response time (nor interacted with any of the factors): vocabulary score, age, and hearing acuity. Table IV lists the characteristics of three

TABLE IV. Comparison of several mixed-effect models of the log *RT* data: estimated parameters (β coefficients) for the fixed part, variance of the two random effects, and evaluation characteristics.

		Model 0	Model 1	Model 2

Random	Participant variance	0.01	0.007	0.007
	Item variance	0.003	0.003	0.003
Evaluation	Log likelihood	3478	3491	3501
	Chi-square (compared to previous model)		24.42	20.73
	p-deviance (compared to previous model)		<0.001	<0.001

models: again moving from the simplest model (model 0) that only contains the interaction between the design factors, to a model that contains more predictors (model 1), to a model that contains interactions between factors and predictors (model 2).

The evaluation part of Table IV shows that adding background measures (model 1) improved the model, relative to the simplest model (model 0). The asterisk notation shows that model 1 is better than model 0 only because two, rather than four, background measures (namely, log *RT* in reading and the self-paced measure) were significant: the other two background measures were not significant predictors in model 1. The latter two background measures turn out to be important in their interaction with the compression rate effect in model 2, however. One should also note that the value of the compression rate coefficient was positive in models 0 and 1, meaning that generally, response times became longer in the faster rate condition (as was shown in Fig. 2). The direction of the rate effect is reversed in model 2: now, the faster the speech rate, the shorter the response times ($\beta=-0.809$), as was also seen for the young adults. Thus, the best-fitting model (model 2) showed a significant main effect compression rate on log *RT* [$\beta=-0.809(0.227)$, $p<0.001$], and a main effect of compression type [$\beta=0.011(0.004)$, $p<0.05$], indicating that response times were longer in the sampling conditions than in the PSOLA time-compressed conditions. This effect was stronger at the faster speech rate, as shown by a significant interaction between rate of speech and compression type [$\beta=0.032(0.006)$, $p<0.001$].

Mean detection *RT* in the visual word detection experiment was also a significant predictor: the longer one's detection time in reading, the longer one's detection time in listening [$\beta=0.892(0.179)$, $p<0.001$]. This reflects the shared components in the two analogous studies: first in terms of basic motor speed (how fast can this individual press the response button) and second in terms of speed of language processing and decision making. Self-paced reading time was another predictor that was very close to significance: the longer the reading time, the longer the detection time in listening [$\beta=0.218(0.119)$, $p=0.067$].[4] There was no overall effect of digit symbol coding time on *RT*'s, but it did interact with the compression rate effect [$\beta=0.027(0.010)$, $p<0.01$]. Whereas listeners generally have shorter response times in the fastest rate condition (relative to the 1.5 times normal-rate condition, cf. the negative coefficient for compression rate), this effect is the more counteracted, the longer time one needed to recode a digit to a symbol. A similar interaction was seen between compression rate and the rate effect in the visual word detection experiment, which in itself did not have a main effect on detection *RT*. Again, whereas *RT*'s generally get shorter in the fastest speech condition, this effect is counteracted more for those participants with a larger rate effect in reading [$\beta=0.810(0.227)$, $p<0.001$]. This indicates that participants who responded relatively slowly at the faster rate of visual presentation did not speed up in the listening study either when presented with the faster rate of speech.

Thus, the model fitted to the response times mainly showed interesting predictors for rate effect size: the extent to which participants were affected (i.e., sped up or slowed down) by increased rates of speech. Importantly, hearing acuity was not related to increased fast speech difficulty as measured by response time, but keep in mind that hearing level was the most important measure in explaining detection success. The model did show that increased difficulty with faster rates of speech was predicted by (a) the effect of presentation rate in the visual word detection experiment and (b) by information processing rate (DSS task performance).

VI. DISCUSSION AND CONCLUSION

The present study was set up to investigate why elderly listeners are more affected than young listeners when they are presented with fast, or more particularly, time-compressed speech. This is an old question that has given rise to a large number of studies (Gordon-Salant and Fitzgibbons, 1993, 1995, 1999, 2001; Letowski and Poch, 1996, Tun, 1998, Wingfield *et al.*, 1999; Schneider *et al.*, 2005). Even though many studies have acknowledged the contributions of hearing and cognitive factors to this age × rate interaction, it has been relatively difficult to quantify their relative contributions. The idea behind the present study was that if age-related general cognitive slowing and decreased information processing rate may be (partly) responsible for elderly listeners' increased difficulty with time-compressed speech, it makes sense to focus on this effortful process itself, rather than on just the result of it. Allowing elderly participants unlimited time to come up with a response may blur our conception of why perceptual processing itself has become more effortful. Moreover, the use of an on-line measure yields complementary accuracy and response time data.

The present study showed significant correlations between, on the one hand, hearing acuity and fast speech performance and, on the other hand, between individual presentation rate effects in word-by-word reading and in speech. Hearing loss clearly plays a primary role in explaining elderly listeners' problems with fast speech, as was evident from the detection rate analysis. Having to decode an impoverished speech signal requires more effort and thus takes more time, which becomes all the more problematic when speech rate is fast.

Note that the present data replicated the finding of Humes *et al.* (2007) that *overall* performance of the elderly participants was not affected by rate of visual presentation. Clearly, increased presentation rate affects cognitive processing more in the auditory modality than in the visual modality. This ties in with the suggestion by Humes *et al.* (2007) that high-frequency hearing loss is associated with central auditory problems, such as poorer spectral and temporal resolution, over and above the loss of audibility. In their results, high-frequency hearing loss turned out to be a significant predictor of fast speech performance, even after spectral shaping had been applied to compensate for loss of audibility. Nevertheless, despite the fact that overall performance of the elderly participants was not affected by rate of presentation, the present focus on processing time has resulted in two important findings. Even though correlations in performance across modalities have been found before (Zekveld *et al.*,

2007; Humes *et al.*, 2007), the present study is the first to show correlations between *rate effects* across modalities. Furthermore, the present results provide support for a direct relationship between individual differences in processing speed (DSS) and fast speech perception (cf. Sommers, 2005). It is not surprising that performance in the two reading tasks, being language measures, turned out to be better predictors than the more general cognitive measure of information processing rate (DSS).

The combination of correlations between fast speech performance and self-paced reading rate (detection accuracy analysis) and between individual rate effects in the two analogous word detection studies (*RT* analysis) provides support for an underlying problem with fast language processing: language being a particularly complex type of information to process. At first sight, it seems that the present study's "fast rates" of visual presentation were not fast or challenging enough. Note, however, that normal reading rate for the elderly listeners was estimated at 400 ms per word, which turned out to be remarkably close to elderly participants' mean self-preferred reading time (419 ms per word) in the first sentences of the folk story.

Self-paced reading may have given a more reliable insight into individual speed of language processing than the visual target detection study. It seems unlikely that participants ignored the content of the sentence while detecting pre-assigned target words: the target item that elicited the fastest detection time may have been more predictable from its preceding sentence context than average *(All of a sudden tapped he with a pencil on the window).* However, there was no check on whether all participants actually remembered some of the visually presented sentences afterward, which leaves the possibility that (some) participants only scanned the sentences for an orthographic match to the target. Even though self-paced reading had the better predictive power of the two for fast speech performance (cf. the individual detection rate analysis), the related effects of speeding in the visual and auditory modalities provide support that there is a "general cognitive" component to the age × rate interaction in listening to fast speech.

This brings us back to the claim by Schneider *et al.* (2005) that elderly listeners' problems with speeded speech should be attributed mainly to their inability to cope with the acoustic artifacts involved in methods of time compression, rather than to cognitive slowing. The present results did not show a clear age group × compression type interaction, but Schneider *et al.* (2005) may be right that, in general, any acoustic artifact is more disrupting for elderly than young listeners. Yet, the rate correlations across modalities provide solid evidence that there is more to the age × rate interaction than acoustic artifacts. Future research could investigate the potential benefits of non-linear over linear time compression, given their finding that elderly listeners were not more affected if speeding was accomplished by only removing silences and steady-state portions of the signal.

In conclusion, the present study has provided direct evidence that auditory and cognitive factors underlie elderly listeners' problems keeping up with fast rates of speech. Hearing loss, combined with central auditory problems that may be linked to high-frequency hearing loss, is certainly the primary cause of the problem. Nevertheless, be it at a more subtle level, general information processing problems also affect rate of language processing in auditory and non-auditory domains.

ACKNOWLEDGMENTS

[1] *p*-values (obtained by generating 10 000 simulations of the data sample) were computed with an ancillary function pvals.fnc defined in the LANGUAGER package. This function can be applied to the fitted model (http://cran.r-project.org, see Baayen, 2008).

[2] When raw age was in the model (instead of age minus 65) it was not a significant predictor either.

[3] A somewhat weaker, but still significant, predictor of detection rate is individual self-paced reading time per word averaged over the entire story, rather than averaged over only the first two sentences of the story [β = −2.899(1.187), p=0.015].

[4] If self-paced reading time is averaged over the entire story, rather than over the first two sentences, it is not a significant predictor [β =0.119,(0.098), *n.s.*].

(Received 17 April 2007; revised 12 January 2009; accepted 12 January 2009)

This paper investigates the theoretical basis for estimating vocal-tract length (VTL) from the formant frequencies of vowel sounds. A statistical inference model was developed to characterize the relationship between vowel type and VTL, on the one hand, and formant frequency and vocal cavity size, on the other. The model was applied to two well known developmental studies of formant frequency. The results show that VTL is the major source of variability after vowel type and that the contribution due to other factors like developmental changes in oral-pharyngeal ratio is small relative to the residual measurement noise. The results suggest that speakers adjust the shape of the vocal tract as they grow to maintain a specific pattern of formant frequencies for individual vowels. This formant-pattern hypothesis motivates development of a statistical-inference model for estimating VTL from formant-frequency data. The technique is illustrated using a third developmental study of formant frequencies. The VTLs of the speakers are estimated and used to provide a more accurate description of the complicated relationship between VTL and glottal pulse rate as children mature into adults.

I. INTRODUCTION

The purpose of this paper is to establish a framework for estimating the vocal-tract length (VTL) of a given speaker from small segments of their voiced speech sounds and thereby to establish a method for continuous estimation of VTL during speech processing. A VTL track, or contour, would assist speaker segregation and vowel normalization in multi-source environments (e.g., Welling and Ney, 2004). The principle is illustrated in Fig. 1 which shows the magnitude spectra (vertical lines) of two synthetic /i/ vowels like those that might be produced by (a) a small child (about 95 cm in height) with a short vocal tract (9.4 cm) and (b) a tall woman (about 188 cm in height) with a long vocal tract (15 cm). The glottal-pulse rate (GPR) and the spectral envelope of a real vowel can be modified in an analogous way using the high quality vocoder referred to as "STRAIGHT" (Kawahara *et al.*, 1999; Kawahara and Irino, 2004). For simplicity, the GPR (the voice pitch) is 200 Hz in both cases; it determines the spacing of the spectral components. The spectral envelopes of the vowels are shown by the smooth lines; they represent the transfer functions of the vocal tracts that produced these vowels. The soft-shouldered peaks in the envelopes represent the vocal-tract resonances which are referred to as formants. The spectra and envelopes are plotted on a logarithmic frequency axis (base 2) and the reference frequency associated with a log value of 0 is 100 Hz.

It is assumed that the child and the adult have formed their vocal tracts into the same shape to produce their /i/ vowels, and as a result, the pattern of formant information is the same for the two tokens of the vowel, on this logarithmic frequency axis. It is only the position of the pattern that differs; the formant pattern for the adult is shifted toward the origin, with respect to that of the child, because the vocal tract of the adult is much longer than that of the child. This very simple model of vowel development is referred to as the fixed-formant-pattern hypothesis in the current paper. It is similar to the uniform scaling hypothesis (e.g., Fant, 1966) and to formant ratio theory (e.g., Miller, 1989). The differences will be discussed below where relevant.

These simple models of vowel development are important because they imply that vowel-type information and VTL information are *covariant* in the log-frequency vowel spectrum (Patterson *et al.*, 2007), and this, in turn, suggests a relatively simple method for performing VTL estimation in conjunction with vowel identification. The process involves taking the formant pattern for each vowel type, in turn, and shifting it back and forth along the frequency axis to find out which formant pattern (vowel type) leads to the best fit, and the position in which this best fit is achieved. The position specifies the VTL of the speaker to within a fixed constant. Accordingly, the purpose of the paper is to review the developmental data pertaining to the spectral envelopes of vowel

sounds to determine the extent to which the formant-pattern hypothesis is true and to investigate the practical implications of estimating VTL from existing developmental data on formant patterns.

Section I A describes a quantitative reanalysis of the classic developmental data of Peterson and Barney (1952) in which the formant pattern is summarized by estimates of the first three formant frequencies, extracted from spectrograms of the vowels by humans. The analysis shows that children and adults produce vowels in which the formant pattern is, at least approximately, fixed, and the main source of variability, after vowel type, is the acoustic counterpart of VTL (i.e., acoustic scale; Cohen, 1993 and Umesh *et al.*, 1999). This suggests that it should be possible to use the formant-pattern principle to estimate VTL as outlined above from formant-frequency data. However, two problems were encountered when attempting to develop a procedure for VTL estimation. (1) There was a small but significant discrepancy from fixed formant patterns in the data of Peterson and Barney (1952) which suggested the presence of another source of variability in the data. Fant (1966, 1975) observed the discrepancy some time ago in the course of investigating the uniform scaling hypothesis. He suggested that the discrepancy might be associated with the fact that the pharyngeal cavity grows proportionately more than the oral cavity as children mature into adults. The extent of the non-uniformity of the growth of the anatomical cavities of the vocal tract is quantified in Sec. I B using the magnetic resonance imaging (MRI) data of Fitch and Giedd (1999). The analysis shows that the non-uniformity is actually much larger than would be required to explain the discrepancy from uniform scaling of formant frequencies in the data of Peterson and Barney (1952). (2) There is also an oddity in the Peterson and Barney (1952) data; there are an excessive number of formant frequencies which are integer multiples of the GPR of the vowel; that is, harmonics of the voice pitch. This suggests that the discrepancy might represent a measurement bias, arising from the well known problem of estimating formant frequencies from the harmonic spectra of voiced vowels. The problem is illustrated in the lower panel of Fig. 1. In this vowel token, there are harmonics (vertical lines) below and above the center of the first formant frequency (which is the first peak of the spectral envelope), but no harmonics right at the formant frequency. The problem is reviewed by de Cheveigné and Kawahara (1999) who concluded that it is inherent in spectrographic representations of speech sounds and extends to automatic transcription methods based on linear predictive coding (LPC).

The purpose of the remainder of the paper is to develop a model of vowel sounds that incorporates a statistical approach to deal with the formant measurement problem. This new approach to formant-frequency data has the distinct advantage that it can determine whether the residual formant variability in the data of Peterson and Barney (1952) is due to errors in formant-frequency estimation or to the non-uniform growth of one or more components of the vocal tract, as suggested by Fant (1975). The result is surprising; once the measurement noise has been properly modeled, it is observed that the formant patterns of the vowel sounds do not vary systematically, either with the size or the sex of the speaker, *despite the obvious non-uniformity* in the growth of the anatomical cavities (oral and pharyngeal). Moreover, a statistical analysis of the *fixed-formant-pattern* hypothesis at the heart of the model indicates that more complex growth functions with non-linear terms are less likely than the fixed pattern model, given the data of Peterson and Barney (1952). This means that the formant resonators are not affected by developmental changes in the oral-pharyngeal ratio and that it is reasonable to assume that formant-frequency values are effectively determined by vowel type and VTL, independent

of the position of the junction between the oral and pharyngeal cavities, as suggested by McGowan (2006). The results derived from the classic data of Peterson and Barney (1952) are confirmed by replicating the analyses on the massive developmental database reported by Lee *et al.* (1999). They recorded ten vowels from each of 436 children, ages 5–18, plus 56 adults. Section III shows how the statistical inference model can be used to estimate VTL from a separate set of developmental data reported by Huber *et al.* (1999) and to illustrate how GPR and VTL evolve from age 4 to adulthood in the human population.

A. Evaluating the fixed-formant-pattern assumption with the data of Peterson and Barney (1952)

The classic formant data of Peterson and Barney (1952) were reanalyzed to quantify the proportions of inter-vowel and intra-vowel variability and to assess the role of speaker size in the intra-vowel variability. Briefly, the analysis reveals that about 80% of the total variability in formant frequencies is accounted for by vowel type, and a second variable, which is referred to as acoustic scale (Cohen, 1993) and which is closely related to VTL and speaker height, accounts for up to 90% of the remaining intra-vowel variability. This indicates the potential value of VTL normalization for speech recognition as noted by, for example, Welling and Ney (2004), and it supports the hypothesis that it should be possible to estimate VTL from vowel sounds.

1. Inter-vowel variability: Vowel type

In their classic study, Peterson and Barney (1952) recorded two repetitions of ten American vowels in hVd words (heed /iy/, hid /ih/, head /eh/, had /ae/, hod /aa/, hawed /ao/, hood /uh, who'd /uw/, hud /ah/, and heard /er/) from 76 men, women, and children. From the spectrogram of each recording, they estimated the frequencies of the first three formants (F1, F2, and F3) and the pitch of the vowel (F0). When the data were plotted in F1-F2 space, the tokens of each vowel were found to cluster into relatively well defined regions that Peterson and Barney (1952) delimited with hand-drawn ellipses (their Fig. 8). In order to quantify the analysis, we have fitted three-dimensional Gaussian distributions to the F1-F2-F3 values of all of the tokens in each vowel cluster. The contours of constant probability associated with this distribution are ellipsoids; the contour associated with one standard deviation along each of the axes has been plotted for each of the ten vowels in Fig. 2. The formant frequency values have been converted into their corresponding wavelengths $(\lambda_1,\lambda_2,\lambda_3)$ because the focus of this paper is VTL and the analysis is more direct when presented in terms of wavelengths.

The positions of the ellipsoids in wavelength space reveal the established observations concerning inter-vowel variability. (1) There is virtually no overlap between the ellipsoids in this space. (2) The separation between the clusters is significantly greater in the λ_1-λ_2 plane than in the λ_2-λ_3 plane or the λ_1-λ_3 plane, indicating that the first two formants carry most of the vowel-type information. (3) The back vowels and front *unrounded* vowels occupy different

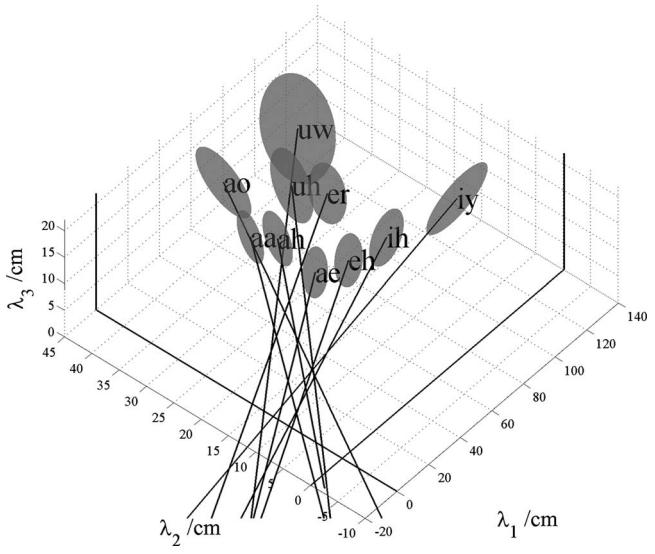

FIG. 2. Ellipsoids showing the distribution of formant wavelengths associated with each vowel in the classical formant data of Peterson and Barney (1952). The ellipsoids were derived using PCA; they represent one standard deviation from the mean of the vowel clusters (enclosing 29% of the data points). The lines show the orientation of the major axes of the ellipsoids; their extensions point toward the origin of the space, but there is a consistent bias away from the origin.

planes in wavelength space due to the relatively high and roughly constant second formant in front unrounded vowels (Broad and Wakita, 1977). The analysis shows that inter-vowel variability accounts for about 80% of the total formant variability in the Peterson and Barney (1952) data.

2. Intra-vowel variability: Vocal tract length

The intra-vowel variability is largely summarized by the eccentricity of the ellipsoid, its orientation, and its distance from the origin. With regard to *eccentricity*, in each case, one of the three principal axes of the ellipsoid is much longer than the other two. This is basically because the vocal tract increases in length as a child grows up. The eccentricity can be quantified with the aid of a principal components analysis (PCA), and it shows that approximately 90% of the intra-vowel variability lies in the direction of the major axis of the ellipsoid. With regard to the *orientation*, the ellipsoids all point in the direction of the origin of the space, as illustrated by the lines in Fig. 2; they show the extension of the major axis of each ellipsoid in the direction of the origin (given by the major-eigenvector of the covariance matrix). Together the eccentricities and orientations of the ellipsoids indicate that, within each vowel cluster, the formant pattern is approximately fixed for all members of the population. This is the basis of formant ratio theory (e.g., Lloyd, 1890; Potter and Steinberg, 1950; and Miller, 1989) and the uniform scaling hypothesis (e.g., Fant, 1966; for a review see Adank *et al.*, 2004). The principle has also been used to develop transforms intended to improve the performance of computer speech recognizers (e.g., Irino and Patterson, 2002; Umesh *et al.*, 2002; Welling and Ney, 2004). Similarly, it would appear that if vowel type and VTL account for virtually all of the variability in the formant-frequency data, then it would

TABLE I. Summary statistics for two tests of the fixed-formant-pattern hypothesis: The values in the upper pair of rows are based on a deterministic PCA; those in the lower pair of rows are based on a SFP model. Within each pair, the upper row shows the proportion of variability accounted for by the first component, and the lower row shows the angle that component makes with the uniform scaling line. Notice that the proportion of the variance explained by the principle component for the second analysis is often smaller than that for the first. This is because the second analysis explicitly models the observation noise and, once this contribution has been removed, there is less variability for the principal component to explain.

Vowel	/aa/	/ae/	/ah/	/ao/	/eh/	/er/	/ih/	/iy/	/uh/	/uw/	Ave
PCA: variability in direction of the PC	0.91	0.94	0.88	0.84	0.94	0.87	0.97	0.99	0.89	0.91	0.91
PCA: angle (deg)	11	14	6.0	7.5	8.5	13	6.6	5.6	3.9	8.0	8.4
SFP: variability in direction of the PC	0.85	0.95	0.97	0.85	0.96	0.70	0.96	0.87	0.98	0.83	0.89
SFP: angle (deg)	5.2	4.6	4.0	7.3	2.6	5.8	1.8	8.2	6.8	6.3	5.2

seem a relatively easy matter to estimate VTL given vowel type, as outlined in the Introduction (Sec. I).

3. Mathematical formulation of the formant-pattern model

The mathematical form for the simplest version of the formant-pattern model is

$$\underline{\lambda}_i^v = a_i \langle \underline{\lambda}^v \rangle, \tag{1}$$

where v is vowel type, i is the individual speaker, and $\underline{\lambda}_i^v$ is a three-component vector of formant wavelengths, which represents the formant pattern for vowel v of speaker i. $\langle \underline{\lambda}^v \rangle$ is the vector representation of the average formant pattern for vowel v in the population. The scalar, a_i, specifies the length of the individual's vocal tract relative to the mean of the population. The fixed-formant-pattern model is very simple; there is a single parameter for each formant and a single value of a_i that relates the individual's formants to those of the population. It is the "acoustic scale" (Cohen, 1993) of the formants relative to that of the population.

Peterson and Barney (1952) were not able to measure the VTL of their speakers; indeed, it is very difficult (Fitch and Giedd, 1999). However, the prediction is that variability in VTL across a population of speakers causes systematic variability in the formant wavelengths of their vowels. Specifically, the fixed-formant-pattern hypothesis predicts that the vowel clusters are ellipsoids and that the orientation of each vowel cluster, which is determined by the direction of the principal component of the variability in the data, will correspond to the direction along which the formant pattern is fixed. This direction, which is the major axis of the ellipsoid, passes through the origin. The eccentricity of the ellipsoid is partly determined by the variability of VTL in the population and partly by the distance of the ellipsoid from the origin of the space. In fact, the relative lengths of the ellipsoids along their major axes are predicted to depend entirely on their relative distances from the origin of the space according to

$$\sigma^v = \langle (\lambda^v - \langle \lambda^v \rangle)^2 \rangle^{1/2} = \sigma_a |\langle \underline{\lambda}^v \rangle|, \tag{2}$$

where σ^v is the magnitude of the principal component of the vowel cluster (which is equivalent to the length of the ellipsoid along the major axis), σ_a is the standard deviation of the VTL scalar in the population, and $|\langle \underline{\lambda}^v \rangle|$ is the magnitude of the vowel-cluster mean or the distance from the origin of the space to the center of the ellipsoid.

Thus, the model predicts that VTL is the largest source of intra-vowel variability and it can be used to assess the accuracy of the fixed-formant-pattern hypothesis. For example, the angle formed between the major axis of each ellipsoid and the line from the center of that ellipsoid to the origin provides a measure of the accuracy of the hypothesis. The angles are presented in Table I for the ten vowels in the Peterson and Barney (1952) database, along with the proportion of the intra-vowel variance accounted for by the principal component. The angles are very small and they show that VTL accounts for about 90% of the variability not attributable to vowel-type. Here, then, is a quantitative basis for the fixed-formant-pattern hypothesis as observed in the classic data of Peterson and Barney (1952).

4. Residual variability

Although the analysis of formant variability indicates that the fixed-formant-pattern hypothesis is largely correct, a detailed examination of Fig. 2 shows that when the main axes of the ellipsoids are extended toward the origin, they actually intercept the $\lambda_1=0$ plane at points where λ_2 and λ_3 are slightly, but consistently, positive, and they intersect the $\lambda_3=0$ plane at points where the values of λ_1 are consistently negative. This consistent bias in the intercepts suggests that there might be one more factor making a small, but consistent contribution to formant frequency variability. A clue to the form of the remaining variability is provided in Fig. 3 which shows the sub-clusters for men, women, and children plotted separately for six of the vowels in Fig. 2; the centroids of the sub-clusters for men, women, and children are relatively widely separated on the uniform scaling lines. This indicates that VTL variability is greater between speaker groups than within speaker groups—an observation that has been confirmed by Gonzalez (2004). Moreover, the principal axes of the sub-clusters with the more extreme values of λ_1 are more closely aligned with the first-formant axis than with the fixed formant-pattern line; the most obvious examples are the vowels /iy/ and /ih/. This suggests that within speaker sub-clusters, there may be another consistent source of variability *which is only revealed in conditions where VTL variability is small*.

There are several candidates for the source of this effect: Fant (1966, 1975) suggested that variability in the formant

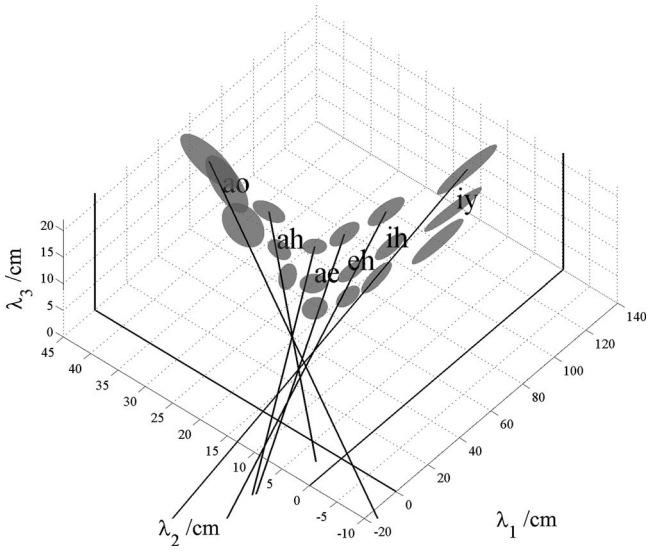

FIG. 3. Ellipsoids showing the distribution of formant wavelengths associated with the population subgroups (men, women, and children) for six vowels in the classical formant data of Peterson and Barney (1952). The ellipsoids were derived using PCA; they represent one standard deviation from the mean of the vowel clusters (enclosing 29% of the data points). The lines show the orientation of the major axes of the ellipsoids shown in Fig. 2; the sub-clusters of each vowel are well separated along the scaling line, but the principal axes of these sub-clusters are more closely aligned with the first-formant axis than the scaling line, especially for the vowels with a low first formant (e.g., /iy/).

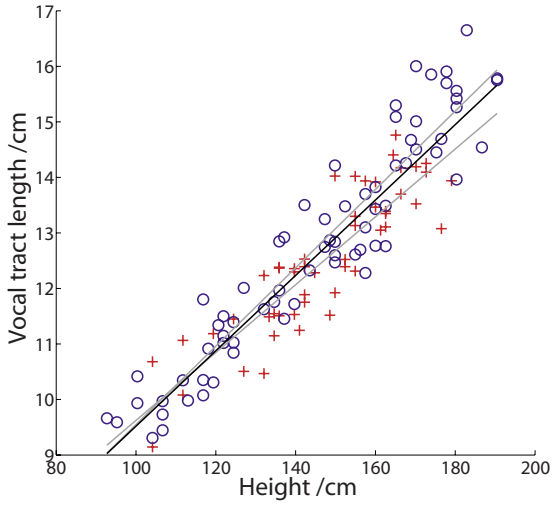

FIG. 4. (Color online) VTL as a function of height from the data of Fitch and Giedd (1999). The upper and lower faint trend lines are the fits to the males (circles) and females (crosses), respectively. The solid trend line is the fit to the male and female data combined.

pattern across speakers arises, at least in part, because the pharynx is proportionately larger in men than in women and children. He proposed a non-uniform scaling procedure with separate scale factors for each formant of each vowel to represent the non-uniform growth of the different components of the vocal tract and to take into account the changing formant-cavity-affiliations over vowels. The MRI data of Fitch and Giedd (1999) (reanalyzed below) confirm that the pharynx is proportionately larger in men, but this does not immediately indicate how the scale factors would be affected by VTL. Subsequently, Umesh *et al.* (2002) showed that Fant's (1966, 1975) scale factors could be averaged across vowels to form a single non-uniform scaling function that describes the scale factor as a function of formant frequency. In both cases, the implication is that there is one main, latent variable in this system, which is the acoustic scale of the vowel, but that this variable affects different formants in different ways, necessitating extra parameters to be added to the fixed pattern model. In Sec. I B, we develop a statistical model of formant-frequency data that can accommodate more complicated growth dependencies, should they be required, and which has the power to reveal any remaining sources of variability beyond those accounted for by vowel type and the fixed pattern hypothesis. In the event, however, what appears as an "effect" is revealed to be a bias caused by well known problems in formant-frequency estimation (e.g., de Cheveigné and Kawahara, 1999).

B. The form of the non-uniform growth of the oral and pharyngeal cavities

Fitch and Giedd (1999) used MRI to examine the growth of the components of the vocal tract as children mature into adults. The study included 129 men, women, and children ranging in age from 2.8 to 25 years. They recorded each subject's age, height, and weight, but they did not record samples of their speech sounds. The measurements were made with the subjects in the nasal breathing posture, and care was taken to exclude those who were overweight, or whose families had a history of language or developmental problems. Figure 4 shows VTL as a function of height separately for all of the males (○) (men and boys) and all of the females (+) (women and girls); VTL is effectively a linear function of height in both cases. There are proportionately more men at the tallest heights, but the two populations fall along lines with very similar slopes. It is also the case that the vocal tract grows proportionately slower than height because the head is proportionately larger than the body in children, but the proportionality is the same for the two groups. The growth rate is 0.067 cm/cm.

Figure 5 shows the relative lengths of the oral and pharyngeal portions of the vocal tract as a function of VTL, separately for males (○) and females (+). The figure shows that the length of the oral cavity decreases, and the length of the pharyngeal cavity increases, *relative to* VTL, as VTL increases. This is because the size of the oral cavity is largely determined by the size of the head which decreases as a proportion of body height as a person grows up. The figure makes it clear that the growth of the oral and pharyngeal cavities is *decidedly* non-uniform. Note, however, that the changes are linear in these coordinates and, for a given VTL, there is no difference between males and females in terms of the *proportions* of the cavities. This suggests that models, which relate growth in the main vocal tract cavities to the progressive decrease in formant frequencies with age, need not be excessively complex.

It is the pronounced non-uniform growth of the oral and pharyngeal cavities that prompts us to avoid the phrase "uniform scaling" when describing formant-frequency variability and to adopt instead the phrase "fixed formant pattern." The phrase uniform scaling is too readily misinterpreted as im-

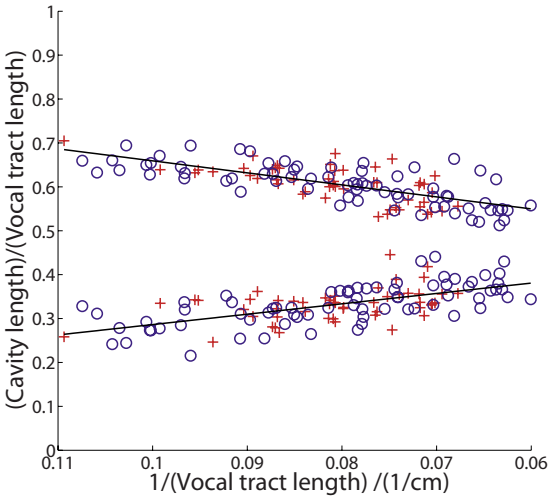

FIG. 5. (Color online) Growth functions for the oral cavity (upper cluster) and the pharyngeal cavity (lower cluster) from the data of Fitch and Giedd (1999). The abscissa is the reciprocal of VTL which orders the subjects according to size from left to right across the cluster. The ordinate is the relative length of the cavity and so the figure illustrates the change in the oral-pharyngeal ratio as people grow up. The trend lines show linear fits to the two clusters. The data of the males (circles) and females (crosses) cluster along the same line in both cases.

plying that the consistency of the formant pattern is the result of uniform growth of the anatomical components of the vocal tract, which is clearly incorrect in the case of the oral and pharyngeal cavities.

The fact that the formant patterns of vowel sounds do not vary markedly, either with the size of the speaker or their sex, may in retrospect seem surprising, given the striking non-uniformity in vocal-tract growth illustrated in Fig. 5. The analysis suggests that the anatomical distinction between the oral and pharyngeal divisions of the vocal tract is immaterial to the acoustic result of speech production. For a given vowel, the tongue constriction is simply positioned where it produces the appropriate ratio of front-cavity length to back-cavity length, independent of the location of the oral-pharyngeal junction

II. A STATISTICAL VERSION OF THE FORMANT PATTERN MODEL

The fact that the growth functions for the oral and pharyngeal cavities are linear suggests that it might be fairly simple to incorporate these growth functions into a model of formant-frequency data and in so doing realize Fant's (1966, 1975) original ambition. It is necessary, however, to adopt statistical methods to learn the relationship between formant frequency and acoustic scale from the data, and it is necessary to treat the acoustic scale of the vowel as a "latent variable" which is to be inferred from the data. Broadly speaking, the purpose of this section is to construct a statistical model of formant-wavelength data, which can determine the extent to which the complexities in the formant data of Peterson and Barney (1952) are due to non-uniform vocal tract growth, which needs to be included in the model, and the extent to which the complexities are attributable to measurement noise and are therefore artefactual. The development of this statistical formant pattern (SFP) model begins in Sec. II A, where a linear-model is developed to represent the growth functions of the oral and pharyngeal cavities, and the model is shown to be consistent with the developmental data of Fitch and Giedd (1999). Section II B explains why the model has to include explicit terms for the variability of the individual formants and why acoustic scale has to be incorporated as a latent variable. Section II C explains that it is also necessary to include explicit terms for the variability of the components of the measurement noise. Finally, in Sec. II D, the SFP model is applied to the developmental data of Peterson and Barney (1952), and then to the developmental data of Lee *et al.* (1999), to determine whether non-uniform vocal-tract-growth factors need to be incorporated into formant data models.

A. Modeling vocal tract length

As children mature and their height increases, so does the length of their vocal tract and thus the acoustic scale of their speech sounds. Height, VTL, and acoustic scale also depend on the sex of the speaker beyond about age 12 when VTL and acoustic scale become somewhat greater in males relative to their height. The SFP model employs a latent or hidden variable to represent the general growth factor associated with developmental changes in formant frequencies; that variable is designated a. This general growth factor is directly related to both VTL and to acoustic scale (Cohen, 1993), and it is assumed to be multi-modal in the population with clusters corresponding to men, women, and children.

More specifically, it is assumed that the lengths of the various cavities and components of the vocal tract are linearly related to VTL and therefore to the growth factor, a, via the average length of the cavity, or component, and a weighting factor, which can be thought of as reflecting the growth rate of the cavity or component [see Eq. (3) below]. For cavities like the pharynx, where the proportion changes with growth, the dependence is strong and the weighting factor is large. For components like the lips, where the proportion changes little with growth, the dependence is weak and the weighting factor is small. The weighting factors enable us to construct a model of the vocal tract in terms of VTL, where the growth of the components of the vocal tract is non-uniform but, nevertheless, a *linear* function of height. Mathematically, the model is

$$L_c^v = \langle L_c^v \rangle + a\frac{dL_c^v}{da}, \tag{3}$$

where $\langle L_c^v \rangle$ is the average length for cavity c for people articulating the vowel v, and a is the relative VTL of the individual. dL_c^v/da is a constant that does not depend on the individual. This relationship is consistent with the analysis of vocal-tract component lengths presented by Fitch and Giedd (1999) as will now be shown. If the total length of the vocal tract is written as the sum of the component lengths as follows;

$$L^v = \sum_c L_c^v = \sum_c \left[\langle L_c^v \rangle + a \frac{dL_c^v}{da} \right] = \langle L^v \rangle + a \frac{dL^v}{da}, \tag{4}$$

this expression can be substituted back into Eq. (3) to eliminate the unknown acoustic scale factor, a, and produce an expression for "the ratio of a cavity or component's length," L_c, to "the total length of the vocal tract," L.

$$\frac{L_c^v}{L^v} = \left[\langle L_c^v \rangle - \langle L^v \rangle \frac{dL_c^v}{dL^v} \right] \frac{1}{L^v} + \frac{dL_c^v}{dL^v}. \tag{5}$$

Thus, in this model of vowel production, the growth of the individual cavities and components is predicted to be linear when plotted against the reciprocal of L, which is precisely what was observed in Fig. 3. There is variability in the data that the model does not absorb, but there does not appear to be any consistent deviation as a function of speaker height of the sort that would warrant including quadratic or higher-order terms in the model.

It is now possible to determine *quantitatively* whether higher-order terms are warranted by fitting Nth-order polynomials to the data, and learning maximum-likelihood parameters for the terms and corresponding error-bars on these inferences. The linear model can then be compared to models of higher order by weighting the best-fit likelihoods of the more complicated models by penalty factors known as Occam factors, which depend both on prior knowledge and the error bars on the maximum-likelihood parameter estimates. In Bayesian statistics, this is a non-arbitrary form of hypothesis test (Mackay, 2003). In the current case, the linear model is found to be much more probable than models with higher-order terms. Moreover, the linear terms in the higher-order approximations were found to have similar values to those of the linear model, and the higher terms were found to contribute little *within the range of the data*. This, then, is a quantitative justification for using the non-uniform but *linear* model of VTL variability, and it can now be used to deconvolve the effect of vocal tract changes on vowel formant frequencies.

B. The formant pattern model and the non-uniform growth of the oral and pharyngeal cavities of the vocal tract

The next step in the development of the model is to relate VTL to formant wavelength. Broadly speaking, the higher formants in Peterson and Barney's (1952) data, F2 and F3, are well modeled as simple standing wave resonances, so they will have wavelengths which are linearly dependent on the length of the vocal tract for a given vowel and formant. A simple standing wave is not, however, a good model of the first formant. *To wit*, the wavelength of the first formant can be as much as eight times the length of the vocal tract, which is twice the maximum length that would be expected for a simple standing wave resonance. Fant (1966) argued that the first formant is commonly a Helmholtz resonance, in which case, the relationship between the frequency of the first formant and the growth of the vocal tract might be expected to be more complicated. In the event, however, when the correlations between formants for all of the vowels were analyzed (using the Bayesian techniques described in Sec. II A) the relationships were found to be well approximated by a line. As a consequence, any pair of formants in a vowel is linearly related; that is,

$$\lambda_l^v = m_{l,m}^v \lambda_m^v + c_m^v, \tag{6}$$

where l and m are formant numbers, 1, 2, or 3. This means that a fairly simple model might be expected to capture the majority of the variability in Peterson and Barney's (1952) data, so long as it incorporates the model of vocal tract growth derived earlier in Sec. II A. A straightforward approach, consistent with the data, is to describe each resonator in terms of an effective wavelength, that is, a simple linear function of VTL, regardless of its physical complexity. That is, $\lambda_l^v = n_l^v L_l^v$. Each of the effective wavelengths might be expected to develop in exactly the same way as the physical dimensions of the vocal tract [Eq. (3)], in which case the predicted relationship between formant wavelengths is linear, as observed previously in this section. This description can be generalized to the three-component vowel vectors

$$\underline{\lambda}^v = \underline{c}^v + a\underline{m}^v \quad \text{where } \underline{c}^v = \underline{n}^v \circ \langle \underline{L}^v \rangle \text{ and } \underline{m}^v = \underline{n}^v \circ \frac{d\langle \underline{L}^v \rangle}{da}, \tag{7}$$

where $\circ$ denotes the element-wise product. The prediction of this model is that the vowel clusters will form on segments of lines oriented in the direction m^v with centroids at c^v. If the growth rate of the effective lengths is uniform, then m^v and c^v are parallel and the fixed-formant-pattern model is recovered as a simple limit. If the distribution of the acoustic scale factor, a, is Gaussian then this model is equivalent to PCA and the analysis of Sec. I A is recovered. However, as noted earlier, the distribution is not Gaussian; there are three distinct classes of speaker (men, women, and children). Therefore, a more sensible choice is a mixture of Gaussians, with a Gaussian component for each group.

Two versions of the statistical model were developed, distinguished by their assumptions concerning the source of the vowels in each vowel cluster. In the first and simpler version, the vowels in each cluster were treated as if they all came from different speakers, and thus the clusters can be fitted individually. In point of fact, the vowels in the clusters are not independent with respect to VTL; each speaker contributes two tokens to each of the ten vowel clusters. The second version of the model incorporates this constraint, which, in turn, makes it possible to fit all the vowel clusters simultaneously. Although the inferred acoustic scale factors estimated with the second version of the statistical formant pattern model are almost certainly more accurate, the parameter values derived from the two models are very similar. Accordingly the discussion is restricted to the results from the second version of the model, and it is these values that are reported in the lower rows of Table I.

C. The variability of formant measurements

Having included the effects of vowel type and VTL in the statistical version of the formant pattern model, the question is whether the formant-frequency data contain other

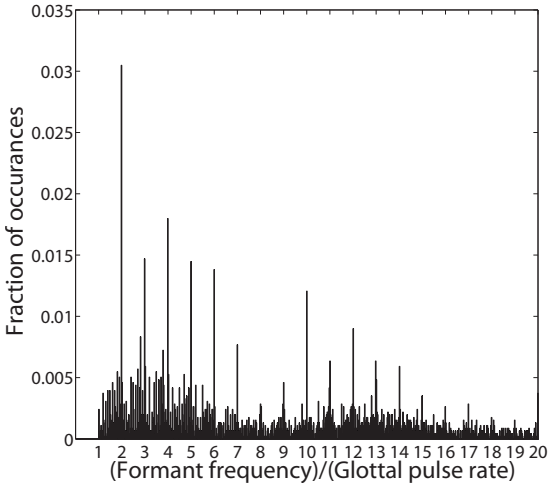

FIG. 6. Histogram of formant frequencies normalized to glottal pulse rate, illustrating the over-abundance of formant frequencies which are integer multiples of the GPR (i.e., GPR harmonics).

consistent sources of variability or whether the remaining variability is just due to measurement noise. To answer the question, it is necessary to include an explicit term for the residual noise in the SFP model. When the model, with its noise term, is applied to the data, the result is surprising; most of the remaining variability in the formant wavelength data is due to a consistent measurement error, and when the error is properly modeled, the fixed-formant-pattern model is observed to absorb most of the remaining variability. This indicates that if there is another natural factor, then its effect is limited to a very small contribution—a contribution that would be difficult to characterize because its effect is obscured by measurement noise.

The measurement error arises from the fact that it is difficult to estimate formant-frequency values from a spectrogram, particularly for the first formant, as noted in the Introduction and illustrated in Fig. 1. Formant-frequency estimation based on LPC is also prone to errors in this situation; it can only guarantee accuracy of approximately a quarter of the glottal pulse rate (Monsen and Engebretson, 1983; Vallabha and Tuller, 2002). Peterson and Barney's (1952) method was less sophisticated; they used a simple weighted average of the harmonics, f_n, in the neighborhood of the formant (see Potter and Steinberg, 1950),

$$\text{formant frequency} = \frac{\Sigma_n f_n \times a_n}{\Sigma_n a_n}. \tag{8}$$

Statistically, their method has similar restrictions to those of LPC with respect to accuracy, but the observed errors are somewhat larger. Moreover, an analysis of the data shows that a curiously high proportion of the formant estimates ($\sim$20%) are integer multiples of the GPR, as shown in Fig. 6. It appears that the estimate of formant frequency is attracted by a nearby harmonic frequency, which it would only rarely be by chance. It is also clear that many of the formant-frequency estimates were based on a single harmonic frequency. It turns out that this consistent measurement error is the source of much of the remaining variability in the vowel formant data. The measurement noise is roughly the same in

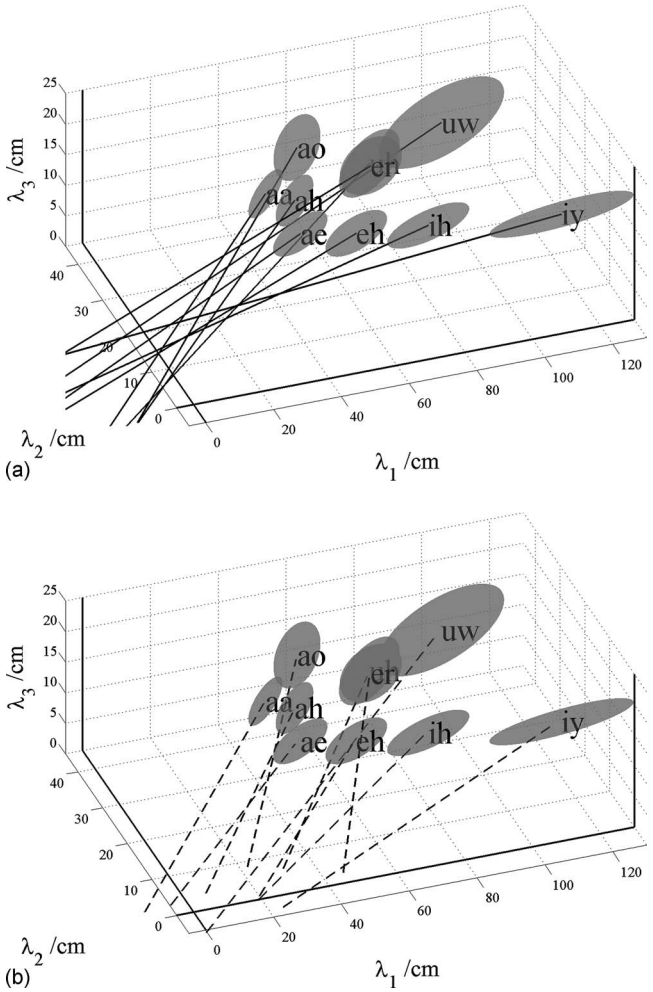

FIG. 7. (a) Rotated view of Fig. 2, showing the composite ellipsoids for the vowels in Peterson and Barney (1952), to emphasize the bias of the intercepts away from the origin in the λ_1 dimension. (b) The same view of the composite ellipsoids using the statistical formant-pattern model with explicit terms for formant measurement error. The bias of the intercepts is considerably reduced.

absolute terms for all of the formants and so, as a proportion, the effect is largest for the first formant and smallest for the third formant. In wavelength terms,

$$\frac{\sigma_\lambda}{\lambda} = n\frac{f_0}{f}. \tag{9}$$

The distortion that the measurement error imparts to the vowel clusters is illustrated in Figs. 7(a) and 8(a), which show views of the respective spaces presented in Figs. 2 and 3, but with the view rotated to emphasize the λ_1-λ_3 plane and thereby to emphasize the variability in λ_1. In Fig. 8(a), for vowels having a large λ_1, such as /iy/ and /ih/, the individual ellipsoids for men, women, and children are observed to be highly elongated in the λ_1 direction. The elongation is a very unusual form of variability, and it is not clear how factors like the non-linear growth of the oral-pharyngeal ratio could explain this form of variability since it does not vary with speaker size. The form of the variability led to the hypothesis that the lack of an explicit noise term in the deterministic formant pattern model (Sec. I A) leads to a bias in formant wavelength estimation that, in turn, produces the elongation

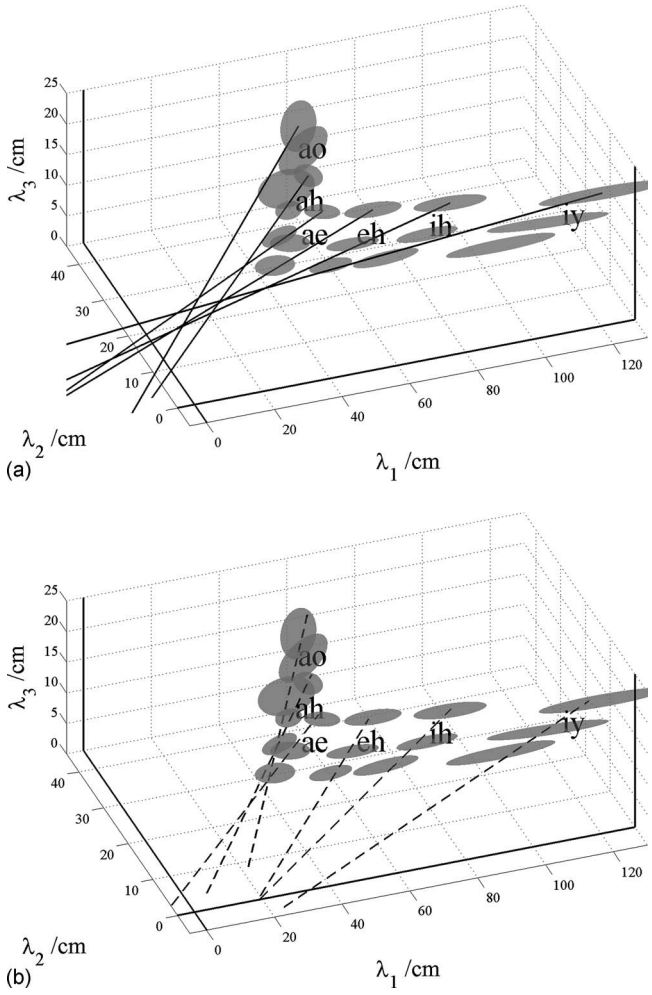

FIG. 8. (a) Rotated view of Fig. 3, showing the individual ellipsoids for the population subgroups for six of the vowels in Peterson and Barney (1952). The view emphasizes the bias of the intercepts away from the origin in the λ_1 dimension, and the elongation of the ellipsoids in the λ_1 dimension for vowels /iy/ and /ih/. (b) The same view of the individual ellipsoids using the statistical formant-pattern model with explicit terms for formant measurement error. The bias of the intercepts is considerably reduced.

of the ellipsoids in Fig. 8(a). It also produces the twisting of the angle of the main axis of the composite ellipsoid, as observed in Figs. 2 and 7(a), which, in turn, causes the intercept of the axis to shift away from the origin. The generation of the bias is illustrated schematically in Fig. 9; Sec. II D shows how to model the noise statistically to eliminate the bias in the full SFP model. The SFP model avoids the bias by introducing explicit terms for the noise associated with each formant,

$$\underline{\lambda}^v = \langle \underline{\lambda} \rangle^v + a\underline{m}^v + \underline{\eta}^v + \sum_{j=1}^{J} b_j^v \underline{n}_j^v, \tag{10}$$

where $\underline{\eta}^v$ is the formant-specific noise term. It is a vector of zero mean Gaussian noise with covariance given by $\underline{\underline{\Psi}}^v = \mathrm{diag}(\sigma_1^2, \sigma_2^2, \sigma_3^2)$. A factor, b_j^v, was also added to capture any other consistent source of natural variability in the data.

This model of formant wavelengths is a modified version of factor-analysis (FA) (Roweis and Ghahramani, 1999), where the distribution over the latent variable, $p(a)$, is a mixture of Gaussians (one for each speaker type; man, woman, and child) rather than a single Gaussian. The mixture of Gaussians was used to represent the statistics of the noise, $p(b)$, as well, but the divergence from a simple Gaussian was found to be minimal.

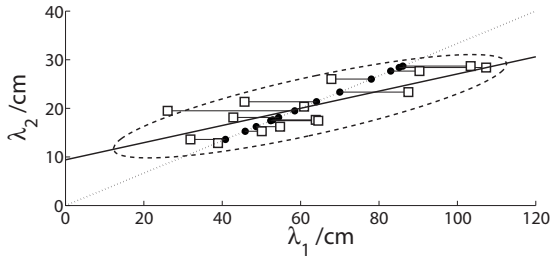

FIG. 9. Illustration of how measurement noise can bias the orientation of the major axis of the ellipsoid derived with a traditional deterministic analysis of noisy data. The true data (circles) lie on a uniform scaling line (dotted line), but are corrupted by anisotropic measurement noise (squares). Both the values of the measurement noise and the formant frequencies have been chosen to be typical of the vowel /iy/. A traditional fit with PCA derives a biased ellipse (dotted) with a principal axis which is biased away from the uniform scaling line. The more sophisticated analysis developed in this paper, which can learn the differing contributions from observation noise in each dimension, can recover the true directions, and it is unbiased in this regard.

In order to assess the relative contributions of an extra natural factor, on the one hand, and measurement noise, on the other, and to infer the acoustic scale factor of an unknown speaker from their formant data, the values of the model's parameters must be learned from the data. That is, they must be learned from the statistics of (i) the relative vocal tract lengths, $p(a)$, (ii) the noise, $\underline{\underline{\Psi}}^v$, and (iii) the factor loadings, $\underline{m}^v$. The learning and inference is accomplished using probabilistic methods, in particular, the variational expectation-maximization (EM) algorithm of Ghahramani and Hinton (1996). This algorithm repeatedly optimizes a lower bound on the log-likelihood of the parameters in two steps: in the expectation (E) step, the algorithm infers the acoustic scale factors of the speakers, given the current parameter estimates; in the maximization (M) step it finds the most likely parameters given the inferred acoustic scale factors. The iteration of the two steps typically converges in the region of the maximum-likelihood estimate for the parameters (Ghahramani and Hinton, 1996).

D. Application of the statistical, formant-pattern model to developmental formant data

We are now in a position to assess the relative contribution from the hypothetical extra natural factor, $\underline{n}_j^v$, on the one hand, and measurement noise, $\underline{\underline{\Psi}}^v$, on the other hand. The result is illustrated for the Peterson and Barney (1952) data in Figs. 7(b) and 8(b); they showed the major axes of variability for the vowel ellipsoids after they have been corrected for measurement noise. These corrected vectors point more accurately toward the origin of the space, as would be predicted by the fixed-formant-pattern hypothesis, indicating that there is no need for an extra natural factor to explain this data set (that is, $\underline{n}_j^v = 0$). The orientation of each component derived with the statistical model was compared to the orientation of the corresponding component derived from the original analysis. The results are presented in the lower rows

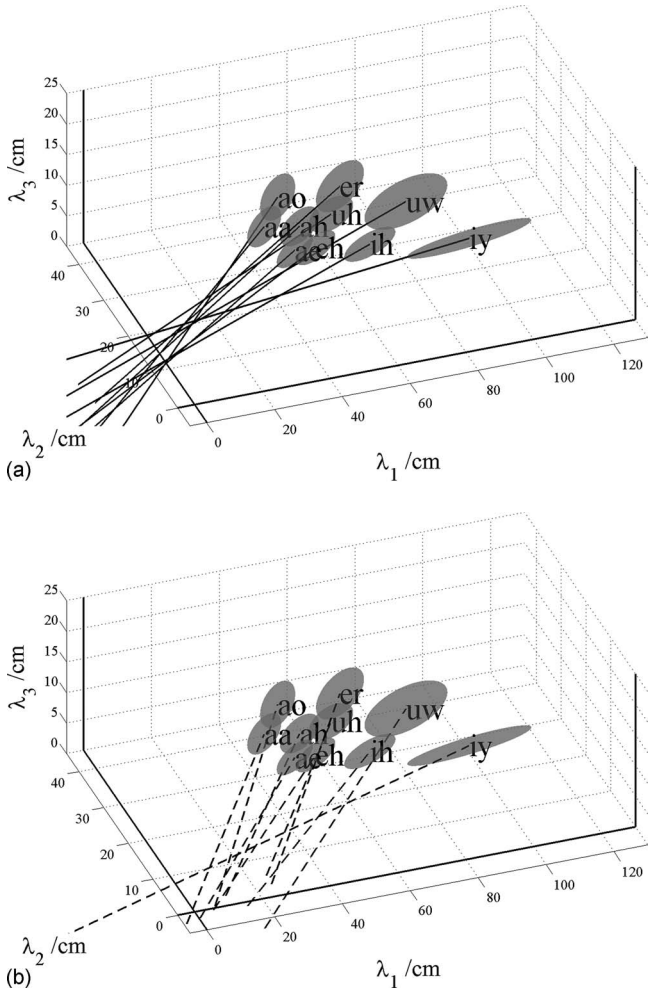

FIG. 10. (a) The composite ellipsoids for the vowels in Lee *et al.* (1999). The view emphasizes the bias of the intercepts away from the origin in the λ_1 dimension. (b) The same view of the composite ellipsoids using the statistical formant-pattern model with explicit terms for formant measurement error. The bias of the intercepts is considerably reduced.

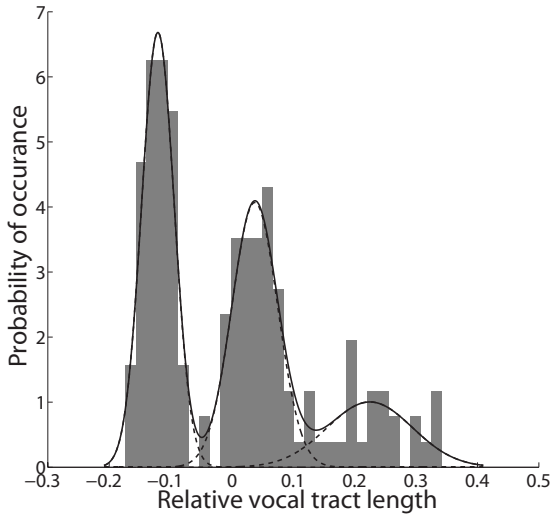

FIG. 11. Histogram of VTLs derived from the data of Peterson and Barney (1952) using the statistical formant-pattern model. The mixture of Gaussians derived by the model is shown by the solid line; the Gaussians which make up the fit are shown by dotted lines.

of Table I; they show that if measurement noise and other sources of natural variability are modeled statistically, the component of variability attributable to VTL becomes more uniform, while the residual noise decreases correspondingly.

In more recent developmental studies of formant frequency, such as those of Hillenbrand *et al.* (1995) and Lee *et al.* (1999), the formant-frequency values were estimated automatically from spectral frames of vowel sounds using LPC. The deterministic and statistical versions of the formant-pattern model were fitted to the data of both Hillenbrand *et al.* (1995) and Lee *et al.* (1999) to determine (a) whether the extended axes of the vowel ellipsoids would still show the bias away from the origin when the deterministic version of the model was fitted to the LPC data and (b) whether the bias would be reduced when the statistical version was fitted to the data.

The results for the data of Lee *et al.* (1999) are presented in Fig. 10 in the same format as shown for the data of Peterson and Barney in Figs. 7 and 8. The database of Lee *et al.* (1999) is far larger than that of Hillenbrand *et al.* (1995) and it covers a much greater range of ages. Lee *et al.* (1999) recorded ten vowels spoken by 436 children, ages 5–18, and 56 adults. Figure 10(a) shows the location of the ellipsoids for each vowel in wavelength space. The distribution of the ellipsoids is very similar to that shown for the Peterson and Barney (1952) data in Fig. 7(a), and the extensions of the major axes show the same bias away from the origin. There is also the same pronounced elongation of the ellipsoid for the vowel /iy/ in the λ_1 direction, probably due to the problem of estimating λ_1 which is particularly long in this vowel. The results for the SFP model are presented in Fig. 10(b), where the main axes of the ellipsoids are observed to intercept the λ_1-λ_3 plane at points much closer to the origin, indicating that the average bias is considerably reduced for this version of the formant-pattern model. Similar results were obtained with the data of Hillenbrand *et al.* (1995) indicating that the LPC method of extracting formant frequencies has a similar problem to that observed with the spectrogram reading method, as would be expected. The figure for the data of Hillenbrand *et al.* (1995) is omitted for brevity.

Finally, the assumptions made in Sec. II B, concerning the distribution of acoustic scale factors and the observation noise, need to be verified. With regard to the distribution of acoustic scale factors, which was modeled as three Gaussian sub-populations for men, women, and children, Fig. 11 shows the inferred scales together with the fitted mixture of Gaussians. The distribution is clearly multi-modal, justifying the assumptions of the model. With regard to the measurement noise, the SFP model learns that the average error is 50 Hz which is consistent with the inherent inaccuracy in the formant extraction process described in Sec. II C.

The formant measurement error produces a particular problem for deterministic versions of formant ratio theory (e.g., Miller, 1989), inasmuch as ratios accentuate variability. Moreover, it is traditional to use ratios that have F1 in the denominator, and F1 is the formant estimate that is most prone to error, so the accentuation of the variability is particularly large in the traditional version of formant ratio theory. The variability introduced by the measurement error and the accentuation of the variability associated with the use

of ratios are likely to have hampered efforts to normalize for acoustic scale using formant ratios. In the statistical analysis of formant-frequency data, the vectors of formant frequencies are treated as stochastic patterns and the three formants are fitted simultaneously, without the calculation of ratios. This shift in emphasis is important and it is why the model is referred to as a statistical formant-pattern model rather than formant ratio theory. The phrase "formant pattern" is intended to emphasize that the vector of formant wavelengths is a representation of the spectral envelope of the vowel. The shape and position of the spectral envelope are best estimated using a vector of formant peaks which are statistically defined, which is why the acronym for the model includes the "S." To reiterate, deterministic formant ratios provide a rather unreliable measure of the spectral envelope of a vowel because they amplify the error of the formant in the denominator and, unfortunately, it is common practice to use the most error prone of the formants as the denominator.

III. ESTIMATING VTL FROM FORMANT-FREQUENCY DATA

In this section, the SFP model is extended to produce an algorithm for estimating VTL, which involves calibrating the acoustic scale factors to a measure of absolute size. The algorithm is then applied to the developmental formant data of Huber *et al.* (1999) to estimate the VTLs of their speaker groups. Huber *et al.* (1999) reported the average values for the first three formants in /a/, separately, for groups of ten males and ten females in each of nine age bins (4, 6, 8, 10, 12, 14, 16, 18, and adults). Developmental studies of formant frequency often include developmental data on GPR and a comparison of the growth rates for VTL and GPR, since the growth rates change radically at puberty. The study of Huber *et al.* (1999) includes GPR data which we combine with the VTL estimates to illustrate the complicated developmental relationship between the excitation and resonance components of vowel production.

A. Inferring a speaker's VTL: Calibration of the data of Huber *et al.* (1999) to the VTLs of Fitch and Giedd (1999)

The main issue in the VTL estimation algorithm, as in the vowel production model, is to identify and correctly characterize the different components of the variability in the formant-frequency measurements. It is assumed that the measurement noise for individual vowel samples in the data of Huber *et al.* (1999) has approximately the same form as that in the Peterson and Barney (1952) data. The articulation of the vowels is assumed to be the same in the two studies. Both of these assumptions can be verified retrospectively. The methods developed in Sec. II can now be used to infer the acoustic scale factors for each group of speakers in each age category. In order for these estimates to be converted into absolute VTLs, we need to assume that the studies of Huber *et al.* (1999) and Fitch and Giedd (1999) were sampling from the same distribution of people, which was modeled as a mixture of Gaussians earlier. In this case, the relative VTLs from the study of Huber *et al.* (1999) can be scaled using the mean and variance data from Fitch and Giedd (1999). The VTLs inferred from the study of Huber *et al.* (1999) and the lengths measured by Fitch and Giedd (1999) are presented together in Fig. 12. The correspondence is surprisingly good, particularly for the male speakers. The male values from the study of Huber *et al.* (1999) seem a little high at 4 and 6 years, and the female values seem a little low for age 16 and above, but the deviations are not large relative to the overall variability.

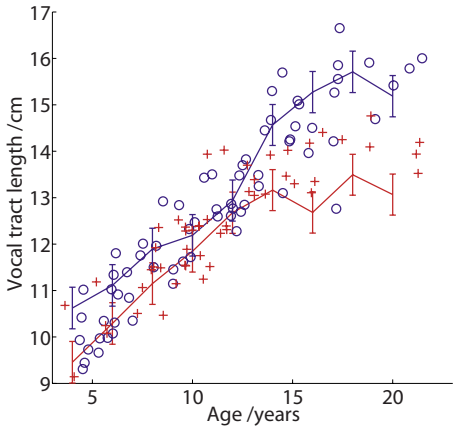

FIG. 12. (Color online) VTLs inferred for men and women from the data of Huber *et al.* (1999), plotted as a function of the speaker's age. For comparison, the data of Fitch and Giedd (1999) are presented by circles for men and crosses for women. The correspondence is impressive given that the populations in the two studies are not the same.

B. The GPR-VTL plane: Development and natural variability

Finally, the data from Peterson and Barney (1952) and Huber *et al.* (1999) were combined to characterize the developmental trajectory of vowel sounds in the log GPR-log VTL plane. The domains occupied by men, women, and children in the plane were delineated using the Peterson and Barney (1952) data. The 20 vowel sounds produced by each speaker (two tokens of each of ten vowels) were used to produce an estimate of each speaker's VTL, using the EM algorithm and the procedure described in Sec. III A; when combined with the corresponding GPR estimates, each individual provides 20 GPR-VTL points on the GPR-VTL plane. Two-dimensional Gaussian distributions were fitted separately to the data of the men, women, and children to characterize the domain of each speaker class on the plane. Contours of constant probability in these distributions are elliptical in form, and the contours that enclose about 80% of the individuals in each speaker class are shown by the three ellipses in Fig. 13. Unfortunately, the record of the Peterson and Barney (1952) data currently available does not contain information regarding the ages of individual children or their heights, and so the VTL estimates of the children had to be calibrated using the values for the adult males. Specifically, the mean and variance for the VTL estimates of the adult males [derived from the Peterson and Barney (1952) data] were equated to the mean and variance of the VTL values for the adult males reported by Fitch and Giedd (1999).

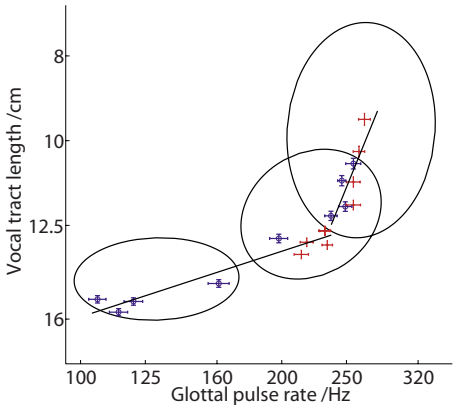

FIG. 13. (Color online) Predicting the population distribution over the log GPR-log VTL plane and the path of an average male and female through it as they develop. The distributions of inferred VTLs and GPRs for the data of Peterson and Barney (1952) are characterized by the three ellipses representing men (lower left), women (center), and children (upper right). The ellipses are drawn at two standard deviations about the mean to enclose ~80% of the data points. The developmental paths derived from the data of Huber *et al.* (1999) for the average female and the average male are shown by circles and crosses, respectively.

The mean VTL value inferred for each age-by-sex group in the data of Huber *et al.* (1999) was paired with the appropriate mean GPR value and plotted in the logGPR-logVTL plane of Fig. 13 to show the developmental trajectory of the voice for males and females as they mature. The symbols include ± one standard deviation in both dimensions. Within each ellipse, the trajectory from the data of Huber *et al.* (1999) reflects the eccentricity of the ellipse derived from the Peterson and Barney (1952) data. There is good agreement between the developmental data and the positions of the ellipses. It appears that the growth trajectories can be summarized with a pair of straight lines that meet near the center of the ellipse for women. The segment with the steeper slope was fitted to the data of males and females from ages 4 to 10; it has a slope of 1.9, so the VTL of a child is roughly proportional to the square of their GPR. The segment with the shallower slope was fitted to the data of males and females from age 12 upward; it has a slope of 0.25, so the VTL of adults and adolescents is roughly proportional to $GPR^{1/4}$. The figure makes it clear that the developmental trajectory for males changes dramatically around puberty and the change in trajectory is mainly due to the sudden drop in pitch that occurs at this time.

With regard to practical application of the VTL estimation process, it is theoretically possible to estimate VTL from all vowels and sonorant consonants on a frame by frame basis, *when the vowel type is known*. However, VTL would be expected to change at a much slower rate than formant frequency since it mainly changes with the speaker. So a reasonable strategy would probably be to limit VTL estimation to strong vowels where the recognizer is confident of the vowel type.

IV. SUMMARY AND CONCLUSIONS

A PCA was used to cluster the classical formant-frequency data of Peterson and Barney (1952) and provide ellipsoids showing the distribution of formant frequencies associated with each vowel and population subgroup. The analysis revealed that vowel type accounts for 80% of the variability in formant frequencies and 90% of the remaining variability is accounted for by VTL. Sufficient variability remained to support the hypothesis that there might be another consistent source of variability, such as developmental changes in oral-pharyngeal ratio. The MRI data of Fitch and Giedd (1999) were reanalyzed to evaluate this hypothesis, and the analysis confirmed that the growth of the oral and pharyngeal cavities is non-uniform, with the pharyngeal cavity growing faster than the oral cavity. However, the growth functions are linear. Moreover, the growth functions for men, women, and children are all the same. Despite the non-uniform growth of the anatomical cavities of the vocal tract, there is no commensurate non-linearity in the formant-pattern data. Indeed, for a given vowel, the formant pattern is essentially fixed on a log-frequency axis, shifting toward the origin without changing shape as VTL increases. This means that the systematic variability in formant-frequency data (at least the first three formants) is effectively divided between vowel type and VTL, and it suggests that speakers adjust the shape of the vocal tract as they grow to maintain a specific spectral pattern for each vowel type, independent of the relative size of the oral and pharyngeal cavities. The conclusion is important because it means that it should be a straightforward matter to estimate VTL from the voiced sounds in continuous speech.

A statistical formant-pattern model of formant-frequency data was developed with (a) a latent variable to absorb the variability of all size related factors, (b) non-uniform, but linear growth functions for the oral and pharyngeal cavities, and (c) separate measurement-noise terms for each of the formants. A modified version of factor analysis was developed to infer the acoustic scale factor of the vowels and, thus, the VTL of an unknown speaker, from the formant data of a given vowel type. The use of statistical methods to model the measurement noise revealed that the vast majority of the variability not attributable to vowel type is associated with VTL, and if there are any other natural sources of systematic variability their contribution is small with respect to the error in formant frequency estimation. The statistical version of the formant-pattern model was used to correct the biases of the deterministic version of the model, and the effect of the correction was illustrated with the formant-frequency data of both Peterson and Barney (1952) and Lee *et al.* (1999).

Finally, the SFP model was used to analyze the developmental data of Huber *et al.* (1999). The mean VTL was estimated for each age group, and the results were used to chart the development of VTL and GPR in children as they mature into adults.

ACKNOWLEDGMENTS

We would like to thank Dr. T. Fitch for kindly providing the individual data on the lengths of the parts of the vocal tract from their MRI data. R.E.T. was supported by the Gatsby Charitable Foundation through the writing of this paper. The research was supported by the UK Medical Re-

search Council (G0500221 and G9900369) and by the Air Force Office of Scientific Research, Air Force Material Command, USAF, under Grant No. FA8655-05-1-3043.

Likelihood-ratio forensic voice comparison using parametric representations of the formant trajectories of diphthongs[a)]

Geoffrey Stewart Morrison[b)]
School of Language Studies, Australian National University, Canberra, Australian Capital Territory 0200, Australia

(Received 12 September 2008; revised 11 January 2009; accepted 15 January 2009)

Non-contemporaneous speech samples from 27 male speakers of Australian English were compared in a forensic likelihood-ratio framework. Parametric curves (polynomials and discrete cosine transforms) were fitted to the formant trajectories of the diphthongs /aɪ/, /eɪ/, /oʊ/, /aʊ/, and /ɔɪ/. The estimated coefficient values from the parametric curves were used as input to a generative multivariate-kernel-density formula for calculating likelihood ratios expressing the probability of obtaining the observed difference between two speech samples under the hypothesis that the samples were produced by the same speaker versus under the hypothesis that they were produced by different speakers. Cross-validated likelihood-ratio results from systems based on different parametric curves were calibrated and evaluated using the log-likelihood-ratio cost function (C_{llr}). The cross-validated likelihood ratios from the best-performing system for each vowel phoneme were fused using logistic regression. The resulting fused system had a very low error rate, thus meeting one of the requirements for admissibility in court.

I. INTRODUCTION

In determining the admissibility in court of evidence based on a scientific methodology, the Supreme Court of the United States ruled that the judge should consider multiple factors including whether the scientific methodology has been empirically tested, whether it has an acceptable error rate, and whether it has been subject to peer review and publication [Daubert versus Merrell Dow Pharmaceuticals (92-102), 509 U.S. 579 (1993)]. A number of other jurisdictions have adopted similar standards. The present paper describes a test of the use of parametric representations of vowel formant trajectories as part of a forensic-voice-comparison system. It is hoped that this paper will contribute toward meeting admissibility-of-evidence standards for this methodology. This paper is part of a larger project "Catching criminals by their voice: Combining automatic and traditional methods for optimum performance in forensic speaker identification." A phonetic-acoustic analysis of vowel formant trajectories is combined with a generative likelihood-ratio formula (this formula has previously been used in research and in court cases in conjunction with phonetic-acoustic analyses), and the results are evaluated, calibrated, and fused using procedures which have been developed for use with automatic speaker recognition.

If an acoustic variable has a between-speaker variance which is greater than its within-speaker variance then it contains information which can be used to help distinguish speakers. A number of studies have found that information relevant to speaker identity can be extracted from the dynamic spectral properties of vowels (Eriksson *et al.*, 2004; Eriksson *et al.*, 2004; Goldstein, 1976; Greisbach, 1995; Ingram *et al.*, 1996; Kasuya *et al.*, 1994; McDougall, 2004; Rodman *et al.*, 2002; Nolan and Grigoras, 2005); however, these studies were not conducted in a framework which is appropriate for the evaluation of forensic evidence. It is the position of many forensic statisticians, forensic scientists, and legal experts that the logically and legally correct method for the evaluation of forensic evidence is via likelihood ratios (LRs) (Aitken and Stoney, 1991; Aitken and Taroni, 2004; Balding, 2005; Broeders, 1999, 2004; Evett, 1998; Friedman, 1996; González-Rodríguez *et al.*, 2007; Hodgson, 2002; Jessen, 2008; Lucy, 2005; Rose, 2002, 2003, 2005, 2006b). LRs can be used to present the probability of observing the evidence given one hypothesis versus the probability of observing the same evidence given the alternative hypothesis, for example, the probability of observing the measured acoustic differences between two speech recordings under the hypothesis that the speech in the two recordings was produced by the same speaker versus under the hypothesis that it was produced by different speakers, see Eq. (1).

$$\mathrm{LR} = \frac{p(\text{observed acoustic difference}|\text{same speaker})}{p(\text{observed acoustic difference}|\text{different speakers})}. \quad (1)$$

LRs are therefore the ratio of the conditional probabilities of two competing hypotheses, and if the prior probabilities for the hypotheses were known they could be combined

[a)]Portions of this work were presented in Morrison, Rose, and Kinoshita, "Extraction of likelihood-ratio forensic evidence from the formant trajectories of diphthongs," Acoustics '08, July 2008, and in Morrison and Kinoshita, "Automatic-type calibration of traditionally derived likelihood ratios: Forensic analysis of Australian English /o/ formant trajectories," Proceedings of Interspeech 2008, September 2008.

[b)]Electronic mail: geoff.morrison@anu.edu.au

with the LR via Bayes' theorem to produce posterior probabilities, the probabilities of the hypotheses given the evidence. The forensic expert cannot, however, provide posterior probabilities. There are both logical and legal reasons for this (see the discussion in Rose, 2002, Chap. 4): Although it may be possible to make pragmatic estimates of prior probabilities, such estimates would be based on assumptions, and, under one interpretation of the Bayesian framework, the priors are the results of the trier-of-fact's (the judge or jury depending on the legal system) initial assumptions plus changes in their belief as to the relative probability of the hypotheses as a result of all the evidence already presented. Such prior probabilities are not knowable by the forensic expert and therefore they cannot calculate posterior probabilities. Determining the posterior probabilities of the guilty versus not-guilty hypotheses is the purview of the trier-of-fact, and the forensic expert should not usurp this role (Aitken and Taroni, 2004, p. 4; Evett, 1998). The expert's task is to present the weight of one piece of evidence derived via a forensic comparison of suspect and offender samples, and the judge or jury's task is to assign priors and weigh all the evidence. It is arguably preferable that the forensic expert knows as little as possible about the circumstances of the trial and the other evidence presented so that there can be no suggestion that their testimony is influenced by anything other than a scientific evaluation of the particular samples with which they were provided.

It should be stressed that a forensic-voice-comparison system with a soft LR output is quite different from a speaker-identification system which chooses one individual from a finite number of enrolled voices, and is also quite different from a speaker-verification system which determines whether a questioned voice differs from a specific enrolled voice by less than a certain threshold (Rose, 2006b).

A few studies have conducted LR analyses using information about the dynamic properties of vowel formants. Rose (2006c) and Rose *et al.* (2006) used the formant values from the initial and final targets of Australian-English diphthongs, and Kinoshita and Osanai (2006) used the initial-target values and the slope of the formants between the initial and final targets. Simple parametrizations of vowel inherent spectral change such as dual-target or target-plus-slope models, which each use two parameters, have been found to be adequate for vowel-phoneme identification (Gottfried *et al.*, 1993; Nearey and Assmann, 1986), and more sophisticated curve-fitting models do not appear to outperform simple models (Hillenbrand *et al.*, 2001). This suggests that if only simple cues such as initial and final formant values are necessary for signaling phoneme identity, then speakers may have considerable freedom in the path taken between the initial and final formant values. If the constraints on formant trajectories are relatively lax with respect to vowel-phoneme identity, then with respect to speaker identity there may be considerable information contained in the details of formant trajectories. Differences in physiology and idiosyncracies in the use of motor commands may mean that different individuals consistently produce different formant trajectories between the beginning and end of the same vowel phoneme (see Nolan, 1997).

McDougall (2006) and McDougall and Nolan (2007) conducted a series of experiments in which they fitted polynomial curves to the formant trajectories of sonorant sequences in three different data sets. Polynomials offer relatively low dimension parametrizations of formant trajectories (e.g., three parameters for quadratic and four parameters for cubic) which can capture more information about the shape of the trajectories than is available from simpler two-parameter models; however, the analyses were not conducted in a LR framework. Rose *et al.* (2006) performed a LR analysis using initial and final target values from Australian-English /aɪ/ tokens. Morrison (2008) reanalyzed the recordings from Rose *et al.* (2006) and obtained substantially better results by fitting polynomial curves to the formant trajectories and using the estimated coefficient values to calculate LR. Based on evaluation via Tippett plots, he concluded that the best results were achieved using cubic polynomials fitted to equalized-duration hertz-scaled formant trajectories. Morrison and Kinoshita (2008) conducted LR analyses using estimated coefficient values from parametric curves fitted to formant trajectories from Australian English /oʊ/ tokens. The parametric curves were second- and third-order (quadratic and cubic) polynomials and second- and third-order discrete cosine transforms. Results were evaluated using the log-LR cost (C_{llr}, Brümmer and du Preez, 2006), and again the conclusion was that the best results were achieved with cubic polynomials fitted to equalized-duration hertz-scaled formant trajectories. The current paper expands on the latter two papers by testing LR forensic-voice-comparison systems using parametric curves (polynomials and discrete cosine transforms) fitted to five vowel phonemes, /aɪ/, /eɪ/, /oʊ/, /aʊ/, and /ɔɪ/, produced by Australian-English speakers.[1] Systems based on different versions of parametric curve fitting are tested via cross-validation, calculating LR for non-contemporaneous same-speaker pairs of recordings and for different-speaker pairs of recordings. The cross-validated LR results obtained from the best-performing system for each vowel phoneme are fused to produce an overall LR for each cross-validated same-speaker and different-speaker comparison. Results are evaluated using the log-LR cost.

II. METHODOLOGY

A. Data

Data consisted of laboratory-quality audio recordings extracted from a corpus of recordings which was previously described in Kinoshita and Osanai (2006). Portions of this corpus were previously analyzed in Kinoshita and Osanai (2006), Rose *et al.* (2006), Morrison (2008), and Morrison and Kinoshita (2008).[2] The recordings were of 27 male speakers of Australian-English aged between 19 and 63 with a median of 39. The speaker was shown a card with a word written on it, for example, "high," the card was removed, and the speaker responded by saying a sentence of the form "High, H-I-G-H spells high." Table I provides a list of the words recorded and analyzed in the present study. Each speaker was recorded on two separate occasions separated by approximately 2 weeks. Within each session, written prompts were presented in random order, with each word

TABLE I. Words from the Australian English corpus which were analyzed in the present study.

	Consonant context					
Vowel	/h_/	/h_t/	/h_d/	/b_/	/b_t/	/b_d/
/aɪ/	High	Height	Hide	Buy	Bite	Bide
/eɪ/	Hay	Hate	Haydes	Bay	Bait	Spade
/oʊ/	Hoe	Hote	Hoed	Bow	Boat	Bode
/aʊ/	How	⋯	How'd	Bough	Bout	Bowed
/ɔɪ/	(Coy)	Hoytes	⋯	Boy	⋯	Buoyed

presented twice. Recordings were made using a Sony ECM-MS907 microphone and an Edirol R-1 recorder, with the signal digitized at 44.1 kHz.

B. Acoustic analysis

The first and final words from each sentence were analyzed. The beginning and end of each vowel were manually marked.[3] The trajectories of the first three formants (F1, F2, and F3) of each vowel were tracked using the formant tracking procedure outlined in Nearey *et al.* (2002): The number of linear-predictive-coding coefficients was fixed at 9. Measurements were obtained every 2 ms using a 100 ms wide power-four-cosine window. Formants were tracked using the algorithm described in Markel and Gray (1976). The formants were tracked eight times using eight different cutoff values for F3 (range 2500–4000 Hz). Each of the eight formant-track sets was visually displayed overlain on a spectrogram. Fundamental frequency was measured using the algorithm of Boersma (1993), and intensity was also measured. The measured intensity, fundamental frequency, and formant frequencies were used to synthesize a vowel. The researcher could listen to the original vowel and a synthesized vowel based on any desired track set. On the basis of visual and auditory inspection, the researcher selected what he judged to be the best formant-track set. The researcher also had the option of manually editing formant tracks and of adjusting parameters for fundamental frequency measurement.[4]

C. Parametric curve fitting

Two types of parametric curves were fitted to the formant trajectories, polynomials and discrete cosine transforms (DCTs). Earlier studies have found that DCTs are effective for vowel-phoneme discrimination and can outperform polynomials (Watson and Harrington, 1999; Zahorian and Jagharghi, 1991, 1993). A DCT is similar to a discrete Fourier transform in that it approximates a complex curve by summing a series of simple functions. DCTs are designed to be fitted to curves of finite length. The simple functions used to construct DCTs are a series of cosines with a set sequence of frequencies. The frequencies and phases are constrained so that each component has a maximum or minimum at each of the beginning and end of the complex curve. Coefficient values specify the amplitude of each cosine component (the coefficients are scaled by a factor related to the length of the signal). The zeroth DCT coefficient corresponds to the offset, the first DCT coefficient corresponds to the amplitude of a half period of a cosine, the second corresponds to the amplitude of a whole period of a cosine, the third corresponds to the amplitude of one-and-a-half periods of a cosine, etc. The formulas for constructing polynomials and DCT curves from their coefficient values are given in Eqs. (2) and (3), respectively:

$$y(x) = \sum_{k=0}^{K} \beta_k x^k, \tag{2}$$

$$y(x) = \beta_0 \frac{1}{\sqrt{N}} + \sum_{k=1}^{K} \beta_k \frac{2}{\sqrt{N}} \cos\left(\frac{(2x+1)\pi k}{2N} \right), \tag{3}$$

where $y(x)$ is the amplitude of the curve at time-point x (for DCT calculations, x values are sample frame numbers $\{0, \ldots, N-1\}$), N is the number of time points, β_k are coefficients of order k, and K is the order of the curve (total number of coefficients less 1). For DCTs the maximum value for K is $N-1$.

A priori we do not know which parametric representation of formant trajectories will produce the best results, nor do we know whether certain scales for time and frequency will produce better results than other scales; therefore, a factorial combination of curve types, orders, and scales was tested: First, second, and third degree (linear, quadratic, and cubic) polynomials and first, second, and third degree DCTs were fitted to the trajectory of each of the three formants of each vowel in the data. Curves were fitted to formant trajectories with frequency measured in hertz and in log hertz. They were also fitted to formant trajectories with time measured on the original timescale (vowels varied in duration) and on an equalized-duration timescale (all vowels linearly interpolated to have 126 points, a nominal timescale of 0–250 ms in 2 ms steps).

D. Calculation of cross-validated likelihood ratios

In general, between-speaker differences may be expected to be greater than within-speaker differences; however, it is important to note that even if two speech samples differ substantially in their acoustic properties they could have been produced by the same speaker. Speakers' voices are inherently variable and there may be substantial differences in recordings of the same speaker made only hours apart.

It is also important to note that even if two speech samples have very similar acoustic properties they could still have been produced by different speakers. If only a small

proportion of speakers in the population produce speech with acoustic properties close to some set of acoustic values A, then this set of values is atypical. If speech samples from two different speakers are drawn at random, the probability of them both having acoustic properties in the vicinity of A is low. However, if a large proportion of the population produces speech with acoustic properties close to some other set of acoustic values B, then this set of values is typical. If speech samples from two different speakers are drawn at random, the probability of them both having acoustic properties in the vicinity of B is relatively high.

Thus although in general between-speaker differences may be expected to be greater than within-speaker differences, in some instances two samples produced by different speakers could be more similar than two samples produced by the same speaker.

In order to present to the court the strength of evidence which can be extracted from speech recordings, the forensic scientist calculates a LR which quantifies the probability of obtaining the observed differences between suspect and offender samples under the hypothesis that they were produced by the same speaker versus under the hypothesis of that they were produced by different speakers (probability of evidence given hypotheses). No same-speaker versus different-speaker hard-categorization decision (probability of hypotheses given evidence) can be made.

LRs were calculated using the multivariate-kernel-density (MVKD) formula developed by Aitken and Lucy (2004).[5] The formula has previously been applied to speech data in González-Rodríguez *et al.* (2007), Ishihara and Kinoshita (2008), Morrison (2008), Morrison and Kinoshita (2008), Rose (2006c, 2007), Rose *et al.* (2006), Rose *et al.* (2008), and Zhang *et al.* (2008). The MVKD formula evaluates the similarity of two speech samples with respect to the within-speaker variation estimated from a sample of the population, and the typicality of the speech samples with respect to an estimate of the probability density of the population (based on the same sample of the population as is used to estimate the within-speaker variance). The within-speaker variance is estimated via a normal distribution, and the between-speaker population probability density is estimated via a kernel model.

Systems based on different combinations of parametric curves and time and frequency scales were tested via cross-validation. A cross-validation procedure was adopted so as to produce a more realistic picture of how each system would perform on previously unseen data, as would be the case if it were applied to a speech sample of known origin (a suspect sample) and a sample of unknown origin (an offender sample). Cross-validated LRs were calculated for each same-speaker and different-speaker pair in the data set. Each speaker's session 1 recording was compared with their own session 2 recording (a non-contemporaneous same-speaker comparison) and with every other speaker's session 2 recording (different-speaker comparisons). This produced a set of LRs where it is known whether each LR was the result of a same-speaker or a different-speaker comparison. The background sample used to estimate the within-speaker variance and the population probability density consisted of all the speakers in the data except for the speakers being compared. For example, when a same-speaker comparison was being conducted on speaker 1, then the background sample consisted of data from all speakers except speaker 1, and when a different-speaker comparison was being conducted on speakers 1 and 2, then the background sample consisted of data from all speakers except speakers 1 and 2. (Because of limitations in the MVKD formula, data from both sessions were pooled within speaker in the background sample.)

Cross-validated LRs were calculated separately for each vowel phoneme based on the estimated coefficient values from each formant trajectory obtained using each type and degree of parametric curve and using each combination of frequency and time scaling. Only combinations in which all three formant trajectories were measured on the same time and frequency scales and with the same parametric curve type and degree were considered. Because suspect and offender recordings submitted for forensic voice comparison are often recorded via telephone systems which have band-pass properties which may compromise F1, especially for vowel phonemes with intrinsically low F1, additional sets of LRs were calculated using F2 and F3 trajectories only.

E. Evaluation of system performance

The results of the cross-validated LR calculations were evaluated and calibrated using the log-LR cost, C_{llr} (Brümmer *et al.*, 2007; Brümmer and du Preez, 2006; González-Rodríguez, *et al.*, 2007; Morrison and Kinoshita, 2008; Ramos Castro, 2007; van Leeuwen and Brümmer, 2007). C_{llr} is an error metric which is independent of prior probabilities and costs, and has been adopted for use in the National Institute of Standards and Technology Speaker Recognition Evaluations (NIST SRE). The aim of calibration in forensic voice comparison is to present the information in such a way as to best aid the trier-of-fact in making appropriate decisions (Ramos Castro, 2007). Given two sets of values derived from two categories (such as same-speaker versus different-speaker comparisons) and a fixed decision boundary for classifying the values, calibration monotonically shifts and scales the values so as to produce the smallest possible error rate.

LRs are used here to express the probability of obtaining the observed acoustic difference between two speech samples given the hypothesis that the samples were produced by the same speaker over the probability of obtaining the observed acoustic difference between the two speech samples given the hypothesis that the samples were produced by different speakers. The decision boundary for LRs is 1: Values greater than 1 favor the same-speaker hypothesis and values less than 1 favor the different-speaker hypothesis (or if a logarithmic scale is used, log-LR values greater than 0 favor the same-speaker hypothesis and values less than 0 favor the different-speaker hypothesis). An ideal forensic-voice-comparison system would produce large positive log LRs for same-speaker comparisons and large negative log LRs for different-speaker comparisons. Negative log LRs from same-speaker comparisons and positive log LRs from different-speaker comparisons can be counted as errors since

they favor the contrary-to-fact hypothesis. Further, the greater the magnitude of the log LR in the wrong direction, the more egregious the error in that it is more likely to contribute toward a miscarriage of justice. If, in fact, the two speech samples being compared were produced by the same speaker, then it would be worse to present a LR of 10 000 in favor of the different-speaker hypothesis than a ratio of 10 in favor of the different-speaker hypothesis.[6] The severity of the error is captured by the C_{llr} which can be calculated using Eq. (4):

$$C_{\mathrm{llr}} = \frac{1}{2}\left(\frac{1}{N_{\mathrm{ss}}}\sum_{i=1}^{N_{\mathrm{ss}}} \log_2\left(1+\frac{1}{\mathrm{LR}_{\mathrm{ss}_i}}\right) + \frac{1}{N_{\mathrm{ds}}}\sum_{j=1}^{N_{\mathrm{ds}}} \log_2(1+\mathrm{LR}_{\mathrm{ds}_j})\right), \tag{4}$$

where N_{ss} and N_{ds} are the number of same-speaker and different speaker comparisons, and $\mathrm{LR}_{\mathrm{ss}}$ and $\mathrm{LR}_{\mathrm{ds}}$ are the LRs derived from same-speaker and different-speaker comparisons. C_{llr} is a continuous function which is small for correct LRs (same-speaker comparisons with LRs greater than 1 and different-speaker comparisons with LRs less than 1) and asymptotes toward zero as correct LRs diverge from 1, but which is large for incorrect LRs (same-speaker comparisons with LRs less than 1 and different-speaker comparisons with LRs greater than 1) and becomes exponentially large as incorrect LRs diverge from 1. C_{llr} can be decomposed into the sum of two parts: $C_{\mathrm{llr}}^{\mathrm{min}}$ is the minimum error which can be achieved for an optimally calibrated system and $C_{\mathrm{llr}}^{\mathrm{cal}}$ is the (mis)calibration error, which can be removed by optimally calibrating the system. Calibration is a monotonic shifting and scaling of the scores relative to the decision boundary and $C_{\mathrm{llr}}^{\mathrm{min}}$ is achieved using a non-parametric monotonic function (pool adjacent violators). For practical applications, systems will be calibrated using a parametric monotonic function and post-calibration C_{llr} values will therefore be greater than $C_{\mathrm{llr}}^{\mathrm{min}}$. In the present paper post-calibration C_{llr} will be used to compare the performance of different forensic-voice-comparison systems.

Pre-calibration $C_{\mathrm{llr}}(C_{\mathrm{llr}}^{\mathrm{pre}})$, post-calibration $C_{\mathrm{llr}}(C_{\mathrm{llr}}^{\mathrm{post}})$, and $C_{\mathrm{llr}}^{\mathrm{min}}$ were calculated for the sets of cross-validated LRs from each vowel phoneme. Each set of cross-validated LRs was calibrated using a linear transformation with C_{llr} as the loss function to be minimized. The C_{llr} calculations and calibration were performed using Brümmer's FOCAL toolkit.[7] Calibration was performed using cross-validation: For example, in order to calibrate the LR obtained from the same-speaker comparison of speaker 1's two recording sessions, calibration intercept and slope values were calculated using all of the LRs except those which were obtained from comparisons which included speaker 1; likewise, in order to calibrate the LR obtained from the different-speaker comparison of speakers 1 and 2, calibration intercept and slope values were calculated using all of the LRs except those which were obtained from comparisons which included speaker 1 or 2. This provides a more accurate picture of how the system might perform on previously unseen data.

F. Fusion of likelihood ratios across vowel phonemes

If LRs contain independent information, then they can be multiplied together using naïve Bayes to obtain LRs for a fused system (log LRs can be added together). In speech data and especially vowel formant data, however, substantial correlation is expected. For example, all else being equal, a speaker with a longer vocal tract will have lower average formant values for all vowel phonemes. A simple fusion procedure which takes correlation between sets of LRs into account is logistic regression (Brümmer *et al.*, 2007; González-Rodríguez *et al.*, 2007; Pigeon *et al.*, 2000; Ramos Castro, 2007). A multivariate binomial logistic regression model is fitted to a matrix of log LRs from each same-speaker and different-speaker comparison. Each row of the matrix consists of a set of log LRs from a comparison of a single pair of speech samples. The set consists of the log LRs from each of the phonemes compared, with each phoneme in a different column. The rows of the matrix are also categorically coded according to whether they were the result of a same-speaker or a different-speaker comparison. The logistic regression analysis determines the optimal hyperplane for separating the same-speaker and different-speaker comparisons. The estimated coefficient values from the logistic regression analysis are then used as weights on a linear summation of the sets of log LRs from each phoneme. Note that if equal priors are chosen for the logistic regression, then the optimization object (the deviance statistic) is the same as C_{llr}, and logistic-regression fusion therefore automatically includes calibration (Brümmer *et al.*, 2007; Brümmer and du Preez, 2006).

Logistic-regression fusion was performed using Brümmer's FOCAL toolkit.[7] Because complete separation between the training set of same-speaker and different-speaker comparisons was achieved when LRs from different phonemes were combined, the logistic regression model was trained on 999 copies of the same-speaker LRs plus 1 copy of the different-speaker LRs mislabeled as same-speaker and 999 copies of the different-speaker LRs plus 1 copy of the same-speaker LRs mislabeled as different-speaker. This prevented the algorithm from generating infinite values for coefficients (see Menard, 2002). Fusion was conducted using cross-validation, as described above for calibration, and the models were trained on the non-calibrated cross-validated LRs (results using the calibrated cross-validated LRs would be identical).

III. RESULTS AND DISCUSSION

A. Mean formant trajectories

Figure 1 provides plots of the mean equalized-duration formant tracks pooled across all tokens and speakers. Note that the pronunciation of these vowels in Australian-English may differ considerably from their pronunciation in other dialects of English such as General American and also from the pronunciations suggested by the relatively dialect neutral phonemic transcriptions used in the present paper. See Cox and Palethorpe (2007) for a brief description of Australian-English pronunciation.

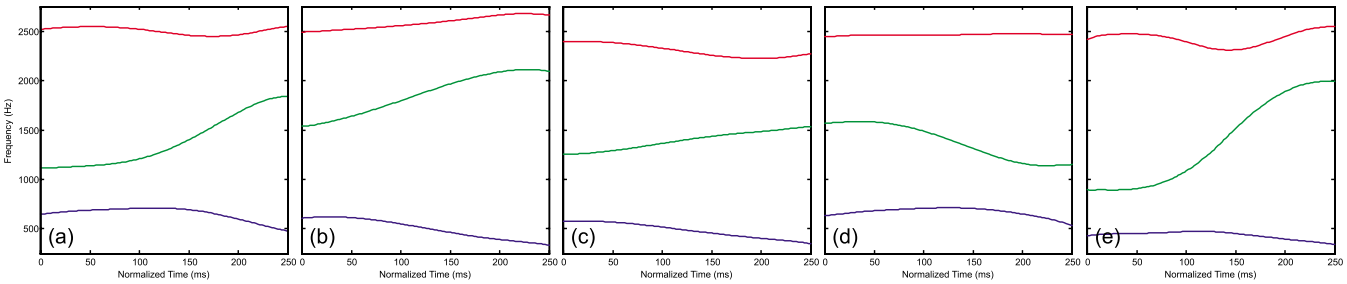

FIG. 1. (Color online) Mean equalized-duration formant tracks for Australian-English (a) /aɪ/, (b) /eɪ/, (c) /oʊ/, (d) /aʊ/, and (e) /ɔɪ/.

B. Numerical C_{llr} evaluation of forensic-voice-comparison systems

Table II provides the C_{llr} values obtained from the best-performing system for each vowel phoneme. For each phoneme the best-performing system was determined as being that based on estimated coefficient values from the type and order of parametric curve fitted to the frequency- and time-scaled formant trajectories which resulted in the lowest post-calibration C_{llr} value for the cross-validated LRs. These may be thought of as the parametric curves whose coefficients had the smallest ratio of within-speaker to between-speaker variance, and which thus extracted the greatest amount of speaker-discriminating information from the formant trajectories. Patterns of differences between different systems were often most clearly discernible for the systems based on /ɔɪ/, and to aid the discussion below Fig. 2 therefore presents a full set of pre- and post-calibration C_{llr} (C_{llr}^{pre} and C_{llr}^{post}) values covering all combinations of parametric curve type and order, and frequency and duration scales.

In general systems based on higher-order parametric curves outperformed systems based on lower-order curves. This is as would be expected if the formant trajectories are relatively complex and the highest-order curves are not modeling noise. The pattern was most clear in the C_{llr}^{post} results for /ɔɪ/ but less so for /aɪ/ or /oʊ/. There were also exceptions to this pattern: For /aʊ/ second-order polynomials generally outperformed third-order polynomials, and for /eɪ/ there was relatively little difference between the performance of first-, second-, and third-order curves for three-formant systems.

DCTs clearly outperformed polynomials for /ɔɪ/, but in general there was little difference in C_{llr}^{post} between the best DCT systems and the best polynomial systems. The best curve to fit may depend on the idiosyncracies of the shape of particular formant trajectories of particular vowel phonemes, in which case the *post hoc* procedure adopted here is preferable to *a priori* choosing a particular parametrization which may turn out to be sub-optimal.

With the exception of the two-formant systems for /aɪ/ and three-formant systems for /eɪ/, the best results were obtained using a linear-hertz frequency scale. The superiority of linear hertz over log Hz was very clear for /ɔɪ/; however, in general, there was little difference in C_{llr}^{post} between the best linear-hertz and the best log Hz systems. Again, this may depend in the idiosyncracies of the shapes of each formant trajectory and the relationships between the shapes of the different formant trajectories for each vowel phoneme.

With respect to time scaling, in many cases using equalized-duration improved system performance, but in some instances using the original non-equalized time scale produced better results. From the perspective of an articulatory model of speech production, both the time scales adopted here may appear crude. It may be that greater success can be achieved using a more sophisticated model; however, the ultimate performance of the systems presented here was very good, and the extra complexity of an articulatory-production-based model is probably not warranted at this stage.

A final observation with respect to C_{llr} values is that, in

TABLE II. Pre- and post-calibration C_{llr} values and C_{llr}^{min} values for the best-performing system for each vowel phoneme. (a) Systems based on F1, F2, and F3 trajectories. (b) Systems based on F2 and F3 trajectories.

				Scale		C_{llr} (bits)		
	Vowel	Curve type	Order	Freq.	Time	Pre-calib.	Post-calib.	C_{llr}^{min} (bits)

general, systems based on /ɔɪ/ and /eɪ/ (and especially the two-formant systems) were initially much better calibrated than systems based on other diphthongs—the difference between their pre-calibration and post-calibration C_{llr} values was smaller (for all the three-formant systems for /aɪ/, $C_{\text{llr}}^{\text{pre}}$ was at least four times greater than $C_{\text{llr}}^{\text{post}}$). This may be due to the relatively small size of the data set which was used for calculating covariance matrices. It may also be due to the fact that the Aitken and Lucy (2004) MVKD formula does not take into account all the potential sources of variance in speech data. In estimating the within-speaker variance and the population probability density, the MVKD formula does not take inter-session variance or variation due to phonetic context into account. The results based on /ɔɪ/ and /eɪ/ could therefore have been better calibrated than for the other vowels if these two vowels had less contextual variance or less inter-session variance. In the case of /ɔɪ/, this could be related to the fact that a smaller number of consonant contexts were tested for /ɔɪ/ than for other vowels (see Table I). Although the MVKD formula has been applied to speech data it was originally developed for use with trace evidence such as glass fragments. In contrast to acoustic measurements taken from speech which can vary from recording session to recording session, trace elements in panes of glass can be assumed to remain constant over time. Lacking a generative LR model which takes all the relevant sources of variance for speech data into account, calibration offers a discriminative solution for ameliorating potentially problematic raw results (see Morrison and Kinoshita, 2008).

C. Graphical Tippett-plot evaluation of forensic-voice-comparison systems

Figures 3–7 provide Tippett plots (see González-Rodríguez *et al.*, 2006; González-Rodríguez *et al.*, 2007; Rose, 2006a) of the LR results from the best-performing system for each vowel. In the Tippett plots the curves rising to the left represent the proportion of different-speaker comparisons with $\log_{10}$ LRs equal to or greater than the value indicated on the x-axis, and the curves rising to the right represent the proportion of same-speaker comparisons with $\log_{10}$ LRs equal to or less than the value indicated on the x-axis. In general, better performance is indicated by the same-speaker curve being further to the right (having more positive log LR values) and the different-speaker curve being further to the left (having more negative log LR values). The proportion and magnitude of the same-speaker curve to the left of $\log_{10}(\text{LR})=0$ and the different-speaker curve to the right of $\log_{10}(\text{LR})=0$ are indicative of errors where the calculated LRs support the contrary-to-fact hypothesis with respect to whether the comparisons were same-speaker or different-speaker comparisons. Note that the cumulative proportions in each curve are a set of discrete values determined by the number of LRs in the set as a result of the number of comparisons made. All the same-speaker curves in all the

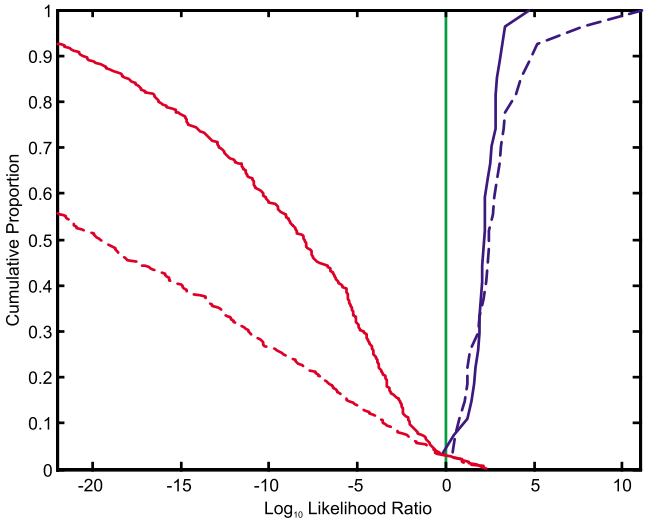

FIG. 4. (Color online) Tippett plot of the best-performing calibrated three-formant (solid line) and two-formant (dashed line) forensic-voice-comparison systems based on Australian-English /eɪ/ formant trajectories.

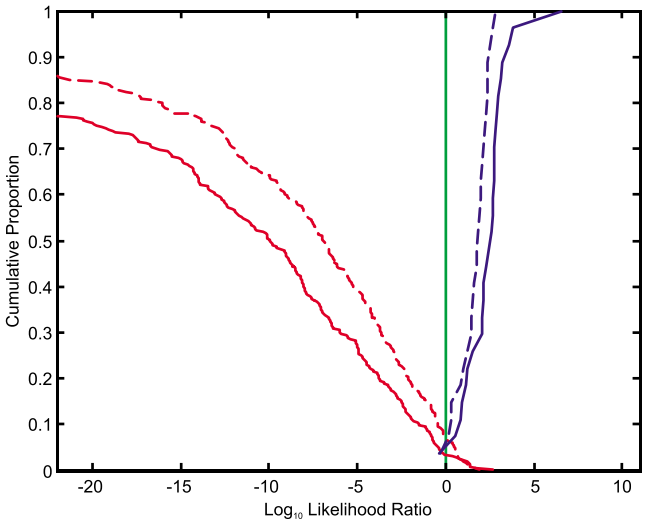

FIG. 5. (Color online) Tippett plot of the best-performing calibrated three-formant (solid line) and two-formant (dashed line) forensic-voice-comparison systems based on Australian-English /oʊ/ formant trajectories.

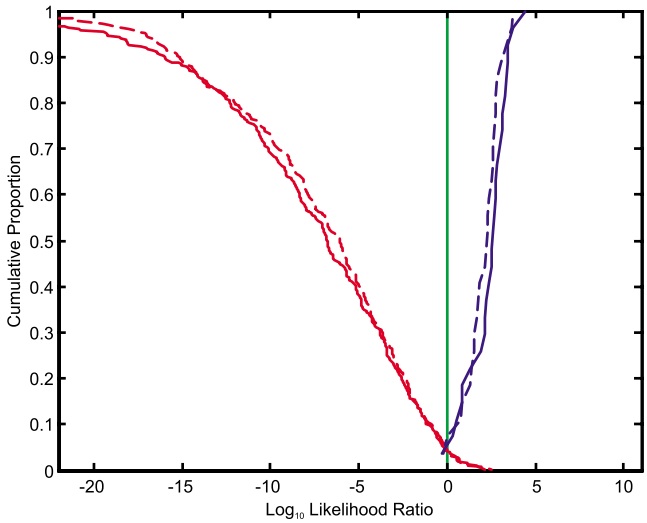

FIG. 7. (Color online) Tippett plot of the best-performing calibrated three-formant (solid line) and two-formant (dashed line) forensic-voice-comparison systems based on Australian-English /ɔɪ/ formant trajectories.

Tippett plots presented here are a result of the same number of comparisons on the same speech samples and therefore they all have the same discrete values for cumulative proportions. The same goes for the different-speaker curves. The differences between curves are therefore due to differences in the $\log_{10}$(LR) values.

For /ɔɪ/ and /aɪ/ the Tippett plots for the best-performing three-formant and two-formant systems were quite similar (Figs. 7 and 3). This suggests a high degree of correlation between the information extracted from F1 trajectories and the information extracted from F2 and F3 trajectories. For /oʊ/ and /aʊ/ the Tippett plots (Figs. 5 and 6) show a more noticeable deterioration in performance when the F1 formant trajectory is excluded (compared to the three-formant models the two-formant models resulted in Tippett plots in which the same-speaker curves have more negative log LRs and the different-speaker curves have more positive log LRs). This indicates that the F1 trajectories contained substantial extractable information about speaker identity over and above that which was extracted from the F2 and F3 trajectories. In contrast, the Tippett plot for /eɪ/ (Fig. 4) shows that substantially larger log LRs were achieved using only F2 and F3 trajectories compared to using the trajectories of all three formants. Note that $C_{\text{llr}}^{\text{post}}$ for the two-formant system was less than that for the three-formant system (Table II). This suggests that F1 trajectories for this vowel may have had relatively large within-speaker variation compared to between-speaker variation. In contrast the combination of F2 and F3 trajectories for /eɪ/ produced the best performance of any of the formant combinations tested on any vowel.

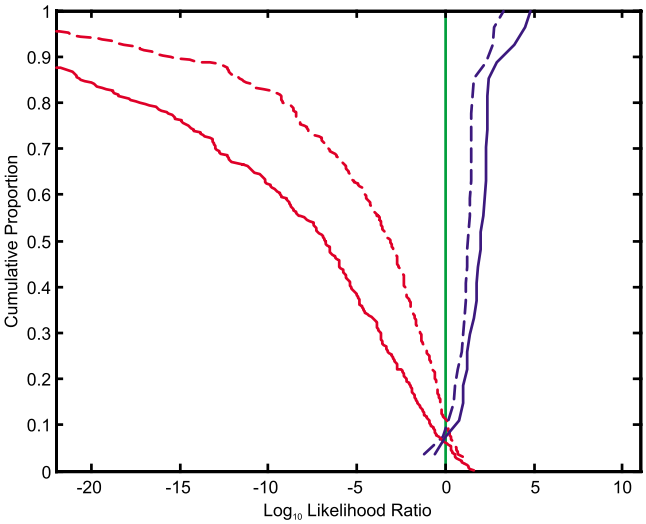

FIG. 6. (Color online) Tippett plot of the best-performing calibrated three-formant (solid line) and two-formant (dashed line) forensic-voice-comparison systems based on Australian-English /aʊ/ formant trajectories.

The cross-validated calibrated LRs from same-speaker comparisons had a low incidence of contrary-to-fact support for the different-speaker hypothesis. The worst result from a best-performing system was for the two-formant system for /aʊ/, which had a LR from a same-speaker comparison which had a magnitude of 17 in favor of the different-speaker hypothesis. For the remainder of the systems the worst LRs from same-speaker comparisons were less than 4 in favor of the different-speaker hypothesis. Given the proximity of these values to 1 they would not be interpreted as providing meaningful support for the different-speaker hypothesis. The cross-validated calibrated LRs from different-speaker comparisons had a higher incidence of contrary-to-fact support for the same-speaker hypothesis: The worst result from a best-performing system was from the three-formant system for /aɪ/, which had a LR from a different-speaker comparison which had a magnitude of 863 in favor of the same-speaker hypothesis. The best cross-validated calibrated LRs for same-speaker comparisons from the best-performing systems ranged from 726 for the two-formant system for /oʊ/ to around 147×10^9 for the two-formant system for /eɪ/.

D. Fused system

Figure 8 provides a Tippett plot of the cross-validated LRs resulting from fusing the best-performing systems for

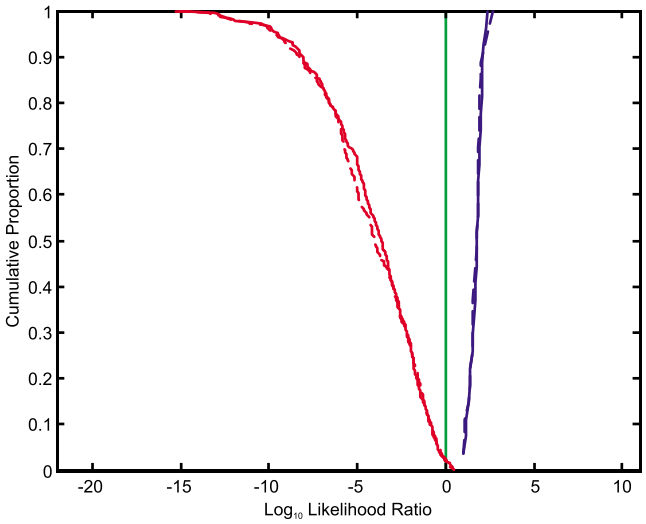

FIG. 8. (Color online) Tippett plot of the fused calibrated three-formant (solid line) and two-formant (dashed line) forensic-voice-comparison systems based formant trajectories from Australian-English /aɪ/, /eɪ/, /oʊ/, /aʊ/, and /ɔɪ/.

each vowel phoneme. The three-formant fused system included the best-performing two-formant model for /eɪ/ since that system outperformed the best-performing three-formant model for this vowel. The results for the fused two-formant and three-formant systems were very similar, suggesting that one would still obtain good results even if the bandpass properties of a telephone transmission channel rendered use of F1 trajectories impossible.

When testing via cross-validation of the training set, the fused systems achieved complete linear separation between same-speaker and different-speaker comparisons. In fact, complete linear separation could be achieved for several combinations of cross-validated LRs from only two vowel phonemes, for /aɪ/-/oʊ/, /aɪ/-/ɔɪ/, /eɪ/-/oʊ/ and for /aɪ/-/ɔɪ/.

In terms of C_{llr}, the fused systems substantially outperformed any of the single-phoneme systems: $C_{\text{llr}}^{\text{min}}$ was zero and post-fusion (post-calibration) C_{llr} was 0.057 for the three-formant system and 0.056 for the two-formant system.

There were no LRs from same-speaker comparisons which contrary-to-fact favored the different-speaker hypothesis. The smallest same-speaker LRs were 10 for the three-formant system and 11 for the two-formant system. LRs from different-speaker comparisons which contrary-to-fact supported the same-speaker hypothesis were reduced to innocuous magnitudes of less than 3. However, the largest same-speaker LRs achieved were only 229 for the three-formant system and 437 for the two-formant system.

IV. CONCLUSION

Parametric curves, polynomials and discrete cosine transforms, were fitted to the formant trajectories of tokens of /aɪ/, /eɪ/, /oʊ/, /aʊ/, and /ɔɪ/ produced by male speakers of Australian-English. The estimated coefficient values from the parametric curves were used as input to the Aitken and Lucy (2004) multivariate-LR formula, a generative formula which calculated a set of LRs for each vowel phoneme. The LRs were then calibrated and evaluated using the LR-cost function (C_{llr}). Finally the results from the best-performing system for each vowel phoneme were fused and evaluated.

There were trends indicating that DCTs generally outperformed polynomials, that third-order parametric curves generally outperformed lower-order curves, that curves fitted using a hertz frequency scale generally outperformed curves fitted using a log Hz frequency scale, and that curves fitted using an equalized-duration time scale generally outperformed curves fitted using the original non-equalized time scale. However, the parametric curve with the best performance for each vowel phoneme could only be determined on a case-by-case basis. The recommended procedure for future research and casework is therefore to proceed in the same manner as the study described here: Test a series of parametric curves using training and test data from the population sample and determine the best-performing system *post hoc* rather than *a priori* deciding a particular system which may turn out to be sub-optimal. Once the best-performing system has been chosen, that system should then be applied to obtain LRs for comparisons of suspect and offender samples (the suspect and offender samples should not be used in the process of determining the best-performing system).

Of the best-performing systems per vowel phoneme, the best performance was obtained for /eɪ/ and the poorest performance for /aʊ/ (the full rank order was /eɪ/, /aɪ/, /oʊ/, /ɔɪ/, /aʊ/). For most vowel phonemes, systems which fitted curves to the trajectories of F1, F2, and F3 outperformed systems which only fitted curves to the trajectories of F2 and F3; however, this relationship was reversed for /eɪ/. Thus although for most vowel phonemes the F1 trajectory contained extractable speaker-differentiating information in addition to that extracted from the F2 and F3 trajectories, the F1 trajectory for /eɪ/ contained confounding information. Again the implication for future research and casework is that the choice of which formant trajectories to include should be determined on a case-by-case basis.

The fused two-formant and three-formant systems produced similar results, indicating that performance would not deteriorate substantially even if F1 trajectories could not be included because of them being compromised by the bandpass properties of a telephone transmission channel. The fused systems performed extremely well in terms of having very low C_{llr} values. In cross-validated tests, complete separation was achieved between same-speaker and different-speaker comparisons. There were no same-speaker comparison results which contrary-to-fact favored the different-speaker hypothesis, and different-speaker comparison results which contrary-to-fact favored the same-speaker hypothesis were restricted to having innocuous LRs of less than 3 in favor of the same-speaker hypothesis. As far as I am aware, these are better results than have previously been achieved for any acoustic-phonetic forensic-voice-comparison system trained and tested on a database of this size.

In addition to producing very low error rates, the fusion-calibration process also resulted in what appear to be quite conservative magnitudes for LRs. The largest same-speaker LR value of 147×10^9 reported for a single phoneme is within the expected range for DNA evidence, but is suspiciously large for speech data and may be the result of poor

estimates of probability densities due to factors such as outliers or small sample sizes. For the fused system the largest same-speaker LR value was a much more conservative 437. There would therefore seem to be little danger of the expert witness overstating the degree of support for one or other of the hypotheses when using LRs generated by the fused system.

It is argued that the results presented here therefore constitute a step toward meeting the Daubert requirement that a methodology be tested and be found to have an acceptable error rate. However, additional testing will still be required before this methodology can be admitted into evidence: The present paper used data from only 27 speakers recorded under highly controlled laboratory conditions. The methodology will need to be tested using data from a larger number of speakers collected under more forensically realistic conditions, for example, extemporaneous speech from telephone conversations. In addition, since the alternative hypothesis is more likely to be "the speaker in the offender sample is someone who sounds like the speaker in the suspect sample" rather than the less-constrained "the speaker in the offender sample is someone other than the speaker in the suspect sample," the methodology should also be tested using recordings from a set of speakers who are judged to be similar by phonetically naïve listeners such as police officers and lawyers.

ACKNOWLEDGMENTS

This research was supported by Australian Research Council Grant No. DP0774115. Thanks to Yuko Kinoshita for providing the speech data. Thanks to Philip Rose, Shunichi Ishihara, Cuiling Zhang, and two anonymous reviewers for comments on an earlier draft of this paper.

[1]The author has chosen to use phonemic representations of these diphthongs which may be considered generic for English in general, and thus likely to be familiar to a larger number of readers. For consistency with the representation of the other diphthongs, the so-called phonetic diphthongs have been represented using two symbols each, /eɪ/ and /oʊ/, rather than one each, /e/ and /o/. For an alternative transcription system specifically tailored to Australian-English see Cox and Palethorpe (2007). The acoustic realizations of the five phonemes in the present study are represented graphically by the mean formant trajectories presented in Fig. 1.

[2]Of these papers, only Morrison and Kinoshita (2008) made use of a portion of the same acoustic analysis results as are reported in the present paper.

[4]A revised version of the software used to measure the vowels "FormantMeasurer" is available on the author's website: http://geoff-morrison.net (last viewed January 11, 2009).

[5]A MATLAB implementation of Aitken and Lucy's (2004) MVKD formula is available on the website of the author of the present paper: http://geoff-morrison.net (last viewed January 11, 2009).

[6]Although LR which favor the different-speaker hypothesis have values of less than 1, it is often easier to understand the presentation if the LR is inverted and a verbal clarification that it is in favor of the different-speaker hypothesis rather than the same speaker hypothesis is added, i.e., state "a likelihood ratio of 10 in favor of the different-speaker hypothesis" as opposed to stating "a likelihood ratio of 0.1."

[7]The FOCAL toolkit is available from http://niko.brummer.googlepages.com/focal (last viewed January 11, 2009). Linear calibration was achieved using the logistic-regression-fusion functions in the FOCAL toolbox with a single predictor variable.

(Received 6 October 2008; revised 15 January 2009; accepted 18 January 2009)

Absolute pitch (AP), the ability to name a musical note in the absence of a reference note, is extremely rare in the U.S. and Europe, and its genesis is unclear. The prevalence of AP was examined among students in an American music conservatory as a function of age of onset of musical training, ethnicity, and fluency in speaking a tone language. Taking those of East Asian ethnicity, the performance level on a test of AP was significantly higher among those who spoke a tone language very fluently compared with those who spoke a tone language fairly fluently and also compared with those who were not fluent in speaking a tone language. The performance level of this last group did not differ significantly from that of Caucasian students who spoke only nontone language. Early onset of musical training was associated with enhanced performance, but this did not interact with the effect of language. Further analyses showed that the results could not be explained by country of early music education. The findings support the hypothesis that the acquisition of AP by tone language speakers involves the same process as occurs in the acquisition of a second tone language. © *2009 Acoustical Society of America.* [DOI: 10.1121/1.3081389]

I. INTRODUCTION

Absolute pitch (AP)—the ability to name a musical note in the absence of a reference note—is very rare in North America and Europe, with an estimated prevalence of less than 1 in 10,000 (Bachem, 1955; Profita and Bidder, 1988). This ability is not necessarily accompanied by superior performance on other auditory or musical tasks (Bachem, 1937; Rakowski, 1972; Lockhead and Byrd, 1981; Rakowski and Morawska-Büngeler, 1987; Miyazaki, 1992, 2004; Burns and Campbell, 1994; Miyazaki and Rakowski, 2002; Fujisaki and Kashino, 2002), and its genesis is unclear.

Perhaps the most surprising feature of AP is its rarity. Most people readily identify hundreds of musical passages by name, yet AP involves choosing between only the 12 notes of the chromatic scale: C, C#, D, and so on. Furthermore, this ability is rare even among professional musicians, who spend tens of thousands of hours reading musical scores and playing the notes they read. Indeed, the vast majority of documented attempts to train adult musicians to acquire AP have been strikingly unsuccessful (Takeuchi and Hulse, 1993; Ward, 1999; Rakowski and Miyazaki, 2007).

Reports from possessors of AP indicate that the earlier the onset of musical training the higher the probability of acquiring this ability (Bachem, 1955; Miyazaki, 1988; Profita and Bidder, 1988). Large-scale studies involving both surveys (Baharloo *et al.*, 1998) and direct tests (Deutsch *et al.*, 2006) have found AP to be most prevalent among those who had begun musical training by ages 4–5, less prevalent between ages 6–8, and very rare after age 9. This association between the possession of AP and age of onset of musical training has led to the surmise that a critical period beginning at around age 2 or 3 is involved in its acquisition (see, for example, Takeuchi and Hulse, 1993). However since it is impractical to initiate formal musical training at an earlier age, the possibility arises that, in principle, this critical period might extend down to infancy. Indeed, Saffran and Griepentrog (2001) found that infants were able to perform a perceptual learning task that required referring to the absolute pitches of tones.

There is an intriguing parallel between the time frames involved in acquiring speech and language, on the one hand (Kuhl *et al.*, 1992), and AP on the other. Concerning first language acquisition, there are rare documented cases of children who had been socially isolated early in life and were later placed in a normal environment; these children were found unable to acquire normal language (Lane, 1976; Curtiss, 1977). Studies of recovery of speech following brain injury have indicated the same time frame: The prognosis for recovery has been found most positive for those whose injury occurred before age 6, less positive between ages 6 and 8, and very poor after puberty (Dennis and Whitaker, 1976; Bates, 1992; Duchowny *et al.*, 1996; Doupe and Kuhl, 1999). Second language acquisition beyond early childhood occurs far more readily than does acquisition of a first language, presumably because the basic underlying circuitry has already been established. However, acquisition of a second

[a]Electronic mail: ddeutsch@ucsd.edu

 0001-4966/2009/125(4)/2398/6/$25.00

language is also subject to a critical period: It occurs extremely readily in infancy (Kuhl *et al.*, 2003), with proficiency in its acquisition declining with increasing age of initial exposure to the second language, reaching a plateau in adulthood (Lennenberg, 1967; Johnson and Newport, 1989; Newport, 1990).

Given the similarity between the time frames for acquiring speech, on one hand, and AP, on the other, it has been suggested that AP was originally packaged in with other features of speech, so that it might be expected to be heavily influenced by the speech-related critical period (Deutsch, 2002; Deutsch *et al.*, 2004, 2006). This hypothesis was first proposed based on the finding that speakers of two tone languages (Vietnamese and Mandarin) displayed a remarkably precise and stable form of AP in reciting lists of words on different days (Deutsch *et al.*, 2004). In tone languages, words take on arbitrarily different lexical meanings depending on the "tones" in which they are pronounced. Tones are defined by both their pitch heights and contours. In Mandarin, for example, the first tone is characterized as high and level, the second as mid-high and rising, the third as initially low and descending and then rising, and the fourth as high and falling. For example, the word "ma" means "mother" when spoken in the first tone, "hemp" in the second, "horse" in the third, and a reproach in the fourth. When, therefore, speakers of Mandarin hear the word "ma" spoken in the first tone, and attribute the meaning "mother," or when they hear "ma" spoken in the second tone and attribute the meaning "hemp," they are using pitch (along with other features of speech) in the process of attributing a verbal label to the sound. Analogously, when people with AP hear the tone F# and identify it as "F#," or hear the note E and identify it as "E," they are also using pitch to attribute a verbal label to the sound.

On this line of reasoning, it was hypothesized that in cultures where tone languages are spoken, infants generally acquire AP for the tones of their language during the critical period in which they acquire other features of their native language (Deutsch, 2002). When they reach the age at which they can begin musical training, they acquire AP for musical tones in the same way as they would acquire the tones of a second tone language (see, for example, Wayland and Guion, 2004). For such individuals, therefore, the acquisition of AP for musical tones should also be subject to a critical period, but its overall prevalence should be considerably higher than for those who had instead acquired a nontone language in infancy and so would not have had the opportunity to develop the basic underlying circuitry at that time.

In a study designed to evaluate this hypothesis, two large groups of music students were administered a direct on-site test of AP, without self-selection from among the target populations. The first group comprised students at the Central Conservatory of Music in Beijing; these were all tone language speakers. The second group comprised students at Eastman School of Music who were nontone language speakers. The data from both groups displayed large and orderly effects of age of onset of musical training, and importantly, the speakers of tone language far outperformed those of nontone language for all levels of age of onset of training (Deutsch *et al.*, 2006).

The above findings are in accordance with the hypothesis that the acquisition of AP is subject to a speech-related critical period. However, the findings are also consistent with a genetic explanation for the difference between the two groups in prevalence of AP. The present study was designed to evaluate the hypothesis that AP is influenced by a speech-based critical period, holding genetic factors constant.

We compared four groups of subjects. The first group, termed *nontone*, consisted of those who were Caucasian and spoke only nontone language. The remaining subjects were of East Asian ethnic heritage, with both parents speaking an East Asian tone language. These subjects were assigned to three groups in accordance with their responses to a questionnaire. Those in group *tone very fluent* responded that they spoke an East Asian tone language very fluently; those in group *tone fairly fluent* responded that they spoke an East Asian tone language fairly fluently; those in group *tone nonfluent* responded that they were not fluent in speaking a tone language. By comparing the prevalence of AP in these four groups, we evaluated the relative contributions of ethnic heritage and language to the probability of acquiring AP.

II. METHOD

A. Procedure

Subjects were administered a test for AP that was identical to that given in the study of Deutsch *et al.* (2006). They were presented successively with the 36 tones spanning three octaves from C_3 (131 Hz) to B_5 (988 Hz) and were asked to write down the name of each tone (C, C#, D, and so on) when they heard it. In order to minimize the use of relative pitch as a cue, all successively presented tones were separated by an interval larger than an octave. The stimuli were piano tones that were generated on a Kurzweil K2000 synthesizer tuned to A_4=440 Hz. The tones were all 500 ms in duration and were presented in three blocks of 12, with 4.25-s intervals between onsets of tones within a block and 39-s pauses between blocks. The three test blocks were preceded by a practice block in which four successive tones were presented. The subjects were given no feedback, either during the test blocks or during the practice blocks. The tones were presented via a compact disk player, amplifier, and two loudspeakers.

Following the test, the subjects filled out a questionnaire that enquired into their music education, ethnic heritage, where they and their parents had lived, languages they and their parents spoke, and how fluently they spoke each language. Specifically concerning linguistic fluency, the subjects chose between the following options: (a) I speak the language very fluently, (b) I speak the language fairly fluently, and (c) I can understand the language, but don't speak it fluently.

B. Subjects

There were 203 subjects in this study. These were 110 males and 93 females, with average age 19.5 years (range

18–33 years). 162 subjects were first- or second-year students taking a required course at Thornton School of Music at the University of Southern California (USC); the remaining 41 subjects were members of the USC Community Orchestra. All those who were invited to take the test agreed to do so, so there was no self-selection of subjects in this experiment. All subjects were free of hearing problems, as indicated by self-report.

Based on their responses to the questionnaire, the subjects were divided into four groups. Those in group *nontone* were Caucasian and spoke only nontone language fluently. These were $n=176$, 98 males and 78 females, with average age 19.4 years (range 18–33 years). The remaining subjects were all of East Asian (Chinese or Vietnamese) ethnic heritage, with both parents primarily speaking an East Asian tone language. These were assigned to three further groups in accordance with their responses to the questionnaire. Those in group *tone very fluent* reported that they spoke an East Asian tone language "very fluently." These were $n=15$, 6 males and 9 females, with average age 20.3 years (range 18–28 years). Those in group tone *fairly fluent* reported that they spoke a tone language "fairly fluently." These were $n=7$, 4 males and 3 females, with average age 21.3 years (range 18–29 years). Those in group *tone nonfluent* responded "I can understand the language, but don't speak it fluently." These were $n=5$, 2 males and 3 females, with average age 18.6 years (range 18–19 years).

Each of the four groups was divided into subgroups by age of onset of musical training: One subgroup consisted of those who had begun musical training at ages 2–5. For *nontone*, $n=49$; for *tone very fluent*, $n=12$; for *tone fairly fluent*, $n=3$; and for *tone nonfluent*, $n=4$. Another subgroup consisted of those who had begun musical training at ages 6–9. For *nontone*, $n=87$; for *tone very fluent*, $n=3$; for *tone fairly fluent*, $n=4$; and for *tone nonfluent*, $n=1$. A third subgroup of nontone language speakers ($n=40$) comprised those who had begun musical training at age ≥ 10. However, all the subjects of East Asian ethnic heritage had begun musical training at age ≤ 9. For this reason, the data from the nontone language speakers with onset of musical training at age ≥ 10 are displayed but not compared statistically with that of any of the other groups.

III. RESULTS

Figure 1 shows, for each subgroup, the mean percentage correct on the test for AP. As is evident, all groups showed clear effects of age of onset of musical training: Performance levels on this test were higher for those who had begun musical training at ages 2–5 than at ages 6–9 (and also than at age ≥ 10 in the case of the nontone language speakers). This association with age of onset of musical training is in accordance with earlier findings (Baharloo *et al.*, 1998; Deutsch *et al.*, 2006).

It can also be seen that those subjects who stated that they spoke a tone language very fluently (*tone very fluent*) displayed remarkably high performance levels on this test. Indeed, their performance was far higher than that of the nontone language speakers (*nontone*). It was also far higher than that of the subjects of same ethnicity but who did not speak a tone language fluently (*tone nonfluent*). In addition, it was higher than that of the *tone fairly fluent* speakers, which was in turn higher than that of the *tone nonfluent* speakers and of the nontone language speakers (*nontone*).

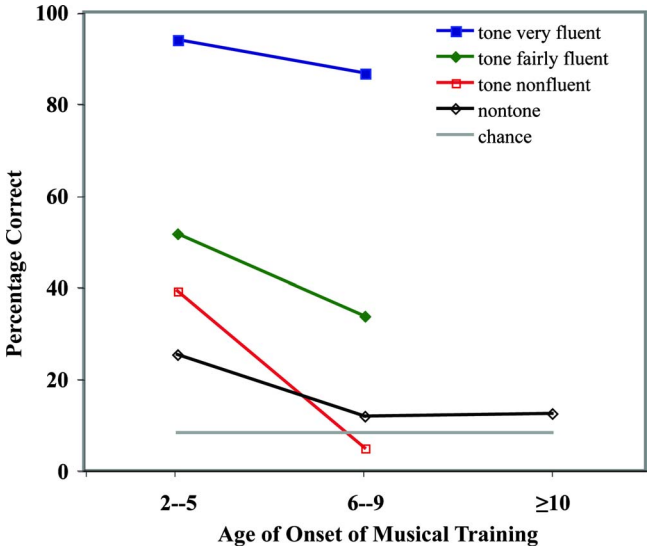

FIG. 1. (Color online) Percentage correct responses on the test of AP, as a function of age of onset of musical training and fluency in speaking a tone language. Those in groups *tone very fluent*, *tone fairly fluent*, and *tone nonfluent* were all of East Asian ethnic heritage. Those in group *nontone* were Caucasian and spoke only nontone language. The line labeled *chance* represents chance performance on the task.

To make statistical comparison between the groups, an overall test for the effect of gender was first performed and found to be nonsignificant ($F<1$); the data from males and females were therefore combined in all further analyses. A 4×2 analysis of variance (ANOVA) was performed, with group (*nontone*, *tone very fluent*, *tone fairly fluent*, and *tone nonfluent*) and age of onset of musical training (*2–5* and *6–9*) as factors. A significant effect of age of onset was found $[F(1,\ 148)=5.15, p=0.025]$. In addition, a highly significant effect of group was found $[F(3,\ 148)=35.43, p<0.001]$. The interaction between group and age of onset was nonsignificant ($F<1$).

On post hoc comparisons, the performance level was significantly higher for *tone very fluent* compared with *nontone* ($p<0.001$, one-tailed), for *tone very fluent* compared with *tone nonfluent* ($p<0.001$, one-tailed), and for *tone very fluent* compared with *tone fairly fluent* ($p<0.001$, one-tailed). The performance level for *tone fairly fluent* was significantly higher than for *nontone* ($p=0.003$) and also higher than for *tone nonfluent* (though the latter comparison was not statistically significant; $p>0.05$). The performance level for the *tone nonfluent* group did not differ significantly from that for the *nontone* group ($p>0.05$). These findings indicate strongly that the differences in performance levels between the groups were determined by language rather than ethnicity. Indeed, taking those subjects of East Asian ethnic heritage, a regression analysis found that fluency in speaking a tone language was a highly significant predictor of performance ($R^2_{\text{adj}}=0.54$, $F(2,24)=16.09$, and $p<0.001$).

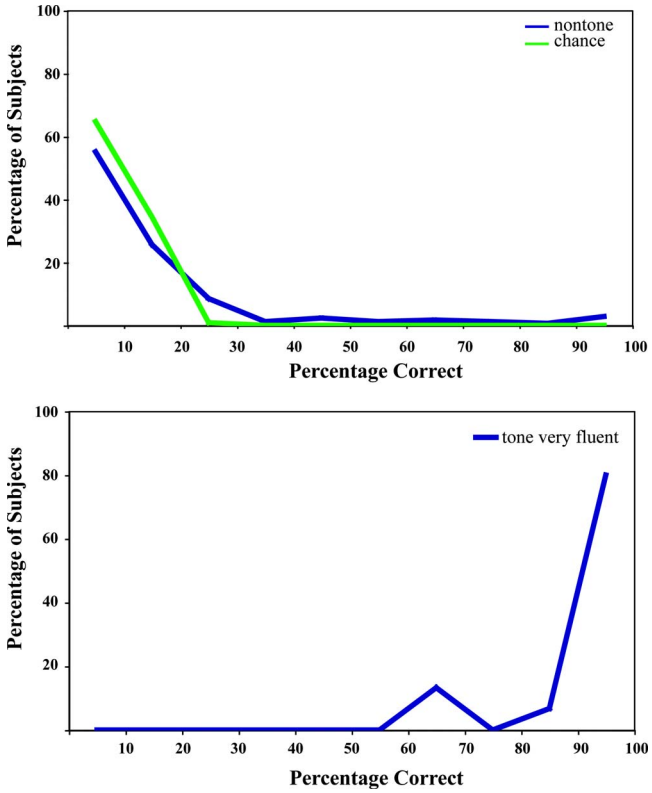

FIG. 2. (Color online) Upper graph: Relative distribution of scores of the nontone language speakers (group *nontone*), together with the hypothetical distribution of scores expected from chance performance. Lower graph: relative distribution of scores in the group *tone very fluent*.

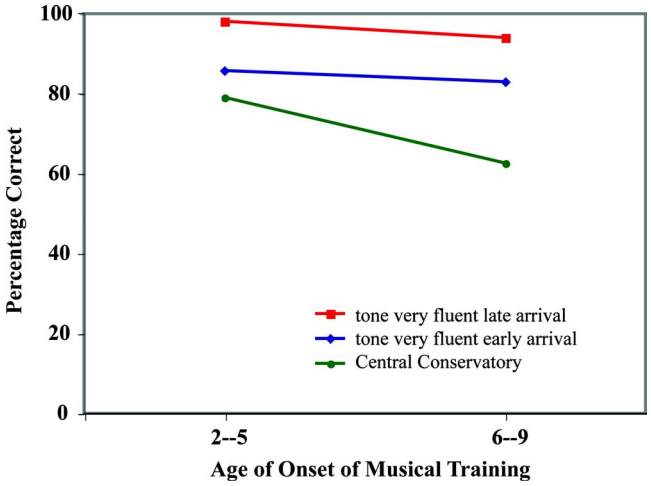

FIG. 3. (Color online) Percentage correct responses on the test of absolute pitch, as a function of age of onset of musical training, among those who were very fluent in speaking a tone language. Those in group *tone very fluent early arrival* had been born in the U.S. or had arrived in the U.S. before age 9. Those in group *tone very fluent late arrival* had arrived in the U.S. after age 9. The data from group *Central Conservatory* were obtained in an earlier study (Deutsch *et al.*, 2006), taken from subjects who had grown up in China and were tested at the Central Conservatory of Music in Beijing, China.

The strong relationship between the prevalence of AP and fluency in speaking a tone language is also reflected in the data shown in Fig. 2. The upper graph shows the relative distribution of scores of all nontone language speakers in the study, together with the hypothetical distribution of scores expected from chance performance (i.e., assuming a 1/12 chance of guessing correctly across 36 trials). We can note that there is the striking similarity between the two plots, with a very slight increase in the prevalence of AP in the 90%–100% region. The lower graph shows, in contrast, the relative distribution of scores in the *tone very fluent* group. As can be seen, the performance level of most of these subjects was in the 90%–100% region.

One issue that arises from these findings concerns the country in which the subjects received their music education. To evaluate this factor, comparison was made, taking only the *tone very fluent (TVF)* group, between those who had been born in the U.S. or who had arrived in the U.S. before age 9 (*TVF early arrivals*) and those who had arrived in the U.S. after age 9 (*TVF late arrivals*). For *TVF early arrivals*, $n=6$, with average age=19.3 (range=18–21). For *TVF late arrivals*, $n=9$, with average age=20.9 (range 18–28). A 2×2 ANOVA was performed, with group (*TVF early arrivals* vs *TVF late arrivals*) and age of onset of musical training (*2–5* vs *6–9*) as factors. The effect of age of onset of musical training was nonsignificant ($F<1$); however, this can be accounted for by a ceiling effect. The difference between the *TVF early* and *late arrivals* was also nonsignificant $[F(1,11)=2.107, p>0.05]$.

Given the remarkably high performance of the two *tone very fluent* groups, we compared their performance levels with those obtained by Deutsch *et al.* (2006) from the students at the Central Conservatory of Music in Beijing who had been administered the identical test for AP. The subjects tested in Beijing had all been born and grown up in China. In this study, we had compared the numbers of subjects in each group who obtained at least 85% correct on the test. In the present experiment, as with the other analyses we performed here, we instead employed the more sensitive measure of percentage correct for each subject. We divided the subjects from the Central Conservatory of Music into the same two categories based on age of onset of musical training as for the subjects in the present experiment, i.e., ages 2–5 and ages 6–9. The *Central Conservatory* subgroup with age of onset of musical training 2–5 consisted of 46 subjects, and the subgroup with age of onset of musical training 6–9 consisted of 34 subjects.

Figure 3 displays the average performance levels of each of these six subgroups. A 2×3 ANOVA was carried out with age of onset (*2–5* and *6–9*) and group (*TVF early arrival*, *TVF late arrival*, and *Central Conservatory*) as factors. The effect of age of onset was nonsignificant ($F<1$). However, this was presumably attributable to the ceiling effect within the TVF groups described above. Taking the *Central Conservatory* group alone, where performance was not at ceiling, the effect of age of onset was clearly significant $[F(1,78)=5.69, p=0.02]$.

Interestingly, the overall effect of group was also nonsignificant $[F(2,89)=1.76, p>0.05]$. In *post hoc* comparisons, the performance of the *TVF early arrivals* was not significantly different from either the *TVF late arrivals* ($p>0.05$) or the *Central Conservatory* group ($p>0.05$). However, the performance level of the *TVF late arrivals* was significantly higher than that of the *Central Conservatory*

group (p=0.013), and the performance level of the *TVF early arrivals* was also higher as a trend than that of the *Central Conservatory* group. This pattern of results shows that the higher performance level among the *tone very fluent* USC students in this study cannot be attributed to country of early music education.

IV. DISCUSSION

The findings presented here indicate strongly that the enhanced prevalence of AP among tone language speakers found by Deutsch *et al.* (2006) was language-related rather than genetic in origin. The present findings further show that when degree of fluency in speaking a tone language is held constant, differences in prevalence of AP among the various groups cannot be explained by the country in which the subjects had received their music education.

Specifically, with respect to the genetic issue, we found, among subjects of the same ethnic heritage, significant differences in performance level depending on degree of fluency in speaking a tone language. In addition, we found no significant difference in performance level between the (genetically East Asian) *tone nonfluent* group and the (genetically Caucasian) *nontone* group. With respect to the surmise that the differences we obtained might be related to country of early music education, we found no significant difference in overall performance level between the *tone very fluent (TVF)* subjects and those tested in the study of Deutsch *et al.* (2006) who were students at the Central Conservatory of Music in Beijing and who had all received their music education in China. Furthermore, we found no significant difference between the (USC) *TVF early arrivals* and *TVF late arrivals*, who all spoke a tone language very fluently. Indeed, the prevalence of AP was higher as a trend among the *TVF early arrivals*, who had received their music education in the U.S., than among the *Central Conservatory* students, who had received their music education in China. This difference might be accounted for by the fact that many of the *Central Conservatory* students would have had extensive experience with Asian musical scales, and this could have interfered to some extent with the note naming task employed here. It is further interesting to observe that there was a trend for the *TVF late arrivals* to perform better than the *TVF early arrivals*, and we may conjecture that this superior performance resulted from their more extensive experience with tone language. Furthermore, since the *TVF late arrivals* were studying at USC we may conjecture that they would have been more immersed in the tradition of Western tonal music, and so with Western musical scales, than were the *Central Conservatory* students; this could account for the higher performance levels of the *TVF late arrivals* compared with the *Central Conservatory* group.

It is also interesting to note that, taking the subjects of Chinese or Vietnamese ethnic heritage, those who spoke a tone language fluently were considerably more numerous than were those who were not fluent in speaking a tone language, and further that for all subjects of Chinese or Vietnamese ethnic heritage (including those born in the U.S.) both parents spoke a tone language fluently. This contrasts with the assumption that is frequently made that East Asian students in music schools in the U.S. would include many who speak only English. The present findings show that using the criterion of "ethnicity" without considering linguistic factors could lead to incorrect conclusions about the genesis of AP [see also the survey study by Gregersen *et al.* (2001) and the Comment on this study by Henthorn and Deutsch (2007)].

It is further interesting to note that all subjects in the *tone very fluent*, *tone fairly fluent*, and *tone nonfluent* groups would have been exposed to tone language in infancy. This shows that exposure to tone language during the critical period for language acquisition is not, in itself, sufficient to produce an advantage for the acquisition of AP. Our findings are, however, in accordance with those of others showing substantial first language attrition in children who, having initially been exposed to one language, later primarily speak a different language (see, for example, Kaufman and Aronoff, 1991; Nicoladis and Grabois, 2002; Ventureyra *et al.*, 2004). We must conclude from our present findings that continuity in speaking a tone language is an important factor in the probability of acquiring this ability.

The present findings leave open the question of the genesis of AP among individuals who speak only nontone language. On the present line of reasoning, there would be an advantage to those who are born into families of musicians since they would have had the opportunity to associate musical tones with their names very early in life—frequently before they begin formal musical training. This could account for findings of familial aggregation of AP (Bachem, 1955; Profita and Bidder, 1988; Baharloo *et al.*, 1998) though such findings are also in accordance with genetic explanations. It has further been conjectured (Deutsch, 2002, 2006; Deutsch *et al.*, 2004) that those who are not born into a strongly musical environment and nevertheless acquire AP may have a language-related critical period of unusually long duration, so that it extends to the age at which they can begin taking music lessons. Such an extended critical period might well have a genetic basis. The finding of an enhanced leftward asymmetry of the planum temporale among Western AP possessors (Schlaug *et al.*, 1995; Zatorre *et al.*, 1998; Keenan *et al.*, 2001) would indicate that hardwired, and so possibly genetic, factors could be involved here. Nevertheless, the factors determining the acquisition of AP by nontone language speakers remain unresolved.

ACKNOWLEDGMENTS

We are grateful to David Walsh, Robert A. Cutietta, Frederick Lesemann, and Sharon Lavery for their help in various phases of the experiment and to Rachael Lapidis and Jing Shen for discussions.

Trombone bore optimization based on input impedance targets

Alistair C. P. Braden,[a] Michael J. Newton, and D. Murray Campbell
School of Physics, University of Edinburgh, Edinburgh EH9 3JZ, United Kingdom

(Received 28 August 2008; revised 2 February 2009; accepted 2 February 2009)

Optimization methods based on input impedance target functions have been proposed for the design of brass musical instruments. Criteria for target functions in trombone bore optimization are discussed, drawing on experimental input impedance data from a variety of high-quality trombones of differing sizes. An "inharmonicity plot" is introduced and used to aid the interpretation of impedance curves. An efficient optimization technique is described and is shown to be capable of predicting bore changes which achieve specified modifications to the input impedance curve while maintaining a smoothly-flaring bell contour. Further work is required to clarify the relationship between input impedance targets and the preferences of professional players.

I. INTRODUCTION

A player produces a note on a brass musical instrument by expelling a stream of air through the lips, which are pressed against the mouthpiece of the instrument. For an appropriate mechanical configuration, and a suitable range of fluid parameters, the flow of air over the lip surfaces causes them to destabilize and to vibrate. The resulting periodic modulation of the volume flow through the lips acts as an acoustical source, and is the origin of the musical sound radiated by the instrument. When the lip vibration frequency is close to the frequency of one of the acoustical modes of the downstream resonator, a significant pressure variation develops in the mouthpiece, leading to an acoustical feedback from the resonator to the lips. This feedback loop encourages the development of a powerful self-sustained oscillation of the coupled system at a frequency close to that of the acoustical mode in question.

At least for moderate playing levels,[1] the brass instrument may be modeled as a non-linear flow control valve coupling a linear mechanical oscillator (the lips) to a linear acoustical resonator (the air column).[2] The playing behavior of the instrument depends on the properties of both the lips and the resonating tube. In learning to play the instrument, the player develops expertise in lip control; the role of the instrument designer is to optimize the acoustical behavior of the resonating tube when coupled to the lips of a player. The linear acoustical properties of the resonator are described by the input impedance $Z_{\mathrm{in}}=p_{\mathrm{in}}/U_{\mathrm{in}}$, where p_{in} is the acoustic pressure in the mouthpiece and U_{in} the volume flow into the mouthpiece. For a conventional brass instrument such as a trumpet, trombone, or horn, Z_{in} is almost completely determined by the bore-profile $r(x)$, where r is the tube radius and x the axial distance from the mouthpiece entrance plane.

In the 1970s, Smith and Daniell developed a method for calculating the bore perturbations necessary to achieve specified changes in the input impedance curves of brass instruments.[3] More recently, Kausel[4] and Noreland[5] described approaches to the optimization of bore-profiles of brass instruments using targets based on input impedance curves. However, this approach relies on the ability to define the target input impedance curve; it is not yet clear which features of the input impedance curve correspond to optimum behavior as judged by the player.

Poirson *et al.*[6] conducted research into the effect of mouthpiece depth on trumpet timbre, using the spectral centroid to measure the brightness. The results show a correlation (but not necessarily a causal relationship) between the brightness and the inharmonicity, magnitude, and Q-factor of the input impedance peak corresponding to the second harmonic of the played frequency.

Bertsch and co-workers[7–9] made extensive studies into the correlation between input impedance and playing characteristics as determined through blind testing. Chick *et al.*[10] examined the inharmonicity of various French Horns in all valve positions. An extensive comparison of objective and subjective tests of trumpet leadpipes by Poirson *et al.* suggested that the optimum impedance curve as determined by player choices did not correspond to perfect harmonic alignment of acoustic resonances.[6]

Several previous studies[11–17] have identified minor discrepancies between measured and calculated input impedance curves for wind instruments. These discrepancies can arise from uncertainties and calibration problems in the experimental techniques, or from approximations made in the calculations. Real instruments have been successfully optimized in spite of these discrepancies,[18] although they may limit the application of this approach to very fine work. The development of improved optimization techniques is not constrained by this problem, since the efficacy of such techniques as applied to theoretical instruments is independent of the accuracy of the underlying impedance calculations.

In Sec. II of this paper, the use of the input impedance curve as a target for trombone optimization is further explored. Measurements of the input impedance of several trombones which are very highly rated by professional players are presented and analyzed, using a plotting method which allows simultaneous visualization of the resonance

frequencies, peak amplitudes, and peak widths. In Sec. III an improved computational method for bore optimization is described, and its use is illustrated in Sec. IV by predicting the bore changes required to achieve specified changes in the frequencies and amplitudes of input impedance peaks of a trombone. Finally, Sec. V discusses the usefulness and limitations of the currently available techniques, and reviews the work which needs to be done to provide a firm foundation for the choice of input impedance targets for brass instrument optimization.

II. INPUT IMPEDANCE TARGETS FOR OPTIMIZATION

A. Measurement and analysis of input impedance curves

A typical input impedance curve for a tenor trombone is illustrated in Fig. 1. Peaks in the curve occur at frequencies corresponding to air column standing waves with a pressure antinode at the mouthpiece. Since the lips behave as a pressure-controlled valve, each impedance peak is close in frequency to one of the pitches which can be strongly sounded; these pitches are known as the natural notes of the instrument.

While an input impedance plot unquestionably contains the essential information about the linear acoustical behavior of an instrument, a number of important features are not obvious when examining such a plot. The most important of these features is probably the mode inharmonicity, which describes the extent to which the peak frequencies deviate from a single harmonic series. Chick *et al.*[10] used the method of *Equivalent Fundamental Pitch* to plot the mode frequencies of horns in a manner which highlights the deviation from perfect harmonicity. For the ith resonance f_i, the fundamental frequency of which it is an exact ith harmonic is calculated, along with the intonation of this equivalent fundamental pitch relative to an arbitrary reference frequency F. This gives a measure, in cents, of the individual harmonic alignment of the peak frequencies, and therefore how closely the peaks collectively match a harmonic series. An example EFP plot is given in Fig. 2; the modes of an instrument with perfect harmonicity would lie on a vertical line on this plot. In this paper, F is chosen such that the fourth resonance lies on the vertical axis.

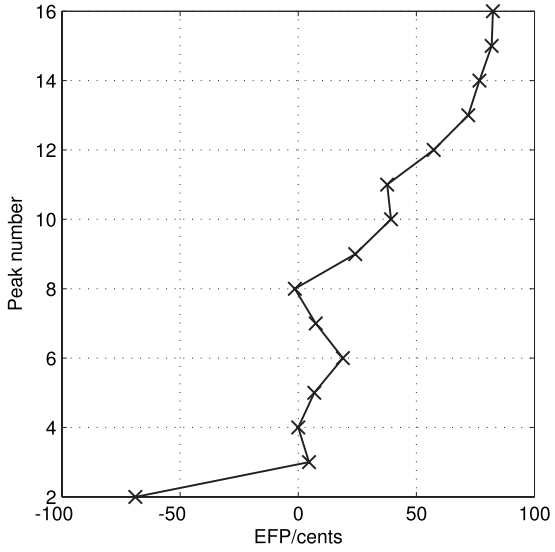

FIG. 2. EFP plot of a typical large-bore tenor trombone, showing resonances 2–16 (F=58.3 Hz).

Although the inharmonicity of the resonances is easily read from an EFP plot, one major disadvantage is the lack of data describing the magnitude and Q-factor of the peaks. The influence of a small, narrow, harmonic peak may be somewhat less than that of a tall, broad inharmonic peak; the EFP does not represent this and can therefore be misleading. For this purpose, an *inharmonicity plot* is introduced; this is a development of the EFP plot including both the magnitude and the Q-factor. For each mode, the impedance magnitude at a series of frequencies corresponding to a pitch interval ±100 cents around the reference frequency F is plotted on an EFP plot as a thin horizontal band, with color or grayscale denoting the impedance magnitude. Figure 3 shows the inharmonicity plot of a typical tenor trombone (this, along with the EFP plot in Fig. 2, is taken from the impedance curve in Fig. 1). The inharmonicity, relative magnitudes, and shapes of the peaks can be viewed simultaneously on this plot; an instrument with strong narrow and harmonic impedance peaks would appear as a narrow white vertical band.

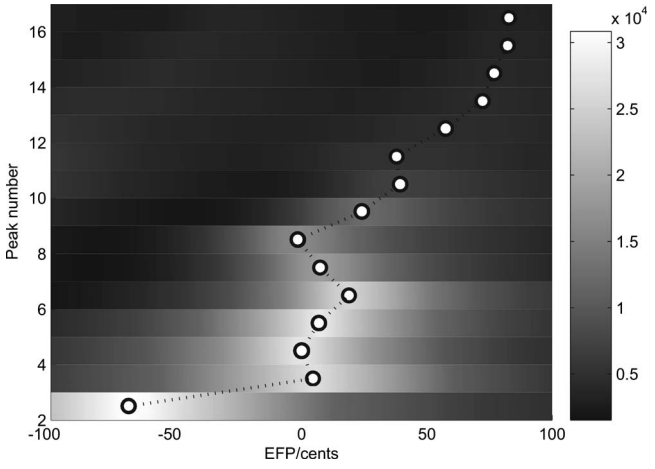

FIG. 3. Inharmonicity plot of a typical large-bore tenor trombone, showing resonances 2–16 (F=58.3 Hz).

B. Inharmonicity and mode-locking

Backus and Hundley[19] first suggested that an approximately harmonic alignment of the resonator peaks would help to maintain stable oscillations of the lips. For example, B♭$_2$ played on a trombone excites the resonances numbered 2, 4, 6, etc., represented by the corresponding input impedance peaks (Fig. 1). Fletcher[20] pointed out that, if the inharmonicity of the modes were sufficiently small, a self-sustained vibration regime could be established in which several modes maintained a fixed phase relationship. This mode-locked regime was described by Benade[21] as a "cooperative regime of oscillation."

Because of the non-linear character of the lip valve, the relative influence of each of the higher resonances on the regime is dependent on the dynamic level played; qualitatively, at pianissimo the excitation is nearly sinusoidal and only the sounded resonance has a significant influence, whereas at forte (excluding "brassy" cases[22]) the higher resonances have a much larger effect. It should be noted that some peaks (e.g., 4, 6, and 8) are part of the regimes of several sounded notes, whereas others (those of prime index) contribute only to one regime.

Worman[23] attempted to describe the overall intonation and resonance characteristics of a regime based on the sum-function

$$\mathrm{SF}(f) = \frac{1}{n}\sum_{n} \mathrm{Re}(Z_0(nf)), \tag{1}$$

where n is the harmonic number, Z_0 the input impedance, and f the frequency in question. Under this assumption, a perfectly-harmonic set of resonances would provide the tallest possible peaks in the sum-function, and therefore offer the strongest response to the player. The harmonic content in the radiated sound would be maximized (for the given peak magnitudes) and the intonation of the played regimes would have integer relationships. A modified version of the sum-function, altering the weighting such that higher peaks have a progressively greater influence at higher dynamics, was originally proposed by Worman and has recently been implemented in commercial software.[24]

The most strongly coupled oscillation regime would occur for a perfectly-harmonic series of acoustical resonances. However, it is not obvious that this should be the goal of the brass instrument designer, who must balance various issues including timbre, playability, stability, and intonation. A perfectly-harmonic series of bore resonances may produce a very stable oscillation, provided the player can match the embouchure to the note, but the resulting regime would be very difficult to "bend" or "lip" in musically expressive ways that alter the playing frequency of the note. Jazz players, and performers on natural instruments like the baroque trumpet, often require to bend a note away from its nominal pitch, a technique that is certainly easier when the instrument bore has some inharmonicity.[25]

The structure of musical scales also implies that a perfectly-harmonic series of resonances would not necessarily yield perfect musical intonation in all circumstances. Apart from the octave, none of the intervals of the equally-tempered scale corresponds exactly to an interval of the harmonic series; playing in tune requires frequent subtle modifications in playing pitch to fit the musical context. The balance to be drawn between stability and flexibility of intonation will depend on the playing style and repertoire of the individual musician.

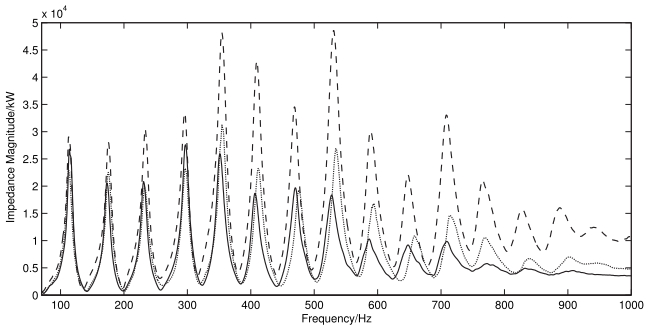

FIG. 4. Measured impedance plots for trombones A (dashed), B (dotted), and C (solid).

C. Input impedance measurements on high-quality trombones

In choosing an instrument, a professional player takes many different criteria into account.[6,8] To investigate how these choices are reflected in the input impedance curves, impedance measurements were made on three contrasting professional-standard models of trombone, all from the same highly-regarded British manufacturer. Trombone A was a medium-bore jazz trombone, B was a large-bore orchestral tenor, and C a bass trombone; each was fitted with an appropriate mouthpiece. The measurements were made using the BIAS input impedance measurement system.[24]

Figure 4 shows the input impedance magnitude plots. The most striking difference is in the peak heights for trombone A, which are consistently taller than for the larger bore instruments. The peak heights of the bass trombone C are generally, but not always, lower than those for B, particularly in the upper range of the instrument. The peaks of A in the upper range are particularly tall, which may be linked with the comparative ease of playing in this register with this instrument.

From these magnitude plots are produced inharmonicity plots (Fig. 5). It is clear that the peak frequencies do not represent an exact harmonic series. For each trombone, the first mode is several semitones below the nominal pitch of B$_1^{\flat}$ and is not shown on the EFP plot. The second peak is also rather flat, although markedly less so for the bass trombone C than for the tenor trombones. Given the similar peak heights and shapes in the lower ranges of these instruments, and the knowledge that the bass is generally preferred to the tenor for low pitch music, this preference can be tentatively linked with the large difference in the alignment of mode 2.

Each instrument shows a general right-hand diagonal trend on the EFP plot, denoting that higher peaks are tuned to a progressively sharper equivalent fundamental; the effect is considerably lesser in the smaller trombone. Similar results were taken with the same BIAS equipment on French Horns,[10] and demonstrate that B♭ horns have peaks which

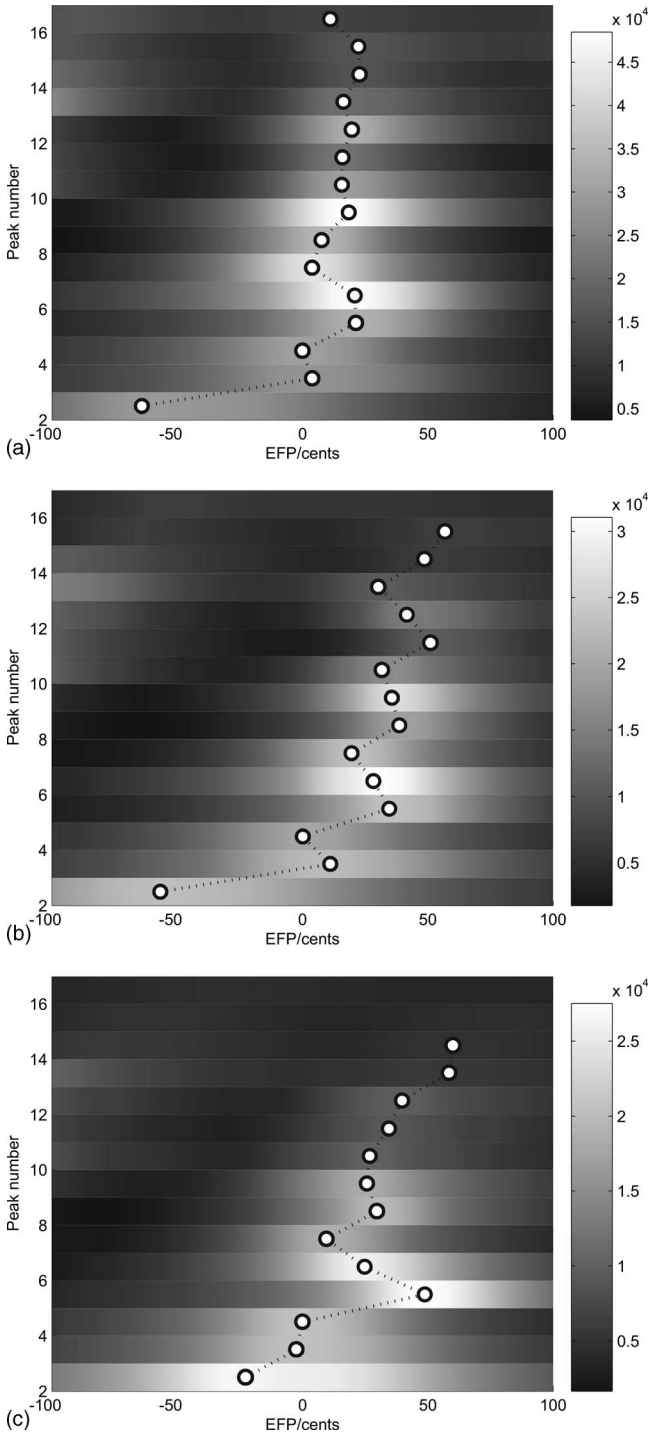

FIG. 5. Inharmonicity plots, showing resonances 2–16.

are considerably closer to a harmonic series than those of the trombones here. From these two studies, given that these instruments are considered of first-rate quality, it can be concluded that inharmonicity of this kind is a desirable feature contributing to the characteristic sound of the trombone, and particularly the large-bore trombone.

III. BORE OPTIMIZATION USING SPECIFIED INPUT IMPEDANCE TARGETS

For some years now, computer optimization techniques have been applied to brass instrument design problems. By taking an established model to calculate the impedance of an instrument with given bore-profile, and combining it with a search algorithm, a computer can be used to find the bore-profile whose impedance best matches specified performance characteristics (such as the location of resonances). Such optimization techniques allow many possible instrument designs to be tried quickly, without the material expenses of building many prototypes. Optimization can be used for *bore reconstruction* (deducing an unknown bore from a known impedance) and for *performance optimization* (modifying an existing design to alter certain characteristics while maintaining others).

The first attempt at such optimization was by Kausel,[4] representing the instrument using a piece-wise linear interpolation of points along the bore ("point-wise") and optimizing with the 0th-order Rosenbrock search algorithm. This method is commercially available and has been used by a manufacturer to design trumpet leadpipes.[18] Noreland[5,26] used a point-wise representation of the second derivative of the bore radii and the gradient-based Levenberg–Marquardt algorithm to give smoother bore-profiles. Both of these techniques assume plane-wave propagation. Similar techniques have been applied to the optimization of xylophones[27,28] and to leak detection.[29]

This section describes briefly the computer optimization technique developed by Braden, further details of which are given elsewhere.[15,30] This technique combines n-mode impedance modeling with the Rosenbrock optimization algorithm to search within a space of possible instrument designs to find that one whose input impedance best matches target criteria. The technique given is well-suited to optimizing complete instruments with realistic geometries, giving smooth bell flares. We show here results demonstrating the latter, using a design space constrained to include only "reasonable trombone shapes."

Any design optimization problem must combine a numerical representation of the object being designed, a quantitative method of evaluating possible designs, and an algorithm for the next "try" given previous tries.

A. Objective function

Input impedance magnitude is an objective acoustic property, contains much useful information about the performance of the instrument, is experimentally measurable, and can be calculated numerically; this combination of features allows us to center our optimization around it. The peak locations (frequency and magnitude) have the greatest influence on the performance, though other properties, such as the width and shape of peaks, also have an effect. The aim is to find the instrument shape whose impedance properties best match certain targets; these targets will be defined in terms of another impedance curve and/or certain specific characteristics of the impedance peaks.

Given an instrument shape, which is denoted symbolically by α, a method for computing the input impedance must be chosen. Previously, this has been a plane- or spherical-wave model,[31] which both Kausel and Noreland employed; the results in this paper were also computed using

this method. However, the optimization technique described here has also been successfully employed[15] with a model including higher modes.[12,14,32] Qualitatively similar optimization results were found with either model (with appropriate targets), so either model could have been chosen in principle. In practice, the computationally rather less expensive plane-wave model is more convenient for repeated experiments investigating the full capabilities of the optimizer, as is the primary goal of this paper, and was therefore chosen.

An objective function must be chosen to compare the impedance properties of each "tested" instrument to target impedance data. Three objective functions are used here in different combinations depending on the task, each giving scores between 0 (a perfect match) and 1 (no match). Typical tuning-parameter values are given. The objective functions are formulated as a minimization problem. The first function is a windowed linear least-squares comparison of the entire (discrete) impedance magnitude curve with N_{pt} points:

$$\mathcal{O}_1(\alpha) = \frac{1}{N_{\mathrm{pt}}} \sum_{i=1}^{N_{\mathrm{pt}}} \begin{cases} \dfrac{(\delta z_i)^2}{\nu^2} & \text{if } \delta z_i < \nu, \\ 1 & \text{if } \delta z_i \geqslant \nu, \end{cases} \tag{2}$$

where $\delta z_i = |z(f_i) - \bar{z}(f_i)|$, i.e., the difference between tested impedance magnitude z and target $\bar{z}$ measured at a series of frequencies f_i, and ν is the half-width of the window (usually 100–300 kΩ). Any valid method for computing $z(f_i)$ from α may be used. Both Kausel and Noreland used this least-squares approach but without the windowing, which eliminates cases where a very bad feature can overwhelm the more subtle difference in score between another feature being good and very good, thus improving overall convergence. In addition to the least-squares approach, a windowed-Gaussian comparison is used, scoring only the peak frequencies:

$$\mathcal{O}_2(\alpha) = \frac{1}{N_{\mathrm{pk}}} \sum_{i=1}^{N_{\mathrm{pk}}} \begin{cases} \dfrac{1 - \exp\left(\dfrac{-\mu_\phi (\delta\phi_i)^2}{\nu_\phi^2}\right)}{1 - \exp(-\mu_\phi)} & \text{if } \delta\phi_i < \nu_\phi, \\ 1 & \text{if } \delta\phi_i \geqslant \nu_\phi, \end{cases} \tag{3}$$

where $\delta\phi_i = |\phi_i - \bar{\phi}_i|$, i.e., the difference between tested peak-frequency ϕ_i and target peak-frequency $\bar{\phi}_i$ of peak i, the window half-width ν_ϕ (typically 10 Hz), μ_ϕ is a "strictness" parameter (typically 20), and N_{pk} the number of impedance peaks being tested. The function joins smoothly at the window bounds $\phi_i \pm \nu_\phi$ to take a value of 1. The gradient of the Gaussian function is much steeper at a moderate distance from the target than the equivalent least-squares function, and consequently offers improved convergence speed in this region.

A very similar function $\mathcal{O}_3$ is also used for the peak heights, using difference $|z(\phi_i) - \bar{z}(\bar{\phi}_i)|$ and magnitude-dependent window half-width $\nu_z z(\phi_i)$, with parameters ν_z and μ_z (typically 0.05 and 10, respectively). An overall objective function is then defined as

$$\mathcal{O}(\alpha) = \frac{\zeta_1 \mathcal{O}_1(\alpha) + \zeta_2 \mathcal{O}_2(\alpha) + \zeta_3 \mathcal{O}_3(\alpha)}{\zeta_1 + \zeta_2 + \zeta_3}, \tag{4}$$

where $\zeta_{1,\ldots,3}$ are weights which can take any real value, but are usually 0 or 1. The goal is to find the α which minimizes $\mathcal{O}(\alpha)$.

B. Instrument representation

The convergence rate of optimization algorithms is strongly dependent on the number of design variables N_v and the size of the design space; by reducing each of these, the performance of the optimization can be improved. Care must be taken to avoid pre-determining the eventual solution by constraining the space too restrictively; the optimizer must be given enough freedom to explore many reasonable solutions.

In Kausel's method, no attempt is made to constrain inappropriate designs, so many outlandish shapes are possible; for example, Fig. 6 in Ref. 33 is too "jagged" to be a realistic instrument. Noreland's smoothing method makes jagged results unlikely, but instead "wiggly" shapes are common (for example, Fig. 14 in Ref. 26). Designs such as these would be rejected out of hand by any manufacturer, regardless of their playing characteristics; the present method attempts to remove them from the design space altogether.

To a first approximation, a trombone is a long cylindrical tube, of given length and radius, connected smoothly to a Bessel-horn, defined as

$$r(x) = b(-x)^{-\gamma}, \tag{5}$$

where r is the bore radius a distance x along the axis of instrument, γ is a flare constant, and b is a constant defined in terms of specified length and input/output radii. Given appropriate constraints, it is possible to define a five-dimensional space (i.e., $N_v = 5$) of possible designs, all of which are reasonable (albeit simple) trombone shapes. Bessel-horns, however, are not exact matches for real trombone bells, so the design space here is too limited. The bell is therefore described as a number of shorter Bessel-horns placed end-on-end,[30] to achieve much closer *piece-wise Bessel-horn interpolations* of real instruments. By confining the design space in this manner, many unacceptable possible solutions have been eliminated, significantly reducing the size of the design space. As with other piecewise interpolation techniques, a small discontinuity of gradient at the joints between pieces must be accepted; some unrealistic designs with large gradient discontinuities therefore exist in the space, but are proportionately far less frequent than for other representations.

In practice, the shape of a real trombone bell can be very closely described by five Bessel-horns of different flares, giving $N_v = 12$, where one variable is the length of the sections, six describe the input and output radii of the sections, and five give their flare coefficients (previous approaches typically require $N_v \sim 100$). Use of such a higher-order parametrization of the design of the instrument therefore con-

fers a significant reduction in the number of design variables as well as a reduction in the size of the design space, giving an increase in optimization speed.

Other practical necessities in realistic instrument design, such as discontinuities caused by the joins between sections, tuning slides, etc., can be included in such parametrizations. In this manner, a description can be given of the complete general shape of the instrument to be designed;[30] this is termed a *design template*, and it is a representation of the detailed geometry of the instrument without the exact dimensions. A template can be constructed that can describe all trombones fairly closely; however, in practice it is more effective to have more detailed templates for more specific problems, such as tenor and bass trombones. Preset mouthpiece geometries can be specified and held fixed throughout the optimization.

Approaching optimization problems in this manner trades off generality against improved convergence. One of the advantages of the pointwise approach was the suitability to any given problem with little or no prior knowledge of the instrument shape—so-called "black-box" problems. The approach given here assumes that the rough shape of the instrument is already known, while this is less attractive in principle, the disadvantage is negligible in practice. Given that the primary objectives are the reconstruction and optimization of brass instruments, it is not unreasonable to assume that the class of the instrument (e.g., trumpet or trombone) is already known, and therefore that the rough shape is also known; a template can thus be chosen from prior knowledge of these instruments. The constraints are set to be large enough that the design space includes all known instruments of that class, so that it is still general enough to include all solutions to the specific problem in hand, but removes many of the unreasonable solutions that another, more general, approach would include. This approach favors pragmatism over rigorous generality, but it should be noted that templates can be constructed to consider general problems in the same (point-wise) way as Kausel,[4] so, rather than being lost, this generality is merely put aside unless needed.

C. Optimization algorithm

Noreland successfully applied a gradient-based method to instrument optimization. Use of such methods, however, requires a derivative of the objective function with respect to the design variables, and therefore a derivative of the input impedance. Noreland provided such a derivative for the plane-wave model. The technique described here was developed to be applicable to a broader range of impedance techniques, including methods for higher modes[14] and bent waveguides.[34] In principle, derivatives of these methods can be found and combined with a gradient-based method. Such derivation is outside the scope of the current work and has not yet been attempted; the present study is therefore restricted to the use of optimization algorithms which do not require derivatives. In the vein of Kausel, the Rosenbrock[35] method is chosen; this has been found to be superior to evolutionary approaches even in low-N_v parametrized problems.[30]

IV. OPTIMIZATION RESULTS

A. Tuning peak 2

It has been established through experimental comparison of a tenor and bass trombone that the tuning of peak 2 relative to the higher even-numbered peaks (particularly peak 4) has a significant effect on the lower playing register of the instrument. In this experiment, an attempt was made to improve a popular design of tenor trombone by shifting peak 2 into a closer alignment without compromising any other resonance properties.

The starting point was based on detailed geometrical measurements of a large-bore tenor trombone. The impedance of the instrument was then calculated with the spherical-wave model and the peak frequencies set as an optimization target, with the following modifications: the target frequency of peak 2 was shifted from 112.0 to 115.0 Hz (a shift of +45 cents), and the target frequency of peak 5 was shifted from 292.5 to 295.0 Hz (a shift of +15 cents). It was found that allowing freedom in the location of peak 5 granted greater flexibility in the location of peak 2.

Figure 6 shows that the optimizer produced a solution which closely matches the target set. Peaks 2 and 5 are now located at 114.7 and 295.1 Hz, respectively. Peaks 3 and 4 have not been significantly altered. It is evident from the EFP plot [Fig. 6(b)] that the desired re-alignment of peak 2 has occurred. As a compromise, the higher peaks have all been shifted by between +5 cents and +20 cents; these are all rather smaller than the +41 cents shift of peak 2. The impedance magnitudes of the peaks have been affected, notably peaks 3–6, which have been shortened, and peaks 8 and 9, which are taller.

Figure 6(c) shows the optimized bore-profile. The bore design is smooth, realistic, and could be built by a manufacturer with no additional difficulty; it can be described as a modified version of an existing design. The bore of the cylindrical section (i.e., the main slide) has been reduced from 6.95 mm radius (or, in the conventions of the instrument industry, 0.547 in. diameter) to 6.63 mm radius (0.522 in. diameter). The overall instrument length is some 26 mm shorter than before, and the bell contour has been subtly altered, as has the taper of the tuning slide. Given the performance target, these results are somewhat surprising; since the optimization is attempting to replicate a feature of a bass trombone, it might have been expected that the bore of the cylindrical section would have increased.

Clearly the trombone design space is complicated. Certain regions of high performance are well-established in the industry, and it may be that the optimizer has uncovered a region which might have otherwise been unexplored. Musical judgments of the success of the optimization will not be available until an example has been built and tested; however, the exercise has demonstrated the capability of the software to perform whole-instrument intonation optimization.

B. Modifying peak magnitudes

In a second test of the optimization software, an attempt was made to modify the magnitudes of specified impedance peaks. The target impedance was again a modification of the

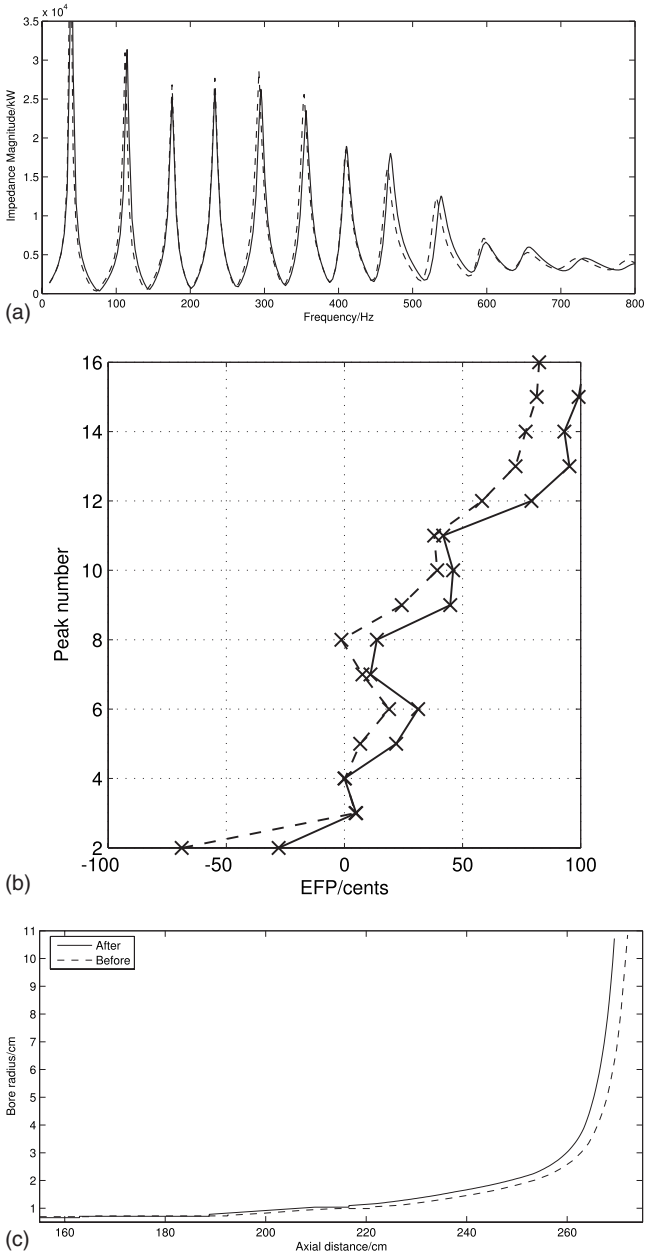

FIG. 6. Results of tuning peak 2 before (dashed) and after (solid) optimization.

measured impedance curve for the large-bore tenor trombone: this time peaks 8, 9, and 10 were targeted to increase in magnitude by 10%, and no target was set for the magnitude of peaks 1–7. The peak frequencies were left unchanged.

It can be seen from Fig. 7(a) that the optimization was successful, increasing peak 8 from 16 110 to 17 602 kΩ, peak 9 from 12 358 to 13 668 kΩ, and peak 10 from 7094 to 8064 kΩ, respectively, increases of 9.2%, 10.6%, and 13.6%. Certain lower-index peaks were reduced in amplitude, most notably peak 5 from 28 671 to 25 820 kΩ, a decrease of 9.9%. The frequency (and therefore EFP) of peaks 2–10 was not significantly changed; higher peaks were each made roughly 5 cents sharper. The bore-profile [Fig. 7(b)] again shows a reduction in the radius of the main slide from 6.95 mm (0.547 in. diameter) to 6.65 mm (0.524 in.

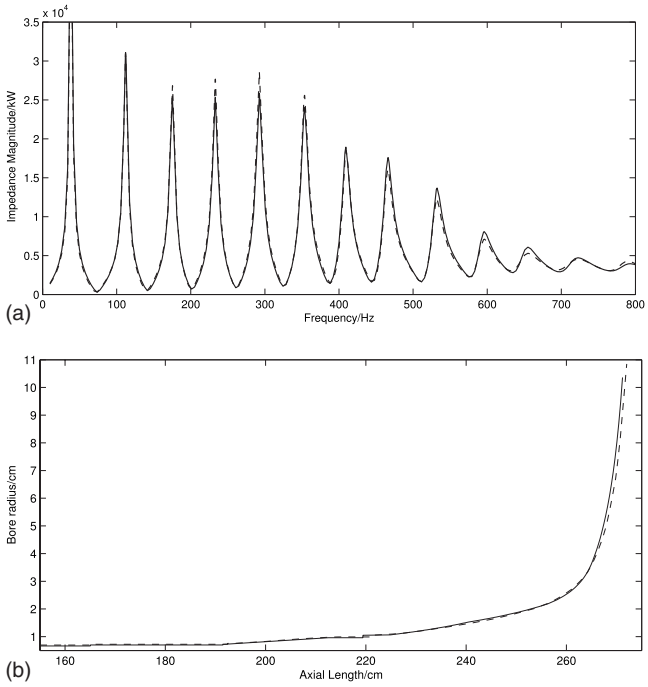

FIG. 7. Results of increasing the magnitudes of peaks 8–10 before (dashed) and after (solid) optimization.

diameter), and some subtle changes (a maximum of 0.5 mm) to the bell contour. The experiment was repeated but with 20% increases specified; the optimizer was unable to converge to a geometrically-satisfying solution, suggesting that such a result was not possible within the constraints of the design space.

These results demonstrate that it is possible to modify the impedance envelope without substantially modifying the peak intonation. The changes made here to the envelope are of similar proportion to those found in the previous experiment, but had only a small effect on intonation. As a result of these changes, the optimized trombone would be expected to produce a somewhat brighter timbre than its predecessor and possess a higher register which is somewhat easier to play.

V. CONCLUSIONS

Modern brass instruments have sets of acoustic resonances which approximate closely to a harmonic series. When a normal note is sounded, the player's lips interact with a subset of these resonances to create a mode-locked regime of oscillation. The pitch of the radiated sound is that of the lip vibration, which will not necessarily correspond exactly to one of the acoustic resonance frequencies. The magnitude of the impedance at the sounding frequency and at its harmonics will affect the stability of the note and the timbre of the sound.

Is it a reasonable assumption that the peak frequencies of an "ideal" brass instrument should be harmonically related? Experimental measurements of several professional-standard models of trombone, intended for use in orchestral and in jazz idioms, suggest that this is not the case: having higher resonances tuned to a progressively sharper equivalent fundamental appears to be a desirable characteristic of

trombones, particularly those of larger bore. From a purely musical standpoint, the designer's objective is not to maximize the stability or brightness of tones, but to produce an instrument which is easy to play, sufficiently in tune, and produces a timbre which is appropriate to the musical style and context of the performance.

Why might the inharmonicity present in a large-bore trombone be desirable? Consider a hypothetical trombone with many tall harmonic peaks (similar to trombone A in many respects). This instrument would be expected to have a large tonal range and produce a relatively bright timbre.[6,21] If this brightness were undesirable (as it generally is in orchestral settings), then a designer might combat this by reducing the heights of the middle and upper peaks, thus reducing the harmonic content in the sound. However, this would have the knock-on effect of reducing the stability of the higher tones. In order, therefore, to reduce the brightness without affecting the tonal range, some inharmonicity is necessary to reduce the influence of the higher peaks on the lower tones. In reality the orchestral tenor trombone may be thought of as a compromise between these two solutions, featuring shorter, less harmonic peaks than the jazz trombone, but having a similar tonal range. Trombonists are accustomed to making small corrections in the position of the hand-slide in any given musical situation for the purposes of fine intonation, and are therefore likely to be more tolerant of small alterations to the intonation of the instrument than would the player of a valved instrument.

The study described here has demonstrated the ability of an improved optimization procedure to propose technologically feasible and visually acceptable brass instrument bore shapes whose impedance curves correspond to a predetermined target. When the target requirements are compatible with the limitations imposed on the bore by non-acoustic design considerations, the optimization converges rapidly to a solution: roughly 1500 designs of the complete instrument are needed to converge to within a design tolerance of 0.01 mm. Lack of convergence indicates that the requirements of the target cannot be met without relaxing the limitations imposed on the design space.

Discrepancies between calculated and experimentally measured input impedance curves[12,15] currently limit the applicability of computer optimization to the solution of subtle problems in real instrument design. The optimization method described here is applicable to any impedance model, and any future improvements in numerical modeling could be immediately applied to optimization problems. This provides a strong motivation to develop further the underlying theoretical models and experimental impedance measurement techniques.

It should also be recognized that the input impedance describes only the linear behavior of the acoustic resonator. Since the interior acoustic pressure in a brass instrument can reach 180 dB in loud playing, non-linear sound propagation plays an important role in the development of timbre with increasing dynamic level. Once the bore-profile has been determined by the optimizer, non-linear effects can be calculated and their significance estimated.

The major limitation in the optimization of brass instrument design remains an inadequate understanding of the ideal target impedance function. The work of Poirson[6] on trumpets has shown the feasibility of a multidimensional scaling approach to finding correlations between player judgments of instruments and objective impedance criteria. Similar studies on a wide range of players and instrument types are required, in order to establish clearly which features of the impedance curves correlate closely with player ratings based on musical judgments. With this information available, the optimizer can become a valuable tool in the production of brass instruments of the highest quality.

Modeling the acoustical process of soft biological tissue imaging and understanding the consequences of the approximations required by such modeling are key steps for accurately simulating ultrasonic scanning as well as estimating the scattering coefficient of the imaged matter. In this document, a linear solution to the inhomogeneous ultrasonic wave equation is proposed. The classical assumptions required for linearization are applied; however, no approximation is made in the mathematical development regarding density and speed of sound. This leads to an expression of the scattering term that establishes a correspondence between the signal measured by an ultrasound transducer and an intrinsic mechanical property of the imaged tissues. This expression shows that considering the scattering as a function of small variations in the density and speed of sound around their mean values along with classical assumptions in this domain is equivalent to associating the acoustical acquisition with a measure of the relative longitudinal bulk modulus. Comparison of the model proposed to Jensen's earlier model shows that it is also appropriate to perform accurate simulations of the acoustical imaging process.

I. INTRODUCTION

Ultrasonic imaging is a complex process during which a focused beam is transmitted through a soft biological tissue and scattered by inhomogeneities stemming from local variations in the intrinsic mechanical properties. Ideally, knowing the electromechanical transfer function of the probe and the measured backscattered signal, called the radiofrequency (RF) signal, should solve the inverse problem, thus retrieving the real scattering profiles. This consists in removing the influence of the acquisition tool and displaying an ultrasonic image of higher quality. Unfortunately, the problems that arise from the complexity of the scattering process[1–6] in the tissues and from the technical limits of the ultrasonic probes render the mathematical inversion an open problem. To be solved, the problem has to be regularized by formulating assumptions on the propagating ultrasound wave, the behavior of the continuous collection of scatterers, and finally the range of variation of the local mechanical properties. Among the possible approaches and the hypothesis these approaches imply, one solution consists in searching for a linear description of the problem,[7–9] transforming the inversion step into a well-known deconvolution process.[10] A linear description means that the response of a collection of scatterers is the sum of the responses of each constituent scatterer. This form then makes it possible to quantitatively solve the inverse problem, while the mathematical expression of the problem can reveal the dependence of the estimated scattering coefficient on a particular intrinsic mechanical parameter. Specifically, this sheds light on the consequences of the assumptions on the nature of the resulting scattering coefficient and also reveals *a posteriori* the approximations required, as a cost for obtaining a simplified description of the acoustical process.

Linear descriptions for the ultrasonic imaging process of soft tissues are well known and have been extensively developed in literature, such as in Refs. 1, 2, 7, and 8. As previously shown, one of their main results consists in expressing the scattering coefficient as a function of the local intrinsic properties of the medium. In the past, Gore and Leeman[1] and

[a)]Electronic mail: jm.mari@imperial.ac.uk

more recently Zemp *et al.*[7] showed that under various assumptions in the field and the insonified medium, the scattering coefficient depends on the adiabatic compressibility coefficient and density. The approach of Zemp *et al.*[7] contributes an original solution to space-varying point spread functions (PSFs) and allows for a statistical approach to the problem. Fatemi and Kak[2] expressed the scattering coefficient as a function of sound speed only, though strong hypotheses were imposed. Jensen[8] derived the scattering coefficient as a function of sound speed and density. This model is very interesting because it provides an expression of the model where each part can be measured or defined, so that one can, respectively, partly retrieve the scatterer distribution or simulate medical ultrasound imaging. Unfortunately, the first-order expression of Jensen's scattering coefficient[8] does not take advantage of the stronger hypothesis involved and the final expression contains unused approximations.

In this paper, it is shown that those expressions of the ultrasonic process and their scattering coefficients, a function of sound speed and density, can be linked to the variations in the sole longitudinal bulk modulus. As a result, the ultrasound scanning process may be interpreted under the classical assumptions as the measurement of a single parameter—related to the medium's properties—rather than a local reflectivity combining several parameters that is noninvertible. Fatemi and Kak[2] calculated this coefficient as a function of sound speed, though this was done by ignoring local density variation, which is an unreasonable assumption in medical imaging. We show that their coefficient can be interpreted as an approximation of a more general expression.

The expansion and solution of the wave equation proposed are very close to Jensen's approach;[8] consequently the results that have already been demonstrated in detail are used directly, and our contribution is highlighted. Jensen's development[8] was chosen because it offers flexible and widespread solutions for the simulation of ultrasonic imaging with various probe geometries, and, like the model of Zemp *et al.*,[7] it can also take into account both attenuation[11] and space-varying PSFs.

The paper is organized as follows: First, the general wave equation is modified to establish the expression to be solved under the assumptions chosen. An expression of the received signal is established in Sec. III and the results are discussed in Sec. IV.

II. DERIVATION OF THE WAVE EQUATION

Assuming that the particle velocity in the medium is small, which is usually the case at the power dissipated by medical ultrasound scanners, the wave equation can be written as[8]

$$\nabla^2 p_1(\boldsymbol{r},t) - \frac{1}{c(\boldsymbol{r})^2}\cdot\frac{\partial^2 p_1(\boldsymbol{r},t)}{\partial t^2} = \frac{1}{\rho(\boldsymbol{r})}\,\boldsymbol{\nabla}\,\rho(\boldsymbol{r})\cdot\boldsymbol{\nabla} p_1(\boldsymbol{r},t), \tag{1}$$

where p_1 is the pressure perturbation due to the propagation, at location $\boldsymbol{r}$ (Fig. 1) and time t, ρ is the local density, and c is the local speed of sound. Bold characters stand for three-dimensional triplets. $\boldsymbol{\nabla}$ is the gradient operator and ∇^2 is the Laplace operator. The solution method consists in isolating all the terms expressing a propagating wave at a constant speed on the left-hand side of the equation, and keeping the others on the right-hand side, which stands for the scattering operator. Since it assumes that the particle velocity is small in the insonified medium, this development is only suitable for linear imaging and does not take into account harmonic tissue imaging[12,13] and contrast agent imaging.[14–17] In the later developments, when no ambiguity is possible, the function's variables will be omitted for purposes of legibility.

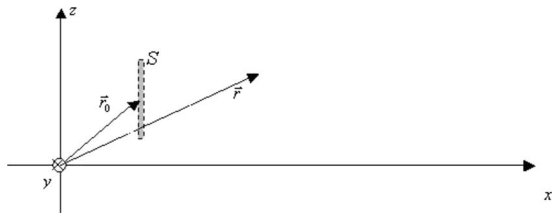

FIG. 1. Definition of the transducer's surface (S), position (r_0), and the transmission/scattering location $\boldsymbol{r}$.

Reorganizing the left- and right-hand terms of Eq. (1) gives

$$\underset{c_0}{\Xi} p_1 = Fop[p_1] \tag{2}$$

with

$$\underset{c_0}{\Xi} = \nabla^2(\cdot) - \frac{1}{c_0^2}\cdot\frac{\partial^2}{\partial t^2}(\cdot) \tag{3}$$

the D'Alembert operator in c_0 and

$$Fop = \frac{c^2}{c_0^2}\cdot\frac{\boldsymbol{\nabla}\rho}{\rho}\cdot\boldsymbol{\nabla}(\cdot) - \left(\frac{c^2}{c_0^2} - 1\right)\cdot \mathrm{div}(\boldsymbol{\nabla}(\cdot)) \tag{4}$$

the scattering operator. The ultrasonic process is described as the propagation of a progressive wave [left member of Eq. (2)] at constant speed c_0, which is perturbed by local inhomogeneities (described in the right member). However, contrary to Ref. 8, no first-order expression is made of $c(\boldsymbol{r})$ and $\rho(\boldsymbol{r})$ for the elaboration of the scattering operator Fop, given in Eq. (4), even if it will be developed considering small perturbations. Equation (2) is the equation that has to be solved in order to calculate the expression of the received signal.

III. CALCULATION OF THE RECEIVED SIGNAL

The solution is obtained by assuming that the incident field is a solution of the homogeneous part of Eq. (2) and its expression is established following Jensen's method.[8] Then the scattered field is calculated under the first-order Born approximation, and its integration over the transducer surface finally gives the expression of the received signal, which is a function of the local scattering coefficient.

A. Calculation of the incident field

The incident field propagating in tissues is assumed to be an eigensolution of the homogeneous part of Eq. (2) and is assumed to derive from a velocity potential ψ in Eq. (5). It is implicitly expressed by Eq. (6) as follows:

$$\boldsymbol{v}(\boldsymbol{r},t) = \nabla\psi(\boldsymbol{r},t), \tag{5}$$

$$\nabla p_i(\boldsymbol{r},t) = -\rho \cdot \frac{\partial \boldsymbol{v}(\boldsymbol{r},t)}{\partial t}. \tag{6}$$

Combining Eqs. (5) and (6) gives

$$\nabla p_i = -\rho \cdot \frac{\partial \nabla \psi}{\partial t}, \tag{7}$$

where $\psi(\boldsymbol{r},\boldsymbol{r}_0,t)$ is given at $\boldsymbol{r}$ for a single transducer in $\boldsymbol{r}_0$ by the following expression:[2]

$$\psi(\boldsymbol{r},\boldsymbol{r}_0,t) = v_n(t) \underset{t}{*} h(\boldsymbol{r},\boldsymbol{r}_0,t), \tag{8}$$

where $\underset{t}{*}$ denotes time convolution, and

$$h(\boldsymbol{r},\boldsymbol{r}_0,t) = -\int_{\boldsymbol{q}\in S} \frac{\delta\left(t - \frac{|\boldsymbol{r}-\boldsymbol{r}_0+\boldsymbol{q}|}{c_0}\right)}{4\cdot\pi\cdot|\boldsymbol{r}-\boldsymbol{r}_0+\boldsymbol{q}|} \cdot d^2\boldsymbol{q}, \tag{9}$$

where $v_n(t)$ is the normal speed of the transducer's surface S, and $h(\boldsymbol{r},\boldsymbol{r}_0,t)$ is the PSF in transmission for a transducer element placed in $\boldsymbol{r}_0$.

Then, Eq. (7) gives

$$\nabla p_i(\boldsymbol{r},\boldsymbol{r}_0,t) = -\rho \cdot \frac{\partial \nabla \psi(\boldsymbol{r},\boldsymbol{r}_0,t)}{\partial t}$$

$$= -\rho \cdot \frac{\partial v_n(t)}{\partial t} \underset{t}{*} \nabla h(\boldsymbol{r},\boldsymbol{r}_0,t). \tag{10}$$

The hypothesis of constant sound speed has been made for propagation (i.e., $c=c_0$), and we have assumed that $v_n(t)$ is constant over the transducer's surface. Equation (10) does not directly provide an expression of the incident field p_i, but this implicit expression is sufficient for the expression of the received signal. The use of ρ in this equation, and not ρ_0 as in Ref. 8, is discussed in Sec. IV.

B. Calculation of the scattered field

The pressure at $\boldsymbol{r}$ is calculated by integrating the ambient field p_1 over the volume space V. This is done using Green's function[18] and leads to the scattered field[8]

$$p_s(\boldsymbol{r},\boldsymbol{r}_0,t) = \int_V \int_T Fop[p_1(\boldsymbol{\xi},\boldsymbol{r}_0,\tau)] \cdot G(\boldsymbol{\xi},\tau|\boldsymbol{r},t) \cdot d\tau \cdot d^3\boldsymbol{\xi}, \tag{11}$$

where integration is through space ($\boldsymbol{\xi}\in V$) and time ($\tau\in T$), and G is Green's function of the homogeneous equation [Eq. (2)]

$$G(\boldsymbol{\xi},\tau|\boldsymbol{r},t) = -\frac{\delta\left(t-\tau-\frac{|\boldsymbol{r}-\boldsymbol{\xi}|}{c_0}\right)}{4\cdot\pi\cdot|\boldsymbol{r}-\boldsymbol{\xi}|}. \tag{12}$$

Under the first-order Born approximation, it is shown[8] that p_1 is close to the incident field p_i, and p_s becomes

$$p_s(\boldsymbol{r},\boldsymbol{r}_0,t) = \int_V \int_T Fop[p_i(\boldsymbol{\xi},\boldsymbol{r}_0,\tau)] \cdot G(\boldsymbol{\xi},\tau|\boldsymbol{r},t) \cdot d\tau \cdot d^3\boldsymbol{\xi}. \tag{13}$$

p_s now has to be integrated over the transducer's surface in order to express the received signal.

C. Calculation of the received signal

The received signal is the scattered pressure field p_s integrated over the transducer's surface S, convolved with the electromechanical impulse response $E_m(t)$ of the transducer,

$$p_r(\boldsymbol{r}_0',\boldsymbol{r}_0,t) = E_m(t) \underset{t}{*} \int_S p_s(\boldsymbol{r}_0'+\boldsymbol{\xi},\boldsymbol{r}_0,t) d^2\boldsymbol{\xi} \tag{14}$$

for a receiving transducer placed at point r_0'. Then, considering that

$$p_s(\boldsymbol{r},\boldsymbol{r}_0,t) = \int_V \int_T Fop[p_i(\boldsymbol{\xi},\boldsymbol{r}_0,\tau)] \cdot G(\boldsymbol{\xi},\tau|\boldsymbol{r},t) \cdot d\tau \cdot d^3\boldsymbol{\xi} \tag{15}$$

$$= \int_V \int_T Fop_2[\nabla p_i(\boldsymbol{\xi},\boldsymbol{r}_0,\tau)] \cdot G(\boldsymbol{\xi},\tau|\boldsymbol{r},t) \cdot d\tau \cdot d^3\boldsymbol{\xi} \tag{16}$$

with

$$Fop_2 = \frac{c^2}{c_0^2} \cdot \frac{\nabla\rho}{\rho} \cdot (\cdot) - \left(\frac{c^2}{c_0^2} - 1\right) \cdot \mathrm{div}(\cdot), \tag{17}$$

inserting Eqs. (10) and (16) into Eq. (14) leads to

$$p_r(\boldsymbol{r},\boldsymbol{r}_0,t) = -\frac{E_m(t)}{4} \underset{t}{*} \frac{\partial v(t)}{\partial t} \underset{t}{*} \int_V Fop_2[\rho \cdot \nabla h(\boldsymbol{\xi},\boldsymbol{r}_0,t)]$$

$$\underset{t}{*} h'(\boldsymbol{r}_0,\boldsymbol{\xi},t) \cdot d^3\boldsymbol{\xi}, \tag{18}$$

where $h'(r_0',\xi,t)$ is Green's function integrated over the transducer's surface, that is, the spatial impulse response of the transducer for reception. This expression is equivalent to

$$p_r(\boldsymbol{r},\boldsymbol{r}_0,t) = -\frac{E_m(t)}{4} \underset{t}{*} \frac{\partial v(t)}{\partial t} \underset{t}{*} \int_V Fop_3[h(\boldsymbol{\xi},\boldsymbol{r}_0,t)]$$

$$\underset{t}{*} h'(\boldsymbol{r}_0,\boldsymbol{\xi},t) \cdot d^3\boldsymbol{\xi} \tag{19}$$

with

$$Fop_3 = \frac{c^2}{c_0^2} \cdot \nabla\rho \cdot \nabla(\cdot) - \left(\frac{c^2}{c_0^2} - 1\right) \cdot \mathrm{div}(\rho \cdot \nabla(\cdot)). \tag{20}$$

This expression is approximated by assuming that the perturbation operator is, in fact, applied to the full PSF

$$pr(\mathbf{r},\mathbf{r}_0,t) = \frac{Em(t)}{4} *_t \frac{\partial v(t)}{\partial t} *_t \int_V Fop_3[h] *_t h' \cdot d^3\xi$$

$$\approx \frac{Em(t)}{4} *_t \frac{\partial v(t)}{\partial t} *_t \int_V Fop_3[h *_t h'] \cdot d^3\xi. \quad (21)$$

This approximation and its implications are discussed in Sec. IV.

Then, defining

$$h_{pe}(\mathbf{r},\mathbf{r}_0,t) = h(\mathbf{r},\mathbf{r}_0,t) *_t h'(\mathbf{r}_0,\mathbf{r},t) \quad (22)$$

can be written as

$$\int_V Fop_3[h_{pe}] \cdot d^3\xi = \int_V [\alpha \cdot \nabla\rho \cdot \nabla h_{pe} - (\alpha - 1) \cdot \mathrm{div}(\rho \cdot \nabla h_{pe})] \cdot d^3\xi, \quad (23)$$

where $\alpha(\mathbf{r}) = c(\mathbf{r})^2 / c_0^2$.

Then the Green–Ostrogradsky theorem and the properties of the divergence can be written as

$$\int_V \mathrm{div}(u \cdot \boldsymbol{f}) \cdot \mathrm{div} = \int_V (\nabla u \cdot \boldsymbol{f} + u \cdot \mathrm{div}(\boldsymbol{f})) \cdot \mathrm{div} = \int_{S_V} u \cdot \boldsymbol{f} \cdot \mathbf{n} \cdot ds \quad (24)$$

with $\mathbf{n}$ the outward normal vector to the surface S_V of the integration volume V. If $u \cdot \boldsymbol{f}$ decreases rapidly, the integral is null for an unbounded space, leading to the relationship

$$\int_V u \cdot \mathrm{div}(\boldsymbol{f}) \cdot \mathrm{div} = -\int_V \nabla(u) \cdot \boldsymbol{f} \cdot \mathrm{div}. \quad (25)$$

Assuming that h_{pe} varies slowly toward infinity and tends to zero, which is the case for ultrasound beams, and using Eq. (25), Eq. (23) becomes

$$\int_V Fop_3[h_{pe}] \cdot d^3\xi = \int_V [\alpha \cdot \nabla\rho \cdot \nabla h_{pe} + \nabla(\alpha - 1) \cdot \rho \cdot \nabla h_{pe})] \cdot d^3\xi, \quad (26)$$

$$= \int_V \nabla(\alpha \cdot \rho) \cdot \nabla h_{pe} \cdot d^3\boldsymbol{\xi}, \quad (27)$$

$$= -\int_V (\alpha \cdot \rho) \cdot \nabla^2 h_{pe} \cdot d^3\boldsymbol{\xi}, \quad (28)$$

and the final expression for the scattered field is

$$p_r(\mathbf{r}_0,t) = \rho_0 \cdot \frac{E_m(t)}{4} *_t \frac{\partial v(t)}{\partial t} *_t \int_V \left[\frac{c^2 \cdot \rho}{c_0^2 \cdot \rho_0}\right] \cdot \nabla^2 h_{pe}(\boldsymbol{\xi},\mathbf{r}_0,t) \cdot d^3\boldsymbol{\xi}, \quad (29)$$

$$\Leftrightarrow p_r(\mathbf{r}_0,t) = \rho_0 \cdot \frac{E_m(t)}{4} *_t \frac{\partial v(t)}{\partial t} *_t \int_V \nabla^2 \left[\frac{K(\boldsymbol{\xi})}{K_0}\right] \cdot h_{pe}(\boldsymbol{\xi},\mathbf{r}_0,t) \cdot d^3\boldsymbol{\xi}, \quad (30)$$

where $K = c^2 \cdot \rho$ is the longitudinal bulk modulus, which is the inverse of the compressibility modulus and in this very case equal to the longitudinal Young modulus,[3,4] and K_0 its average value such that

$$K(\mathbf{r}) = K_0 + \Delta K(\mathbf{r}), \quad (31)$$

assuming that h_{pe} is the solution of the homogeneous part of Eq. (2). Using Eq. (30) leads to

$$p_r(\mathbf{r}_0,t) = \frac{\rho_0}{2 \cdot c_0^2} \cdot E_m(t) *_t \frac{\partial^3 v(t)}{\partial t^3} *_t \int_V h_{pe}(\boldsymbol{\xi},\mathbf{r}_0,t) \cdot \left[\frac{K(\boldsymbol{\xi})}{K_0} + \varphi\right] \cdot d^3\boldsymbol{\xi}, \quad (32)$$

where $K/K_0 + \varphi$ is the scattering coefficient R. The term φ is a constant that is naturally discarded by the convolution form, since the imaging process is only sensitive to the variations in the local properties. It is introduced so that the scattering coefficient can be extracted from the general equation while retaining a physical meaning, but has no impact on the scattered pressure. As the scattering coefficient itself should be zero when $K = K_0$, the value for the constant is $\varphi = -1$, and the complete expression for R is

$$R = \frac{K - K_0}{K_0}. \quad (33)$$

Finally, the model expression can be reduced to

$$p_r(\mathbf{r}_0,t) = v_{pe}(t) *_t h_{pe}(\mathbf{r},\mathbf{r}_0,t) *_r R(\mathbf{r}), \quad (34)$$

where $*_r$ denotes spatial convolution and

$$v_{pe}(t) = \frac{\rho_0}{4c_0^2} \cdot E_m(t) *_t \frac{\partial^3 v(t)}{\partial t^3}, \quad (35)$$

$$h_{pe}(\mathbf{r},\mathbf{r}_0,t) = h(\mathbf{r},\mathbf{r}_0,t) *_t h(\mathbf{r}_0,\mathbf{r},t), \quad (36)$$

$$R(\mathbf{r}) = \frac{K(\mathbf{r}) - K_0}{K_0}, \quad (37)$$

$$K = c^2 \cdot \rho. \quad (38)$$

The term R in Eq. (37) is the scattering term, which is defined here as the relative radial bulk modulus. This expression is valid only for small variations in the bulk modulus around its average value, that is, with $\Delta K(\mathbf{r}) \ll K_0$, if $\Delta K(\mathbf{r})$ is the variation of K at point $\mathbf{r}$. As in the previous model, the speed of sound and density variations cannot be estimated independently; however, under the assumptions, in the scattering coefficient, they form the expression of another local parameter: longitudinal bulk modulus.

IV. DISCUSSION

The proposed model is developed under the same main hypotheses as the usual linear descriptions of the ultrasonic imaging process,[1,2,7,8] essentially linear propagation and the Born approximation. The main difference is the use of non-approximated forms for c and ρ, but other assumptions have been modified or adapted.

A. Expression of the incident field

The expression of the incident field used in this model is slightly different from Jensen's expression.[8] We hypothesize that it is possible to consider that the density ρ is fully unknown at the measurement point and thus not "partially" equal to ρ_0, as implied by Eq. (27) in Ref. 8. Indeed, in Ref. 8, ρ_0 is the density at $\boldsymbol{r}$ where density is assumed to be unknown. The present hypothesis is not newly introduced because once the influence of sound speed and density on the propagation are considered separately, and once a linear behavior of the system is assumed (which means that the response of the scattering coefficient collection is the sum of the responses of each one), there is no need to consider, at a certain point $\boldsymbol{r}$, the past density along the propagation profile, which is implicitly set to ρ_0. Here the field is assumed to be known until the ultrasound pulse reaches inhomogeneity, where the density and sound speed variations are then fully taken into account. This appears in the model being developed through the use of ρ in Eq. (6). The solution was performed assuming that the propagation medium's density and speed of sound are equal to their average values ρ_0 and c_0 everywhere, scattering point $\boldsymbol{r}$ included, but also that these quantities are varying at this point. This contradiction regarding the density changes is moved here by making the same hypothesis until the incidence on a measurement point $\boldsymbol{r}$, but *not* at this point. The difference is that the pressure changes at point $\boldsymbol{r}$ are more accurately estimated, through a better use of the assumptions required to assume that the incoming pressure is known.

On the other hand, the use of c_0 in Eqs. (9) and (12) emphasizes that a linear development includes contradictions, because this assumption of propagation at the mean speed of sound includes the estimation point $\boldsymbol{r}$. This last problem cannot be avoided here. A more complete description should imply the local variations in the speed of sound so as to take into account phase changes during propagation, as done very recently in Ref. 19.

B. Approximation of Equation (21)

The development proposed is possible by considering that the scattering operator is taken as Eq. (21) on the entire PSF, including the time convolution with the reception profile h'. This operation expresses the typical assumption of linear approaches that the received signal is the result of a convolution with h'. Indeed, the linearization of the initial equations implies that the resulting model will express the received pressure as a function of a convolution product with the PSF. It could also be expressed by taking h' out of the volume integral, ignoring the spatial aspect of the convolution (for h'), and considering that h' is applied along the propagation axis (or ultrasonic line). This approximation is equivalent to saying that h' can be roughly viewed solely as a function of time. In this case, the time convolution makes it possible to move it at will inside the equation. It is also equivalent to assuming that the local variations of the medium properties are concomitant, so that the terms that are only a function of density can be expressed by its mean value. Following this point of view, consulting a table giving the speed of sound and density of different biological materials[6] shows that the variations in the speed of sound in most cases imply a variation in density.

This assumption would imply in the volume integration that a term that is a function of the convolution of the gradients of the transmission and reception functions h and h' is removed, which underlines the approximate aspect of such approaches and the importance of slow variations of h and h' over the integration volume. It should also be noted that this is equivalent to Jensen's approximation,[8] when he assumed that h_{pe} is the solution of the homogeneous part of the wave equation, which consists in considering that h can be replaced with h_{pe} straightforwardly, discarding the additional terms that would appear when convolving the D'Alembert of h by h'.

C. Expression of the established scattering coefficient

Equations (37) and (38) clearly show the influence of the speed of sound c on the scattering coefficient. A square dependence is obtained, in coherence with Fatemi and Kak's[2] results. The expression of R as a function of bulk modulus K can also be linked to Gore and Leeman's[1] result, and to the result of Zemp *et al.*,[7] which are partially a function of the local compressibility. Replacing c and ρ in Eq. (37) with Jensen's development [Ref. 8, Eq. (12)] expressed in Eq. (39) we have

$$c = c_0 + \Delta c,$$

$$\rho = \rho_0 + \Delta\rho \tag{39}$$

with $\Delta c \ll c_0$ and $\Delta\rho \ll \rho_0$, and ignoring the higher-order terms gives

$$R \approx \frac{\Delta\rho}{\rho_0} + \frac{2\Delta c}{c_0}, \tag{40}$$

which is, except for the minus sign, Jensen's expression [Ref. 8, Eq. 47]

$$R_{\text{Jensen}} = \frac{\Delta\rho}{\rho_0} - \frac{2\Delta c}{c_0}. \tag{41}$$

The negative dependence of Jensen's scattering coefficient[8] on the speed of sound variations Δc does not seem to reflect a physical property of reflection because it implies that a positive variation of c would reduce the local reflectivity or generate a negative scattering coefficient. Indeed, the nonlinear scattering coefficient for normal incidence $R_{\text{NL}} = (Z - Z_0)/(Z + Z_0)$ shows that an increase in the local mechanical properties results in a positive scattering coefficient. Checking both developments suggests that a sign change is missing

between Jensen's Eqs. (40) and (41) in Ref. 8. Fortunately, this sign mistake has no real impact on the extensive use of the simulator[9] based on these equations, since Eq. (41) is not usually applied, the scattering coefficient R_{Jensen} being directly defined instead. Finally, the comparison of Eqs. (40) and (41) suggests that R_{Jensen} can be seen as a partial development of the expression of the scattering term R, and should be modified such that

$$R^{+}_{\text{Jensen}} = \frac{\Delta\rho}{\rho_0} + \frac{2\Delta c}{c_0} \tag{42}$$

is the corrected Jensen coefficient.[8]

It should be noticed that transforming the corrected Jensen coefficient[8] would lead back to

$$R^{+}_{\text{Jensen}} = \frac{\Delta\rho}{\rho_0} + \frac{2\Delta c}{c_0} = \frac{c_0^2 \cdot \Delta\rho + 2 \cdot \rho_0 \cdot c_0 \cdot \Delta c}{\rho_0 \cdot c_0^2} \tag{43}$$

with the expression of $\rho_0 \cdot c_0^2 = K_0$ at the denominator underlining the closeness with the proposed model, while the numerator is like the first-order expression of K.

The expression of the scattering coefficient as function of the bulk modulus K may be counterintuitive. On another hand, some assumptions such as the fact that the medium is considered as homogeneous until scattering occurs is also counterintuitive when considering imaging biological tissues, as well as the assumption that the waves are traveling at constant speed. The proposed model merely takes the typical set of assumptions close to their limits, showing their real impact on the expression of the scattering coefficient.

Figure 2 displays the values of the proposed scattering coefficient R and the corrected Jensen coefficient R^{+}_{Jensen}.[8] Figure 2(a) illustrates the behavior of the scattering coefficients when the density is set at ρ_0 and Fig. 2(b) illustrates the behavior when the speed of sound is set at c_0. In this latter case, both coefficients are equal, but when density is set at ρ_0 [Fig. 2(a)], the R and R^{+}_{Jensen} curves are tangential in c_0, showing their equivalence for small variations. However, R remains greater than -1 when c tends toward zero. The model presented in this paper is not quantitatively valid for large local variations K, but one can see in Eq. (37) that R also tends to -1 as K tends to zero and retains a physical meaning ($R > -1$), which is advantageous for a linear approach of such cases. Unfortunately, the model suffers from its approximations for strong positive variations of K above K_0, and Eq. (37) does not have any physical signification for $K > 2 \cdot K_0$, slightly sooner than R^{+}_{Jensen}, with the scattering coefficient then greater than 1. Nevertheless, the result given here provides an interesting approach for linearly modeling large local decreases in the mechanical properties of the tissue below their mean values. Those large decreases could reflect the existence of local very light inhomogeneities in the propagating medium, such as large bubbles or local vacuums.

For the simulation of such large variations, if needed, one should use the following definition to compute the scattering coefficient or to interpret the estimation results of local reflectivity:

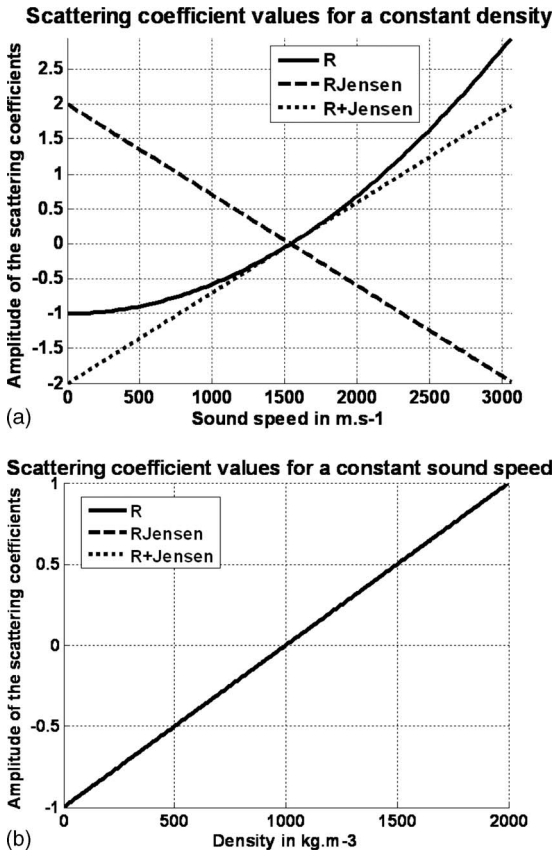

FIG. 2. Illustration of the dependence of the relative bulk modulus scattering coefficient R on changes in speed of sound (a) and density (b) separately, compared to the values provided by the Jensen coefficient R_{Jensen} (Ref. 8) and its modified version R^{+}_{Jensen}.

$$R = \frac{K - K_0}{K_0}, \quad K \in [0;2K_0],$$

$$R = 1, \quad K > 2K_0. \tag{44}$$

Equation (44) underlines that, in the model proposed, when K is greater than $2 \cdot K_0$, the solution of the inverse linear approach cannot distinguish dense matter and systematically underestimates the values of their mechanical properties. However, below K_0, the proposed model is coherent and more reliable [Fig. 2(a)] than Jensen's coefficient.[8]

Given that these two models—the one proposed by Jensen[8] and the one proposed in this paper—have very close, nearly equal expressions and given that their scattering coefficients, once corrected, are tangential around their mean value, they have the same ability to simulate the ultrasonic imaging process.

V. CONCLUSION

An expansion of the wave equation for propagation in an inhomogeneous medium has been established under the assumption of linear propagation. Solving it under the classical assumptions leads to an expression of the received rf signal that describes the local scattering coefficient as the variation of a single mechanical parameter. This model shows that considering the scattering as a function of small variations in density and speed of sound around their mean values is

equivalent to associating the acoustical acquisition with a measure of the relative longitudinal bulk modulus. The model developed thus offers a way to estimate the bulk modulus of the imaged matter through the solution of the inverse problem in the case of small local variations. The final expression of the scattering coefficient is shown to be coherent with previous developments, while the model proposed is very close to the one presented by Jensen in 1991 (Ref. 8) and now widely used for ultrasonic imaging simulation. The similarity of the two models also implies that our model presents all the abilities of Jensen's model[8] for simulating ultrasonic imaging and is more accurate when the scattering coefficient distribution is derived from the speed of sound and density fields. Moreover, the expression proposed is particularly convenient for the linear simulation of extremely soft inclusion imaging. The corresponding scattering coefficient, even if a linear model is intrinsically not well suited for such uses, retains a physical meaning when density or speed of sound decreases, even to zero.

(Received 20 August 2008; revised 12 January 2009; accepted 20 January 2009)

Both mechanically induced acoustic cavitation and thermally induced boiling can occur during high intensity focused ultrasound (HIFU) medical therapy. The goal was to monitor the temperature as boiling was approached using magnetic resonance imaging (MRI). Tissue phantoms were heated for 20 s in a 4.7-T magnet using a 2-MHz HIFU source with an aperture and radius of curvature of 44 mm. The peak focal pressure was 27.5 MPa with corresponding beam width of 0.5 mm. The temperature measured in a single MRI voxel by water proton resonance frequency shift attained a maximum value of only 73 °C after 7 s of continuous HIFU exposure when boiling started. Boiling was detected by visual observation, by appearance on the MR images, and by a marked change in the HIFU source power. Nonlinear modeling of the acoustic field combined with a heat transfer equation predicted 100 °C after 7 s of exposure. Averaging of the calculated temperature field over the volume of the MRI voxel ($0.3\times0.5\times2$ mm^3) yielded a maximum of 73 °C that agreed with the MR thermometry measurement. These results have implications for the use of MRI-determined temperature values to guide treatments with clinical HIFU systems.

I. INTRODUCTION

The use of high intensity focused ultrasound (HIFU) for tissue ablation is rapidly achieving clinical acceptance for a wide range of medical applications.[1–4] The tissue ablation mechanism in the majority of these applications is coagulative necrosis, induced by heating of the tissue due to absorption of the intense ultrasound. Heating is often monitored by magnetic resonance imaging (MRI), in which the tissue temperature is calculated from direct measurements of the MR-signal phase change resulting from the water proton resonance frequency shift.[5] The temperature measurements are then used to calculate the region of necrosed tissue—the lesion—based on a thermal dose criterion.[6] MRI monitoring and lesion determination are used in the only clinical, transcutaneous HIFU device approved by the United States Food and Drug Administration (FDA).[7] New treatment protocols are also being developed on this and similar machines that use high-amplitude ultrasonic pulses on the presumption of creating cavitation bubbles in tissue for enhanced heating.[8–11] However, enhanced heating can also occur due to nonlinear propagation effects, and such heating may be sufficient to cause boiling bubbles.[12] When bubbles and enhanced heating have been observed *in vivo*, the MRI-determined temperature was less than 100 °C, and the result

 0001-4966/2009/125(4)/2420/12/$25.00

was interpreted as cavitation-enhanced heating.[10] We speculate that the peak temperature may have been higher and that bubbles were due to boiling, the consequence, not the cause, of enhanced heating.

Acoustic cavitation and nonlinear acoustic propagation are two nonlinear mechanisms that can enhance HIFU heating beyond that expected to be produced by absorption at the HIFU excitation frequency. Nonlinear acoustic propagation distorts the HIFU wave and causes acoustic energy to be pumped from the fundamental excitation frequency to higher harmonic frequencies. Higher frequencies are more readily absorbed than lower ones and thus generate enhanced heating.[12–14] An additional effect of nonlinear propagation is that the extra heating and initial boiling, if attained, are more localized than would be expected assuming linear propagation conditions.[14,15] One way to increase nonlinear effects is to increase the acoustic pressure as this accelerates the waveform distortion. With a sufficient pressure amplitude, nonlinear acoustic propagation results in a shock wave, which contains hundreds of harmonics and can cause boiling in milliseconds.[16]

Cavitation bubbles are nonlinear scatterers that result in acoustic re-radiation at frequencies higher than the fundamental HIFU wave and therefore generate enhanced HIFU heating.[9,11] The bubbles may also cause heating by viscous damping of their oscillations[17] and by diffusion of heat from their gaseous interiors that are heated when compressed in oscillation.[18] Increasing acoustic pressure amplitude may increase cavitation-enhanced heating as more bubble nuclei are recruited and bubbles are driven into more violent oscillation. Cavitation-enhanced heating has been demonstrated in tissue-mimicking phantoms, where the cavitation threshold is likely lower than in tissue, and only at low HIFU pressures (peak negative pressure amplitude <4 MPa).[9,19] Within this range, a small increase in HIFU pressure amplitude led to both detectable cavitation activity and significantly greater heating measured by thermocouples.[9,19] Other observations of enhanced heating that were attributed to cavitation are summarized in Ref. 9.

Cavitation and boiling bubbles created by HIFU are visibly distinct when observed in optically transparent gel, tissue phantoms.[16] The cavitation or mechanically generated bubbles are diffuse and micron-sized, whereas the boiling or thermally generated bubbles are focal and millimeter-sized. Given sufficient acoustic pressures within the clinical range, both types of bubbles can appear quickly—cavitation in microseconds and boiling in milliseconds.[16,20] Several acoustic techniques have been reported to differentiate the two phenomena.[15,16,21,22] However, few of these techniques have yet been applied in bio-effect studies.

In bio-effect studies, in particular, all bubble activity is often categorized as cavitation, and the appearance of a bubble is a treatment-altering event.[23] Bubbles cause backscatter of HIFU which results in distortion and migration of the lesion,[24] scatter of imaging ultrasound that can be detected and used for guidance,[25] and mechanical erosion of tissue.[26] *In vitro* studies suggest that the contribution of cavitation in at least the first two of these effects—acoustic backscatter and lesion distortion—is negligible compared to that of boiling, which might be expected since boiling bubbles are much larger.[15] The tissue ablation arising from boiling and cavitation bubbles may also be different because of their size, motion, and surrounding temperature. Whether the clinical goal is to use cavitation or boiling bubbles or to avoid them in treatments, it is necessary to understand how the bubbles are created.

One example is to determine how enhanced heating and the presence of bubbles are related. A study that is commonly cited in the HIFU literature of cavitation-enhanced heating *in vivo* is that by Sokka *et al.*[10] In this study, a short (0.5-s) high-amplitude pulse, preceding a long low-amplitude pulse, caused a greater MR-measured temperature rise compared to only a long low-amplitude pulse. The authors may have assumed that the detected bubble activity was not boiling (and therefore bubbles were the *cause* not the *result* of enhanced heating) because the temperature measured by MRI did not reach 100 °C. This threshold temperature for HIFU-induced boiling to occur in tissue has been justified by calculations[16,22] and thermocouple measurements.[22,27] Although bubbles have been detected in MRI measurements in tissue, there have been no results reporting the use of MRI to detect HIFU-induced boiling and to distinguish boiling from cavitation.

The goal of this research was to use MR as an imaging technique to observe boiling during HIFU exposure and simultaneously to use MR thermometry to measure the temperature when boiling occurred. The accuracy of MRI temperature measurements was investigated by comparing the time to boil and the temperature rise measured by MR to those determined using other experimental techniques as well as theoretical modeling based on the Khokhlov-Zabolotskaya-Kuznetsov (KZK) equation. The study was designed to enable a high MRI resolution and to work under well-controlled experimental conditions. Prior to the MR experiments, the acoustic field of the HIFU source was characterized, the cavitation pressure threshold and the temperature when boiling started in the phantoms were determined, and numerical simulations of the acoustic and temperature fields were performed.

II. THEORY

The temperature rise in the gel tissue phantom was numerically modeled by coupling an acoustic propagation model with a heat transfer model. The model equations and solution techniques have been described in previous publications and are only briefly summarized here.[12,15] A comparison of simulations and measurements of the acoustic field in water and gel for a source nearly identical to the one used here has also been reported.[28]

The HIFU field was modeled using a KZK-type nonlinear parabolic equation,[15] generalized for the frequency-dependent absorption properties of the propagation medium:

$$\frac{\partial}{\partial \tau}\left(\frac{\partial p}{\partial z}-\frac{\beta}{\rho_0 c_0^3}p\frac{\partial p}{\partial \tau}-L_{\mathrm{abs}}(p)\right)=\frac{c_0}{2}\Delta_{\perp}p. \quad (1)$$

Here p is the acoustic pressure, z is the propagation coordinate along the axis of the beam, $\tau=t-z/c_0$ is the retarded

time, c_0 is the sound speed, ρ_0 is the ambient density of the medium, β is the coefficient of nonlinearity, $\Delta_\perp = \partial^2/\partial r^2 + r^{-1}\partial/\partial r$ is the Laplacian with respect to the transverse coordinate r, and L_{abs} is the linear operator that accounts for absorption and dispersion in the medium.

The propagation of ultrasound was through a two-layer medium, consisting of water and gel. For water, the thermoviscous absorption was included as

$$L_{\text{abs}} = \frac{b}{2c_0^3\rho_0}\frac{\partial^2 p}{\partial \tau^2}, \tag{2}$$

where b is the dissipative parameter of water. For the tissue phantom, the operator L_{abs} accounted for the measured power law of absorption:

$$\alpha(f) = \alpha_0(f/f_0)^\eta, \tag{3}$$

where α_0 is the absorption coefficient at the fundamental frequency f_0. Small variation in the sound speed with frequency was calculated from the absorption law, Eq. (3), using local dispersion relations.[12]

The boundary condition for Eq. (1) was determined using the combined modeling and measurement calibration technique developed in a previous paper.[28] Equation (1) was then solved numerically in the frequency-domain. First, the acoustic pressure waveform was represented as a Fourier series expansion. Next, the set of nonlinear, coupled differential equations for the amplitudes of the harmonics were derived and integrated numerically using the method of fractional steps with an operator-splitting procedure.[15] Acoustic waveforms $p(\tau,z,r)$, spatial distributions of the intensities I_n of the harmonics nf_0, and total intensity of the wave

$$I(z,r) = \sum_{n=1}^{\infty} I_n(z,r) \tag{4}$$

were calculated. The distribution of heat sources q_v due to absorption of ultrasound,

$$q_v(z,r) = 2\sum_{n=1}^{\infty} \alpha(nf_0)I_n(z,r), \tag{5}$$

was obtained for further simulation of the temperature rise in the phantom.

The values of the physical constants used for acoustic modeling were $\rho_0 = 1000$ kg/m^3, $c_0 = 1486$ m/s, $\beta = 3.5$, and $b = 4.33 \times 10^{-3}$ kg s^{-1} m^{-1} for water and $\rho_0 = 1044$ kg/m^3, $c_0 = 1544$ m/s, $\beta = 4.0$, and $\alpha_0 = 1.6$ m^{-1} at 1 MHz, $\eta = 1$, for the tissue phantom.[29] Changes in the acoustic parameters of the phantom due to HIFU-induced heating were not considered in the simulations.

To quantify the effect of acoustic nonlinearity under the experimental conditions employed in this study, simulations were also performed assuming linear HIFU propagation by setting $\beta = 0$ in Eq. (1). In linear simulations, the HIFU waveforms remained sinusoidal; the intensity I_L included the intensity of the first harmonic only,

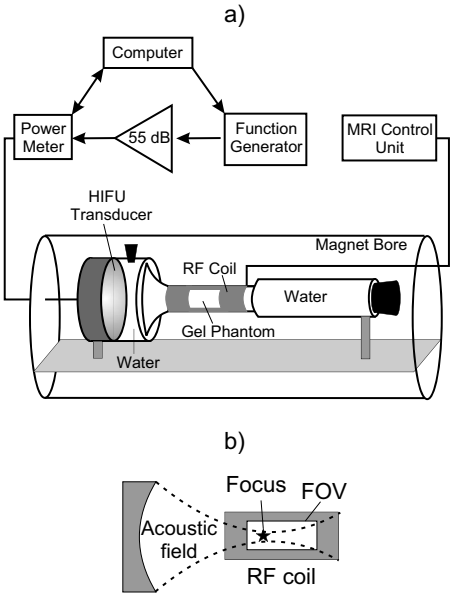

FIG. 1. Experimental arrangement (a) and relative position of the transducer focus and the MRI field of view (FOV) (b).

$$I_L(z,r) = I_1(z,r), \tag{6}$$

and corresponded to the more common but less accurate linearly derated intensity typically used in HIFU studies. The distribution of heat sources was calculated as twice the product of the intensity and the absorption coefficient at the source operating frequency

$$q_v(z,r) = 2\alpha(f_0)I_L(z,r). \tag{7}$$

The temperature rise in the phantom was modeled using the heat transfer equation

$$\frac{\partial T}{\partial t} = k\Delta T + \frac{q_v}{c_v}, \tag{8}$$

where T is the temperature in the phantom, c_v is the heat capacity per unit volume, k is the thermal diffusivity, and q_v is the distribution of thermal sources obtained from either nonlinear, Eq. (5), or linear, Eq. (7), acoustic simulations. Equation (8) was integrated numerically using finite differences.[12] The thermal properties of the phantom used in simulations were $c_v = 5.3 \times 10^6$ J m^{-3} °C^{-1} and $k = 1.3 \times 10^{-7}$ m^2/s.[29]

III. EXPERIMENTAL METHODS

The experimental arrangement is shown in Fig. 1. The transducer, coupling medium (degassed water), and tissue phantom were housed in a custom-designed cylindrical acrylic enclosure that was centered within the bore of the magnet. The 5-cm-long, 2.5-cm-diameter phantom sample was positioned at the focus of the transducer in the narrowest part of the enclosure, which was wrapped by an Alderman–Grant type radiofrequency (rf) volume coil. The phantom was narrow and could therefore be placed in a small volume coil, which provided a good filling factor, increased the signal-to-noise ratio, and optimized the spatial and temporal resolution. A water-filled Tygon tube capped with an acous-

tically absorptive rubber stopper was placed distal to the coil to prevent reflections in the experimental arrangement. The driving electronics were located outside the magnet room and consisted of a laptop computer running LABVIEW (National Instruments, Austin, TX), an HP33150 function generator (Palo Alto, CA), and an ENI A150 amplifier (Bloomington, NY).

The HIFU transducer had an aperture and radius of curvature of 44 mm and a resonant frequency of 2.185 MHz, and was mounted within the wall of the acrylic enclosure. The source was identical to one previously characterized,[28] but the housing was made of polycarbonate instead of metal to be MRI-compatible. The experimental exposure was continuous for 20 s. The electrical power delivered to the source was 63 W, and the acoustic power, measured by radiation force balance, was 49 W.

The tissue-mimicking phantom used in all of the experiments was polyacrylamide gel containing bovine serum albumin (BSA).[15,29] This optically transparent gel tissue phantom has acoustic and thermal properties similar to tissue, although the acoustic attenuation is lower, about one-third of the attenuation in tissue. Advantages of using a tissue phantom instead of tissue include the repeatability and uniformity of the phantom's acoustic, thermal, and magnetic properties. Samples were degassed in a desiccant chamber for 1 h prior to polymerization. The axial distance from the transducer face to the proximal end of the sample was 35 mm. The geometrical focus of the transducer was within the sample, 9 mm from its proximal end.

Before the MRI experiment, a fiber-optic probe hydrophone (FOPH 2000, RP Acoustics, Leutenbach, Germany) with 100-μm active diameter was used to measure the focal pressure waveform in water and in the gel for the chosen 63-W source output. Waveforms were measured at the spatial maximum of the peak positive pressure, which coincided with the geometric focus of the source and was 44 mm from the transducer in water and in the water/gel path. Measurements in water were performed with and without the cylindrical housing attached to ensure that the housing did not alter the waveform through reflection or scattering. Measurements in gel were performed without the housing in a slightly different experimental arrangement, but with the same propagation path in gel as used in MRI experiments. The focal waveforms were also modeled in water and in gel using source parameters (aperture, curvature, and electroacoustic efficiency) determined through previously described calibration of an identical source.[28]

A rf power meter (model 21 A, Sonic Concepts, Woodinville, WA) was used to monitor the electrical power delivered to the transducer. The power meter readings were recorded by a digital acquisition (DAQ) board (model 6062E, National Instruments, Austin, TX) at 1 kHz. Fluctuation in the power meter signal was used as an indicator of boiling as has been reported previously.[19,30] Fluctuation in the power delivered to the source is the result of variations in the acoustic impedance, caused by the ultrasound that is backscattered from bubbles. The fluctuation is the most pronounced when bubbles appear at the transducer focus. Before the experiments in the magnet, this system was tested simultaneously with other indicators of boiling and cavitation, including a 20-MHz passive acoustic detection[9,16,19] and a high-speed video camera.[31] Obvious fluctuation in the power meter signal was observed only with boiling and not with cavitation. Passive acoustic detection, however, did detect cavitation and was also used to measure the acoustic pressure threshold for cavitation in the tissue phantom. Time to boil, yielded by all the measuring techniques, agreed within a few milliseconds (roughly the camera frame period and the DAQ sampling period). In replicate samples, boiling occurred in 7.2 ± 0.3 s. The slight variation was attributed to the possible small difference among the sample batches, initial temperature, and the distance between the sample face and the transducer as well as stochastic variability in the distribution of boiling nuclei.[31] The water temperature in the bench-top experiments was 22 ± 1 °C. In the magnet, the initial temperature of each sample was measured using a thermocouple 2 min before HIFU exposure and was 21 ± 1 °C.

In another set of preliminary experiments, bare-wire thermocouples (130 μm, type E, Omega Engineering, Stamford, CT) were implanted in gels at the focus of the transducer and exposed to the treatment conditions along with simultaneous high-speed camera observation to determine the temperature when boiling occurred. Temperature measurements were recorded at a sampling rate of 250 Hz using a data acquisition device (HP34970A, Hewlett-Packard Corp., Palo Alto, CA). A mount was used to cast the thermocouple and the FOPH in the gel 1 mm apart in the focal plane. Alignment of the HIFU focus with the thermocouple was performed by first finding the peak pressure with the FOPH and then by moving the transducer 1 mm to the thermocouple.

MRI experiments were performed in a 4.7-T Bruker magnet (Bruker Medical Systems, Karlsruhe, Germany) with a 30-cm-diameter bore equipped with a Varian (Varian Inc., Palo Alto, CA) INOVA spectrometer and a custom-built, Alderman-Grant type, rf volume coil with an inner diameter of 2.5 cm. All of the MRI data were collected using a gradient-echo sequence. Both magnitude and phase of the MR signal were acquired to obtain primarily axial images, i.e., images in the plane containing the axis of the cylindrical magnet.

In three of the experimental samples, images were collected during very low energy ultrasound exposure (<2 °C temperature rise for <2 s) 10 min prior to experimental exposure in order to confirm the location of the HIFU focus relative to the center of the magnet and, therefore, to define the location of the acquisition volume. This step was deemed unnecessary for the other three samples, and no difference was observed between the two groups. Single-slice gradient-echo MR images were then acquired continuously for 24 s before, 20 s during, and 100 s after HIFU exposure. The following acquisition parameters were used: matrix size 64×128 pixels, TE=4.2 ms, TR=20 ms, flip angle=20 deg, total image acquisition time of 1.3 s, and field of view (FOV) 30×40 mm^2. The in-plane resolution was 0.3×0.5 mm^2 and the slice thickness was 2 mm. Several minutes after HIFU exposure, high spatial resolution axial and transverse MR images were acquired to locate and resolve residual

bubbles. In the axial sequences, the following parameters were used: 256×256 pixels, TE=7.4 ms, TR=300 ms, flip angle=20 deg, FOV=30×40 mm^2, and slice thickness was 2 mm. The voxel volume in these high-resolution images was 120 μm×160 μm×2 mm.

The gradient-echo data were reconstructed to generate both magnitude and phase images. The magnitude images were used to visualize bubbles, and the phase images were used to determine the proton resonance frequency shift.[5] Phase shifts were converted to temperature changes using a calibration curve that was obtained for heated water prior to the HIFU measurements.[32] The calibration measurement was performed in water, not in the tissue phantom, which is 95% water, to ensure the most uniform temperature throughout the sample volume. To obtain the calibration curve, hot (initially boiling) water was poured into a 6-mm-diameter plastic tube centered in the rf coil used in the HIFU experiments. The tube was plugged to ensure that there was no water flow. A thermocouple was positioned on the tube axis, 2 cm away from the coil center. Gradient-echo images (TR/TE/flip angle=24 ms/4.1 ms/20 deg, matrix size 64×32, FOV 2×2 cm^2, and slice thickness 2 mm) were acquired to monitor resonance frequency changes as the water cooled from 90 to 40 °C.

Eddy currents within the gel, generated by the rapidly switching gradients, caused transient, repeatable phase shifts to occur at the onset of MR data acquisition in the absence of temperature changes. These phase shifts could be mistaken for substantial temperature changes. To correct for this potential artifact, a series of control images was acquired from each gel prior to heating. The MR parameters were identical to those described for the gradient-echo images above, and the resulting series of phase images was subtracted, image by image, from those acquired during HIFU exposure.

IV. RESULTS

A. Measurements and calculations to characterize experimental conditions

An experimentally measured calibration curve was obtained to determine temperature changes from the MR acquired phase shifts in the tissue phantom. In Fig. 2, the calibration curve of the temperature versus the absolute value of the water proton chemical shift is plotted. A third-order polynomial was determined based on a least-squares fit of the experimental data points:

$$\delta T = 0.000\,947\,87\delta\varphi^3 - 0.004\delta\varphi^2 + 0.7742\delta\varphi, \qquad (9)$$

where $\delta\varphi$ is the phase shift of the MR signal and δT is the temperature change relative to 40 °C.[32] Equation (9) was used to obtain temperature maps during HIFU exposure instead of the linear relationship 0.009 ppm/°C that is commonly used for lower field magnets and smaller temperature variations.[33,34] The calibration measurement was only performed one time because it was very difficult safely to get a sufficient volume of water uniformly heated to near 100 °C into the bore of the magnet. Hence, a degree of skepticism should be applied when interpreting the results in Fig. 2. While there are evidence in literature, including Ref. 37

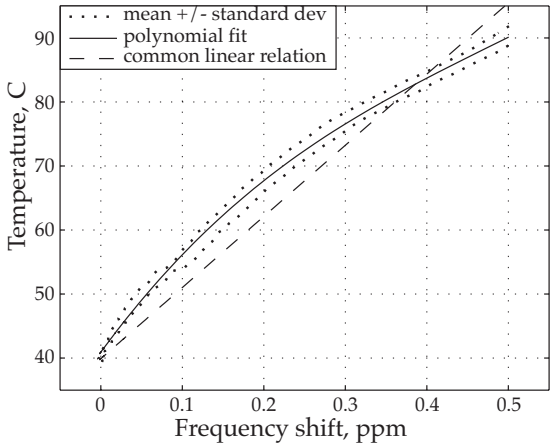

FIG. 2. Water proton resonance frequency shift calibration curve obtained in the 4.7-T magnet that was used for MR thermometry in present work. The solid line shows a third-order polynomial fit to the mean temperature as determined from 12 measurement points located near the center of the rf coil. The dotted lines show the mean ± standard deviation of the measurements. The linear conversion curve (dashed line) often used in 1.5-T magnets is also shown for comparison.

commonly cited for the linear relation, that the dependence between proton resonance frequency and temperature is nonlinear,[35–38] the exact nature of the dependency over broad temperature ranges at 4.7 T requires further validation. Nevertheless, note that the use of the linear relationship would yield *lower* peak MR-determined temperatures than those reported here.

Focal waveforms were measured and modeled in water [Fig. 3(a)] and in the tissue phantom [Fig. 3(b)]. The excellent agreement between the waveforms measured in water with and without the cylindrical sample housing attached to the transducer (Fig. 1) indicates that the housing in the MRI experiments did not alter the acoustic field. Modeling of the field could thus be performed assuming free field conditions. The modeled waveforms also agree well with those measured experimentally both in water and in the phantom [Figs. 3(a) and 3(b)], which supports the use of simulations to determine acoustic and temperature distributions in the phantom. Note also that part of the calibration procedure[28] is to attain agreement between model and measurement in the acoustic distribution for low acoustic excitation. Figure 3 shows that for the source power used in experiments, the combined effects of nonlinear propagation and diffraction led to a typical asymmetric and distorted focal waveform.[12] The compression phase was higher in amplitude, steeper, and shorter in duration than in the linearly predicted waveform (shown as a dashed curve). The peak positive pressure was 30 MPa in water and 27.5 MPa in the phantom. The rarefaction phase was lower in amplitude, smoother, and longer in duration than in the linear waveform with peak negative pressure of 8.4 MPa in water and 8.6 MPa in the phantom. Since nonlinear distortion was clearly observed in the focal waveform, enhanced heating due to nonlinear acoustic propagation effects was expected.

Figure 4 summarizes the results of linear (dashed curves) and nonlinear (solid curves) simulations for various acoustic field parameters and temperature rise in the phan-

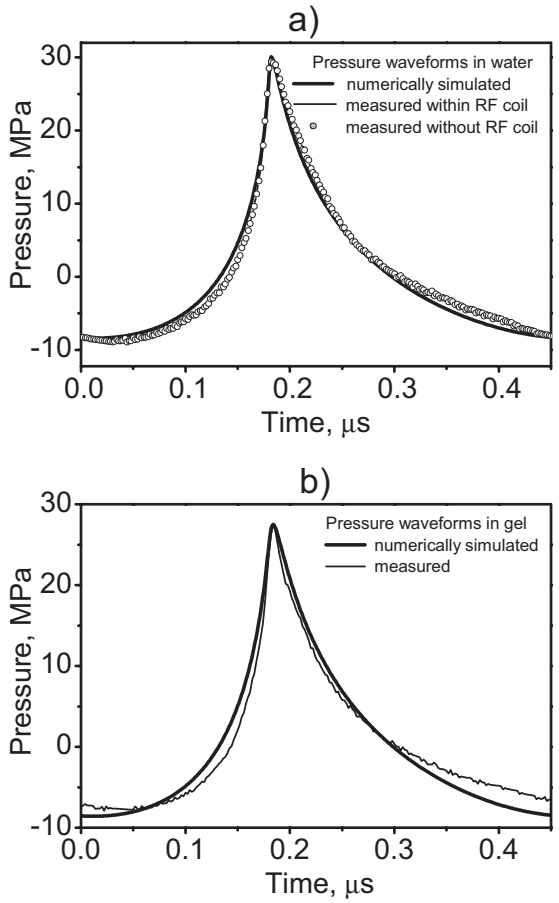

FIG. 3. Focal waveforms simulated numerically and measured by the fiber-optic hydrophone in water with and without the cylindrical, water-filled chamber attached (a) and in the phantom (b). The cylindrical housing did not alter the waveform, and the numerical data are in excellent agreement with the measurements.

tom. Distributions of peak pressure (a), acoustic intensity (b), heat deposition rate (c), and temperature after a 7-s exposure (d) are presented on the HIFU axis (top row) and across the axis in the focal plane $z=44$ mm (bottom row). The −6-dB pressure beam width and length calculated linearly were 1 mm and 6 mm. Nonlinear effects result in reduction in the focal dimensions for the peak positive pressure (0.5 mm and 4 mm) and enlargement of the dimensions for the peak negative pressure (1.2 mm and 8 mm). The maximum value of the peak positive pressure doubled, and the peak negative pressure dropped 30% from the linear to the nonlinear waveform. The *in situ* spatial peak intensity $I=5670$ W/cm^2, Eq. (4), is slightly higher than the linearly calculated, Eq. (6), intensity $I_L=4830$ W/cm^2. The heat deposition rate at the focus is twice that calculated linearly. However, since the heating is over a long time (in seconds) and the extra nonlinear heating is so localized in space, diffusion smoothes the temperature distributions over time, and the final peak temperatures differ much less between the linear and nonlinear simulations than do the peak heating rates. Nonlinear simulations indicate a peak temperature of 99 °C, which we will refer to hereafter as 100 °C because it is so close, while linear simulations yield 86 °C after 7 s of exposure. Dashed vertical lines in Figs. 4(c) and 4(d) show the slice thickness, 2 mm, of the MR voxel. The other voxel dimension in the focal plane is 0.5 mm, and the voxel length in the axial direction is 0.3 mm. The dimensions of the voxel are comparable to those of the heated region. In particular, the 2-mm thickness of the voxel is larger than the half maximum beam width of both the heat sources and even the radial temperature rise profile. Spatial averaging over one voxel can, therefore, be of importance in MR temperature measurements.

At the acoustic exposure levels used in the MR experiments (Fig. 4), cavitation was observed immediately (within a few acoustic cycles) in the phantom with a 20-MHz passive cavitation detector (PCD); in other words, cavitation was present throughout all of the MRI experiments. Figure 5(a) shows the measured threshold curve for cavitation in the phantom for 5-s exposures. For *in situ* peak negative pressures larger than 5 MPa, cavitation was measured immediately in all samples. As shown above, the peak negative pressure at the focus in this study was 8.6 MPa (Figs. 3 and 4)

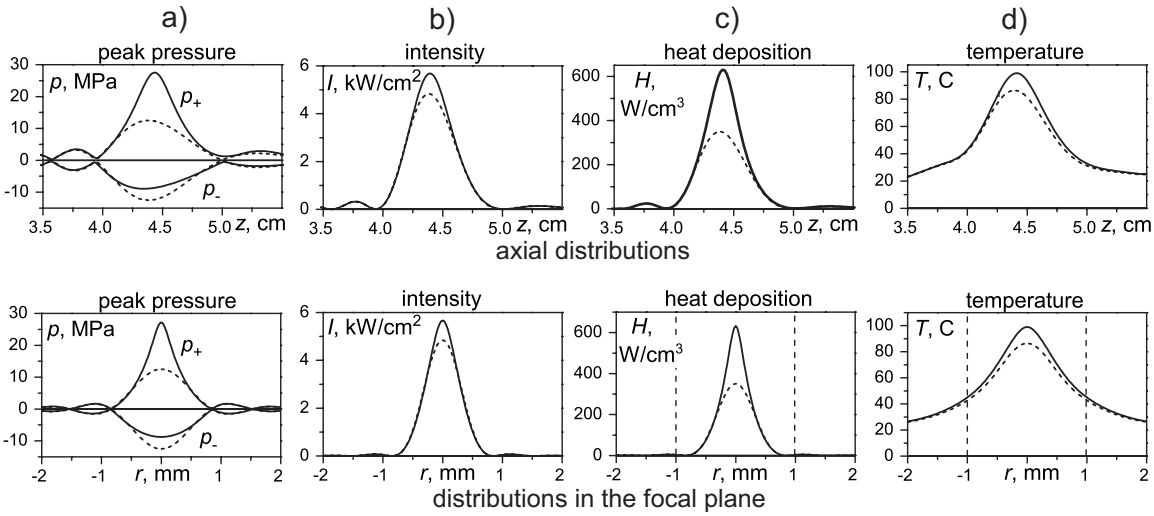

FIG. 4. Simulation results for acoustic and temperature fields in the phantom obtained assuming nonlinear (solid) and linear (dashed) acoustic propagations. Spatial distributions of the peak positive and peak negative pressures, intensity, heat deposition rate, and temperature after 7 s of HIFU exposure are presented axially (upper row) and in the focal plane radially (lower row). Dashed vertical lines on the heat deposition and temperature plots indicate the width of the voxel.

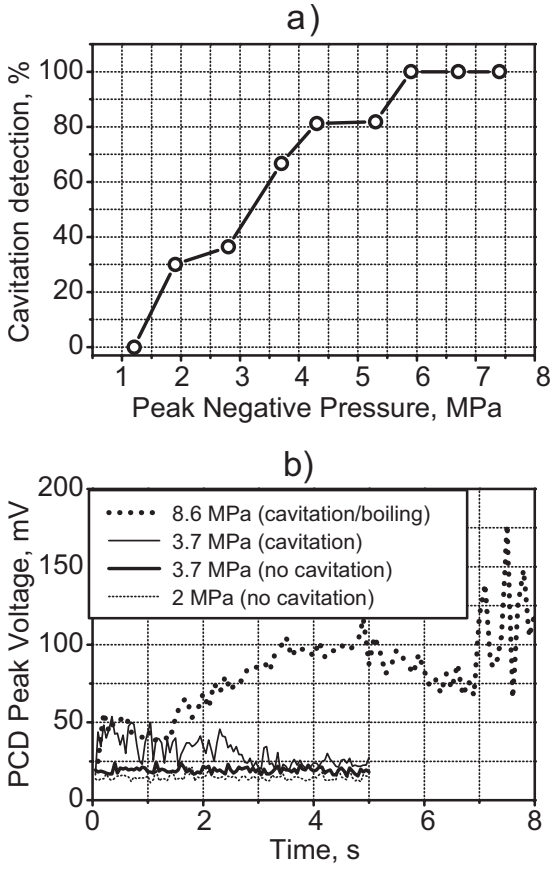

FIG. 5. (a) Percent of times in seven 5-s exposures that cavitation was detected versus peak negative pressure of the HIFU exposure. Cavitation was detected with a 20-MHz PCD high-pass filtered at 15 MHz. Peak negative pressures larger than 8 MPa were used in this work; therefore, cavitation was present in all experiments. (b) Peak-detected representation of time-domain trace recorded by the PCD for three HIFU exposure levels. At the lowest exposure (2-MPa negative pressure), the signal was at the noise level, which was 20 mV. An increase to 3.7-MPa negative pressure caused little change in one case and significant increase in signal amplitude in the other. The large increase in signal was attributed to broadband emissions from cavitation. Under the exposure used in the MR experiments (8.6-MPa negative pressure), the elevated signal due to cavitation was observed immediately after HIFU was turned on, and the signal further increased at 7 s when boiling occurred.

and was, therefore, above the cavitation threshold of the tissue phantom. In an effort to simplify the display of the cavitation signals in Fig. 5(b), time-domain traces measured by the PCD were broken into 100-μs segments, and the peak value of each segment is shown. The background noise level was 20 mV. At an output of 2-MPa peak negative pressure, the signal was only slightly above the noise level of the detection system and was, therefore, interpreted as not having cavitation activity present. Separate exposures at a peak negative pressure of 3.7 MPa created two distinct curves. The lower one was only slightly higher than the curve for the 2-MPa negative pressure exposure, and again the interpretation was that no cavitation occurred. Increasing the applied pressure had little effect on the amplitude of the detected signal without cavitation. However, when cavitation was present as in the upper curve for the 3.7-MPa negative pressure exposure, the signal level from time zero is significantly elevated. Exposure to the conditions described in Fig. 4 and used in the MR experiments here produced the upper curve

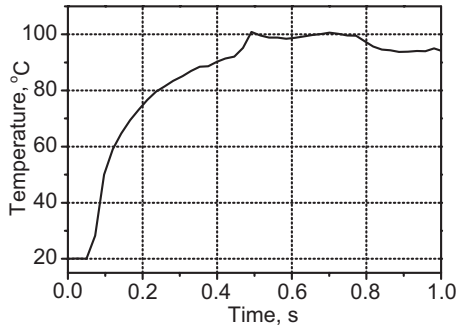

FIG. 6. Temperature measured by a thermocouple at the focus. At the point boiling was visually observed in simultaneous high-speed camera images, 100 °C was measured, and the temperature rise suddenly plateaued. However, the presence of the thermocouple accelerated heating, and therefore, boiling occurred at 0.5 s with the thermocouple present compared to 7 s without it.

labeled 8.6 MPa. An elevated signal due to cavitation is seen immediately at 0 s after HIFU was turned on. The signal is significantly increased when boiling starts at 7 s and is, therefore, distinguishable from the cavitation signal.

The results of temperature measurements with a thermocouple at the focus under the HIFU exposure conditions stated above are shown in Fig. 6. At the instant a boiling bubble appeared, 100 °C was recorded. However, clearly the measurement tool, the thermocouple, affected the measurement: boiling occurred on the thermocouple, and boiling occurred in 7 s without the thermocouple present and in 0.5 s with the thermocouple. Thermocouples are known to create additional heating, near the thermocouple surface, from the viscous damping of the ultrasound-induced motion of the tissue phantom relative to the thermocouple.[39,40] This heating can be reduced by placing the thermocouple at a pressure null instead of at the focus; however, it is evident from Fig. 4(d) that in this case the peak temperature could not be revealed since the linear and nonlinear simulations show the same temperature at the null but significantly different peak temperatures. Viscous heating of the thermocouple is likely responsible for the accelerated heating measured at the focus in the presence of the thermocouple (Fig. 6); nevertheless, when boiling inception was observed by high-speed camera, which visually appeared similar with and without the thermocouple present, the temperature was 100 °C.

B. MRI measurements of HIFU heating in tissue phantom

The following data were all collected in the MRI system from a single exposure of a single sample. The results were repeated in five other samples. The standard deviation in the time to boil between different samples was 0.2 s and was attributed to differences in the sample length, initial temperature, and gas content, as well as variations in the distribution of bubble nuclei.

Power fluctuation was detected by the power meter, suggesting the presence of boiling, after 7.1 s of HIFU heating (Fig. 7). The power fluctuation continued to the end of HIFU exposure. Evidence of boiling was also observed in the amplitude MR images beginning from 7 s (Fig. 8). During

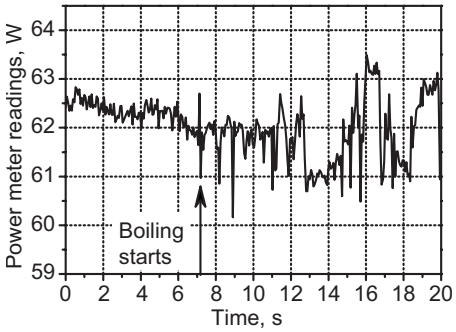

FIG. 7. Indication of boiling after 7-s exposure by fluctuation of the electrical power delivered to the transducer in the MRI experiment.

HIFU exposure, before boiling [Fig. 8(a)], a dark region was seen at the transducer focus. We speculate that this dark region was due to heating, which shifted the resonance frequency away from the bandwidth of the rf excitation pulses and altered the T1 and T2 relaxation times. The first image frame obtained within the time interval of 6.5–7.8 s, following the observed fluctuation in the power meter, contains what looks like bubbles. There is at least one mm-sized, circular, dark region in the image. The dark region indicates a loss of MR signal and would be expected if air or water vapor were present. There is also white and dark mottled "ghosting" around the circular cores. This motion artifact would be expected if the bubbles were oscillating and displacing nearby protons. Figure 8(c), taken 14.3 s after the start of HIFU exposure, shows a dark region of heated tissue containing a bubble. The motion artifact is not seen in this image, possibly because bubble collapses may become less violent over time. For several minutes following treatment, the slowly dissolving bubble or bubbles persisted in the gel sample and were visible to the naked eye and in the MR images. We believe that the reason for bubble persistence is that the samples were incompletely degassed and outgassing into the initially vapor-filled bubbles took place. Figure 8(d) shows a high-resolution image taken 2 min after HIFU exposure when the sample had cooled. Evidence of a bubble is seen within a few voxels of the hottest voxel in the sound field.

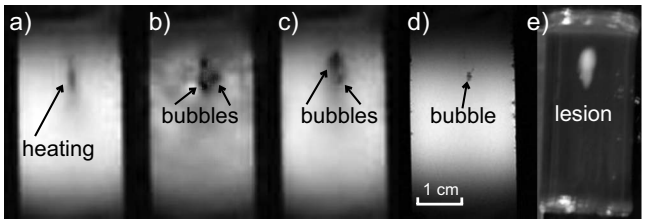

FIG. 8. MR magnitude images of the tissue-mimicking phantom during and after HIFU exposure. The transducer was located above the top of the images, and the sample was exposed for 20 s. (a) The image taken 5.2 s after the start of the exposure shows evidence of heating in the focal region, but boiling had not yet occurred. No evidence of cavitation is observed in the image. (b) After 7.8 s, the image shows large boiling bubbles surrounded by motion artifact. (c) After 14.3 s, motion artifacts are less evident as bubble motion may have become less violent. (d) Even 2 minutes after HIFU exposure, a high-resolution image shows the residual bubble at the HIFU focus. The bubble position corresponded to the distal end of the region of thermally denatured protein (the lesion) photographed in (e). The lesion had grown and enlarged in the direction of the transducer as has been reported to be caused by the presence of boiling (Ref. 15).

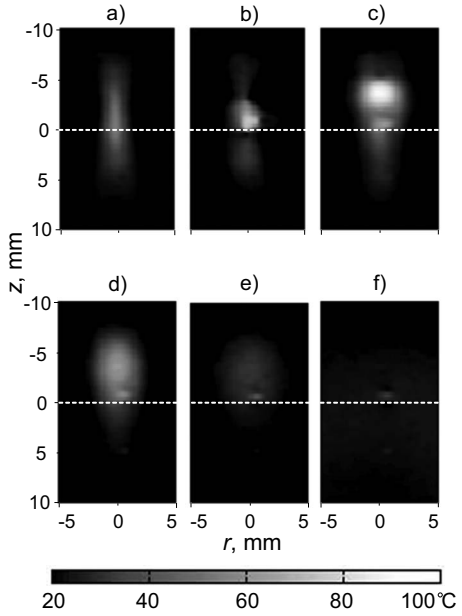

FIG. 9. Two-dimensional temperature distributions measured by MR thermometry: (a) 6.4 s, (b) 7.7 s, and (c) 12.8 s after HIFU was turned on and (d) 3.4 s, (e) 20.3 s, and (f) 40 s after HIFU was turned off. Before boiling (a), the region grew nearly symmetrically about the focus. No temperature field distortion was observed even though cavitation was present. After boiling occurred at 7.1 s, the heated region migrated upward toward the HIFU source and broadened.

The lesion—the region of thermally denatured protein—is not observed in the MR images in Figs. 8(a)–8(d), which is typical with the non-contrast gradient-echo sequence magnitude imaging method employed here.[5] But the final lesion shape, shown in the photograph in Fig. 8(e), indicates that boiling occurred. The lesion continued to be exposed to HIFU for 13 s following the start of boiling, and therefore the lesion grew toward the transducer and broadened on its proximal side arguably because of backscattering from the boiling bubble.[15]

The MRI temperature map in Fig. 9 shows the heated region migrating and broadening in the direction of the transducer. Figure 9(a) shows the MR temperature map acquired just before boiling started. The heated region was nearly symmetric about the focus. However, after boiling started, the hot spot migrated and broadened in the direction of the transducer, as seen in Figs. 9(b) and 9(c). Following treatment, the region cooled [Figs. 9(d)–9(f)], and all that remained was evidence of the bubble (that could also be seen in Fig. 8) at the focus. This bubble appears as a region of slightly elevated temperature on the MR temperature map; however, it had undoubtedly cooled to the ambient temperature. The phase difference that appeared as elevated temperature was likely due to the difference in magnetic susceptibilities of the gel and the gas in the bubble.[37] Both this susceptibility artifact and the motion artifact discussed above mean that MR temperature measurements contain errors once bubbles form and these errors persist as long as the bubbles last.

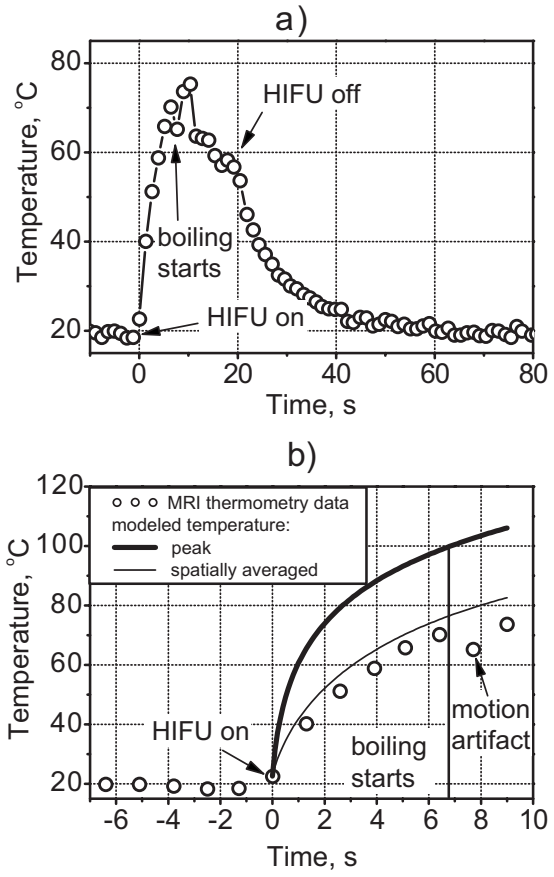

FIG. 10. MR-measured temperature at the focus of the transducer over the course of the treatment (a) and comparison of measurement and calculation in the pre-boiling part of the curve (b). MRI generally tracked the heating during and the cooling following HIFU. However, because of the presence of boiling bubbles during HIFU exposure from 7 to 20 s, temperature readings were erratic. Immediately before boiling (7 s), the calculated peak temperature was 100 °C. The temperature measured with MRI in the focal voxel and the calculated temperature averaged over the voxel volume was only 73 °C.

Boiling started at 7.1 s of exposure as was indicated by fluctuation in the power to the source and the appearance of what look like bubbles in the MR magnitude image; however, immediately before boiling the MR-measured temperature did not reach 100 °C. Figure 10(a) depicts the temperature versus time of the voxel that corresponded to the focus of the transducer. This voxel had the highest temperature in the field at each time point before boiling. Time $t=0$ corresponded to the beginning of the HIFU exposure. For the first 6.5 s, the temperature rose smoothly to 73 °C, which was repeated to within 5 °C in the replicate samples. At 7 s, the bubble appeared in the location of this voxel, and the temperature readings became erratic. The erratic fluctuation was greatest during HIFU exposure when bubble-induced motion artifacts were present. Some of the temperature fluctuation may also have been due to the moving bubbles deflecting the ultrasound and causing local cooling and heating.[17,41] This part of the time-temperature curve varied from sample to sample in a random manner. After 20 s, the voxel began to cool and returned to ambient temperature in about the time expected from calculations. Note that there was no residual artificial elevation in temperature reading for this particular voxel. Although the initial bubble did form in the voxel of interest, its violent and rapid growth moved the bubble off the voxel. In other data sets, the bubble remained in the voxel of interest, and the temperature readings returned to about 10 °C above ambient because of the magnetic susceptibility difference between gas and gel.

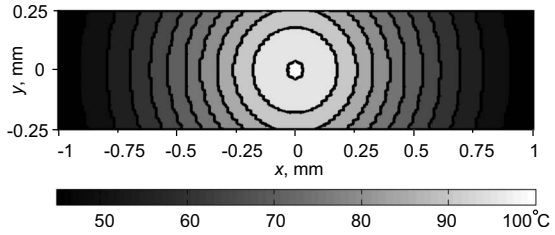

FIG. 11. Temperature distribution after 7-s exposure calculated within a single voxel in the plane perpendicular to the acoustic axis at the spatial peak of temperature. The measured MRI temperature was the temperature averaged over the voxel volume and not the peak temperature.

C. Comparison of MRI measurements and modeling

Unlike the measured temperature of the voxel, the calculated peak temperature did reach 100 °C at 7 s. The thick line in Fig. 10(b) shows the calculated temperature rise using the approach outlined in Sec. II. The circles are the MR-measured data points from Fig. 10(a). However, the temperature field was calculated on a fine grid, and it was necessary to account for the spatial averaging taking place over the finite volume of the MRI voxel (Fig. 4). Figure 11 shows the calculated focal temperature field at 7 s within the voxel cross-section transverse to the acoustic axis. The calculated temperature field was converted to phase using the calibration curve. Then, all phase values within the volume of a voxel were averaged. Finally, the average value was converted back to temperature and indicated the value recorded from the voxel by the MR system. In this manner, the thin line in Fig. 10(b) was obtained, and agreement with measurement is excellent. Indeed, since the spatial temperature distribution close to the focus is very narrow, after averaging it over the size of one voxel the temperature becomes 27 °C lower.

Thus, when spatial averaging was taken into account, the measured maximum of 73 °C corresponded directly to the calculated 100 °C peak temperature. The measured data are shifted slightly to the right of the calculated line, but it is accurate to add a 1.3-s long error bar to the left of the measurement, corresponding to the MR image acquisition time.

V. DISCUSSION AND CONCLUSIONS

In this paper, MR was used as an imaging technique to observe HIFU-induced boiling in a tissue phantom and simultaneously to monitor the temperature as boiling was approached. Standard techniques for MR thermometry were used, but the experiment was designed such that the MR temporal and spatial resolution was better than likely to be achieved clinically. The MR measurements were performed under well-controlled experimental conditions. Homogeneous phantoms with repeatable acoustic and thermal properties were used, the pressure and temperature fields produced by the HIFU source were characterized, the cavitation

threshold in the phantom was measured, and MRI temperature measurements were calibrated prior to the experiment. In other words, the timing and appearance of boiling and of cavitation were well established in advance of testing MR magnitude imaging and thermometry.

Boiling was detected in the MR magnitude images after 7 s of HIFU exposure as circular dark regions surrounded by mottled ghosting indicative of a motion artifact. MRI-detected initiation of boiling correlated with simultaneous observation of fluctuation in the power to the HIFU transducer due to reflections from the bubble and a temperature of 100 °C in numerical simulations. The dark regions in the MR images were about the size of visually observed boiling bubbles (~1-mm diameter), and the motion artifact was thought to be due to bubble motion in the HIFU field. The artifact went away when HIFU exposure was ceased, but a dark spot indicating the presence of the bubble remained.

Although cavitation was present from the beginning of HIFU exposure, cavitation, unlike boiling, was not readily observable in either the power meter reading or the MR magnitude image. The MR image showed darkening in the focal region that grew with time prior to the bubble appearance, but this effect was consistent with the formation of a growing heated region shifting the resonance in the region from the imaging frequency and not with cavitation that is arguably more diffuse and sporadic and less likely to grow symmetrically over time. We speculate that cavitation activity was not observed in the MR imaging because the micrometer-sized cavitation bubbles were much smaller than the millimeter-sized boiling bubbles. In addition, there was no evidence that the cavitation caused additional heating in the samples. Cavitation was present in experiments but not included in the model, yet calculations showed 100 °C at the precise time when boiling bubbles were observed by camera and by artifacts in the MR images. Note that by 100 °C we mean that the temperature was within a few degrees of 100 °C. Boiling may occur at 100 °C or within a few degrees of superheat because of stochastic delays in obtaining a nucleus.[31] In our experiments, the time to boil varied ~4% from sample to sample. In addition, the physical properties of the phantom used in simulations are also known to about this resolution. Thermocouple measurements showed a temperature of 100 °C when boiling started.

Although several independent measures detected either boiling or 100 °C at the same time, the MRI thermometry measurements showed only 73 °C when boiling occurred. If a MR phase versus temperature curve had not been measured and a common linear relationship used instead (Fig. 2), temperatures determined by MR thermometry would have been even lower. MRI alone, therefore, underestimated the peak temperature. However, the results of MR thermometry agree very well with simulations when the modeled temperature distribution was averaged over the volume of the MRI voxel. Spatial averaging was, therefore, shown to be an important factor in this MRI experiment, even though the size of the voxel was much smaller than the voxel size used in clinical MRI systems.[1] Conversely, the transducer, the frequency, focal dimensions, and heating volumes fall within the ranges reported for HIFU clinical work.[12] If only MR thermometry were employed, it would be easy to misinterpret boiling as cavitation because the MRI showed a temperature significantly lower than 100 °C. The temperatures measured by MRI before boiling occurred were underestimated by about 30% due to spatial averaging, which implies that MR thermometry would not have yielded reliable estimations of the thermal dose. Higher frequency, longer focal lengths, and higher amplitudes would shrink the focal width and exacerbate the problem, whereas slower heating allows more time for heat diffusion and tissue motion, which creates other problems, to broaden the heated region.

A deeper look at the spatial and temporal resolutions, particularly, the relation between MR image acquisition time and temperature increase rate, reveals further challenges. We acquired 64 lines of *k*-space at a rate of one line every 20 ms. During the 1.3-s acquisition period the temperature—and therefore the resonant frequency—in some voxels changed substantially, by as much as 20 °C at the focal point. We then used a Fourier transform, which assumes stable resonant frequencies throughout the *k*-space acquisition, to convert to image space and determine the resonant frequency shift in each image voxel.[42,43] Although it is potentially flawed, this same general approach is typically implemented to monitor HIFU procedures using state of the art clinical MR systems. While modern clinical magnets, using parallel imaging techniques combined with rapid acquisition schemes, could provide better temporal resolution than we achieved, it would be very challenging to acquire images of human anatomy with sub-millimeter spatial resolution and acquisition times short enough to adequately reduce resonant frequency changes as *k*-space is filled.

It is important to distinguish boiling from cavitation in clinical research, as detection of boiling could be a useful surrogate for a temperature measurement. Its appearance indicates that the temperature has risen close to 100 °C. Anand and Kaczkowski[22] and Khokhlova *et al.*[44] proposed to use the measured time to boil, combined with calculations, to obtain *in situ* pressures and *in situ* heat rates, which enable these authors to control more precisely clinical HIFU exposure. Further, it is also important to know when boiling occurs or preferably when it will occur because once boiling begins, the treatment is dramatically and irreversibly changed as evidenced by the distortion of the lesion shown in Fig. 8. Undetected boiling will result in lesions that are larger in size and possibly in the wrong location. The clinical significance of this work is that MRI-based temperature measurement alone may be insufficient to monitor and control therapy when treatment temperatures reach 100 °C.

Another point of clinical concern is that boiling can occur in HIFU much more quickly than might be expected. The relationship between focal heating and either focal pressure or drive power is highly nonlinear, especially when output levels are sufficient to cause shock waves. The HIFU heating rate used in our experiments was relatively slow in order to accommodate the long MR image acquisition time. The transducer was excited by 63 W of electrical power, which resulted in a focal pressure waveform that was distorted but not yet shocked, and boiling occurred in 7 s. However, if the power is increased, the heating rate increases significantly. In

our previous experiments, an identical transducer (2.158-MHz, 42-mm aperture and 44.4-mm radius of curvature) was driven up to 300 W, shock waves formed at the focus, and boiling was obtained in under 3 ms in a similar tissue phantom.[16] This time is much shorter than the 1.3-s MR slice acquisition time used in the current study.

These results—HIFU initiation of boiling is unlikely to register 100 °C on MR thermometry and high power can result in millisecond boiling—lead us to a new interpretation of the paper by Sokka *et al.*,[10] which is often cited as the *in vivo* evidence for cavitation-enhanced heating by HIFU. Except for the HIFU power, the study reported here was very similar to the one reported by Sokka *et al.* MRI acquisition time in that work was 4.4 s, and the voxel size was $0.8 \times 1.2 \times 3$ mm^3—larger than in our case. In addition, the authors averaged nine voxels to obtain one temperature reading, which further reduced the spatial resolution. The HIFU source was larger but more focused than the one used in our work (aperture 10 cm and radius of curvature 8 cm), with about the same frequency, 1.7 MHz. The tissue path was 1–2 cm as was ours in phantom. Sokka *et al.* compared two exposures that each had the same total energy delivered to the source: the first was a continuous excitation with electrical power of 28 W for 20 s, and the second contained a 300-W, 0.5-s long burst followed by continuous excitation with electrical power of 21 W for 19.5 s. The authors found that the MR-measured temperature was higher for the second type of treatment, particularly because of greater temperature rise during the initial high-amplitude burst, and the resulting lesions were larger and had migrated toward the source. Bubble activity was detected only in the exposure that included the initial high-amplitude pulse and was attributed to cavitation, not boiling, presumably on the argument that 100 °C was not measured by MRI. The conclusions were, "…cavitation can be reliably used to create significantly larger lesions (three times larger lesions than with conventional focused ultrasound) *in vivo*." In light of our results, an alternative interpretation can be proposed. Heating from the incident HIFU waves, which were arguably shocked or at least significantly distorted, accounted for the enhanced temperature rise during the first 0.5 s of exposure, and the detected bubble activity was boiling, not cavitation. A temperature of 100 °C was not detected just before boiling started because the heated region was smaller than the volume of the MR voxels averaged to measure temperature. Furthermore, after boiling started within 0.5 s of the high-amplitude burst exposure, the presence of bubbles distorted MR temperature readings. By this interpretation, the paper of Sokka *et al.* provides evidence of nonlinearly enhanced or shock-wave-enhanced heating and boiling *in vivo*, not cavitation-enhanced heating *in vivo*. Since MR-based temperature measurements are currently used to calculate ablation volumes in MR-guided HIFU systems, it is important that the respective roles of cavitation and boiling be more clearly understood.

(Received 6 August 2008; revised 29 January 2009; accepted 5 February 2009)

Auditory evoked potentials (AEPs) were recorded during echolocation in a false killer whale *Pseudorca crassidens*. An electronically synthesized and played-back ("phantom") echo was used. Each electronic echo was triggered by an emitted biosonar pulse. The echo had a spectrum similar to that of the emitted biosonar clicks, and its intensity was proportional to that of the emitted click. The attenuation of the echo relative to the emitted click and its delay was controlled by the experimenter. Four combinations of echo attenuation and delay were tested (−31 dB, 2 ms), (−40 dB, 4 ms), (−49 dB, 8 ms), and (−58 dB, 16 ms); thus, attenuation and delay were associated with a rate of 9 dB of increased attenuation per delay doubling. AEPs related to emitted clicks displayed a regular amplitude dependence on the click level. Echo-related AEPs did not feature amplitude dependence on echo attenuation or emitted click levels, except in a few combinations of the lowest values of these two variables. The results are explained by a hypothesis that partial forward masking of the echoes by the preceding emitted sonar pulses serves as a kind of automatic gain control in the auditory system of echolocating odontocetes. © *2009 Acoustical Society of America.*

I. INTRODUCTION

The biosonar of odontocetes (toothed whales, dolphins, and porpoises) operates with echo levels varying by many tens of decibels because of the variation of target strengths and distances. Therefore, the performance of the biosonar requires that its receiving part (the auditory system) be capable of analyzing echoes under widely varying intensities. This capability requires either a kind of automatic gain control (AGC) to decrease the range of variation of intensities of the returning echoes in the auditory system, or a capability of the auditory system to analyze the echo signals over a very wide variety of neuronal response levels. We do not yet know how the odontocete's auditory system solves this problem. One way to keep the echo level within a reasonable range is to vary the level of the outgoing signal. Experiments on animals in the wild have shown that dolphins and whales may vary the intensity of their echolocation pulses according to the distance to the target, roughly at a rate of 20 dB per distance decade (Rasmussen *et al.*, 2002; Au and Benoit-Bird, 2003; Au and Herzing, 2003; Au and Würsig, 2004). To some extent, the variation of the level of the emitted biosonar pulses may compensate for the echo attenuation with distance. However, this mechanism does not control the gain in the receiving part of the biosonar, i.e., in the auditory system. Variation of the emitted pulse intensities does not influence the ratio of neuronal responses to the emitted acoustic pulse and the echo. Since the echo-response may be partially or completely masked by the much more intense preceding emitted pulse, the ratio of responses to the emitted pulse and the echo should also influence the neuronal response to the echo depending on the target strength and distance.

It has been hypothesized that the odontocete auditory system, i.e., the receiving part of the biosonar, possesses an AGC mechanism that is capable of compensating for the distance-dependent variation of responses to the echo. According to this hypothesis, this mechanism is based on partial forward masking of neuronal echo-responses by the more intense preceding emitted acoustic pulses. Originally, the hypothesis was based on results obtained during conditions of *external* double-pulse stimulation instead of natural echolocation. It has been shown that when the evoked response to a test click is forward masked by a more intense conditioned click, the rate of release from this masking was 30–40 dB per delay decade in bottlenose dolphins (Popov and Supin, 1990) or 25–30 dB per delay decade in a false killer whale (Supin *et al.*, 2007). The double-pulse stimulation may be considered as simulating the interaction between the emitted biosonar pulse and the echo in natural echolocation. The first (conditioning) pulse in the pair simulates the emitted pulse and the second (test) pulse simulates the echo. The rates of release from masking found in those experiments were remarkable since they were close to the physical rate of echo attenuation with distance that is between 20 and 40 dB per distance decade depending on the target size. Thus, there was good

[a)]Electronic mail: alex_supin@mail.ru

 0001-4966/2009/125(4)/2432/11/$25.00

reason to hypothesize that if the same forward masking takes place between the emitted pulse and echo, it may make responses to a target invariable of distance. In other words, with distance increase, the decrease in the echo intensity and the release from masking by the emitted pulse compensate one another, thus keeping the auditory response magnitude nearly constant.

There have been some data obtained in favor of this hypothesis. Recordings of brain stem evoked potentials during natural echolocation have shown that the response to the echo remained almost constant with variation of target distance, although the intensity of emitted echolocation pulses varied only slightly (Supin *et al.*, 2004, 2005). These data indicate that AGC in the odontocete biosonar involves a variation of sensitivity of the auditory system. It appears as though the echo-response was kept nearly constant because of its delay-dependent release from forward masking by the previous louder emitted pulse, as predicted by the release from forward-masking hypothesis.

The data on the rate of release from masking obtained with external double-pulse stimulation cannot be directly applied to conditions of natural echolocation, particularly because the rate of release from masking depends on the relation of intensities and frequency bands of the two pulses (Popov *et al.*, 2001). The measurement of the rate of release from masking with conditions closer to real echolocation would be a much more trustworthy confirmation of the hypothesis. Some confirmation has been obtained. Psychophysical measurements in a false killer whale (Supin *et al.*, 2008) have shown that thresholds of detection of simulated electronic echo decrease with the echo delay increase with a rate of −31.5 dB per delay decade. This threshold decrease was interpreted as release from forward masking and the obtained rate of release was not substantially different from that (25–30 dB) previously obtained in passively presented double-pulse evoked-potential measurements and predicted by the forward-masking AGC hypothesis. Note that depending on the target features, the echo level varies with distance at a rate from 20 dB/decade (a flat mirror) to 40 dB/decade (a small object), i.e., 30 ± 10 dB. If the masked threshold depends on distance at a rate near −30 dB/decade and the echo sound pressure level depends on distance at nearly the same rate, then the echo sensation level (relative to the masked threshold) should not be dependent on distance.

However, threshold data do not always allow the prediction of variation in supra-threshold response magnitude because of a possible non-linearity in the auditory system. Therefore, the goal of the present study was to assess the possibility of forward-masking based AGC in the odontocete sonar at supra-threshold echo levels.

We approached the problem by examining the brain auditory evoked potentials (AEPs) during echolocation in an odontocete subject. This approach has demonstrated its potential for the investigation of the odontocete biosonar beginning with the first attempts made by Bullock and Ridgway (1972), which showed that voluntary click emission by a dolphin as well as external stimulation ("artificial echo") resulted in AEPs. The quantitative investigation of outgoing pulse-related and echo-related AEPs has been accomplished in a variety of recent studies using a non-invasive recording technique (Supin *et al.*, 2003, 2004, 2005).

Unlike our previous studies, in the current work, we used a simulated electronic (phantom) echo technique to produce echoes rather than using real echolocation targets (Aubauer and Au, 1998). Using this technique, the echo is produced by electronically playing back an acoustic pulse that is triggered by the animal's emitted biosonar pulse. An advantage of this technique is the possibility of flexibly and independently varying the parameters of the echoes, which is not always possible with real physical targets. By using this technique, we investigated how the echo-produced AEP magnitude varied when the echo delay and level varied in the same manner as expected for a real target at different distances.

II. METHODS

A. Subject and experimental conditions

The experiments were carried out at the facilities of the Hawaii Institute of Marine Biology, Marine Mammal Research Program. The subject was Kina, a false killer whale *Pseudorca crassidens*, an experienced approximately 30–35 year-old female kept in a wire-net enclosure in Kaneohe Bay, HI. This same whale was used in previous evoked-potential studies of echolocation (Supin *et al.*, 2003, 2004, 2005, 2007, 2008; Nachtigall and Supin, 2008). The animal was trained to echolocate, to recognize electronic echoes, and to report the echo presence or absence using a go/no-go reporting paradigm. The subject had significant hearing loss at frequencies above 35–40 kHz; however, its hearing sensitivity below 30 kHz was satisfactory (Yuen *et al.*, 2005).

The experimental facilities were laid out as follows (Fig. 1). The experimental enclosure was constructed of a floating pen frame (1), 8×10 m in size, supported by floats and bearing an enclosing wire net. This enclosure (the animal section) linked to a target presentation section—another floating frame (2), 6×8 m in size that served as a platform for mounting targets or transducers and did not bear net. In the net divider separating these two sections, there was an opening bounded by a hoop (3), 55 cm in diameter that served as a hoop station for the animal. In front of the hoop, a hydrophone (4) was positioned 1 m from the animal's blowhole to record the echolocation pulses. At a distance of 2 m, a transducer (5) was positioned to play-back electronic echoes. The hoop station (3), the hydrophone (4), and the transducer (5) were in a longitudinal straight line; altogether at a depth of 80 cm. In front of the animal, there was a movable baffle (6). When pulled up, this baffle screened the hydrophone and play-back transducer from the animal positioned in the hoop station; when it was lowered down, it opened the space in front of the animal. Near the hoop station, a response ball (7) was mounted above the water surface serving as a target or echo-present response indicator. The animal's position in the stationing hoop was monitored through an underwater video camera (8). The electronic equipment and experimenter were housed in a shack (9) with

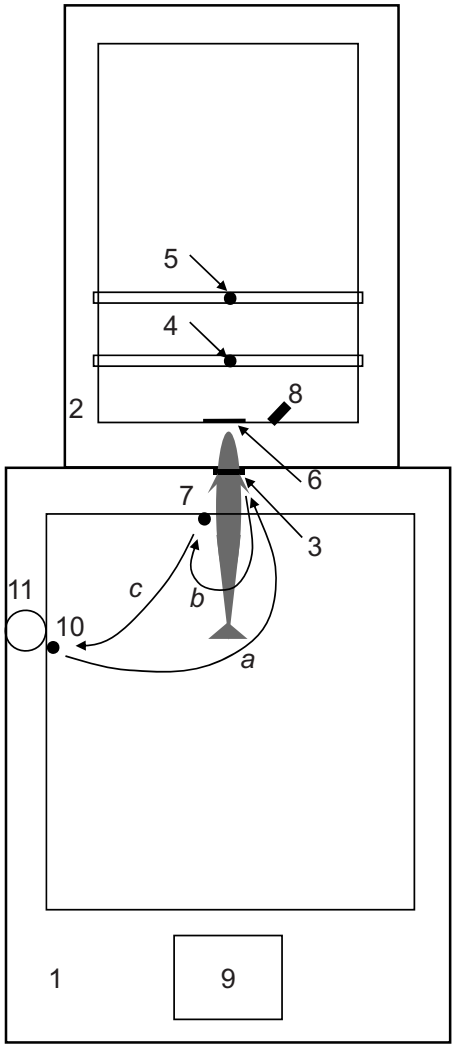

FIG. 1. Experimental design. (1) Experimental pen, (2) transducer-holding frame, (3) hoop station, (4) receiving hydrophone, (5) playing-back transducer, (6) baffle, (7) response ball, (8) video camera, (9) shack, (10) start-position ball, and (11) trainer's position.

a window facing the pen. A ball (10) mounted in the water at the side pen deck nearly the trainer's position (11) marked the start position for the animal.

B. Experimental procedure

Each session consisted of 50 trials randomly alternating: 20 trials of electronic echo play back, 15 trials of real physical target presence (a hollow aluminum cylinder, 38.1 mm outer diameter, 25.4 mm inner diameter, 180 mm long, −22 dB target strength, and 3 m distance), and 15 trials of neither electronic echo nor real target (echo absence). Electronic echo trials served to collect AEP data. Real target trials served to maintain the skill of the subject to detect and discriminate targets, which was necessary for other tasks. Echo-absent trials served to maintain correct echolocation activity reporting echo or target presence or absence. The experimental procedure was as follows.

(i) Each session began with the trainer attaching suction-cup electrodes for AEP recording (see below for detail). (ii) The animal was sent to a hoop station (trace *a* in Fig. 1); the animal swam into the hoop in such a position that the hoop was at the level of the pectoral fins. During the animal's positioning, the baffle (6 in Fig. 1) was in the raised position that prevented the animal from echolocation. (iii) When the animal took the proper position in the hoop station, the baffle was lowered for 3 s, thus allowing the animal to inspect the space by echolocation. The animal immediately emitted a train of echolocation clicks, normally 10–40 clicks in a train. (iv) When either the electronic echo or real target was presented, the animal was required to signal its detection by leaving the hoop and touching a signal ball (trace *b* in Fig. 1), then coming to the trainer for the fish reward (trace *c*). During the no-echo, no-target trials, the animal was required to wait 6 s in the hoop, then it was signaled to leave the hoop (trace *b* was absent) and come for the fish reward (trace *c*).

During the electronic echo trials the electronic echo generation and AEP-acquisition system (see below) were turned on as soon as the baffle was lowered down, and it was kept on until the end of the echolocation click train. Thus, AEPs triggered by echolocation clicks were collected. In real target or echo absent trials, AEP acquisition was turned on for the same time, but the echo generation was turned off.

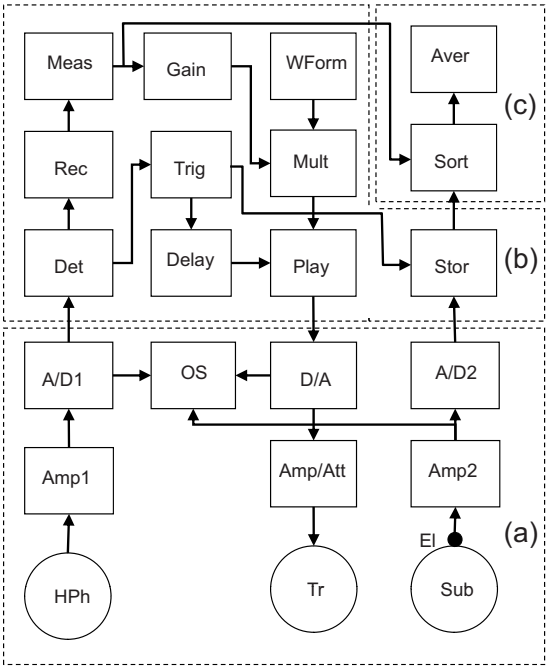

FIG. 2. Instrumentation and data processing. (a) Hardware, (b) on-line software, (c) off-line software. HPh—hydrophone, Amp1—hydrophone amplifier, A/D1—analog-to-digital converter for sound signals, Det—sonar pulse detection, Rec—sonar pulse waveform recording, Meas—sonar pulse amplitude measurements, Gain—echo level control, WForm—echo waveform, Mult—multiplication, Trig—echo and data acquisition triggering, Delay—echo delay control, Play—echo playing back, D/A—digital-to-analog converter, Amp/Att—output amplifier/attenuator, Tr—playing transducer, Sub—subject, El—electrodes, Amp2—brain-potential amplifier, A/D2—analog-to-digital converter for brain-potential signals, Stor—data storage in computer memory, Sort—brain-potential record sorting, Aver—off-line averaging, and OS—oscilloscope.

C. Instrumentation and data collection

The experimental equipment was designed as shown in Fig. 2. It contained two channels, one for recording and pro-

cessing the biosonar sound clicks and another for recording the brain potentials.

The emitted biosonar pulses were picked up by a hydrophone (HPh in Fig. 2) B&K 8103 with the flat frequency response up to 170 kHz. The picked-up signals were amplified by 20–40 dB within a frequency range of 5–100 kHz by a custom-made amplifier (Amp1 in Fig. 2) based on a chip AD820 (Analog Devices). The amplified signal was led to an analog-to-digital converter (A/D1 in Fig. 2) of a data acquisition card NI DAQ-6062 (National Instruments). The digitizing was done at a sampling rate of 512 kHz. The digitized signal was processed by a standard personal computer. The processing included steps as follows.

A sonar click was detected when the input signal exceeded a pre-adjusted threshold level (Det in Fig. 2). The click waveform within a 100-μs window was acquired and stored in computer memory for further off-line analysis (Rec in Fig. 2). The peak-to-peak amplitude of the stored click was measured (Meas in Fig. 2). A pre-synthesized echo waveform (WForm in Fig. 2) was multiplied (Mult in Fig. 2) by the amplitude value of the picked-up click and by a proportionality factor (Gain in Fig. 2); therefore, the amplitude of the synthesized signal was proportional to amplitude of the picked-up sonar click. The proportionality factor was controlled by the experimenter to vary the level of the electronic echo from trial to trial. The obtained signal was played back (Play in Fig. 2) being triggered at the instant that the biosonar click was picked up (Trig in Fig. 2) with a controlled delay (Delay in Fig. 2). The played-back digital signal was digitally-to-analog converted (D/A in Fig. 2) by the same acquisition card NI DAQ-6062, amplified and attenuated (Amp/Att in Fig. 2), and played through an ITC-1032 (International Transducer Corporation) transducer (Tr in Fig. 2).

Brain potentials were picked up by the surface electrodes (El in Fig. 2), which were 10-mm golden-plated disks mounted in 50-mm silicon suction cups. The active electrode was placed at the dorsal head surface midline, 7 cm behind the blowhole; the reference electrode was fixed at the dorsal fin lateral surface. The electrodes were connected by 10-m flexible shielded cables with the input of a custom-made brain-potential amplifier (Amp2 in Fig. 2) providing 20 000 times amplification within a frequency range of 200–5000 Hz. The amplified signal was analog-to-digitally converted (A/D2 in Fig. 2) by the same acquisition card NI DAQ-6062. Fragments of the signal 15–25 ms long (depending on the used electronic echo delay) were extracted and the acquisition of each fragment was triggered by the same trigger (Trig in Fig. 2) as the played-back echoes, however, without delay; thus, the acquired fragment included events in the brain potentials beginning immediately after the biosonar-click detection. The extracted brain-potential fragments were stored in computer memory *without* averaging. Each of the records was marked by the decibel-level of the triggering sonar click.

This cycle of data processing repeated automatically at each picked-up biosonar click. Both input (sound and brain-potential) and output (played-back) signals were monitored by an oscilloscope Tektronix TDS1002 (OS in Fig. 2).

Further analysis of brain potentials was performed off-line. All the brain-potential records were sorted in 5-dB bins by the levels of the triggering clicks. After collection of all the brain-potential records at a certain combination of the echo gain and delay, the records in each bin were averaged, thus obtaining the final records of the brain responses to the emitted pulse and echo, separately for different emitted click levels with a tolerance of ± 2.5 dB. With this procedure, the number of original records was not constant among different averaged records because it depended on the number of biosonar clicks produced by the animal at each particular level. Only those averaged records that were based on not less than 250 original records were accepted as having enough data to produce a satisfactory signal-to-noise ratio.

The biosonar-click data processing (recording the click waveform, measuring its amplitude, and synthesizing the played-back echo waveform) required up to 3–3.5 ms. This resulted in a time limitation for available echo delays. Together with the acoustic delay of 2 ms (sound propagation for 1 m from the animal to the receiving hydrophone plus 2 m from the playing transducer to the animal), the minimal available echo delay could not be less than 5–5.5 ms if the echo was triggered by the same biosonar pulse that was used for calculating the echo parameters. To avoid this limitation, each emitted sonar pulse triggered playing-back the echo waveform computed using the amplitude value of not the current but the *previous* pulse. After triggering, the program computed the signal to be triggered by the next biosonar pulse. With this mode, triggering was possible as soon as a few microseconds after the sonar pulse detection, i.e., with virtually zero delay. Together with the acoustic delay, the low limit of echo delays was 2 ms. This solution was based on an assumption that during a biosonar-click train, the amplitude of the clicks vary rather gradually, not by big jumps from high to low amplitude or vice versa. If so, the error resulting from computation based on previous instead of current sonar pulse would not be large. The validity of this assumption is examined and discussed below based on the click statistical results.

Data processing was controlled by a custom-made program ("virtual instrument") designed on the base of LabVIEW software (National Instruments).

D. AEP magnitude measurements

Amplitudes of both emission-related and echo-related AEPs were measured as peak-to-peak differences within a 3-ms time window around the anticipated response appearance. In doing so, it was kept in mind that the addition of background electrical noise to the response might have increased the peak-to-peak span in the measurement window, thus resulting in overestimate of the response amplitude. To compensate for this effect, the noise power was subtracted from the response power. This was done by subtracting background noise power from an estimate of AEP power using a formula

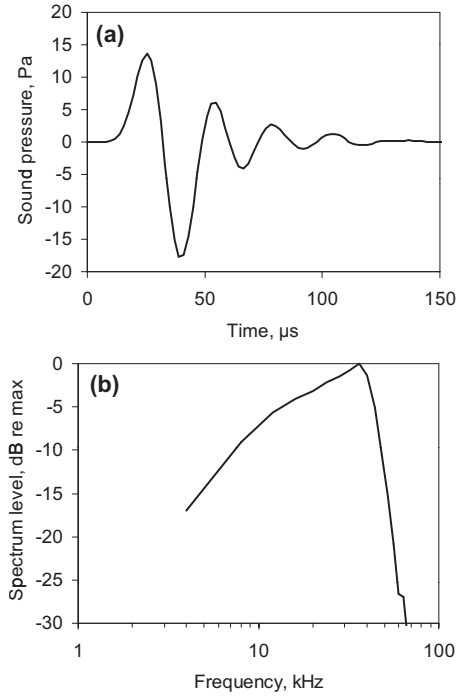

FIG. 3. Electronic echo pulse (150 dB re 1 μPa peak/peak) waveform (a) and frequency spectrum (b).

$$A_r = \sqrt{A_m^2 - (2\sqrt{2}N)^2},$$

where A_m is the measured peak-to-peak amplitude, N is noise rms, A_r is the resulting amplitude estimate, and the factor of $2\sqrt{2}$ relates peak-to-peak to rms values; this value was arbitrarily chosen as valid for a sinusoid. This correction was negligible for responses well exceeding the background noise but reduced the resulting estimates when a measured peak-to-peak span within the measuring window approached the noise level. When the expression under the square root was negative, A_r was adopted as zero.

E. Echo pulse features and variation ranges

Waveform, spectrum, and level of the played-back electronic echo were monitored in the absence of the animal by positioning a receiving hydrophone (B&K8103) in the center of the hoop station.

The spectrum of the acoustic echo pulse was close to those of typical emitted biosonar pulses (see below). The waveform (a) and frequency spectrum (b) of the acoustic echo pulse (150 dB re 1 μPa p/p) are presented in Fig. 3. The echo pulse had a spectrum peak at 35 kHz with high-frequency decay down to −20 dB at 55 kHz and low-frequency decay down to −20 dB at 3 kHz. Note that the spectrum peak fell into a frequency range where the subject had minimal hearing loss.

A distinguishing feature of the experimental design was that the level of electronic echo was not directly controlled by the operator. It was proportional to the amplitude of the emitted biosonar pulses, thus imitating an important feature of the real echo. Instead of the level, the *attenuation* of the echo signal relative to the emitted sonar pulse was controlled by the operator and used to specify the echo. This attenuation was calculated as a decibel-difference between the echo level next to the animal's head and the source level (i.e., level at 1-m distance from the head) of the emitted sonar pulse. With the instrumentation designed as described above, the echo attenuation was determined by (i) the transduction factor of the receiving hydrophone (HPh in Fig. 2), (ii) the transduction factor of the playing-back transducer (Tr in Fig. 2), (iii) the distance from the animal's head to the hydrophone, (iv) the distance from the play-back transducer to the head, (v) the gain of the hydrophone amplifier (Amp1 in Fig. 2), (vi) the gain of the output amplifier-attenuator (Amp/Att I Fig. 2), and (vii) the digital multiplication factor (Gain in Fig. 2). The factors (i)–(iv) were kept constant throughout all the present study, whereas variation of parameters (v)–(vii) allowed echo attenuation variation within a wide range.

Apart from the attenuation, the delay of the electronic echo relative to the instant of the detection of the emitted sonar pulses was varied. Since acquisition of every final record required at least a few experimental sessions, only a limited number of combinations of the echo attenuation and delay were tested in this study, namely,

(1) 2 ms delay and −31 dB attenuation;
(2) 4 ms delay and −40 dB attenuation;
(3) 8 ms delay and −49 dB attenuation; and
(4) 16 ms delay and −58 dB attenuation;

i.e., the echo attenuation and delay were associated with a rate of 9 dB per delay doubling (i.e., 30 dB per delay decade). This rate was chosen because an earlier investigation in the same subject with double-pulse external stimuli had shown that the time of release from forward masking depended on the conditioning-to-test stimuli ratio with just this rate, around 9 dB per delay doubling (Supin *et al.*, 2007). On the other hand, the rate of 9 dB per delay doubling is the midpoint of the range of echo intensity variation depending on distance (from 6 to 12 dB per distance doubling, depending on the target size), so this rate was expected to satisfactorily reproduce the conditions of real echolocation. Assuming the attenuation-vs-delay rate of 9 dB per delay doubling, all the used combinations of attenuation and delay corresponded to a target strength of −26 dB at sound velocity of 1500 m/s.

III. RESULTS

A. Subject performance statistics

In all of the sessions, the subject featured a high percentage of correct responses. The electronic echo was correctly detected in 649 of 670 trials (99.1%), the physical target was correctly detected in 508 of 510 trials (99.6%), and correct rejections were in 500 of 510 trials (98.0%). Only AEP records obtained during correct detection trials were used for further AEP analysis.

B. Emitted sonar clicks' parameters and statistics

During the echo threshold measurements, 21 687 waveforms of emitted sonar clicks were collected and analyzed off line. Representative click waveforms of the most typical

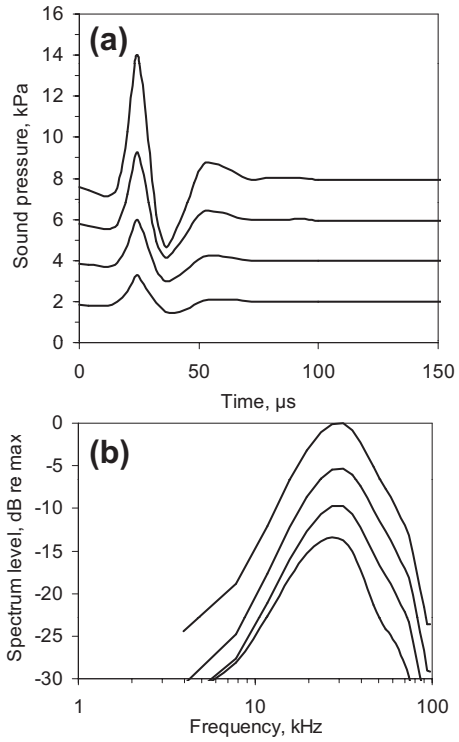

FIG. 4. Emitted sonar pulses of various levels. (a) Waveforms, from top to bottom: 200 ± 2.5, 195 ± 2.5, 190 ± 2.5, and 185 ± 2.5 dB re 1 μPa peak/peak, shifted relative one another by 2 kPa for better discrimination. (b) Corresponding spectra (from higher to lower, respectively).

levels, from 185 ± 2.5 to 200 ± 2.5 dB re 1 μPa peak/peak, are presented in Fig. 4(a), each as an average of 200 examples. The clicks of all levels consisted of a few waves, the main compression wave and decreasing rarefaction-compression oscillations. The frequency spectra of these waveforms had peaks at 27–32 kHz and fell down to −20 dB at 80–88 kHz at the high-frequency branch and at 5–7 kHz at the low-frequency branch. Note that the spectrum peak fell into the frequency range where the subject had minimal hearing loss.

Statistical distributions of click levels are presented in Fig. 5, separately for the four investigated combinations of echo attenuation and delay [(a)–(d)]. From 5367 to 6350 clicks were collected and measured at each of the combinations. All of the distributions demonstrated a rather wide range of click level variation, from 165 to 205 dB re 1 μPa peak/peak; however, more typically click levels ranged from 185 to 200 dB. Mean peak levels noticeably differed among different combinations: from 180.0 dB (at 4 ms, −40 dB) to 191.2 dB (at 16 ms, −58 dB). The means featured a trend: The deeper the echo attenuation, the higher the mean emitted pulse level (Fig. 6). As Fig. 6 shows, the plot substantially deviated from the straight line; however, the limited number of experimental points did not allow consideration of this deviation as either systematic non-linearity or as random scatter. As a first approximation, we assessed this trend by linear regression. Being expressed as dependence on the echo attenuation, the trend and its standard error were −0.38 ± 0.17 dB/dB (r^2=0.71). Being expressed as dependence of the echo delay, the same trend was 3.46 ± 1.57 dB per delay doubling.

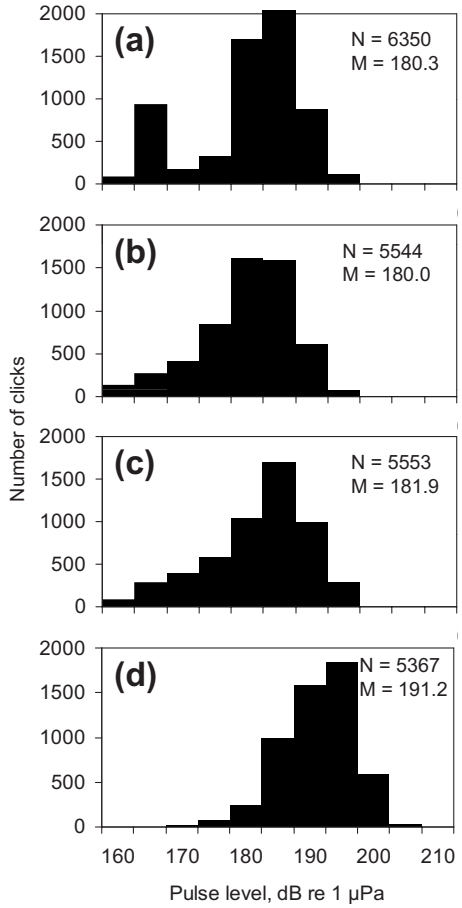

FIG. 5. Distributions of emitted pulse levels for four used combinations of echo attenuation and delay: (a) 2 ms, −31 dB; (b) 4 ms, −40 dB; (c) 8 ms, −49 dB; and (d) 16 ms, −58 dB. *N*—number of collected clicks and *M*—mean of the distribution.

Because of methodological restrictions (see Sec. II), it was important to find out how large the level difference was between successive sonar clicks. In order to do that, the level difference between each click and the next click was calculated. The result of the statistical analysis of 5274 click pairs from 300 randomly chosen click trains was conducted and is presented in Fig. 7. In some number of cases, the difference reached from −20 dB (a successive click was lower than the preceding one) to +20 dB (a successive click was higher than the preceding one). However, these sorts of cases were

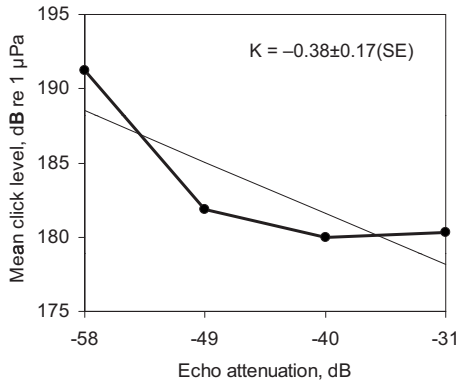

FIG. 6. Mean click level dependence on echo attenuation. Bold line—experimental data, thin straight line—regression, and *K*—regression slope.

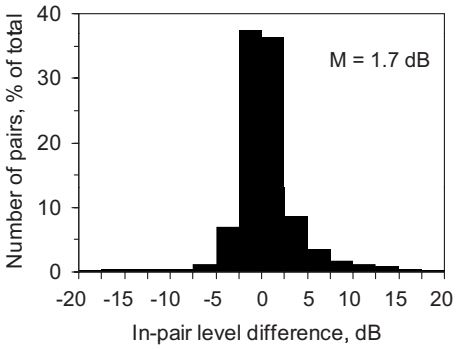

FIG. 7. Distribution of level difference between successive pulses. *M*—mean.

very rare. For the majority of the click pairs (73.8%), the difference between clicks was within a limit of ±2.5 dB, and for 89.3% the difference was within a limit of ±5 dB. This result shows that during each click train, the levels of clicks varied mostly in a gradual manner, with minor level differences between successive clicks.

C. AEP waveforms and magnitudes

All the obtained averaged AEP waveforms are presented in Fig. 8 at the four used combinations of echo parameters: (a) 2 ms delay and −31 dB attenuation, (b) 4 ms delay and −40 dB attenuation, (c) 8 ms delay and −49 dB attenuation, and (d) 16 ms delay and −58 dB attenuation. At each of the panels, AEP waveforms are presented at different levels of the emitted clicks, as obtained by sorting by click levels to 5-dB bins: from 170 ± 2.5 to 195 ± 2.5 dB re 1 μPa. Note that not all of the levels are presented in each panel. This is because not all bins contained enough original records (the number of available original records in each bin was equal to the number of collected clicks of corresponding level, see Fig. 5). If the bin contained less than 250 original records, the average record was omitted as not providing sufficient noise reduction.

All of the records presented here contained two characteristic AEP waveforms. The first one occupied a time window approximately lasting from the second to the fifth millisecond at the highest click level and shifting to the third to the sixth millisecond at the lowest click level, equally in all the records. This was interpreted as the response to the self-heard emitted biosonar pulse and further it is referred to as the emission-related response. The second waveform occupied a time window delayed relative to the first one by 2 ms (a) to 16 ms (d), according to the used echo delay. This was interpreted as the response to the echo and it is referred to as the echo-related response (Supin *et al.*, 2003).

D. AEP amplitude dependence on emitted click level and echo parameters

Peak-to-peak amplitudes of all emission-related and echo-related AEPs were measured. In doing this, we took into consideration that in spite of the large number of original records collected (in some bins, more than 1500, see Fig. 5), all the averaged records were substantially contaminated by background noise. The computation of rms values of presumably response-free pre- and post-response fragments of the records resulted in values of around 60–80 nV. Therefore, to specify the response amplitudes, a correction was made by subtracting the background noise power from the response power (see Sec. II). The peak-to-peak span was measured within 3-ms long windows; these windows are shown in Fig. 8. Note that the window offset increased with decreasing the click level with a rate of 0.15 ms per each 5-dB step (0.03 ms/dB). This was done because of an increase in AEP latency with decreasing stimulus level.

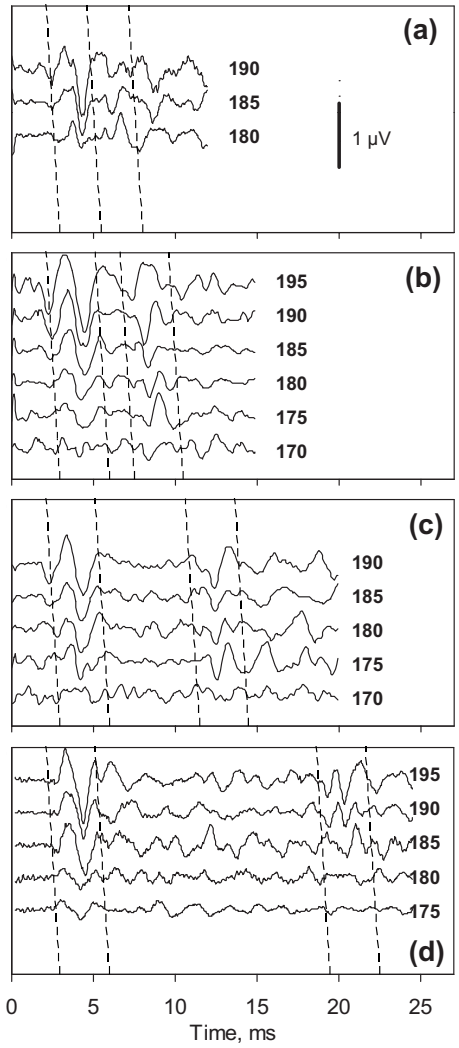

FIG. 8. Averaged AEP waveforms at four used combinations of echo attenuation and delay: (a) 2 ms, −31 dB; (b) 4 ms, −40 dB; (c) 8 ms, −49 dB; and (d) 16 ms, −58 dB. Emitted click levels for each of the records are indicated on the right (sorted in 5-dB steps with ±2.5 dB tolerance). Dashed straight lines delimit temporal windows where peak-to-peak span was assessed as an AEP amplitude. AEP amplitude calibration bar in (a) is common for all the records.

The results of measurements made in this way are presented in Figs. 9 and 10. The results revealed a substantial difference between the emission-related and echo-related responses.

For the emission-related AEPs, the only measurable variable influencing their amplitude was the level of the emitted click, so in Fig. 9 AEP amplitude is presented as a function of click level. The function demonstrated an obvious amplitude dependence on click level. This dependence

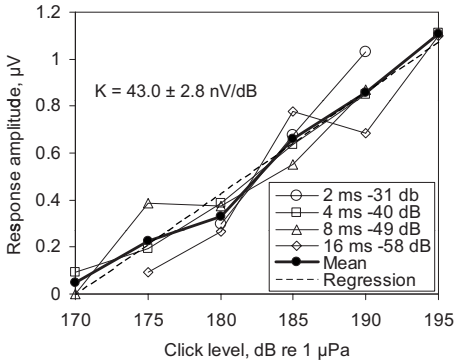

FIG. 9. Emission-related AEP amplitude dependence on emitted click level. Thin lines—plots for different combinations of echo attenuation and delay: (2 ms, −31 dB), (4 ms, −40 dB), (8 ms, −49 dB), and (16 ms, −58 dB), as specified in the legend; bold line—mean of the four plots, dashed straight line—regression, and *K*—regression slope.

was not much different between all four tested combinations of echo parameters; therefore it seemed reasonable to average these four plots. The averaged dependence could be successfully (r^2=0.98) approximated by a regression straight line with a slope of 43.0 ± 2.8 (SE) nV/dB.

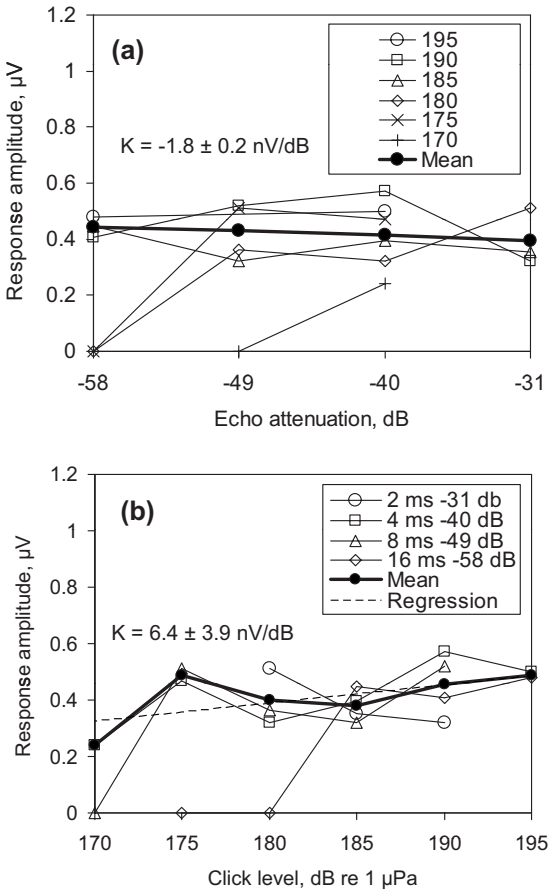

FIG. 10. Echo-related AEP amplitude dependence on echo attenuation and emitted click level. (a) Dependence on echo attenuation keeping click level as a parameter and (b) dependence on click level keeping echo attenuation as a parameter. Thin lines—plots for corresponding parameter values, as specified in the legends; bold line—mean of all the plots, excluding the points of AEP amplitudes below 0.2 μV; dashed straight line—regression; and *K*—regression slope. In (a) the regression line is not distinguishable from the mean plot.

The echo-related AEPs displayed quite different features. Since echo-related AEP depends on two variables, the echo attenuation and emitted click level, the results are presented in two forms: amplitude as a function echo attenuation, keeping the emitted click level as a parameter [Fig. 10(a)], and vice versa [Fig. 10(b)].

Functions presented in Fig. 10(a) demonstrated an absence of systematic amplitude dependence on echo attenuation within a wide range of variation of both echo attenuation and emitted click level. Except for three zero-amplitude points presenting combinations of the lowest values of both variables (−49 dB attenuation at 170 dB click level and −58 dB attenuation at 175 and 180 dB click levels), all of the other amplitude values were within a range from 0.24 to 0.57 μV and demonstrated random scatter rather than a systematic trend. Being averaged across emitted click levels (excluding the three zero-amplitude points), the amplitude dependence on echo attenuation was almost flat. It could be approximated by a regression straight line (in Fig. 10(a), it is not distinguishable from the mean plot) with a negligible slope of −1.8 ± 0.2 (SE) nV/dB.

Functions presented in Fig. 10(b) demonstrated almost no dependence of the echo-related AEP amplitude on the emitted click level within wide ranges of click levels and echo attenuations. Except for the three points mentioned above as combinations of the lowest values of the variables, AEP amplitude demonstrated more random variation rather than trend. Being averaged across different echo attenuations (again, excluding the three zero-amplitude points), the dependence on click level could be approximated by a straight regression line with a small slope of 6.4 ± 3.9 (SE) nV/dB.

IV. DISCUSSION

A. Validity of the echo attenuation control

As described in Sec. II, technical limitations did not allow us to compute and adjust attenuations of shortly delayed echoes based on the amplitude of the triggering emitted biosonar click. Instead, we controlled the echo attenuation based on the level of the click preceding the triggering one. We adopted this technique assuming that the click generating apparatus did not likely change the level very much from click to click when the clicks follow rapidly one after another. The statistical analysis of click levels confirmed this assumption. For the overwhelming majority of the biosonar clicks, the level difference between successive clicks did not exceed ±2.5 dB, and only in a few cases did this difference exceed ±5 dB (see Fig. 7). This means that for the majority of clicks, the error resulting from the substitution of the current click level by the previous click level could not exceed one bin-width of sorting click levels (±2.5 dB), and only in rare cases could the error be as large as one bin (±5 dB). In general, the systematic error should be even less because both positive and negative differences between successive clicks might compensate one another. In comparison with the overall range of click level variation (30–40 dB, see Fig. 5), we adopted the possible error as negligible as a first approximation.

B. AEP record quality and data scatter

In spite of large numbers of original records averaged (in some cases, more than 1500, in one case, more than 2000, see click statistics in Fig. 5), all the obtained averaged waveforms were substantially contaminated by background electrical noise (see Fig. 8). The noise frequency band overlapped the AEP band; so it could not be filtered out by regular frequency filtering. Therefore, the AEP records were of not the best quality.

Searching for a possible cause of the noise, it might be noted that AEP records obtained in the same subject and in very similar recording conditions (underwater voluntary positioning of the free moving animal with suction-cup electrodes) but in conditions of external sound stimulation (Supin *et al.*, 2007) were of much lower background noise, whereas AEP records obtained in the same subject in conditions of natural echolocation of real targets (Supin *et al.*, 2003, 2004, 2005) were noise-contaminated at approximately the same degree as in the present study. There might be a few reasons for the difference in noise level between the external-stimulation and echolocation conditions. First of all, the increased noise level might be a result of increased muscle activity during echolocation. This increased muscle activity might either result from the process of sonar click generation, or appear because the animal did not relax well enough during a short time (2–3 s) between the movement into the hoop station and movement back of the hoop to respond and signal the echo presence, whereas in external-stimulation experiments the animal stayed quietly relaxed in the hoop station for around 1 min of continuous brain-potential recording. The contribution of AEPs to multiple intra-head or external sound reflections should also be taken into consideration; however, no correlation of the noise level with the emitted pulse level was observed.

During the present investigation, we did not manage to reduce the background electrical noise down to the level characteristic of external-stimulation experiments. However, even in the background of the noise characteristic of the present study, definite AEPs were detectable and measurable, although the precision of measurements appears to have been reduced.

C. Echo-related AEP constancy: Implication to AGC problem

A remarkable feature of the data presented above is the nearly constant amplitude of echo-related AEPs within a wide range of echo attenuations and emitted click levels when the attenuation varied in association with echo delay. At a majority of the combinations of echo parameters and emitted click levels, the amplitude of the echo-related AEPs displayed random variation within a range from 0.24 to 0.57 μV but no systematic variation. Note that the echo *level* within these ranges of parameters varied as widely as by 38 dB: from 126 dB (175 dB emitted click level, −49 dB echo attenuation) to 164 dB (195 dB click level, −31 dB echo attenuation). At the same time, emission-related AEPs demonstrated obvious regular amplitude dependence on the stimulus levels within a markedly narrower level range of 25 dB (from 170 to 195 dB source level). Thus, the slight dependence of the echo-related amplitude on signal level is not an intrinsic feature of AEP; this is a feature of echo-related AEP in the current experimental conditions.

This specific feature of the echo-related AEP well confirms the hypothesis described in the Introduction. According to this hypothesis, the partial forward masking of an echo by the preceding emitted pulse may result in the constancy (or near-constancy) of a neuronal response to the echo, thus providing a kind of AGC within the auditory system of the echolocating subject. Indeed, the echo delay and attenuation in our experiments varied in a way that echo delay doubling was associated with 9-dB echo attenuation decrease. This is the same rate that characterized prolongation of forward masking with decreasing the test-to-conditioning click ratio in passive listening double-click experiments (Supin *et al.*, 2007) and echo detection threshold dependence on delay (Supin *et al.*, 2008). Exactly as predicted, the decreased echo attenuation, and release from forward masking due to increased echo delay, almost completely compensated one another when measured in an actively echolocating whale.

It is noteworthy that amplitudes of echo-related AEPs displayed an absence of dependence not only on echo attenuation but also on emitted click level. This effect can also be explained by features of the forward masking. Indeed, it has been shown in double-click experiments that duration of the forward masking depends on the stimulus level even if the conditioning-to-test ratio is kept constant. A proportional increase in both the conditioning and the test stimuli may result in a prolongation of forward masking; therefore, in spite of increasing the test stimulus level, the AEP amplitude may remain almost constant within a certain range (Supin and Popov, 1995). As these data indicate, the same effect took place during active echolocation by the animal. Increasing the emitted biosonar-click level should have resulted in a proportional increase in the echo level; however, within the range of action of forward masking, the amplitude of echo-related AEP remained nearly constant.

Of course, this mechanism of gain control is only capable of functioning while the echo level remains well above the absolute threshold of echo detection or a threshold of masking by the background noise. When the echo level is below the absolute or pseudo-absolute (in background noise) threshold, forward masking by the emitted click becomes useless, and it cannot function when there is nothing to mask. This can explain why combinations of the lowest values of echo attenuation and emitted click level in this experiment produced very low-amplitude AEPs. These combinations simply fell out of the AGC range. This may be made much clearer by presenting the echo-related AEP amplitudes as functions of not *echo attenuation* (as in Fig. 10) but absolute *echo level* (SPL) calculated in a simple way as

$$E = L - k,$$

where E is the echo SPL (dB re 1 μPa), L is the emitted click source level (dB re 1 μPa at 1 m), and k is the used echo attenuation factor (dB). Being presented in this way, the echo dependence appears as shown in Fig. 11. When the echo level was equal or above 125 dB re 1 μPa, the AEP

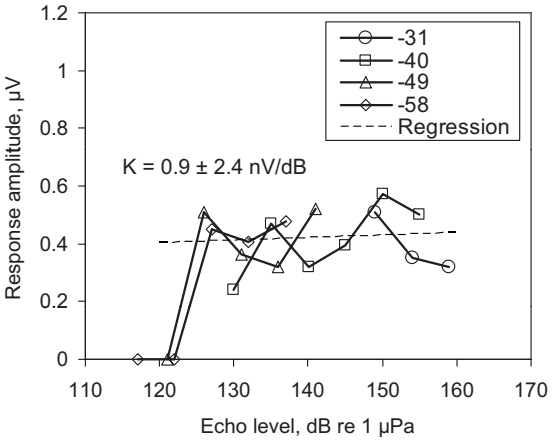

FIG. 11. Echo-related AEP amplitude dependence on echo SPL at four echo attenuation values, as specified in the legend. Dashed straight line—regression of all points except those below 0.2 μV, and *K*—regression slope.

amplitude fluctuated within a range 0.24–0.57 μV. The regression line drawn through these points had a negligible and statistically insignificant (less than the standard error) slope of 0.9 ± 2.4 (SE) nV/dB, i.e., it was almost flat. When the echo level approached a limit of 120 dB re 1 μPa, the AEP amplitude dropped down steeply. All of the three experimental points featuring zero AEP amplitude corresponded to the echo level nearly 120 dB re 1 μPa. This is the very same level that was determined as the AEP threshold for the subject whale during prior conditions of external stimulation (Supin *et al.*, 2007). So it is obvious that even a complete release from forward masking could not result in high AEP amplitude at echo levels so low. Thus, all the experimental data presented herein are in agreement with the hypothesis of the forward masking by emitted pulses as an AGC mechanism in the odontocete sonar.

It should be noted that in a study by Beedholm *et al.* (2006) AGC was not found in the auditory system of a harbor porpoise. However, AGC could not be observed with the experimental conditions that were used in that study. The echo-imitating signals were not proportional to the emitted biosonar signals but instead were kept at a relatively high level of 128 dB re 1 μPa and were triggered by biosonar pulses at a trigger threshold of 132 dB. This sort of relationship between the animal's emitted signal and the echo is not typical for the biosonar of odontocetes, which operates with echoes that are usually tens of decibels lower than the emitted biosonar signal. It has been shown (Supin *et al.*, 2006) that emitted biosonar pulses are heard by a whale at a sensation level down to −45 dB below the source level. Supposing, as a first approximation, that in the harbor porpoise the ratio is roughly the same, the emitted biosonar signals at the trigger level are perceived at the same sensation level as external signals at the level of 87 dB re 1 μPa. Even if the emitted pulses exceed the trigger level up to 40 dB, they still remain at a *lower* sensation level than the 128-dB electronic echo. In these sorts of conditions (where the conditioning signal is lower than the test signal), the forward masking would be negligible or absent. Since no forward masking would occur, no AGC would be expected. Thus, the results of Beedholm *et al.* (2006) do not contradict the hypothesis of forward-masking AGC but, to the contrary, actually confirm them. When the forward-masking mechanism was eliminated by an inadequate emission-to-echo ratio, AGC was, in fact, absent.

Therefore, we conclude that the forward masking of the echo by the preceding emitted pulse may well serve as an AGC mechanism for odontocete sonar.

This article presents a method for reducing the computation time required for estimating cumulative sound exposure levels. Sound propagation has to be computed from every source position to every desired receiver location; so if there are many source positions, then the problem can quickly become computationally expensive. The authors' solution to this problem is to extract all possible source-receiver pathways and to cluster these with a self-organizing neural net. Sound propagation is modeled only for the cluster centroids and extrapolated for the entire geographic region. The tool is illustrated for the example of a marine seismic survey over a tropical coral reef. Resident fish species were expected not to flee the reef, but to stay among the corals for the entire duration of the survey. In such cases, the modeling of cumulative sound exposure levels is sometimes requested as part of environmental impact assessments. The tool developed combines a seismic source model, a near-field sound propagation model, and a far-field sound propagation model. The neural network reduces the computation time by a factor of 55. The cost is an error in modeled received levels of less than -1 ± 3 dB re 1 μPa^2 s.

I. INTRODUCTION

To assess the likelihood of impact on marine mammals around seismic surveys, regulatory bodies generally require the modeling of sound exposure levels (SELs) around single shots.[1–3] From pre-defined exposure thresholds, maximum ranges are determined, over which visual observation and a number of mitigation methods are suggested. With common techniques such as ramping-up and shutting-down if marine mammals are detected within a proximal zone, it is hoped that marine mammals will not be exposed to harmful sound levels. One underlying assumption is that marine mammals will try to avoid zones of potentially harmful levels, if possible. If the area is determined to constitute critical habitat though, animals might not flee and a desertion of habitat might not be "desired," therefore regulations differ.[1]

In the case of fish, some studies have reported a desertion of the area ensonified by seismic sounds,[4–6] measured as a decline in catch rate; occasionally the abundance of fish increased tens of kilometers away from the source. Slotte *et al.*[7] showed that fish descended to deeper water when airguns operated above. Some fish species are "attached" to a particular habitat and do not suddenly flee tens of kilometers in the horizontal to escape sound exposure. This can be the case in river deltas[8] or coral reef environments.[9] Both environments have shallow water. In the case of tropical coral reefs, the water depth is usually less than 25 m.[10,11] Reef fish that simply hide among coral when "danger" is perceived from above will not be able to escape sound exposure from a seismic survey. For this reason, environmental impact assessments in such areas are beginning to look at cumulative effects from multiple exposures.

Within the bioacoustic research community, cumulative effects are still poorly understood.[12] Hastings and Popper[13] summarized the published effects on fish (behavioral responses, physiological responses, hearing loss, and tissue damage) until 2005. Yelverton *et al.*[14] exposed fish to blasts, identifying a relationship between the total energy in the blast and mortality due to organ damage. Stuhmiller *et al.*[15] summarized data on blast injury to the lung in terrestrial animals of different sizes and found that the incidence of injury and lethality correlated with total energy. McCauley *et al.*[16] looked at effects from one seismic airgun towed toward and away from caged fish. Fish ears experienced substantial damage after cumulative exposure. Govoni *et al.*[17] concluded that acoustic trauma in fish was proportional to total energy in acoustic impulses. Popper *et al.*[8] exposed fish to 5 airgun shots and 20 shots, showing a higher temporary threshold shift after 20 shots, hinting at a cumulative effect.

Estimating sound exposure requires the modeling of sound propagation through the marine environment. Etter[18] tabulated a range of sound propagation models as they existed in 2003. Sound propagation models require certain environmental input parameters such as sound speed profiles for the water column, sound speed and attenuation data for the seafloor, and bottom topography measurements. Data on seafloor geoacoustics are sometimes hard to come by, but in many environments, the geology does not vary drastically over the required modeling ranges and one profile (e.g., obtained from bore hole measurements prior to full-scale seis-

mic surveys) suffices. Sound speed profiles for the water column are usually easier to obtain; they vary with time of day and season and should be matched to the planned operation. Many sound propagation models are range-dependent and able to model changing acoustic parameters with range. Bathymetry is often known in quite some detail and can vary significantly in all directions throughout an operational area. Particularly in downward refracting (summer) water, bathymetry can play a major role in sound propagation. Modeling sound propagation from all shots in a survey to all possible receiver locations is computationally very demanding. Sound propagation has previously been modeled for a small number of "representative" pathways (bathymetries) and has been applied to the entire survey.[19–21]

This article presents a method of finding an optimum set of representative bathymetries. The method can be used for cumulative sound exposure modeling in environments that are homogeneous with regard to sound speed profile and seafloor geology. The algorithm to estimate cumulative SELs from an entire seismic survey is detailed. This article does not attempt to assess biological impact on marine fauna from cumulative exposure.

II. THE STUDY SITE

The study site was an island reef system (Fig. 1). The mainland lay to the south-west. The continental shelf dropped rapidly toward the north-east. In the center of the study site lay a coral reef that was about 5 m below the water surface at high tide when the survey was planned. Coral was growing on limestone bedrock. The proposed marine seismic survey encompassed six transects. The combined transect length was 121 km. The shot spacing was 25 m, yielding a total number of 4855 shots. The intended shot timing was about 10 s (speed of the towing vessel: 5 kn).

III. MODELING THE SOURCE

The seismic array consisted of ten identical generator-injector (GI) guns arranged in two lines. Each line had five guns separated by 3 m. The spacing between the lines was 5 m. A sketch of the array is shown in Fig. 8, Sec. VI. The tow depth was 2 m. To model the acoustic pressure, we used a full-waveform airgun array source signature model,[22] which was based on the physics of the oscillation and radiation of airgun bubbles.[23] The model solved a set of parallel differential equations, accounting for non-linear pressure interactions between airguns, port throttling, bubble damping, and GI-gun behavior.[24–26] GI guns have two chambers, a generator chamber, which is fired first, and an injector chamber, which is fired at half the generator bubble period (42 ms), in order to reduce the unwanted bubble pulse (Fig. 2). The frequency spectrum of a GI gun is smoothed.

All ten airguns were modeled simultaneously, while accounting for pressure interactions between neighboring guns. The resulting radiation directivity pattern of the array is shown for the horizontal plane in Fig. 3. The source level of the array is a function of azimuth, elevation, and frequency. We computed levels for 24 adjacent 1/3 octave bands between 10 Hz and 2 kHz. The outer thick black line corresponds to the broadband directivity pattern. Integrated over all frequencies, the array resembled a point source (monopole) in the horizontal plane with a source level of 217 dB re 1 μPa. Moving further toward the inside of the polar plot in Fig. 3, the radiation pattern is shown for selected 1/3 octave band center frequencies. At low frequencies, the array behaved like an acoustic monopole source. At about 80 Hz, the radiation pattern became dipolar, at 120 Hz quadrupolar, and for higher frequencies multipolar.

IV. MODELING SOUND PROPAGATION

The geoacoustic properties of the seafloor were taken from standard reference works and research articles[27–32] as

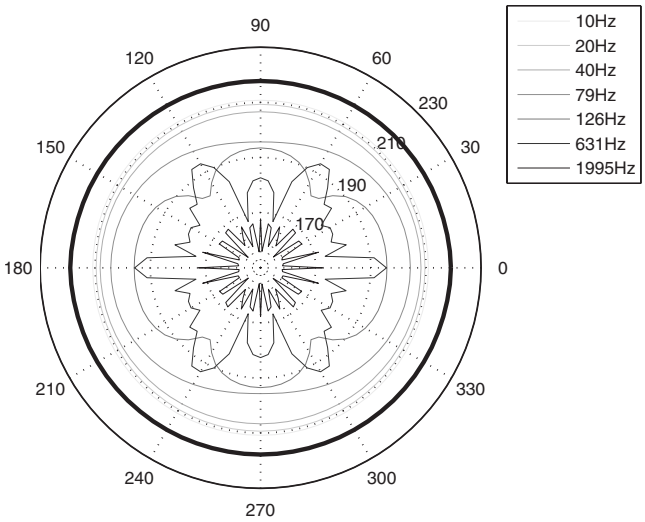

FIG. 3. Directivity pattern of the seismic array in the horizontal plane. Plotted are source levels (decibels re 1 μPa) for seven selected $\frac{1}{3}$-octave bands as a function of azimuth. The tow-direction is along the positive x-axis (0 deg). The outermost thick black line with a radius of 217 dB represents the broadband source level.

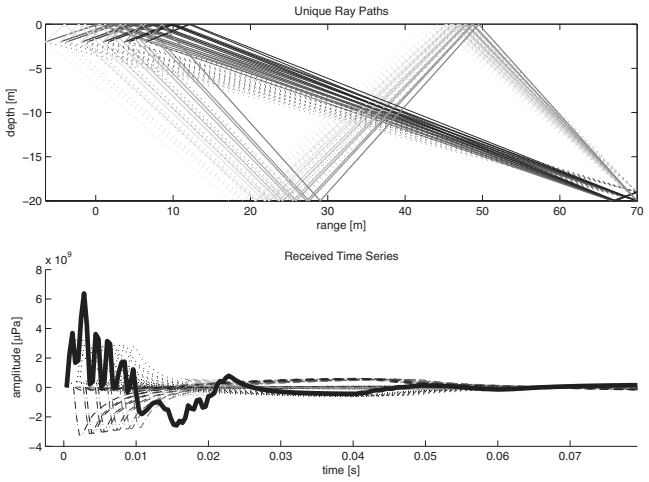

FIG. 4. Eigenray paths from the ten airguns at 2 m depth to a receiver at 19–20 m depth and 70 m range. There are 80 rays, 8 per airgun: (1) downward-direct, (2) downward—1 bottom reflection, (3) dwd.—1 bot. refl.—1 surface refl., (4) dwd—1 bot. refl.—1 sfc. refl.–1 bot. refl., (5) upward—1 sfc. refl., (6) upwd.—1 sfc. refl.—1 bot. refl., (7) upwd.—1 sfc. refl.—1 bot. refl.—1 sfc. refl., and (8) upwd.—1 sfc. refl.—1 bot. refl.—1 sfc. refl.—1 bot. refl. The black line in the bottom picture shows the total received pulse as a sum over all 80 eigenray pulses.

well as bore hole measurements in similar environments. For the example in this article, an averaged and simplified bottom was modeled with constant S and P wave attenuations of 0.3 and 0.2 dB/λ, respectively. Shear speed was modeled as 500 m/s at the seafloor; compressional wave speed increased from 2000 m/s at the seafloor surface to 4000 m/s at 2000 m below the seafloor surface. Density increased linearly from 2.0 to 2.6 g/cm^3 over the first 2000 m of seafloor. Sound speed profiles of the water column were obtained from a local database.

A. In the near-field

Over the first 100 m around the airgun array, we used the ray tracing model RAY (Ref. 33) with added functionality for bottom and surface reflection and scattering losses, and absorption (molecular relaxation).[34] RAY shoots a fan of rays from the source and propagates all rays out to a desired range and depth by repeatedly applying Snell's law. RAY was run from each airgun in the array to a receiver grid in space. Eigenrays were searched for; they have a unique path characterized by the source-departure-angle (up or down) and the number of top and bottom turns and reflections. Turns are due to refraction in a sound velocity gradient. Received sound levels (or transmission losses) were computed as the sum over all eigenrays for all gun-receiver pairs.

RAY treated the seafloor as an infinite layer, at the boundary of which acoustic energy was lost. In many marine environments, the upper seafloor consists of unconsolidated, water-saturated sediment. Loss is calculated as a two-fluid-layer model.[34] At the coral reef, however, the seafloor showed limestone bedrock. The bottom boundary was therefore modeled as a fluid-to-solid boundary, using Eq. (4.25) in Ref. 35 for the reflection coefficient.

For sound sources near the water surface (such as an airgun array towed at a few meters depth), a phenomenon called the surface ghost is important. Sound emitted upward reflects on the water-air interface and overlaps with sound emitted downward. Depending on departure angles, the signals cancel out at certain depth-range combinations in the near-field, and they interfere constructively at others. We accounted for a π phase shift with each surface reflection.

The code took the pressure waveform of each airgun (Fig. 2) and computed the Fourier transform. From this, the transmission loss (TL) was subtracted in the frequency domain at each receiver grid point for each airgun source and for each eigenray. The inverse Fourier transforms were computed, and all eigenray pulses were superposed in the time domain, after applying a time shift depending on the ray travel time (Fig. 4). This yielded the overall received pulse as a function of time at each receiver grid point. The SEL corresponds to the total energy of a signal. It was computed from the pressure pulse time series and measured in decibels re 1 μPa^2 s:

$$\mathrm{SEL} = 10\log_{10}\left(\int_T p(t)^2 dt/p_{\mathrm{ref}}^2\right).$$

B. In the far-field

To model sound exposure at long ranges, we used the Range-dependent Acoustic Model (RAM) (Ref. 36) for the current example. The code solved the parabolic equation using a split-step Padé algorithm[37] and Collins' parabolic equation (PE) self-starter.[38] Energy loss into shear wave propagation was accounted for by applying a complex density approach.[39] The horizontal radiation pattern (Fig. 3) was used for the frequency- and azimuth-dependent source levels in long-range propagation. Figure 5 shows an example of a RAM output: received levels as a function of range and depth. The left graph shows the sound speed profile for the water, which was used for the entire reef. Where the seafloor

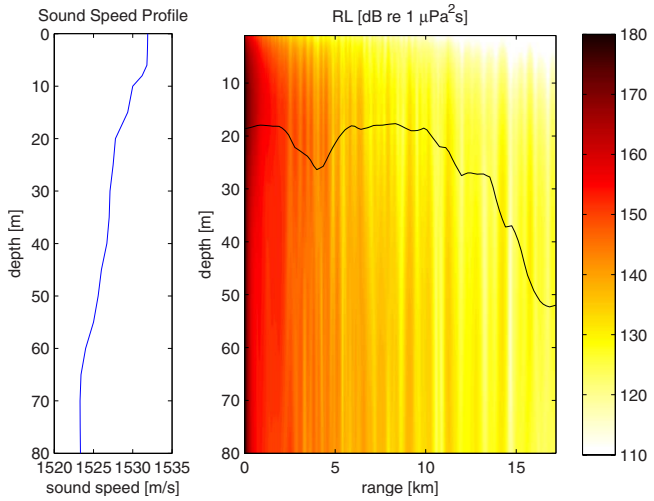

FIG. 5. (Color online) TL as a function of range and depth from one shot of the array. The left graph gives the sound speed profile in the water down to the maximum depth of 80 m in this reef environment.

was shallower than 80 m, the water profile was truncated and replaced with the *P*-velocity profile. The black line in the right plot shows the bathymetry for the example run.

V. MODELING CUMULATIVE SEL: FAR-FIELD

A. Computing a library of bathymetries

1. Generating a subset of shot-receiver pairs

A subset of shot-receiver pairs was generated by sampling shots at 800 m intervals (every 32nd shot), resulting in 154 sampled shot points. A coarse receiver grid was generated, covering the area, with a spacing of 1600 m in both directions, easting and northing. This resulted in 166 receiver grid points.

All receiver points were matched with all shot points, yielding 25 564 shot-receiver-pairs. The distances between all shots and all receivers were computed. All shot-receiver-pairs, which were more than 15 km apart, were discarded under the assumption that shots that far away would not contribute significantly to the cumulative SEL at the particular receiver location. Furthermore, all pairs with distances shorter than 1 km were discarded as these were too short to be useful in a "library" of representative shot-receiver propagation paths. It is reasonable to assume that the bathymetries associated with shot-receiver distances of less than 1 km are automatically included in the longer shot-receiver distances.

At this stage, the number of shot-receiver-pairs was 22 084. For each of these pairs, a bathymetry profile was generated from Fig. 1, by spline-interpolation, to an along-profile sampling distance of 250 m. All profiles were smoothed by applying a convolutional filter with a rectangular window. The spatial window was shorter at the beginning and end of each profile, in order to hold the depths of the start- and end-points fixed. Otherwise, effective zero-padding would bring the end-points closer to the surface than they are in reality.

These bathymetry profiles were considered a representative base of all shot-receiver profiles in the survey, from which an optimized library could be computed.

2. Cluster-analysis of bathymetries

A self-organizing map (SOM),[40,41] also called an unsupervised Kohonen neural network, was used to cluster the 22 084 bathymetry profiles into similar groups. The SOM consisted of 30×30, i.e., 900 neurons, arranged in a hexagonal topology with toroidal shape (wrapped top-to-bottom and side-to-side). After training, each neuron or cell in the SOM "contained" a cluster of similarly-shaped bathymetries, represented by a median or central profile.

To further reduce the number of representative profiles, we utilized *K*-means clustering.[42] It is a fast method of assigning vectors to cluster centers (called centroids) by comparing Euclidean distances. The 900 central SOM profiles were thus clustered into 64 clusters. The centroids were computed as the arithmetic mean of each cluster. Figure 6 shows all 900 SOM profiles (gray) grouped into 64 clusters, and the centroid bathymetries (black) for each cluster. These centroids made up the final library of bathymetries for which sound propagation was modeled.

B. Modeling TL along the library bathymetries

The far-field sound propagation model was run for each of the 64 centroid bathymetries. This yielded 64 matrices of TL as a function of range and depth for each of the 24 frequencies modeled.

C. Assigning library TL matrices to all shot-receiver-pairs

For the computation of the library bathymetries, a shot sampling of 800 m (every 32nd shot) and a receiver grid of 1600 m resolution in both directions (easting and northing) had been used. For the actual computation of cumulative sound exposure, a shot sampling of 400 m (every 16th shot) and a receiver grid spacing of 250 m were used. All shots were matched with all receivers and bathymetry profiles extracted from Fig. 1. Each extracted bathymetry was passed through the Kohonen classifier and *K*-means algorithm to assign the best bathymetry centroid for which TL had been computed.

D. Integrating over all shots

Knowing the array heading at each shot, the source level of the array in the direction of the current shot-receiver-pair was taken from the directivity patterns (Fig. 3) for each of the 24 frequencies modeled. The TL for each frequency was subtracted (in logarithmic terms, i.e., divided in linear terms) along the shot-receiver path. Energy was integrated over all frequencies to yield a broadband SEL at all depths at the current receiver range. This was done for all shot-receiver-pairs.

Finally, at the receiver grid, energy was integrated over all modeled shots. Only every 16th shot had been modeled. Accounting for the missed shots corresponded to four doublings in energy, or an addition of 12 dB to the computed SEL. The resulting sound exposure is illustrated in Fig. 7. The levels were plotted near the seafloor (motivated by the assumption that fish would hide among the coral). Horizontal

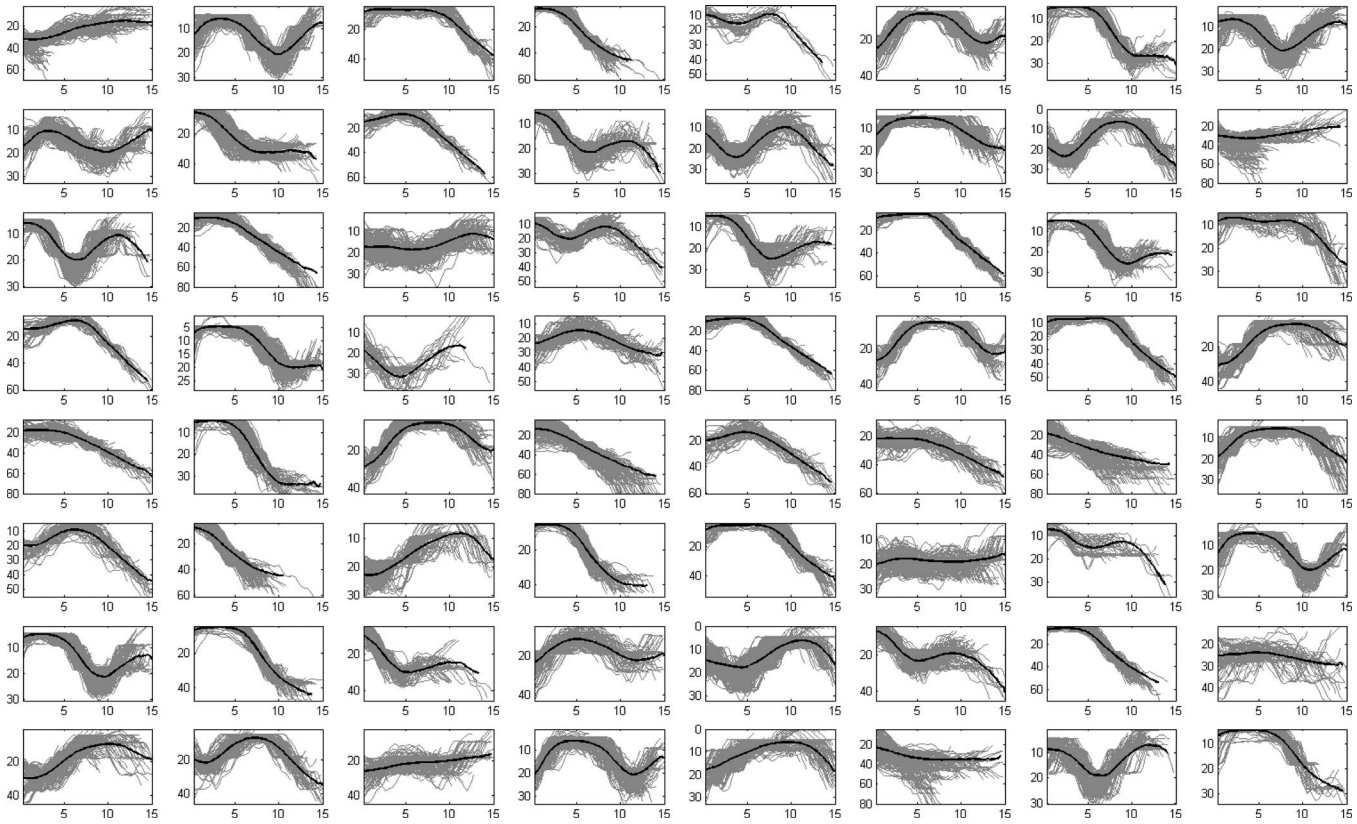

FIG. 6. 64 clusters of bathymetries showing the centroid profile in black and the 900 SOM profiles in gray. *Y*-axes: depth (in meters); *x*-axes: range (in kilometers).

sound propagation in shallow water is very poor. Therefore, SELs drop fast in shallow water. SELs were low over the reef in the center of the figure and toward the islands in the north-west and south-east.

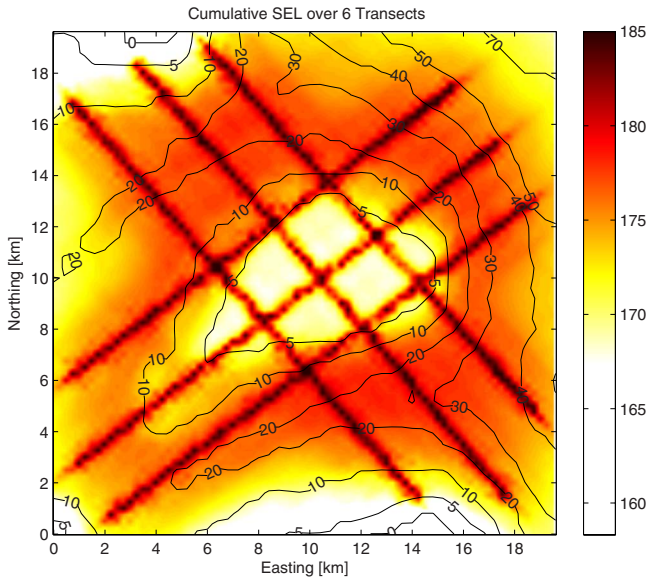

FIG. 7. (Color online) Cumulative SEL (decibels re 1 μPa^2 s) from the entire survey plotted at the seafloor. Given that the far-field propagation model was used, levels directly underneath the transect lines should be considered inaccurate; the reader should instead refer to the near-field results in Fig. 8.

VI. MODELING CUMULATIVE SEL: NEAR-FIELD

A. Near-field to far-field transition

The far-field model calculated TL from an equivalent point-source to receiver locations at various distances, depths, and bearings. However, a seismic array consists of many sources and so the point-source assumption is not valid in the near-field. The maximum extent of the near-field of an array can be estimated by the expression[43]

$$R_{\mathrm{nf}} < \frac{L^2}{4\lambda},$$

where λ is the acoustic wavelength and L is the longest dimension of the array. Along the diagonal of the modeled array, $L \approx 13$ m, and so the maximum near-field range is 28 m at 1 kHz (R_{nf} is less for lower frequencies).

B. Acoustic imprint of the array on the seafloor

RAY was run with a flat seafloor at a series of depths. The source depth (airgun array location) was 2 m below the water surface. Results are shown for four depths in Fig. 8. Plotted were SELs from one shot in the center of the picture as received at the seafloor. The ten airguns in the array were indicated as circles. Contours were drawn at SELs of 180, 185, 190, 195, and 200 dB re 1 μPa^2 s, if these levels were reached.

At seafloor depths of 5 and 10 m, SELs were in excess of 200 dB re 1 μPa^2 s underneath the array. At 20 m depth,

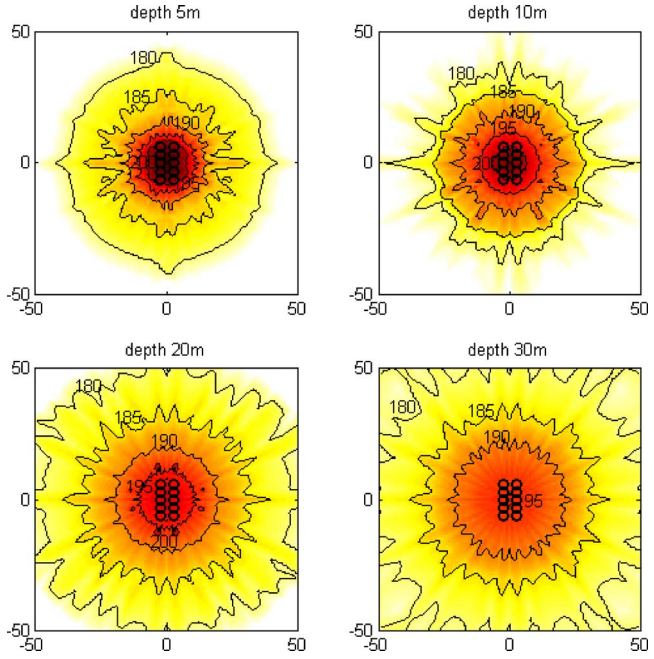

FIG. 8. (Color online) Acoustic imprint of the array at the seafloor. The tow-direction would be straight up, due north in this figure. The ten airguns of the array are shown as circles in the center. Received SELs at the seafloor are plotted for four different seafloor depths. Contours are drawn at 180, 185, 190, 195, and 200 dB re 1 μPa^2 s. *X*- and *y*-axes in meters.

200 dB re 1 μPa^2 s was only reached at four points slightly ahead and behind the array; the tow-direction was upward, or due north. At 30 m depth, levels were below 200 dB; 195 dB re 1 μPa^2 s was reached in a small region directly underneath the center of the array. High SEL disappeared as the seafloor got deeper. In these tropical waters, the sound speed profile was downward refracting. As a result, the decrease in SEL with range was faster over shallow depths. Therefore, the 180 dB contour was closer to the source at 5 m depth than at 30 m depth.

C. Integrating over one transect

Figure 9 shows SEL in shallow water integrated over short pieces of seismic transect. Levels were plotted at the seafloor, which ranged in depth from 5 to 30 m. At 5 and 10 m depths, levels were in excess of 200 dB re 1 μPa^2 s only directly underneath the array. The 195 dB contours (and lower) of two separate shots joined to form bands running parallel to the transect line. At 20 m depth, 200 dB was reached only at two small areas in between two subsequent shots. At 30 m depth, levels were less than 200 dB.

VII. ENSONIFIED AREAS

The model can be used to estimate how much of a reef (what percentage of area) receives certain SELs. One way of doing this is to augment the far-field SEL data with the near-field SEL data and to replot Fig. 7 at a finer resolution. The resulting map can then be overlaid with Geographic Information System (GIS) based habitat maps to estimate ensonified areas. Most of the time, the concern is about high SELs, which are only reached close to the source. Only the near-field results (Fig. 9) are relevant then for the computation of

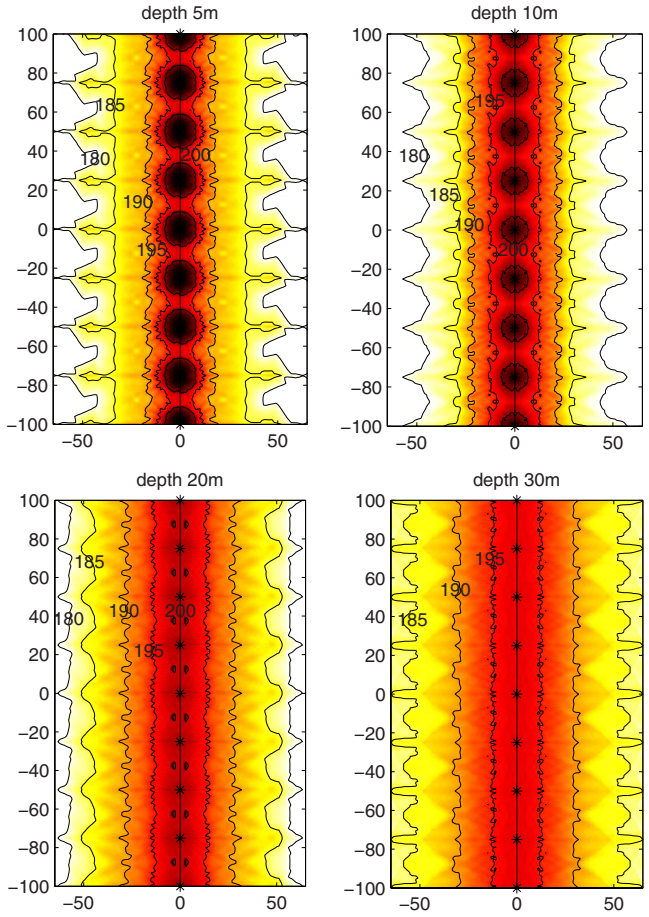

FIG. 9. (Color online) Cumulative SEL underneath short pieces of seismic transect over different seafloor depths. Contours are plotted for 180, 185, 190, 195, and 200 dB SELs, where these levels were reached. Each picture contains nine shots (*) along one transect. *X*- and *y*-axes in meters.

ensonified areas. The model computed the mean area per shot from Fig. 9 for any SEL threshold. In Table I, the areas per shot that received SEL in excess of 190, 195, and 200 dB re 1 μPa^2 s are listed for six different seafloor depths. As the seafloor got deeper, high SEL contours disappeared. Due to the downward refracting acoustic environment, the area of the 195 dB contour increased before it decreased to disappear. The same behavior would be found for the 190 dB contour if the survey was carried out over deeper seafloor depths.

Multiplying the area per shot by the number of shots occurring over different seafloor depths yielded the total ensonified area for each of the three SEL thresholds. Defining the boundary of the reef as the outermost 50 m depth isopleth, the total reef area in Fig. 1 was 376 km^2. The areas within each SEL contour are summarized in Table II.

VIII. COMPUTATIONAL COSTS AND BENEFITS

The cumulative SEL model was programed in MATLAB (The MathWorks Inc.) on a dual core, 2.5 GHz, laptop with 4 Gbyte RAM, running Windows Vista (Microsoft Corp.). It took 31 h from the extraction of shot-receiver-pairs, via the neural net clustering and propagation modeling, to the computation of Fig. 7. By comparison, using the far-field model to compute SEL over the entire reef from only one shot took

TABLE I. Cumulative SEL over different seafloor depths.

Seafloor depth (m)	Area per shot within 190 dB contour (m^2)	Area per shot within 195 dB contour (m^2)	Area per shot within 200 dB contour (m^2)
5	823	460	223
10	1100	568	136
20	1390	674	12
30	1518	571	0
40	1713	425	0
50	1760	0	0

21 min. Modeling all 4855 shots would take 1700 h =71 days. The neural-network-based algorithm is thus a factor of $1700/31 \approx 55$ faster. The increase in speed comes at a cost in accuracy.

In order to assess the accuracy of the SOM-based model, both RAM and the SOM-based algorithm were run for a single shot indicated by an asterisk in Fig. 10. The resulting SELs of the SOM were subtracted from those of RAM. For most receivers, the difference was less than 1 dB re 1 μPa^2 s. The SOM performed well if the bathymetry did not change rapidly; deviations were largest on the slopes of the reef.

IX. DISCUSSION

This article presented a technique to map cumulative sound exposure over a large geographic area from a full marine seismic survey. Modeling each shot of a survey individually is computationally very demanding. Instead, a method was presented to subsample all shot-receiver-pairs and to compute an optimal library of representative shot-receiver paths. This was done by grouping all shot-receiver paths with a SOM (Kohonen neural network) and subsequent *K*-means clustering. Widely-used sound propagation models were used to compute sound propagation along the cluster centroids: ray tracing in the near-field and a parabolic equation model in the far-field. Propagation results for the centroids were then matched with all shot-receiver-pairs, and energy was integrated over all shots on a grid of receiver locations spanning the geographic area. Mapping cumulative SEL with the neural-net-based algorithm reduced the computation time significantly. This came at a cost of error in SEL of <1 dB re 1 μPa^2 s, on average, with a standard deviation of <3 dB. The algorithm worked well in areas where the bathymetry did not change rapidly.

In a previous study of ours, cumulative SEL was modeled for a seismic survey over a coral atoll, which was flat and shallow on the inside, but had steep slopes on the outside. The SOM did not manage to cluster all of the bathymetries satisfactorily at once. Two separate SOMs were used, one for flat and shallow bathymetries, the other for steep and deep bathymetries, significantly improving the classification. More than one SOM will also need to be run if the area is not homogeneous with regard to water sound speed and geoacoustics. If the sound speed profile or the geology varies significantly over the survey area, the geographic region will need to be split into a set of homogeneous environmental provinces, and a SOM will need to be run for each province.

If sound speed profiles in the bottom or water are not known or are known to vary significantly, it is good practice to run the model with the extremes of the profiles to compute upper and lower bounds of expected sound exposure.

The focus of this study was to develop an efficient method to compute cumulative SEL over large areas and not to show absolute levels from some survey over some reef. The examples presented were run with an averaged and sim-

TABLE II. Ensonified reef areas.

Category	Area receiving this level (km^2)	% of total reef area
SEL$>$190 dB re 1 μPa^2 s	5.80	1.54
SEL$>$195 dB re 1 μPa^2 s	2.72	0.72
SEL$>$200 dB re 1 μPa^2 s	0.48	0.13

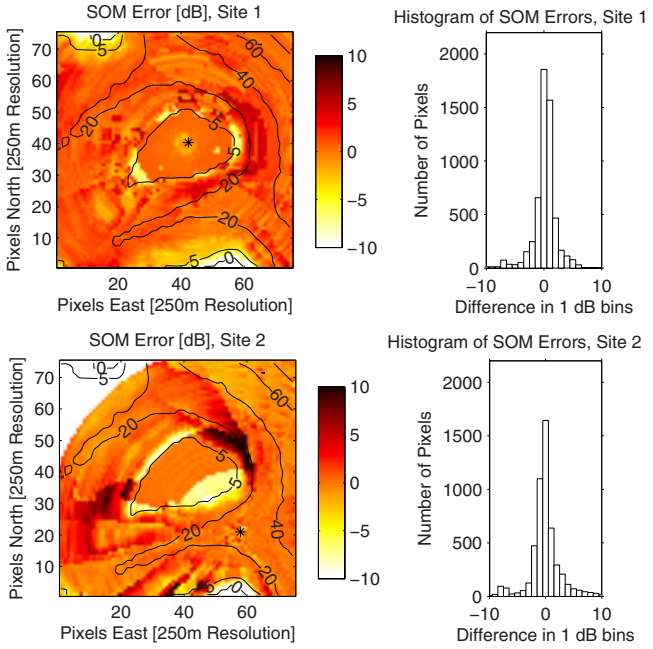

FIG. 10. (Color online) Error analysis of the neural-net-based algorithm. Shown is the difference in modeled SEL between a three dimensional run of RAM and the SOM. Results are shown for two sites; the asterisk indicates the source location. From the histogram, the difference was -0.5 ± 2.0 dB re 1 μPa^2 s for a source in the center of the reef (site 1) and -0.1 ± 2.7 dB re 1 μPa^2 s for a source south-east of the reef (site 2). The white segment in the top-left of the plot at site 2 was beyond the maximum modeled range of 15 km.

plified bottom. If full seafloor velocity profiles are available from bore hole data, then these should be used instead. We ran RAM in our example because it is beautifully stable and because the wave speeds were low enough near the top of the seafloor to apply the complex density approximation[39] for shear wave loss. For limestones of higher sound speeds and lower attenuations, and if modeling to very low SEL (long ranges) is desired, a model that also propagates *S*-waves through the bottom [e.g., RAMS (Ref. 44)] should be used. An acousto-elastic model might also be preferable for coral reefs with large outcrops that can reach the surface and strip away waterborne energy.

The algorithm presented has repeatedly been used to estimate ensonified areas in situations where environmental agencies asked what percentage of a reef received potentially damaging levels. It has to be pointed out that the use of the SEL metric for this generates a single exposure "equivalent" assuming no recovery in between exposures, likely overestimating effects. While any threshold can be modeled, we continuously point out that the bioacoustic impact of cumulative sound exposure is still poorly understood.

Our algorithm computed SEL as the integral of squared pressure over time. Strictly speaking, this relationship is only valid in the far-field. The total energy of a pulse is the integral of the intensity over the duration of the pulse and over the (spherical) surface that it passes through. Acoustic energy consists of kinetic energy and potential energy. The former is contained in particle movement; the latter is equal to the work done by elastic pressure forces. Intensity is the product of pressure and particle velocity. The pressure gradient is proportional to the particle acceleration[45]

$$\nabla p = -\rho \frac{\partial u}{\partial t}.$$

In the far-field, $p = \rho c u$, with p denoting pressure, ρ density, c speed of sound, and u particle velocity. Putting it all together, in the far-field, the energy per unit area (also called energy flux) becomes

$$E = \frac{1}{\rho c} \int p^2 dt.$$

Given that the acoustic impedance ρc can mostly be considered constant in the water column, the first term is usually ignored.

In the near-field, particle velocity has a "quadrature" component that is out-of-phase with acoustic pressure.[45] When talking about acoustic energy, particle velocity and pressure should correctly be both included in the near-field.

What actually are the "damaging" sound characteristics is still not fully understood. Likely, the characteristics will differ depending on what type of "damage" is considered. Is it sound pressure level above sensitivity, as in the linear threshold shift (LINTS) hypothesis?[8,46] Is it intensity, cumulative energy, particle velocity, etc., or a combination of these with differing threshold levels? A full discussion of the effects of noise on fish is beyond the scope of this article, but can be found in recent reviews.[13,47]

Reviewers of Manuscripts, 2008

Each year the Journal endeavors to publish a list of all the persons who reviewed manuscripts during the preceding year. Such a list is a compendium of names supplied by the Associate Editors. Because our peer review system depends strongly on the continuing anonymity of the reviewers, the Journal publishes these names in alphabetical order without identification of the Associate Editors who provided the names and without identification of the papers they reviewed. The primary reason for the publication of the list is to express the Journal's gratitude to its reviewers. Reviewing a paper is often a very time consuming and demanding task, and the anonymity requirement yields no professional recognition to those who generously provide their time to help the Associate Editors decide which papers should be published and to give constructive criticisms to the authors. The Journal is justifiably proud of this list, which includes a goodly proportion of all the researchers and eminent authorities in acoustics and related fields. In a compendium of this length, omissions and errors are inevitable. If anyone notices such, please send the corrections and missing names via e-mail or regular mail to either Elaine Moran (asa@aip.org) or Allan Pierce (adp@bu.edu).

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

2009

18–22 May	157th Meeting of the Acoustical Society of America, Portland, OR [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; Email: asa@aip.org; WWW: http://asa.aip.org].
24–28 June	5th International Middle-Ear Mechanics in Research and Otology (MEMRO), Stanford University, Stanford, CA [http://memro2009.stanford.edu].
26–30 October	158th Meeting of the Acoustical Society of America, San Antonio, TX [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; Email: asa@aip.org; WWW: http://asa.aip.org].

2010

19–23 April	158th Meeting of the Acoustical Society of America, Baltimore, MD [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; Email: asa@aip.org; WWW: http://asa.aip.org].
15–19 November	2nd Iberoamerican Conference on Acoustics (Joint Meeting of the Acoustical Society of America, Mexican Institute of Acoustics, and Iberoamerican Federation on Acoustics), Cancun, Mexico [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; Email: asa@aip.org; WWW: http://asa.aip.org].

ACOUSTICAL NEWS—INTERNATIONAL

W. G. Mayer
Physics Dept., Georgetown University, Washington, DC 20057

International Meetings Calendar

Below are announcements of meetings and conferences to be held abroad. Entries preceded by an * are new or updated listings.

April 2009

5–9 **Noise and Vibration: Emerging Methods (NOVEM 2009)**, Oxford, UK (www.isvr.soton.ac.uk/NOVEM2009).

13–17 **2nd International Conference on Shallow Water Acoustics**, Shanghai, China ([soon]: www.apl.washington.edu).

19–24 **International Conference on Acoustics, Speech, and Signal Processing**, Taipei. R.O.C. (icassp09.com).

June 2009

2–5 **XXI Session of the Russian Acoustical Society**, Moscow, Russia (www.akin.ru/main.htm).

17–19 **3rd International Conference on Wind Turbine Noise**, Aalborg, Denmark (www.windturbinenoise2009.org)

21–25 *__13th International Conference "Speech and Computer,"__ St. Petersburg, Russia (www.specom.nw.ru).

22–26 **3rd International Conference on Underwater Acoustic Measurements: Technologies and Results**, Nafplion, Peleponnese, Greece (www.uam2009.gr).

July 2009

5–9 **16th International Congress on Sound and Vibration**, Krakow, Poland (www.icsvl6.org).

19–23 *__15th International Conference on Photoacoustics and Photothermal Phenomena__, Leuven, Belgium 9WWW.icpppl5.be).

August 2009

12–16 *__7th Triennial Conference of the European Society for Cognitive Science of Music (ESCOM2009)__, Jyväskylä, Finland (www.fyu.fi/hum/laitokset/musikki/en/escom2009).

23–28 **Inter-noise 2009**, Ottawa, Ont, Canada (www.internoise2009.com).

September 2009

6–10 **InterSpeech 2009**, Brighton, UK (www.interspeech2009.org).

9–11 **9th International Conference on Theoretical and Computational Acoustics**, Dresden, Germany (Ictca2009.com).

14–18 **5th Animal Sonar Symposium**, Kyoto, Japan (cse.fra.afrrc.go.jp/akamatsu/AnimalSonar.html).

15–17 **Autumn Meeting of the Acoustical Society of Japan**, Koriyama, Japan (www.asj.go.jp/index-en.html).

19–23 **IEEE 2009 Ultrasonics Symposium, Rome**, Italy (e-mail: pappalar@uniroma3.it).

21–23 **10th Western Pacific Acoustics Conference (WESPAC)**, Beijing, China (www.wespacx.org).

23–25 **Pacific Rim Underwater Acoustics Conference (9pruac)**, Xi'an, China (e-mail: lfh@mail.ioa.ac.cn).

23–25 **TECNIACUSTICA2010**, Cadiz, Spain (www.sea-acustica.es).

October 2009

5–7 *__International Conference on Complexity of Nonlinear Waves__, Tallinn, Estonia (www.ioc.ee/cnw09).

26–28 **Euronoise 2009**, Edinburgh, UK (www.euronoise2009.org.uk).

June 2010

9–11 *__14th Conference on Low Frequency Noise and Vibration__, Aalborg, Denmark (www.lowfrequency2010.org).

13–16 **INTERNOISE2010**, Lisbon, Portugal, (www.internoise2010.org).

August 2010

23–27 **20th International Congress on Acoustics (ICA2010)**, Sydney, Australia (www.ica2010sydney.org).

September 2010

26–30 **Interspeech 2010**, Makuhari, Japan (www.interspeech2010.org).

June 2011

27–1 *__Forum Acusticum 2011__, Aalborg, Denmark, (www.fa2011.org).

August 2011

27–31 **Interspeech 2011**, Florence, Italy (www.interspeech2011.org).

September 2011

4–7 **International Congress on Ultrasonics**, Gdansk, Poland.

4–7 *__Pmternoise 2011__, Osaka, Japan

June 2013

2–7 **21st International Congress on Acoustics (ICA2013)**, Montréal, Canada (www.ica20013montreal.org).

 0001-4966/2009/125(4)/2461/1/$25.00

REVIEWS OF ACOUSTICAL PATENTS

Sean A. Fulop
Dept. of Linguistics, PB92
California State University Fresno
5245 N. Backer Ave., Fresno, California 93740

Lloyd Rice
11222 Flatiron Drive, Lafayette, Colorado 80026

The purpose of these acoustical patent reviews is to provide enough information for a Journal reader to decide whether to seek more information from the patent itself. Any opinions expressed here are those of reviewers as individuals and are not legal opinions. Printed copies of United States Patents may be ordered at $3.00 each from the Commissioner of Patents and Trademarks, Washington, DC 20231. Patents are available via the internet at http://www.uspto.gov.

7,368,862

43.38.Bs ELECTROACTIVE POLYMER GENERATORS

Ronald E. Pelrine *et al.*, assignors to SRI International
6 May 2008 (Class 310/800); filed 24 January 2006

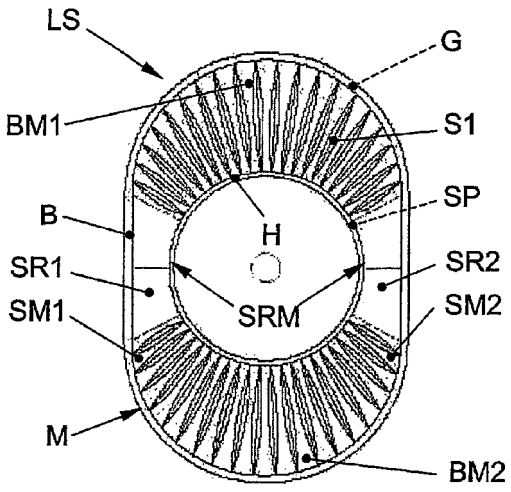
Numerous electroactuator devices are described that use electroactive polymers including an artificial muscle, a flex-tensional actuator, and various bending beams. Methods of enhancing the mechanical forces created in the electromotive polymer are claimed.—AJC

7,416,047

43.38.Ja DIAPHRAGM FOR A LOUDSPEAKER WITH A MOVING COIL

Ewald Frasl, A-2362 Biedermannsdorf and Helmut Wasinger, A-2371 Hinterbruehl, both of Austria
26 August 2008 (Class 181/173); filed in the European Patent Office 29 April 2004

Stress reduction areas **SR1**, **SR2** of diaphragm **M** do not have V-shaped corrugations **S1** as do wide diaphragm portions **BM1**, **BM2**. This enhancement over prior art, in which corrugations **S1** cover the whole of the diaphragm area, is said to reduce the stiffness in areas **SR1**, **SR2**—which are stiff due to their small area between retaining part **H** and fastening part **B**—and so equalizes the stiffness of the narrow and wide areas, reducing the "uneven load on the moving coil **SP**."—NAS



7,418,104

43.38.Ja SPEAKER SYSTEM

Robert G. Spinale, Middleton, New Hampshire
26 August 2008 (Class 381/87); filed 6 August 2002

Loudspeaker **10** is comprised of four speakers—one full range speaker **16** in upper baffle **12** and woofer **18**, a midrange speaker (not shown in this figure), and a tweeter type speaker (not shown) mounted in lower baffle **14**. The novel part is that upper **12** and lower **14** baffles are canted relative to one another so that the angle **A** between them is between 120 and 140 degrees (which can change depending on the embodiment).—NAS

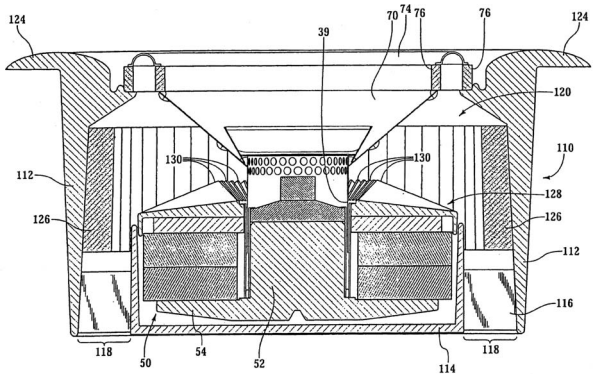
 0001-4966/2009/125(4)/2462/12/$25.00

7,443,995

43.38.Ja ACOUSTIC LOUDSPEAKER

Burton Babb and Alan Babb, assignors to Babb Laboratories
28 October 2008 (Class 381/396); filed 17 February 2005

Perhaps the title of this patent is intended as a kind of Zen exercise, inviting the reader to contemplate the attributes of a nonacoustic loudspeaker. The inventor has patented several earlier loudspeaker designs, most of which utilize a sliding bearing rather than a spider to center the voice coil. The voice coil of this latest variant is a single layer of round or square wire with the windings spaced apart, the width of the gaps being roughly equal to



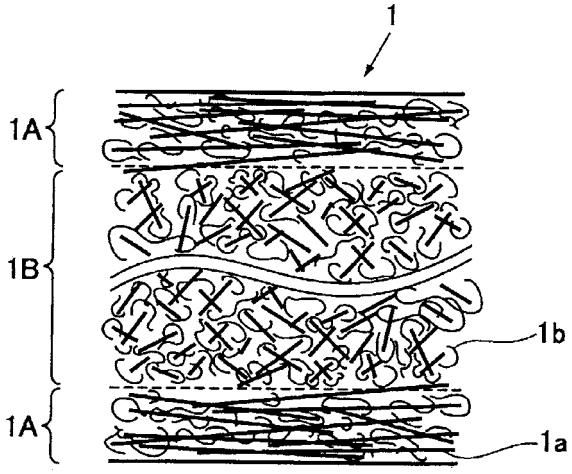
the diameter of the wire. "Thus, contrary to traditional teachings for an efficient loudspeaker 'motor' or transducer, such a coil has better magnetic coupling. With better magnetic coupling and less resistance due to the relatively shorter length of wire used, it is more efficient at converting electrical to acoustic energy and has less mass for a given length than conventional prior art coils." Well, the assertion of better magnetic coupling is certainly easy to test, and one can only hope that the inventor will eventually get around to testing it.—GLA

7,443,998

43.38.Ja SPEAKER DIAPHRAGM AND MANUFACTURING METHOD THEREOF

Satoshi Hachiya, assignor to Pioneer Corporation
28 October 2008 (Class 381/426); filed in Japan 4 June 2002

Over the years, Pioneer has patented a number of new materials and manufacturing techniques for loudspeaker diaphragms. In this patent, fibers from 3 to 5 mm in length are mixed in a matrix resin. The illustration is



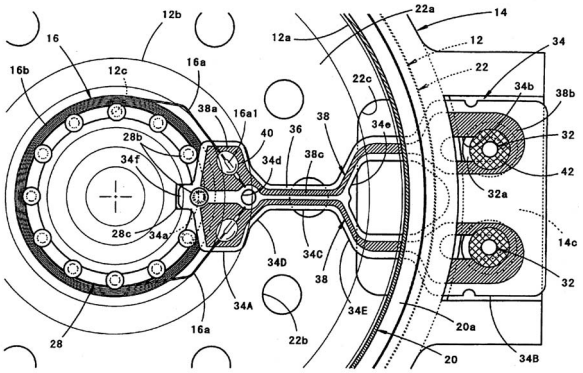
intended to show that the fibers are oriented radially in the surface layers and randomly in the central layer of the diaphragm.—GLA

7,447,327

43.38.Ja FLEXIBLE PCB VOICE COIL CONNECTOR

Hajime Kitamura *et al.*, assignors to Star Micronics Company, Limited
4 November 2008 (Class 381/410); filed in Japan 11 May 2004

Element **34** is a small, lightweight, flexible printed circuit board that provides electrical connections between terminals **32** and voice coil leads **16a** of a miniature loudspeaker. The central portion **34c** is made narrower



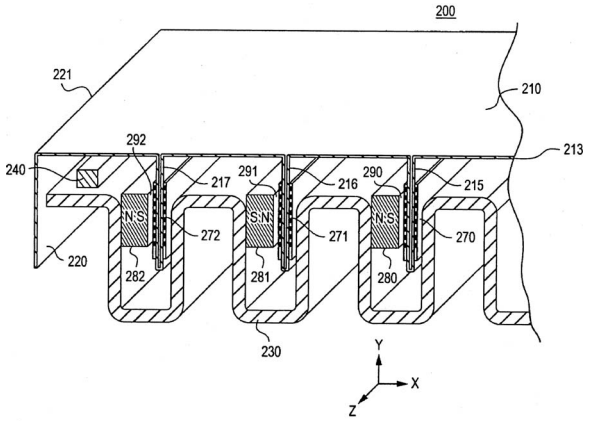
than the ends to minimize stiffness and localized stresses. In practice, the assembly shown is quite small—section **34c** is only about 2 mm wide and less than 0.5 mm thick.—GLA

7,450,729

43.38.Ja LOW-PROFILE TRANSDUCER

An Duc Nguyen and Charles M. Sprinkle, assignors to Harman International Industries, Incorporated
11 November 2008 (Class 381/152); filed 9 April 2004

Elongated rectangular voice coils have been a feature of some planar loudspeaker designs for more than 40 years, and at least half of the claims of



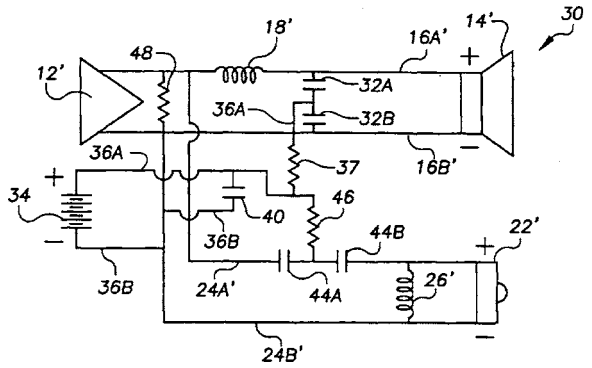
this patent appear to describe prior art. Nonetheless, the magnetic circuit shown is clever, simple, and practical.—GLA

7,443,990

43.38.Lc VOLTAGE BIASED CAPACITOR CIRCUIT FOR A LOUDSPEAKER

Daniel A. Chattin, Harwinton, Connecticut
28 October 2008 (Class 381/111); filed 1 November 2004

Some high-end loudspeaker systems include DC bias for crossover network capacitors. This is usually done to stabilize the long-term perfor-



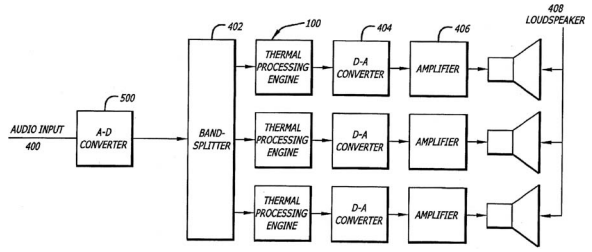
mance of electrolytic capacitors, but is sometimes said to improve the performance of non-polarized capacitors as well. This patent discloses a biasing method using series pairs of capacitors **32**, **44** biased through resistors **37** and **46**. Note that the diagram is drawn incorrectly—resistor **37** connects directly to **36A** and not to **16B**.—GLA

7,447,318

43.38.Lc SYSTEM FOR USING DIGITAL SIGNAL PROCESSING TO COMPENSATE FOR POWER COMPRESSION OF LOUDSPEAKERS

Douglas J. Button and Paul Robert Williams, assignors to Harman International Industries, Incorporated
4 November 2008 (Class 381/55); filed 7 September 2001

Multi-band loudspeaker systems, especially high-power systems, are commonly used in conjunction with a signal processor designed for the particular components employed. The power of digital processing allows the processor to include all sorts of sophisticated functions such as frequency division, equalization, delay alignment, and overload protection. To permit the greatest possible acoustic output without damage, overload protection



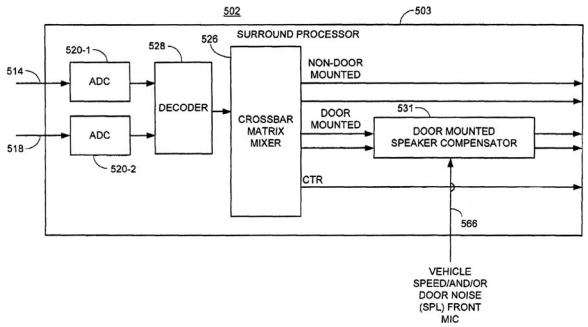
must sense or estimate cone excursion and voice coil temperature. This patent teaches that a computerized thermal model can accurately predict voice coil temperature without the need for additional sensing devices. The predicted value can then be used in real time to protect against overload and also to compensate for frequency response shifts caused by the coil's resistance vs temperature characteristic. The patent text also suggests that the proposed method can be applied to other devices such as motors and transformers. Such applications appear to be in the public domain, however, since they are not covered by any of the 36 patent claims.—GLA

7,451,006

43.38.Lc SOUND PROCESSING SYSTEM USING DISTORTION LIMITING TECHNIQUES

Bradley F. Eid and William Neal House, assignor to Harman International Industries, Incorporated
11 November 2008 (Class 700/94); filed July 2002

This is one of a three-patent package having to do with stereo signal processing in automotive sound systems. Presumably the other two patents are still pending. Looking at any one patent, this one-into-three ploy results in numerous illustrations and long stretches of descriptive text that have little or nothing to do with the patent claims. In the case at hand, the claims seem to cover the concept of dynamically equalizing various channels of a matrixed multi-channel audio system in response to the volume setting and background noise.—GLA

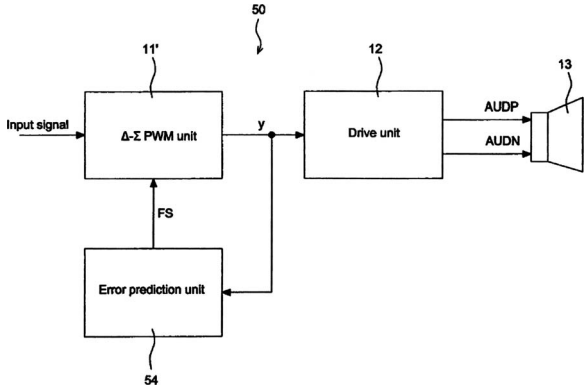


7,439,440

43.38.Md AUDIO PLAYER USING SIGMA-DELTA PULSE-WIDTH MODULATION

Han-Huah Hsu, assignor to Sunplus Technology Company Limited
21 October 2008 (Class 84/600); filed in Taiwan 11 October 2004

The use of pulse-width modulation (Class D) amplifiers in audio playback devices has become commonplace. However, using feedback to reduce



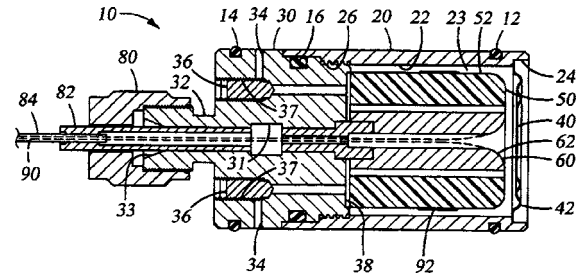
distortion in Class D amplifiers is difficult and costly. This patent asserts that distortion produced by drive unit **12** under loading is predictable, and can therefore be reduced through predistortion rather than feedback. Error prediction unit **54** may use a simple lookup table to generate the required correction. How the process can be accomplished in the digital domain is thoroughly explained in the patent.—GLA

7,369,716

43.38.Pf HIGH PRESSURE AND HIGH TEMPERATURE ACOUSTIC SENSOR

Arne Berg *et al.*, assignors to Weatherford/Lamb, Incorporated
6 May 2008 (Class 385/12); filed 9 March 2004

Borehole hydrophone package **10** having a fiber optics sensor capable of operating in well down-hole high-pressure and high-temperature conditions is claimed. Environmental pressure and sound are admitted through



diaphragm **40** into chamber **22** containing fluid **23** and Teflon mandrel **50** having optical fiber spiral sensor **92** wound on its outer surface. Fiber ends **90** exit through the center of the mandrel **50** and through supporting cable **84**.—AJC

6,906,632

43.38.Si VEHICULAR SOUND-PROCESSING SYSTEM INCORPORATING AN INTERIOR MIRROR USER-INTERACTIION SITE FOR A RESTRICTED-RANGE WIRELESS COMMUNICATION SYSTEM

Jonathan E. DeLine *et al.*, assignors to Donnelly Corporation
14 June 2005 (Class 340/815.4); filed 8 July 2002

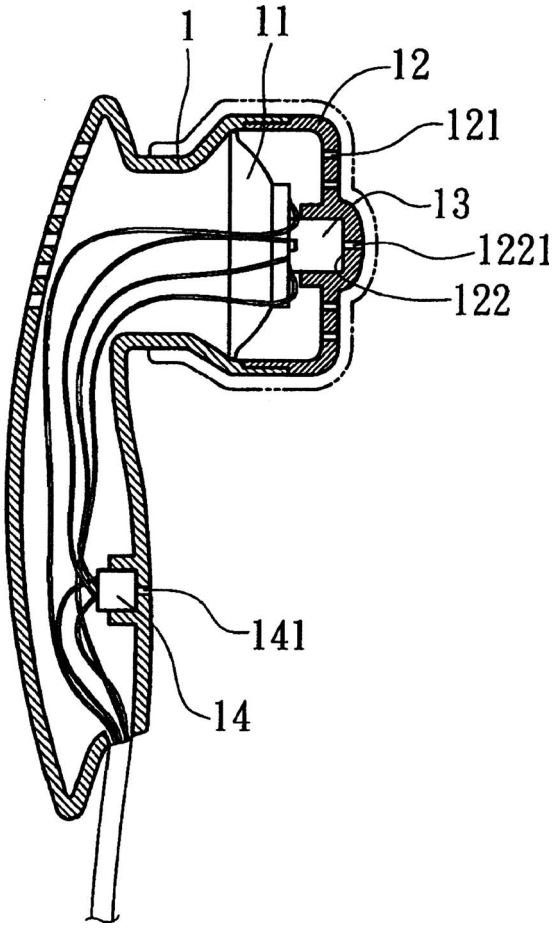
This huge patent, with 517 claims, is primarily based on a wireless control system that is integral to the rear view mirror assembly in an automobile. A voice recognition system is used to control accessories such as cell phones, internet connections, and in-vehicle systems.—KPS

7,447,308

43.38.Si LOW-NOISE TRANSMITTING RECEIVING EARSET

Jin-Chou Tsai, Taipei City, Taiwan
4 November 2008 (Class 379/430); filed 26 August 2005

This noise-cancelling headset is an improved version of an earlier design by the same inventor. Sound from the rear side of loudspeaker **11** reaches the user's ear through holes **121**. Microphone **13** picks up "resonant sound waves from the external auditory canal of the user's ear," and second microphone **14** picks up the user's voice. It appears that the two microphones are connected in parallel. The patent gives no additional clues as to how this arrangement is intended to operate.—GLA

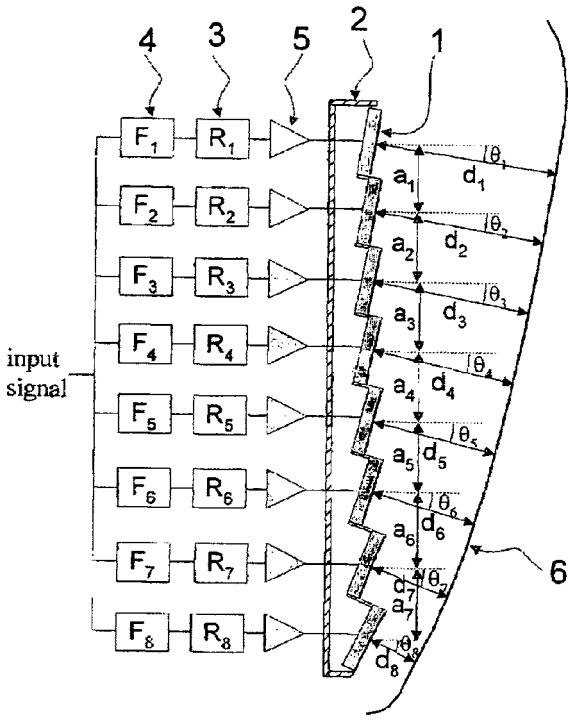


7,426,278

43.38.Tj SOUND DEVICE PROVIDED WITH A GEOMETRIC AND ELECTRONIC RADIATION CONTROL

Xavier Meynial, assignor to Active Audio
16 September 2008 (Class 381/82); filed in France 25 March 2004

Elements **1** of column loudspeaker **2** are angled as shown. Elements are connected to amplifiers **5** which are connected to delays **3** and filters **4**. Elements can be planar type radiators, a combination of planar type radiators, cone type radiators, or even transducer/horn assemblies. "The advantage of the system that is the object of this invention is to combine the advantages of a geometrical network with those of an electronically controlled network…" which allows for control of the main and secondary lobes. The patent describes a device designed by the reviewer in the late 1980s, and he was probably not the first.—NAS

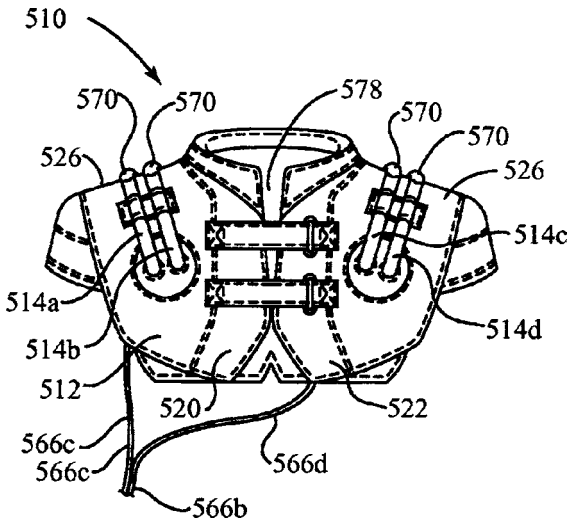


7,440,581

43.38.Vk BACKPACK WITH INTEGRATED SPEAKERS

David Wiener, assignor to Soundtube Entertainment, Incorporated
21 October 2008 (Class 381/388); filed 24 April 2006

Four loudspeakers are attached to backpack **510**: two in front and two on the back. Pairs of loudspeakers are loaded by flexible ducts **514** which



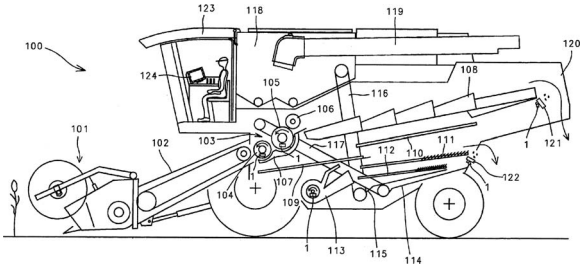
may be circular or rectangular in cross-section, and may include vents or perforations. The ducts are configured with stiffeners or corrugations to prevent collapse during flexing yet not restrict the wearer's movements. Performance goals include enhanced low-frequency response and a physical sensation to the body of the wearer.—GLA

7,415,365

43.40.Le STRUCTURE-BORNE SOUND SENSOR UNIT

Eckehard Jeppe, assignor to CLAAS Selbstfahrende Erntemaschinen GmbH
19 August 2008 (Class 702/56); filed in Germany 30 March 2006

A means of determining the amount of waste grain that exits from straw-walker **108** and from upper sieve **11** in a combine harvester is disclosed that uses structure borne sound sensors **1** that are attached to pulse detectors **121**, **122**. Sensors **1** are multi-purpose units which contain signal conditioning circuitry and so can be used in many situations, another of which can be the chopper drum in a forage harvester. The output from sensors **1** are connected to processing unit **124**. The patent provides a concise description of how these harvesters work.—NAS



7,438,530

43.40.Tm METHOD OF ASSEMBLING ONE-PIECE BLADED DISKS, AND A DEVICE FOR DAMPING VIBRATION OF THE BLADES OF SUCH DISKS

Jean-Pierre Ferte *et al.*, assignors to SNECMA
21 October 2008 (Class 416/198 A); filed in France 17 April 2004

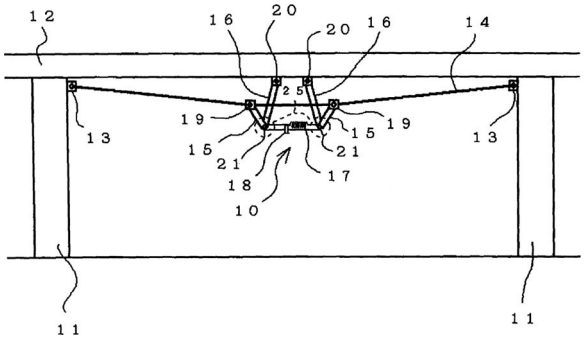
In friction-welding of blades onto a disk, the blades may suffer damage from excessive vibrations. To overcome this problem the blades are damped during the assembly process by clamping them in an annular assembly in which elastomeric elements are pressed against the blade surfaces.—EEU

7,441,376

43.40.Tm BASE ISOLATION DEVICE FOR STRUCTURE

Shinji Ishimaru *et al.*, assignors to Nihon University, School Juridical Person
28 October 2008 (Class 52/167.6); filed in Japan 26 December 2001

The device described in this patent is intended to suppress out-of-plane vibrations of plate-like structural components, such as slabs of elevated



roads or bridges, or roof structures, or glass curtain walls. Cables or other tension members **14** are attached to columns or bridge supports **11** at points **13** underneath the slab **12**. A linkage arrangement is pin-connected to the slab at **20** and to the tension member at **19**, so that out-of-plane deflection of the slab induces axial movement in the damper **18**. The spring **17** is intended to keep the assembly in tension, so that the damper can act during both upward and downward deflection of the slab.—EEU

7,445,685

43.40.Tm ARTICLE HAVING A VIBRATION DAMPING COATING AND A METHOD OF APPLYING A VIBRATION DAMPING COATING TO AN ARTICLE

Martin J. Deakin *et al.*, assignors to Rolls-Royce PLC
4 November 2008 (Class 156/212); filed in United Kingdom 23 March 2004

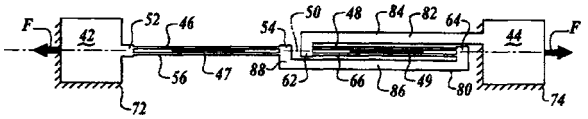
This patent pertains to vibration-damping coatings for blades or vanes of fans, compressors, turbines, and the like. A damping coating, such as a polymer-impregnated ceramic, is deposited on an erosion-resistant material, such as stainless steel, by plasma spraying. The coating may be applied through a mesh mask, which is then removed, leaving the coating in separated segments. The assembly is bonded adhesively to the article to be damped, with the damping coating in contact with the article—so that there results a constrained-layer damping arrangement.—EEU

7,444,883

43.40.Yq VIBRATING BEAM FORCE TRANSDUCER

Mitchell J. Novack, assignor to Honeywell International Incorporated
4 November 2008 (Class 73/826); filed 22 December 2005

Vibrating beam force transducers may be used as force sensors, for example in accelerometers and pressure sensors. It is often advantageous to employ two such transducers in a sensor, with one subjected to tension and the other to compression, in order to cancel common mode errors, such as may occur due to temperature sensitivity and some nonlinearities. This method of error canceling is effective only to the extent that the two force sensing elements experience the same force loading; thus, this patent describes configurations that provide such equal loading and that can be formed on a crystalline substrate. In the illustrative embodiment shown in the figure an arm **82** is connected to the force application element **44**. Sensing element **48** is connected between that arm and a frame **86**. Sensing



element **46** is connected between that frame and the force application element **42**. The sensing elements are aligned so that their axes **47** and **49** are along the axis **50** of the force transducer.—EEU

7,448,268

43.40.Yq MECHANICAL DECOUPLING DEVICE FOR MONOLITHIC DIFFERENTIAL VIBRATING SENSOR

Olivier Le Traon *et al.*, assignors to Onera
11 November 2008 (Class 73/514.29); filed in France 5 May 2004

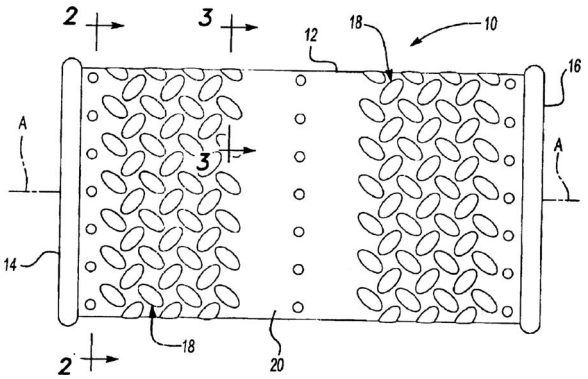
Monolithic differential vibrating sensors consist in essence of two substantially identical vibrating members attached to the same support. Each of the vibrating members is an accelerometric transducer consisting of a proof mass and a resonator whose resonant frequency varies as a function of the applied acceleration. The difference between these two frequencies, which serves as a measure of the applied acceleration, is relatively insensitive to such parasitic disturbances as temperature variations. In order to minimize the undesirable mechanical coupling between the two transducer elements, the support frame for the transducers is designed to have nodes (at the system's working frequency) at the points where the transducers are connected to the frame.—EEU

7,892,855

43.50.Gf EMBOSSED SHELL FOR SPUN MUFFLERS

John Lewis Warmenhoven, assignor to Tenneco Automotive Operating Company Incorporated
17 May 2005 (Class 181/282); filed 25 February 2003

An exhaust muffler having a non-circular (e.g. elliptical) cross-section may have resonance frequencies that coincide with engine frequencies. Embossments (as shown in the figure) are stamped into the surface to stiffen it and thereby raise the resonance frequencies.—KPS



6,905,091

43.50.Gf SYSTEM AND METHOD FOR CONTROLLING THE ACOUSTIC SIGNATURE OF A DEVICE

Barry L. Berson *et al.*, assignors to Supersonic Aerospace International, LLC
14 June 2005 (Class 244/1 N); filed 14 July 2003

Despite the broad, generic title of this patent, it really concerns the control of levels of sonic booms heard on the ground from a supersonic aircraft. An electronic system receives information concerning current flight conditions and determines the resultant boom level at the ground surface. This is compared to a desired level and cues are presented to the pilot regarding corrective actions that can be taken to reduce or maintain the level at the desired value. Options to limit maneuvers and to automatically adjust operating parameters can be enabled. Options to display past, current, and future levels can be selected.—KPS

6,911,158

43.50.Gf SOUND ABSORBING MATERIAL AND ITS MANUFACTURING METHOD

Tsutomu Oishi *et al.*, assignors to Ishikawajima-Harima Heavy Industries Company, Limited
28 June 2005 (Class 252/62); filed in Japan 29 November 2000

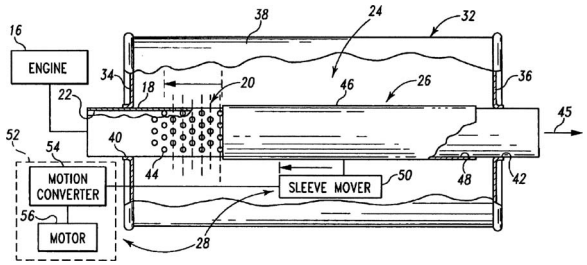
A porous sound absorbing material suitable for hostile environments, such as found in the exhaust duct of a jet engine, is described. A ceramic foam material having 75–80% porosity and a range of cell sizes is designed for broadband absorption. The manufacturing process is composed of two steps: in the first, the raw material containing ceramic grains and a void-forming material (carbon) is formed into a prescribed shape and, in the second, the carbon is removed. Details are provided concerning material selection and performance.—KPS

6,915,876

43.50.Gf EXHAUST PROCESSOR WITH VARIABLE TUNING SYSTEM

Mehmet S. Ciray, assignor to Arvin Technologies, Incorporated
12 July 2005 (Class 181/219); filed 1 December 2003

An exhaust muffler for an automobile includes an adjustable Helmholtz resonator that allows the tuning frequency to match the engine conditions. The tuning is accomplished by means of a movable sleeve that effectively adjusts the throat of the resonator.—KPS

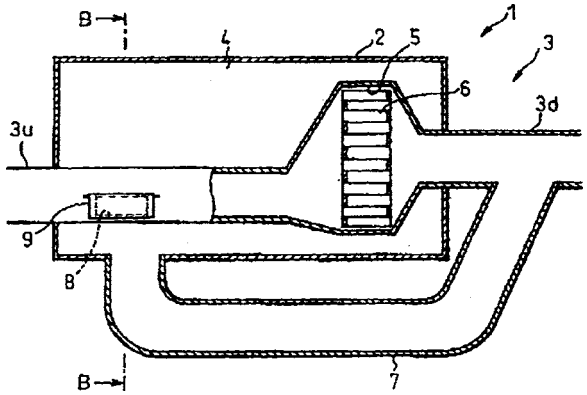


6,918,463

43.50.Gf MUFFLER FOR ENGINE

Masanori Takahashi *et al.*, assignors to Toyota Jidosha Kabushiki Kaisha
19 July 2005 (Class 181/237); filed in Japan 21 May 2002

An engine exhaust muffler containing a particulate filter, **6**, also includes a control valve, **9**. At low engine speeds the valve is closed and all



exhaust gases flow through the filter. At higher speeds the valve opens and a portion of the flow is diverted, thus keeping backpressure low.—KPS

6,920,958

43.50.Gf ANNULAR ACOUSTIC PANEL

Geoffrey E. Harrison, assignor to The Boeing Company
26 July 2005 (Class 181/214); filed 17 October 2003

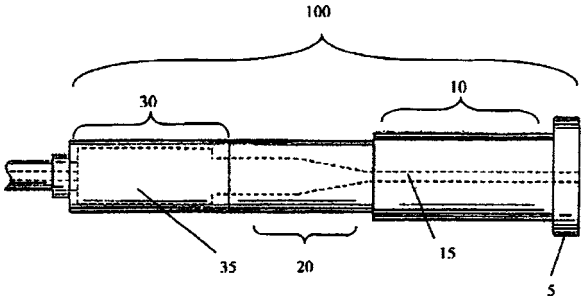
Acoustic absorption treatment in a turbofan engine nacelle is generally installed in sections, resulting in seams and untreated areas. The invention describes a monolithic one-piece design that eliminates seams and provides improved fan noise reduction.—KPS

6,923,292

43.50.Gf ATTACHMENT FOR RECOIL, NOISE, BLAST AND FLASH SUPPRESSION OF THERMODYNAMIC JETTING DEVICES SUCH AS FIREARMS, HIGH PRESSURE EXHAUST MECHANISMS AND OTHER HEAT ENGINE DEVICES, WHICH PRODUCE SUCH JETTING EXHAUST ACTION AS A RESULT OF THEIR FUNCTION

Robert James Woods, Phoenix, Arizona and JeanMarie Evangeline Serrano, Danville, California
2 August 2005 (Class 181/223); filed 15 April 2003

A silencer for a gun is attached to the barrel and consists of "a primary chaotic expansion chamber, **30**, the secondary convergent compression chamber, **20**, and, lastly, the magnetic diversion chamber assembly, **10**." The



latter consists of rare-earth magnetic toroids that "redirect, helically confine and delay, cool, and extract energy from the gaseous exhaust column." No acoustic data are provided.—KPS

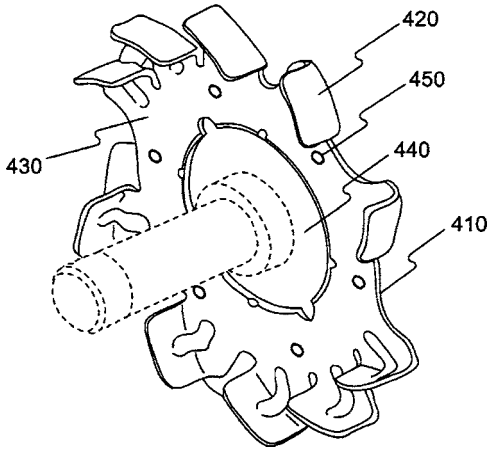
7,365,471

43.50.Gf INTERNAL COOLING FAN WITH A NON-REPEATING BLADE CONFIGURATION

Alex Creviston *et al.*, assignors to Remy Incorporated
29 April 2008 (Class 310/263); filed 28 October 2005

The pitch angle of blades **420** of the internal cooling fan **220** that is attached to the rotating rotor (not shown) of a motor, a generator, or an

220



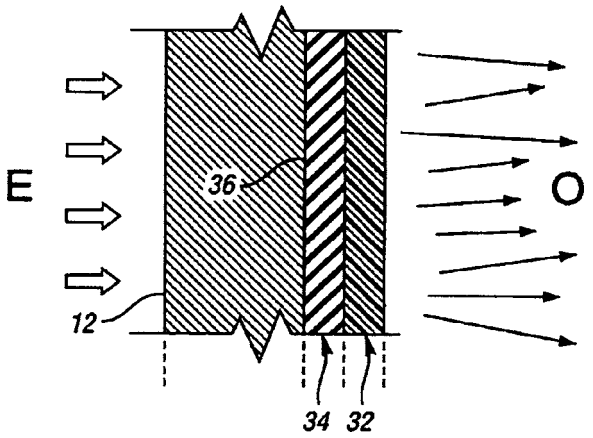
alternator is varied from one blade **420** to the next to reduce the intensity of the blade passage frequency noise.—AJC

7,367,304

43.50.Gf APPARATUS AND METHOD FOR FORCED RESPONSE ACOUSTIC ISOLATION ENCLOSURE IN CAST ALUMINUM OIL PAN

David T. Hanner *et al.*, assignors to GM Global Technology Operations, Incorporated
6 May 2008 (Class 123/195 C); filed 2 December 2005

Cladding **E-O** for the exposed aluminum oil pan bottom of a reciprocating internal combustion engine that reduces the noise emitted therefrom is claimed. Foam rubber isolator **34** is bonded to oil pan **12** outer surface **36**.



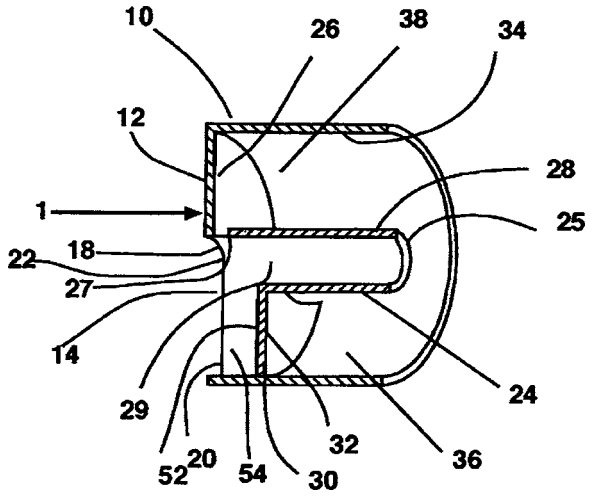
Urethane sound barrier **32** is affixed over all pan surfaces including surfaces that may not be covered by isolator **34**.—AJC

7,412,917

43.50.Gf SOUND SUPPRESSOR SILENCER BAFFLE

George Vais, Boisè, Idaho
19 August 2008 (Class 89/14.4); filed 13 December 2005

Suppressor baffle segment **1** has bulkheads **12** and **32** offset from one another, and central core defining tube **24** contains a longitudinal slot **28** that extends along the top portion of the central core **24** to intersection **37** of rear wall **12**. This provides a relief path for the propellant gasses while also, it is claimed, reducing the effect of gas flow on the projectile. A complete sup-



pressor is comprised of several baffle segments, a means of attachment to the muzzle of the firearm, and an end cap.—NAS

7,448,468

43.50.Gf ACOUSTICALLY EFFECTIVE WHEEL HOUSE COVERING FOR VEHICLES

Hans Rudolf Czerny *et al.*, assignors to Carcoustics Tech Center GmbH
11 November 2008 (Class 181/210); filed in Germany 15 July 2003

A liner to be placed in the wheel housings of automotive vehicles in order to reduce the transmission of water splash noise into the passenger compartment and to absorb tire/road noise consists of three or more air-permeable sandwich layers. The layers, typically of textile materials, have graded permeabilities, thicknesses, and acoustic impedances.—EEU

6,895,290

43.55.Dt LIMITING THE DAMAGING EFFECTS OF LOUD MUSIC FROM AUDIO SYSTEMS, PARTICULARLY FROM AUTOMOBILE AUDIO SYSTEMS

Faisal M. Awada *et al.*, assignors to International Business Machines Corporation
17 May 2005 (Class 700/94); filed 11 July 2002

A scheme that limits the loudness of music played over an automobile sound system is described. Music having predominantly low frequency content results in limiting of the amplifier gain since this is the kind of music most likely to be played at high levels. A nice idea, but not likely to catch on!—KPS

6,896,219

43.55.Dt PROCESS AND APPARATUS FOR NOISE REDUCTION IN MULTI-ENGINE PROPELLER-DRIVEN AIRCRAFT

Ingo Udo Borchers *et al.*, assignors to Dornier GmbH
24 May 2005 (Class 244/1 N); filed in Germany 19 March 2002

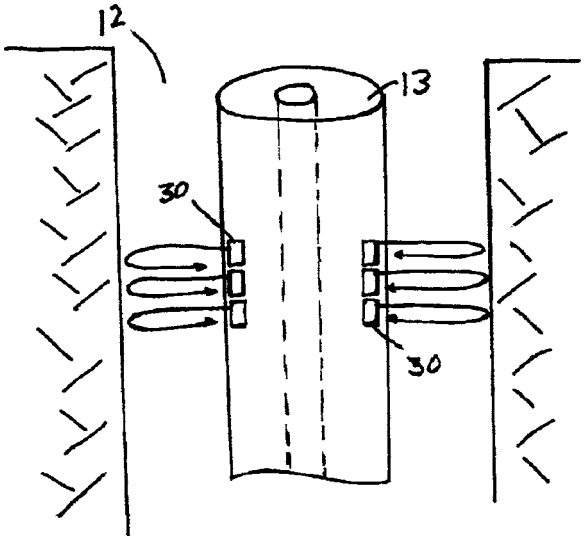
A system to reduce cabin noise of propeller aircraft is based on destructive interference of sound fields from two propellers. Unlike previous schemes based on synchrophasing propellers on opposite sides of the fuselage, this one proposes to use interference between sound fields from adjacent propellers on the same wing. It is thus necessary to compensate for the difference in distance from each propeller to the fuselage sidewall. Various methods are proposed to alter the acoustic fields of the two adjacent propellers, such as different numbers of blades, different rotation speeds, blade geometry, and relative upstream location. No data are presented to indicate that any such methods might work.—KPS

7,364,007

43.60.Qv INTEGRATED ACOUSTIC TRANSDUCER ASSEMBLY

Fernando Garcia-Osuna *et al.*, assignors to Schlumberger Technology Corporation
29 April 2008 (Class 181/108); filed 30 November 2004

An advanced acoustical borehole sensor package is claimed that combines a miniaturized electronics processor with an array of receiver transducer elements that can be variously connected to effect monopole, dipole, and other multipole sound sensor configurations. Shown is a pulse-echo



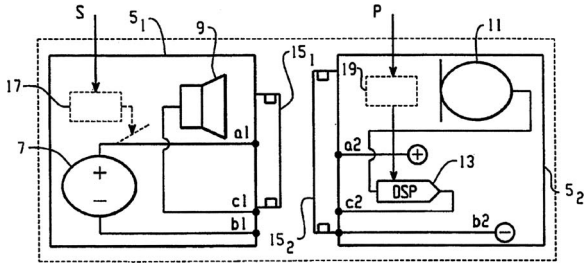
version of the invention where down-hole package **13** has several axially and azimuthally distributed receiver elements **30** which can be switched to perform directional pulse-echo measurements in various directions.—AJC

7,440,579

43.66.Ts HEARING DEVICE HAVING TWO MODULES FOR ASSEMBLING/DISASSEMBLING DEVICE

Andy Vonlanthen, assignor to Phonak AG
21 October 2008 (Class 381/322); filed 21 February 2007

The motivation here is standardization while forming a family of in-the-ear or over-the-ear hearing devices having different audio output power levels. An interchangeable first module, which has an on-off control and is



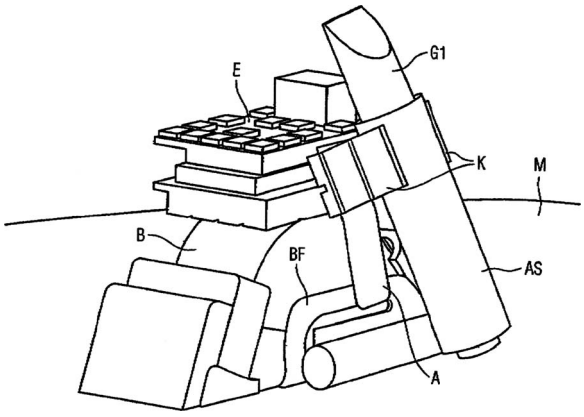
transmission-power-level dependent, houses different batteries including rechargeable types. A standardized second module that is relatively independent of power level, which is interconnected removably to the first module, contains the microphone and digital signal processor.—DAP

7,443,991

43.66.Ts ITE HEARING AID FOR BINAURAL HEARING ASSISTANCE

Torsten Niederdränk *et al.*, assignors to Siemens Audiologische Technik GmbH
28 October 2008 (Class 381/315); filed in Germany 31 March 2004

Antennae are positioned in the left and right hearing aids in a binaural fitting so they will align for good ear-to-ear wireless communication. This is achieved in in-the-ear as well as completely-in-the-canal models by mounting the antennae on a battery contact or on a programming connector at a 10 to 40 degree angle with respect to a perpendicular to the hearing aid faceplates.—DAP

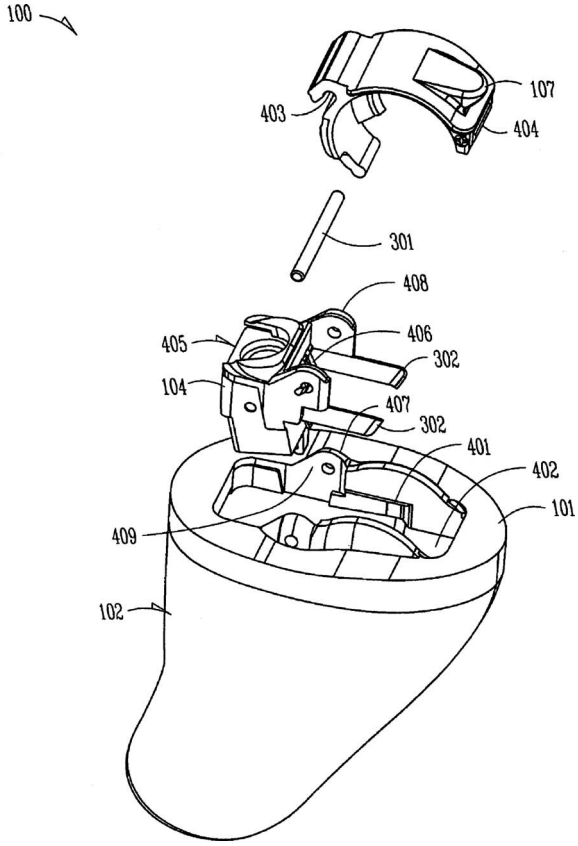


7,443,992

43.66.Ts METHOD AND APPARATUS FOR MODULAR HEARING AID

Brian Fideler, assignor to Starkey Laboratories, Incorporated
28 October 2008 (Class 381/328); filed 15 April 2004

Presented here is a method to assemble a standard-sized microphone housing that fits through an access port in the hearing aid that may or may not have a separate faceplate. The battery contacts, programming terminals, telecoil, signal processing electronics, and receiver interface are in close proximity to the microphone housing and are interconnected electrically with a flexible substrate. A removable fastening pin may be used to retain the microphone housing and adjoining components in place.—DAP

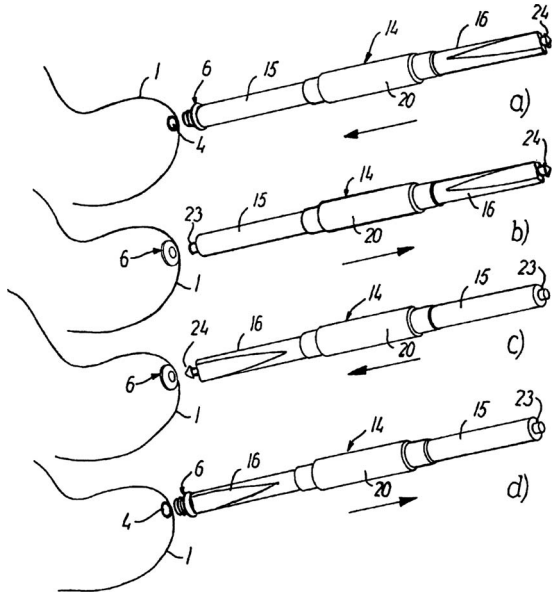


7,443,993

43.66.Ts TOOL FOR INSERTION AND REMOVAL OF A HEARING AID EAR WAX GUARD AND A METHOD FOR ITS USE

Finn Gunnersen and Jan Tøpholm, assignors to Widex A/S
28 October 2008 (Class 381/329); filed in Denmark 10 July 1998

A rod-shaped insertion-removal tool has a stopping abutment and a harpoon-shaped catch element to engage an inside wall in the mouth of the wax guard. When the tool is removed from the hearing aid without rotation, the wax guard comes out with it.—DAP



7,444,877

43.66.Ts OPTICAL WAVEGUIDE VIBRATION SENSOR FOR USE IN HEARING AID

Guann-Pyng Li *et al.*, assignors to The Regents of the University of California
4 November 2008 (Class 73/651); filed 20 August 2003

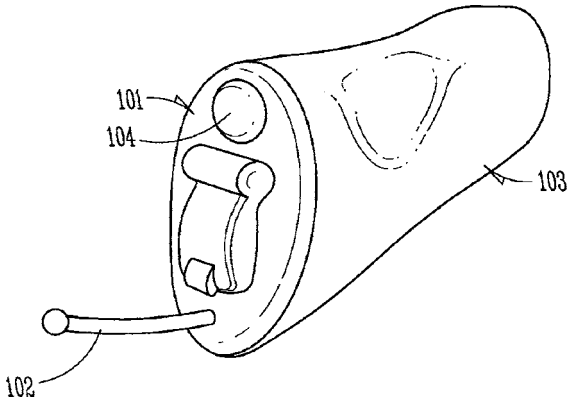
The intensity of an LED light source array output is modulated by a bank of polymeric optical waveguide cantilever resonators according to acoustic or seismic vibrations that are sensed. The resonators, which act as a quasi-Fourier analyzer, are oriented perpendicular to the direction of incoming vibration waves. A photodiode light detector array converts the resulting modulated light into electrical signals which are amplified and sent to a loudspeaker or the electrode array of a cochlear implant. The entire device is manufactured with a combination of traditional semiconductor processes and polymer microfabrication techniques.—DAP

7,446,720

43.66.Ts METHOD AND APPARATUS FOR A WIRELESS HEARING AID ANTENNA

Thomas A. Victorian and James Newton, assignors to Starkey Laboratories, Incorporated
4 November 2008 (Class 343/718); filed 19 February 2007

The insertion-removal handle for a small custom hearing aid incorporates at least a part of a coiled antenna for wireless communication.—DAP

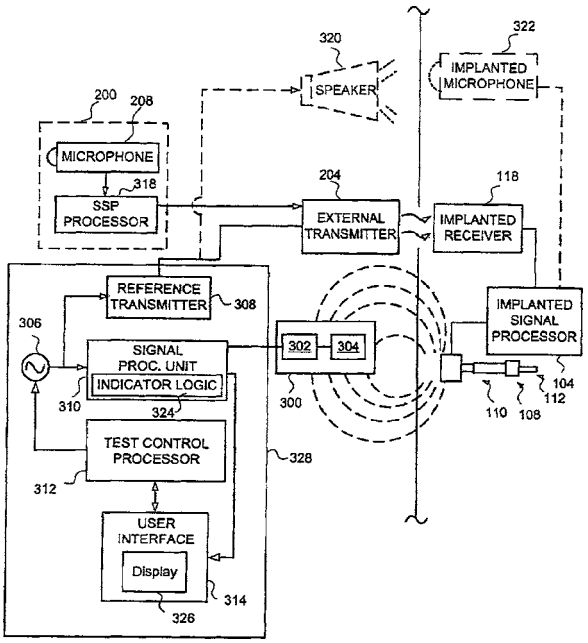


7,447,319

43.66.Ts METHOD AND SYSTEM FOR EXTERNAL ASSESSMENT OF HEARING AIDS THAT INCLUDE IMPLANTED ACTUATORS

Douglas Alan Miller and Scott Allan Miller III, assignors to Otologics, LLC
4 November 2008 (Class 381/60); filed 13 April 2006

An external test device estimates the electrical signal passing through an implanted actuator by measuring the magnetic field generated by the



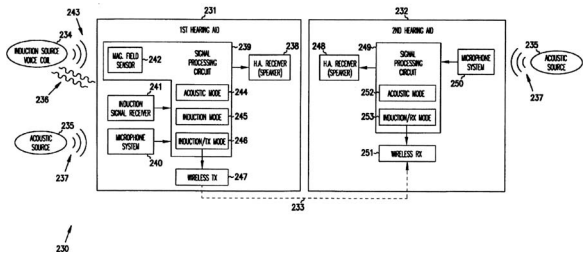
implanted transducer. This signal is an estimate of the electrical impedance of the actuator, which is indicative of the mechanical connection between the actuator and middle ear. Two inductive pickup coils in the test device, which are coaxially positioned in opposite polarity to reduce ambient electromagnetic interference, are used also to signal when the test device is properly aligned relative to the implanted actuator.—DAP

7,447,325

43.66.Ts SYSTEM AND METHOD FOR SELECTIVELY COUPLING HEARING AIDS TO ELECTROMAGNETIC SIGNALS

Mark A. Bren *et al.*, assignors to Micro Ear Technology, Incorporated
4 November 2008 (Class 381/331); filed 12 September 2002

A hearing aid normally processes acoustic signals through a microphone unless a magnetic field sensor detects the presence of a nearby inductive field from a telephone handset. If an inductive field is detected, input to the signal processing circuitry switches automatically away from the microphone to the telephone signal, and the telephone signal is also transmitted wirelessly to a second hearing aid, allowing the telephone input to be heard diotically in both ears. When the telephone handset is no longer adjacent to the ear, the input is switched automatically back to the microphone.—DAP

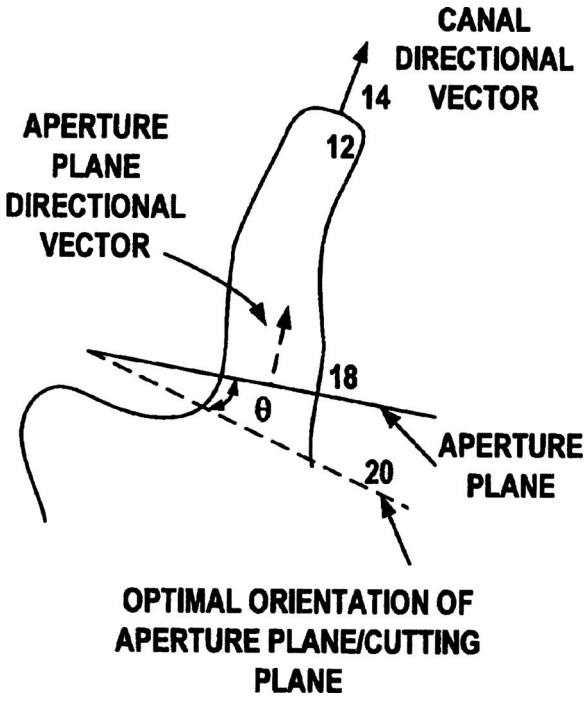


7,447,556

43.66.Ts SYSTEM COMPRISING AN AUTOMATED TOOL AND APPERTAINING METHOD FOR HEARING AID DESIGN

Fred McBagonluri *et al.*, assignors to Siemens Audiologische Technik GmbH
4 November 2008 (Class 700/98); filed 3 February 2006

A digitized geometric model is created of each of the two scanned ear impressions used for a binaural hearing aid fitting. The models are electronically detailed after a manufacturing software tool determines each ear canal direction and the locations of the first and second bends and the bony part of the ear canals. A cutting plane through the aperture of the impression is



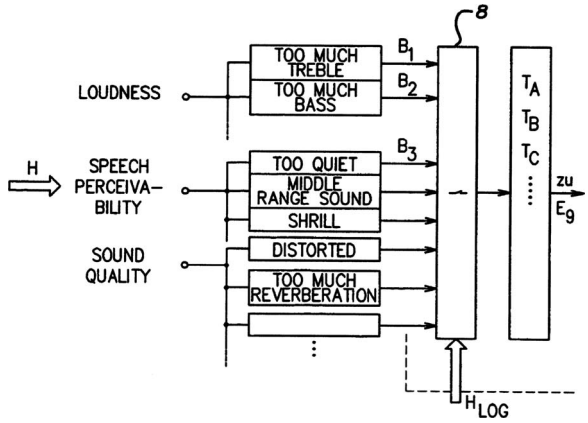
estimated so that a normal vector through the aperture plane aligns with a normal vector in the plane of the second bend of the ear canals. The method applies especially to wireless hearing aids to help ensure good ear-to-ear communication.—DAP

7,450,724

43.66.Ts HEARING AID ADJUSTMENT DEVICE

Michael Greminger, assignor to Phonak AG
11 November 2008 (Class 381/60); filed in Switzerland 17 August 1999

A stored audio test signal, presented from a computerized hearing aid fitting adjustment device, is played from a CD or other audio storage media through a loudspeaker. The wearer's subjective responses to hearing aid fitting parameter variations are gathered via a data entry device and are stored. Subsequent audio test signals are selected automatically, depending on the wearer's responses to the earlier test signals.—DAP

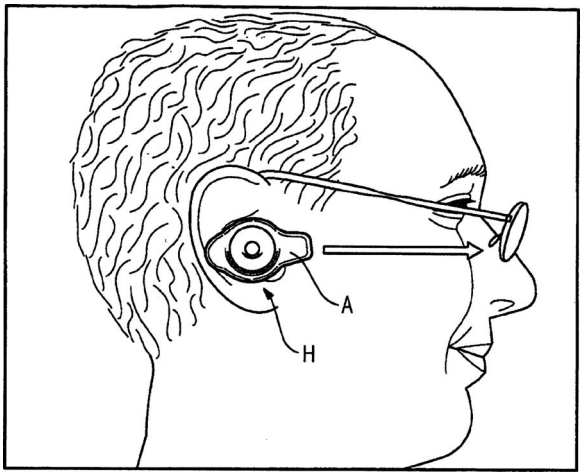


7,450,731

43.66.Ts HEARING AID DEVICE AND CORRESPONDING OPERATING METHOD

Roland Barthel, assignor to Siemens Audiologische Technik GmbH
11 November 2008 (Class 381/313); filed in Germany 4 May 2004

A rotary switch attached to a hearing aid housing selects the operating mode of a directional wireless hearing aid. Hearing aid mode is activated when the directional microphone is pointed with the rotary switching element horizontally. For communication with a telephone, the rotary switch is



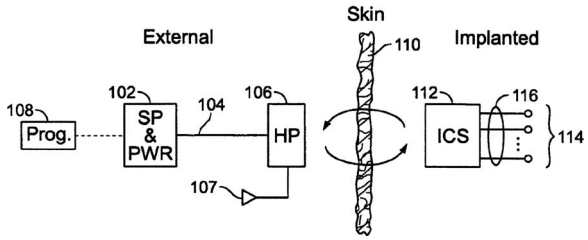
angled downwards toward the wearer's mouth, which automatically powers on and connects a transceiver input and output (e.g., Bluetooth) to the hearing aid. Telephone calls are ended when the rotary switch is returned to horizontal position. The directional microphone and transceiver are housed in a headset-like device.—DAP

7,450,994

43.66.Ts ESTIMATING FLAP THICKNESS FOR COCHLEAR IMPLANTS

Lakshmi Narayan Mishra and Michael A. Faltys, assignors to Advanced Bionics, LLC
11 November 2008 (Class 607/57); filed 16 December 2004

In order to determine an individual optimum magnet strength in the context of how well a cochlear implant microphone/processor module will be held by two magnets in place on the wearer's head behind the ear, the thickness of the skin flap is estimated across which the implanted and external magnets mutually attract. This thickness also is used to determine and adjust the inductive coupling between external transmitter and implanted receiver for through-the-skin communication. Measurements with a skin flap simulator provide reference calibration data.—DAP

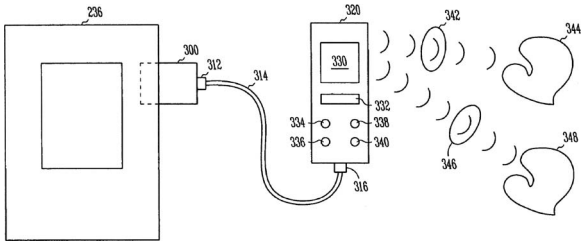


7,451,256

43.66.Ts PORTABLE SYSTEM FOR PROGRAMMING HEARING AIDS

Lawrence T. Hagen and David A. Preves, assignors to Micro Ear Technology, Incorporated
11 November 2008 (Class 710/72); filed 14 January 2005

A non-volatile or volatile memory in a portable device stores hearing aid programming software downloaded from a host computer. A first wireless or wired interface, which is connected to a processor that controls the memory, couples and decouples a hearing aid programmer selectively to a left or right hearing aid so they can be programmed. A second interface, also connected to the processor, couples and decouples the portable device to the host computer to enable downloading the software.—DAP



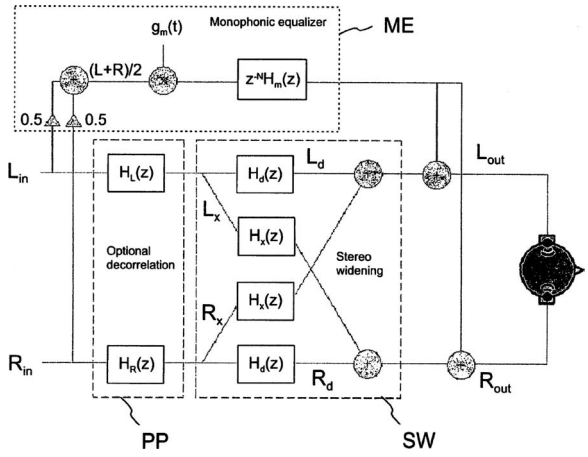
7,440,575

43.72.Gy EQUALIZATION OF THE OUTPUT IN A STEREO WIDENING NETWORK

Ole Kirkeby, assignor to Nokia Corporation
21 October 2008 (Class 381/1); filed in Finland 22 November 2002

The amplitude spectrum of the enhanced monophonic component of the left and right signals of a stereo system intended for headphone listening

is equalized for phase cancellation occurring between the direct path and crosstalk-path signals.—DAP



7,447,640

43.72.Gy ACOUSTIC SIGNAL ENCODING METHOD AND APPARATUS, ACOUSTIC SIGNAL DECODING METHOD AND APPARATUS AND RECORDING MEDIUM

Minoru Tsuji *et al.*, assignors to Sony Corporation
4 November 2008 (Class 704/503); filed in Japan 15 June 2001

The tonal components are extracted from the incoming acoustic time domain signal and are encoded separately for greater accuracy with more bits than are used to encode the remaining components in the signal.—DAP

7,438,685

43.80.Vj APPARATUS AND METHOD FOR REGISTRATION, GUIDANCE AND TARGETING OF EXTERNAL BEAM RADIATION THERAPY

Everette C. Burdette and Dana L. Deardorff, assignors to Computerized Medical Systems, Incorporated
21 October 2008 (Class 600/439); filed 1 November 2002

Real-time ultrasound images are fused with radiographic or computed tomography data to localize a region of the prostate for radiation treatment of cancer. Ultrasonic visualization uses a transrectal probe. The approach allows radiation of normal tissue to be reduced and radiation of the abnormal tissue to be increased.—RCW

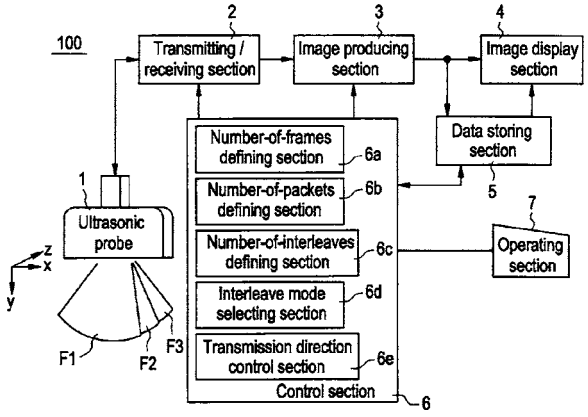
43.80.Vj ULTRASONIC PULSE TRANSMISSION METHOD AND ULTRASONIC DIAGNOSTIC APPARATUS

Tadashi Shimazaki, assignor to GE Medical Systems Global Technology Company, LLC.
11 November 2008 (Class 600/437); filed in Japan 7 November 2002

Ultrasound pulse transmissions are interleaved in different directions and processed in packets to avoid noticeable blocks of updated information on the display.—RCW



7,448,998

43.80.Vj SYNTHETICALLY FOCUSED ULTRASONIC DIAGNOSTIC IMAGING SYSTEM FOR TISSUE AND FLOW IMAGING

Brent S. Robinson, assignor to Koniklijke Philips Electronics, N.V.
11 November 2008 (Class 600/447); filed 22 February 2005

Ultrasound imaging is performed by alternating between the use of synthetic focusing and conventional beam formation. Images can be formed from harmonic-frequency echoes. Speckle in images can be reduced by combining signals from subapertures that have different beam directions. Regions of interest within images can be processed differently from other images.—RCW

7,450,746

43.80.Vj SYSTEM AND METHOD FOR CARDIAC IMAGING

Fuxing Yang *et al.*, assignors to Verathon Incorporated
11 November 2008 (Class 382/131); filed 26 July 2006

Changes in cardiac chamber volume, wall area, wall thickness, and wall mass are found using three-dimensional ultrasound data acquired at systole and diastole phases of the heart cycle.—RCW

Session 1aAA

Architectural Acoustics: Perception and Binaural Effects in Architectural Acoustics

David H. Griesinger, Chair
23 Bellevue Ave., Cambridge, MA 02140

Contributed Papers

10:00

1aAA1. The importance of the direct to reverberant ratio in the perception of distance, localization, clarity, and envelopment, Part one. David Griesinger (23 Bellevue Ave., Cambridge, MA 02140, dgriesinger@verizon.net)

The component of hall sound that travels directly from a musician to a listener carries information on both the location and distance of the sound source and is vital to both the clarity of the sound and the emotional involvement of listeners. Experiments in laboratories and a hall show that the human ability to separately perceive the direct sound in a reverberant field depends both on the time delay between the direct sound and the reverberant energy and on the direct-to-reverberant ratio (D/R). Threshold data for direct sound perception as a function of time delay and D/R will be presented, and their implications for listening room and hall design will be discussed. In large halls the delay can be long enough that the direct sound is perceptable at D/R values less than −10 dB, but in small halls the threshold becomes as high as 0 dB. Consequences for hall design include: early reflections in the best halls need not be lateral, small halls sound better with fewer early reflections (implying the use of non-shoebox shapes, absorbent stage houses, and shorter reverberation times), and in small halls electroacoustic enhancement should increase only the late reverberation.

10:15

1aAA2. The importance of the direct to reverberant ratio in the perception of distance, localization, clarity, and envelopment, Part two. David Griesinger (23 Bellevue Ave., Cambridge, MA 02140, dgriesinger@verizon.net)

Part two explores the practical consequences of the observations in part one. An experimental method will be presented for objective tests on direct sound detection that yield the threshold data in part one. The rate at which the forward integrated reverberation increases to the level of the direct sound from a short note, and the D/R from short notes or syllables is found to be of particular importance. The insensitivity of current acoustic measures to the perception of direct sound will be discussed, and new measures will be proposed that can be used with live music and speech. We will also present subjective and objective results from a series of experiments in a small hall at the Longy School of Music in Cambridge, Massachusetts. Selective addition of absorption to the stage area and to the lateral walls greatly improved subjective clarity and the balance between musicians on stage and in the hall. Electroacoustics was applied to restore the late reverberation to the value of the unmodified hall without altering the improved clarity. The changes were enthusiastically received by the participants. Audio examples from these experiments will be demonstrated.

10:30

1aAA3. Comparisons of different microphones, microphone orientation, and spacing on late lateral energy measurements. Clothilde Giacomoni, Amy Scherma, and Michelle C. Vigeant (Dept. of Mech. Eng., Acoust. Prog. and Lab., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117, vigeant@hartford.edu)

A strong correlation exists between listener envelopment and late lateral energy [J. S. Bradley and G. A. Soulodre, "Objective measures of listener envelopment," J. Acoust. Soc. Am. **98**, 2590–2597 (1995)], but limited work has been conducted on measuring this parameter in actual spaces. Measuring late lateral energy (GLL) requires a figure-of-eight pattern microphone to measure the lateral energy only, but an omnidirectional microphone is also used simultaneously to measure other common room acoustic parameters. An investigation was conducted to determine the effects of various different microphones, microphone orientation, and the spacing between the bidirectional and omnidirectional microphone on measured GLL values. Eight figure-of-eight pattern microphones were used, including both ribbon [(1) Cascade Fat Head II, (2) Royer R-121] and condenser [(2) AKG C414, (1) Neumann KM120, (2) Shure KSM44] microphones. Measurements were taken in an 80-seat lecture-style classroom, using the sine sweep method. The microphones were positioned at three different spacings from the omnidirectional microphone, in both orientations at one spacing, and two different receiver locations. In general, differences of 1–2 dB were found between all of the microphones, while minimal differences were found between the two orientations and various spacings for each microphone. Implications of the results for GLL measurements are discussed. [Work supported by University of Hartford WELFund.]

10:45

1aAA4. Effects of room reverberation time and receiver position on measured binaural room impulse responses. Lauren M. Ronsse and Lily M. Wang (Architectural Engr. Prog., Univ. of Nebraska-Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0681, lronsse@unomaha.edu)

This research examines the effects of room reverberation and receiver position on the fine detail in measured binaural room impulse responses, which can affect psychoacoustic perception in rooms such as speech segregation. Binaural room impulse responses have been gathered in four spaces with a range of shapes and reverberation times for three different receiver positions (center, 1 m from side wall, and 1 m from back wall) and three different source orientations (0, 45, and 90 deg from receiver). The directional loudspeaker is located approximately 0.5 m in front of the receiver for all conditions. Relationships between room reverberation times and measures impacting source localization such as interaural level differences and frequency-to-frequency fluctuations are analyzed. The results will determine if conclusions from previous research in this area conducted in a classroom [B.G. Shinn-Cunningham, N. Kopco, and T.J. Martin, J. Acoust. Soc. Am. **117**, 3100–3115 (2005)] are applicable to spaces with varying shapes and reverberation times.

11:00

1aAA5. Perceptual alignment of early-to-late-reverberant energy ratio and reverberation time to match visual environmental cues of a music performance. Daniel Valente and Jonas Braasch (Commun. Acoust. and Aural Architecture Res. Lab., School of Architecture, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180)

The subject of auditory-visual integration has become increasingly important with the introduction of high-resolution playback devices for on-screen object segregation. What effect does the visual location of an object

have on a participant's expectations of that object's auditory stimulus? Several studies have looked at the phenomenon in recent years, but these studies rely on static photographic images to represent the visual scene and mostly use speech signals for testing. Building on these studies, our aim is to propose a testing method using monochromatic compositing (blue-screen technique) to locate a music performance recorded in a studio in a number of virtual acoustical environments being assessed by a listener. In this study, the participant is asked to perceptually adjust two acoustical parameters, early-to-late reverberant energy ratio and reverberation time, of two music performances in five contrasting visual environments according to his or her expectations of how the room should sound given its visual appearance. This study reveals participant resiliency in the presence of forced auditory-visual mismatch; participants are able to adjust the presented acoustic modeling algorithm in a statistically similar way despite randomized starting values for the monitored parameters. Subjective results of the experiment are presented along with objective measurements for verification.

11:15

1aAA6. The impact of visual cues on perceived intimacy in an acoustic ecology. Shane A. Myrbeck, Daniel Valente, Jonas Braasch, and Bobby Gibbs (School of Architecture, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, myrbes@rpi.edu)

Crossmodal studies of the effects of visual cues on the perceived acoustics of a performance space have suggested the inextricable relationship between vision and audition. When designing a building or virtual environment for music, critical attention must be paid to a visual aesthetic to ensure a desired level of intimacy between the audience and performer. This visual aesthetic is ordinarily left entirely to the main architect or visual artist. However, given the body of research suggesting crossmodal influences on the human auditory system, it is clear that acousticians must also carefully consider the visual effects of their recommendations for acoustic improvement. The objective of this study is to establish the effects of various visual cues on audition as pertaining to intimacy in an ecological context. This study uses digital compositing (bluescreen) techniques to place a musical performance in various virtual environments, and employs real time audio-video processing to create an interactive, cross-modally immersive environment. Participant-adjusted direct-to-reverberant ratio as well as visual cues adapted from stage lighting techniques are used to establish crossmodal relationships. It is hypothesized that the ability to adjust visual cues will significantly effect subjects' perception of intimate acoustic settings.

11:30

1aAA7. Accurate timbre and localization of binaural recordings through headphones using sound pressure measurement at the eardrum. David Griesinger (23 Bellevue Ave., Cambridge, MA 02140, dgriesiner@verizon.net)

Individual HRTFs are almost universally measured with blocked or partially blocked ear canals, and individual headphone equalization is obtained in the same way. Using this method binaural reproduction without head tracking usually results in a significant alteration of timbre as well as inaccurate and/or in the head localization. The error is important—auralizations using incorrect timbre can lead to misleading conclusions. This problem was studied with the help of a dummy head that precisely models the author's pinna, ear canals, and eardrum resonance. A new type of probe microphone was also developed that allows comfortable recordings and measurements at the eardrum. Data from this equipment show that while the spatial variation in HRTFs can be captured with a blocked ear canal up to a frequency of 7 kHz, errors in headphone equalization made with a blocked canal are typically in error by more than 10 dB at midfrequencies. Eardrum measurements of HRTFs and headphones result in superior performance for an individual, and a pair of headphones correctly equalized for an average individual produces out-of-head localization for at least 50% of other individuals in our tests. Data and theory and a noninvasive method for equalization will be presented.

11:45

1aAA8. Influence of vibration on the perception of musical instruments for various stage constructions. Clemeth L. Abercrombie and Jonas Braasch (Rensselaer Polytechnic Inst., Greene Bldg. 110 8th St., Troy, NY 12180, clem@loudensound.com)

Expanding use of multisensory music presentation calls for increased knowledge of human response to audio-tactile stimulus. This presentation outlines an experiment to explore the human ability to distinguish differences in tactile signals generated by musical sources on typical floor constructions. A double bass and bass drum are used to generate binaural audio and tactile signals on various floor constructions. Vibration signals are then compared for differences in arrival time, magnitude, and frequency content. Audio and vibration signals are reproduced in different combination using a calibrated motion platform and headphones. Test participants are asked if they can identify the differences in tactile signals given a fixed audio environment. Test results are compared to those found in other studies obtained using musical signals as well as harmonic and noise signals. The importance of calibrating tactile musical signals is discussed along with the implications of the results with respect to tactile signal synthesis for multimodal music presentation.

1aABa1. The future of fish bioacoustics. Arthur N. Popper (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, apopper@umd.edu) and Richard R. Fay (Loyola Univ. of Chicago, Chicago, IL 60626)

In 1993 (Brain, Behav. Evol. **41**, 14–38 (1993)] we evaluated changes in our knowledge of fish bioacoustics since our 1973 review and proposed ten issues that still needed to be answered. This presentation asks whether we have have made progress on these issues since 1993 and poses questions for future fish bioacoustics research. Many of the topics suggested in 1993, such as sound localization mechanism, the roles of the swim bladder' and other peripheral structures in hearing, and the contributions of pressure and particle motion in hearing are still open. There are also "newer" questions not apparent in 1993, such as mechanisms of ultrasound detection and the effects of increased human-generated noise on fish. The usefulness of thinking of fish as "hearing specialists" and "hearing generalists" still needs to be assessed. Finally, an overriding question related to the significance of the diversity of fishes and diversity in ear structure, has not been resolved. Indeed, we still do not know whether the diversity found in the fish auditory periphery and CNS are convergent mechanisms to glean the same kind(s) of information about sound, or whether the variation reflects different uses of sound by different species.

1aABa2. Fish hearing and bioacoustics since 1973. Richard Fay (Parmly Hearing Inst., Loyola Univ. Chicago, IL 60626) and Arthur Popper (Univ. of Maryland, College Park, MD 20742)

In 1973, we wrote a review in *J. Acoust. Soc. Am.* that summarized our view of fish hearing and bioacoustics. This presentation looks back on the the major questions we had at the time and how the field has dealt with them, or not, to the present. Some of the issues identified included: (1) the roles of the various otolith organs for hearing; (2) lateral line function and its relation to hearing; (3) sound source localization; and (4) how sound stimulation works for fishes without obvious specializations for pressure reception. There have been major advances in these and other aspects of fish sound reception, but in every case, there are significant unanswered questions. For example, it is still controversial whether the utricle plays a role in hearing in most species, and the functional role of the lagena remains an enigma. However, we now have a much better understanding of lateral line stimulation and function, and we now understand that it is not an "accessory auditory organ," as was widely assumed initially. Many questions of sound localization are now thought to be answered theoretically, and in some cases empirically, but many critical and fundamental experiments on localization remain to be done.

8:35

1aABa3. Response of fish sound production to short-term ocean upwelling events at the LEO-15 (Long-term Ecosystem Observatory at 15 m depth) ocean observatory. David A. Mann (Coll. of Marine Sci., USF, 140 7th Ave. S., St. Petersburg, FL 33701, dmann@marine.usf.edu) and Thomas M. Grothues (Rutgers Univ., Tuckerton, NJ 08087)

Understanding factors controlling the distribution and reproduction of fishes is crucial for developing ecosystem models of fish populations. Yet these observations are difficult to make on physically relevant time and space scales. A hydrophone was used to record fish sound production associated with reproduction at the LEO-15 ocean observatory to determine the relationship between variation in fish calling behavior and oceanographic variation. Sound production was dominated by Atlantic croaker (*Micropogonias undulatus*), weakfish (*Cynoscion regalis*), and striped cusk-eel (*Ophidion marginatum*). Striped cusk-eels called with a crepuscular pattern, with a strong peak at dusk, less sound production during the night, and a lesser peak in sound production at dawn. Sciaenids called mostly at dusk and night. Nine advection events bringing colder waters to the LEO-15 site were correlated with greatly reduced levels of sound production in Atlantic croaker and weakfish on daily time scales. Our results show how ocean observatories with passive acoustics can study tightly coupled physical oceanographic influences on fish behavior on daily time scales.

8:50

1aABa4. Stereotypy and variability in the mating call of the Lusitanian toadfish, *Halobatrachus didactylus*. M. Clara P. Amorim, J. Miguel Simoes, Vitor C. Almada (Behavioural Ecology Res. Unit, I.S.P.A., Rua Jardim do Tabaco 34, 1149-041 Lisbon, Portugal), and Paulo J. Fonseca (Univ. of Lisbon, 1749-016 Lisbon, Portugal)

During the breeding season, Lusitanian toadfish males become territorial and emit a tonal advertisement call (the boatwhistle) to attract mates to their nests. We recorded 16 males in the Tagus River estuary (Portugal) during the breeding season and studied boatwhistle variability in a short (minutes) and long time scale (days). We also related boatwhistle acoustic features with male physical characteristics. The recorded males were inside closed artificial nests in groups of eight individuals. Boatwhistles showed individuality in short periods of time but some males showed significant intraindividual variability in a longer time scale. Both social interactions (number of calling males) and tide level changed significantly male calling rate and acoustic characteristics of boatwhistles. The fundamental frequency of boatwhistles (equivalent to the sonic muscle contraction frequency) and boatwhistle emission rate were correlated with male condition (somatic and lipid content). Sound emission rate was also correlated with sonic muscle index. These results suggest that different toadfish males produce distinct boatwhistles, and that they have the ability to modulate the acoustic characteristics of their sounds with the level of social interactions, which increase during rising and high tide. Moreover, boatwhistles characteristics and acoustic activity seems dependent on male condition and sonic muscle index.

1aABa5. Recordings of sonic muscle activity of the Lusitanian toadfish *Halobatrachus didactylus* during sound production. Joana M. Jordão, Maria Clara Amorim, and Paulo Fonseca (Centro de Biologia Ambiental, FCUL, Campo Grande, Lisboa, Portugal)

Male Lusitanian toadfish, *Halobatrachus didactylus*, are territorial and have a wide acoustic repertoire. The sound production apparatus consists of a pair of intrinsic large sonic muscles on the two lobes of the swimbladder. Sonic muscle activity and the variability of the vocalizations were related using electromyograms (EMGs). EMG electrodes were cirurgically implanted on the sonic muscles of several territorial males. After recovery, the subjects were released into an experimental tank with an available nest. Sonic muscle activity was registered and the vocalizations were simultaneously recorded using a hydrophone. Social context was manipulated by releasing different kinds of intruders, male(s) or female(s). This action elicited the production of boatwhistles, while grunts were generated during fish disturbance. Preliminary analysis shows that, unlike previously reported, the bilateral sonic muscles contract simultaneously during the generation of both signal types. The muscle contraction period is halved during the production of the grunt relative to the boatwhistle. The EMG period matches the sound pulse period and determines the fundamental sound frequency. [JMJ was supported by a Post-doc grant (SFRH/BPD/36510/2007).]

9:20

1aABa6. Toadfish boatwhistles also function as territorial keep-out signals. Raquel O. Vasconcelos (Dept. de Biologia Animal and Centro de Biologia Ambiental, Faculdade de Ciências, Univ. de Lisboa. Bloco C2 Campo Grande, 1749-016 Lisbon, Portugal, rfvasconcelos@fc.ul.pt), J. Miguel Simoes (Unidade de Investigacao em Eco-Etologia, 1149-041 Lisbon, Portugal), Paulo J. Fonseca (Univ. de Lisboa, 1749-016 Lisbon, Portugal), and M. Clara P. Amorim (Unidade de Investigacao em Eco-Etologia, 1149-041 Lisbon, Portugal)

Boatwhistles produced by the toadfish *Halobatrachus didactylus* seem to function as mate attraction calls during the breeding season. Recent observations, however, indicate that their emission is not restricted to this period, suggesting that boatwhistles may have other functions. The possible dual function of boatwhistles was tested by eliciting sound production from reproductive males in advertisement and territorial defence contexts. These were simulated by creating aggregations of confined nesting males in an intertidal area and by conducting territorial intrusion experiments in tanks, respectively. Furthermore, we investigated whether parental care (eggs in the nest) affected the behavioral responses of territorial males. Nesting males kept in aggregations emitted boatwhistles spontaneously for several days. The relation between calling rate and number of eggs in the nest is under analysis. During territorial intrusions, resident males prevented the entrance of intruders in their shelters by producing mostly boatwhistles. Parental males revealed higher aggression levels, exhibiting additional threatening and attack behaviors. Agonistic boatwhistles differed from the mating calls by presenting less amplitude modulation and lower dominant and fundamental frequencies. These results suggest that, apart from attracting mates, the boatwhistles of batrachoidids may also function as an active keep-out signal during territorial defence.

9:35

1aABa7. Evolution and diversity of batrachoidid vocalizations. Aaron N. Rice and Andrew H. Bass (Dept. Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853, arice@cornell.edu)

Despite the fact that toadfishes are one of the best-studied taxa for understanding fish vocal communication, vocalizations have only been recorded from a low proportion of taxa within the family. Here, we describe the diverse vocal repertoire and novel swimbladder morphology of a tropical Pacific euryhaline toadfish, *Batrachomoeus trispinosus*. *B. trispinosus* produces four classes of vocalizations: long duration hoots, grunts, grunt trains, and grunts exhibiting acoustic beats; the majority exhibiting prominent harmonic features. Calls with acoustic beats, previously unreported for any individual actinopterygian taxon and convergent with songbirds, typically had a predominant frequency around 2 kHz with a beat frequency around 300 Hz. *B. trispinosus* possesses a bilaterally divided swimbladder, forming two completely separate bladders. Grunts exhibiting beats may be produced by bilateral control of the bladders. Phylogenetic analysis based on available molecular data show that *B. trispinosus* and *Halobatrachus didactylus* represent basal lineages in the Batrachoididae, and the separated swimbladders are an independently derived feature of *B. trispinosus*. Thus, the toadfishes may possess higher levels of vocal, motor, and morphological diversity than previously appreciated, and now provide a framework for understanding integrated mechanisms underlying the evolution of acoustic novelty in fishes.

9:50

1aABa8. Sound production and hearing in coral reef butterflyfishes. Timothy C. Tricas and Kelly Boyle (Dept. of Zoology and Hawaii Inst. of Marine Biol., Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Butterflyfishes (family Chaetodontidae) exhibit a diversity of close affiliative social behaviors. All 87 species of *Chaetodon* have a laterophysic connection and extensions of the anterior horns of the swim bladder near the otic capsule, which are proposed to impart sound pressure sensitivity to the normally mechanosensitive lateral line and acceleration-sensitive inner ear. Video kinematic analyses reveal that the motor action patterns used to produce pulsed sounds vary among species. The sound production mechanisms in *Chaetodon* and *Forcipiger* do not appear to be conserved, thus sound production may have evolved independently within the family. Species with long swim bladder horns have lower AEP hearing thresholds than those without, and deflation of the horns and bladder decreases hearing sensitivity in the former group. When the laterophysic connection and swim bladder horns are physically disrupted in wild fish, movement within their territories decreases and fish pairs swim closer together. Thus, the low intensity sounds produced by butterflyfishes may favor close social behaviors that increase communication efficiency among individuals on a noisy coral reef. We are currently investigating how hydrodynamic flow fields produced during social interactions may be used for intraspecific communication during these natural behaviors.

10:25

1aABa9. Head and body kinematics of pulse sound generation and feeding in longnose butterflyfishes (Genus *Forcipiger*). Kelly S. Boyle and Timothy C. Tricas (Dept. of Zoology, Hawaii Inst. of Marine Biology, Univ. of Hawaii, 2538 McCarthy Mall, Honolulu, HI 96822, kboyle@hawaii.edu)

Both species of butterflyfish (*Chaetododntidae*) in the genus *Forcipiger* produce pulsatile sounds during territorial interactions. Sounds of one species, the forcepsfish (*F. flavissimus*), are approximately 20 ms and occur with rapid dorsoventral head motion (headbob). We performed laboratory sound production and feeding experiments with high-speed video (600 fps) to test predictions of the hypothesis that sound production in this genus results from evolutionary modification of stereotyped feeding behavior. Cranial elevation is an important component of prey capture for a variety of teleost fishes and facilitates opening of the buccal cavity and oral jaws. Studies on kinematics of feeding in *Forcipiger* by other authors revealed a minor contribution of cranial elevation compared to other fishes. Preliminary results indicate cranial elevation during headbobs involves a comparable range of motion relative to prey capture (approximately 3°–7°), but maximal elevation occurs within 12 ms during the headbob compared to 25 ms in feeding. Additionally, sound emission during feeding is weak to nonexistent. Electroymyography has revealed involvement of anterior epaxialis muscles with cranial elevation during feeding and headbob sound production. These experiments will allow further kinematic comparisons of head movements and associated muscle firing patterns during feeding and acoustic behaviors.

10:40

1aABa10. Sound production and localization in loricariid catfishes. Michael E. Smith, Patrick C. Stewart, Amanda L. Webb, and Brian D. Rogers (Dept. of Biology, Western Kentucky Univ., 1906 College Heights Blvd. #11080, Bowling Green, KY 42101, michael.smith1@wku.edu)

Catfishes of the family Loricariidae have bilobed swim bladders that are adjacent to their ears. We hypothesize that this anatomical design assists these fishes in sound localization and/or sound production. Loricariid catfishes produce short, broadband clicks via pectoral spine stridulation. To test whether these clicks can be localized, we used classical conditioning to train groups of *50 Otocinclus affinis* to come to a conspecific sound on one side of a 200-L aquarium. Four types of experiments were performed—naive, trained, test-1, and test-2. During trained trials, food and a conspecific sound stimulus were presented simultaneously, while only the sound stimulus was presented during naïve (untrained) trials. During the test-1 and test-2 trials, only the conspecific sound stimulus or a 500-Hz sound stimulus, respectively, was presented. *O. affinis* were attracted to the conspecific sound post-training, with 60–80% of the fish remaining on the speaker side of the tank during the stimulus. In summary, *O. affinis* are able to localize a conspecific sound source. Future experiments have been designed to examine the acuity of this sound localization using four speakers in a circular tank, and the effects of swim bladder deflation on the sound localization ability of *O. affinis*.

1aABa11. Bocaccio sounds in the Southern California Bight. Ana Širović (Alaska Pacific Univ., 4101 Univ. Dr., Anchorage, AK 99508, asirovic@alaskapacific.edu) and David A. Demer (Southwest Fisheries Sci. Ctr., NOAA Fisheries, La Jolla, CA 92037)

Sound production by many fish species has been studied extensively, but little is known about sound production by rockfishes (genus *Sebastes*), and only a few species have been reported to be soniferous. Passive acoustic recordings were made during 2007 and 2008 at Hubbs-SeaWorld Research Institute and Southwest Fisheries Science Center tanks containing Bocaccio (*S. paucispinis*). Sounds in tanks were recorded using preamplified hydrophones (HTI-94-SSQ) and were digitized at sample rates of 44,100 or 8000 Hz. Recordings were collected at 14 locations in the Southern California Bight (SCB) using passive acoustic moorings, AURALs, sampling at 8000 Hz from August through October 2007. Three low frequency (<900 Hz), short duration (<4 s) sounds were recorded in tanks containing only Bocaccio multiple times. One of these sounds was also commonly recorded in the SCB and is the same sound that was recorded first by Thompson off San Clemente Island in the 1960s. This sound exhibited the same diel pattern as noted by Thompson, with maximum calling at night, peaking at dusk and dawn. This long-term persistence of the same sound indicates that passive acoustic tools may be used for efficient monitoring of changes in rockfish populations over long time periods.

11:10

1aABa12. Sound source localization by the plainfin midshipman fish, *Porichthys notatus*. David Zeddies (Marine Acoust. Inc., 4100 Fairfax Dr., Arlington, VA 22203), Richard R. Fay (Loyola Univ. Chicago, Chicago, IL 60626), Peter W. Alderks (Univ. of Washington, Seattle, WA 98195), Kiel Shaub (Univ. of Washington, Seattle, WA 98195), and Joseph A. Sisneros (Univ. of Washington, Seattle, WA 98195)

Sound source localization of the plainfin midshipman fish (*Porichthys notatus*) was studied using the phonotactic response of gravid females to synthetic male advertisement calls. Playback experiments were conducted in a 3.65-m-diameter outdoor concrete tank at the UC Bodega Marine Laboratory in Bodega Bay, CA using a J-9 transducer placed near the center of the tank. The sound field in the tank was measured at 5-cm intervals using an eight-hydrophone array to measure the pressure gradients from which particle motion vectors were calculated. The acoustic measurements confirmed that the J-9 projector was operating as a monopole source. One hundred twenty-two gravid females were released 100 cm away from the center of the sound source while their behavioral responses were video taped during experiments with playback sound "On" (90 Hz tone) and sound "Off" (Controls). A total of 45 positive phonotactic responses from naïve gravid females were recorded from the 62 trials with sound "On." The phonotactic responses consisted primarily of straight to slightly curved tracks to the sound source while abrupt changes in trajectory to the sound source were rarely observed. The results confirm that fish can locate sound sources in the near field. [Work supported by NSF.]

1aABa13. Passive acoustic determination of herring size. Thomas R. Hahn, Jennifer Wylie, and Xiaojun Chen (Rosenstiel School of Marine and Atmospheric Sci. Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149)

Over the last decade, acoustic signatures of a variety of fishes have been recorded and analyzed. More recently, these vocalizations have been used to passively detect aggregations of fish, demonstrating the potential to supplement and enhance traditional active acoustic surveys. Based on previously published work on acoustic emissions of herring, this paper discusses the possibility of not merely passively detecting absence or presence of aggregations of herring but, additionally, assessing abundance and size. Theoretical considerations as well as data collected in Prince William Sound, Alaska, on Pacific herring (*Clupea Pallasii*) are presented.

Invited Paper

11:40

1aABa14. Assessment of cumulative sound exposure level as criterion for exposure of fish to impulsive sound. Michele B. Halvorsen (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, mb_halvorsen@yahoo.com), Thomas Carlson (Pacific Northwest Natl. Labs., Battelle, Portland, OR 97204), and Arthur N. Popper (Univ. of Maryland, College Park, MD 20742)

Acceptable exposure of fish to pile driving impulsive sound is currently determined by cumulative sound exposure level (SEL). The implicit assumption in this regulatory approach is that cumulative SEL, regardless of how reached, is one of the critical measures of sound exposure for fish health. We are testing this assumption by exposing juvenile Chinook salmon to sequences of impulsive sound differing in individual impulse SEL and number of impulses, but with the same cumulative SEL value. Test fish are exposed in a unique device that permits accurate simulative of impulsive pile driving sound. Following exposure, the hearing of test fish is evaluated using auditory evoked potential methods followed by necropsy for assessment of barotrauma. The null hypotheses we are testing is that the probability of hearing threshold shift $\geqslant$6 dB and the probability of barotrauma mortal injury is the same for all cumulative SEL exposures. The results of these tests will determine the experimental design of additional tests to derive criteria for exposure of fish to pile driving sound. [Work supported by National Cooperative Highway Research Program (NCHRP) and Minerals Management Service (MMS).]

Session 1aABb

Animal Bioacoustics: An Integration of Bioacoustics, Neuronal Responses, and Behavior I

1aABb1. Spatial aspects of acoustic processing in complex environments. H. Steven Colburn, Barbara Shinn-Cunningham, and Kamal Sen (Hearing Res. Ctr., Boston Univ., 44 Cummington St., Boston, MA 02215, colburn@bu.edu)

From the perspective of acoustical signal processing, it is a challenge to analyze a complex sound environment and segregate the acoustic mixture into individual sources, each with its own spatial characteristics and reverberation pattern. However, auditory systems perform this perceptually critical task with impressive ease. This talk will review how acoustical array processors work to separate sound sources. We then consider what most vertebrates, who have two point receivers separated in space, can accomplish by combining the signals that reach their two ears. The nature of the information available to bird and mammalian auditory systems is briefly reviewed, and the computational approaches these systems take to separating sound sources is assessed, including the logic of processing sound within narrow frequency channels over brief time epochs (rather than, e.g., undertaking broadband analysis). Some observations about the ability of classical binaural processing models to implement earlier stages of processing for these complex environments will be discussed. Finally, performance of human and zebra-finch subjects in tasks requiring judgments about individual sources embedded in complex sound mixtures will be considered in the context of physiologically motivated processing schemes. [Work supported by NIDCD: DC00100 (Colburn), DC05778 (Shinn-Cunningham), and DC07610 (Sen).]

8:30

1aABb2. Neural basis of spatial hearing in reverberant environments. Sasha Devore (Eaton Peabody Lab., Boston, MA 02114 and Harvard-MIT Div. of Health Sci. and Technol., Cambridge, MA 02139), Antje Ihlefeld, and Barbara Shinn-Cunningham (Boston Univ., Boston, MA 02215), and Bertrand Delgutte (Eaton Peabody Lab., Boston, MA 02114)

In reverberant environments, acoustic reflections interfere with the direct wavefront reaching a listener's ears, distorting the spatial cues for sound localization. Yet, human listeners have little difficulty localizing sounds in everyday settings. Our research aims to elucidate the neural basis of spatial hearing in reverberant environments. Using a virtual acoustic space (VAS) technique, we investigated the effects of reverberation on the directional sensitivity of binaural neurons in the inferior colliculus (IC) of anesthetized cats and awake rabbits, focusing on neurons sensitive to interaural time differences. Consistent with the buildup of reverberant energy in a sound stimulus, we find that reverberation increasingly degrades the directional sensitivity of single neurons over time, although the amount of degradation depends on the characteristic frequency and the type of binaural cues available. The neurophysiological data can account for results from recent human psychophysical studies of spatial hearing in reverberant environments. In particular, we show how a population rate model for decoding the observed midbrain responses predicts the main trends in human lateralization performance, suggesting a subcortical origin for robust sound localization in reverberant environments. [Work supported by National Institutes of Health (NIH) Grant Nos. R01 DC002258 (BD), P30 DC005209 (BD), and R01 DC05778-02 (BGSC). 8:55

1aABb3. Comparative studies of the cocktail party problem using birdsong. Micheal L. Dent (B76 Park Hall, Dept. of Psych., Univ. at Buffalo, SUNY, Buffalo, NY 14260), Barbara G. Shinn-Cunningham, and Kamal Sen (Boston Univ., Boston, MA 02215)

Many animals are adept at identifying communication calls in the presence of different masking sounds, much like humans navigating a cocktail party. In order to compare human and avian abilities in analyzing signals in complex acoustic mixtures, we measured identification of birdsong by humans and birds in the presence of different maskers and compared results to physiological recordings in zebra finches. In humans, spectrotemporal similarity of targets and maskers causes difficulties in segregating and selecting the target out of the sound mixture; however, for similar targets and maskers, spatial separation alleviates this interference. Field L recordings in finches reveal differences in the forms of neural interference caused by the various masker types, consistent with human behavior. However, avian identification performance is similar for the different maskers. Moreover, spatial separation of target and masker causes little improvement in avian target identification unless target and masker have distinct temporal envelopes. When target and masker envelopes differ, avian identification performance improves significantly, regardless of masker type. These experiments demonstrate that both birds and humans can segregate communication signals from a sound mixture, but suggest that the acoustic attributes that the two species use to solve the cocktail party problem differ.

9:20

1aABb4. Localization and identification of concurrent sounds in the owl's auditory space map. Clifford H. Keller and Terry T. Takahashi (Inst. of Neurosci., Univ. of Oregon, Eugene, OR 97403)

In nature, sounds from multiple sources sum at the eardrums, generating complex cues for sound localization and identification. In this clutter, the auditory system must determine "what is where." We examined this process in the auditory space map of the barn owl's inferior colliculus using two spatially separated sources simultaneously emitting uncorrelated noises, which were uniquely identified by different frequencies of sinusoidal amplitude modulation. The neurons responded when either source was placed within the receptive field, suggesting two clearly segregated foci of activity at appropriate loci on the space map. The spike trains were locked strongly to the AM of the source within the receptive field, while the other source had minimal influence. Two sources AMed at the same rate were successfully resolved, suggesting that source separation is based on differences of fine structure. The spike rate and synchrony were stronger for whichever source had the stronger average binaural level. A computational model showed that neuronal activity was largely proportional to the degree of matching between the momentary binaural cues and the neuron's preferred values. Individual neurons respond to and synchronize with sources in their receptive field if there are frequencies having an average binaural level-advantage over a second source. [NIH-DC003925.]

9:45

1aABb5. Localization of amplitude modulated sounds and their echoes in the barn owl. Brian S. Nelson and Terry T. Takahashi (Inst. of Neurosci., Univ. of Oregon, Eugene, OR 97403)

Echoes that arrive after short delays are not perceived as events separate from sounds arriving directly from an active source, a phenomenon known as localization dominance. Studies have focused on the time-advantage at the onset of an echo/direct-sound pair to explain localization dominance. The head-saccades of barn owls and the responses of neurons in their auditory space maps were measured when sound pairs were gated simultaneously, so that the lead/lag relationship could be discerned only from the ongoing features of the envelopes. The owls behaved as though they experienced localization dominance at short delays, but only if the sounds were deeply amplitude modulated, suggesting the importance of the ongoing envelope. Correspondingly, neurons in the space map fired preferentially to the leading sound, thus paralleling the behavior, but again, deep amplitude modulations were necessary. Analyses of waveforms at the ears suggest that the acoustic features that caused the space map neurons to fire were more abundant for the leading than for the lagging stimuli, thus explaining localization dominance without the need for explicit echo-suppression circuitry. 1aABb6. Coding of sound features in primary and secondary auditory areas of songbirds. Frederic E. Theunissen (Dept. of Psych., Univ. of California Berkeley, 3210 Tolman Hall, Berkeley, CA 94720)

We have used a combination of neuroethological and classical auditory neurophysiological approaches to study how behaviorally relevant sounds are processed in the avian auditory system. One of the contributions of the neuroethological approach has been the discovery of highly specific auditory neurons that appear to be specialized for detecting very specific behaviorally relevant sounds. On the other hand, many auditory neurons recorded in the auditory system of nonspecialists do not exhibit such specificity. At the same time, animals and humans hear and process a large space of sounds and are able to categorize these in much broader perceptual terms, describing them in terms of their pitch, timbre, and rhythm. By systematic analyzing neural responses to song in the ascending avian auditory system and relating receptive fields to the statistics of natural sounds, we have shown that these two approaches can be unified: we found that the spectrotemporal receptive fields of auditory neurons tile a subset of the acoustical space that is particular important for natural sounds. In addition, we found that neurons could be classified into functional clusters. Neurons in different clusters were sensitive to different song features and, we will argue, are involved in mediating distinct perceptual attributes.

10:55

1aABb7. Sound localization acuity in the cat: Integrating data from psychophysical, physiological, and acoustical cue studies. Daniel J Tollin (Dept. of Physio., Univ. of Colorado Med. Sch., 12800 E. 19th Ave., Aurora, CO 80045, daniel.tollin@uchsc.edu)

The minimum audible angle (MAA), a psychophysical measure of auditory spatial acuity, is the smallest angle separating the locations of two sound sources, presented sequentially, that can be reliably discriminated. In humans and cats, the MAA for tone stimuli depends jointly on source azimuth and tone frequency. It is hypothesized that this results from the spatial and frequency dependence of the acoustical cues to location. Thus, for high-frequency ($>$1.5 kHz) stimuli, where the predominant cue for source azimuth is the interaural level difference (ILD), the MAA would be determined by the spatial and frequency dependence of the ILD cue. However, for this to be true, the underlying neural acuity for ILD cues must be frequency independent. Here the hypothesis was tested that the frequency dependence of the psychophysical MAA in cats can be explained by the frequency dependence of the ILD cue with source azimuth and the frequency independence of the acuity of neurons (or neural MAA) in the lateral superior olive (LSO) to ILDs. The LSO is a brainstem structure responsible for the initial encoding ILDs. The data from acoustical cue measurements and physiological and psychophysical studies in cats support this hypothesis. 11:20

1aABb8. Some brain mechanisms for auditory scene analysis. John C. Middlebrooks, Chen-Chung Lee (Dept. of Otolaryngol., Univ. of California, Irvine, CA 92697-5310, j.midd@uci.edu), and Ewan A. Macpherson (Univ. of Western Ontario, London, ON Canada, N6G 1H1)

Detection and discrimination of sounds in complex auditory environments is facilitated by knowledge of the locations of sound sources and by spatial separation of signals and maskers. In studies of the spatial sensitivity of auditory cortical neurons in anesthetized cats, we find that location-dependent variation in temporal spike patterns can signal sound-source locations throughout up to 360 deg of space. In awake cats, spatial receptive fields can be similarly broad, although cortical neurons show a greater diversity of temporal patterns than is seen in anesthetized conditions. Our recent results demonstrate that spatial tuning tends to sharpen when a cat is engaged in an auditory task, compared to idle conditions, and that tuning can sharpen even further when the task involves sound localization. In human psychophysical studies, spatial hearing permits perceptual "stream segregation" of multiple temporally interleaved sequences of sounds. In parallel studies of the auditory cortex in anesthetized cats, we find that interleaved sound sequences, in configurations that likely would be segregated perceptually, result in activation of discrete cortical neuron populations. The spatial acuity for this neuronal stream segregation is substantially sharper than has been observed in studies of cortical representation of single sound sources.

Acoustical Oceanography, Underwater Acoustics, and Signal Processing in Acoustics: Temporal and Spatial Field Coherence Applied to Ocean Sensing: Measurement, Theory, and Modeling I

Timothy F. Duda, Chair
Woods Hole Oceanographic Inst., Woods Hole, MA 02543-1053

Chair's Introduction—10:25

Invited Papers

10:30

1aAO1. On the use of broadband acoustic scattering techniques for observing physical and biological scattering features in the ocean. Andone Lavery (Woods Hole Oceanograph. Inst., Dept. of Appl. Ocean Phys. and Eng., MS11, Woods Hole, MA 02543)

Broadband acoustic scattering techniques, and associated signal processing techniques, are emerging as a powerful tool for the remote sensing of physical and biological scattering features in the ocean. These techniques allow (1) the frequency spectrum of oceanic scatterers to be measured, thereby resulting in enhanced classification and quantification potential relative to more traditional single-frequency scattering techniques, and (2) increased spatial resolution resulting in high-resolution images of oceanic scattering features, obtained through use of pulse compression signal processing techniques that exploit the broadband content of the signal. In this presentation, broadband processing techniques are discussed and results from laboratory and field measurements of broadband acoustic scattering from both physical and biological scatterers, spanning the frequency range from 100–600 kHz, are presented. Controlled laboratory broadband scattering measurements allow coherent ping-to-ping analysis to be performed as well as individual scattering features to be determined. The laboratory approaches are then expanded into the field to investigate physical and biological scattering features in the ocean on relevant temporal and spatial scales. Examples of broadband field measurements are presented from recent field experiments, and include scattering from nonlinear internal waves, zooplankton, turbulent oceanic microstructure, salinity microstructure in rivers, and bubbles.

10:50

1aAO2. Coherence in long-range deep ocean propagation. Michael G. Brown, Francisco J. Beron-Vera (RSMAS, Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149), Ilya A. Udovydchenkov, and Irina I. Rypina (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Acoustic wavefield structure, stability, and coherence properties in deep ocean environments will be discussed. Properties of transient wavefields will be emphasized. Observations, simulations, and some theoretical considerations will be presented. Some important experimental milestones, beginning approximately in 1979, will be noted. It will be argued that the last 30 years have been characterized by a number of pleasant surprises relating to the stability and coherence of transient wavefields in deep ocean environments. [Work supported by ONR.]

11:10

1aAO3. Transverse coherence lengths, processing limits and implications. William M. Carey (Dept. of Mech. Eng., College of Eng., Boston Univ., Boston, MA 02215)

How does scattering in sound channels (deep and shallow waters) limit coherent array processing or what is the limitation of resolution in terms of the mutual coherence function and its temporal and spatial coherence lengths? The resolution of an array is limited by the mutual coherence function; but estimation in a partially coherent noise background with a multipath signal is difficult using the normalized cross power spectral density, magnitude squared coherence, because of the properties of both signals and noise. The measurement of magnitude-squared coherence is a poor statistical estimator since it is a function of the signal-to-noise ratio and multipath interference with large confidence bounds. Array gain measurements and a wave-theoretic coherence functional form can provide estimates of temporal and spatial coherence lengths defined as the 1/*e* value of this function. This paper reviews single path coherence results and those derived from array measurements over the low- to mid-frequency range in deep and shallow water. Representative coherence lengths are discussed in terms of boundary interactions, internal wave scattering, and coastal mesoscale features. The implications for arrays used to estimate geoacoustic properties, mammal locations, and scattering from the boundaries are presented.

11:30

1aAO4. Comparing the effects of internal waves, mode coupling, and change in bandwidth of a radiated signal on low mode energy propagation. Natalie Grigorieva, Gregory Fridman (Dept. of Appl. Math., St. Petersburg State Marine Tech. Univ., 3 Lotsmanskaya Str., St. Petersburg 190008, Russia, nsgrig@natalie.spb.su), James Mercer, Rex Andrew, Michael Wolfson (Univ. of Washington, Seattle, WA 98105), Bruce Howe (Univ. of Hawaii, Honolulu, HI 96822), and John Colosi (Naval Postgrad. School, Monterey, CA 93943)

Wideband signal propagation modeling is carried out for the actual space-time configuration realized during the long-range ocean acoustic propagation experiment (LOAPEX) conducted in the North Pacific in 2004. In particular, the experiment used the Kauai transmit station that was located at a range of 2432 km from a vertical line array (VLA), M-sequence at 75 Hz, and a source depth of 800 m close to the depth of a sound-channel axis. Two sound speed profiles were utilized to get the smooth two-dimensional sound speed field. The first one was the profile obtained from the conductivity-temperature-depth (CTD) measurements at the Kauai station. The second sound speed profile from the VLA location was based on a CTD cast taken at station T50 (50 km from the VLA). To take into account the acoustic fluctuations due to internal waves, the buoyancy frequency profile based on LOAPEX CTD measurements made at station T50 was used. For simulations, 512 values of the horizontal wave number were utilized with the maximal mode number equal to 50. The low modes intensity received by the hydrophones close to the sound channel axis at the VLA is compared with the results of simulations. [Work supported by ONR and ONR Global.]

11:45

1aAO5. On the time-mean state of ocean models and the properties of long-range acoustics. Brian D. Dushaw (Appl. Phys. Lab., Univ. of Washington, 1013 N.E. 40th St., Seattle, WA 98105, dushaw@apl.washington.edu), Matthew A. Dzieciuch, and Peter F. Worcester (Univ. of California at San Diego, La Jolla, CA 92093-0225)

Global and regional circulation models of the ocean have the horizontal and vertical resolution required for realistic simulation of long-range acoustic propagation. These simulations offer a novel test of model accuracy, because acoustic propagation is sensitive to the vertical gradients of sound speed in the models and acoustic arrival patterns are known to have stable and universal properties. The travel time and dispersal of an arrival pattern are examples of such properties. Acoustic receptions on three long vertical line arrays from basin-scale transmissions in the North Pacific in 1996 and 1998 are used to test the acoustical properties of the time-mean state of several ocean models. The NOAA World Ocean Atlas, a global representation of the "average" ocean, yields acoustic predictions whose patterns closely match the observations, but not all ocean models accurately represent oceanic sound speed properties. Acoustical tests of a model do not necessarily require actual data, because basic acoustical properties may be derived from the World Ocean Atlas.

1aNS1. Research into the human response to vibration in residential environments. David C. Waddington, Andrew T. Moorhouse (Acoust. Res. Ctr., Univ. of Salford, Salford M5 4WT, UK, d.c.waddington@salford.ac.uk), and Phil A. Brown (Univ. of Salford, Salford M5 4WT, UK)

This paper describes work being carried out at the Univ. of Salford to develop a method by which human annoyance to vibration in residential environments can be assessed. The objective of this study is to yield a robust relationship between vibration exposure and human response; therefore, providing a reliable basis for the development of standards and guidance for the assessment of vibration in residential buildings. The vibration sources to be considered are those affecting residents that are outside their control, such as construction, road, and rail activities. The protocol involves the measurement of vibration outside and inside residences and a social study questionnaire based on face-to-face interviews with adults. The project is expected to capture a wide-scale study of 2000 case studies, and examples of early field measurements and results are presented. This work is likely to be of interest to planners and practitioners involved in the design of buildings and environmental health officers involved in the assessment of vibration complaints. [Work funded by the Dept. for Environment, Food, and Rural Affairs (Defra) UK.]

8:15

1aNS2. Comparison of tapping machines for impact insulation class (IIC) measurement accuracy. Aaron M. Farbo (Cavanaugh Tocci Assoc., 327F Boston Post Rd., Sudbury, MA 01776, afarbo@cavtocci.com)

This study compares tapping machines from different manufacturers and age for impact insulation class (IIC) measurement accuracy. In addition to the IIC measurement accuracy, the study also compares the impact frequency and effect of different impact surfaces (steel and rubber). The tapping machines were tested in a model condo unit in accordance with impact insulation class testing standards ASTM E1007-04 and ISO 140-6. These standards clearly state the impact frequency and type of impact surface to be used (hardened steel). Previous testing standards did not specify the material type for impact surfaces and many older tapping machines included both steel and rubber feet. The results of this study will be presented to show the effect of age, impact frequency, and impact surface on the resulting IIC measurement for the tapping machines.

8:30

1aNS3. Investigation of damping materials for heavy-weight floor impact sounds in concrete structures. Jin Yong Jeon and Seung Yup Yoo (Dept. of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea)

Multi-layers of surface materials were investigated for the isolation of floor impact sounds in concrete structures. Both resilient and viscoelastic damping materials were tested according to the modified method of ANSI S2.22 for calculating elastic modulus and loss factor. The dynamic characteristics of the concrete structures subjected to heavy-weight floor impacts were modeled by the compressional damping theory, using sandwiched beams. Results show that the viscoelastic damping materials are more effective than the resilient materials. In field measurements, the insertion loss of the heavy-weight impact sounds, which was mainly affected by the modal characteristics at low frequencies, was higher in floor structures with the damping materials.

8:45

1aNS4. Ceiling details in wood frame construction. James Keene (Keene Bldg. Products, 5910 Landerbrook Dr., Mayfield Hts., OH 44124, jrk @keenebuilding.com)

In multifamily projects, the details of floor/ceiling installation have been a known and constant problem. Errors when installing noise control elements have caused lots of failures. Specifically, gypsum board ceiling and wall isolation with caulking is often short circuited when the gaps are incorrect. This paper details a new method of installing gypsum board ceilings and walls to provide a more easily inspected and detail assured isolation system. The system applies a similar system for ceiling installation as has become the standard in floor perimeter isolation. An "L" shaped fabric strip is installed around the perimeter of the room to create the gaps that today are created by the contractor in the field. The paper and presentation will review the methodolgy of the system and the laboratory test results that show performace compared to the present approach. The fire rated test performance will also be summarized. Since this is multifamily, the economic savings of this system are also presented.

9:00

1aNS5. Comparison of apparent field sound transmission class (AFSTC) and outdoor indoor transmission class (OITC) as applied to modular classroom design and field analysis. Norman H. Philipp and Lily M. Wang (Architectural Engr. Prog., Peter Kiewit Inst., Univ. of Nebraska-Lincoln, 1110 S. 67th St., Omaha, NE 68182-0681, nphilipp@mail.unomaha.edu)

Regarding the drafted addendum for ANSI S12.60-2002 Standard on Classroom Acoustics Guideline, it was recently proposed to utilize Outdoor Indoor Transmission Class as a means of rating modular classroom exterior envelope noise reduction performance. This paper provides a comparative analysis of Outdoor Indoor Transmission Class with the Apparent Field Sound Transmission Class. Measurements were conducted in modular classrooms currently in use by the Omaha Public School District in Omaha, NE, along with newer construction units prior to installation on-site. Limitations to both measurement methodologies are discussed in relation to their source noise spectrums.

9:15

1aNS6. Acoustical analysis of an indoor test facility for a 30-mm Gatling gun. Matthew D. Shaw and Kent L. Gee (Dept. of Phys., Brigham Young Univ., N283 ESC, Provo, UT 84602, mdshaw16@gmail.com)

The Air Force commissioned a construction and engineering company to build an indoor test facility for the GAU-8 Avenger at Hill Air Force Base in Layton, UT. The blast pressures from this 30-mm Gatling gun, however, are large enough to cause spalling of the concrete walls over time. The facility is being designed and constructed to last for 20 yrs, requiring several acoustical treatments. The pressures from the gun were measured outdoors, with maximum pressures exceeding 3000 Pa (163 dB) at a distance of 30 ft (9.1 m). A computer model of the room was designed using EASE, and impulse responses were generated at several positions. These impulse responses were convolved with an ideal blast wave pulse train to mimic the sound of the gun in the room. From these data and results collected from preliminary tests in the range, recommendations have been provided as to placement and types of necessary treatments. [Work supported by HHI Corporation.]

9:30

1aNS7. The effective bandwidth of the enhanced transmission loss across a wall with Helmholtz resonators. Joel Garrelick (Appl. Physical Sci., Inc., 49 Waltham St., Lexington, MA 02421, jgarrelick@aphysci.com)

It is long known that the introduction of Helmholtz resonators can enhance the transmission loss of a wall in the vicinity of their natural frequencies. Resonance is typically achieved by creating open-mouthed cavities in the wall. The effective bandwidth of the phenomenon is a key factor in its practical utility. It is dependent on the internal resonator resistance as well as the *in situ* external acoustic impedance at the cavity mouth. This paper is an analysis of the bandwidth for a variety of resonator configurations, including cavities with septa and differing volumes. The mathematical model, driven by a normally incident plane wave, will treat the wall as rigid but moveable, and the cavities will be infinitely periodic arrays. Influences of wall impedance, resonator resistance, cavity array spacing and natural frequencies will be described. In addition, the potential for minimizing the deleterious effects of diffraction between neighboring cavities by placing the cavity mouths on both sides of the wall will be assessed.

9:45

1aNS8. Vertical profile of community noise in high-rise built environment. Alam Sheikh Mahbub, Lee Siew Eang (Dept. of Bldg., Natl. Univ. of Singapore, Singapore), and W. L. H. Johnny (Housing and Development Board)

High-rise public housing apartments in Singapore are often subjected to different types of community noise sources in close proximity. Community noise in housing estates comprises noise sources such as food center noise, children playground noise, soccer court noise, basketball court noise, waste disposal truck noise, etc. It was found as one of the major noise source categories in residential environment. With the enhanced performance quality in many aspects of public housing in recent years, it is imperative that the acoustics performance of the apartments can be enhanced to match overall quality of public housing environment through appropriate characterization of these noise sources. A scientific and reliable approach for characterizing noise propagation from these sources is vital in the implementation of projects. Software modeling and simulation were carried out to study noise propagation characteristics of five types of community noise sources. Five 16-storey residential buildings were investigated with noise measurement from these sources, conducted on each level of the buildings. The predicted results were verified with field measured data. This study observes that noise level from these sources reduces between 3.7 and 12.8 dBA at a height between 43 and 46.5 m above the ground with the increase in building height.

10:00

1aNS9. Prediction of the reverberation times and sound pressure levels in town streets. Kai Ming Li (Ray W. Herrick Lab., Purdue Univ., 140 S. Martin Jischke Dr., W. Lafayette, IN 47907-2031) and Chenly Y. C. Lai (Hong Kong Polytech. Univ., Kowloon, Hong Kong)

The current study was devoted to investigate the propagation of noise along a town street where building façades and road surfaces form a street canyon. An energy based approach was used to estimate reverberation times and the sound pressure levels due to a point source located along the town street. An image source method was developed to compute sound energy in this semienclosed space. However, the image source model can be simplified leading to the numerical solutions expressed in an integral formulation. The absorption coefficients of the boundary surfaces and the air absorption factor can be included in the present analysis. The integral can further be evaluated analytically with the sound pressure levels expressed in a closed form solution. Both outdoor full scale measurements and indoor scale model experiments were conducted and compared with the computed results. The numerical results due to the proposed formula not only agree well with the experimental measurements but were also in accord with the published data.

10:15—10:30 Break

10:30

1aNS10. Modeling sound transmission through large rectangular openings in a damped enclosure. Buye Xu and Scott D. Sommerfeldt (Dept. of Phys. and Astron., Brigham Young Univ., Provo, UT 84602)

The understanding of sound transmission through large rectangular openings in a damped enclosure plays an important role in designing noise reduction solutions where enclosures and openings are often involved. A complete solution for this problem should consider diffraction, coupling between exterior and interior sound fields, and damped boundaries, each of which is a challenging task. A theoretical model will be introduced in this paper that deals with all these phenomena and, in addition, also considers the effects of the direct sound field in the solution. Numerical simulations and experimental results will be presented and analyzed.

10:45

1aNS11. Prediction of sound propagation in rectangular ducts by a ray-tracing model with phase. Behrooz Yousefzadeh and Murray Hodgson (Acoust. and Noise Res. Group, Univ. of British Columbia, 3rd floor, 2206 East Mall, Vancouver, BC V6T 1Z3, Canada, behroozy@interchange.ubc.ca)

A ray-tracing model which includes phase changes due to distance traveled and surface reflection has previously been developed for predicting sound field in rectangular rooms. Including phase has removed the limitation associated with energy-based models, that room dimensions must be larger than the sound wavelength. The model has been applied to a rectangular room with dimensions not large compared to the wavelength. The room dimensions are that of a real-world ventilation duct, with the boundary conditions idealized as a point source at one end and anechoic termination at the other end. Predictions have been made of the pressure field inside the duct and the results have been compared with analytical solutions. The model is found to be capable of predicting the modal characteristics of the duct.

11:00

1aNS12. Assessing the origin of tonal sound emanating from refrigerant piping in the historic Mattress Factory project at the University of Washington Tacoma Campus. Elizabeth Bogomolov and Julie A. Wiebusch (The Greenbusch Group, Inc., 1900 West Nickerson St., Ste. 201, Seattle, Washington 98119)

UW Tacoma campus is located in the Union Depot Warehouse National Historic District. Siting the campus in this area and renovating rather than demolishing some of the remaining historic, industrial buildings as campus classrooms and offices has stimulated the city's urban renewal. Mattress Factory was one of these historic structures, regulated by the Tacoma Landmarks Commission. The new chilled water system in Mattress Factory consists of two 70-ton chillers located in a mechanical room on the lowest level of the four-story building. Air-cooled condensing units, located on the roof, connect to the chiller compressors. The refrigerant piping was required to be incorporated within the building envelope so as not to alter the appearance of the historic exterior. The piping path between the compressors and condensers was somewhat circuitous due to existing structural elements. A discernable, tonal whine was exhibited in spaces on the second and third floors when the chiller was running. The sound corresponded with the location of the refrigerant piping within the wall cavity, with the dominant sound level at the second floor in the area of an existing beam. This paper outlines the process of identifying the cause of the sound and the ultimate mitigation treatment.

11:15

1aNS13. Noise from rooftop mechanical equipment in residential buildings. Anthony Nash (Charles M. Salter Assoc., 130 Sutter St., Ste. 500, San Francisco, CA 94104, anthony.nash@cmsalter.com)

Community planning codes restrict building heights with the intent that the building is in general conformance with the character of the neighborhood's built environment. Although these codes prescribe the maximum height, they do permit a limited amount of rooftop space to be used for elevator penthouses, exhaust fans, cooling towers, and miscellaneous other rotating mechanical equipment. Thus, the stage is set for a potential acoustical conflict between the need for building mechanical services on the rooftop above and the expectations of people occupying residences below (ironically, the most expensive space in the building). This paper discusses a number of design and retrofit projects involving rooftop equipment installations over noise-sensitive spaces. The cases include rooftop equipment such as small corridor exhaust fans, rotary chillers, traction elevators, etc. The paper describes both the noise generating mechanisms and transmission paths as well as techniques for mitigating mechanical equipment noise into occupied spaces.

11:30

1aNS14. Active feedback control of broadband noise from a small axial fan. Cole V. Duke, Scott D. Sommerfeldt, and Kent L. Gee (Dept. of Phys. and Astron., Brigham Young Univ., N283 ESC, Provo, UT 84602)

In the past, significant progress has been made in actively controlling the tonal noise of axial cooling fans. Current work focuses on the control of broadband fan noise, which presents different challenges. Because the broadband noise is not deterministic, a feedback system will be used, and the total system delay must be reduced as much as possible. To ensure stability of the closed-loop control system, the phase and magnitude characteristics of the filter must be chosen to produce attenuation in the target frequency band without augmenting the noise outside the band. A practical analog feedback controller will be presented, and results will be shown for a single input single output control system, as well as a configuration using multiple independent control systems.

11:45

1aNS15. The prediction of airflow generated noise in ventilation system bends. David C. Waddington (Acoust. Res. Ctr., Univ. of Salford, Salford M5 4WT, UK, d.c.waddington@salford.ac.uk) and David J. Oldham (Univ. of Liverpool, Liverpool L69 3BX, UK)

This paper describes recent work on the prediction of airflow generated noise in ducts based upon pressure loss characteristics. Strategies employed to reduce turbulence by smoothing the flow around a bend include the use of turning vanes, and a large radius of curvature with the associated use of splitters. The effect of these strategies on the regenerated noise is examined for a range of common bends including mitred bends, with and without turning vanes, and radiussed bends, with and without splitters. The effect of bends with different aspect ratios is also examined. An excellent collapse of measured data onto a single characteristic curve is reported for each configuration based upon standard values of pressure loss coefficients. It is suggested that that these characteristic curves might form the basis for a practical prediction method.

Frank H. Guenther, Cochair
Dept. of Cognitive and Neural Systems, Boston Univ., Boston, MA 02215

Invited Papers

8:30

1aSCa1. Three-dimensional mechanical tongue and vocal cord models for human speech production. Kotaro Fukui, Eiji Shintaku, Yuma Ishikawa, Nana Sakakibara, Yoshikazu Mukaeda, Atsuo Takanishi (Dept. of Modern Mech. Eng., School of Creative Sci. and Eng., Waseda Univ., 3-4-1, Ookubo, Shinjuku-ku Tokyo, 196-8555, Japan, kotaro@toki.waseda.jp), and Masaaki Honda (Waseda Univ., Saitama, Japan)

We have developed talking robot Waseda Talker series, which mimicked human speech production mechanism. This robot is consisted of mechanical vocal cords, tongue, lips, and nasal cavity. The current version, WT-7R (Waseda Talker No. 7 Refined), has 16 DOF (7 DOF in tongue, 1 DOF in jaw, 4 DOF in lips, 1 DOF in velum, 2 DOF in vocal cords, and 1 DOF in lung), having same vocal tract length as average adult male. The mechanical vocal cord model is made of styrene based thermoplastic elastomer "Septon" and the shape is mimicking vocal folds of human with three dimensions. The vocal code model has pitch control mechanism by adjusting the cord tension and glottal opening-closing mechanism, and it could reproduce the vocal cord vibration of the vocal fry (double pitched) and the breathy voice (unclose in one cycle) as well as the modal voice with variable pitch. The three-dimensional tongue model is constructed by the rigid link mechanism covered by the Septon soft rubber. The tongue model could be controlled so as to configure the tongue shape in a three-dimensional way. We will describe the details of the mechanism of talking robot by showing some demonstration videos.

8:50

1aSCa2. Gesture controlled synthetic speech and song. Sidney Fels (Elec. and Comput. Eng., Univ. of British Columbia, 2332 Main Mall, Vancouver, BC, Canada, V6T 1Z4, ssfels@ece.ubc.ca), Bob Pritchard (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z2), Eric Vatikiotis-Bateson (Univ of British Columbia, Vancouver BC, V6T 1Z4 Canada, and The Visual Voice Team)The Visual Voice Team

We describe progress on creating digital ventriloquized actors (DIVAs). DIVAs use hand gestures to synthesize audiovisual speech and song by means of an intermediate conversion of hand gestures to articulator (e.g., tongue, jaw, lip, and vocal chords) parameters of a computational three-dimensional vocal tract model. Our parallel-formant speech synthesizer is modified to fit within the MAX/MSP visual programming language. We added spatial sound and various voice excitation parameters in an easy-to-use environment suitable for musicians. The musician's gesture style is learned from examples. DIVAs will be used in three composed stage works of increasing complexity performed internationally, starting with one performer initially and culminating in three performers simultaneously using their natural voices as well as the hand-based synthesizer. Training performances will be used to study the processes associated with skill acquisition, the coordination of multiple "voices" within and among performers, and the intelligibility and realism of this new form of audio/visual speech production. We are also building a robotic face and computer graphics face that will be gesture controlled and synchronized with the speech and song. [This project is funded by the Canada Council for the Arts and Natural Sciences and Engineering Research Council, Canada. More information is at: www.magic.ubc.ca/VisualVoice.htm]

9:10

1aSCa3. Biomimetic vocal tract modeling: Synthesis of speech articulation. Robin Hofe and Roger K. Moore (Univ. of Sheffield, Dept. of Comp. Sci. Regent Court, 211 Portobello, S1 4DP, Sheffield, UK, R.Hofe@sheffield.ac.uk)

In recent years, a number of researchers have started to investigate cognitive aspects of speech production using "speaking robots." This paper introduces AnTon–the Animatronic Tongue and vocal tract model developed at the University of Sheffield, UK. AnTon's distinctive feature is its design principle. Whereas other speaking robots are motivated by functionality—to produce a good imitation of human speech—AnTon mimics human anatomy, including tissue properties and muscle (actuator) configurations. Any ability to produce speech sounds emerges solely as a consequence from that anatomy. Such imitation of a biological system is called "biomimetic." The reason to choose a biomimetic approach lies in the need for an experimental tool that makes speech articulation processes transparent. The use of realistic muscle configurations means that the model's speech gestures can be mapped directly to human behavior, facilitating the evaluation of both the quality of AnTon's speech gesture reproductions as well as any predictions about human behavior inferred from experiments with AnTon. AnTon will be used to clarify speech articulation processes, specifically in relation to energy efficiency of articulatory gestures and the importance of an auditory feedback loop. The project's progress is continually documented on http://www.dcs.shef.ac.uk/~robin/anton/anton.html.

9:30

1aSCa4. Synthesizing vowel transitions with an analog vocal tract. Michael C. Brady (Dept. of Cognit. Sci. Indiana Univ., 1910 E. 10th St., Bloomington, IN 47406, mcbrady@indiana.edu)

A mechanical vocal tract with a pneumatic sound source, silicone tongue, and lip rounding mechanism is introduced. The tract is designed to make controlled transitions between static articulatory vowel configurations. The focus on transitions is important because many argue that it is the change between steady-state sounds that the nervous system is tuned for in extracting information from the speech signal. I draw on examples and experimental results as I review this steady state versus transition distinction. The notion of articulatory transitions as the motor control targets of robotic speech production is then discussed. Video demonstrations of the mechanical tract helps to illustrate how transitions as control targets may be implemented. In conclusion, I argue for why an analog vocal tract with its true aerodynamics (as opposed to synthesis using a cascade of digital filters) is called for in generating articulator-transition-based speech sounds.

9:50

1aSCa5. A talking robot and the interactive speech training for hearing-impaired. Hideyuki Sawada (Dept. of Intelligent Mech. Syst. Eng., Faculty of Eng., Kagawa Univ., 2217-20 Hayashi-cho, Takamatsu, Kagawa, 761-0396, Japan, sawada@eng.kagawa-u.ac.jp)

A speech trainer employing a talking robot for auditory-impaired people will be introduced. The talking robot consists of mechanically-designed vocal organs such as a vocal tract, a nasal cavity, artificial vocal cords, and a sound analyzer with a microphone system, and the mechanical parts are fully controlled by ten servomotors for generating humanlike voices. The robot autonomously learns the relation between motor control parameters and the generated vocal sounds by an auditory feedback control, in which a Self-organizing neural network is employed for the adaptive learning. By employing the robot and its properties, the authors have constructed an interactive speech training system. The training is divided into two approaches; one is to use the robot for showing the shape and the motion of the vocal organs, and the other is to use a topological map for presenting the difference of phonetic features of a traine's voices. While referring to the robot motions and the phonetic characteristics, a trainee is able to interactively practice vocalization for acquiring clear speech with appropriate speech articulations. To assess the validity of the training system, a practical experiment was conducted by 19 subjects in a school for the deaf children. The talking robot is expected to intensively teach auditory-impaired patients the clear speech articulations.

1aSCa6. Real-time speech synthesis for neural prosthesis. Frank H. Guenther (Dept. of Cognit. & Neural Syst., Boston Univ., 677 Beacon St., Boston, MA 02215)

The idea of building an artificial vocal tract that could serve as a prosthetic device for mute individuals has been pursued since the pioneering work of Wolfgang von Kempelen and contemporaries in the 18th century. These early speaking machines were built out of wood, metal, rubber, and other materials fashioned into a mechanical vocal tract whose shape was manipulated manually by the user while air was forced through it. In the mid-20th century, Gunnar Fant and colleagues constructed electrical resonating circuits capable of producing speechlike sounds over loudspeakers, and shortly thereafter fully computer-based speech synthesizers were developed, including formant synthesizers and articulatory synthesizers. The recent development of brain-computer interfaces driven by neuronal activity raises the possibility of a speech prosthesis that would allow mute paralyzed individuals to directly control a speech synthesizer to create speech output. We have implemented such a brain-computer interface in a 25-year-old volunteer suffering from locked-in syndrome, characterized by complete loss of movement but intact perception and consciousness. To date the volunteer has successfully used the prosthesis to produce vowel sounds. Future developments in speech synthesis necessary for allowing full conversational speech via brain-computer interface will be outlined. [Work supported by NIH/NIDCD and NSF.]

1aSCb1. Response of synthetic vocal fold models with geometry based on visible human project data. Brian A. Pickup and Scott L. Thomson (Dept. of Mech. Eng., Brigham Young Univ., 435 CTB, Provo, UT 84602, thomson@byu.edu)

Numerous synthetic and computational models have been and are currently being used in research studies of human vocal fold vibration. Model geometry plays an integral role in governing dynamic response. However, the various model geometry definitions have typically been idealized and often exhibit wide variability with each other. The present research compares the response of synthetic vocal fold models of different geometries. One model is based on idealized geometry, while the other is based on geometry obtained from the National Library of Medicine's visible human project (VHP). The process for image extraction, model definition, and model fabrication is described, including: (1) image conversion from 2-D VHP image sequences to 3-D stereolithography (STL) format, (2) conversion to 3-D computer model format in which model geometric manipulations can be performed, and (3) fabrication of synthetic models using rapid prototyping. Results of measurements to characterize the dynamic response of self-oscillating synthetic vocal fold models, including onset and offset pressure, instantaneous glottal width using high-speed imaging, and glottal jet velocity profiles using particle image velocimetry (PIV), are presented for models based on both VHP data and idealized geometries. The sensitivity of the models to geometry changes is also reported.

1aSCb2. Analysis of recent experimental studies of phonation threshold pressure done with a physical model of the vocal fold mucosa. Lewis P. Fulcher (Dept. of Phys. and Astronomy, Bowling Green State Univ., Bowling Green, OH 43403), Ronald C. Scherer, Chen Liu, and Marco Nardone (Bowling Green State Univ., Bowling Green, OH 43402)

The pioneering work on the physics of small amplitude oscillations of the vocal folds by Titze resulted in a simple analytic formula that predicted the phonation threshold pressure of the uniform glottis to be a linear function of the glottal half-width, to be directly proportional to energy dissipation properties of the vocal fold, and to be reduced by the presence of a vocal tract. These relationships have been examined in a series of experiments [R. Chan and I. Titze, "Dependence of phonation threshold pressure on vocal tract acoustics and vocal fold tissue mechanics," J. Acoust. Soc. Am. **119**, 2351–2362 (2006)], and the linear connection with glottal half-width has been observed in several cases. However, the analysis described above did not consider the role of viscosity of the air, which may be important at small widths, as suggested by Lucero. The present study examines these experiments in the context of the surface wave model developed by Titze using intraglottal pressure distributions taken with the static physical model of the glottis M5. The M5 data include effects of viscosity and of flow separation. Preliminary results indicate that the threshold pressure should decrease as glottal width decreases, over the entire range of glottal widths examined by Chan and Titze. [Work supported by NIH R01DC03577.]

1aSCb3. Nonlinear viscoelastic response of the vocal fold lamina propria under large-amplitude oscillatory shear. Roger W. Chan (Otolaryngol., Biomed. Eng., Univ. of Texas Southwestern Med. Ctr., Dallas, TX 75390) and Miwako Kimura (Univ. of Texas Southwestern Med. Ctr., Dallas, TX 75390)

Viscoelastic properties of the vocal fold lamina propria have been reasonably quantified beyond the linear range for describing tissue behavior under uniaxial stretch or tensile deformation, but the same cannot be said for oscillatory shear deformation, which is more relevant for understanding the mechanics of large-amplitude vocal fold vibration. Previous studies reporting the viscoelastic shear properties of vocal fold tissues have been limited to characterization of the small-amplitude viscoelastic response in the linear viscoelastic region, partly due to the fact that derivation of the elastic and viscous shear moduli is based on the assumption of linearity, and also because of the lack of a coherent framework for describing any nonlinearities beyond the linear viscoelastic region. Based on a recently proposed rheological framework for quantifying such nonlinearities, this study examined the viscoelastic response of human vocal fold cover specimens subjected to large-amplitude oscillatory shear, up to a shear strain amplitude of around 1.0. Results indicated that the linear viscoelastic moduli (G' and G'') cannot adequately describe the tissue response under large-strain shear deformation, whereas geometrical interpretations of Lissajous–Bowditch curves could unveil nonlinearities that are obscured by the use of G' and G'', such as the phenomenon of strain stiffening.

1aSCb4. Effects of the airway surface liquid on vocal fold vibration. David Daily, Dan Lo Forte, and Scott L. Thomson (Dept. of Mech. Eng., Brigham Young Univ., 435 CTB, Provo, UT 84602)

A two-layer airway surface liquid (ASL), comprised of a Newtonian sublayer and a non-Newtonian surface layer, lines the laryngeal lumen. During phonation the layers on opposing vocal folds experience merging, squeezing, stretching, and rupture. Various aspects of the ASL have been studied, but its role in vocal fold vibration remains largely understudied. This presentation describes the results of experiments and computational simulations aimed at improving our understanding of the role of the ASL, in particular the non-Newtonian layer, in phonation. The experimental setup for measuring the liquid properties is described, and results are presented. The measured liquid properties are input into a finite element model of the vocal folds, which includes a simulated non-Newtonian layer, using the software package ADINA. The non-Newtonian liquid is also incorporated into a two-mass vocal fold model, which includes the effects of the ASL during colli-

sion and separation. The finite element and two-mass models are compared with each other and with experimental results to assess the influence of the non-Newtonian component of the ASL on vocal fold vibration.

1aSCb5. Rapid three-dimensional magnetic resonance imaging of vocal tract shaping using compressed sensing. Yoon-Chul Kim, Shrikanth Narayanan, and Krishna S. Nayak (Ming Hsieh Dept. of Elec. Eng., Univ. of Southern California, 3740 McClintock Ave., Los Angeles, CA 90089, yoonckim@usc.edu)

Conventional 3D magnetic resonance imaging (MRI) of vocal tract during sustained sound production takes prohibitively long and requires repetitions of the same articulation with pauses of the scan. This can produce image misregistration artifacts possibly due to different positioning of the jaw, tongue, and lips at each repetition. Within a scan time limit of 6–10 seconds, a duration practical for sustained sound production, it is desirable to accelerate high-resolution 3D imaging by undersampling 3D *k*-space. In this study, compressed sensing theory was adopted to achieve the acceleration by incoherent undersampling of 3D *k*-space and minimum L1-norm reconstruction. The increase in transform sparsity was exploited by constraining image phase in which rapid phase variation is expected in air-tissue boundaries due to large magnetic susceptibility difference. Vocal tract volume of interest was imaged during sustained sound production of English consonants /s/, /sh/, /r/, and /l/. Vocal tract area functions were measured using OsiriX software. The visualization of 3D tongue shape was demonstrated via image segmentation and volume rendering process. MR acquisition for each consonant took 6 sec without any repetitions of the articulation. The reconstruction of a whole 3D vocal tract was achievable with a 1.33 $\times$1.33$\times$1.33 mm^3 isotropic resolution. [Work supported by NIH.]

1aSCb6. An analysis-by-synthesis approach to modeling real-time MRI articulatory data using the task dynamic application framework. Erik Bresch (Dept. of Elec. Eng., Univ. of So. California, Los Angeles, CA 90089, bresch@usc.edu), Louis Goldstein, and Shrikanth Narayanan (Univ. of So. California, Los Angeles, CA 90089)

We report on a method of modeling real-time MRI articulatory speech data using the Haskins task dynamic application (TaDA) framework. TaDA models speech using a set of discrete dynamical regimes that control the formation of vocal tract constrictions (gestures). An utterance can be specified by a gestural score: the pattern of activation of these regimes in time. Individual model articulator degrees of freedom are automatically coordinated according the concurrent demands of the unfolding constrictions. Our modeling procedure consists of two stages: (1) After determining the outline of the midsagittal upper airway, time series of constriction measurements are derived which allow the estimation of the subject-specific parameters relating the articulator and constriction domains. (2) Gradient descent is utilized to adjust the activation intervals of the gestural score generated by TaDA for that utterance so that the synthesized vocal tract constriction evolution matches the observed MRI time series. Additionally, information related to glottal control, which cannot be derived from the MR images, is extracted from the simultaneously recorded audio, and it is used to optimize the timing of glottal abduction gestures in the score. Adequacy of fit is evaluated at articulatory, constriction, and perceptual levels. [Work supported by NIH.]

1aSCb7. Vowel recognition from articulatory position time-series data. Jun Wang (Dept. of Comput. Sci. & Engr., Univ. of Nebraska-Lincoln, Lincoln, NE 68508, junwang@cse.unl.edu), Ashok Samal , Jordan Green , and Tom Carrell (Univ. of Nebraska-Lincoln, Lincoln, NE 68583)

The goal of this project is to determine the accuracy and processing speed of different approaches for mapping time-varying articulatory positional data to vowels. Three widely used classifiers were compared on two datasets: one single speaker and one multiple speaker. The single-speaker dataset was acquired using the Articulograph AG500. The multiple-speaker dataset was obtained from seven speakers in the Xray Microbeam Speech Production Database (Westbury, 1994). The recognition rate for single speaker dataset (eight English vowels) ranged from 94.25% to 98.1%, and from 62.38% to 99.35% for the multiple-speaker dataset. For the single-speaker dataset, recognition accuracy was comparable across classifiers. For the multiple-speaker dataset, recognition accuracy was better for the Support Vector Machine and C4.5 than for the neural networks. The decision tree generated by C4.5 was consistent with articulatory features commonly used to descriptively distinguish vowels. Moreover, the Support Vector Machine and C4.5 performed much faster than did the neural network. The high recognition rates observed suggest that static vowels can be accurately recognized from articulatory position time-series data. The findings are intended to improve the accuracy and response time of a real-time articulatory-movement based speech synthesizer.

1aSCb8. Recovering area functions from acoustics and midsagittal profiles. Richard S. McGowan and Rebecca W. McGowan (CReSS LLC, 1 Seaborn Pl. Lexington, MA 02420)

Simultaneously recorded midsagittal pellet positions and acoustic output for several subjects comprise the Wisconsin X-Ray Microbeam Speech Production Database (XRMB-SPD). An articulatory synthesizer, EASY, was used to help recover area function parameters corresponding to the production of vowels by subjects in the XRMB-SPD by means of analysis-by-synthesis. Specifically, for each subject, an initial personalized midsagittal profile was created based on the pellet positions, pellet trace, and pharyngeal wall trace during neutral vowel production. Based on the scales of this initial profile for a subject, subsequent midsagittal profiles were generated from the pellet data during various vowel productions. Each midsagittal profile and the corresponding first three formant frequencies were used to optimize the parameters of an area function in the EASY for closest acoustic match. The optimization was performed with a genetic algorithm. The results are examined in terms of consistency within a subject for different vowels and consistency within vowel for different subjects. Synthesized examples of vowel production will also be presented. [Work partially supported by Grant DC-001247 to CReSS LLC.]

1aSCb9. Korean articulatory speech synthesis using physical vocal tract model. Huynh V. Luong (Univ. of Ulsan, Korea), Jong-Myon Kim (Univ. of Ulsan, Korea), and Cheol Hong Kim (Chonnam Natl. Univ., Korea)

Artificial vocal tract models provide the support of learning a second language and the therapy of speech disorders. Moreover, phonetic education and research can benefit from articulatory speech synthesis. Articulatory speech synthesis models are constructed by the source-filter model of the human vocal tract. In this study, we generated a Korean articulatory speech synthesis model using Artisynth [Fels *et al.*, ISSP, 419–426 (2006)], which is a 3-D biomechanical open-source simulation platform. As the origin of the Korean language, it has 10 basic vowel phonemes and 11 complicated vowels in which some vowels can be rounded and unrounded such as /eu/, /yeo/, /wae/, etc. To synthesize these specific vowels, we created a new physical vocal tract model, which interconnects to form a complete integrated biomechanical system. The created model efficiently supports recording the Korean vowel sounds and linguistic analysis based on the linear prediction model. As a result, parameters of the glottis and controllable vocal tract filter are automatically evaluated. The acoustic quality of the synthesizer for Korean vowels is comparable with that of the existing commercial speech synthesis systems such as concatenation synthesizers [Donovan (1996)] and [Hamza (2000)]. [Work supported by the MKE, Korea, under the ITRC supervised by IITA (IITA-2008-(C1090-0801-0039)).]

1aSCb10. Vocal and postural coupling in singing and speech. Eric Vatikiotis-Bateson, Martin Oberg, Adriano Barbosa (Linguist., Univ. of British Columbia, 2613 West Mall, Vancouver, BC, Canada, V6T 1Z4), Nancy Hermiston, and Richard Kurth (Univ. of British Columbia, Vancouver, BC, Canada, V6T 1Z1)

This study examines behavioral measures during speech and singing to assess the interaction of the postural control system and the production of expressive vocal behavior at different levels of vocal effort. We know that head motion is essential to both expressive speech and to balanced posture, suggesting that the head must be entrained to some extent by both subsystems simultaneously. This study shows that increased vocal effort (defined here as loudness) affects rigid body (6D) head motion and other measures of postural behavior acquired from force plates (6D) and video-

based motion analysis (2D). Specifically, as vocalizations becomes louder, the postural system becomes more simply coupled spatially and temporally to the vocal system.

1aSCb11. Optimization of articulator trajectories in producing learned nonsense words. Mark Tiede (Haskins Lab., 300 George St., New Haven, CT 06511 & Speech Comm. Group, MIT-R.L.E., tiede@haskins.yale.edu), Christine Mooshammer (Haskins Laborities, New Haven, CT 06511), Louis Goldstein (U.S.C., Los Angeles, CA 90089), Stefanie Shattuck-Hufnagel, Joseph Perkell, and Melanie Matthies (MIT-R.L.E., Cambridge, MA 02139)

Previous work assessing motor learning in novel speech utterances has shown that kinematic duration and variability are reduced as a function of practice [Schulz *et al.* (2001)]. In this study EMA was used to observe articulator movements during production of a variety of polysyllabic nonsense words conforming to English phonotactics (e.g., "thraimpoframodis"). Target words were elicited eight times in block-random order, with each block separated by ten minutes of an unrelated task serving as a distractor. Analysis of EMA sensor trajectories between initial and final repetitions shows in general reduction of overall duration, lower STI [Smith *et al.* (1995)], reduced stiffness, and fewer acceleration peaks, with intermediate productions indicating that these trends occur asymptotically. Comparison of consonant closure timings delimited using velocity extrema and aligned through nonlinear time normalization [Lucero *et al.* (1997)] suggests that as fluency increases, the overlap between adjacent consonantal gestures also increases. The patterns of articulatory optimization illustrated by these results will be contrasted with similar analyses of real but difficult-to-pronounce sequences (tongue twisters) collected from the same subjects, with the goal of identifying similarities between pre-fluent and dysfluent utterances. [Research supported by NIH.]

1aSCb12. Measuring articulatory similarity with algorithmically reweighted principal component analysis. Jeff Mielke and Joseph Roy (Arts 401, 70 Laurier Ave. E., Ottawa, ON Canada, K1N6N5, jmielke @uottawa.ca)

Articulatory similarity was assessed for a corpus of 2700 ultrasound images of 75 cross-linguistically frequent speech sounds produced by four subjects in three segmental contexts (a_a, i_i, u_u). Cross-distances were generated for the entire length of the vocal tract using the Palatron algorithm and realistic estimates of the location of the pharyngeal wall and teeth, resulting, after interpolation, in 60 cross-distances per token. A standard principal component analysis of these data is overwhelmed by the coarticulatory effects of the context vowels. Algorithmically reweighted principal component analysis was devised in order to use coarticulatory variation to isolate the most distinctive cross-distances for each target segment. The reweighting algorithm considers the variance across repetitions in each of the 60 cross-distances, as well as variance in the slope of the cross-distance function, in order to identify areas of stability across tokens. For each target sound, cross-distances with the greatest variance are reset to the mean for all target segments, while cross-distances with the least variance maintain their original values. This has the effect of defining each target sound by the cross-distances, which are most stable across contexts.

1aSCb13. The influence of dynamic flow conditions on sound generation in fricative consonants. Gordon Ramsay (Haskins Lab., 300 George St., New Haven, CT 06511)

Studies of speech production have often remarked that frication noise in voiced fricatives is weaker than that produced in homorganic voiceless fricatives. This is traditionally attributed to the reduction in mean flow (and, hence, Reynolds Number) produced by the glottal constriction needed to induce voicing. However, research in fluid mechanics has demonstrated that turbulence may develop quite differently in steady and unsteady background flows. Strong flow gradients may inhibit the transition to turbulence, or even relaminarize an already-developed turbulent flow. This paper describes a series of mechanical modelling experiments designed to investigate the effect of dynamic flow conditions on sound generation in fricatives. A feedback-regulated Kolvenbach flow valve, controlled by computer, is used to create carefully-shaped dynamic modulations of the air flow through a stereolithographic replica of the vocal tract, about a series of static flow conditions. A multitaper spectral analysis technique is then used in conjunction with sweeptone measurements to separate out the contribution of source and filter components to the far-field sound spectra recorded with a microphone, and source properties are compared across flow conditions. The observed variations cannot be explained by differences in mean flow alone, suggesting that dynamic effects may be important.

1aSCb14. Effects of sleep deprivation on nasalization in speech. Xinhui Zhou (Dept. of Elect. and Comp. Eng., Univ. of Maryland, College Park, MD 20742, zxinhui@glue.umd.edu), Suzanne Boyce (Univ. of Cincinnati, Cincinnati, OH 45267), Joel MacAuslan (Speech Technol. and Appl. Res. Corp., Bedford, MA 01730), Walter Carr, Balkin Thomas, Picchioni Dante (Walter Reed Army Inst. of Medicine, Silver Spring, MD 20910), and Carol Espy-Wilson (Univ. of Maryland, College Park, MD, 20742)

Various aspects of speech appear to be subtly affected by sleep deprivation [Boyce *et al.*, "Landmark-based analysis of sleep-deprived speech," J. Acoust. Soc. Am. **123**(5), 3887 (2008)]. An automatic procedure for detection of nasalization in the acoustic spectrum of vowels was applied to a database of speech recordings from 15 subjects in rested and sleep-deprived conditions. Results showed acoustic differences consistent with differences in sleep condition, suggesting that lack of sleep affects the motor organization/execution of speech articulation in general, and for oral/nasal coupling during vowels in particular. Significant differences in male vs female patterns were also observed. Correspondences between these patterns and those reported in the clinical and linguistic literature will be discussed. [Work supported by NIH.]

1aSCb15. Gestural intrusions in Taiwanese and English. Man Gao (Haskins Labs., 300 George St., Suite 900, New Haven, CT 06511), Yueh-chin Chang, Feng-fan Hsieh (Grad. Inst. of Linguist., Natl. Tsing Hua Univ., Taiwan), Hosung Nam, Mark Tiede (Haskins Labs., New Haven, CT 06511), and Louis Goldstein (U.S.C, Los Angeles, CA 90089; & Haskins Labs., New Haven, CT 06511)

Kinematic studies of repetitive speech production tasks involving English sequences such as "cop top" have provided abundant evidence for gestural intrusion errors: errorful constrictions that are co-produced with intended target constrictions (Pouplier and Goldstein, 2005; Goldstein *et al.*, 2007). These intrusions have been analyzed as transitions to more dynamically stable coordination modes. This work investigates Taiwanese speakers' production of similar repetitive sequences such as [kap tap]. If the speech sequences are planned and executed in Taiwanese in the same way as in English, similar patterns of intrusive speech errors should be observed. However, analysis of the kinematic data from three speakers shows that these effects in Taiwanese differ from those in English in a number of ways. A systematic comparison of Taiwanese and English intrusions is presented in terms of frequency of occurrence (much higher in Taiwanese), standard deviation of magnitude (smaller in Taiwanese), and temporal relationships to intended gestures. The results are discussed with respect to the language-specific regularities of gestural coordination and their implications for the mode-locking account of speech errors. [Work supported by NIH-NIDCD DC008780.]

1aUW1. Transport theory for shallow water propagation with rough boundaries. Eric I. Thorsos, Frank S. Henyey, W. T. Elam, T. Brian Hefner, Stephen A. Reynolds, and Jie Yang (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

At frequencies of about 1 kHz and higher, forward scattering from a rough sea surface (and/or a rough bottom) can strongly affect shallow water propagation and reverberation. The need exists for a fast, yet accurate method for modeling such propagation where multiple forward scattering occurs. A transport theory method based on mode coupling will be described that yields the first and second moments of the field. This approach shows promise for accurately treating multiple forward scattering in one-way propagation. The method is presently formulated in two space dimensions, and Monte Carlo rough surface PE simulations are used for assessing the accuracy of transport theory results. [Work supported by ONR Ocean Acoustics.]

8:15

1aUW2. Wave refraction at an interface: Snell's law versus Chapman's law. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Earth System Res. Lab., Boulder, CO 80305, Oleg.Godin@noaa.gov)

Wave energy streamlines determine the paths along which energy is transported from a wave source. The energy streamlines provide insights into mechanisms of wave propagation and scattering and are often utilized to visualize wave fields. In contrast to rays, which are essentially an asymptotic, short-wave concept, energy streamlines adequately represent arbitrary wave fields. However, usefulness of energy streamlines in studies of wave fields is limited by the fact that, unlike rays, no general laws governing energy streamline refraction are known. Here a simple refraction law is derived for energy streamlines of acoustic and linearly polarized electromagnetic waves. The refraction law is an extension of a result recently established by D. M. F. Chapman for sound refraction at plane interfaces of homogeneous media. While Snell's law of ray refraction at an interface is formulated in terms of the ratio of sound speeds in media in contact in the case of acoustic waves, Chapman's law implies that refraction of acoustic energy streamlines is controlled by the ratio of mass densities. Similarities and differences between Snell's and Chapman's refraction laws are discussed. It is shown that analysis of energy streamlines provides a new, helpful perspective on wave transmission through an interface.

1aUW3. Parabolic equation modeling of anisotropic waves in heterogeneous media. Adam M. Metzler, William L. Siegmann (Rensselaer Polytech. Inst., Troy, NY 12180), Ralph N. Baer, and Michael D. Collins (Naval Res. Lab., Washington, DC 20375)

Wave propagation in heterogeneous media can be modeled efficiently with the parabolic equation method, which has been extended to problems with homogeneous anisotropic layers [A. J. Fredricks *et al.*, Wave Motion **31**, 139–146 (2000)]. This approach is currently being extended to the heterogeneous case, including piecewise continuous vertical dependence and horizontal dependence that is relatively gradual but which may be large over sufficient distances. Vertical dependence is included by applying appropriate heterogeneous depth operators in the equations of motion. Horizontal dependence is included by extending the single-scattering solution [E. T. Kusel *et al.*, J. Acoust. Soc. Am. **121**, 808–813 (2007)] to the anisotropic case. [Work supported by the Office of Naval Research.]

1aUW4. A two-dimensional coupled mode model for acoustic propagation in a range-dependent waveguide. Wenyu Luo and Henrik Schmidt (Dept. of Mech. Eng., MIT, 77 Massachusetts Ave., Cambridge, MA 02139, lwy@mit.edu)

A two-dimensional, two-way coupled mode model is presented in this work. By combining a forward marching and a backward marching, this model is valid for problems where backscattering is significant. This two-way solution provides great accuracy, and it also features in efficiency, which is achieved by applying the single-scatter approximation. In addition, this model is stable with appropriately normalized range solutions in the formulation. This model is capable of handling two-dimensional problems with either a point source in cylindrical geometry or a line source in plane geometry. The computer code CSNAP is adopted to provide the fundamental model solutions and their associate coupling matrices in this model. This two-dimensional model can be easily extended to a three-dimensional model with the feasibility to solve large-scale realistic three-dimensional problems. Numerical examples are presented to demonstrate the accuracy, efficiency, and stability of this two-dimensional, two-way coupled mode model. [Work supported by the Office of Naval Research.]

1aUW5. Shallow water tomography: Ray theory vs travel-time sensitivity kernels. I. Iturbe (GIPSA-lab, 961 Rue de la Houille Blanche, BP 46, 38402 Saint Martin d'Heres, France, ion.iturbe@gipsa-lab.inpg.fr), P. Roux (Univ. Joseph Fourier, 38042 Grenoble, France), B. Nicolas (GIPSA-lab, 38402 Saint Martin d'Heres, France), J. Virieux (Univ. Joseph Fourier, 38042 Grenoble, France), and J. Mars (GIPSA-lab, 38402 Saint Martin d'Heres, France)

In underwater acoustics, ray tomography is the classical method used to estimate velocity variations, but recently. Travel-Time Sensitivity Kernels (TSK) approaches have been developed. In this paper, we deal with TSK for two source-receive arrays in an acoustic waveguide for shallow water tomography. As a first step, we show that separation of the different raypaths is improved by using a recently proposed new array processing [time-delay double beamforming (DBF) algorithm]. DBF consists of changing the 3-D data space from source depth, receiver depth and time into a new 3-D space related to ray propagation expressed by the beamformed variables, source angle, receive angle and time. As a consequence, each eigenray of the multipath propagation for a source-receiver couple can be identified and separated through DBF. In this context of DBF, the TSK is no longer point-to-point as usual, but relies on all source-receiver time series. Kernels are computed using the fact that the processed signal is a linear combination of time-delayed signals between all sources and receivers. Results in simulated data and in real datasets recorded in an ultrasonic tank prove that combination of TSK and DBF increases the resolution and robustness performance of shallow-water acoustic tomography.

1aUW6. Computationally efficient parabolic equation solutions to seismoacoustic problems. Jon M. Collis (Math and Comput. Sci., Colorado Sch. of Mines, 1500 Illinois St., Golden, CO 80401, jcollis@mines.edu)

Improving the capabilities and accuracy of the elastic parabolic equation method has been an active area of research. Variable rotation [D. A. Outing *et al.*, J. Acoust. Soc. Am. **120**, 3534–3538 (2006)] is an effective solution for treating variable bathymetry and has recently been extended to handle variable sediment thicknesses [J. M. Collis *et al.*, J. Acoust. Soc. Am. **123**, 51–55 (2008)] and beach interactions. To accurately resolve the field in elastic sediments, much finer grid spacing may be needed than is necessary to propagate the acoustic field in the water. In particular, as the shear wave speed in the elastic medium approaches zero, the governing system becomes singular, and very fine grid spacing is necessary to capture subtle effects of the field. In this presentation we show how elastic parabolic equation solutions can be computed with greater efficiency, through the use of multiple resolution grids. Interface conditions and derivative approximations on a nonuniform grid will be described. Finally, applications of multiple grid solutions will be discussed for rough surface scattering and treating near-singular low-shear speed sediments.

9:30

1aUW7. Acoustic wave scattering in turbulence and in internal waves. Tokuo Yamamoto, Clair Paris (AMP, RSMAS, Univ. of Miami, 4600 Rickenbacker Cswy, Miami, FL 33149, tyamamoto@rsmas.miami.edu), and Mohsen Badiey (Univ. of Delaware, Newark, DE 19716)

Analytical solutions of acoustic wave scattering have been obtained for turbulent currents and for shallow water internal waves. The scattering characteristics of the two are quit different. The most striking difference is that the maximum scattering is in only one direction by turbulence. Whereas there are two directions of maximum scattering in internal waves. In turbulence, acoustic waves scatter quite strongly while internal waves acoustic waves scatter very weakly. Therefore, turbulence changes acoustic wave (coherent) energy rapidly into (incoherent) scattered acoustic energy. The scattering of acoustic energy by internal waves is weak, on the order of 0.001 of that of turbulence. The theoretical results are verified with transmission loss measured in Kanmon Strait and at New Jersey Shelf with good agreements. [Work supported by ONR Code 322 OA.]

1aUW8. Resonant forward scattering of sound in the deep ocean by internal tides. Irina I. Rypina (Dept. of Physical Oceanogr., Woods Hole Oceanograph. Inst., 266 Woods Hole Rd., Woods Hole, MA 02543), Ilya A. Udovydchenkov, Timothy F. Duda (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), and Michael G. Brown (Univ. of Miami, Miami, FL 33149)

The importance of resonant forward scattering of sound by highly directional large amplitude nonlinear internal waves in shallow water environments has been well established. In contrast, most deep ocean environments are characterized by the presence of a sound speed perturbation (due mostly to internal waves) whose horizontal wave number spectrum is broad and approximately horizontally isotropic; under such conditions, the importance of resonant forward scattering is less clear. Exceptional deep ocean conditions are found in the vicinity of submarine ridges, which serve to generate internal tides that are both highly directional and have a narrow horizontal wave number spectrum. In this talk, ray, mode, and PE simulations are presented to explore the importance of resonant forward scattering by such structures under fairly realistic oceanographic conditions. [Work supported by ONR.]

10:15

1aUW9. The second order resolution operator of a nonlinear ocean acoustics inverse problem. Robert I. Odom and Andrew A. Ganse (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, odom@apl.washington.edu)

The resolution operator for a linear inverse problem indicates how much smearing exists in the map between the true model and the estimated model. The trace of the resolution operator provides an estimate of the number of model parameters model that are resolved. In a series representation of the resolution operator for a nonlinear problem, the higher-order terms indicates how much spurious nonlinear leakage there is from the true model to the estimated model. In previous work, the solution of a simple nonlinear ocean acoustic inverse problem as a perturbation series in the horizontal wavenumber was constructed, and the linear data kernels were presented. This linear problem permitted the quantification of the magnitude of the perturbation and indicated when nonlinear effects must be taken into consideration. In this extension of previous work, the second order resolution kernel is constructed, which describes how effectively nonlinear effects can be removed from the reconstructed model. [Work supported by ONR.]

10:30

1aUW10. A finite element model for acoustic propagation in shallow water waveguides. Marcia Isakson (Appl. Res. Lab., The Univ. of Texas at Austin, Austin, TX 78713, misakson@arlut.utexas.edu)

A finite element model is developed using a commercial code to calculate the backscattering of acoustic waves in a two-dimensional shallow water waveguide with rough interfaces. Finite elements approach an exact solution to the Helmholtz equation as the discretization density increases. A time series for the backscattering is computed from time harmonic computations using Fourier synthesis. A parametric study of the roughness parameters for the sediment/water interface and the air/water interface will be presented in order to assess the range of validity of approximate methods. [Work sponsored by Internal Research and Development, Applied Research Laboratories.]

10:45

1aUW11. A comparison of acoustic uncertainty approximations in a Pekeris waveguide. David R. Dowling and Kevin R. James (Dept. of Mech. Eng., Univ. of Michigan, 2212 G. G. Brown, Ann Arbor, MI 48109, drd@engin.umich.edu)

Uncertainty in environmental parameters is often the dominant source of error in underwater acoustic field predictions. This presentation provides comparisons of three techniques for assessing uncertainty in a predicted acoustic field caused by uncertainty in environmental parameters: field shifting, polynomial chaos expansion, and coarse uniformly sampled direct simulations. The uncertainty assessments are performed in a 100-m deep Pekeris waveguide with an uncertain water-column sound speed for frequencies of 100 Hz to 1 kHz at ranges of 1 to 10 km with a variety of common bottom types. The accuracy and computational efficiency of each approximation are quantified in terms of an absolute-difference error norm for the probability density function (PDF) of acoustic field amplitude and the number of acoustic field calculations necessary to predict this PDF, respectively. In all cases, the true field-amplitude PDF is determined from numerically converged direct numerical simulations. The strengths and limitations of each technique are highlighted and the applicability of these results to other sound channels and uncertain parameters is discussed. In particular, polynomial chaos expansion produces the highest accuracy but does so at the highest computational cost, while field shifting produces acceptable accuracy for the least computational cost. [Work sponsored by the Office of Naval Research.]

11:00

1aUW12. Modeling gradients in ocean acoustics. Robert I. Odom (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, odom@apl.washington.edu) and Karsten James (California Polytechnic State Univ., San Luis Obispo, CA 93407)

Modeling acoustic propagation in the ocean requires a representation of the ocean sound speed. For a 1-D, range independent ocean, probably the most common representation comprises constant sound speed layers and/or gradient layers. Gradients of the form $1/c^2(z)$, admitting an exact solution for the acoustic pressure field in terms of Airy functions, are commonly employed. A disadvantage of using the Airy functions is that they are spe-

cific to that profile. For more general profiles, the best representation may be a stack of constant sound speed layers for which the pressure field is expressible in terms of simple exponentials. As an example, computing the backscattering strength from a stack of layers containing volume heterogeneities requires evaluation of an integral proportional to the 4th power of the pressure field. Integrating the simple exponential solutions for constant sound speed layers is trivial. Integrating a product of four Airy functions, either analytically or numerically, is not. If the medium is represented only by constant sound sound speed layers, what is the best way to choose the layers, and how many layers are needed? These questions are investigated by employing an algorithm originally due to Fuchs (1968). [Work partially supported by ONR.]

MONDAY AFTERNOON, 18 MAY 2009 GRAND BALLROOM II, 1:00 TO 4:50 P.M.

Session 1pAA

Architectural Acoustics and Noise: Acoustics of Green Buildings: A 360 Degree Perspective

David M. Sykes, Cochair
The Remington Group LP, 23 Buckingham St., Cambridge, MA 02138

Brandon D. Tinianov, Cochair
Serious Materials, 1250 Elko Dr., Sunnyvale, CA 94089-2213

Chair's Introduction—1:00

Invited Papers

1:05

1pAA1. National Academy of Engineering "Technology for a quieter America" project—impact on "green acoustics"? Patricia Davies (Sch. of Mech. Eng., Ray W. Herrick Labs., Purdue Univ., 140 Martin Jischke Dr., West Lafayette, IN 47907-2031, daviesp@ecn.purdue.edu) George C. Maling, Jr. (Inst. of Noise Control Eng., Harpswell, ME 04079) and Gregory C. Tocci (Cavanaugh Tocci Assoc., Inc., Sudbury, MA 01776)

In 2006, the National Academy of Engineering (NAE) initiated an investigation of the potential benefits of a focused effort to control noise in the workplace, communities, and homes that may be of interest to professionals engaged in "green" acoustics. It covered three initiatives: (1) applications of current technology; (2) research and development initiatives for noise control technology; and (3) intragovernmental and public relations programs. Several workshops were held in the 2005–2008 period with representatives from industry, academia, professional societies, private consultants, and government agencies who examined existing and potential solutions along with policies that would help to develop and deploy solutions. Members of the committee were George C. Maling, Jr., Robert J. Bernhard, Robert Bruce, Elizabeth A. Cooper, Patricia Davies, Carl Hanson, Robert Hellweg, Gerald Lauchle, Richard Lyon, Gregory Tocci, Ian Waitz, and others. In mid-2009, a consensus report will be issued that: (a) summarizes the state of current noise control engineering practice; (b) recommends how existing knowledge can address current challenges; (c) presents a research and education agenda that promotes the generation of new knowledge that can provide the greatest benefit to society; and (d) recommends policies that government agencies can develop to further improve the American soundscape.

1:20

1pAA2. LEED (Leadership in Energy and Environmental Design) and indoor environmental quality—What about office acoustics? Kevin M. Powell (Office of Appl. Sci. GSA Public Bldg.s Service, 555 Battery St., Rm. 518, San Francisco, CA 94111, kevin.powell@gsa.gov)

Recent research conducted by the US General Services Administration and the Center for the Built Environment disclosed an anomaly about "green building" interiors, that is, an apparently unintended consequence of the current LEED rating system. The anomaly is this: while occupants of offices that have been upgraded to achieve LEED certification express high levels of satisfaction with the "indoor environmental quality" of these spaces on most dimensions, there is one exception where scores actually decrease. This exception is the only dimension where occupant DISsatisfaction grows—it is acoustics. What is it about LEED-rated offices that cause this anomaly to occur? Why are occupants dissatisfied with the "acoustical comfort" of the new LEED-certified offices? Is it because there are more reflective, hard surfaces causing noise to reverberate? Or because the HVAC system has become quieter? Or because partition heights have been lowered to allow better airflow and more natural light, resulting in less privacy? Since increased occupant dissatisfaction may result in reduced productivity or increased absenteeism, the GSA's office of research has been examining this issue and will report on its findings and conclusions.

1:35

1pAA3. An acoustical consultant's experiences with the leadership in energy and environmental design (LEED) green building rating system(s). Ethan Salter (Charles M. Salter Assoc., Inc., 130 Sutter St., Ste. 500, San Francisco, CA 94104)

The panelist will discuss his experiences with several leadership in energy and environmental design (LEED) green building rating systems, developed by the U.S. Green Building Council (USGBC). He will provide insight into the process, advantages, and challenges of becoming a LEED accredited professional, his observations of how the promulgation of LEED acoustics credits will impact acoustics professionals, and also how the systems affect the solutions and products he recommends. The panelist became LEED accredited in 2006 and has consulted on several LEED projects across the country. He is active in his local chapter of the USGBC. Additionally, the panelist has attended the last four Greenbuild conferences put on by the USGBC.

1:50

1pAA4. The Human Factor: Healthcare, sustainability, and acoustics. Jane Rohde (JSR Assoc., Inc., 8191 Main St., Ellicott City, MD 21043, jane@jsrassociates.net)

There are several areas of concern within healthcare environments, which include staff turnover, infection control, patient satisfaction, and constant increase in costs with diminishing reimbursements. The healthcare systems used are under tremendous scrutiny and those that understand the necessity of creating sustainable care models are headed for future success. Sustainable care models are supported by the physical environment, which has to be based upon evidence-based design principles. This presentation will discuss a case study that is seeking to demonstrate the connection between the person, the place, and the product, resulting in improved patient and resident outcomes. Acoustics, both in the general population and the neonatal/pediatric population, is addressed. Examples of how noise causes disruption to sleep and negative patient and resident outcomes will be provided. Higher stress levels and other issues related to noise will be discussed regarding impacts on staff and performance. The sense of place and how this information can be impacted by design will then be reviewed. Many design professionals know little about acoustics or how to handle mitigating noise in the physical environment. The discussion will then turn to the discussion of products and how products tie into potential multi-faceted solutions.

2:05

1pAA5. Balancing acoustical performance with sustainability in LEED 2009 (Leadership in Energy and Environmental Design). Marsha Bischel and Amy Costello (Armstrong World Industries, Inc., 2500 Columbia Ave., Lancaster, PA 17603)

USGBC's LEED 2009 rating system provides minimal guidance for achieving optimal acoustical performance in sustainable spaces; however, there are opportunities within the rating systems to combine acoustics with other performance attributes to create spaces with optimal indoor environmental properties. Many acoustical finishes are composed of materials that can help achieve LEED points in several categories and can be critical differentiators in determining total building performance and occupant comfort. Strategies to be discussed will include highly light reflectant surfaces, high recycled content, passive energy reduction, and others. By employing such strategies, the acoustical performance of the building may be enhanced while meeting the sustainability objectives.

2:20

1pAA6. Application of acoustic materials for comfort and safety. Robert Matheson, Joseph King, and Natalia Levit (DuPont, 5401 Jefferson Davis Hwy., Richmond, VA 23234, natalia.v.levit@usa.dupont.com)

This work presents an overview of two high performance acoustic products from DuPont™ with various case studies on lowering low frequency noise transmission using DuPont™ LoWave™, low-weight thin blanket with enhanced low frequency performance, and lowering noise with cleanable, dust free sound absorptive panels protected by DuPont™ Tyvek®, a distinctive flash spun plexifilamentary film-fibril sheet, combining excellent barrier properties and characteristic porous structure to make it acoustically transparent in the voice frequency range.

2:35

1pAA7. Case studies and installation data on the acoustical properties of a new class of translucent, lightweight insulation material from NASA called aerogel. James Satterwhite (Cabot Corp., 157 Concord Rd., Billerica, MA 01821, james_satterwhite @cabot-corp.com)

Aerogels are well-known as a class of thermal insulation with "green" benefits including translucence, hydrophobicity, and light weight. However, before 2008, the acoustical properties of aerogels had not been characterized. Used by NASA in the 1970s, aerogels became available in the 1990s as insulation for the construction industry in skylights, underwater pipelining, and roofing fabric. In 2008, laboratory testing and field research began on the acoustical properties of thin profile (2–8 mm) architectural "tensile membrane" fabrics incorporating silica aerogel granules. Data from a tension structure in Vancouver—where aerogel-enhanced fabric was used to block aircraft noise—exhibited excellent acoustic absorption and acoustic impedance matching properties compared to insulators of comparable thickness. In this installation the material increased transmission loss of exterior to interior noise, and reduced indoor reverberation. Also in 2008, U.S. field tests demonstrated an aerogel blanket material as a surface treatment in offices to reduce broadband reverberation, resulting in increased speech intelligibility and enhanced acoustical comfort (an important factor in the 2009 LEED rating system). The acoustical attributes—combined with aerogel's thermal value, thin form factor, translucence, hydrophobicity, light weight, and absence of VOCs has led to growing interest in applications ranging from aircraft interiors to hospitals.

Contributed Papers

3:05

1pAA8. Sustainablity and noise: An exploration of perception of noise as a significant component in sustainable design in a variety of cities internationally. Andreas Gerlsbeck (Zimmer, Gunsel, Frasca Architects, LLP., 320 SW Oak St., Rm. 500., Portland, OR 97204, agerlsbeck@zgf.com) and Paul van Orden (City of Portland Oregon, Portland, OR 97201)

The current acceptance in the sustainability design field of noise and acoustics as a holistically related design concern to the overarching discipline varies widely around the world. The authors' unique experiences on different continents help in the exploration of the current state of the acceptance of acoustical engineering in the sustainability field. An exploration of the paper from F. D. Henry [F. D. Henry, *Proc. 8th International Congress on Noise as a Public Health Problem* (2003)] is taken into account. The authors place notable focus on review of the efforts on the topic by several German research institutions such as: The German Federal Institute for Environmental Issues; The Federal Institute for Occupational Safety and Health; and The DEGA (The German Association of Acoustics). The authors expound on possible reasons why noise and acoustical design elements are often an afterthought by government development and environmental agencies, and design firms focused on sustainable design. The authors explore a number of suggestions for enabling forward movement toward increased inclusion of acoustical design in the sustainable design portions of future projects internationally.

3:20

1pAA9. Green building acoustics: Scoring user performance factors. Glenn E. Sweitzer (Sweitzer LLP, 4504 N. Hereford Dr., Muncie, IN 47304-1235, glenn.sweitzer@gmail.com)

Architectural acoustics lacks specificity in the LEED for Schools (2007), green building rating system, which is based on a checklist score. Uncorrected, this edition lacks the guidance needed to meet, consistently, the stated intent: to facilitate better teacher-to-student and student-to-student communications. An alternative system—user performance based—is developed for scoring speech transmission index (STI), and tested in K–5 elementary school classrooms. K–5 teachers are surveyed and then interviewed regarding sound and noise control strategies employed in their respective classrooms, by academic subject; AV media; and teacher/student configuration. Reported outcomes are compared with STI contours. The requisite background noise level and room impulse response measurements are made using a binaural acoustic mannequin at each listening position. It is expected that STI will vary among listening positions, and by academic subject and teacher/student configuration. Accordingly, scoring for the classroom will vary. Results are discussed, and based on the findings, passive means are suggested for improving STI in the classrooms studied.

3:35

1pAA10. Two challenges to achieving acoustical privacy in open offices: Going green in Switzerland. David A. Conant and William Chu (McKay Conant Hoover Inc., 5655 Lindero Canyon Rd., Ste. 325, Westlake Village, CA 91362, DConant@MCHinc.com)

An unusual human resources office building under construction in Basel, Switzerland presented several acoustical challenges stimulated by both the architect and owner. Extensive studies demonstrated that without electronic speech sound masking, normal privacy would likely be unachievable until the receiver moved at least one floor level away from the talker. Still, the owner opted to provide no accommodation for masking for reasons we have not encountered before. Novel designs arose for absorptive chilled beams including a glass roof with chilled beam baffles. The design approaches and RASTI modeling via CATT-Acoustic are described.

3:50

1pAA11. How easy is it being green? Jesse J. Ehnert (Arpeggio Acoust. Consulting, LLC, 1947 Aspen Dr. NE, Atlanta, GA 30345, jehnert@arpeggioacoustics.com)

In 2007, the United States Green Building Council (USGBC) issued its Leadership in Energy and Environmental Design (LEED) for Schools Reference Guide defining requirements for certification which included classroom acoustical criteria. These criteria, which were based partially on the ANSI S12.60-2002 classroom acoustics standard, defined certification prerequisites (as well as additional credit requirements) in terms of three areas: reverberation time, sound isolation, and background noise level. In response to several issues related to compliance with these requirements, in 2008 the USGBC issued a Performance/Intent Equivalent Compliance Path (PIEACP) to provide alternate, and somewhat easier, means to meet LEED acoustic criteria. This presentation will weigh the potentially impractical aspects of the original guidelines and the possibly ineffective aspects of the PIEACP and will discuss the emergent areas of resistance on the part of designers and owners in relation to acoustical requirements in the context of several examples. It is the hope that properly addressing these points of resistance, and their inherent economic motivations may, perhaps, lead to a more reasonable, coherent, and enforceable set of criteria to achieve LEED certification.

4:05

1pAA12. Building ventilation and acoustics for people who don't know much about building ventilation. Michael Ermann (School of Architecture and Design, Virginia Tech, 201 Cowgill Hall, Blacksburg, VA 24061-0205, mermann@vt.edu)

The architectural composition required for building ventilation, used both for low energy cooling and improved air quality, can be anathema to acoustical goals of speech privacy and noise control. This paper presents a short tutorial on the basics of cross ventilation, stack ventilation, comfort ventilation, and indoor air quality as it relates to climate, building type, and indoor pollutants. It is geared to those without significant prior knowledge and follows a similar tutorial on geothermal systems, presented at the Miami ASA conference.

4:20—4:50 Panel Discussion

1:00

1pABa1. The swimming motions of fish as hydroacoustic signals. Sheryl Coombs (Dept. of Biological Sci. , Bowling Green State Univ., Bowling Green, OH 43402)

Discussions about bioacoustic communication in fishes largely neglect the hydroacoustic fields produced by the swimming motions of fish, focusing instead on sounds produced by stridulation (the rubbing of body parts) and the drumming of swimbladder walls by surrounding muscles. This talk will describe some of the temporal and spatial characteristics of swimming-generated signals, the evidence for their ability to stimulate both the lateral line and auditory systems of fish, and their potential role in behaviorally-relevant contexts, including courtship and spawning, predator avoidance by fish schools, and spatial exploration of novel environments.

1:15

1pABa2. Auditory research from the sleeper goby to zebrafish. Zhongmin Lu (Dept. of Biology, Univ. of Miami, 1301 Memorial Dr., Coral Gables, FL 33146)

This presentation covers neural coding of acoustic particle motion by a hearing generalist (the sleeper goby, *Dominator latifons*) and research transition to a hearing specialist (the zebrafish, *Danio rerio*). Unlike sound pressure, particle motion, a component associated with sound pressure in any sound wave, provides the directional information about sound source. In recent years progress has been made in neural representation of acoustic particle motion by several hearing generalists that are primarily sensitive to the particle motion mode of sound. Here a review will be given on single-unit physiology of octavolateral afferent and efferent neurons as well as neurons in the descending octaval nucleus of the sleeper goby in response to linear acceleration that simulates underwater acoustic particle motion, providing insights into their functions. In the second half of the presentation, two preliminary projects in my lab will be introduced using the zebrafish that has become an increasingly important vertebrate model organism for biomedical research. The projects are development of the auditory function of zebrafish and alcohol effects on the octavolateral system of zebrafish. Advantages and disadvantages of different fish models will be discussed. [Work supported by NIH/NIDCD R01DC003275 and Gabelli Fellowship.]

1:30

1pABa3. Evidence of binaural directional computations in the auditory pathway of a teleost fish. Peggy Edds-Walton (Neurosci. Inst., Marine Biol. Lab, Woods Hole, MA 02543, plewalton@yahoo.com) and Richard Fay (Loyola Univ., Chicago, IL 60626)

Although binaural processing is known to be critical for sound source localization in terrestrial vertebrates, binaural processing for sound source localization in fishes has not been demonstrated. Previous physiological and neuroanatomical studies have indicated that interaural convergence is present in auditory pathway of oyster toadfish (*Opsanus tau*). In this study, we introduce a reversible method, otolith tipping, to evaluate the presence of binaural inputs. The normal directional response pattern (DRP) was recorded extracellularly for auditory cells in the first-order descending octaval nucleus (DON) or the midbrain torus semicircularis (TS) using directional stimuli in the horizontal and midsagittal planes. The DRP was re-evaluated while gently tipping the ipsilateral or contralateral otolith of the saccule to alter the normal relationship with the auditory epithelium. The DRP was also evaluated post-tipping to ensure no damage had occurred. In the DON, ipsilateral or contralateral tipping most often altered or eliminated spike activity; in the TS, tipping most often caused a change in the shape or orientation of the DRP. The data indicate complex interactions of excitatory and inhibitory inputs, which appear to be associated with the convergence of binaural inputs in the DON and TS. [Work supported by the NIH.]

1:45

1pABa4. Determining underwater auditory thresholds in fish based on particle motion. Mardi C. Hastings (Appl. Res. Lab., Penn State Univ., P. O. Box 30, State College, PA 16804, mch26@psu.edu)

Acoustic particle motion is believed to play a significant role in the auditory scene of fishes even though most all hearing sensitivity data are measured with respect to sound pressure level. Auditory motion thresholds have been measured in air for goldfish (*Carassius auratus*), oscars (*Astronotus ocellatus*), and toadfish (*Opsanus tau*) by moving the fish's body using a carefully calibrated shaker table [R. R. Fay, Science **225**, 951–954 (1984); Z. Lu, A. N. Popper and R. R. Fay, J. Comp. Physiol. A **179**, 227–233 (1996); R. R. Fay and P. L. Edds-Walton, Hearing Res. **111**, 1–21 (1997)]. These responses depend on both direction and amplitude of the motion. Thus, underwater particle motion thresholds must include both direction and amplitude, but most experimental setups are not designed for this purpose. Passive and active methods to control the direction and amplitude of acoustic particle motion underwater are presented. It is not enough just to measure the local particle motion in a small tank and report its amplitude as a threshold, especially when incidental sound pressure could be contributing to the auditory response and the orientation of the fish with respect to the direction of the particle motion vector is ill defined.

2:00

1pABa5. Peripheral neural coding strategies for spectral analysis and sound source location in the nonteleost bony fish, *Acipenser fulvescens*. Michaela Meyer, Arthur N. Popper (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, michaela_meyer@meei.harvard.edu), and Richard R. Fay (Loyola Univ. of Chicago, Chicago, IL 60626)

Coding mechanisms for spectral analysis and sound source location were investigated in *Acipenser fulvescens*, the lake sturgeon. *A. fulvescens* belongs to one of the few extant nonteleost ray-finned fishes, with a phylogenetic history that dates back about 200 million years. A shaker system was used to simulate the particle motion component of sound during electrophysiological recordings of isolated single units from the eighth nerve. Data were compared to teleosts and land vertebrates. Peripheral coding strategies for spectral analysis and sound source location in *A. fulvescens* resembled those found in teleosts. Frequency characteristics generally resembled that of low-frequency afferents of other fishes and land vertebrates and the auditory periphery in *A. fulvescens* appears to be well suited to encode the intensity of sound. Eighth nerve afferents responded to directional stimuli in a cosinelike manner (as in teleosts). However, differences from teleosts were found that may have implications for the mechanisms for sound source location in azimuth. The common physiological characteristics among *A. fulvescens*, teleosts, and land vertebrates may reflect important functions of the auditory system that have been conserved throughout the evolution of vertebrates.

2:15

1pABa6. Auditory saccular potentials of the little skate, *Raja erinacea*. Joseph A. Sisneros (Dept. of Psych., Univ. of Washington, 337 Guthrie Hall, Seattle, WA 98195) and Richard R. Fay (Loyola Univ. Chicago, Chicago, IL 60626)

Previous behavioral studies have shown that elasmobranch fishes can be attracted to low-frequency sound sources (< 80 Hz) in their natural habitat, but relatively few studies have characterized the auditory response properties of the elasmobranch inner ear to low-frequency sounds. Here, we examine the response properties of evoked saccular potentials from the skate inner ear to determine the auditory threshold sensitivity and frequency response of saccular hair cells to low-frequency stimuli. Saccular potentials were recorded from the medial region of the saccule while sound was generated using a shaker table designed to mimic the particle motion component of sound. Four test frequencies (50, 64, 84, and 100 Hz) and 11 directions were used to characterize the displacement sensitivity, frequency response, and directional response properties of the skate saccule. Saccular potentials were evoked and measured at twice the stimulus frequency *in vivo* using a wave analyzer, while stimuli were generated via the shaker table system. The right and left saccule appeared to have an omnidirectional response based on our initial measurements, but the frequency response of the skate saccule had lower displacement thresholds at 84 and 100 Hz compared to stimuli at 50 and 64 Hz.

2:30

1pABa7. Sensitivity of utricular afferent fibers to intraspecific calling via inductive neural telemetry in free ranging oyster toadfish, *Opsanus tau*. Allen F. Mensinger (Biology Dept., Univ. of Minnesota Duluth, 1035 Kirby Dr. Duluth, MN 55812, amensing@d.umn.edu) and Karen P. Maruska (Stanford Univ., Stanford, CA 94305)

Male toadfish acoustically attract females to nesting sites by producing boat-whistle calls. To determine how the fish localize sound underwater, inductive neural telemetry was used to record from microwire electrodes chronically implanted into the utricular nerve of the toadfish, *Opsanus tau*. The telemetry tag allowed both laboratory and field monitoring of unrestrained, naturally behaving fish. The sensitivity of utricular afferent nerve fibers to male toadfish boat whistle calls and pure tone stimulus was determined in water depths ranging from 0.4 to 1.0 m via underwater speakers. Hydrophones were placed approximately 5 cm above the otoliths to determine the physical characteristics of the sound impinging on the utricle. Approximately 75% of the afferent fibers exhibited increased firing to sound stimulus, with many showing directional sensitivity. Thus, toadfish may be able to use information from the utricular afferents to localize sound underwater. [Work supported by NSF Grant 0316130.]

2:45

1pABa8. Phylogenetic analysis of high-frequency hearing in teleost fishes. Dennis M. Higgs (Dept. Biological Sci. , Univ. of Windsor, 401 Sunset, Windsor ON N9B 3P4, Canada, dhiggs@uwindsor.ca)

The evolutionary drivers responsible for the selection of high-frequency hearing in teleosts remain unclear. It is generally accepted that low-frequency hearing is the basal (plesiomorphic) condition, with specializations evolving to allow expansion of hearing bandwidth. While selective forces, usually habitat-based, have been proposed to explain the evolution of high-frequency hearing, phylogenetic analysis is currently lacking. The current study examines all available teleost hearing abilities in relation to habitat parameters,

salinity, and maximum depth of occurrence of each species. There was no statistical correlation between any of these parameters and maximum frequency of detection and only a weak relationship to best frequency. Phylogenetic position, at the subdivision/superorder level, did significantly predict both maximum and best frequency of detection, but there was no consistent pattern of high-frequency hearing within the Teleostei, suggesting independent evolution of this ability. These trends were also consistent at the family level. The current reanalysis of available data therefore suggests little evidence for the habitat-based hypotheses of high-frequency hearing evolution in the Teleostei. Interesting families and approaches will be highlighted in the current talk in an attempt to foster a more systematic approach to future studies of hearing in fish. [Work supported by NSERC.]

3:00—3:20 Break

3:20

1pABa9. Repetition is the branding iron of knowledge: Lessons from the mulitple origins of enhanced hearing. Christopher B. Braun (Dept. of Psych., Hunter College, 695 Park Ave., New York, NY 10021)

Enhanced hearing, the ability to detect minute fluctuations in ambient pressure, has evolved independently or nearly so within every major group of vertebrates. Within Teleost fishes, enhanced hearing has evolved perhaps as many as 20 times. Within one subset of cichlid fishes, the Malagasy and south Asian Etroplinae + Ptychochrominae, several lineages appear to have independently evolved morphological specializations that might enhance hearing. There are approximately 25 species of cichlids on Madagascar and all are narrowly endemic with well-defined habitats ranging from shallow floodplain lakes to rheophilic habitats. The gas bladders of individual species range from unspecialized (*Katria katria*) to highly modified (*Paretroplus sp*). All species of Paretroplus possess paired intracranial auditory bulla, but individual species vary in the degree of gas bladder modification (e.g., tunic stiffness, diverticula structure). This diversity presents a unique opportunity to explore the relationships among habitat noise and hydrodynamics, morphological specializations, and hearing ability within a specific phylogenetic hypothesis. This talk will present the history of hearing evolution within Malagasy cichlids, covering ecological, morphological, and functional aspects. The multiple independent origins of hearing will be emphasized as replicates of evolutionary experiments. Such replication highlights the commonalities behind the evolution of hearing in all vertebrates.

3:35

1pABa10. Comparative studies of the auditory periphery of deep-sea fish. Xiaohong Deng (Dept. of Biology and Neurosci. and Cognit. Sci. Program, Univ. of Maryland, College Park, MD 20742, xhdeng@umd.edu), H. Jochen Wagner (Univ. of Tubingen, Tubingen, D-72074, Germany), and Arthur N. Popper (Univ. of Maryland, College Park, MD 20742)

Many species of deep-sea fish have special sensory adaptations to help them survive at great depths and with lack of light. While such adaptations are best known in the visual system, it is likely that there are also auditory system adaptations that enable the fish to make use of the auditory scene. However, there are few data on the auditory system of deep-sea fish. The study compared inner ear structures between several such species. Some features in the ears in the species studied were similar to structures associated with enhanced hearing ability in the ears of some shallow water hearing specialists. These findings support the hypothesis that some deep-sea fishes have evolved specializations for hearing. We also report some features in the ears of deep-sea fishes that have never been seen in the ears of other vertebrates. These include specializations in the orientation of sensory hair cells, diversity in hair cell ciliary bundle shapes, and a number of unique otolith characteristics. While it is not possible to test hearing in deep-sea fishes, the various adaptations found suggest that at least some have evolved highly specialized adaptations to enable them to use sound in the deep sea.

1pABa11. Ontogeny of auditory saccular tuning in the plainfin midshipman fish, *Porichthys notatus*. Peter W. Alderks and Joseph A. Sisneros (Dept. of Psych., Univ. of Washington, Box 351525, Seattle, WA 98195, pwa2@u.washington.edu)

Sensory systems are important throughout an animal's life history, allowing it to detect and respond to biologically relevant stimuli important for survival and reproduction. The auditory system of the plainfin midshipman fish (*Porichthys notatus*) plays an important sensory receiving role for encoding vocal-acoustic communication signals produced by adults, but the response properties and function of this receiver system during ontogeny are less understood. Here, we examine the response properties of evoked saccular potentials in two size classes of juveniles [small = 1.9–3.0 cm standard length (SL) and large = 5.0–8.0 cm SL] and in nonreproductive adults ($>$ 9.0 cm SL) to determine the auditory sensitivity of saccular hair cells during ontogeny. Saccular potentials, maximally evoked at twice the stimulus frequency, were recorded in vivo using a lock-in amplifier while playing pure tone stimuli via an underwater speaker. Results indicate an ontogenetic retention of saccular tuning sensitivity with size/age with peak sensitivity ranging from 75 Hz (lowest frequency tested) to 185 Hz. In addition, maximum detectable frequency of the saccule also increased with size/age. These results suggest that the midshipman saccule is best suited to detect low frequency components ($<$ 105 Hz) of conspecific vocalizations throughout ontogeny.

4:05

1pABa12. Central auditory processing and neuropeptide modulation of hearing in the damselfish. Karen P. Maruska (Biology Dept., Stanford Univ., 371 Serra Mall, Stanford, CA 94305, maruska@stanford.edu) and Timothy C. Tricas (Univ. of Hawaii, Honolulu, HI 96822)

Acoustic communication is important for social behaviors in many fishes, but how the central auditory system encodes complex sounds and how neuromodulators influence hearing is poorly understood. The Hawaiian sergeant damselfish produces pulsed low-frequency low-intensity sounds during agonistic and reproductive behaviors, and provides an ideal model to study auditory processing and hormone effects in a species that does not possess special adaptations to enhance hearing. Single-cell recordings were used to (1) compare response properties and sensitivity of auditory neurons between the hindbrain and midbrain to both simple tones and playbacks

of complex conspecific sounds, and (2) test the effects of the neuromodulator gonadotropin-releasing hormone (GnRH) on midbrain auditory response properties. Auditory neurons in both the hindbrain and midbrain showed similar high phase-locking ability and best frequencies of 80–400 Hz, but midbrain neurons were more sensitive to conspecific sounds compared to hindbrain neurons. GnRH application to the midbrain showed primarily inhibitory effects on evoked auditory responses, evidenced by a GnRH-induced decrease in spike rate compared to saline controls. These data highlight the importance of using natural stimuli to test hearing abilities, and indicate that GnRH has the potential to influence central auditory processing during natural social behaviors in the damselfish.

4:20

1pABa13. Substrates for vocal-acoustic plasticity: Neuroestrogen and steroid hormone receptor expression in midshipman fish. Paul Forlano (Dept. of Neurobiology and Physio., Northwestern Univ., Evanston, IL 60208, p-forlano@northwestern.edu), Margaret Marchaterre, David Deitcher, and Andrew Bass (Cornell Univ., Ithaca, NY 14853)

In a teleost fish, the midshipman *Porichthys notatus*, androgens and estrogen rapidly modulate vocal motor patterning and contribute to seasonal changes in the frequency encoding of the eighth nerve. To identify potential sites of action of these steroids, as well as local estrogen synthesis (via conversion from testosterone by the enzyme aromatase), in situ hybridization was employed to identify estrogen receptor alpha (ER), androgen receptor (AR), and aromatase mRNA distribution in vocal and auditory circuitry. AR expression was more widespread than ER and found at all levels of the vocal motor pathway and in vocal-acoustic integration centers, while aromatase was particularly abundant in the vocal motor system. Both AR and ER were identified in midbrain and forebrain auditory nuclei and in the saccular epithelium of the inner ear, the main auditory end organ in midshipman and most teleosts. Aromatase was found in ganglion nerve cells of the eighth nerve, suggesting that the ear itself is a local source of estrogen driving peripheral auditory plasticity. In sum, expression of steroid receptors in vocal and auditory nuclei, and the inner ear, support neurophysiological evidence for the role of estrogen and androgens as modulators of vocal output and auditory encoding in midshipman fish. [Work supported by NIMH, NIH, and NSF.]

4:35

1pABa14. Otolith crystallization in salmonid fishes: Possible causes and consequences for the fish. Allison B. Coffin (Dept. of Otolaryngol.-H&S Surgery, Univ. of Washington, Box 357923, Seattle, WA 98195, coffina@u.washington.edu)

The primary hearing organ in most fishes is the saccule, which contains a calcareous otolith composed of aragonite and its associated sensory epithelium. In some fish populations, particularly salmonids, the aragonite in the saccular otolith is partially or mostly replaced by vaterite, a phenomenon known as otolith crystallization. Despite the relatively common occurrence of otolith crystallization, the cause of this switch in calcium carbonate type and the consequences for the fish are not understood. The present study looks at both proximal and distal mechanisms that may contribute to otolith crystallization in various salmonid species, particularly with regard to environmental stress and physiological consequences of that stress. Structural and functional data on the ears of salmonids with crystallized otoliths will also be presented. Auditory evoked potential recordings from juvenile chinook salmon demonstrated that fish with at least one vaterite otolith have significantly increased hearing thresholds compared to conspecifics with two aragonite otoliths. These findings suggest that otolith crystallization can have potential negative consequences for the animal.

1pABb1. Ultrasonic upward FM vocalization of Mongolian gerbils, *Meriones unguiculatus*. Kohei Nishiyama, Kohta Kobayasi, and Hiroshi Riquimaroux (Faculty of Life and Medical Sci. , Doshisha Univ., 1-3 Miyakotani Tatara, Kyotanabe 610-0321, Japan, hrikimar@mail.doshisha.ac.jp)

Mongolian gerbils, *Meriones unguiculatus*, have been used for auditory physiological studies. However, few studies have investigated precise relationships between a specific vocalization and a specific behavior. The purpose of this study was to examine the process to produce a specific vocalization: Greeting call. Their vocalizations and behaviors were separately recorded when two gerbils are put in the same experimental chamber. The sound data were synchronized with movie data to analyze their movement loci by using behavioral analysis software. The results showed that gerbils tended to emit ultrasonic upward FM calls, Greeting calls (average frequency range: 29.4 to 34.9 kHz, duration: 27.0 ms, $n=$ 1185 calls), when the distance between two gerbils was close. About 45% of the calls were emitted when the distance was less than 10 cm. Moreover, in the situation where one gerbil quickly approached to the other, timings of Greeting call emission and footsteps of the approaching gerbil appeared to be synchronized. However, they did not vocalize at all when they were isolated, even when they moved in the same way. We may conclude that the repetitive upward FM ultrasonic emissions were not by-products of their movements but for their communication. [Research supported by ONR grant.]

1pABb2. Jamming of bat sonar by meadow katydids (*Conocephalus*). James A Simmons (Dept. of Neurosci., Box G-LN, Brown Univ., Providence, RI 02912)

Meadow katydids (Orthoptera: family Tettigoniidae, genus *Conocephalus*) are small (1–2 cm) grasshopperlike insects that congregate in late summer on low bushes and tall grass near ponds where males then emit calls to attract females. These sounds are entirely ultrasonic, consisting of sequences of brief (20–25 ms) bursts, repeated at 30 ms intervals, of 10–20 clicks separated by 1–1.5 ms within each burst. Each click covers frequencies of 20–90 kHz. The same frequencies are used for sonar by big brown bats (*Eptesicus fuscus*), which frequent the same ponds while hunting for prey and nearly always fly in audible range of the meadow katydids but do not attempt to capture any of them. Calls of several male insects usually overlap at slightly different inter-click intervals so that the acoustic waveform wavers, thus creating moving virtual acoustic sources for the bat's binaural listening. Aggregate calling is virtually continuous at sound pressures exceeding 90–100 dB SPL at distances of 1–2 m. Neuronal recovery-times in the bat's auditory system are ~0.5 ms to accommodate reception of closely-spaced echolocation emissions and multiple echoes, so click bursts will reliably evoke volleys of responses at successive stages of the bat's auditory pathway, preempting biosonar echoes received by approaching bats.

3:05

1pABb3. FM echolocating bats avoid pulse-echo ambiguity by shifting broadcast frequencies. Shizuko Hiryu (Doshisha Univ., 1-3 Tatara Miyakotani, Kyotanabe, Kyoto 610-0321, Japan), Mary Bates, James A. Simmons (Brown Univ., Providence, RI 02912), and Hiroshi Riquimaroux (Doshisha Univ., Kyotanabe, Kyoto 610-0321, Japan)

Big brown bats pursue flying insects in open areas, but they also hunt for prey near vegetation. The proximity of obstacles requires emission of sounds at short interpulse intervals (IPIs) to guide collision-avoidance maneuvers, yet the bat has to locate obstacles distributed in depth for path planning, which requires longer IPIs. If IPIs are too short, the stream of echoes for one sound will still be arriving when the second sound is emitted, creating ambiguity about matching echoes to broadcasts. We investigated how bats cope with pulse-echo ambiguity by recording sounds with a miniature radio microphone (Telemike) carried during flights through a dense array of obstacles (vertically hanging chains) that were distributed in depth. Array density forced bats to emit FM sounds at short intervals (strobe groups) with consequent pulse-echo ambiguity. We found that when ambiguity occurred, bats shifted the FM sounds in strobe groups upward and downward in frequency by several kiloHertz to distinguish each broadcast's echoes. Overlap of echo streams from the bat's own FM broadcasts causes extreme clutter interference, and bats react by slightly shifting FM frequencies to distinguish one sound's echo stream from another sound's. [Research supported by an ONR grant.]

3:20

1pABb4. Relationships between wingbeat and pulse-emission timings in three echolocating bats, *Rhinolophus ferrumequinum, Pipistrellus abramus*, and *Miniopterus fuliginosus*. Yu Watanabe, Shizuko Hiryu, Hiroshi Riquimaroux, and Yoshiaki Watanabe (Doshisha Univ., 1-3 Tatara Miyakotani, Kyotanabe, Kyoto 610-0321, Japan)

To investigate relationships between flight and echolocation behaviors in one CF-FM (*Rhinolophus ferrumequinum*) and two FM (*Pipistrellus abramus* and *Miniopterus fuliginosus*) Japanese echolocating bats, relationships between wingbeat and pulse-emission timings during landing flight were examined. Wingbeat timings were measured by a dual high speed video camera system (500 fps) and pulse-emission timings were precisely recorded by a wireless telemetry microphone mounted on the bats' head. The *R. ferrumequinum* and *P. abramus* emitted multiple pulses in a burst (pulse trains) per single wingbeat cycle, and pulse-emission timings were perfectly synchronized with their wingbeat, indicating that pulse-emission timings were affected by wingbeat. On the other hand, relationships between wingbeat and pulse-emission timings in *M. fuliginosus* were different compared with two other bats. The *M. fuliginosus* never emitted pulse trains, but proportionally increased emission rate of single pulse after approach phase started. As a consequent, pulse-emission timings were controlled regardless of wingbeat, and synchronization between wingbeat and pulse-emission timings was occasionally disturbed during approach phase. These results suggest that we need further discussion about the reason why synchronization between flight and echolocation behaviors appears to be formed by species-specific way among these bats. [Work supported by MEXT of Japan.]

1pABb5. Multisensory integration in the tadpole medulla arises from discrete and overlapping regions of endorgan projection. Andrea M. Simmons, Victoria Flores, and Seth S. Horowitz (Dept. of Psych., Brown Univ., 89 Waterman St., Providence, RI 02912)

Vestibular and auditory nuclei in the medulla are inherently multimodal in developing bullfrogs (Rana catesbeiana), responding to pressure, particle motion, and lateral line input. While brainstem and midbrain connectivity of these nuclei have been well mapped across metamorphic development, developmental changes in projection patterns from individual endorgans in the otic capsule (sacculus, utricle, lagena, and amphibian and basilar papilla) to the medulla are less well understood. Using small (26 nl) focal injections of neurobiotin in preganglionic branchlets for specific endorgans, we were able to map input from the separate peripheral organs to different medullary nuclei (medial, superior and lateral vestibular nuclei, the dorsal medullary nucleus, and the anterior lateral line nucleus). Some secondary transsynaptic label of the reticular gray and cerebellum was also noted. Projection patterns are correlated with different patterns of medullary responses to vibratory and to pressure stimulation. Endorgan projection patterns appear relatively stable across metamorphic development. These data suggest that changes in functional response properties in the medulla across development do not reflect rewiring of inner ear input, but instead depend on changes in connectivity between the medullary nuclei and their more central target zones. 1pAO1. Spatial and temporal coherence of scattered field from large fish groups instantaneously imaged with ocean acoustics waveguide remote sensing (OAWRS). Purnima Ratilal, Mark Andrews, Zheng Gong (Dept of Elec. and Comp. Eng., Northeastern Univ., 360 Huntington Ave., Boston, MA 02115, purnima@ece.neu.edu), and Nicholas Makris (MIT, Cambridge, MA 02139)

Wide area sonar system, such as OAWRS (ocean acoustics waveguide remote sensing), can instantaneously image large shoals of fish spanning tens of kilometers from long ranges in an ocean waveguide. An analytic and numerical model is developed for the spatial and temporal coherence of the scattered field from a large group of fish in a shallow water waveguide. The temporal coherence of the received signal depends on both the temporal coherence of the random waveguide through the medium Green's function and the correlation time scale for fish group distribution. The spatial coherence of the received signal depends on both the spatial correlation scale of the random waveguide inhomogeneities and that for the imaged fish group distribution. The temporal and spatial correlation scale for the fish group distribution are determined from experimental data acquired in the Gulf of Maine during the 2006 Ocean Acoustics Waveguide Remote Sensing (OAWRS) Experiment. The effect of temporal and spatial coherence of the scattered field on subsequent coherent array processing and matched-filtering is discussed.

1:25

1pAO2. Investigation of the impact of water column variability on acoustic inversions in a shallow water ocean. Ying-Tsong Lin, James F. Lynch, and Timothy F. Duda (Woods Hole Oceanograph. Inst., AOPE Dept. MS 11, Woods Hole, MA 02543)

Underwater sound propagation in a rapidly evolving shallow-water ocean has high temporal and spatial variability. To ensure the performance of acoustic inversion techniques to locate a sound source or estimate the sea-bottom parameters, it is necessary to take into account the water column variability, which can be done by introducing the empirical orthogonal functions (EOFs), which describe the water column variability, into the environmental model used for the inversions. However, in a range-dependent and time varying ocean, one needs to regularly update the EOFs according to the scales of environmental, spatial, and temporal coherence, or the EOFs may not be the most efficient and optimal vector bases to decompose the dynamic ocean field. In this paper, the environmental data collected during the New Jersey Shallow Water 2006 (SW06) experiment are analyzed to check the environmental coherence scales in the experimental site. The analysis results provide a guideline as to when and where one should update the EOF bases. The observation of the SW06 acoustic signal coherence is reported and correlated to the environmental variability. Finally, acoustic inversions using the SW06 data are performed, and the effects of using insufficient water-column EOFs are investigated.

1:45

1pAO3. Extracting waveguide parameters from the coherent field measured on a synthetic aperture horizontal array. Kyle M Becker (Pennsylvania State Univ./Appl. Res. Lab., P.O. Box 30, State College, PA 16804-0030)

For a time-harmonic source in a stratified waveguide, the acoustic field can be approximated by a coherent sum of modes propagating in range. In range-dependent waveguides, the phase contribution from mode n is the product of a range-dependent wave number $k_n(r)$ and range. At any given range, k_n is dependent on water depth and the depth-dependent geoacoustic parameters of both the water column and the seabed. To exploit these relationships, inversion algorithms have been developed for estimating range-dependent seabed properties from the acoustic field measured on synthetic aperture horizontal arrays. These methods are based on inferring information about the waveguide environment by extracting information contained in the phase of the acoustic signal as a function of range. In this talk we examine the individual contributions to the total phase from each of the propagating modes based on changes in depth, sediment sound speed, and water column properties. Sensitivity of individual modes to each of these changes will be examined along with their contribution to the total field. Issues associated with estimating modal content from field data and their use in inverse problems will then be discussed.

2:05

1pAO4. Passive remote sensing through cross-correlation of nondiffuse ambient noise. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Earth System Res. Lab., Boulder, CO 80305, Oleg.Godin@noaa.gov)

Under rather restrictive assumptions about ambient noise field and its sources, it has been demonstrated theoretically by a number of authors that one can retrieve the exact acoustic Green's function (GF) of an inhomogeneous medium from the noise cross-correlation function (NCCF). These assumptions are rarely valid for ambient noise in the ocean. In this paper, asymptotic approaches are used to investigate the information content of two-point correlation functions of ambient noise and their possible use for passive remote sensing of the environment under more general conditions, when there exists no simple, exact, local relation between NCCF and deterministic GFs. For noise sources distributed on a surface or in a volume of a moving or motionless, inhomogeneous fluid, a relation is established between contributions of ray arrivals to NCCF and GFs. A similar relation is derived for contributions to NCCF and GFs due to adiabatic normal modes in a horizontally inhomogeneous waveguide. The impact of nonuniformity of the spatial distribution of noise sources on accuracy of passive measurements of acoustic travel times is quantified. Effects of finite correlation length of noise sources on GF retrieval from ambient noise are discussed. [Work supported by ONR.]

2:20

1pAO5. Extension of path-integral theory to shallow-water coherence. Peter C. Mignerey (Acoust. Div. 7120, Naval Res. Lab., Washington, DC 20375, peter.mignerey@nrl.navy.mil)

A path-integral approach to the mutual coherence function of acoustic signals propagating in deep water was developed in the late 1970's. This theory requires a single dominant ray path that interacts weakly with the boundaries, a restriction which has precluded direct application to acoustic propagation in shallow water. Here, path-integral theory is extended to the mutual coherence of mode amplitudes defined over the horizontal plane. In this domain, the mode amplitudes follow a principal ray that has no interaction with lateral boundaries. The mutual coherence is found to be related to the spectrum of sound-speed fluctuations via a Fourier transform along a direction transverse to the acoustic propagation path. For sound-speed fluctuations generated by a linear internal-wave field, solutions are obtained that predict the mutual coherence with no free parameters. Such solutions were computed for a winter environment existent during an experiment that took place on the New Jersey shelf in December 2003. Comparison between theoretical and measured coherence is encouraging with respect to both the power-law behavior at short separations, and the transition to saturation at large separations. [Work supported by the Office of Naval Research.]

2:35

1pAO6. Effect of the internal tide on midfrequency transmission loss in the Shallow Water 2006 Experiment. Jie Yang, Daniel Rouseff, Dajun Tang, and Frank S. Henyey (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

Nonlinear internal waves depress the high-gradient region of the thermocline. After the waves have passed, it may take several hours for the thermocline to rise to its prewave level. To examine consequent acoustic effects, two acoustic data sets collected 18–19 August in SW06 were analyzed with one at a fixed range of 550 m and the other along a tow track out to 8.1 km. Both data sets allow the effects of the rising thermocline on acoustic propagation to be examined over a range of temporal and spatial scales. Signals transmitted are in the midfrequency band 1.5–10.5 kHz. The gradual rising of the thermocline is shown to change acoustic intensity by 5 and 2 dB for the fixed and towed source data, respectively. Using nearby oceanographic moorings, a simple plane wave ocean model is developed to provide time-dependent environmental input to broadband acoustic modeling assuming range-independency. Modeling results are shown to produce mean transmission loss results consistent with experimental observations at both the short and the long ranges. The results suggest that the rising thermocline effect of nonlinear internal waves on mean transmission loss is observable, significant, and predictable. The result has implications on geoacoustic inversion. [Work supported by ONR.]

2:50

1pAO7. Inversions from source of opportunity data collected on horizontal and vertical line arrays. Steven A. Stotts, Robert A. Koch, Sumedh M. Joshi, Vian T. Nguyen, and David P. Knobles (Appl. Res. Labs., The Univ. of Texas at Austin, 10000 Burnet Rd., Austin, TX 78758, stotts @arlut.utexas.edu)

Environmental and source track parameter values were extracted by coherent spatial and temporal field processing of data from a ship of opportunity source that were recorded on collocated horizontal and vertical arrays. The data were collected during the Shallow Water 2006 (SW06) experiment in a continental shelf, sandy sediment environment with a water depth of approximately 70 m. Inversion solutions for environmental and source track parameter values were obtained from both conventionally and adaptively beamformed subaperture data over a 5-km range scale. The inversion solution for the data from the source to the closest point of approach (CPA) is presented and compared to the prior information on the seabed parameter values provided by geophysical measurements and inversions using other measured acoustic data. The coherent received field structure for the source departing from CPA is compared to the model predictions obtained from the inversion solution for the seabed parameter values. Inversion solutions from the vertical line array data are compared to those obtained from the horizontal line array data. [This work is supported in part by ONR.]

3:05—3:30 Break

3:30

1pAO8. The evolution of vertical spatial coherence with range from source. Peter H. Dahl (Appl. Phys. Lab. and Dept. of Mech. Eng., Univ. of Washington, Seattle, WA 98105), Dajun Tang (Univ. of Washington, Seattle, WA 98105), and Jee Woong Choi (Hanyang Univ., Ansan, Korea)

Vertical spatial coherence for shallow water propagation at frequencies 1–10 kHz is studied as function of range (50 to 5000 m), as part of the Shallow-Water 2006 program that took place off the coast of New Jersey in August 2006 in waters 80 m deep. An acoustic source was deployed from the R/V Knorr at depths 30 and 40 m and signals were recorded on a moored receiving system consisting of two 1.4 m long vertical line arrays (VLA) centered at depths 25 and 50 m. At all ranges, spatial coherence, Γ (normalized spatial correlation), is locally stationary and depends on element vertical separation d up to the maximum kd (59) afforded by the VLA, where k is acoustic wave number. For range normalized by depth, r^*, less than about 10, Γ is oscillatory, with non-zero imaginary part, reflecting the inclusion of multipaths for which no single path dominates. For r^* greater than 10, Γ tends to exhibit a monotonic decay with kd and the imaginary part vanishes reflecting symmetry about 0 deg vertical arrival angle. The coherence also increases with r^* reflecting the change in modal structure. [Research supported by ONR Ocean Acoustics.]

3:45

1pAO9. Exploiting correlation in passive sonar Bayesian localization techniques. Colin W. Jemmott, R. Lee Culver (Penn State Graduate Program in Acoust., P.O. Box 30, State College, PA 16804), N. K. Bose, and B. E. Bissinger (Penn State, State College, PA 16804)

Low frequency acoustic signals in shallow water are strongly affected by interference between multiple paths resulting from boundary interactions. As the acoustic source moves through this interference pattern, the spatial variation in transmission loss can result in strong temporal modulation of the received signal, which can be used to localize the source. Acoustic propagation models can produce accurate transmission loss field predictions, but are sensitive to ocean environmental parameters such as bottom composition, bathymetry, and sound speed profile. If the uncertainty in the undersea environment can be described by probability density functions of these param-

eters, Monte Carlo forward models can be used to produce an ensemble of possible transmission loss realizations. A probabilistic model representing this ensemble must include a density function of transmission loss at each location, as well as correlation of transmission loss between locations. In addition, the choice of probabilistic model has a large impact on the form of the resulting Bayesian localization algorithm. Previous results have shown that including spatial correlation of transmission loss can result in improved localization. This talk will introduce a non-Gaussian probabilistic model for representing uncertainty in transmission loss predictions that includes correlation, and discuss the resulting recursive Bayesian localization algorithm.

4:00

1pAO10. Effect of noise sources motion on the performance of passive imaging from ambient noise cross-correlation. Karim G. Sabra (School of Mech. Eng., Georgia Inst. of Technol., 771 Ferst Dr. NW, Atlanta, GA 30332-0405)

It has been demonstrated theoretically and experimentally that an estimate of the Green's function between two receivers can be obtained from the long-time average of the cross-correlation of ambient noise at these two receivers in various environments and frequency ranges of interest: ultrasonics, underwater acoustics, and seismology. The coherent wavefronts emerge from a correlation process that accumulates contributions over time from noise sources whose propagation path passes through both receivers. Previous theoretical studies of the performance of this noise-based passive imaging technique assumed that the noise sources remain stationary. The influence of the motion of the noise sources (Doppler effect) on this passive imaging technique was investigated theoretically in both free spaces using a stationary phase approximation and extended to waveguide environments. Although the Doppler effect typically degrades the performance of standard wideband coherent processing schemes, such as time-delay beamforming of fast moving sources, it was found that the Green's function estimates extracted from ambient noise cross-correlations are not affected by the Doppler effect. Practical implications for at-sea passive tomography experiments using shipping noise will be discussed. [Work supported by ONR, Code 321.]

4:15

1pAO11. Measurements of acoustic propagation with accompanying high-resolution sound speed structure containing internal waves. Frank S. Henyey, Kevin L. Williams, and Dajun Tang (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, frank@apl.washington.edu)

During the Shallow Water 2006 experiment, simultaneous measurements were made of the sound speed structure associated with nonlinear internal waves and acoustic propagation at frequencies of 2–10 kHz over a 1 km path. The internal waves were measured by a towed CTD chain in order to get high resolution. These measurements were coordinated so that the nonlinear waves can be interpolated onto the acoustic path, allowing predictions of their effects on the acoustics. An internal wave train was measured that passed the acoustic path on August 13. When the wave train was in between the sound source and receiver, distinctive arrival time oscillations on three acoustic paths were measured, which are all rays having an upper turning point. Using the CTD chain data, a deterministic explanation is given to the arrival time oscillations.

1pBB1. Estimation of average acoustic concentration of Chinese hamster ovary cells using ultrasonic backscatter. Jun Song and William O'Brien, Jr. (URH326, Univ. of Illinois at Urbana-Champaign, 1111 W. Nevada St., Urbana, IL 61801, junsong2@illinois.edu)

Average acoustic concentration (AAC) is one important parameter of quantitative ultrasonic assessment of soft tissues. The objective of this study is to examine the AAC of Chinese hamster ovary (CHO) cells at varied cell densities using ultrasonic backscatter. The CHO cells were evenly distributed in 2% agar and the densities ranged from 500,000 to 54,000,000 cells /mL. Measurements of backscattered ultrasound were obtained over the frequency range of 17 to 80 MHz. Estimates of Average Scatterer Diameters and AAC were made by comparing the backscattered power spectra with three scattering models: Fluid-filled Sphere model (FFSM), Spherical Gaussian model (SGM), and Concentric Sphere Model (CSM). Over the frequency range of 28 to 50 MHz, the estimated ASDs were 20.0 ± 0 μm with FFSM, 22.2 ± 6.0 μm with SGM, and 20.1 ± 6.1 μm with CSM. In the cell density range of 500,000 to 10,000,000 cells/mL, the estimated AACs increased almost linearly from 10 to 34 dB/mm^3 using FFSM, from 16 to 39 dB/mm^3 using SGM, and from 8 to 31 dB/mm^3 using CSM. [Work supported by NIH Grant CA111289.]

1pBB2. Mammary tumor classification using envelope statistics from ultrasound backscatter and the homodyned K distribution. David Hruska, William D. O'Brien, Jr., and Michael Oelze (Dept. of Elec. and Comp. Eng., Univ. of Illinois at Urbana–Champaign, 405 N. Mathews Ave., Urbana, IL 61801)

Envelope statistics from ultrasound backscatter based on the homodyned K distribution were used to characterize organizational patterns of tissue microstructure in three rodent models of breast cancer: a mouse mammary carcinoma, a mouse mammary sarcoma, and a rat fibroadenoma. The homodyned K distribution was used to model the amplitude of the envelope of backscattered ultrasound yielding two parameters to characterize tissues: one related to the effective scatterer density and the other related to periodicity of scatterer locations. Ten tumors of each of the three kinds of tumors were scanned. Envelope statistics model parameters were estimated for regions of interest measuring 1×1 mm in each of the tumor images. These estimates were then averaged together for each tumor. A linear combination of the two estimated parameters was derived for each tumor in order to obtain a lumped parameter for discriminating between the different kinds of tumors. This linear combination yielded the following (mean$\pm$SD): carcinomas 9.58 ± 1.17, sarcomas 12.01 ± 0.78, and fibroadenomas 11.66 ± 1.15. These estimates were statistically significant in distinguishing carcinomas

from sarcomas ($p<0.05$) and carcinomas from fibroadenomas ($p<0.05$), but a statistically significant difference was not observed between the sarcomas and fibroadenomas ($p=0.44$). [Work supported by NIH CA111289.]

1pBB3. On the use of coded excitation and pulse compression to reduce estimate error of average scatterer diameters obtained from ultrasonic backscatter. Jose R. Sanchez, Darren Pocci, and Michael L. Oelze (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, 405 N. Matthews, Urbana, IL 61801)

A technique that extends the tradeoff of variance of average scatterer diameter (ASD) estimates and the spatial resolution in quantitative ultrasound (QUS) images is proposed. Resolution enhancement compression (REC), a coded excitation and pulse compression technique, was used to enhance the −6-dB bandwidth of an ultrasonic imaging system. The objective of this study was to combine REC with QUS (REC-QUS), and evaluate and compare improvements in ASD estimates obtained using the REC technique to conventional pulsing (CP) methods. Simulations and experimental measurements were conducted with a 10 MHz weakly focused (f/4) single-element transducer (−6-dB bandwidth of 80%). Using REC, the −6-dB bandwidth was enhanced to 152%. In simulations, a homogeneous phantom with scatterers 50 μm in diam was evaluated. In experimental measurements, a tissue-mimicking phantom that contained glass spheres with scatterer diam that range from 45 to 53 μm was evaluated. Estimates of ASD were obtained by comparing the normalized backscattered power spectra to theory. Simulation results indicate that for a constant variance, a reduction in region-of-interest size from 15 CP pulse lengths to 1.5 CP pulse lengths was achieved by using REC-QUS. In experimental measurements, the estimate variance decreased by 88% by using REC-QUS over conventional QUS. [Work supported by NIH-R21-EB006741.]

1pBB4. Improvements in compression of coded excitation echoes by using a spatially varying Wiener filter. Jose R. Sanchez and Michael L. Oelze (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, 405 N. Matthews, Urbana, IL 61801)

Coded excitation schemes require compression of echoes to restore pulse resolution after transmission of an elongated signal. Compression schemes are often performed using a Wiener filter, which contains a smoothing parameter that controls the trade off of gain in echo signal-to-noise ratio (eSNR), sidelobe levels, and axial resolution. A Wiener filter that takes into consideration the spatially varying nature of the pulse-echo impulse response of the ultrasound imaging system within the depth of field was explored. This spatially varying Wiener filter (SVWF) generates numerous compressed outputs within the depth of field that are compounded into one final output, i.e., one final image. The final image using the SVWF has improved sidelobe levels and eSNR when compared to not using the SVWF for compression. Experimental measurements were conducted with a 2.25 MHz weakly focused (f/3) single-element transducer (−6-dB bandwidth of 75%). The imaging targets evaluated consist of planar reflectors, wire targets in water, and wire targets in urethane rubber (ATS 539 multipurpose tissue-mimicking phantom). To evaluate the performance of the SVWF, the spatial resolution, eSNR, and sidelobe-to-mainlobe ratio were evaluated from the images. Preliminary results suggest that compressing at each spatial location within the depth of field improved sidelobe levels leading to improved imaging performance. [Work supported by NIH-R21-EB006741.]

1pBB5. Extending the trade-off between spatial resolution and variance in quantitative ultrasonic backscattering imaging (QUS) using full angular spatial compounding. Roberto J. Lavarello, Jose R. Sanchez, and Michael L. Oelze (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana–Champaign, 405 North Mathews Ave., Urbana, IL 61801)

Tissue microstructure properties can be estimated using backscattered power measurements and quantitative ultrasound (QUS) techniques. The objective of this study was to evaluate the use of full angular (i.e., 360°) spatial compounding as a means of extending the trade-off between QUS variance and spatial resolution. Simulations and experimental results were conducted with a 10 MHz, *f*/4 transducer. In simulations, a synthetic phantom consisting of two eccentric cylindrical regions with Gaussian inclusions with 50 and 25 μm average scatterer diameter (ASD) values was analyzed. The use of multiple view data reduced the corresponding ASD standard deviations from 13.7 and 19.6 μm to 2.5 and 3.7 μm, respectively. In experimental measurements, a phantom that contained glass spheres with diameters between 45 and 53 μm was evaluated. The ASD standard deviation obtained using single view data was 10.4 μm. When using 32 angles of view and reducing both region-of-interest (ROI) dimensions by a factor of 2, the ASD standard deviation was reduced to 4.8 μm. The results presented here demonstrate that both QUS spatial resolution and precision can be improved simultaneously by using full angular spatial compounding. This method finds direct applicability for breast tissue characterization, for which full angular coverage is available.

1pBB6. A study of two techniques for three-dimensional ultrasonic tomography using inverse scattering. Roberto J. Lavarello and Michael L. Oelze (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana–Champaign, 405 North Mathews Ave., Urbana, IL 61801)

A majority of inverse scattering works consider 2D imaging problems. Therefore, the study of 3D inverse scattering methods is necessary for future applications of ultrasonic tomography. Two approaches were examined through simulations for image reconstruction of spherical targets. In the first approach, transducers focused on elevation were used to produce a series of 2D image slices of the object using the distorted Born iterative method (DBIM). The resulting 3D image reconstruction was rendered by stacking serial 2D slices. Typical mean average error (MAE) values in sound speed contrast reconstructions were above 25%. Reconstruction artifacts due to large multiple scattering were identified in addition to the limited spatial resolution in the vertical direction predicted by linear imaging theory. The magnitude of the artifacts decreased with decreasing focal number and also depended on properties of the imaging target (i.e., sound speed contrast and radius). In the second approach, pointlike transducers were used to produce a fully 3D DBIM image reconstruction by inverting the 3D wave equation. Reconstructions using 3D DBIM resulted in MAE values around 13%, and no noticeable artifacts when transducers were properly distributed. The dependence of reconstruction quality on transducer arrangement was studied by analyzing three different array configurations.

3:05

1pBB7. Fractal ladder models and power-law wave equations. James F. Kelly (Dept. of Appl. Math., Spanagel Hall, Rm. 250, 833 Dyer Rd., Monterey, CA 93943-5216) and Robert J McGough (Michigan State Univ., East Lansing, MI 48823)

Extensive measurement of the ultrasonic attenuation coefficient in human and mammalian tissue has revealed a power-law dependence on frequency. To describe this power-law behavior in tissue, a hierarchical fractal network model is proposed. The viscoelastic and self-similar properties of tissue are captured by a constitutive equation based on a lumped-parameter infinite-ladder topology involving alternating springs and dashpots. In the low-frequency limit, this ladder network yields a stress-strain constitutive equation with a time-fractional derivative. By combining this constitutive equation with linearized conservation principles and an adiabatic equation of state, the fractional partial differential equations previously proposed by [M. Caputo "Linear models of dissipation whose *Q* is almost frequency independent--II," Geophys. J. R. Astron. Soc. **13**, 529–539 (1967)] and [MG. Wismer "Finite element analysis of broadband acoustic pulses through inhomogeneous media with power-law attenuation," J. Acoust. Soc. Am. **120**, 3493–3502 (2006)] are derived. The resulting attenuation coefficient is a power-law with exponents ranging between 1 and 2, while the phase velocity is in agreement with the Kramers–Kronig relations. The power-law exponent is interpreted in terms of the mechanical structure and related to the spectral dimension of the underlying fractal geometry.

3:20

1pBB8. Shear wave elastography of cetacean tissues. Michael Gray, James Martin, and Peter Rogers (Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405)

An ultrasound-based elastography system is being developed to noninvasively measure the complex shear speed in cetacean head tissues, including brain, jaw fat, and melon. The system instrumentation features a pair of dual-element confocal ultrasound transducers, one of which is used to remotely generate low frequency shear waves in soft tissues via radiation force, while the other is used as a vibrometer to measure the resulting shear wave displacements. Results are presented for in situ measurements on formalin fixed tissues from a bottlenose dolphin (tursiops truncatus). [Work supported by ONR.]

3:35

1pBB9. Tissue shear elasticity assesment using time reversal. Gallot Thomas, Catheline Stefan (LGIT,1381 rue de la Piscine, 38041 Grenoble, France), Benech Nicolas, Negreira Carlos, and Brum Javier (LAU, 11400, Montevideo, Uruguay)

Shear waves in a soft solid can be focalized using time-reversal (TR) methods. The wavelength depending on the elasticity of the medium is related to the focal spot width through the Rayleigh critera. This study proposes to quantitatively estimate the mechanical properties inside a 3-D soft solid cavity from one channel TR experiments. Shear waves are created with an external low-frequency ($<$300 Hz) mechanical excitation. The first step of the TR experiment consists in the observation of the forward reverberant elastic field; in a second step the backward field is computed in order to refocus the shear waves. Then the wavelength is deduced from the TR focus spot. Two methods for the observation step have been tested, the first one measuring one component of the vectorial field inside the solid by ultrasonic techniques developed in elastography. This method takes advantage of the ultrasound spatial accuracy and its robustness as regard to shear wave source allows to think about many applications in the medical field, including deep or moving organs. The second one is based on the surface wave measurement by acoustic sensors. This low-cost method could be useful in food industry.

3:50

1pBB10. Time-reversal Rayleigh wave for soft solid characterization. Brum Javier, Benech Nicolas, Negreira Carlos (LAU, Inst. de Fisica, Facultad de Ciencias, Iguá 4225, 11400, Montevideo, Uruguay), Catheline Stefan, and Gallot Thomas (LGIT, 38041 Grenoble, France)

In this work the shear elasticity of soft solids is measured from the surface wave speed estimation. An external source creates mechanical waves in the audible frequency range. Surface waves are detected using acoustic sensors. The surface wave speed estimation is extracted from the complex reverberated elastic field through a time-reversal analysis. These quantitative measurements in a hard and a soft gelatin-based phantom are validated by independent transient elastography estimations. In contrast with other quantitative elasticity assessment methods, one advantage of the present approach is that it is based on a low cost sound technology. Moreover, the robust and simple experiments performed in cheese and soft phantoms, allows thinking of applications in food industry and medicine.

4:05

1pBB11. Towards predicting intracranial pressure using transcranial Doppler and arterial blood pressure data. Pierre D. Mourad (Appl. Phys. Lab., Dept. of Neurosurgery, Box 356470, Univ. of Washington, Seattle, WA 98195, pierre@apl.washington.edu), Caren Marzban, and Michel Kliot (Univ. of Washington, Seattle WA 98195)

Pressure within the cranium (intracranial pressure, or "ICP") represents a vital clinical variable whose assessment—currently via invasive means—and integration into a clinical exam constitutes a necessary step for adequate medical care for those patients with injured brains. In the present work we sought to develop a non-invasive way of predicting this variable and its corollary–cerebral perfusion pressure (CPP), which equals ICP minus arterial blood pressure (ABP). We collected transcranial Doppler (TCD), invasive ICP and ABP data from patients at a variety of hospitals. We developed a series of regression-based statistical algorithms for subsets of those patients sorted by etiology with the goal of predicting ICP and CPP. We could discriminate between high and low values of ICP (above/below 20 mmHg) with sensitivities and specificities generally greater than 70 percent, and predict CPP within $\pm$5 percent, for patients with traumatic brain injury. TCD and invasive ABP data can be translated into useful measures of ICP and CPP. Future work will target use of non-invasive ABP data, automation of TCD data acquisition, and improvement in algorithm performance.

4:20

1pBB12. *In-utero* imaging of developing mouse embryos using a 34-MHz annular array and chirp-coded excitation. Jonathan Mamou, Jeffrey A. Ketterling (F. L. Lizzi Ctr. for Biomedical Eng., Riverside Res. Inst., 156 William St., 9th Fl., New York, NY 10038, mamou@rrinyc.org), Orlando Aristizábal, and Daniel H. Turnbull (New York Univ. School of Medicine, New York, NY 10016)

High-frequency ultrasound (HFU) is becoming a prevalent modality to image biological tissues with fine resolution. HFU imaging is routinely used for ophthalmologic, dermatological, and small-animal applications. Fine-resolution imaging is obtained at the expense of limited depth-of-field and acoustic penetration depth. In this study, a 34-MHz, five-element annular array was excited using chirp-coded signals and a synthetic-focusing algorithm was used to form images. This imaging approach allowed for the simultaneous increase of depth-of-field and penetration depth. Three-dimensional ultrasound datasets of 12.5-day-old mouse-embryo heads were acquired *in utero* using chirp and conventional excitations. From the synthetically focused images, brain ventricles and embryonic head were segmented and rendered in three dimensions. Significant artifacts such as segmenting ventricles outside the embryonic head were significantly more pronounced on the conventional-imaging reconstruction than on the chirp-based reconstruction. Furthermore, the total ventricle volume obtained with the chirp (6.3 mm^3) was similar to that estimated using a μMRI dataset (i.e., 7.5 mm^3). The conventional method greatly over evaluated the ventricle volume (11.4 mm^3). The results of this study suggest that HFU chirp-annular-array imaging could become a valuable method for medical imaging applications, such as *in utero* developmental biology. [Work supported by NIH Grants EB006509 and EB008606.]

1pBB13. Micro flexible ultrasound imaging array systems. Michael Lee, Rahul S. Singh, Martin O. Culjat, Elliott R. Brown, Warren S. Grundfest, and Hua Lee (CASIT, UCLA, Los Angeles, CA 90095)

Medical ultrasonography has continued to be an important biomedical imaging modality for its various advantages. Conventional medical ultrasound systems typically utilize a rigid transceiver phase array, with a relatively small transceiver contact area. A micro conformal system increases observation aperture by using a large, flexible transducer array that conforms to curved body surfaces, providing increased angular coverage and 3-D imagery. In addition, the frequency-modulated continuous wave (FMCW) signaling format requires lower peak power than pulse-echo systems and exhibit more favorable receiver noise characteristics. This paper provides an overview of the hardware development of the micro flexible ultrasound array system. The image formation procedure is first presented in the form of pulse-echo imaging modality. Subsequently, image reconstruction algorithms are formulated for the FMCW imaging format. In addition, the equivalence between the pulse-echo and FMCW imaging modes is developed. This enables us to conduct image reconstruction process in both space as well as spatial-frequency domain. The presentation includes theoretical analysis, image formation algorithms, and laboratory experiments. 1pMU1. Mapping the vibroacoustic behavior of harp soundboxes. Shira Daltrop, Andrzej Kotlicki, and Chris Waltham (Dept. of Phys. and Astronomy, Univ. of British Columbia, 6224 Agricultural Rd., Vancouver, BC V6T 1Z1, Canada)

Modern harp soundboxes typically consist of a thin soundboard made of an acoustic wood with a definite set of resonances, and a relatively heavy conical or polygonal back in which there are several holes. These holes exist to allow access to the string attachments but also have important acoustical properties. Harps more than 200 years old frequently have small holes in the soundboard itself, and none in the back. The quality of the sound radiation from a harp is determined in large measure by the vibrational behavior of the soundboard and the motion of air in the soundholes. Using an impact hammer, accelerometer and acoustic-velocity probe, we have mapped the velocity of a harp soundboard, and that of the air in the soundholes, in response to excitation at the string attachment points. The relationship between these motions is complex but also crucial in determining the quality of the instrument.

1:30

1pMU2. Real-time guitar radiation sound synthesis of forced string and body eigenfrequency vibrations using microphone array techniques. Rolf Bader (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstr. 13, 20354 Hamburg, Germany, R_Bader@t-online.de)

A guitar top plate vibration is investigated for different frequency regions taking string driving point dependencies into consideration using a microphone array of 128 microphones and back-propagating the recording to the top plate positions. These radiation patterns are integrated in space at arbitrary virtual microphone positions. A guitar tone or piece is then synthesized using these radiation patterns where the microphone positions can be changed as in a real recording situation. The synthesis process takes the pressure and phase relations of more than 100 positions on the top plate and the sound hole into consideration for two cases of waves, the traveling waves of forced top plate vibration of the string frequencies and the eigenfrequencies of the guitar body appearing mostly during the initial transient phase. These eigenfrequencies are integrated using the much more simple mode shapes of the top plate eigenmodes. The amplitude behavior of these frequencies, appearing and decaying during the initial transient, is calculated by integrating the energy which is supplied by the string acting with a force on the top plate as an impulse train.

2:00

1pMU3. Acoustic holography measurements in comparison with a three-dimensional finite element method modulation of the body of a classical guitar. Jan Richter (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstrasse 13, 20354 Hamburg, Germany, janrichter81@web.de)

The body of a classical guitar (consiting of the rib, back plate, top plate with bridge and fan bracing, soundhole and wooden block) which had been performed by 3-D finite element method (FEM) was presented at the 151st meeting of the ASA (session 3aMU3 in Providence, RI). As a submittal, a real guitar was used whose geometrical parameters had precisely been modeled using a computer. The resulting computation has subsequently been matched to the measurements of an acoustical holography taken from the same guitar body. This time the aim was to demonstrate how closely the FEM model resembles the "real" sound radiation of the guitar. Acoustic holography graphically displays the characteristics of sound radiation from a given body. Again the mode-shapes are of interest, but this time the characteristics of the sound in relation to the frequencies are of greater importance. They demonstrate how realistic the modulation is compared to the actual acoustics of the guitar.

2:45

1pMU4. Realtime virtual banjo model and measurements using a microphone array. Florian Pfeifle (Musik-wissenschaftliches Institut, Univ. of Hamburg, Alte Raabenstrasse 13, 20345 Hamburg, Germany, Florian.Pfeifle@haw-hamburg.de)

A model of a full-scale banjo was programmed in MATLAB and C using the finite differences method. Because of the highly complex algorithm, the model could not be put into practice in real time. A similar model was then written in VHDL, a hardware description language and implemented on a FPGA board. This hardware allows highly parallelized computation at highest clock rates, thereby, a realistic banjo model could be computed in real time. This virtual banjo could now be used to alter instrument-specific parameters in real-time. A large set of tests was conducted ranging from simple calibration of the most realistic parameters to the research of nonlinear effects on the membrane of the banjo. The findings where compared to the measurements of a real banjo done with a microphone array consisting of 128 microphones.

3:15

1pMU5. Acoustic and vibrometry analysis of beating in a large Balinese gamelan gong. David W. Krueger, Kent L. Gee (Dept. of Phys. and Astron., Brigham Young Univ., N283 ESC, Provo, UT 84602, dvdkrueger@gmail.com), Jeremy Grimshaw (Brigham Young Univ., Provo, UT 84602), Dorothy Manuel (Spelman College, Atlanta, GA 30314), and Molly E. Jones (Univ. of Michigan, Ann Arbor, MI 48109)

A large Balinese gamelan gong, the gong ageng wadon, is similar to other Indonesian gongs in that it is tonal. A previously undocumented phenomenon is the fact that this gong produces distinct beating, which is essential to Balinese gamelan music. In this study of Brigham Young University's gong ageng wadon, acoustical and vibrometry measurements were performed to analyze the source of the beating. Scanning laser Doppler vibrometer results show a beat frequency of about 3 Hz is produced near 150 Hz by closely spaced structural modes. A slightly slower beat frequency (around 2.5 Hz) is also produced at about 120 Hz. The difference in this case is that there is only one structural mode measured near this frequency. It appears that the acoustic radiation from this mode beats with a harmonic of the radiation from a lower structural mode and that this harmonic is caused by nonlinear acoustical phenomena.

3:30

1pMU6. Dampening vibration modes of the snare drum batter head. Barry Larkin (Dept. of Music, Iowa State Univ., 2825 W. Lincoln Way, Ames, IA 50014, blarkin@iastate.edu) and Andy Morrison (Northwestern Univ., Chicago, IL)

Percussionists have always had to contend with an undesirable ringing sound while performing on the snare drum. It is usually referred to as the "edge ring." A common method to eliminate this sound comes from placing some type of dampening material on the edge of the drum head. Manufacturers of drums have provided many ways of dealing with this problem including internal dampening devices, customized drums heads, or material designed to be placed on the drum head. Using electronic television holography, it was revealed the source of this "ring" to be the third mode of vibration that produces a pitch approximately one octave and a half step above the fundamental. During this presentation, laser holographic images from the fundamental to the 16th mode will be displayed. In addition, new and recent holography work will show the effect of dampening devices on the third and other modes. "I certify that I have complied with ASA ethical principles" Telephone number: 515.294.2818, FAX: 515.294.6409. Send Notice to Barry Larkin.

3:45

1pMU7. Normal modes of a circular drum head under nonuniform applied tension: Mode splitting with respect to perturbation symmetry. Randy Worland (Dept. of Phys., Univ. of Puget Sound, 1500 N. Warner, Tacoma, WA 98416, worland@ups.edu)

The effect of nonuniform tension on the normal modes of single headed musical drums is examined. Using the common (m,n) designation, ideal circular membrane modes with $m>0$ are doubly degenerate. This degeneracy may be lifted by a perturbation to the circular symmetry. Of practical interest to drummers are perturbations caused by nonuniform tension applied at the rim of the drum in the tuning process, leading in some cases to audible frequency splitting. The symmetry of the perturbation determines which of the various two-fold degenerate modes will split, and to what degree the two resulting frequencies will differ. A selection rule taken from group theory is used, along with principles of perturbation theory, to describe a general model of the frequency splitting of drum modes under the influence of nonuniform applied tension. This model is compared with results of finite element modeling of the membrane normal modes. Experimental results obtained using electronic speckle pattern interferometry (ESPI) are also compared with the model.

4:00

1pMU8. Importance of visual cues in networked music performances. Jonas Braasch (Sch. of Archit., Rensselaer Polytech. Inst., 110 8th St., Troy, NY 12180, braasj@rpi.edu)

Although music is predominantly an acoustic event, the importance of visual cues should not be underestimated. In this paper, a number of observations will be presented that were derived both from laboratory experiments and ongoing music collaborations over the Internet. Different requirements exist for networked music performances than for telematic speech conferences for which most Internet-based telecommunication systems have been developed. For example, audio/visual synchronicity is essential for speech applications, but it was often found advantageous to run the audio ahead of the video in networked music performances to minimize the audio delay, which needs to be below a critical value if the remote ensembles perform together rhythmically. Other aspects of speech and music applications are very similar, for example, the need to exchange documents, which are in the case of music predominantly music scores. In the common telepresence approach, it is typically asked how realistic the recreated environment has to be for satisfying results. In this paper, an alternative, more abstract approach based on virtual functionality will be discussed that also includes the integration of music scores into the virtual environment. 1pNS1. Predicting the effects of masking noise on communication distance in birds. Robert J. Dooling (Dept. of Psych., Univ. of Maryland, College Park, MD 20742), Marjorie Leek (Portland, OR 97225), and Ed West (West Ecosystems Anal., Inc., Davis, CA 95616)

Anthropogenic noise (e.g., highway noise) that exceeds natural ambient sound levels potentially can mask important acoustic signals used by birds during communication. Signals degraded by masking can in turn adversely affect critical behaviors such as mate attraction, territorial defense, parent-offspring communication, predator avoidance, and prey detection. The amount of masking depends not only on the physical characteristics of the noise (intensity, frequency, temporal pattern, etc.) but also the auditory capacity of the species, the acoustic structure of their vocal signals, the proximity of the birds to the noise source and each other, and the sound attenuation properties of the habitat. Here we present a quantitative model for predicting effective communication distances between birds subject to different levels and types of anthropogenic noise. Cross-species analysis shows that communication distances are largely context /environment dependent and species specific. Extrapolation of noise impact distance estimates even within groups of similar species should be exercised with caution. This model should be useful in environmental impact analysis of anthropogenic noise on birds and other wildlife, particularly species of conservation concern.

1:50

1pNS2. Metrics for characterizing the sources of ocean anthropogenic noise. John A. Hildebrand (Scripps Inst. Oceanogr., Univ. of California, San Diego, La Jolla, CA 92092-0205)

Decibels are the standard shorthand for describing acoustic intensity and sound pressure level, but may lead to misunderstanding when applied as bioacoustic metrics. Acoustic power and source transmission energy are alternate metrics with intuitive appeal. Acoustic power, calculated from the acoustic intensity multiplied by the emitted solid angle, yields units of watts. Likewise, the energy per source transmission, given by multiplying acoustic power by the duration of the transmission, yields units of joules. For continuous (or quasicontinuous) signals, the standard procedure is to measure the root-mean-square (rms) of the signal. However, this presents problems for short duration signals where the duration of the signal being measured is an important parameter. In these cases it may be more appropriate to measure the peak-to-peak signal, rather than rms. Bandwidth is another important component of how the signal is described, typically in a narrow-band for ambient noise and broad-band for discrete sources. The characteristics of ocean anthropogenic noise sources in terms of these metrics will be discussed.

2:10

1pNS3. Marine mammal noise exposure criteria: Initial scientific recommendations. Brandon L. Southall (NOAA/NMFS Ocean Acoust. Prog., 1315 E-W Hwy. #12539, Silver Spring, MD 20910), Ann E. Bowles (Hubbs-SeaWorld Res. Inst., San Diego, CA 92109), William T. Ellison (Marine Acoust., Inc., Middletown, RI 02842), James J. Finneran (Space and Naval Warfare Sys. Ctr., San Diego, CA 92152), Roger L. Gentry (ProSci. Consulting, LLC, Dickerson, MD 20842), Charles R. Greene, Jr. (Greeneridge Sci. , Inc., Santa Barbara, CA 93110), David Kastak (U.C. Santa Cruz, Santa Cruz, CA 95060), Darlene R. Ketten (Woods Hole Oceanog. Inst., Woods Hole, MA 02543), James H. Miller (Univ. of Rhode Island, Narragansett, RI 02882), Paul E. Nachtigall (Hawaii Inst. of Marine Biol., Kaneohe, HI 96744), W. John Richardson (LGL Ltd., King City, ON, Canada), Jeanette A. Thomas (Western Illinois Univ.-Quad Cities, Moline, IL 61265), and Peter L. Tyack (Woods Hole Oceanog. Inst., Woods Hole, MA 02543)

An expert panel reviewed the expanding literature on marine mammal (cetacean and pinniped) auditory and behavioral responses to sound exposure to develop comprehensive, scientifically based noise exposure criteria [Aquatic Mammals **33**(4)]. They used precautionary extrapolation procedures to predict exposure levels above which adverse effects (both physical and behavioral) could be expected. Due to the paucity of data on long-term exposures, criteria were developed for single exposure events only. Marine mammals were broken into functional hearing groups. Exposure types were lumped into three broad classes (single pulses, multiple pulses, and nonpulses). Levels estimated to induce permanent noise-induced hearing loss were determined for each of 15 sound type/animal group combinations. For example, injury criteria for pinnipeds in water exposed to multiple pulses were 186 dB re 1 μPa^2 -s (weighted SEL) and 218 dB_{pk} re 1 μPa (unweighted peak SPL). Discrete behavioral disturbance thresholds could only be determined for exposure to single pulses. For other exposures, available data on behavioral responses were ranked by severity and significance. This severity scaling and the resulting conclusions will be described. New research required to improve criteria and to assess cumulative and ecosystem-level effects will also be considered, along with current policy and/or regulatory applications.

2:30

1pNS4. The importance of incorporating signal characteristics in the evaluation of noise exposure impacts on marine life. Michael Stocker (Ocean Conservation Res., P.O. Box 559, Lagunitas, CA 94938)

Auditory thresholds are used to establish mitigation guidelines for anthropogenic noise exposure on marine animals. These thresholds are determined using either sinusoidal signals at specific frequencies or band limited, sinusoidal-derived Gaussian noise. Given that the preponderance of naturally occurring noise in the marine environment is sinusoidal, marine animals may have lower thresholds and, thus, lower tolerance to non-sinusoidal noise. Fast rise time impulse noise, continuous non-sinusoidal noise, or a combination of these characteristics may induce biological responses at lower levels than sinusoidal noise with an equivalent power density. The author proposes a metric to evaluate and express signal characteristics as a component of determining noise exposure impacts on marine animals.

1pNS5. Role of the National Marine Fisheries Service in underwater acoustics: Integration of science and policy. Amy R. Scholik-Schlomer, Shane Guan, and Jolie Harrison (Natl. Marine Fisheries Service, Office of Protected Resources, 1315 East-West Hwy., Silver Spring, MD 20910, amy.scholik@noaa.gov)

The National Marine Fisheries Service, Office of Protected Resources (NMFS OPR) is responsible for protecting marine mammals and other endangered marine species and works to conserve and recover these species under the Marine Mammal Protection Act and Endangered Species Act. Accurately assessing the impacts of anthropogenic underwater noise on the marine environment and implementing appropriate measures to reduce such impacts is one of its primary focuses. To do this successfully requires the integration of science with policy. This integration combines a complex set of factors. NMFS OPR has jurisdictions over a variety of marine species, considers a wide range of potential impacts, and regards a diverse assortment sound sources. Additionally, it works collaboratively with other federal, state, and local government agencies, academia, nongovernmental organizations, and industry, as well as solicits public input on the actions it regulates. NMFS OPR uses and relies on scientific data to make informed decisions on numerous issues relating to anthropogenic underwater noise, including developing appropriate acoustic thresholds for assessing impacts and best protecting marine species via the establishment of practicable mitigation and monitoring protocols. To most effectively achieve these goals requires continual interaction with and input from those in the scientific community.

3:00

1pNS6. Methods for computing the impact of sonar on the marine environment. Martin Siderius (Dept. of Elect. and Comput. Eng., Portland State Univ., 1900 SW 4th Ave., Portland, OR 97201, siderius@pdx.edu), Dorian Houser (BIOMIMETICA, Santee, CA 92071), Daniel Hernandez, and Michael Porter (HLS Res. Inc., La Jolla, CA 92037)

Federal agencies are required to estimate the impact to the environment resulting from major federal actions. The U.S. Navy is required to prepare environmental impact statements (EISs) for a number of its training ranges, in part, due to the controversial nature of the sonar systems used at these sites. Over the past several years these EISs have been prepared by both government agencies and by contractors. This multi-institution approach has led to different methodologies being used to estimate impacts on marine mammals. Different impact estimates and confusion as to the real risk posed by a particular sonar system has resulted. As part of the Office of Naval Research program on the effects of sound on the marine environment (ESME), we have been assembling state-of-the-art modeling software to provide the Navy and the Public the best risk assessment tools currently available. One of the challenges to this effort is determining which approaches provide the best estimates of risk and which are practical to implement. Related to this is the development of an objective set of metrics to make such evaluations. In this presentation we will describe the risk modeling methodologies and the metrics being used for analysis in the ESME model.

1pNS7. Ambient noise properties in a region of Puget Sound. David Dall'Osto and Peter H. Dahl (Appl. Phys. Lab. and Dept. of Mech. Eng., Univ. of Washington, Seattle, WA 98105)

Ambient noise data collected during August 2007 at a site near the Smith Island Marine Sanctuary in North Puget Sound, Washington, depth 100 m, is discussed. This marine sanctuary is representative of a marine mammal habitat, where adverse impacts of noise are of concern. Properties of the ambient noise environment are inspected relating to frequency content and vertical directionality. Wind speed and wave spectral data for correlations were provided by the Smith Island weather station and a nearby NOAA buoy. Two co-located systems were used to estimate spectral levels of the ambient noise environment. The directional information is provided by one of these systems consisting of a pair of omni-directional elements vertically separated by 15 cm. Candidate models for noise directionality are tested against the array gain for this simple system evaluated as a function of frequency, giving an approximate picture of the noise density as a function of vertical arrival angle at particular frequencies of interest. [Research supported by Washington Sea Grant.]

3:45

1pNS8. Seismic airgun sounds recorded in the North Atlantic. Sharon L. Nieukirk, David K. Mellinger (Coop. Inst. for Marine Resour. Stud., Hatfield Marine Sci. Ctr., Oregon State Univ., 2030 S. Marine Sci. Dr., Newport, OR 97365, sharon.nieukirk@oregonstate.edu), Sue E. Moore (Univ. of Washington, Seattle, WA 98105), Karolin Klinck, Sara L. Heimlich, and Holger Klinck (Oregon State Univ., Newport, OR 97365)

Between 1999 and 2008, a consortium of international investigators deployed autonomous hydrophones to monitor seismic activity along the Mid-Atlantic Ridge. Although this experiment was designed to monitor low-frequency sounds from earthquakes, other natural and man-made sounds were also recorded. The periodic impulses produced by airguns from exploration activities around the Atlantic basin were one of the dominant signals detected in this dataset. Sounds associated with seismic exploration, particularly sounds from airgun arrays, have garnered interest recently due to concerns regarding the potential impact on marine mammals. In a previous publication, we reported that in 1999–2001 airgun sounds were recorded year-round on all hydrophones, but airgun activity peaked in the summer months. For this study, we used an automatic algorithm to detect airgun sounds in the 2001–2008 portion of the dataset. Raw detections were then visually examined by an experienced analyst to verify the accuracy of the detections. When airgun impulses were simultaneously recorded on four or more hydrophones, the location of the seismic exploration vessel was estimated. Results from this dataset will be presented in light of current knowledge of marine mammal distribution and migration patterns in the Atlantic.

1pNS9. Assessment of bubble curtain attenuator techniques for underwater pile driving noise mitigation. Michael A. Slater (SAIC Maritime Technologies, 26279 Twelve Trees Ln., Ste. B, Poulsbo, WA 98370)

Public concern for prudent management of marine resources due to anthropogenic activity is large and growing. In particular, the potential for causing negative impacts to marine species including salmonids and mammals is sufficient motivation to consider all reasonable mitigation strategies to minimize these effects. An impact pile driver can introduce extremely high sound pressure levels into the environment, and a bubble curtain attenuator is one means to reduce noise propagated from each driven pile by changing the impedance along the primary path of propagation. Available literature describing the observed effectiveness of reductions measured dur-

ing *in situ* pile driving monitoring while using a bubble curtain range from completely ineffective to substantially effective. As a result, opposing views both seek acoustic evidence to support the need to use, or not use, bubble curtain attenuators during impact pile driving activities. This paper provides a description of the current state of knowledge on the use of bubble curtain attenuators, outlines on-going activities to address the issue, identifies limitations to the knowledge base, and suggests recommendations to close the information gap.

4:15

1pNS10. Measurements of industrial noise and vibration in artificial polar bear (*Ursus maritimus*) dens, Flaxman Island, Alaska. Alexander O. MacGillivray, David E. Hannay, and Craig J. Perham (JASCO Res. Ltd., Markham St., Ste. 2101-4464, Victoria, BC V8Z 7X8, Canada, alex@jasco.com)

Noise and ground vibration generated by environmental remediation activities were measured in man-made polar bear (*Ursus maritimus*) dens at Flaxman Island, Alaska in Mar. 2002. The remediation activities involved use of heavy excavation equipment, ground vehicles, and blasting. Comparison of sound levels measured inside and outside the dens permitted estimation of the sound-insulating properties of the dens. Vibration data were acquired from sensors placed in the tundra and in the snow of the den floors. Measurements of noise and vibration were made for the following vehicles: front-end loader, trimmer, gravel hauler, fuel truck, pickup truck, Hägglunds tracked vehicle, and a Tucker Sno-Cat. A single 8.7 kg blast event at 19 m underground, which was used to cut a well pipe, was recorded in the dens at distances from 500 to 1300 m. Additional noise and ground vibration data were obtained for Bell 212 and Bell 206 helicopters performing maneuvers above the dens. The man-made dens were found to have good sound-insulating properties. Sound levels inside the dens were lower than directly outside the dens by 25 dB at 50 Hz, and by 40 dB at 1000 Hz.

4:30

1pNS11. Mediterranean fin whale migration movements altered by seismic exploration noise. Manuel Castellote (Oceanografic of Valencia and Psychobiology Dept., Univ. Complutense of Madrid, Spain, mcastellote@oceanografic.org), Christopher W. Clark (Cornell Univ., New York), Fernando Colmenares (Univ. Complutense of Madrid, Spain), and José Antonio Esteban (Oceanografic of Valencia, Spain)

Seafloor recorders were deployed along the Spanish Mediterranean coast during 2006–2009 to further contribute to the little knowledge regarding Mediterranean fin whale (*Balaenoptera physalus*) movement patterns. Typical long patterned sequences of 20-Hz pulses were identified in different periods. Detection results suggest that at least part of the Mediterranean fin whales aggregating in the Ligurian-Corsican-Provençal basin during summer migrate through French and Spanish waters toward southern Mediterranean regions, including the south of Spain. Continuous airgun explosions from a seismic survey were detected during 8–17th December 2006 in the south of Spain. A concurrent fin whale reaction in acoustic behaviour was documented: All singing whales moved away from the airgun area and out of the detection area during the following 20 days, even after the airgun noise ceased on the tenth day, and remained weak after the 20-day period. Twenty-hertz pulse bearings for this period revealed that calling whales were moving through the sensors detection area and not that whale acoustic behaviour was reduced by the seismic activity. We therefore conclude that the seismic airgun activity caused fin whales to avoid their potential winter ground for a period of time that extended well beyond the duration of the seismic airgun array activity.

4:45

1pNS12. Acoustic characterization of whale watching boats in the Azores. Cláudia Oliveira, João Gonçalves, Maria João Cruz, Mónica A. Silva, Rui Prieto (Dept. de Oceanografia e Pescas, Centro do IMAR da Univ. dos Aores, Horta, Portugal), Marc Lammers (Univ. of Hawaii, Kaneohe, HI), and Ricardo S. Santos (Centro do IMAR da Univ. dos Aores, Horta, Portugal)

The whale-watching activity has been growing in the Azores during the last 15 years. To contribute to the sustainability and management of the activity it is crucial to monitor its influence on cetacean populations. This work aimed to determine the sound produced by whale-watching boats, in terms of frequencies and sound pressure levels (SPLs). Different types of boats were recorded between May and Sept. 2007 around the islands of Faial, Pico, and S. Miguel. Recordings were made with a hydrophone from a drifting platform. The whale-watching boats carried out several tracks with different speeds and changed gear (forward/reverse). SPL values varied between 74 and 116 dB re 1 μPa (1/3 octave band level) for both outboard and inboard engines, without any obvious difference between the two. One inboard catamaran produced 106 dB re 1 μPa at 50 kHz (18 knots, 50 m distance), which is higher than all the other SPLs, at the same frequency. Forward/reverse maneuvers in inboard engines had lower frequencies but a longer duration than in outboard boats. Frequency range produced by the Azorean whale-watching boats is wide and the way boats are maneuvered is important to minimize their impact on cetaceans. 1pPA1. Effects of soil water potential and moisture content on sound speed. Zhiqu Lu and James Sabatier (Natl. Ctr. for Physical Acoust., The Univ. of Mississippi, 1 Coliseum Dr., University, MS 38677)

In order to monitor and understand the temporal variations of sound speed due to the changes of soil physical properties under natural conditions, a long-term field soil survey has been conducted. Measurements of sound speed, soil temperature, soil moisture content, and water potential were performed continuously, along with the measurements of surface temperature and precipitation over a period of 2 years. The effects of water potential, moisture content, soil temperature, and depth on sound speed were assessed. Analysis of the data shows that there is a power law relationship between the sound speed and water potential. It is also found that the water potential is the dominant influence on the sound speed, whereas the moisture content and temperature have relatively minor impacts. Brutsaert and Luthin's theory was employed to calculate the sound speed as a function of the effective stress. The theoretical predictions were compared with the experimental data and they are in good agreement. The study suggests that sound speed measurement could be used as a new and effective tool for water potential measurement.

1pPA2. Multichannel analysis of surface waves method for shallow soil profile exploration. Zhiqu Lu and James Sabatier (Natl. Ctr. for Physical Acoust., The Univ. of Mississippi, 1 Coliseum Dr., University, MS 38677)

In order to explore shallow soil properties in a noninvasive manner, a multichannel analysis of surface waves method was employed to obtain soil shear wave velocity profile up to a couple of meters. In the study, an electromechanical shaker operating in a frequency-sweeping mode was placed on the ground to excite Rayleigh waves propagating along the surface. A laser Doppler vibrometer (LDV) was used as a noncontact receiver to detect the surface vibration. The LDV was mounted on an aluminum frame and driven by a stepper motor to move along a straight line. Multichannel surface vibrations were obtained and analyzed to determine the dispersive curve; i.e., the Rayleigh wave velocity as a function of frequency. An inversion algorithm was used to transform the dispersion curve into the shear wave velocity profile. This technique can be developed for the applications of levee and dam evaluation as well as shallow soil properties imaging and characterization.

1pPA3. Wideband multidomain ultrasonic transducer. Andriy Nadtochiy and Igor Ostrovskii (Dept. of Phys., Univ. of Mississippi, University, MS 38677)

Wideband multidomain ultrasonic transducer (WMUT) based on a ZX-cut aperiodically poled LiTaO3 is considered and demonstrated. For a wide band operation inside a frequency range of 40–80 MHz, the domain sizes within a multidomain array vary from 25–50 μ, and the total number of ferroelectric domains N varies from 25–266. The partial-waves method computation yields a strong effect of a narrow acoustic signal formation by a WMUT. For instance, an ultrasonic signal in water is about 10 times shorter than input rf chirp burst applied to the WMUT. As the number N increases, more frequencies in the acoustic signal are present. Experimentally it is demonstrated a wideband delay line for a chirp signal within the frequency range of 32–64 MHz. The delay line is fabricated in a 500-μ thick LiTaO3 wafer, and has two WMUTs with variable domain sizes from 25–50 μ. Ultrasound is generated by an input WMUT having $N=14$, and then detected with output WMUT having $N=134$. The experimental measurements are in agreement with theoretical computations. [Work supported by UM.]

1pPA4. Modeling acoustic response of permeability variation in deepwater wells using spectral method. Florian Karpfinger (Dept. of Expl. Geophy., Curtin Univ. of Tech., P.O. Box U1987, Perth, WA 6845, Australia), Boris Gurevich (Curtin Univ. of Tech., Perth, WA 6845 Australia and CISIRO Petroleum, Benteley, WA), and Andrey Bakulin (WesternGeco, Houston, TX 77042)

Petroleum production in deepwater oil fields often hinges on the ability to safely complete and effectively draw down a small number of very challenging wells. The success of this operation requires regular completion monitoring, which is most effectively achieved using real-time surveillance tools. Real-time completion monitoring with acoustic waves (RTCM) has great potential for diagnosing problems in sand-screened deepwater completions. RTCM uses tube waves to detect permeability changes and passive noises to characterize perforation flow. Interaction of a single tube wave with permeable formations in open boreholes is well explained by Biot's theory of poroelasticity. However, experimental studies in laboratory models of sand-screened completions reveal existence of two tube wave modes: fast and slow, supported by completion and sand screen, respectively. Development of quantitative monitoring methodology of acoustic surveillance requires better understanding on how signatures of fast and slow tube waves depend on completion properties. To this end, we simulate two tube dispersion and attenuation by examining the solutions of Biot's equations of poroelasticity in cylindrical structures using a spectral method. The results show dependence of the velocity and attenuation of both tube waves on completion permeability. These modeling results are in a qualitative agreement with laboratory experiments.

2:30

1pPA5. Spectral method for modeling waves in cylindrical poroelastic structures. Florian Karpfinger (Dept. of Expl. Geophys., Curtin Univ. of Technol., P.O. Box U1987, Perth, WA 6845, Australia), Boris Gurevich (Curtin Univ. of Technol., Perth, WA 6845, Australia and CISIRO Petroleum, Bentley, WA), Andrey Bakulin (WesternGeco, Houston, TX 77042), and Henri-Pierre Valero (Schlumberger–Doll Res., Cambridge, MA 02141)

The modeling of propagating modes in poroelastic fluid-saturated cylindrical structures is important for the interpretation of acoustic and seismic measurements in hydrocarbon wells as well as laboratory measurements on core samples. In order to obtain the velocities of different modes the roots of the appropriate dispersion equation have to be found. This is a very difficult task especially when some layers are represented by poroelastic materials with frequency-dependent attenuation. A new technique is presented for modeling those modes, which adopts a spectral method to discretize the underlying partial differential equations using Chebyshev differentiation matrices. The corresponding system of linear equations can then be solved as a generalized eigenvalue problem. This means that, for a given frequency, the eigenvalues correspond to the slownesses of different modes. This approach is implemented for an arbitrary number of cylindrical fluid and solid

layers as well as poroelastic layers. In addition to the dispersion, the attenuation curves are computed as well as radial profiles of displacements and stresses for various frequencies. The resulting approach can be used to model wave propagations in open and completed boreholes surrounded by permeable formations. This can pave the way to invert for formation and completion permeability from acoustic measurements.

2:45

1pPA6. The penetration of sound into an extended reaction ground due to an arbitrarily oriented dipole. Kai Ming Li and Sheng Liu (Ray W. Herrick Labs., Purdue Univ., 140 S. Martin Jischke Dr., W. Lafayette, IN 47907-2031)

An asymptotic solution is derived for the sound fields below an extended reaction ground due to an arbitrarily oriented dipole placed near the air /ground interface. The derived approximate solutions are compared with accurate numerical schemes based on the fast field formulation and the direct numerical integration of the Fourier integral. It has been shown that the sound field above the ground can be computed accurately by using the concept of effective impedance [K. M. Li *et al.*, J. Acoust. Soc. Am. **104**, 679–685 (1998)]. The effective impedance approach is used to derive the asymptotic formula for predicting the penetration of sound into the extended reaction ground. However, there are apparent discrepancies in the predicted sound fields according to the analytical solution and the accurate numerical schemes. A modified analytical formula is then developed that leads to more accurate numerical results. The resulting analytical formula due to an airborne acoustic excitation may be used as a basis for a future study to compute the particle displacements induced by an elastic object buried in a rigid-frame porous medium.

1pPA7. Energy flux imaging method for time reversal in elastic media. Brian E. Anderson, Robert A. Guyer, Timothy J. Ulrich, Pierre-Yves Le Bas, Carene Larmat, Michele Griffa, and Paul A. Johnson (Geophys. Group EES-17, Los Alamos Natl. Lab., Los Alamos, NM 87545)

An energy flux imaging method for use in locating sources of wave energy during the back propagation stage of the time reversal process will be presented. During the back propagation phase of an ideal time reversal experiment, wave energy coalesces from all angles of incidence to recreate the source event; after the recreation, wave energy diverges in every direction. An energy flux imaging method based on this convergence/divergence behavior has been developed. The energy flux imaging method yields better spatial resolution in source reconstruction than is possible with traditional imaging methods. [This work is supported by Institutional Support (LDRD) at Los Alamos National Laboratory.]

3:30

1pPA8. Impedance tube measurements of gravel at frequencies between 25 and 200 Hertz. Michael J. White (U.S. Army Engineer Res. and Develop. Ctr., PO Box 9005, Champaign, IL 61826), George W. Swenson, Jr., and Michael L. Oelze (Univ. of Illinois, Urbana, IL 61801)

The sound absorption properties for a few materials have been examined for noise control, yet few materials are as durable and as cheap as gravel. We have measured the attenuation coefficient and wavelength in crushed limestone and pea gravel using an impedance tube. The tube is made of heavy steel, has 0.76-m inner diameter, height 7.3 m, and is fitted with 31 microphones flush-mounted on a line along the inside wall, using 0.2-m spacings. The tube can be filled with a variable depth (0–7 m) of test material, to be supported by either a perforated or solid rigid end plate. Over the frequencies 25–200 Hz, sound speed in 12-mm crushed limestone and 6-mm unsifted pea gravel increased from 160 to 200 m/s. Strongly graded 6-mm pea gravel was poorly dispersive, with sound speed averaging 210 m/s. Over the same frequency interval, the absorption coefficient increased from 0.4 to 1.1 Np/m in coarsely-graded pea gravel. The same positive trend, but successively lower attenuation, was found for crushed limestone and strongly-graded pea gravel. So far, the impedance has been more difficult to determine. Next, we plan to incorporate measurements of complex pressures in an attempt to improve the estimates.

3:45

1pPA9. Penetration depth for measurements with ultrasonic diffraction grating spectroscopy. Margaret S. Greenwood (Pacific Northwest Natl. Lab., P.O. Box 999, Richland, WA 99352, margaret.greenwood@pnl.gov)

The current status of ultrasonic diffraction grating spectroscopy was described at the Acoustics 08 Conference in Paris. An important question remains: What is the penetration depth of the ultrasound for such measurements? Although the spectral order $m=1$ at 90 deg is of primary interest, much insight can be gained by investigating a range of angles. The first step was to measure the amplitude of the $m=1$ transmitted beam in the liquid as a function of the transmitted angle. Data were obtained by sending a toneburst signal to the send transducer and measuring the response of a receive transducer immersed in the liquid. The angle of the receive transducer was varied in half-degree steps from about 50 to 90 deg. The data were compared with a formulation for the interference of N wavelets from N grooves and showed very good agreement. In addition, an experimental technique was developed to measure the penetration of ultrasound into the liquid. Experimental parameters that affect this penetration depth were also investigated. The results of these measurements will be discussed and compared with the theory.

4:00

1pPA10. Self-calibrating measurements of the density and velocity of sound from the reflection of ultrasound at two solid-liquid interfaces. Margaret S. Greenwood (Pacific Northwest Natl. Lab, P.O. Box 999, Richland, WA 99352, margaret.greenwood@pnl.gov)

This report describes a method to measure the density of a liquid and velocity of sound by observing two reflections of ultrasound from a solid-liquid interface: one for perpendicular incidence of a longitudinal wave and the second for incidence of a shear wave at an angle of 45 deg. In previous research [J. Fluids Eng. **126**, 189 (2004)], transducers were mounted on the outside of a stainless steel pipeline, 6 mm thick. Multiple reflections within the wall yielded the acoustic impedance. This method is self-calibrating because each echo is affected in the same way by any change in transducer voltage. The velocity of sound was obtained from the time-of-flight (TOF) across the pipeline. The current research replaces the TOF measurement by using a triangular stainless steel wedge (45, 90, 45 deg). A 1-MHz shear wave transducer is mounted on one short side of the wedge, with the longer side immersed in the liquid. Multiple reflections from the opposite side of the wedge are obtained. The two reflection coefficients can be used to solve for the density and velocity of sound. Greater precision can be obtained by using fused quartz instead of stainless steel.

4:15

1pPA11. Numerical simulation of fluctuated ultrasound wave propagation through random medium. Hideyuki Nomura and Tomoo Kamakura (Dept. of Electron. Eng., Univ. of Electro-Commun., 1-5-1 Chofugaoka, Chofu-shi, Tokyo 182-8585, Japan, nomu@ee.uec.ac.jp)

Multiply scattered ultrasound wave propagation in a random medium is numerically simulated to consider the relationship between the physical properties of the random medium and wave fluctuations propagating through that medium. The medium is assumed to be randomly distributed scatters, which are characterized by the means and variances of number, size, density, and volume elasticity of scatters in a host medium. The ultrasound propagation is simulated using a finite-difference time-domain method. To evaluate the fluctuation of propagating ultrasound wave, the ratio of coherent intensity to incoherent and the ratio of the average wave energy to difference wave are statistically estimated. Numerical experiments show that the ratios of intensities and average and difference wave energies decrease with increasing the randomness and number density (scattering cross-sectional area) of scatters. This result suggests that the statistical estimation of wave

pulse propagation is useful for measurements of physical properties of distributed particles in a solution. It is our expectation that the proposed numerical model will provide fundamental understandings on multiple scattering of ultrasound in a random medium.

4:30

1pPA12. Modeling focused ultrasonic beams through liquid-solid interfaces: Applications to diffuse scattering. Joseph A. Turner (Dept. of Eng. Mech., Univ. of Nebraska-Lincoln, W317.4 Nebraska Hall, Lincoln, NE 68588-0526, jaturner@unl.edu) and Goutam Ghoshal (Univ. of Illinois, Urbana, IL 61801)

When a focused ultrasonic beam interacts with a liquid-solid interface, the beam profile changes due to the acoustic impedance mismatch between the two materials at the interface. A normal incidence focused beam, for planar or curved liquid-solid interfaces, can be modeled with good accuracy using several well established models such as single Gaussian, a multi-Gaussian, Gauss–Hermite, or Bessel beams, which are often used with a paraxial approximation as well. For oblique angles of incidence, these theories break down and the displacements within the solid are not modeled accurately. If such models are applied to diffuse backscatter experiments, accurate extraction of microstructural parameters becomes difficult. In this presentation, ray models of ultrasonic beams are examined with respect to focusing through a liquid-solid interface at oblique incidence as a function of space and time. The integration of such a beam model within the framework of a diffuse ultrasonic scattering theory is discussed, and the theory is used to interpret diffuse ultrasonic scattering experimental data for which focused beams are used at oblique incidence on polycrystalline metals. These results are anticipated to impact ultrasonic nondestructive evaluation of heterogeneous media.

MONDAY AFTERNOON, 18 MAY 2009 GRAND BALLROOM I, 1:30 TO 4:30 P.M.

Session 1pPP

Psychological and Physiological Acoustics: Psychophysics, Modeling, and Signal Processing (Poster Session)

Walt Jesteadt, Chair

Boys Town National Research Hospital, 555 North 30th St., Omaha, NE 68131

Contributed Papers

All posters will be on display from 1:30 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 4:30 p.m.

1pPP1. The influence of masker fringe on sound localization in noise. Brian D. Simpson (Air Force Res. Lab., 2610 Seventh St., Wright-Patterson Air Force Base, OH 45433), Robert H. Gilkey (Wright State Univ., Dayton, OH 45435), Douglas S. Brungart, Nandini Iyer, and Griffin D. Romigh (Wright-Patterson Air Force Base, OH 45433)

Several studies have shown that detection of a dichotic target signal in a concurrent diotic noise masker improves when the masker onset occurs prior to that of the target and/or the masker duration extends beyond the target offset (so-called masker fringe; McFadden, 1966; Trahiotis *et al.* 1972). It has been argued that this improved performance results from the fact that the masker fringe provides a baseline set of interaural parameters against which a change in parameters, associated with the signal onset or offset, can be detected. As the duration of the fringe increases, more time is available to estimate these baseline parameters, thus improving signal detectability. However, little is known about the relation between masker fringe and spatial hearing. In this study, the localization of a 250-ms click train signal presented in a broadband directional noise masker was measured as a function of the duration of the masker fringe and the signal-to-noise ratio. The results indicate that the presence of masker fringe improves localization performance relative to the case in which the masker and signal are pulsed on and off simultaneously. Moreover, the benefit of masker fringe increases with decreasing signal-to-noise ratio. [Work supported by a grant from AFOSR.]

1pPP2. The effect of flanking bands on sensitivity to interaural time differences. Christopher A. Brown and William A. Yost (Dept. of Speech and Hearing Sci. Arizona State Univ., P.O. Box 870102, Tempe, AZ 85287-0102)

We are examining the potential for cochlear implant patients who retain some low-frequency residual hearing in both ears to benefit from interaural time differences (ITDs) to improve speech reception. Given the likelihood of asymmetrical loss in the low-frequency region, the relationship between spectral overlap and ITD sensitivity is of interest. We previously measured ITD sensitivity using narrow-band noise carriers, while varying the amount of spectral overlap between the ears. We found very good sensitivity when the bands completely overlapped, but for most listeners, sensitivity declined as the center frequency of one band was moved away from the other. When, for example, 2/3-octave bands were offset by 1/3 octave and presented to each ear, ITD sensitivity declined. This condition consists of three bands, a 1/3-octave center band that is spectrally similar across ears, and two 1/3-octave flanking bands, each of which is present in one or the other ear. Because the center band alone produces good ITD sensitivity, we hypothesized that moving the flankers away in frequency from the center band would result in improved sensitivity. However, the presence of the spectrally displaced bands led to poorer ITD sensitivity. [Work supported by grants from NIDCD.]

1pPP3. Does random temporal jitter reduce onset dominance in temporal weighting functions for high-rate click trains? Andrew D. Brown and G. Christopher Stecker (Dept. of Speech & Hearing Sci. , Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, andrewdb@u.washington.edu)

Several studies have noted poor sensitivity to interaural time differences (ITD) among users of bilateral cochlear implants (CIs) compared to normal hearing listeners. One hypothesis for this impairment is that CI users are subject to a higher degree of binaural adaptation—a loss of sensitivity to binaural cues after onset—than normal hearing listeners, as a result of CI electrical stimulation. [Laback and Majdak, PNAS **15**, 814–817 (2008)] demonstrated improved ITD discrimination in CI users by imposing random temporal jitter on CI pulse trains bilaterally. A candidate explanation for this improvement is that temporal jitter causes a "restarting" of the adapted binaural system, and, thus, improved sensitivity to ITD after onset. In the present study, temporal weighting functions of normal-hearing listeners were measured for discrimination of ITD and interaural level differences carried by trains of 4000 Hz Gabor clicks. Interclick intervals of 1.25 and

2.5 s were tested with and without additional random temporal jitter. The results have implications for mechanisms of binaural adaptation as well as for binaural performance in CI users.

1pPP4. Modeling temporal weighting of interaural time and level differences in high-rate click trains. G. Christopher Stecker and Andrew D. Brown (Dept. of Speech & Hearing Sci. , Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, cstecker@u.washington.edu)

Accurate localization of sound sources requires that information be integrated over time and across multiple spatial cues in a manner that reflects the reliability of those cues over time. Several past studies have investigated the relative weighting of multiple cues (e.g., interaural time-intensity "trading") as well as the temporal weighting applied to brief stimuli such as noise bursts and impulse trains. The results have demonstrated reduced sensitivity to ongoing envelope interaural time differences in high-frequency, high-rate stimuli and a consequent shift in weighting to favor onset and interaural-level cues. The dominance of onset over ongoing cues is consistent with the precedence effect [Wallach *et al.*, Am. J. Psych. **62**:315–336 (1949)] and binaural adaptation [Hafter and Dye, J. Acoust. Soc. Am. **73**: 644–651 (1983)] and may reflect a combination of (1) peripheral auditory factors, (2) effective modulation, (3) postonset inhibition of binaural information, and (4) temporal integration of ongoing cues. In this study, simple mathematical models are used to study the effects of these factors on temporal weighting of interaural time and level differences in narrowband click trains varying in spectral composition, click timing, and cue availability.

1pPP5. The effectiveness of multiple harmonics in eliciting the precedence effect in normal-hearing listeners. John Ellison and Jonas Braasch (School of Architecture, Rensselaer Polytechnic Inst., Greene Bldg., 110 8th St., Troy, NY 12180, ellisj2@rpi.edu)

Localization dominance due to the precedence effect refers to the ability of listeners to localize a primary auditory event in the presence of reflected sound. It has been shown that localization dominance becomes more stable as the bandwidth of a noise burst increases, which suggests the role of cross-frequency interactions on localization dominance. Currently, little is known about how stimuli containing multiple harmonics influence localization dominance. The present investigation uses a multiple harmonic complex to investigate localization dominance due to the precedence effect. Listeners locate the perceived lateral position of stimuli presented binaurally via headphones by adjusting the interaural-level difference (ILD) that approximates the location of the stimulus. Stimuli are presented as lead and lag signals that simulate direct and reflected sound, respectively. The interstimulus interval (ISI) is varied from 0 to 4 ms, and the phase of the harmonic complex is varied between ears. For both the test stimulus and broadband noise bursts (control condition) physical ILDs occur as a result of lead/lag interference, but in the case of the harmonic complexes, the ILD often does not average out over frequency, as is the case for broadband noise.

1pPP6. Are there specialized mechanisms for pitch interval perception? Josh H. McDermott, Michael V. Keebler, and Andrew J. Oxenham (Dept. of Psych., Univ. of Minnesota, 75 E. River Rd., Minneapolis, MN 55455, oxenham@umn.edu)

Pitch intervals are a central feature of most musical systems. It has seemed likely that pitch uniquely permits precise perception of the interval by which two sounds differ, perhaps due to mechanisms specialized for music. We tested this notion by measuring interval discrimination thresholds for pitch, brightness, and loudness in the same subjects. We compared thresholds across dimensions by computing: (1) Weber fractions (the ratio of the interval threshold to the base interval size) and (2) the ratio of the interval threshold to the basic discrimination threshold for a dimension. We found that Weber fractions were comparable across dimensions (although Weber's law did not hold, as thresholds were roughly constant across the range of interval sizes used), and that the threshold ratio was actually higher (worse) for pitch than for loudness or brightness. Interval thresholds thus provide no evidence that pitch interval perception has unusually high fidelity, as might be expected if it were the product of a specialized mechanism. The ubiquity of pitch in music may simply be due to basic discriminability, which, in contrast to interval discriminability, is far superior for pitch than for other dimensions. [Work supported by NIH grant R01DC05216.]

1pPP7. Exploring the acoustic basis of consonance using individual differences. Josh H. McDermott, Andriana J. Lehr, and Andrew J. Oxenham (Dept. of Psych., Univ. of Minnesota, 75 E. River Rd., Minneapolis, MN 55455, oxenham@umn.edu)

Despite its central role in music, the origins of the preference for consonant over dissonant intervals remains controversial. We applied an individual differences approach to this question. Subjects were first tested for their aversion to pure-tone beats, and to inharmonic spectra of single complex tones. Consistent individual differences were observed in the magnitude of subjects' aversion to beats and inharmonicity, but the two effects were uncorrelated across subjects, suggesting independent factors. Subjects then rated the pleasantness of musical intervals and three-note chords. If particular acoustic factors determine consonance, stronger sensitivity to those factors should predict stronger musical preferences. In each of two cohorts, only the preference for harmonic spectra was consistently correlated with preferences for consonant over dissonant chords and intervals. Although the strength of a subject's consonance preference was also correlated with their musical experience, so was their harmonicity preference, which explained most of the effect of experience on consonance ratings. The results suggest that much of consonance perception is rooted in the basic acoustic property of harmonicity. Harmonicity is evidently predictive of important structures in Western music, and with exposure to music, listeners learn to attend to it. [Work supported by NIH grant R01DC05216.]

1pPP8. Relative contribution of frequency and duration cues to estimates of frequency change in tone sequences and glides. Molly J. Henry and J. Devin McAuley (Dept. of Psych., Bowling Green State Univ., Bowling Green, OH 43403, mcauley@bgsu.edu)

This research compared use of frequency and duration cues in magnitude estimates of frequency change (velocity). In two experiments, listeners rated how quickly tone sequences (Experiment 1) or glides (Experiment 2) changed in frequency on a scale ranging from 0 (not changing at all) to 100 (changing very quickly). In both experiments, velocity was specified in terms of semitones per second (ST/s), with ascending and descending stimuli presented at one of eight velocities on each trial (0, 2, 4, 6, 8, 10, 12, and 14 ST/s) with a variable starting frequency. Frequency and duration cues to velocity were varied orthogonally. The different stimulus velocities ($\Delta f / \Delta t$) were created by either holding Δt constant and varying Δf (frequency cue condition) or by holding Δf constant and varying Δt (duration cue condition). For tone sequences, magnitude estimates of velocity were based almost entirely on duration cues, with very little contribution of frequency cues. This finding contrasted with magnitude estimates of glides where both duration and frequency cues were equally effective at conveying velocity information.

1pPP9. Gender differences in the ability to ignore distracters in frequency discrimination tasks. Blas Espinoza-Varas (Dept. Commun. Sci. & Disord., Univ. Oklahoma Health Sci. Ctr., Oklahoma City, OK 73117–1215) and Praveen Jajoria (Univ. of Texas Medical Branch, Galveston, TX 77555-0570)

Whether there are gender differences in the ability to ignore distracting auditory information remains a matter of debate; such differences could be in basic, involuntary, novelty responses or in elaborate, voluntary, directed attention. To investigate this issue, frequency discrimination thresholds (FDTs) were measured in 20 males and 20 females (young, healthy adults with normal hearing). Targets tones (T) were presented in isolation or followed by a distracter tone (D) after a 90- or a 250-ms silent interval (ISI). Both tones were 1000 Hz, 70 dB SPL, and duration was 40 and 80 ms for T and D, respectively. Target frequency differences were specified by an adaptive rule targeting 71 percent-correct FDTs; irrelevant differences in D frequency were 40 or 45 Hz. On each subject, FDTs were measured for T in isolation or followed by D, with or without irrelevant differences; a total of 12 trial blocks per condition were completed. Across gender, the largest FDT disparity was observed in conditions with irrelevant differences in D

frequency and 90-ms ISI; in the other conditions the gender effect was small or negligible. There appears to be a gender difference in the initial, involuntary, response to distracters.

1pPP10. The relative weighting of energy and envelope-modulation cues in increment detection. Harisadhan Patra, Jessica J. Messersmith, and Walt Jesteadt (Boys Town Natl. Res. Hospital, 555 N 30th St., Omaha, NE 68131, patrah@boystown.org)

Recent findings suggest that listeners primarily rely on envelope-modulation cues rather than energy cues in an increment detection task, where one of the two sounds contains a brief increment in intensity in a longer duration tone. The relative contributions of energy and envelope-modulation cues in increment detection were evaluated in six normal-hearing young adults. The detection thresholds for a 20 ms increment added in the middle of a 420 ms pedestal of either 500 or 4000 Hz were obtained as a function of pedestal level. On-frequency or off-frequency maskers were either 30- or 150-Hz wide random-phase Gaussian noise (RPN) or low-noise noise (LNN), centered either at 500 or 4000 Hz. The envelope fluctuation in LNN is minimal compared to that in RPN. The detection thresholds were greater in RPN than LNN in on-frequency, but not in off-frequency masking conditions. The detection thresholds increased at the wider masker bandwidth. Results suggest that listeners may rely on a decision process that is based on within-channel energy and envelope-modulation cues, where the within-channel envelope-modulation cues predominate. The relative weighting of these cues are pedestal and masker dependent. [Work supported by R01 DC006648 and T32 DC000013.]

1pPP11. Effect of temporal uncertainty on psychometric functions for increment detection. Walt Jesteadt, Harisadhan Patra, and Donna L. Neff (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

Increased temporal uncertainty might be expected to produce increased internal noise, resulting in poorer detection and shallower psychometric functions. An alternative model in the literature predicts steeper psychometric functions with increased uncertainty. As a test of these two alternatives, detection of a 20-ms intensity increment was assessed for eight subjects in a two-interval, forced-choice adaptive procedure where the increment was presented 100, 150, 200, 250, or 300 ms after the onset of a 400-ms, 4-kHz tone presented at 70 dB SPL. In one condition, the temporal position varied randomly from trial to trial. In the other, the temporal position was fixed for an entire 50-trial block. Detection thresholds were higher and psychometric functions obtained by analyzing the trial-by-trial data from the adaptive tracks were shallower in the higher temporal uncertainty condition. Thresholds in both conditions were higher for temporal positions more distant from the center of the 400-ms tone. Results support a model in which temporal uncertainty contributes to internal noise resulting in shallower psychometric functions. [Work supported by R01 DC006648 and T32 DC000013.]

1pPP12. Increment discrimination. Walt Jesteadt, Harisadhan Patra, and Jessica Messersmith (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

Subjects rely on different information in an intensity-discrimination task, where the two sounds to be compared differ only in intensity, than in increment detection, where one of the two sounds contains a brief increment in intensity in a longer duration tone. To explore the transition from one task to the other, ten subjects were tested in a two-interval forced choice discrimination task in which both intervals contained 50-ms increments in a 400-ms, 500-Hz tone and subjects were asked to vote for the interval with the larger increment. The size of this second increment was adapted to obtain an estimate of threshold. Increment-discrimination thresholds were better than increment-detection thresholds when the standard increment was less than or equal to detection threshold. Increment-discrimination thresholds became poorer for standard increments in the range from 1.5 to 12 dB above the level of the longer duration tone. For standard increments above that level, increment discrimination approximated intensity discrimination. Slopes of psychometric functions became shallower as the standard increment increased, consistent with a transition from an increment-detection to an intensity-discrimination decision process. [Work supported by R01 DC006648 and T32 DC000013.]

1pPP13. Effect of narrowband noise maskers on increment detection. Jessica J Messersmith, Harisadhan Patra, and Walt Jesteadt (Hearing Res., Boys Town Natl. Res. Hospital, 555 N 30th, Omaha, NE 68131, messersmithj@boystown.org)

The ability to detect a brief increment in intensity in a longer duration stimulus is often used as a measure of the intensity resolution of the auditory system, but it is unclear how listeners perform the task. Early investigators suggested that detection of an increment in intensity was based on the overall energy within the critical band centered on the signal frequency. The use of signal energy falling outside of the critical band is often limited by introducing a noise masker. Recent findings indicate that envelope fluctuations in a masker can increase thresholds in increment detection, suggesting a decision process based on envelope modulation. A modulation-based decision device was evaluated by adding irregularity to the envelope of an increment detection task via noise maskers of varying bandwidth. Results indicate that thresholds for detection of an increment in the intensity of a pure tone increase with increasing bandwidth for an on-frequency noise masker, but are unchanged by an off-frequency noise masker. A model that includes a modulation filter bank analysis of envelope modulation can account for observed data, but a model based on discrimination of spectral patterns does equally well. [Work supported by R01 DC006648 and T32 DC000013.]

1pPP14. Modulation detection of sawtooth-wave modulated tones: Effect of temporal asymmetry. Yi Shen and Jennifer Lentz (Dept. of Speech & Hearing Sci. , Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, shen2@indiana.edu)

Large perceptual differences can be observed between ramped and damped sounds. In the present study, the effect of temporal asymmetry on amplitude modulation detection was studied with the use of two types of modulators: a ramped sawtooth wave, characterized by a gradual linear rise in amplitude followed by a sharp drop within each period, and the damped sawtooth wave which is the time reverse of the ramped wave. Results showed that a puretone carrier modulated by these two modulators led to differences in modulation detection thresholds with the damped modulation pattern being easier to detect than the ramped modulation pattern. The size of this effect was also dependent on the modulation rate. A model of auditory processing was proposed to account for the temporal asymmetry in modulation detection with the hypothesis that the asymmetric threshold originated at processing stages more central to the auditory nerve.

1pPP15. Monaural envelope correlation perception and broadband temporal analysis. Joseph W. Hall, III, Emily Buss, and John H. Grose (Dept. of Otolaryngol., UNC Chapel Hill, CB 7070, Chapel Hill, NC 27599-7070, jwh@med.unc.edu)

Monaural envelope correlation perception [V. M. Richards, J. Acoust. Soc. Am. **82**, 1621–1630 (1987)] is a paradigm that reflects sensitivity to the correlation between the temporal envelopes of carriers that are separated in frequency. Previous experiments investigating this paradigm have employed narrowband noise stimuli, presumably because of a desire to ensure that the temporal envelopes of the bands are faithfully represented at the outputs of frequency selective auditory filters. Although wide comodulated bands can be generated, a reasonable expectation is that the representations of the bands at the outputs of auditory filters corresponding to their center frequencies would have substantially reduced comodulation, partly due to the fact that the absolute width of the auditory filter increases with increasing stimulus frequency. Our preliminary data nevertheless indicate robust sensitivity to envelope correlation for noise bandwidths that greatly exceed the bandwidths of peripheral filters. This sensitivity persists even when manipulations are employed that should interfere with the ability to use spectral profile cues or cues based upon envelope comparisons across subsets of

auditory filters. Results will be discussed in terms of cues supporting envelope correlation perception with stimuli that are broad with respect to auditory filters. [Work supported by NIDCD 5R01DC000418.]

1pPP16. Randomized phase effects in amplitude modulated/ quasi-frequency modulated discrimination. Hisaaki Tabuchi, Ewa Borucki, and Bruce G. Berg (Dept. of Cognit. Sci., Univ. of California, Irvine, 3151 Social Sci. Plaza, Irvine, CA 92617-5100)

This study investigated the bandwidth of phase sensitivity (i.e., discrimination of waveform envelopes). Subjects discriminated amplitude modulated (AM) tones, and quasi-frequency modulated (QFM) tones in a 2IFC. An adaptive threshold procedure was used to estimate modulation depth m needed to make the discrimination as a function of carrier and modulation frequency. Nonmonotonic threshold functions were often observed at higher modulation frequencies. The effect is discussed in terms of two potential cues: (1) waveform envelope, (2) cubic distortion products. In order to degrade the information obtained from the distortion products, the phase for the carrier frequency was randomly sampled with a range of, $\Delta\theta = \pi/3$. The randomized phase diminishes the nonmonotonicities of the threshold functions. Final results show that bandwidths of maximum sensitivity are not proportional to carrier frequencies. There are also noticeable individual differences in both the effects of the distortion products and the maximum bandwidths of sensitivity. [Work supported by NSF BCS-07464003.]

1pPP17. The range of signal-to-noise ratios needed to equalize identification of different consonants. E. William Yund, Pierre L. Divenyi, Matthew A. I. Ua Cruadhlaoich (Res. Service, VA NCHCS, 150 Muir Rd., Martinez, CA 94553, yund@ebire.org), and David L. Woods (Neurology Dept., VA NCHCS & UC Davis, Martinez, CA 94553)

Individual consonants vary in intelligibility when speech is presented in constant-intensity speech-spectrum noise. This variation in consonant intelligibility is explained at various levels, ranging from bottom-up energetic masking of different-intensity auditory cues needed to identify different consonants, to the top-down use of context information. This study focuses on bottom-up auditory cues by measuring the differences in signal-to-noise ratio (SNR) needed to equate consonant identification in consonant-vowel-consonant (CVC) syllables. The goal is to develop a CVC test with high sensitivity to changes in consonant perception because each consonant is presented at SNRs above the perceptual floor and below the perceptual ceiling. In order to present the initial and final consonants of each CVC at independently controlled SNRs, the intensity of the noise was changed during 100 ms centered in the vowel. In 16 young normal-hearing listeners, the SNR range required to equate identification across the 20 leading and trailing consonants was greater than 40 dB. In spite of these large SNR variations occurring during the test (and sometimes even within a single CVC) the expected pattern of consonant confusions was obtained, suggesting that the mid-vowel adjustment of noise intensity did not interfere with normal consonant-perception processes.

1pPP18. Relationships between timing in reading and language ability and auditory temporal masking. Cynthia M. Zettler (Waisman Ctr., Univ. of Wisconsin-Madison, 1500 Highland Ave., Madison, WI 53705), Rose A. Sevcik, Robin D. Morris, Mary Ann Romski, Colleen O'Rourke, and Marsha G. Clarkson (Georgia State Univ., Atlanta, GA 30303)

Broad timing difficulties may play a role in reading problems, but its role and a potential relationship with auditory temporal processing are unclear. The present study explored relationships between variables that might identify timing as a possible link between reading and auditory temporal masking. Tone identification thresholds were measured for 75 adults for backward masking and comodulation masking release (CMR) stimuli. Adults also completed a battery of nonverbal IQ, naming speed, motor speed, language, and reading measures. Backward masking stimuli consisted of a 20-ms, 1-kHz tone immediately preceding a 300-ms, 600–1400 Hz bandpass noise masker. A notched-noise condition included a spectral notch between 800 and 1200 Hz. CMR stimuli consisted of a reference condition in which a 1-kHz tone was temporally centered in a 20-Hz wide narrowband modulated noise masker alone and one with eight flanking bands of modulated noise in adjacent frequency regions present. CMR was measured as the improvement in threshold with flanking bands present relative to the single-masker reference. Auditory stimuli were presented via headphones. Results indicated that nonverbal intelligence predicted performance on masking tasks, supporting previous research. Likewise, motor speed predicted performance for some of the masking tasks, suggesting that the underlying timing elements are not independent.

1pPP19. Is intelligibility of adjacent passbands hypoadditive or hyperadditive? Richard M. Warren, James A. Bashford, Jr., and Peter W. Lenz (Dept. of Psych., Univ. of Wisconsin-Milwaukee, P.O. Box 413, Milwaukee, WI 53201)

Based on their own findings and reports from other laboratories, H. Müsch and S. Buus [H. Müsch and S. Buus, J. Acoust. Soc. Am. **109**, 2896–2909 (2001)] suggested that when heard together, the intelligibilities of adjacent passbands were hypoadditive, and those of disjoint passbands were hyperadditive. A subsequent study employed extremely high order far infrared filtering that had been shown to effectively eliminate contributions from transition band slopes [R. M. Warren, J. A. Bashford, Jr., and P. W. Lenz, J. Acoust. Soc. Am. **118**, 3261–3266 (2005)]. That study measured the intelligibility for each of the 15 possible pairings of six one-octave effectively rectangular passbands (3 dB/Hz filter skirts) that spanned the speech spectrum with center frequencies ranging from 0.25 to 8 kHz. Each pairing, whether contiguous or disjoint, exhibited hyperadditivity. The present study determined whether decreasing the filter skirts to 0.5 dB/Hz (considered quite steep by conventional standards) would produce the hypoadditivity reported in literature for adjacent bands. Results obtained support the hypothesis that redundancy introduced by overlapping transition band slopes could be responsible for the redundancy correction factor employed by some models for estimating intelligibility of paired adjacent passbands. [Work supported by NIH.]

1pPP20. Auditory stream segregation in six-month-old infants and adults. Nicholas A. Smith (Boys Town Natl. Res. Hosp., 555 North 30th St., Omaha, NE 68144, smithn@boystown.org) and Laurel J. Trainor (McMaster Univ., Hamilton, ON L8S 4K1, Canada)

Auditory stream segregation in six-month-old infants was examined in a paradigm adapted from Bregman and Rudnicky (1975). In a conditioned head-turn procedure, listeners' detection of changes in the temporal order of 2200 and 2400 Hz target tones was tested under three conditions. For developmental comparison, as well as validation of the stimulus design, adults were tested in an identical procedure. Adults clearly detected changes in the order of the target tones when presented alone, but performance suffered when the target tones were preceded and followed by 1460 Hz flanker tones. However, performance improved when the flanker tones were embedded within a series of additional 1460 Hz tones, which captured the flanker tones into an isochronous stream of tones, perceptually segregated from the targets. Although infants performed worse than adults under the same conditions, infants also benefited from the addition of captor tones, suggesting that they too can use grouping cues to organize and attend to elements in the auditory scene.

1pPP21. Effect of selective attention on the segregation of interleaved melodies. Aymeric Devergie, Nicolas Grimault, Barbara Tillmann (UMR CNRS 5020, Univ. Lyon 1, 50 av T Garnier 69366 Lyon Cedex 09 France), and Frédéric Berthommier (GIPSA-LAB, INPG, Grenoble, France)

The role of attention in streaming remains controversial and the data from the literature appear at first sight to be inconsistent [C. Alain and L. J. Bernstein, Curr. Opin. Otolarygol. Head Neck Surg. **16**, 485–489 (2008)], aimed to reconcile these data arguing that selective attention may increase segregation via a sensory mechanism that enhances the processing of task-relevant acoustic information, and a suppression mechanism that attenuates the processing of task-irrelevant stimuli. To test this hypothesis, we proposed an interleaved melody paradigm with various rhythm conditions applied to familiar target melodies and unfamiliar masking melodies. All targets and maskers had the same pitch ranges and timbre variations. No rhythm cue was available in condition 1 (irregular target and masker rhythms). The masker was presented at a regular rhythm in condition 2, the target remaining irregular. Performance over chance in condition 1 indicated that attention enables listeners to extract a familiar melody from a background melody. The better performance in condition 2 can be interpreted in terms of suppression of the masker melody based on the rhythm regularity.

Overall, the current findings are consistent with Alain and Berstein's hypothesis that selective attention can modulate neural processes involved in auditory scene analysis.

1pPP22. Effects of on- and off-frequency maskers on speech recognition. Frederic Apoux and Eric W. Healy (Dept. of Speech and Hearing Sci. The Ohio State Univ., 1070 Carmack Rd., Columbus, OH 43210, apoux.1@osu.edu)

The present study investigated the relative influence of on- and off-frequency noise bands on speech recognition. The target speech stimuli consisted of 64 consonant-vowel consonants. The background noise was simplified speech spectrum-shaped noise or a sentence played backward. All stimuli were divided into 30 contiguous auditory filter width bands spanning 80 to 7563 Hz. Normal-hearing listeners were presented with 15 target speech bands having frequency locations determined randomly from trial to trial to simulate the quasi-random masking effect of noise on the distribution of speech cues across frequency. Results showed that high levels of noise had little impact on recognition when that noise resided only in the 15 off-target bands. Performance was similar when noise was present in all bands versus when present only in the 15 target bands, further indicating a modest effect of off-frequency noise on speech recognition. Performance with sine-wave vocoded speech bands was systematically lower than that obtained with the unprocessed speech bands, supporting the assumption that fine structure information plays a significant role in speech recognition in noise.

1pPP23. Intelligibility of sequentially presented speech signals. Nandini Iyer, Douglas S. Brungart, and Brian D. Simpson (Air Force Res. Lab., 2610 Seventh St., Bldg. 441, Area B, WPAFB, OH 45433)

In some operational environments, listeners are required to monitor several channels of simultaneous time-critical communication. There are two possible ways to reduce the transmission time for multiple speech messages: (1) present information from two or more speech channels simultaneously or (2) time compress the competing speech messages and present them sequentially. Previous studies have shown that the intelligibility of a single speech message is fairly impervious to high degrees of time compression. However, it is not clear if intelligibility is preserved when several such highly compressed messages are presented sequentially. The current experiment investigated speech intelligibility when two, three, or four time-compressed speech signals were presented sequentially. Three results were apparent: (1) speech intelligibility was near ceiling when time-compressed signals were presented sequentially and listeners were required to identify and respond to only one of the signals in the sequence; (2) speech intelligibility decreased dramatically when the listeners were required to respond to all the messages in the sequence, particularly at high compression rates; and (3) overall performance in the multiple-message identification task depended primarily on the total time interval between the onset of each new message, and not on the degree of time compression of the speech message contained in that interval.

1pPP24. Further studies on the benefit of a carrier phrase for word recognition in a two-talker masker: Contributions of coarticulation and auditory stream segregation. Angela Y. Bonino, Lori J. Leibold (Dept. of Allied Health Sci., Univ. of North Carolina, Campus Box 7190, Chapel Hill, NC 27599, abonino@med.unc.edu), and Emily Buss (Univ. of North Carolina, Chapel Hill, NC, 27599)

In adults with normal hearing, word recognition has been shown to benefit from inclusion of a carrier phrase in the presence of a continuous two-talker masker, but not with speech-shaped noise [Bonino *et al.*, Association for Research in Otolaryngology MidWinter Meeting, Baltimore, MD (2009)]. One explanation for this finding is that a carrier phrase aids in the perceptual segregation of the target word from the two-talker background, either through auditory stream segregation or through coarticulation of the carrier and target. Two experiments were conducted to investigate the benefit of the carrier phrase, "say the word," presented prior to a monosyllabic target word. In experiment 1, performance was assessed as a function of signal-to-noise ratio (SNR) in either a two-talker masker or a speech-shaped noise, presented at 0, +5, and +10 dB SNR. In experiment 2, performance was compared across two carrier conditions utilizing either the carrier/target pairs from the original recording or a single utterance of the carrier preceding all target presentations; the time delay between the carrier phrase and target word was also manipulated. Results from these experiments will be discussed, with a focus on the implications for understanding the underlying mechanism responsible for the carrier phrase benefit. [This work was supported by NIH NIDCD grant R03 DC008389 and American Academy of Audiology/American Academy of Audiology Foundation Research.]

1pPP25. Effects of training format on perceptual learning of spectrally degraded voices. Sangsook Choi, Karen Kirk (Dept. of Speech, Lang., and Hearing Sci., Purdue Univ., 500 Oval Dr., West Lafayette, IN 47907, choi111@purdue.edu), Tom Talavage Vidya Krull Chris Smalt, and Steve Baker (Purdue Univ., West Lafayette, IN 47907)

There is evidence that familiarity with the talker facilitates speech recognition (see Nygaard, 2005 for reviews). Identifying talker voices from an auditory speech signal is difficult for cochlear implant users due to the lack of spectral detail conveyed by their processors. Recently, Sheffert and Olson (2004) demonstrated facilitation in voice learning when listeners with normal hearing were trained using audiovisual speech. In the present study, normal hearing listeners were presented with speech processed through a 12-channel noise band cochlear implant simulator and trained to recognize voices in an auditory-only or audiovisual format. Listeners in the audiovisual format required fewer sessions to reach criterion (80% accuracy) than those in the auditory-only format. Voice learning varied as a function of the talkers included in the training set. For the talkers that were more difficult to identify, audiovisual training yielded greater improvements in voice identification than did auditory-only training. After training, participants completed a word recognition task using processed sentences produced by training talkers and novel talkers. Talker familiarity did not influence word recognition performance for either training group. This may be due to ceiling effects with the 12-channel noise band processor. Additional testing in noise is underway.

1pPP26. Spectral modulation detection training: Different outcomes for different trained stimuli. Andrew T. Sabin (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr. Evanston, IL 60201, a-sabin@northwestern.edu), David A. Eddins (Univ. of Rochester, Rochester, NY 14618), and Beverly A. Wright (Northwestern Univ., Evanston, IL 60201)

The pattern of peaks and valleys of sound level spread across audio frequency (spectral modulation) is a key stimulus cue used for sound identification and localization. However, little is known about how practice can influence the ability to detect this modulation. Here we trained three separate groups of normal-hearing adults to detect one of three different spectral modulations. Listeners practiced distinguishing a noise with a flat spectrum from one with a sinusoidal spectral modulation 1 hr/day for 7 days. We varied the modulation depth adaptively to determine the detection threshold. On average, the groups trained to detect 0.5 cyc/oct or 1 cyc/oct spectral modulation across a 200–1600 Hz carrier improved significantly, while the group trained to detect 2 cyc/oct spectral modulation across a 400–3200 Hz carrier did not. Further, it took multiple sessions for the 0.5-cyc/oct group to reach optimal performance, but only one session for the 1-cyc/oct group. Thus it appears that the current training had a smaller and more rapid effect as spectral modulation frequency increased from 0.5 to 2 cyc/oct (if we assume no influence of carrier). Pre-training thresholds also decreased over this range, suggesting that there is less room to improve at higher spectral modulation frequencies.

1pPP27. Difference limen for dynamic center-of-gravity signals. H. Dean Hudson (Air Force Res. Lab, 2610 Seventh St., Bldg 441, Area B, WPAFB, OH 45431), Evelyn M. Hoglund, and Lawrence L. Feth (Columbus, OH 43210)

We hypothesize that central auditory processing of the dynamic center-of-gravity (COG) of a pair of tones is similar to that for a single tone that undergoes sinusoidal frequency modulation (FM). The signal COG can be moved dynamically by introducing amplitude modulation to two fixed-frequency anchor tones separated by one, or more, equivalent rectangular bandwidths (ERB). The phase relationship between the sinusoidal amplitude modulators of the anchor tones is used to control the magnitude of the COG deviation. In this study, the amplitude of the anchor tones and the depth of AM were identical between intervals. The phase relationship of the modulators was manipulated to control the deviation in the COG. To test our hy-

pothesis, we compared FMDLs with COGDLs at three center frequencies and three modulation rates. First, difference limens were measured for the FM signals in partial replication of [Ozimek and Sek (1990)]. Next, COGDLs were measured. Initial attempts to match COG deviation to FM deviation were unsuccessful because the task was too difficult. Consequently, the modulation depth of the COGDL signals was fixed at 0.5, which resulted in replicable performance across subjects. Data for both the FMDL and COGDL task will be discussed. [Work supported by NIH and ASEE.]

1pPP28. Distortions in the perceived relative temporal positions of a signal and masker. Beverly A. Wright (Dept. of Comm. Sci. and Disord., Northwestern Univ., 2240 Campus Dr. Evanston, IL 60208, b-wright@northwestern.edu) and Matthew B. Fitzgerald (New York Univ., New York, NY 10016)

Simultaneous and non-simultaneous masking tasks are often introduced to listeners in terms of the veridical relative positions of the signal and masker. Here we report that the actual perceived temporal positions of the signal and masker do not always match those descriptions. We asked normal-hearing adults about the perceived presentation time of a brief "signal" that was presented either before, during, or after a longer "masker." The task was either to mark the perceived presentation time of the signal on a schematic diagram of the masker, or simply to judge whether the signal occurred inside or outside of the masker. Listeners tended to perceive the signals as having occurred later than they actually had. This temporal distortion was most marked for signals that were presented near the end of the masker. Signals that were presented 25–100 ms before the end of the masker were perceived as occurring outside of the masker 50% of the time. Similar results were obtained with different masker durations (150, 300, and 450 ms), and various combinations of signal and masker spectra. This phenomenon may provide a measure of the time it takes to switch attention from a foreground to a background stimulus. [Work supported by NIH.]

1pPP29. Detection of warning signals while operating a motorcycle and wearing hearing protection. Andrew D. DeSherlia (6643 N. Newgard, Chicago, IL 60626, andyds23@gmail.com)

It has been shown that operators of motorcycles are exposed to dangerous levels of wind noise at high speeds [McCombe *et al.*, J. Laryngol. Otol. **109**, 599–604 (1995)]. Many governmental regulatory bodies have developed restrictions that ban the use of earplugs while operating a motorcycle, due to their obstruction of warning signals. In order to test this theory, 20 people with normal hearing were exposed to recordings of motorcycle wind noise accompanied by warning signals at different amplitudes. As the warning signal's amplitude was adjusted, the listener was asked to indicate when it could be detected. This determined the threshold at which the warning signal could be detected for listeners with and without hearing protection. This study should broadly indicate whether hearing protection allows the listener to detect warning signals at a lower threshold than if no protection were used.

1pPP30. Model-based direction estimation of concurrent speakers in the horizontal plane. Mathias Dietz, Stephan D. Ewert, and Volker Hohmann (Medizinische Physik, Univ. Oldenburg, Germany)

A computational auditory model for the direction estimation of concurrent speakers in the horizontal plane is presented. The auditory signal processing is motivated by mammalian physiology and human psychoacoustic data, extending the binaural model by Dietz *et al.* [Brain Res., **1220**, 234–245 (2008)]. The model exploits a wide range of interaural parameters, namely, the interaural level difference, the interaural phase difference of the fine structure, and the interaural coherence. The parameters are determined at the output of auditory filters allowing for a simultaneous estimation of several sound source directions in a multidimensional internal representation. By focusing on time segments with high interaural coherence [Faller and Merimaa, J. Acoust. Soc. Am. **116**, 3075–3089 (2004)] in the auditory bands, which likely stem from a localized sound source, the robustness of the direction estimation of the model was considerably improved: for two well-separated speakers in quiet, the estimation error is generally less than or equal to 10 deg. In noisy environments, the direction of a single speaker can be estimated for signal-to-noise ratios below 0 dB. Further improvements of the model by concurrent pitch estimation to reduce permutation errors between nearby speakers are investigated and discussed.

1pPP31. A comparison of modulation indices for describing amplitude-compressed speech. Pamela Souza (Dept. of Speech and Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, psouza@u.washington.edu), Frederick Gallun (Portland VA Medical Ctr., Portland, OR 97239), and Eric Hoover (Univ. of Washington, Seattle, WA 98105)

This presentation explores two approaches to characterizing changes to speech with amplitude-compression amplification. In the first, we considered changes to waveform morphology using the envelope difference index (EDI); [Fortune *et al.* (1994)] to quantify the effects on amplitude envelope in the time domain. In the second, the spectral correlation index (SCI); [Gallun & Souza (2008)] was used to compare signal envelopes in the frequency domain. In the SCI, similarity is represented by the correlation of the average modulation spectra at six octave-spaced amplitude modulation frequencies (1–32 Hz) in six octave-spaced carrier frequency regions (250–8000 Hz) for a pair of phonemes. Test stimuli were a set of 16 vowel-consonant-vowel (VCV) syllables spoken by four talkers. The VCVs were digitally processed to limit spectral information using a signal-correlated noise technique [Schroeder (1968)] then submitted to a compression amplification simulation in which parameters (compression ratio and release time) were selected to achieve a range of temporal alteration. Consonant identification scores for 10 normal-hearing listeners were obtained and related to the modulation indices. Although the SCI was more sensitive to changes in specific compression parameters, the EDI was more closely related to recognition. [Work supported by R01 DC0060014 and VA RR&D CDA-2 C4963W.]

1pPP32. Extending the sawtooth wave form inspired pitch estimator with an auditory-based preprocessing stage. Arturo Camacho (Escuela de Ingen. Eléct., Univ. de Costa Rica, Apdo. Postal 11501-2060 UCR, San José, Costa Rica)

The sawtooth wave form inspired pitch estimator (SWIPE) [A. Camacho, J. Acoust. Soc. Am. **124**, 1638–1652 (2008)] is extended by introducing an auditory-based preprocessing stage consisting of two main steps. First, a system consisting of a gammatone filterbank followed by half-wave rectifiers and low-pass filters is applied to the signal. This system tends to boost low-order harmonics of the signal, as shown in a work by Klapuri [A. Klapuri, IEEE Trans. Audio, Speech, Lang. Process. **16**, 255–266 (2008)]. Second, the square root of the amplitude spectrum is computed on every channel, and they are summed to form a *summary square-root spectrum* (SSRS). SWIPE is then applied to this SSRS. Results show that the proposed method significantly outperforms the original SWIPE on music and telephonelike speech, albeit producing a small decrease in performance on high-fidelity speech.

1pPP33. Head shadow effect and pinna effect by sound intensity. Yen-Sheng Chen (Taiouan Interdisciplinary Otolaryngol. Lab., Chang Gung Univ.), Jen-Fang Yu (Chang Gung Univ.,), Chin-Kuo Chen (Chang Gung Memorial Hosp.), Wei-De Cheng, Yi-Hsin Lin (Chang Gung Univ.), and Go-Long Tsai (Natl. Taipei Univ. of Technol., Taipei, Taiwan)

This study is to develop a procedure of measuring the influences of the head shadow effect and pinna effect by stimulus intensities and stimulus frequencies (125 Hz to 8 kHz) based on the stimulus source at azimuth angles (0°–180°). In this study, the head shadow effect would be affected by the stimulus frequencies at 3–8 kHz, and the difference of sound pressure for bilateral ears was 7.46–41.40 dB SPL. The pinna effect would be affected by the stimulus frequencies at 3–8 kHz. The difference of sound pressure for all sound sources was 6.62–35.69 dB SPL. The pinna effect would occur most apparently at 135° of azimuth. Consequently, the sound intensity would not affect the head shadow effect and the pinna effect. On the con-

trary, the pinna effect, the head shadow effect, the frequency of stimuli and the sound location should be considered for hearing aids selection for hearing-impaired listeners.

1pPP34. Matching the waveform and the temporal window in stimulus generation. William M. Hartmann (Dept. of Phys. and Astron., Michigan State Univ., 1226 BPS Bldg., E. Lansing, MI 48824 hartmann@ps.msu.edu) and H. Steven Colburn (Boston Univ., Boston, MA 02215)

The discrete Fourier transform (DFT) of a signal that is windowed with a rectangular window having duration T_D is given by the coefficients of the Fourier series for a periodic waveform having period T_D. This periodic waveform is "matched" to the rectangular window because of a special relationship between the components of the windowed signal (windowed sine or cosine functions) and the harmonics of the periodic waveform (sine or cosine functions). Component m of the windowed signal is orthogonal to harmonic n of the waveform ($m \neq n$). If the window (overall duration T_D) is not rectangular, the DFT still corresponds to a periodic waveform having period T_D, but that waveform is not matched to the window because the components of the windowed signal are not orthogonal to the harmonics of the periodic waveform. If the window has raised-cosine edges, with durations τ, on either end, the components of the windowed signal are orthogonal to harmonics of a periodic waveform only if the period of the waveform is $T_D - \tau$, not T_D. The distinction becomes important in generating stimuli for psychoacoustical and physiological experiments. [Work supported by the NIDCD, Grants DC00181 and DC00100.]

1pPP35. An efficient code for environmental sound classification. Robert Lutfi (Dept. of Communicative Disord., Univ. of Wisconsin, Madison, WI 53706, ralutfi@wisc.edu), Raman Arora, and Ching-Ju Liu (Univ. of Wisconsin, Madison, WI 53706, chingjuliu@wisc.edu)

Much work has been devoted in recent years to the goal of developing an automated sound recognition system that can accurately and efficiently classify a wide variety of common environmental sounds according to their generating source. The effort is driven, in part, by the desire to understand our own ability to reconstruct from sound an accurate perception of everyday objects and events present in our natural environment [cf. A. S. Bregman, *Auditory Scene Analysis*, MIT Press (1990)]. Here an efficient code is described for classifying environmental sounds that exploits a recent significant advance in sparse signal reconstruction known as compressed sensing (CS) [cf. D. L. Donoho, IEEE Trans. Inf. Theory, **52**, 1289–1306 (2006)]. CS involves a novel approach to sampling in which the salient information in signals is recovered from the projection onto a small set of random basis functions. The advantage of CS over traditional Fourier or wavelet representations is its capacity to allow accurate classification at low signal-to-noise ratios based on few samples and little or no prior information about signals. To demonstrate we compare CS-based and Fourier-based classification for several representative environmental sound classification tasks. [Work supported by NIDCD].

1pPP36. A computational model for auditory saliency of environmental sound. Bert De Coensel (Dept. of Elec. Eng. and Comput. Sci., Univ. of California at Berkeley, 415 Soda Hall, Berkeley, CA 94720-1776, bert.decoensel@intec.ugent.be), Dick Botteldooren (Ghent Univ., B-9000 Ghent, Belgium), Birgitta Berglund, and Mats E. Nilsson (Stockholm Univ. and Karolinska Inst., SE-106 91 Stockholm, Sweden)

Because the information flow received by the human auditory system exceeds the processing capacity of the brain, neural mechanisms engage and guide attention toward prominent parts of the auditory scene. Several computational models for auditory saliency have been proposed recently. Most of these are concerned with speech recognition, and therefore apply high temporal and spectral precision to relatively short sound fragments. Here, a simplified model is described that specifically targets the long exposure times usually considered in soundscape research. The model trades temporal and spectral accuracy for computational speed, but nevertheless implements the key elements that are present in the calculation of complex auditory saliency maps. A simplified "cochleagram" is calculated from the 1/3-octave band spectrogram using the Zwicker model for specific loudness. Saliency is determined based on spectro-temporal irregularities, extracted in parallel at different feature scales, using a center-surround mechanism. Finally, conspicuous peaks are selected using within-feature and between-feature competitions. The model is shown to behave as expected for a number of typical sounds. As an illustration, saliency calculation results for a set of recordings in urban parks are compared with other acoustical descriptors and with perceptual attribute scales from questionnaire studies.

1pPP37. Signal-processing strategies for electric-acoustic stimulation. Christopher A. Brown and Sid P. Bacon (Dept. of Speech and Hearing Sci. Arizona State Univ., PO Box 870102, Tempe, AZ 85287-0102)

Electric-acoustic stimulation (EAS) occurs when a cochlear implant recipient receives some amount of acoustic stimulation, typically as a consequence of residual low-frequency hearing. This combined stimulation often leads to significant improvements in speech intelligibility, especially in the presence of a competing background. We have demonstrated EAS benefit when target speech in the low-frequency region is replaced with a tone modulated in frequency with the target talker's F0, and in amplitude with the amplitude envelope of the target speech. We have hypothesized that in some instances, the modulated tone may be more beneficial than speech. For example, a patient possessing extremely limited residual hearing (e.g., only up to 100 Hz) may not show EAS benefit because the F0 of many talkers is too high in frequency to be audible. In support of this hypothesis, we demonstrated that the tone can be shifted down considerably in frequency without affecting its contribution to speech intelligibility. In the current experiment, while generating the tone, we manipulated various signal-processing parameters to examine their effects on the benefits of EAS. One goal of this work is to develop a real-time processor that provides EAS benefit to implant users with limited residual hearing. [Work supported by NIDCD.]

Session 1pSC

Speech Communication: Clinical, Methodological, and Technological Issues in Speech (Poster Session)

Michelle R. Molis, Chair
National Ctr. for Rehabilitative Auditory Research, Portland, OR 97207

Contributed Papers

All posters will be on display from 1:30 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 4:30 p.m.

1pSC1. Developing objective measures of listening effort. Mini N. Shrivastav, Rahul Shrivastav, and James D. Harnsberger (Dept. of Commun. Sci. and Disord., Univ. of Florida, 336 Dauer Hall, Gainesville, FL 32611, mnshriv@ufl.edu)

The goal of the present work is to develop valid measures of listening effort independent of task difficulty. Various markers of effort will be measured for listening conditions of varying difficulty but with equal performance. The experimental task will involve tracking a previously specified keyword(s) in a speech sample. The task difficulty will be manipulated by changing the number of keywords to be tracked and by changing the level of a noise masker so that the signal-to-noise-ratio changes from favorable to unfavorable. The participants will be a group of young normal-hearing individuals. Effort will be measured using several physiological markers such as galvanic skin response, heart rate, and blood oxygen level. Subjective ratings of listening effort will also be collected. For each level of difficulty, the percent correct detection performance will be calculated. Conditions that result in equal performance (for example, greater than 90% scores) will be selected for analyses. Any difference in physiological measures between these conditions will then likely reflect differences in listening effort. The study will provide preliminary candidates for developing an objective and real-time measure of listening effort.

1pSC2. Semiautomatic measurement of speech error data recorded with ultrasound. Stefan Frisch (Dept. of Commun. Sci. and Disord., Univ. of South Florida, 4202 E Fowler Ave., PCD1017, Tampa, FL 3362, frisch@cas.usf.edu)

Ultrasound has been shown to be a useful articulatory research tool. However, ultrasound imaging produces video data that is time-consuming to analyze. In this study, previous work on imaging of articulatory errors between velar and alveolar stops is extended to a larger group of participants through the use of measures extracted from semiautomatically created tongue contours that were generated using EDGETRAK software. Speech errors were induced in word onset consonants using nonsense tongue twisters. Consistent with previous research, onset stop errors were quantified using raising of the tongue dorsum toward the palate and angle of elevation of the tongue blade toward the alveolar ridge. In the majority of cases, it was found that errors created productions that were statistically indistinguishable from normal productions of the wrong category. However, some intermediate or gradient errors between categories were also found. The semiautomated measurement technique appears to be an efficient alternative to manual measurement of the data, producing qualitatively similar results. [This work was supported by NIH R03 DC06164.]

1pSC3. Gradient measures of children's speech production: Visual analog scale and equal appearing interval scale measures of fricative goodness. Kari Urberg-Carlson, Benjamin Munson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, Minneapolis, MN 55455, urbe001@umn.edu), and Eden Kaiser (Univ. of Minnesota, Minneapolis, MN 55455)

Cross-sectional and longitudinal studies of speech-sound development utilizing phonetic transcription often show an apparently discontinuous acquisition of speech sounds. Instrumental studies, in contrast, suggest that children acquire speech-sound contrasts gradually. An ideal perceptual-rating measure of children's production should capture this gradient change in production, correlate well with acoustic data, and be fast and easy both to administer and to score. A previous experiment in our laboratory compared three methods of collecting continuous judgments of children's consonant productions of /s/ and /ʃ/: Of the three, visual analog scaling (VAS) correlated best with acoustic parameters. However, as was administered in that experiment, VAS allowed only two-way comparisons between phonemes. To determine whether VAS could be used for multiple-way comparisons, two experiments were conducted. In the first, participants first made a forced choice between two phonemes, then used VAS to make a judgment of the goodness of the phoneme, from perfect to bad. A second experiment was conducted using a seven-point EAI scale in place of the VAS. The results will be correlated with acoustic data as in the previous experiment and will further our knowledge of optimal methods for measuring children's speech production perceptually.

1pSC4. Voice quality contour measurements for prosody detection. Jeung-Yoon Choi (Dept. of Elect. and Elect. Eng., Yonsei Univ., 134 Shinchon-dong, Seodaemun-gu, Seoul, Korea 120-749)

Voice quality contour measurements were used to detect prosody markers. This work is an extension of an earlier paper that examined static voice quality measures for prosody detection. Voice quality measures include those related to the voice source, such as open quotient, spectral tilt, and harmonic component distributions. Specifically, the measurements comprise: the relative amplitudes of the first two harmonics; the relative amplitudes of the first harmonic in relation to the amplitudes of the first and third formants. Contour measurements over several syllables, in addition to static measurements at the nucleus of each syllable, were used to detect ToBI markers for accent and boundaries. Experimental results show varying improvements over using only static measurements.

1pSC5. An algorithm for token-by-token linear predictive coding analysis of oral monophthongs. Leonardo Oliveira and Pablo Arantes (Dept. of Linguist., Campinas State Univ., PO Box 6045, Campinas, SP, Brazil 13083-970, leo.oliveira@gmail.com)

Linear Predictive Coding (LPC) is the most reliable vowel formant estimation method. LPC trajectories closely approximate formants and are preferable as a means of avoiding human bias. Nevertheless, formant analysis by LPC is not error free, as it can be affected by fundamental frequency, noise and vocal tract morphology. Error minimization is usually achieved through manual checking of LPC results with spectral contour. An algorithm to find optimal LPC parameters (Burg method) on a token by token basis was developed and implemented as a Praat script. The algorithm minimizes inter- and intra-vowel formant variability without knowledge of vowel identity. Algorithm results were compared with results of manual adjustment of LPC parameters on a trial and error basis on a corpus of 180 stressed and unstressed oral monophthongs of Brazilian Portuguese from a male speaker. First and second formants linear correlations are $r^2 = 0.98$ and 0.99 respectively. The areas of /i, a, u/ vocalic triangles (mean values as vertices) of manual and automatic measurements showed only 4.5% difference. These

results suggest the algorithm can be generalized to any speaker and speed up the measurement of vowel formants in large corpora. [Work supported by CNPq and Fapesp.]

1pSC6. Advanced time-frequency displays applied to forensic speaker identification. Sean A. Fulop (Linguist. PB92, Cal. State Univ. Fresno, 5245 N. Backer Ave., Fresno, CA 93740, sfulop@csufresno.edu) and Sandra Ferrari Disner (Univ. of Southern California, Los Angeles, CA 90089)

Forensic phoneticians have long utilized conventional spectrograms as the basis of the the auditory-acoustic method of speaker identification. Recent investigations [S. A. Fulop and K. Fitz, "Using the reassigned spectrogram to obtain a voiceprint," J. Acoust. Soc. Am. **119**, 3337 (2006); S. A. Fulop and S. Disner, "The reassigned spectrogram as a tool for voice identification," Int. Congress of Phonetic Sciences **XVI**, 1853–1856 (2007)] have suggested that a newer technology, i.e., the reassigned spectrogram, may be at least as valuable in the service of speaker identification. The present paper describes methods for forensic speaker identification using enhanced time-frequency displays including reassigned spectrograms and Zhao-Atlas-Marks distributions. Identification methods which employ the aforementioned displays are compared with the more established auditory-acoustic method, using recordings of 10 speakers saying several short phrases two times each. The results point to the efficacy of these newer time-frequency displays for speaker identification, particularly when used to corroborate conventional methods. One important development is the ability to focus on the detailed time-frequency features of the phonation process, thereby obtaining a new speech biometric indicative of vocal cord dynamics.

1pSC7. Automatic acquisition device identification from speech recordings. Daniel Garcia-Romero and Carol Y. Espy-Wilson (Dept. of Elec. and Comput. Eng., Univ. of Maryland, A.V.W. Bldg. 3180, College Park, MD 20742)

In the field of speaker recognition (SR), the artifacts left in the speech signal by the acquisition device are highly detrimental. When the speech signals used in the enrollment and testing phases come from different devices, the recognition accuracy decreases significantly. Hence, most SR systems try to remove these artifacts by using some general knowledge about the acquisition device. However, the degree of specificity used in the characterization of the devices is very broad (e.g., GSM handset as opposed to CDMA). This study focuses on the dual problem with a higher degree of specificity. That is, given a speech recording, how to automatically determine the exact make and model of the acquisition device regardless of the speaker and speech content. For this purpose, the HTIMIT and LLHDB databases, comprising short sentences from more than 300 speakers over 10 different acquisition devices, were used. Closed set identification experiments were conducted to assess the performance of different feature sets (i.e., MFCC and linear-FCC) along with a Gaussian mixture model classifier . The results show that statistical modeling of the device characteristics in terms of MFCC provides an excellent discriminative power among the 10 devices tested. Classification accuracies higher than 90% are reported.

1pSC8. Parametric study on speaker identification biometric system using formant analysis. Binsu C. Kovoor (Dept. of Comput. Sci., Cochin Univ. of Sci. and Technol., Cochin, India 682022, binsu@cusat.ac.in), M. H. Surpiya and K. Poulose Jacob (Cochin Univ. of Sci. and Technol., Cochin, India 682022)

Speech is the most suitable bio-feature for environments where hands free is a requirement in the security system. Speaker identification is done successfully utilizing formant frequencies in the human speech. In the prototype system developed, which can be operated without the knowledge of the users, representative features are extracted and compared with speaker specific features stored in the knowledge base. The algorithm mainly consist of four modules, namely, recording of samples and building a knowledge base of the vowel sounds, building autoregressive models, recognizing vowel and thereby identifying the speaker. The important parameters to be fixed for obtaining optimum output for a given input data of the proposed model are envelope threshold and order of parametric AR model. The envelope threshold is the parameter that differentiates numerous peaks in the speech signal while an appropriate value of the order of AR model helps to compute the frequency response of the input signal accurately. The influences of various parameters have been studied and are discussed in this paper. It is expected that the results of the study will help a biometric system developer to choose appropriate value for the parameters in the algorithm for different applications.

1pSC9. Automatic analysis of vocal manifestations of psychological states. Elizabeth Rosenfeld and Jared Bernstein (Tasso Partners, 1330 Tasso St., Palo Alto, CA 94301, elizabeth@eRosenfeld.com)

Previous research identified acoustic indicators of mood and emotion in speech [I. Murray and J. Arnott, J. Acoust. Soc. of Am. **93**, 1097–1108 (1993)], suggesting that speech signals could be measured automatically to estimate the perceived mood or affect of the speaker. Forty experimental subjects produced 1584 spoken renditions of neutral sentences, either read-aloud or repeated verbatim from a spoken model. An automatic speech processing system extracted ten paralinguistic parameters from each of these spoken responses. Samples of spoken responses were then played to psychotherapists who assigned an apparent mood to each recording. Results indicate that very reliable (0.98) estimates of speaker mood can be derived from as few as 12 judgments made when listening to spoken renditions of fixed material that contains no indication of mood in the linguistic content. Furthermore, these reliable estimates can be predicted with a correlation coefficient of 0.79 from a linear combination of only three of the ten parameters: rate of speech, response latency, and maximum speech amplitude. This prediction accuracy was achieved without using any parameters based on fundamental frequency and without any sophisticated pattern matching techniques applied to the data.

1pSC10. A step in the realization of a speech recognition system based on gestural phonology and landmarks. Vikramjit Mitra (Dept. of Elec. and Comput. Eng., Univ. of Maryland, A.V.W. Bldg., #3180, College Park, MD 20742, vmitra@umd.edu), Hosung Nam (Haskins Labs., New Haven, CT 06511), and Carol Y. Espy-Wilson (Univ. of Maryland, College Park, MD 20742)

Current state-of-the-art speech recognition systems poorly perform in casual speech as they are not robust against acoustic variations. Variability is an intrinsic problem of phone-based recognition systems as phone-units may be distinctive in the cognitive domain, but their physical characteristics can vary considerably due to coarticulation. Articulatory phonology proposes that articulatory constriction gesture is an invariant action unit and speech can be decomposed into a constellation of gestures. Speech recognition studies have recently employed this framework in the sense that speech acoustic variations can be accounted for by gestural coarticulation and reduction. The VT time-functions are time-varying physical realizations of gestural constellations at distinct vocal tract sites for a given utterance. This study aims to predict VT time-functions from acoustic signals as a component model in a complete gesture-based speech recognition system. We will compare artificial neural-network (ANN) based nonlinear regression models against hierarchical support vector regression (SVR) to obtain VT time-functions from the speech signal. A single ANN can generate all 8 VT time functions, whereas SVRs generate one output at a time, necessitating use of 8 SVRs. We also explore usage of spectral parameters such as MFCC and PLPs against knowledge-based acoustic parameters (APs).

1pSC11. Discriminating dysarthria type and predicting intelligibility from amplitude modulation spectra. Susan J. LeGendre (Speech, Lang., and Hearing Sci. , Univ. of Arizona, P.O. Box 210071, 1131 E. 2nd St., Tucson, AZ 85721-0071, sjlegend@email.arizona.edu), Julie M. Liss, and Andrew J. Lotto (Arizona State Univ., Tempe, AZ 85287-0102)

Subtypes of dysarthria are often described in terms of particular disruptions in speech rhythms. In an attempt to quantify these differences, the envelope modulation spectrum (EMS) was computed on sentences read by speakers with hypokinetic, hyperkinetic, ataxic, and mixed flaccid-spastic dysarthria, and a group of normal speakers (43 speakers total). The EMS consists of the spectra of the slow-rate (up to 10 Hz) amplitude modulations of the full signal and within seven octave bands ranging in center frequency from 125–8000 Hz. From these spectra, six variables were calculated for each band relating to the peak frequency and amplitude and the relative energy above, below, and in the region of 4 Hz. According to stepwise discriminant analysis, six of these EMS variables could correctly discriminate speaker group membership with an accuracy of 84% (better performance was obtained for distinguishing individual groups). Further, 85% of the vari-

ance in the intelligibility of the dysarthric speakers (derived from a separate set of sentences) was predictable from a subset of six of these variables. These results suggest that there are reliable perturbations of speech temporal patterns associated with dysarthria subtypes and that these perturbations play an important role in intelligibility. [Work supported by NIH-NIDCD.]

1pSC12. Beyond acoustic data: Characterizing disordered speech using direct articulatory evidence from real time imaging. Edward Holsinger (Dept. of Linguist., Univ. of Southern California, GFS 301, Los Angeles, CA 90089, eschlon@mac.com), Vikram Ramanarayanan, Dani Byrd, Louis Goldstein (Univ. of Southern California, Los Angeles, CA 90089), Maria Luisa Gorno Tempini (Univ. of California, San Francisco, San Francisco, CA 94117), and Shrikanth Narayanan (Univ. of Southern California, Los Angeles, CA 90089)

The traditional view of disordered speech characterizes speech errors as deletions, insertions, or transpositions of one or more phonetic symbols in sequence. Recent articulatory research, however, suggests that such a characterization of disordered speech is at best incomplete, and at worst incorrect. A consequence of abandoning the traditional view is that the value of phonetic transcription as a tool for analyzing speech errors is in question. We examine the discrepancy between the phonetic transcription and the actual articulatory events produced by an apraxic speaker whose articulation was imaged with real-time MRI with synchronous noise-canceled audio in a speak-after-me shadowing task. Results indicate that transcription was somewhat reliable between two trained transcribers, but several systematic discrepancies existed. In addition to the transcription being an incomplete record, we also found cases in which the transcription was misleading, unhelpful, or simply incorrect regarding the actual articulation produced by the speaker. Further examination of the acoustic signal revealed that the problems with the transcription cannot easily be overcome with detailed analysis of the acoustics. This study suggests that accurate characterization of disordered speech requires data of a type that cannot be provided solely by transcripts or acoustics. [Work supported by NIH]

1pSC13. Transition characteristics in speakers with dysarthria and in healthy controls: Part III: liquids and glides. Gary Weismer, Christina Kuo (Dept. Communicative Disord., UW-Madison, 1975 Willow Dr., Madison, WI 53706), and Yunjung Kim (LSU, Baton Rouge, LA 70803)

In two previous reports [Weismer, Kuo, & Chung, J. Acoust. Soc. Am. **121**, 3135 (2007); Kuo and Weismer, J. Acoust. Soc. Am. **124**, 2558 (2008)] the transition characteristics of speakers with dysarthria, secondary to Parkinson disease and amyotrophic lateral sclerosis (ALS), were compared to transition characteristics of healthy controls. The previous reports described the characteristics of obstruent-vowel [Weismer >etal/> (2007)] and diphthong [Kuo and Weismer (2008)] transitions extracted from an extended passage reading. Our hypothesis was that distributional analyses would show the CV, obstruent-vowel transitions to be less affected by the neurological disease as compared to diphthong transitions. The hypothesis was not supported by the data, which showed both types of transitions to be slower and less extensive than in healthy controls. The present report completes this analysis with documentation of transition characteristics of liquids and glides. Our expectation is that liquid and glide transition types will be slower and more extensive in talkers with dysarthria,as compared to healthy controls [Work supported by DC 003273.]

1pSC14. Acoustical analysis of vowel production in people with Parkinson's disease. Gabrielle Richard (Dept. de linguistique et de didactique des langues, Univ. du PQ a Montreal, Case postale 8888, succursale Ctr.-ville, Montreal, QC H3C 3P8, Canada, richard.gabrielle@gmail.com), Lucie Menard (Univ. du PQ a Montreal, succursale Ctr.-ville, Montreal, QC H3C 3P8, Canada), Henri Cohen (Univ. Paris-V, Edouard Vaillant 92774 Boulogne-Billancourt Cedex, France), and Emmanuelle Pourcher (Clinique Ste-Anne Memoire et Mouvement, PQ, QC G1R 3X5, Canada)

Speech is the sound wave produced by the vibration of the vocal chords finely tuned by the supraglottal articulators: the tongue, the lips, and the jaw modulate the vocal tract shape to produce sounds that are distinctive enough to be distinguished. But how can people who suffer from a motor control disease such as Parkinson's disease (PD) produce comprehensible speech? This work aims at studying the differences between speakers with PD and control speakers (C) regarding acoustical space, coarticulation, and contrastive emphasis. Eight speakers with PD and eight control speakers have been recorded in a speech production task. The Quebec French vowels /a/ and /i/ have been produced, in coarticulation with /b/ and /d/, in neutral and under emphasis contexts. The value of the first and second formants at the middle of the vowel, and the value of the second formant at the onset of the vowel have been extracted. Durations have also been extracted. The analysis showed that the coarticulation consonant has a greater impact on formantic values for the group with PD than the C group. Moreover, the formantic difference between the neutral and emphasis condition is greater for the group with PD than for the C group.

1pSC15. Articulatory modification induced by speaking rate change in Parkinson's Disease. Yunjung Kim (Dept. of Comm. Sci. and Disord., Louisiana State Univ., Baton Rouge, LA 70803, ykim6@lsu.edu) and Gary Weismer (Univ. of Wisconsin-Madison, Madison, WI 53706)

One of the most well-known treatment techniques to improve speech intelligibility of speakers with dysarthria involves the reduction of speaking rate (Duffy, 1995). The theory of this strategy is that a slower rate provides more time to attain articulatory targets. However, the underlying mechanism of enhanced speech intelligibility at slow speaking rate is not yet clear. In other words, it has not been directly examined whether this strategy causes measurable articulatory improvements or simply provides listeners with greater time to process impaired speech. This is an important question especially in clinical practice, related to establishing a treatment target, and furthermore, an overall treatment plan for the client. In this presentation, we will report some articulatory and acoustic indices of articulatory characteristics of speakers with Parkinson's Disease and healthy controls, producing the same utterances at three different speaking rates. [Work supported by internal funds from LSU.]

1pSC16. Acoustic characteristics of vowels in dysarthria: A comparison of clear and conversational speech. Kris Tjaden, Jennifer Lam, Joan Sussman, Stacy Blackburn, and Katrina Fulcher (Dept. of Communicative Disord. Sci., Univ. at Buffalo, 3435 Main St., Buffalo, NY 14214, tjaden @buffalo.edu)

The impact of dysarthria on vowel production has been demonstrated in a variety of studies. Acoustically, these deficits often take the form of a reduced or collapsed vowel space area, reduced F2 interquartile range, and reduced vowel transition slopes and extents. Research further suggests that these segmental deficits may help to explain reduced intelligibility or overall speech severity, at least for some speakers with dysarthria. Clear speech shows some promise for improving vowel production in dysarthria as well as for maximizing intelligibility. Comparative group studies investigating clear speech in dysarthria are lacking, however. The current study will report acoustic measures of vowel production for individuals with dysarthria secondary to Multiple Sclerosis, Parkinson's Disease, and healthy controls. As part of a larger study, speakers read 25 Harvard Sentences in a variety of speaking conditions, including Habitual or conversational and Clear. Static and dynamic segmental measures of vowel production will be reported. Group effects as well as individual speaker trends will be explored. [Work supported by NIH.]

1pSC17. The differential effects of dysarthria type on lexical segmentation. Julie M. Liss, Stephanie M. Spitzer, Kaitlin Lansford (Dept. of Speech and Hearing Sci. Arizona State Univ., Tempe, AZ 85287-0102, julie.liss@asu.edu), and John N. Caviness (Mayo Clinic Arizona, Scottsdale, AZ 85259)

Although intelligibility deficits are common across various forms of dysarthria, it was hypothesized that the causes of intelligibility reductions depend on the ways the degraded signal challenges listener cognitive-perceptual strategies. This hypothesis was confirmed by analyzing the lexical boundary errors (LBE) elicited by 44 speakers with one of four forms of dysarthria (ataxic, hypokinetic, hyperkinetic, mixed spastic-flaccid) . Error patterns from 60 listener transcripts revealed reliance on metrical stress to segment the 80 six-syllable phrases. However, reductions and disturbances in the acoustic cues to syllabic stress associated with each form of dysarthria resulted in different LBE patterns. Explanations for these unique patterns are found, in part, in the metrical structures of the dysarthric speech. For example, the temporal relationships among stressed and unstressed syllables varied widely in hyperkinetic speech, which ostensibly prevented lis-

teners from optimally exploiting metrical stress as a cue for segmentation. The equal-even temporal structure of the spastic-flaccid speech resulted in the highest proportion of boundary insertions. The presence of interword pauses facilitated the assignment of word onset to strong syllables. Results will be presented relative to models of lexical segmentation and clinical implications for targets of remediation in the dysarthrias. [Work supported from NIH-NIDCD 5R01 DC6859.]

1pSC18. Acoustic effects of familiarity on speech. Joel MacAuslan (S.T.A.R. Corp., Bedford, MA 01730, joelm@starspeech.com) and Suzanne Boyce (Univ. of Cincinnati, Cincinnati, OH 45267-0379)

In earlier work, we have reported subtle differences in acoustic measures of speech from 15 subjects who produced the Rainbow Passage at eight hour intervals over 36–42 hours of sleep deprivation. To determine whether results are due to sleep deprivation per se, or to the effect of increasing familiarity with the speech materials, we collected Rainbow Passage recordings from 15 subjects at eight hour intervals over three days while following their normal sleep/wake pattern. These data were subjected to the same measures (based on automatic detection of acoustic landmarks) as reported in our previous work. Results showed no consistent effect of familiarity with speech materials under these experimental conditions, supporting the contention that sleep deprivation affects speech articulation. [Work supported by NIH.]

1pSC19. Comparison of voice intensity effects on electroglottographic versus acoustic jitter and shimmer. Meike Brockmann (Dept. for Phoniatry/Speech Pathology, University Hospital Zurich, Frauenklinikstrasse 24, 8091 Zurich, Switzerland), Michael J. Drinnan (Newcastle General Hospital, Newcastle upon Tyne NE4 6BE, UK, M.J.Drinnan@ncl.ac.uk) and Paul N. Carding (Freeman Hospital, Newcastle upon Tyne NE7 7DN, UK, paul.carding@ncl.ac.uk)

Electroglottographic (EGG) jitter and shimmer have been described as more sensitive than acoustic perturbation. Recent studies documented significant voice intensity effects on acoustic parameters even in "normal" voice intensity. The aim of this cross-sectional single cohort study was to compare voice intensity effects in acoustic and electroglottographic measurements in several voice tasks. Forty healthy adults (1:1 f:m) aged 20–40 years phonated /a/ at subjective "soft," "medium," and "loud" voice and at 65, 75, 85, and 95 dB. Voice intensity and perturbation measurement method effects were assessed with ANOVA. Electroglottographic and acoustic perturbation were significantly different ($p<0.001$) at all intensity levels and lowest at highest voice intensities. Biggest differences were found between "soft" and "loud" voice in EGG measurements. Electroglottographic results were significantly higher in all tasks, for example mean shimmer in "soft" voice: acoustic 4.4% (SEM: 0.58%) and electroglottographic 7.35% (SEM: 1.02%). The measurement difference was smaller in prescribed intensities (mean shimmer at 65dB: acoustic 2.5% (SEM: 0.23) and electroglottographic 3.0% (SEM: 0.28%). Voice intensity changes strongly influence acoustic and electroglottographic perturbation and are minimized when patients control for voice intensity. Electroglottographic measurements are generally higher and stronger influenced by voice intensity changes. Future work should cover if this reflects a better sensitivity or more measurement error.

1pSC20. Refinement of speech motor control in preschool-aged speakers. Jennell C. Vick (Univ. of Texas at Dallas Callier Ctr. for Commun. Disord., 1966 Inwood Rd., Dallas, TX 75235, jennell@utdallas.edu), Christopher A. Moore (Natl. Inst. on Deafness and other Commun. Disord., Bethesda, MD 20892-7180), Thomas F. Campbell (Univ. of Texas at Dallas, Dallas, TX 75235), Lawrence D. Shriberg (UW-Madison, Madison, WI 53705), and Jordan R. Green (Univ. of Nebraska-Lincoln, Lincoln, NE 68583-0738)

This investigation explored whether meaningful subgroups of children would emerge from a heterogeneous population of typical preschool speakers as a result of convergences of measures from multiple speech production subsystems: behavioral, phonatory, articulatory, and respiratory. Because variability is a ubiquitous characteristic of preschool speech production, the goal of this classification was not only to minimize within-subgroup variability, but to identify the latent parameters across speech subsystems that characterized each resulting subgroup with the goal of better understanding the refinement of speech motor control that takes place at this stage of development. It is critical to understand the range of performance and interactions among speech production subsystems that exist in children with typical speech development so that we can better quantify the deviancies observed in children with speech disorders. Data were gathered from 60 speakers, aged 37–59 months, and analyzed using multivariate pattern-based classification analyses. The result was two distinct clusters of individuals whose performance across speech subsystems was differentiated by stability. One group was characterized by higher levels of variability across phonatory, articulatory, and respiratory subsystems compared to the second group. The groups did not differ significantly by composition in terms of age or sex.

1pSC21. Allophones, voice onset time, and aphasic speech errors. Adam Buchwald (Dept. of Speech-Lang Pathol. & Aud., NYU, 665 Broadway, Ste. 910, NY, NY 10012, buchwald@nyu.edu), Brenda Rapp (Johns Hopkins Univ., Baltimore, MD 21218), and Michele Miozzo (Downing St., Cambridge CB2 3EB UK)

This paper examines the speech of DLE, an aphasic English speaker who regularly deletes /s/ from /s/-stop onset clusters in English words (e.g., /spik/→ [pik]). DLE's production of stops in these words provides a window through which to examine the treatment of allophones by the speech production system. In English, the voiceless unaspirated stops that follow word-initial /s/ (e.g., the [p] in *speak*) are considered allophones of the voiceless stop (e.g., /p/), although the VOT more closely resembles that of phonologically voiced stops (e.g., /b/) which are often realized as voiceless unaspirated stops in word-initial position. Deletion errors occurring at a level before phonetic detail is generated should match the VOT of word-initial voiceless stop (e.g., peak), whereas those arising at a later phonetic level should match the VOT of the unaspirated stop (e.g., beak). In contrast to either of these possibilities, the partial activation of both aspirated and unaspirated allophones of /p/ should yield stops with a VOT that is intermediate between the voiced and voiceless phoneme productions. Thus, DLE's errors can inform our understanding of the phonetic processing of allophones in speech production.

1pSC22. Perception of talker information by children with typical and impaired linguistic development. Susannah Levi (Dept. Speech-Lang. Pathol. and Audiol., New York Univ., 665 Broadway, 9th Fl., New York, NY 10012, svlevi@nyu.edu) and Richard Schwartz (CUNY Grad Ctr., New York, NY 10016)

Despite the relatively large number of studies documenting the interaction of talker and linguistic information during speech perception in adults, such as talker-contingent phoneme processing or language-dependent processing of talker information, there is little work examining the development of talker processing in children. This study investigated the extent to which language familiarity affects the perception of the talker dimension of the speech signal by testing children's discrimination of bilingual voices across two different languages. Children—aged 7 to 12—heard pairs of words either in English (familiar language) or German (unfamiliar language) and judged whether the two words were spoken by the same or different talkers. The results of this study indicate that children are able to perform this task at above-chance levels, revealing that the perception of indexical information appears early in development. Furthermore, children are able to process this information even when they are unfamiliar with the language and, therefore, lack access to linguistic information. A comparison between children with typical language development and those with specific language impairment suggests that the perception of indexical information can be retained even when linguistic perception is impaired.

1pSC23. Non-native speech processing in children with phonological disorders. Dongsun Yim (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, sunyim@northwestern.edu)

This study examined how children with and without phonological disorders (PD) process accented speech spoken by a non-native speaker. Two research questions were asked in this project. First was to compare how children with and without PD perform on accented speech and second was to investigate whether the exposure to the accented speech allows children's increase in overall performance. Children were aged from 3 to 8 years old who were native English speakers. The task was to identify the final words

of low- and high-context sentences spoken by two non-native Chinese speakers. Overall, it is expected that older children perform better than younger children and children perform better on high- than low-context sentences which shows children's ability to use contextual cues. For the first research question, it is hypothesized that typical children will outperform children with PD when processing accented speech which suggests unstable phonological representation in children with PD. For the second research question, it is hypothesized that children in both groups will benefit when exposed to the accented speech for the second time. However, whether children with PD will require more time to adapt to accented speech compared to typical children is of interest in the discussion.

1pSC24. Audiovisual speech perception in children with autism spectrum disorders and typical controls: Implications for development. Julia Irwin (Haskins Labs., 300 George St., New Haven, CT 06511)

For typically developing perceivers, visual speech information influences what listeners hear. For example, when the place of articulation of visual and auditory speech tokens are incongruent, perceivers often report hearing a visually influenced response (the McGurk effect; McGurk and MacDonald, 1976). To better understand the role of visual speech information in development, children with autism spectrum disorders (ASD), children with typical development and adults with typical development were assessed on: (1) sensitivity to mismatched auditory and visual speech (McGurk); (2) visual gain in the presence of auditory noise; and (3) detection of auditory and visual asynchrony. Implications for the development of audiovisual speech processing in typically developing children and adults and children with ASD will be discussed. [Work supported by NIH.]

1pSC25. Distinctive feature analysis of errant responses to Diagnostic Rhyme Test words. Edward L. Goshorn and Brett E. Kemker (Dept. of Speech and Hearing Sci., Psychoacoustics Lab., 118 College Dr. #5092, Hattiesburg, MS 39406-0001)

Ten subjects responded in a conventional multiple-choice format to two randomized lists of Diagnostic Rhyme Test (DRT) words in white noise at 3-dB signal-to-noise ratio. The DRT consists of 96 word-pairs whose initial phonemes differ by one feature: voice-unvoiced, nasal-oral, sustained-interrupted, sibilated-unsibilated, grave-acute, and compact-diffuse. List one consisted of DRT words counterbalanced for each feature and list two contained the contrasting feature. Six replicates were obtained for each subject. Errant responses were analyzed for DRT features as well as by a Chomsky-Halle feature system that permitted assigning numerical values that ranged from one to six to phonetic differences in DRT word-pairs. Results are consistent with previous findings for equality of percent correct across DRT word lists. However, DRT feature contrasts within word pairs were not equally difficult. For example, sibilated and unvoiced stimuli were significantly more difficult than their unsibilated or voiced counterpart, respectively. Also, there was no significant correlation between word error rate and the corresponding Chomsky-Halle feature value for differences in word-pairs. Thus, word difficulty appears to be unrelated to degree of feature difference in a word-pair, but rather is associated with relative phoneme audibility for the type of noise employed.

1pSC26. Context-related variability in adolescents' misarticulated and typically produced /s/. Laura L. Koenig (Haskins Labs., 300 George St., New Haven, CT 06511; Long Island Univ., One Univ. Plaza, Brooklyn, NY 11201, koenig@haskins.yale.edu) and Jonathan Preston (Haskins Labs., New Haven, CT 06511)

Acquisition of the sound /s/ is widely variable in normal development, but misarticulations that persist longer than approximately age 10 are considered to represent residual speech sound errors (RSSEs). Recent studies suggest that RSSEs may reflect subtle underlying difficulties in developing phonological representations, which, in turn, correlate with reading and spelling skills. Thus, RSSEs, even if restricted to a few sounds, may have larger clinical relevance. The acoustic characteristics of /s/ have been investigated in normally developing adolescents, but less work exists on the acoustics of misarticulated /s/, particularly considering across phonetic contexts. The current work is an exploratory study of /s/ acoustics in adolescents who do and do not misarticulate /s/. Speech samples include word lists as well as connected speech. Syllable-initial /s/ is analyzed across words varying in the following context. Of particular interest is the extent of /s/ variability as a function of the upcoming vowels and consonants (i.e., the degree of anticipatory coarticulation), and how this changes over the duration of the fricative. Instrumental data of this sort may ultimately provide greater insight into the phonological systems of adolescents with RSSEs as compared to their normally speaking peers. [Work supported by NIH.]

1pSC27. Predicting consonant recognition in quiet for listeners with normal hearing and hearing impairment using an auditory model. Tim Jürgens, Thomas Brand, and Birger Kollmeier (Medizinische Physik, Carl-von-Ossietzky Universität Oldenburg, Carl-von-Ossietzky-Str. 9-11, 26111 Oldenburg, Germany, tim.juergens@uni-oldenburg.de)

Contrary to listeners with normal hearing, listeners with high-frequency sensorineural hearing loss suffer especially from a poor consonant recognition. This is mainly attributed to the loss of audibility within high-frequency regions. In a former study [Jürgens and Brand, J. Acoust. Soc. Am. (submitted)] it was shown that consonant recognition rates in noise can be predicted well for normal-hearing listeners using an auditory model combined with a speech recognizer. The speech reception threshold (SRT) in noise could be predicted with an accuracy of 1–2 dB. In this study consonant recognition in quiet for normal-hearing and hearing-impaired listeners is investigated by regarding the individual absolute hearing threshold within the model. Observed and predicted psychometric functions of the consonant discrimination performance, consonant recognition rates of single consonants, and confusions are compared and discussed. The results show that the SRT in quiet can be predicted well for both normal-hearing and hearing-impaired listeners. Furthermore, the auditory model is modified to the signal processing of listeners with mild to moderate hearing impairment by, e.g., including a reduced dynamic compression, in order to investigate the influence on the predictions. [Work supported by DFG.]

1pSC28. Infant-directed speech to infants with a simulated hearing loss. Christa Lam and Christine Kitamura (MARCS Auditory Lab., Univ. of Western Sydney, Bankstown Campus, Locked Bag 1797, Penrith South DC NSW 1797, Australia, c.lam@uws.edu.au)

The acoustic/phonetic features of infant-directed speech (IDS) were measured during face-to-face interactions between mothers and their six-month-old normal hearing infants ($N=32$) using a setup in which the mother and infant are seated in separate rooms and interact over their respective video monitors. There were two sound conditions, (i) a *hearing condition* in which infants could hear their mothers at 55 dB SPL, and (ii) a *hearing loss condition* in which the sound was turned off, and the infants could not hear their mothers. All mothers were told *your baby cannot hear you*. Mothers and infants interacted for 10 min using three labeled toys (sheep, shoe, and shark) to facilitate the production of exemplars of the corner vowels /i/, /u/, and /a/. The results showed that mean fundamental frequency (F0), F0 range, and the duration of the IDS vowels were comparable across the two conditions. However, vowel hyperarticulation was only evident in the *hearing condition*, not in the *hearing loss condition*. These results suggest that mothers adapt their speech input according to signs of infant responsiveness. That is, when their infant cannot hear them, they maintain their modifications to IDS F0 and duration, but at the expense of vowel hyperarticulation.

1pSC29. The combined effects of distortions on vowel identification. Michelle R. Molis, Melissa A. Teahen, and Marjorie R. Leek (Natl. Ctr. for Rehab. Aud. Res., Portland VA Medical Ctr., 3710 SW US Veterans Hospital Rd., Portland, OR 97239, michelle.molis@va.gov)

The effects of intrinsic and extrinsic distortions on vowel perception were evaluated. Potential sources of distortion were high presentation level, background noise, stimulus ambiguity, and hearing status. Vowel identifications were collected for three sets of synthesized vowels that varied in both F1 and F2 (front and back vowels), or F2 and F3 (central vowels). The systematic variation in formant frequencies produced stimulus sets that contained both clear, unambiguous category tokens as well as relatively ambiguous tokens that could be identified as more than one vowel category. As overall presentation level increased from 75–90 dB SPL, identification by normally hearing listeners became less consistent for ambiguous stimuli. Additional reductions in categorization precision occurred in the presence of background noise. The effects were highly dependent on stimulus set, with the largest effects observed for the central vowels. Data from hearing-impaired listeners at high presentation levels and in noise will also be

reported. Evaluation of response patterns in the presence of combinations of these sources of distortion will help explore the difficulty people with hearing loss have processing speech in adverse listening conditions. [Work supported by OHSU Medical Research Foundation, Portland, OR.]

1pSC30. Understanding vocoded speech in steady and amplitude modulated bandpass noise. Yingjiu Nie and Peggy Nelson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 115 Shevlin Hall, 164 Pillsbury Dr. SE, Minneapolis, MN 55455, niex0008@umn.edu)

Vocoded speech perception was investigated in amplitude-modulated bandpass noise to assess normal-hearing listeners' speech understanding through cochlear implant simulations with temporal and spectral interference. Sixteen vocoder bands were applied to IEEE sentences and white noise [Fu and Nogaki (2004)]. The lower 10 bands were maintained for speech, eliminating the upper bands. The spectra of vocoded noises were set to be completely overlapping, partially overlapping, and completely separate from the speech bands. Amplitude modulations (AMs) were imposed on the noises, varying from 25–300 Hz. AM detection thresholds were measured for 80-ms white noise carriers, with rates of 25, 100, and 300 Hz. Preliminary data showed that: (1) vocoded speech perception scores were significantly different between listeners, ranging from 53–80% in quiet and from 10–54% in overlapping noise; (2) the spectra of the noise bands affected vocoder speech perception, with greater overlap causing reduced scores; (3) the noise AM rate did not significantly affect speech scores; however, vocoded speech perception in noise was significantly correlated with AM detection thresholds at 25 Hz. Results suggest that the spectral overlap of noise and speech causes reduced performance even when the noise is modulated. [Research supported by the Univ. of Minnesota.]

1pSC31. Consonant identification for hearing impaired listeners. Feipeng Li and Jont Allen (1006 N Broadway Ave., Urbana, IL 61801, fli2@illinois.edu)

This research investigates the impact of sensorineural hearing loss on consonant identification. Two elderly subjects, AS with a moderate to severe sloping hearing loss and DC with a severe sloping high-frequency hearing loss, volunteered for the pilot study. Speech perception test reveals that AS has no problem with /ta/, and has little difficulty with /pa, sa, da, za/, but never reports /ka/ and /ga/ due to a cochlear dead region from 2–3.5 kHz in the left ear, which blocks the perceptual cues for /ka/ and /ga/. In contrast, her right ear hears these sounds. Although NAL-R improves the average perception score from 0.42 to 0.53 under quiet conditions, it provides little help for noisy speech (a 3% increase at 12 dB signal to noise ratio); /ka/ and /ga/ remain unintelligible with NAL-R. The other subject DC can hear all the 16 consonants tested in both ears with the assistance of NAL-R. However, it only improves the recognition scores of low and midfrequency sounds such as /pa, ba/ and /ka, ga/. It degrades the high-frequency sounds such as /ta/ and /da/. No cochlear dead region is confirmed for DC.

1pSC32. Spectral differences between live and replayed speech measured in occluded ear. Dragana Barac-Cikoja and Jose N. Reyes (Gallaudet Res. Inst., Gallaudet Univ., 800 Florida Ave. NE, Washington, DC 20002)

To further our understanding of the transfer function between the mouth and the eardrum for occluded ears, we compared the recordings of live and played-back self-generated speech captured in the speaker's ear canals. The airborne speech feedback (during the speech production) and its recording (during the playback phase) were delivered binaurally via earmolds or insert earphones (ER-2, Etymotic Research, Inc.). Three earmold styles were tested: Full shell with the canal portion extending either to the first or the second bend of the participant's ear canal, and a custom open-fit (Microsonic 19A). In four separate conditions, in-the-canal speech recordings were made using a pair of probe tube microphones (ER-7C, Etymotic Research, Inc.) that were inserted at a fixed distance from the eardrum. Two female speakers provided samples of four word-imbedded vowels (heed, head, hawed, who'd). The participants spoke at a comfortable speaking level, and their speech was presented at a sound pressure level calibrated to match the level at the ears. The equivalent sound level and long-term average spectra of the corresponding pairs of speech samples were then analyzed as a function of the ear occlusion type. [Support provided by the Rehabilitation Engineering Research Center (RERC) on Hearing Enhancement.]

1pSC33. Acoustic-phonetic variation in word-final alveolar consonants in speech to infants with and without hearing loss. Laura Dilley (Dept. of Commun. Disord. and Dept. of Psych., Bowling Green State Univ., 247 Health Ctr., Bowling Green, OH 43403, dilley@bgsu.edu) and Laura DeMaison (Bowling Green State Univ., Bowling Green, OH 43403)

Relatively little work has examined acoustic-phonetic variability in consonants in infant-directed speech, particularly that directed to children with hearing loss. Assimilation is a form of variability which has been particularly well studied in adult-directed speech in which a word-final alveolar consonant takes the place of articulation of a following word-initial consonant (as when /n/ in *cotton* sounds like /m/ in the phrase *cotton*[m] *balls*). Two studies examined types of acoustic-phonetic variation in assimilable environments, defined as contexts in which a word-final alveolar stop (oral or nasal) is adjacent to a word-initial labial or velar consonant, in speech directed to adults and to infants with and without hearing loss. First, waveform, spectral, and perceptual information were used to classify tokens of word-final alveolar stops into four categories: assimilated, canonical, glottalized, or deleted. Next, the second formant, F2, was measured in a subset of these tokens, to gauge the extent of place assimilation in assimilable contexts. Preliminary results show substantial phonetic and acoustic variability in assimilable environments in infant-directed speech, but the extent of this variability appears similar to that in adult-directed speech. These findings have implications for understanding language development in normal-hearing children and children with hearing loss.

1pSC34. Attention to speech sounds in normal-hearing and deaf children with cochlear implants. Derek M. Houston (Dept. of Otolaryngolgy–Head & Neck Surgery, Indiana Univ. School of Medicine, 699 West Dr., Indianapolis, IN 46202, dmhousto@indiana.edu)

Cochlear implantation (CI) is a treatment for severe-to-profound hearing loss in congenitally deaf children. Although there is very little variability in auditory thresholds among CI recipients, there is a large amount of variability in language outcomes. One possible source of variability in language outcomes is individual differences in attention and cognitive processes, which may be affected by early auditory deprivation. The effect of auditory deprivation on attention to auditory input was investigated by comparing attention to speech sounds in 23 young deaf children with CIs and 23 normal-hearing age-match controls. The deaf children received their CIs between 6 and 23 months and were tested several times during the first 1.5 years after implantation. Participants were seated on their caregiver's lap in front of a TV monitor. On each trial, they were presented with a checkerboard pattern and either silence or a repeating speech sound. Normal-hearing children looked longer at the checkerboard during the sound trials at the youngest ages whereas CI children were delayed in showing a preference for the sound trials. Moreover, performance on this task correlated with language outcome measures taken two years later, suggesting that attention to speech sounds after implantation is predictive of later language development.

1pSC35. Acoustic correlates to perceived age in American English. James D. Harnsberger (Dept. of Commun. Sci. and Disord., Univ. of Florida, Gainesville, FL 32611, jharns@ufl.edu)

An acoustic analysis of voice, articulation, and prosodic cues to perceived age was completed for a speech database consisting of 150 speakers of American English. The speakers (75 male, 75 female) were recorded representing three age groups: young (18–30), middle-aged (40–55), and old (62 years and older). The database included several types of read speech: two passages (Rainbow, Grandfather), 16 sentences incorporating a wide phonemic repertoire, three sustained vowels ([a], [i], [u]), and multiple repetitions of nonsense words. Perceptual judgments of age were collected for the sentence materials from 160 listeners in total. These perceived ages were submitted to a multiple linear regression analysis with up to 34 acoustic measures representing: voice quality (e.g., jitter, shimmer, HNR, CPP), articulation (F1+F2 vowel space size, F1 and F2 of point vowels), fundamental frequency (mean, min, max, SD), intensity (SD), speaking rate, and others. An analysis of the sustained vowel data for the females showed that 14 variables were significantly correlated with perceived age (R-squared =

0.78, $p < 0.01$), while 13 significantly correlated for the male voices (R-squared = 0.57, $p < 0.01$). Results for the other classes of speech materials will also be reported.

1pSC36. Recognition of reduced speech and use of phonetic context in listeners with age-related hearing impairment. Esther Janse (Utrecht Inst. of Linguist. OTS and Max Planck Inst. for Psycholinguistics Nijmegen, Janskerkhof 13, 3512 BL Utrecht, The Netherlands, esther.janse@mpi.nl) and Mirjam Ernestus (Radboud Univ. Nijmegen and Max Planck Inst. for Psycholinguistics, 6500 AH Nijmegen, The Netherlands)

This study investigated identification of reduced words (e.g., "onry" for "ordinary") by young listeners, elderly listeners, and young listeners in whom we simulated a hearing impairment. The main question was whether elderly listeners benefit as much as young listeners from phonetic context in recovering reduced words and whether any context difference should be attributed to hearing loss or cognitive decline. Participants were presented with excerpts from a corpus of spontaneous Dutch, consisting of either the target word in isolation or in its sentential context. The sentence context was not highly semantically/syntactically constraining. As expected, elderly listeners and young listeners with a simulated hearing impairment showed lower accuracy scores than the normal-hearing young adults. More importantly, the two hearing-impaired listener groups benefited less from context than the normal-hearing young group. Within the elderly group, hearing sensitivity also predicted one's amount of context benefit. Additionally, hearing sensitivity and age, but not a cognitive processing measure, predicted overall identification performance among the elderly listeners. In conclusion, our results suggest a double handicap for both young and old hearing-impaired listeners: they have more difficulty interpreting the acoustic signals of reduced words, and also benefit less from phonetic cues contained in surrounding words.

1pSC37. Effect of priming on age-related differences in release from informational masking. Payam Ezzatian (Dept. of Psychol., Univ. of Toronto, 3359 Mississauga Rd. North, Mississauga, ON, Canada L5L1C6, payam.ezzatian@utoronto.ca), Liang Li Kathy Pichora-Fuller, and Bruce Schneider (Univ. of Toronto, Mississauga, ON, Canada L5L1C6)

In a previous study, [Freyman *et al.* (2004)] showed that presenting listeners with all but the last word of a target nonsense sentence immediately prior to presenting the full sentence in a noisy background, produced a greater release from masking when the masker was two-talker nonsense speech than when it was speech-spectrum noise, thereby demonstrating that an auditory prime could produce a release from informational masking. In Experiment 1 of this study we showed that auditory priming produced an equivalent amount of release from informational masking in good-hearing younger and older adults. To investigate the extent to which this release from informational masking was due to the semantic content of the prime, in Experiment 2 we noise-vocoded the prime (using three bands) to remove semantic content, while retaining the prime's amplitude envelope. This manipulation eliminated any release from informational masking. In Experiment 3, when the speech masker, but not the prime was vocoded, the performance of both age groups improved equivalently. These results indicate that younger and older adults benefit equally from semantic priming, and that both age groups make equivalent use of amplitude fluctuations in a masker in an informational masking paradigm.

1pSC38. Far field performance of an anechoic chamber used for speech and hearing research. Richard Godfrey, Christopher Emrick, Allison Goff, Meghan Hiss, Anna Kiener, Katherine Lamoreau, Alexandra MacMeekin, Ashley Minton, Mallory Monjot, Heather Ridenour, Jennifer Sanders, and Dana Ulakovic (Dept. of Speech and Hearing Sci. The Ohio State Univ., 110 Carmack Rd., Columbus, OH 43210, godfrey.20@osu.edu)

The department has a 13×7×8 ft fully anechoic chamber whose commissioning records were misplaced. The graduate acoustics class measured the acoustics of the chamber from 250–2000 Hz in preparation for future research projects. The focus was on the far field and its limits (near field, and approach to wedge tips). Four groups of students made measurements along the same path. The difference in the levels at a location from that at a reference location was calculated. The mean and standard deviations of these differences were then calculated to compare these measurements with the inverse square law theory. Some measurements were also made in the near field, and closer than one-quarter wavelength from the wedge tips. The average of the means from 12–74 in. was 0.73 dB below theory. The average 95% confidence limits of these data in this range was +/− 1.1 dB. These deviations compare favorably with the acceptance criteria in the ANSI standard. The near/far field guideline also appears to be reasonable. Measurements closer than one-quarter wavelength from the wedge tips may be possible. However, further extremes characterization is needed. Envelope noise reduction should also be measured.

1pSP1. Correlation of nonisotropically distributed ballistic scalar diffuse waves in two dimensions. Richard Weaver (Dept. of Phys., Univ. of Illinois, 1110 W. Green St., Urbana, IL), Berenice Froment, and Michel Campillo (Universit Joseph Fourier, Grenoble, France)

Theorems indicating that a fully equipartitioned random wave field will have correlations equivalent to the Greens function that would be obtained in an active measurement are now legion. Studies with seismic waves, ocean acoustics, and laboratory ultrasound have confirmed this. So motivated, seismologists have evaluated apparent seismic travel times in correlations of ambient seismic noise and constructed impressive tomographic maps of seismic wave velocity, and even detected fractional secular changes in seismic wave speed at a level of 0.0001. Inasmuch as the random seismic waves used in these evaluations are usually not fully equipartitioned, it seems right to ask why it works so well, or even if the results are trustworthy. The usual wave field used in long-period seismology is due to distant ocean storms and is, even in the presence of scattering, not isotropic. Here an asymptotic evaluation of the effect, on apparent travel time in a correlation waveform, is made of nonisotropic distributions of ballistic specific intensity. It is shown that for station pairs separated by one or more wavelengths, that the effect is small. A formula is derived permitting estimations of error, and corrections to travel times. It is successfully compared to errors seen in synthetic waveforms.

1:45

1pSP2. On the precision of noise-correlation interferometry. Richard Weaver (Dept. of Phys., Univ. of Illinois, 1110 W. Green St., Urbana IL), Celine Hadziioannou, Eric Larose, and Michel Campillo (Universit Joseph Fourier, Grenoble, France)

Coda Wave Interferometry analyzes changes in diffuse waveforms when source and receiver are fixed. Changes are often due to changing acoustic wave speed, perhaps a change of temperature. Alternatively, changes can be studied in noise correlations. The advantage is in not having to wait for, or generate, a precisely identical source. But interpretation is problematic; changes in the correlation of noise fields due to an uncontrolled set of sources could be due to the sources, or to the environment. Recent studies of ambient seismic noise correlations have shown apparent stretches (potentially corresponding to wave speed slowing by parts in 10 000) over periods of weeks. Changes seen at La Reunion correlate with subsequent volcanic eruptions. Changes seen at Parkfield, California occur quickly after earthquakes and then relax back over many months. Potential for seismic monitoring motivates a study of the relative effects of source and medium changes on apparent stretching or compression. Here it is shown that long duration coda like character in a waveform permits a highly accurate estimate of stretch, an estimate that is relatively independent of changes in sources. The theory is supported by laboratory measurements and seismic data.

1pSP3. Investigation of the spatial and temporal characteristics of the New Zealand seismic noise field. Laura A. Brooks, John Townend, Yannik Behr (Inst. of Geophys., Victoria Univ. of Wellington, New Zealand), Peter Gerstoft (Scripps Inst. of Oceanogr., La Jolla, CA), and Stephen Bannister (GNS Sci., Lower Hutt, New Zealand)

The use of microseismic interferometry methods to construct tomographic models requires an understanding of the spatio-temporal characteristics of the noise field, particularly in regions such as New Zealand, where multiple potential sources exist. Directional variations in noise levels compatible with large-scale differences in sea state have previously been reported (Lin *et al.*, Geophys. J. Int., 2007). The aims of the current study are to further quantify spatial and seasonal variations in the seismic noise field in conjunction with an oceanic wave state model. This involves the analysis of a larger dataset over a longer time period, and requires more sophisticated noise-field analysis. A preliminary comparison of New Zealand and environments in which the azimuthal distribution of seismic noise sources has been investigated using beamforming is presented. The applicability of beamforming to New Zealand conditions is then discussed in the context of regional ambient noise models. Methods by which estimates of the seismic noise field's spatio-temporal characteristics can be related to contemporaneous ocean wave climate observations are also highlighted.

2:15

1pSP4. Experimental active source ocean acoustic interferometry. Laura A. Brooks (Inst. of Geophys., Victoria Univ. of Wellington, New Zealand) and Peter Gerstoft (Scripps Inst. of Oceanogr., La Jolla, CA)

Green's function approximation via ocean noise cross-correlation, referred to here as ocean acoustic interferometry, has previously been demonstrated experimentally for passive noise sources. Active sources offer the advantages of higher frequencies, controllability, and continuous monitoring. Experimental ocean acoustic interferometry is described here for two active source configurations: a source lowered vertically, and one towed horizontally. Results are compared and contrasted with cross correlations of passive noise. The results, in particular differences between the empirical Green's function estimates and simulated Green's functions, are explained with reference to theory and simulations. Approximation of direct paths is shown to be consistently good for each source configuration. Secondary (surface reflection) paths are shown to be more accurate for hydrophones with a greater horizontal separation. [Work supported by the Office of Naval Research under Grant No. N00014-05-1-0264.]

2:30

1pSP5. Geoacoustic inversion using particle swarm optimization. Geoffrey F. Edelmann and Laurie T. Fialkowski (U. S. Naval Res. Lab., 4555 Overlook Ave. SW, Code 7145, Washington, DC 20375, geoffrey.edelmann@nrl.navy.mil)

A novel optimization approach is applied to geoacoustic inversion with a towed horizontal array. Particle swarm optimization, a stochastic, population-based evolutionary algorithm, is applied to geoacoustic inversion

problems in order to estimate unknown sediment and ocean parameters. Geoacoustic inversions with a towed array are applied to both synthetic data and experimental data from MAPEX 2000. Particle swarm optimization yields quick, consistent parameter estimates. These results will be compared with previously published results using an advanced rotated coordinate simulated annealing technique. [Work supported by ONR.]

2:45

1pSP6. Experimental determination of the total scattering cross section of individual scatterers in a multiple scattering medium. Shane Walker, Philippe Roux, and William A. Kuperman (Scripps Inst. of Oceanography, 9500 Gilman Dr., La Jolla, Ca 92093-0238, shane@mpl.ucsd.edu)

A problem of interest in the study of propagation through multiple scattering media is the effective scattering cross section of the individual scattering components. In the multiple scattering regime, one challenge in particular has been to determine the scattering cross section of a component scatterer in the presence of other scatterers. We apply three different methods of experimentally measuring the total scattering cross section of a scattering object. In the first method, the scattering cross of a single scatterer is self-adaptively derived from the attenuation of the coherent field as a function of distance traveled through a multiple scattering medium comprising many identical scatterers. In the second method, the ratio of the coherent to the incoherent fields is used to infer the cross section of a single scatterer in a reverberant cavity. The third method involves a direct measurement of the scattering cross section in free space. We show that the three methods produce similar results.

3:00

1pSP7. Target detection under influence of sound wave scatterers using time reversal. Yoshiaki Tsurugaya (NEC Corp., 1-10, Nishin-cho, Fuchu, Tokyo, 183-8501), Toshiaki Kikuchi (Natl. Defense Acad., Yokosuka, Kanagawa, 238-0024 Japan), and Koichi Mizutani (Univ. of Tsukuba, Tsukuba, Ibaraki, 305-8573, Japan)

In general, it is difficult to detect the forward scattering wave from the target located between the sound source and the array. In a word, because the sound wave from the sound source is strong, the forward scattering wave from the target cannot be isolated. Moreover, when the sound wave scatterers except the target exist, the scattered sound wave acts mutually, and the target cannot be isolated. Therefore, the propagation environment is divided into the reference sound field without the target and the target sound field including the target. Next, the forward scattering wave from the target is extracted by using the signal obtained in each sound field. The time-reversal processing was performed to the extracted scattered wave, and the target position was obtained. As a result, the forward scattering wave was extracted by selecting the referring sound field and the target sound field, and the position of the target could be obtained in the environment that scatterers except target influenced. To establish this method, it is necessary to confirm that the propagation environment retains the phase conjugate.

3:15

1pSP8. Innovations detector for buried ojects. Edmund J. Sullivan (EJS Consultants, 46 Lawton Brook Ln., Portsmouth, RI 02871, paddypriest@aol.com), Ning Xiang (Rensselaer Polytechnic Inst., Troy, NY 12180-3590), and James V. Candy (Lawrence Livermore Natl. Lab., Livermore, CA 94550)

The acoustic detection of buried objects is hampered by the fact that, at frequencies high enough to resolve the object, the ground is a poor conductor of the acoustic probe signal. In order to circumvent this problem, techniques have been developed whereby high-level low frequency probe signals are used to excite resonances in the object, which, in turn, cause microscopic displacement of the ground surface that can be sensed with a laser Doppler vibrometer (LDV). Although this approach shows great promise, it is limited by speckle noise. This is a form of noise arising from the coherent property of the laser signal. In this paper we demonstrate real data results using an innovations detector, which operates by sensing the change in the statistics of the returned laser backscatter signal when a target is present. When there is no target present, the signal can be modeled by a Kalman filter, such that its innovation sequence is zero mean and white. Any deviation of the signal from this model then disrupts the innovation sequence, causing a weighted sum squared residual test to indicate the presence of a signal. Real data results are shown.

1pSP9. Instantaneous frequency analysis of ultrasound Doppler signal using Bayesian probability. Asif Mehmood, Paul Goggans (Dept. of Elec. Eng., Univ. of Mississippi, University, MS 38677, asif.kyani@gmail.com), and James Sabatier (Univ. of Mississippi, University, MS 38677)

In ultrasonic Doppler vibrometry systems, acoustic returned from a moving target is frequency modulated by the components of the target's velocity in the direction of the system's co-located ultrasonic transducers. Because of this, instantaneous frequency (IF) analysis of the receiver transducer output can be used to reveal the velocities of moving components. In this paper, an IF estimation algorithm using Bayesian probability theory is presented. The acoustic returns are represented by suitable localized models that are constructed on the basis of a number of moving components of the target. Then the posterior probabilities of these localized models are computed and compared to determine which model best describes the data under observation. Once the preferred model is chosen, then its parameters are estimated. Our IF estimation method performs parameter estimation and model selection simultaneously, and extends to instantaneous estimation of these nonstationary signals. The calculations are implemented using Markov chain Monte Carlo in conjunction with thermodynamic integration with simulated annealing to draw samples from the joint posterior probability for the model and the parameters. Monte Carlo integration is then used to approximate the marginal posterior probabilities for all the parameters. The performance of this method is demonstrated by simulated and experimental results.

1pSP10. Signal processing agorithms for unmanned undersea vehicles navigation and collision avoidance. Hua Lee (Dept. of Elec. and Comp. Eng., Univ. of California, Santa Barbara, CA 93106)

In this paper, signal processing algorithms for dynamic UUV homing and docking, navigation, and collision avoidance are presented. Many conventional techniques are image-based, which involved computation-intensive image reconstruction procedures, which is ineffective in dynamic real-time environment. Therefore, it is of great importance to develop computationally effective signal processing algorithms for high-precision UUV geolocation. To optimize the applicability, the algorithms presented in this paper cover all key modalities, including both active and passive, with temporal pulse and FMCW signal formats. In terms of operating configurations, the first case is classified as the passive-receiver systems. The transmitting signal format for this case is in the form of a twin-pulse set, with opposite polarity. The bearing angle is estimated from the temporal offset of the pulses. The dual version of this configuration is in the form of an active system and the double-integration algorithm can be effectively applied to both versions. The active configuration can then be extended to incorporate the FMCW signaling format. For the FMCW case, estimation of the bearing angle and range distance can be accomplished with the Fourier transform methods. In this paper, the presentation includes theoretical analysis, signal processing algorithms, and experiments.

4:15

1pSP11. Maximizing mutual information in horizontal linear arrays. Xiaoli Zhu (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Dartmouth, 285 Old Westport Rd., North Dartmouth, MA 02747, xzhu@umassd.edu) and John R. Buck (Univ. of Massachusetts Dartmouth, North Dartmouth, MA 02747)

Estimating the bearing of a sound source using a towed horizontal array is a common array processing problem. In a passive sonar system, it is common to null sources from the forward endfire direction to eliminate the noise of the towing vessel. This research designs linear nonuniform symmetric ar-

rays of a fixed aperture for estimating the bearing of sound source. Specifically, the hydrophone spacings for a symmetric linear array are chosen to maximize the upper bound on mutual information between the true bearing and the bearing estimate in white noise. The arrays' maximizing the mutual information while nulling forward endfire look significantly different from the uniform arrays commonly used in towed systems, and also differ from arrays designed to minimize spacing redundancy. Arrays maximizing mutual information are helpful when bearing estimation is considered as a quantization problem to assign the source to the correct partition. In this approach, increasing the mutual information should reduce the probability of error (P_e) in choosing the partition containing an unknown source. Simulation results demonstrate that the optimum arrays proposed here have much lower P_es than the uniform array. [Work funded by ONR code 321US.]

4:30

1pSP12. Analysis of phased array transmitters and beamformers. Gerard Coutu, Vadim Polonichko, and Paul Wanis (Teledyne RD Instruments, 14020 Stowe Dr., Poway, CA 92064)

As phased array ultrasonic transducers become more wide spread in underwater acoustic measurement applications, a better understanding of their basic performance characteristic is of benefit. The beam patterns of a phased array can be approximated by a steady state analysis. This approach indicates the directional response of an array in response to a sinusoidal excitation. However, a steady state examination does not properly describe transient behavior of the transmit waveform and also the received signal that is subsequently beamformed. We further investigate the transient performance of the beamformer using a closed-form solution to the acoustic wave equation for a multielement ultrasonic phased array transducer. The model produces transducer beam patterns and transient beamformer output for a series of reflective targets in the far-field of the transducer. The results show a close agreement with laboratory measurements and provide a tool for further investigation of phased array transducer design and performance.

4:45

1pSP13. Mathematical characterization of the acoustic brightness and contrast control problem in complex vector space. Minho Song (Graduate School of Culture Technol., Korea Adv. Inst. of Sci. and Technol., Sci. Town, Daejon 305-701, Korea) and Yang-Hann Kim (Korea Adv. Inst. of Sci. and Technol., Sci. Town, Daejon 305-701, Korea)

The acoustic brightness and contrast control methods [J.-W. Choi and Y.-H. Kim, J. Acoust. Soc. Am. **111**, 1695 (2002)] is one of the methods which can generate higher acoustic energy in desired space by controlling multiple control sources. Since the problem is represented with complex valued multidimensional vector, the relation between input control values (magnitude and phase information of control sources) and output value (acoustic energy level in desired zone) is somewhat hard to predict intuitively. In this paper, a visualized analysis method for the acoustic brightness and contrast control problems is proposed. A geometric structure is given to the problem and acoustic variables are corresponded with geometric quantities. To give a geometric structure to acoustic brightness and contrast problem, the problem is reformulated with inner product. From the geometric structure, the acoustic brightness and contrast control problems are interpreted as a simple geometry problem. From the proposed methods, various 2D simulation results with different conditions can be interpreted with simple geometry characteristic.

1pSP14. Analysis of source denoising techniques. Chris Bahr, Tarik Yardibi, Fei Liu, and Lou Cattafesta (Mech. and Aero. Eng. Dept., Univ. of Florida, 231 MAE-A, Gainesville, FL 32611-6250, cbahr@ufl.edu)

A denoising technique for acoustic signals is analyzed. Previous work derived a methodology where three microphones are assumed to view a single signal field, each under the influence of independent channel noise. Statistical relations are used to determine the coherent acoustic field at each microphone [J. Y. Chung, J. Acoust. Soc. Am. **62**, 388–395 (1977)]. The technique is validated using a simulation of a directive acoustic source, specifically a baffled piston, with multiple microphones placed in an arc array in the far field. While the solution is analytically exact for truly incoherent noise, weakly coherent noise is shown to have a significant impact on the technique output. The sensitivity of the denoised output to signal-to-noise ratio and cross-channel noise coherence is studied. In a high-channel-count array, different microphone combinations may be used for the technique. Different microphone selection algorithms are studied to find a rule set most likely to determine the true acoustic signal strength. Outlier rejection is applied to the data and shown to improve simulation results. Additional optimization schemes are applied to the data in an attempt to find alternative methods to three-microphone denoising. [Work partially supported by GE Global Research.]

5:15

1pSP15. Speech intelligence in a room via time reversal method. Gee-Pinn Too, Yu-Hao Hsieh, Chih-Hao Chou, Bo-Hsien Wu (No. 1 Univ. Rd., Dept. of Systems and Naval Mechatronic Eng., Natl. Cheng Kung Univ., Tainan, Taiwan), and Sony Lee (Industrial Technol. Res. Inst., Tainan, Taiwan)

Time reversal method has been widely used in ultrasound and underwater communication. In the present study, this method is applied in a room to enhance the received signal by increasing the signal-to-noise ratio (SNR). A passive time reversal process allows the estimation of source signal at the original source location. Both theoretical simulations and experiments are performed in the present study. The experiments are performed in an anechoic room as well as in reverberation room. The results indicate that SNR has been greatly enhanced by this approach. Also, array length, cross correlation coefficents and other parameters are also considered and discussed in the present study.

5:30

1pSP16. Compact microphone array processing for in-vehicle voice detection applications. Elizabeth A. Hoppe and Michael J. Roan (Mech. Eng., Virginia Tech, Blacksburg, VA 24060)

The main goal of voice activity detection algorithms is to determine the presence of human voice signals in a given environment. Voice activity detection is very challenging in vehicle interiors. The main challenge in detecting the presence of voice signals in vehicles is the presence of a large number of interferers and a high background noise level. Further, many types of interferers such as tire or engine noise have signals that are highly nonstationary. In this work, compact microphone arrays mounted in various locations within a vehicle are used to extract signals from locations of interest. Experimental comparisons of the performance of several voice activity detection algorithms are made for various array configurations (including single microphone) and source extraction processing algorithms. Processing algorithms considered include blind source separation algorithms such as fastICA, transfer function based inversion methods, and both fixed and adaptive beamforming techniques. The performance of compact arrays is also compared to the performance of larger distributed microphone arrays. It is shown that the use of compact microphone arrays can significantly improve voice activity detection algorithms. The gain is quantified using receiver operating characteristic type curves plotting probability of detection vs probability of false alarm.

1pUW1. Environmental variability and acoustic uncertainty in the New England Shelfbreak Test Experiments. Heather R. Hornick and James F. Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, hhornick @whoi.edu)

Two New England Shelfbreak Test experiments were conducted off the coast of New Jersey in the Middle Atlantic Bight, a complex and highly variable environment. Water column observations were collected from moorings, CTDs, and a Scanfish. Such extensive observations are critical to determining an accurate depiction of the sound speed field variability with which to determine the uncertainty of acoustic transmission loss models. Specific environmental parameters are identified as critical keys affecting acoustic uncertainty. By determining which keys have the most significant effect on changes to sound propagation and measuring transmission loss variability based on these parameters, the uncertainty within the region is estimated comparing several previously developed methods. Given the limitations of collecting data of adequate spatial and temporal coverage, it is necessary to determine how increased numbers of observations can reduce the acoustic uncertainty and quantify the improvement in order to balance the cost of observations with an acceptable level of uncertainty.

1:20

1pUW2. Source characterization study 2007: The three-dimensional primary field of a seismic airgun array. Arslan M. Tashmukhambetov, George E. Ioup, Juliette W. Ioup (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, atashmuk@uno.edu), Natalia A. Sidorovskaia (Univ. of Louisiana at Lafayette, Lafayette, LA), Joal J. Newcomb (Stennis Space Ctr., MS), James M. Stephens, and Grayson H. Rayborn (Univ. of Southern Mississippi, Hattiesburg, MS)

During September 2007 the Littoral Acoustic Demonstration Center collected acoustic and related data from three moored arrays and ship-deployed hydrophones spanning the full water column to measure the 3-D acoustic field of a seismic airgun array. A seismic source vessel shot a series of lines to give detailed angle and range information concerning the field of the primary arrival. The data were collected in the western Gulf of Mexico between the East Break and Alamos Canyon regions. Peak pressures, sound exposure levels, total energy spectra, one-third octave band, and source directivity analyses are measures used to characterize the field. Three-dimensional maps of these quantities are generated to show dependence on emission and azimuthal angles and range. Three-dimensional visualizations are being developed using a visualization cave and software for 2-D cave emulation. [Research supported by the Joint Industry Programme through the International Association of Oil and Gas Producers.]

1pUW3. Observation of channel pulse responses at long ranges in the Florida Straits. Harry A. DeFerrari, Wendy Saintval, and Jennifer Wylie (Div. of Appl. Marine Phys., Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149, hdeferrari@rsmas.miami.edu)

Acoustic propagation in shallow water is observed for transmission between a towed source (250 Hz *m*-sequence) and a bottom mounted horizontal array. A total signal processing gain of 45 dB results; 24 dB from *m*-sequence pulse compression and 21 dB from array gain. The tow is out to 60 km along a path parallel to shore. Individual and separable pulse arrivals associated with single normal modes of propagation are resolved in a parameter space of intensity, arrival time, out-of-plane angle of arrival, and Doppler. Two distinct groups of arrivals are observed, direct paths with near zero horizontal arrival angle and curved inshore, out-of-plane, paths with arrival angle of about 17 deg. A typical inshore path makes several bottom bounces both up and then down the sloping bathymetry. The inshore paths have more favorable transmission (less loss) and, at long ranges, exhibit a peculiar decrease in travel time with an increase in range. At short ranges "down" Doppler is observed, consistent with the opening range of the towed source, but at the longer ranges, "up" Doppler or closing range is observed even though the source is moving away from the receiver. A 3-D PE propagation model is applied to explain observations.

1:50

1pUW4. Observations of micromultipath formation at very long ranges in shallow water. Jennifer Wylie, Harry A. DeFerrari, and Wendy Saintval (Div. of Appl. Marine Phys., Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149, jwylie@rsmas.miami.edu)

Long- and very-long-range shallow-water transmission is observed for low-frequency *m*-sequences transmissions with center frequencies of 50, 100, and 250 Hz. The source is suspended from a ship that is holding position at each of three ranges: 10, 20, and 80 km. The receiver is a bottomed horizontal array. The array is used to resolve out-of-plane arrival angles to a small fraction of a degree by observing phase rolls of the spatial coherence function of the various arriving wavefronts. At the 10 and 20 km ranges, distinct pulse arrivals are observed in one-to-one correspondence to normal mode arrivals predicted with PE propagation models. But at the 80 km range, a large number of distinct arrivals appear with intensities or arrival times inconsistent with deterministic normal mode or ray arrivals. One possibility is that these are micromultipaths from out-of-plane paths after reflections from facets or sloping bottom contours. In fact, each of the arrivals has a unique horizontal arrival angle, and the steeper the out-of-plane angle, the later the arrival—an observation that is verified with broadband PE propagation model computations for both random faceted and gently sloping bottoms.

2:05

1pUW5. Three-dimensional modeling of acoustic propagation in the Florida Straits. Wendy Saintval, Jennifer Wylie, and Harry A. DeFerrari (Div. of Appl. Marine Phys., Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149, wsaintval@rsmas.miami.edu)

A 3-D coupled broadband parabolic equation model is used to study shallow-water propagation for a direction of transmission parallel to a sloping inshore bottom bathymetry. Three sets of arrivals result: (1) direct paths—the typical 2-D model results; (2) curved inshore paths that make several bounces first up and then down the sloping bottom; and (3) micropaths that result from reflection off random facets of the bottom around the direct paths. Archival sound speed data from the Florida Straits at the site of a propagation experiment are used as input to investigate the observed anomalously low transmission loss for some of the long-range inshore paths.

It is shown that both temporal and spatial focusing effects are at play to reduce transmission loss by as much as 15 dB for the inshore paths as compared with the corresponding direct paths having nearly the same mode characteristics. Also, the models help explain a peculiar observation for some of the longer inshore paths where the travel time actually decreases with increasing range of transmission.

2:20

1pUW6. Aspect determination using a transducer with a spiral wavefront: Basic concept and numerical modeling. Brian T. Hefner (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698) and Benjamin R. Dzikowicz (Naval Surface Warfare Ctr., Panama City Div. Code T11, Panama City, FL 32407)

A circular cylindrical acoustic transducer whose direction of motion is radial produces an outgoing signal whose wavefronts are concentric circles. A similar transducer can be designed to generate spiral wavefronts where the phase of the outgoing wave changes by 360 deg in one revolution around the transducer. If these two transducers are used in tandem as a beacon, short tone bursts fired consecutively from each transducer can be used to determine the aspect angle to a receiver relative to the beacon. This is an acoustic version of the VHF omnidirectional ranging systems currently in use in airplane navigation. There are several ways of designing a transducer to produce the spiral wavefront required for the beacon. Several of these designs have been modeled numerically to understand the details of the outgoing field and their impact on aspect determination. [Work supported by ONR.]

1pUW7. Aspect determination using a transducer with a spiral wavefront: Prototype and experimental results. Benjamin R. Dzikowicz (Naval Surface Warfare Ctr., Panama City Div. Code T11, 110 Vernon Ave. Panama City, FL 32407, benjamin.dzikowicz@navy.mil) and Brian T. Hefner (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 9815-6698)

An underwater acoustical navigational beacon is built whose operation is similar to the VHF omnidirectional ranging systems used in aircraft navigation. The beacon consists of two disk transducers whose direction of motion is radial: a circular transducer with constant radius and a spiral transducer whose radius varies linearly by one wavelength over 360 deg. To determine aspect, short tone bursts are then sent from each of the transducers. A remote hydrophone can then determine its aspect to the beacon by comparing the phase between the two transducers, with the circular transducer acting as reference. Results from tank experiments demonstrate the viability of this technique. The vertical beam patterns are also determined and compared to numerical results. In addition, other techniques, such as producing a spiral wavefront using a phased array, are also discussed. [Work sponsored by the Office of Naval Research.]

2:50

1pUW8. Three-dimensional source tracking in an uncertain environment via focalization. Dag Tollefsen (Norwegian Defence Res. Establishment (FFI), 3191 Horten, Norway) and Stan E. Dosso (Univ. of Victoria, Victoria, BC V8W 3P6, Canada)

This paper develops an approach to three-dimensional source tracking in an uncertain ocean environment using a horizontal line array (HLA). The tracking algorithm combines matched-field focalization for environmental (seabed and water column) and source-bearing model parameters with the VITERBI algorithm for range-depth estimation, and includes physical constraints on source velocity. The ability to track a source despite environmental uncertainty is examined using synthetic test cases for various track geometries and with varying degrees of prior information for environmental parameters. Performance is evaluated for a range of signal-to-noise ratios in terms of the probability of estimating a track within acceptable position /depth errors. The algorithm substantially outperforms tracking with poor environmental estimates, and generally obtains results close to those obtained with exact environmental knowledge. The approach is also applied to measured narrowband data recorded on a bottom-moored HLA in shallow water (the Barents Sea) and shown to successfully track both a towed submerged source and a surface ship in cases where simpler tracking algorithms failed.

1pUW9. Underwater acoustic measurements of Doppler-shifted Bragg scattering in the vertical plane from interaction with the ocean surface. Stephen D. Lynch and Gerald L. D'Spain (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr. 0701, La Jolla, CA 92093-0701)

High resolution beamformer output in the vertical plane for received fields from narrowband acoustic tones transmitted at 280, 370, 535, and 695 Hz shows evidence of Doppler-shifted Bragg scattering by the ocean surface waves. The sidebands in the beamformer output are offset in frequency by amounts corresponding to ocean surface wave frequencies, while deviations in vertical arrival angle agree with those predicted by the Bragg condition through first-order perturbation theory using measured directional surface wave spectra and measured acoustic mode wave numbers. The acoustic measurements were made by a horizontal hydrophone array on the ocean bottom in a shallow water waveguide under a variety of ocean surface conditions. [Work supported by ONR, Code 321(US).]

3:35

1pUW10. Impulse response based geo-acoustic inversion using a mobile acoustic source. Kevin D. Heaney (OASIS Inc., 11006 Clara Barton Dr., Fairfax Station, VA 22039, oceansound04@yahoo.com) and Chris Emerson (OASIS, Lexington, MA 02421)

Acoustic transmission data was collected during the Office of Naval Research Quantifying, Predicting and Exploiting Uncertainty (QPE) Pilot cruise off Taiwan (Sept. 2008). Two LFM signals were transmitted from the OASIS Mobile Acoustic Source (OMAS), which is an expendable trackable navigable mobile acoustic source paired with a sonobuys receiver for *in situ* TL measurements. The LFM transmissions were centered at 600 Hz (Q=6) and 900 Hz (Q=4.5). These sources and signals have been used in the past to estimate *in situ* transmission loss from the peak of the matched filter output. Stacking the matched-filter output as a function of range leads to a measurement of the signal evolution as a function of range, permitting qualitative geoacoustic inversion from features (number of observable bottom bounces at close range and loss of higher order bottom bounces vs range) and a quantitative time-domain based geoacoustic inversion using the parabolic equation as the forward model. The resulting sediment can then be compared with the (almost independent) measurements of transmission loss to evaluate the inversions accuracy. [Work was supported by the Office of Naval Research, Code 32OA.]

3:50

1pUW11. Calibration of a passive acoustic target scattered data from the Gulf of Maine. Elizabeth T. Küsel (NOAA/PMEL, Hatfield Marine Sci. Ctr., Oregon State Univ., Newport, OR 97365, elizabeth.kusel@noaa.gov) and Purnima Ratilal (Northeastern Univ., Boston, MA 02115)

The scattered field from long vertical cylindrical targets, such as BBN targets, can be calculated by direct application of Green's theorem and making use of appropriate boundary conditions. In a recent paper submitted to J. Acoust. Soc. Am., the authors show that the scattered levels from BBN-type targets in ocean waveguides with depth-dependent sound speed profile are influenced by the refractive nature of the incident field over the target depth extent. In the current work, the scattering model for vertically extended cylindrical (VEC) targets in range-dependent ocean waveguides is validated with experimental data from the 2006 ONR-sponsored ocean acoustic waveguide remote sensing (OAWRS) experiment in the Gulf of Maine. In order to take into account the scintillation in the measured scattered intensity caused by spatial and temporal fluctuations of the ocean waveguide, a stochastic approach is adopted. Monte Carlo simulations of the scattered field statistics are calculated by implementing the VEC model in a range-dependent environment randomized by internal waves. The simulated scattered field statistics for different source-receiver-target configurations is compared to the scattered returns from BBN targets measured during the 2006 Gulf of Maine experiment. Results show good agreement between the simulated and experimental scattered field statistics.

4:05

1pUW12. High frequency scattering from inclusions in marine sediments: Data/model comparisons. Anatoliy Ivakin (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

Recent theoretical modeling has shown that the size-distribution of inclusions in marine sediments, such as gravel-sized grains and shells embedded in sandy bottoms, is critical for high-frequency scattering. Analysis of existing data on the bottom scattering strength and sediment ground truth also shows that the backscatter data are primarily responsive to the coarse contents of the sediment. Previous ground truth data analysis, usually based on the sediment sieving, assumed that particles are nearly spherical, so that the sieve size is approximately equal to the equivalent diameter (diameter of sphere with the same volume). Coarse particles, such as shell fragments, however, appear to be very nonspherical. Therefore, a relationship between the particle sieve size and equivalent diameter, defined by the particle shape, is needed to provide required size-distributions for acoustic scattering models. Recent statistical analysis of sediment samples collected during the SAX04 experiment resulted in a set of such empiric relationships, and also provided estimating the particle shape factor, known to be an important parameter in the sediment transport processes. Obtained size distributions were used for calculations of frequency-angular dependencies of the bottom backscattering strength and provided a good agreement in the SAX04 scattering data/model comparisons. [Work supported by ONR.]

4:20

1pUW13. Source amplitude spectral information in matched-field localization. Michael J. Wilmut and Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria B.C. V8W 3P6, Canada)

This paper examines a variety of approaches to make use of knowledge of the relative amplitude spectrum of an acoustic source (but no knowledge of the phase spectrum) in multifrequency matched-field processing for source localization. A common example of this procedure involves cases where the source amplitude spectrum can be considered flat over the frequency band of interest. The primary issue is how to combine the information of complex acoustic fields at multiple frequencies, given the unknown phase spectrum. Approaches examined include maximum-likelihood phase estimation, pair-wise processing, and phase rotation to zero the phase at a specific sensor or to zero the mean phase over the array. The performance of the various approaches (processors) is quantified in terms of the probability of localizing the source within an acceptable range-depth region, as computed via Monte Carlo sampling over a large number of random realizations of noise and of environmental parameters. Processor performance is compared as a function of signal-to-noise ratio, number of frequencies, number of sensors, and number of time samples (snapshots) included in the signal averaging.

4:35

1pUW14. Mode characterization in shallow water using warping tools. Julien Bonnel, Barbara Nicolas, Jerome I. Mars (GIPSA-Lab, Dept. Images-Signal, Grenoble INP, rue de la houille blanche BP46, 38402 Saint Martin d'Hres, France, julien.bonnel@gipsa-lab.inpg.fr), Gregoire Le Touze (LMA, Aix Marseille Univ., 13402 Marseille, France), and Dominique Fattaccioli (CTSN, DGA, 83 800 Toulon, France)

In underwater acoustics, shallow water is a complex and dispersive medium. For low frequencies, the propagation is described by normal mode theory. Modes are nonlinear structures overlapped in time, in frequency, and in time-frequency domains. Advanced signal processing methods are needed to study them. This paper presents two different warping methods allowing modal separation and estimation of parameters of the modes. As these transformations are invertible, they also allow modal filtering. Thus, they are a good preprocessing tool for source localization or tomography. This is shown on simulations and real data. Warping is a transformation of a propagated signal and is based on an environment model. Here the environment is modeled with isovelocity or Pekeris waveguide. However, both methods are quite robust to mismatches with the real environment and can be used with minimal preliminary knowledge of the real environment. The first warping method is applied on the time domain. It transforms each mode into a sinus function of frequency f_m (with f_m the cutoff frequency of the mode m). The second is applied on the frequency domain. It transforms a chosen mode into a dirac, which is localized on the arrival time of the mode.

4:50

1pUW15. Warping based lag-Doppler filtering applied to motion effect compensation in acoustical multipath propagation. Nicolas Josso (GIPSA-lab, Grenoble Inst. of Technol., GIT, 961, rue de la Houille Blanche, 38402 St Martin d'Hères, France, nicolas.josso@gipsa-lab.inpg.fr), Cornel Ioana, Jérôme Mars (Grenoble Inst. of Technol., 38402 St Martin d'Hères, France), Cédric Gervaise (ENSIETA, Univ. Européenne de Bretagne, 29806 Brest Cedex, France), and Yann Stephan (SHOM, Brest Cedex 2, France)

The estimation of an impulse response of a propagation channel is necessary for a large number of underwater applications: underwater communication, sonar detection and localization, marine mammal monitoring, etc. Basically it informs us about the distortions of transmitted signal in underwater channels and enables geoacoustic inversion. The propagated signal is usually subject to additional and undesirable distortions due to the motion of the transmitter-channel-receiver configuration. This paper points out the effects of the motion while estimating the IR by matching filtering between the transmitted and the received signals. A methodology to compare the IR estimation in motionless and motion contexts is presented. Based on this comparison, a warping-based lag-Doppler filtering method in the wideband ambiguity plane for motion effect compensation is proposed. It aims at reducing the distortions due to the motion phenomena and accurately estimating the IR of the channel. The proposed methodology is applied to real data sets issued from BASE'07 campaign (NURC, SHOM, and FWG, South of Sicilia, 2007). Motion compensated estimations of IRs are computed from sources transmitting broadband linear frequency modulations moving up to 12 knots in the shallow water environment of the Malta plateau.

5:05

1pUW16. Synthesis of adaptive processing of a passive fathometer. Chris H. Harrison (NURC, Viale San Bartolomeo 400, 19126 La Spezia, Italy), James Traer, and Peter Gerstoft (Scripps Inst. of Oceanogr., UC San Diego, La Jolla, CA 92093)

By using ambient noise array-processing techniques, it has been demonstrated that a passive array can be used as a fathometer [Siderius *et al.*, JASA (2006)] and that adaptive processing gives higher temporal resolution. We show that the waveform extracted with the adaptive algorithm has a phase error of pi relative to that of conventional processing (independently observed at SIO and NURC). For the case of an array with regularly spaced hydrophone elements, the cross-spectral density (CSD) matrix is Toeplitz and the symmetry of Toeplitz matrices allows a simple analytic expression for the phase of the fathometer output. This expression is used to characterize the introduction of phase errors by adaptive processing. The effect of this phase error is investigated with simulated and real data on a vertical hydrophone array.

5:20

1pUW17. Model and measurement of high-frequency bottom backscattering intensity envelope. Jinrong Wu, Licheng Lu, Shengming Guo, and Li Ma (Inst. of Acoust., Chinese Acad. of Sci., No. 21, BeiSiHuan XiLu, Beijing, 100190, ymwjr@yahoo.com.cn)

High-frequency bottom scattering, generally, can be attributed to bottom interface roughness and volume inhomogeneities. The full grazing angle (0–90 deg) intensity envelope model of high-frequency bottom backscattering generated by these two kinds of mechanism was presented. Small-slope approximation method was used to explain bottom roughness backscattering. Bottom volume scattering coefficient was used to calculate bottom volume scattering assuming the volume scattering is homogeneous. The model incorporates the shape of transmitted pulse, directionality of transducer, scattering area, bottom characteristic, and so on. Tank experiment result shows the bottom roughness is the key factor to fine sand bottom backscattering. This backscattering intensity envelope model is useful for the application of bottom backscattering signal, such as sediment classification and geoacoustic inversion. [Work supported by the NSFC.]

Meeting of Accredited Standards Committee (ASC) S2 Mechanical Vibration and Shock

A. T. Herfat, Chair S2
Emerson Climate Technologies, Inc., 1675 W. Campbell Rd., P. O. Box 669, Sidney, OH 45365-0669

R. L. Eshleman, Vice Chair S2
Vibration Institute, 6262 Kingery Hwy., Ste. 212, Willowbrook, IL 60527

Accredited Standards Committee S2 on Mechanical Vibration and Shock. Working group chairs will report on the status of various shock and vibration standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAG for ISO/TC 108, Mechanical vibration, shock and condition monitoring, and its five subcommittees, take note - that meeting will be held in conjunction with the Standards Plenary meeting at 9:00 a.m. on Tuesday, 19 May 2009.

Scope of S2: Standards, specification, methods of measurement and test, and terminology in the field of mechanical vibration and shock, and condition monitoring and diagnostics of machines, including the effects of exposure to mechanical vibration and shock on humans, including those aspects which pertain to biological safety, tolerance and comfort.

MONDAY EVENING, 18 MAY 2009 NEWMARK THEATER, 7:00 TO 9:00 P.M.

Session 1eID

Interdisciplinary: Tutorial Lecture: The Art and Science of Unique Musical Instruments

Uwe J. Hansen, Chair
Dept. of Chemistry and Physics, Indiana State Univ., Terre Haute, IN 47809

A tutorial presentation on The Art and Science of Unique Musical Instruments will be given by Ela Lamblin on Monday, 18 May, at 7:00 p.m.

Ela Lamblin has created many unique musical instruments and sound sculptures in the Northwest. Together with his partner and wife, Leah Mann, he founded the performance company Lelavision. Ela and Leah will demonstrate a variety of instruments, and with the help of ASA's acousticians, explain the sounds they produce—some of which are not what we usually hear from traditional instruments. For a preview visit www.lelavision.com/

The presentation and performance will be held in the modern Newmark Theater (www.pcpa.com/events/newmark.php), located two blocks from the Hilton Hotel in Antoinette Hatfield Hall, 1111 SW Broadway (at Main Street).

Session 2aAAa

Architectural Acoustics: Multiple Channel Systems in Room Acoustics

Ning Xiang, Cochair
Architecture, Rensselaer Polytechnic Inst., Troy, NY 12180

Boaz Rafaely, Cochair
Electrical and Computer Engineering Dept., Ben Gurion Univ., Beer Sheva, Israel

Chair's Introduction—8:00

Invited Papers

8:05

2aAAa1. A multi-channel audio system based on the theory of integral equations. Filippo M. Fazi and Philip A. Nelson (Inst. of Sound and Vib. Res., Univ. of Southampton, Highfield, S0171BJ, Southampton, U.K., ff1@isvr.soton.ac.uk)

The basics of a multi-channel audio system, which attempts the reproduction of a desired sound field, are presented. The system's hardware consists of a three-dimensional array of loudspeakers, and can be used in combination with a specially designed microphone array. The mathematical fundamentals on which this technique is grounded consist of the formulation of the problems as an integral equation. The loudspeaker signals are determined from the knowledge of the target sound field on the boundary of a given control volume. The solution to this inverse problem is computed performing a singular value decomposition of the integral operator involved. For some simple array geometries it is possible to calculate an analytical solution to the problem. A regularization method is applied, as required by the ill-posed nature of the inverse problem under consideration. Some insight into the physical meaning of the ill-posedness is given and some analogies to near-field acoustic holography are suggested. The effectiveness of the method proposed has been verified experimentally and some of the experimental results are presented. Finally, it is shown how this technique has been successfully applied to the design of a multi-channel auralization system for room acoustics.

8:25

2aAAa2. Representation of the musical instruments directivity using dodecahedron loudspeakers. Gottfried Behler and Martin Pollow (Inst. of Tech. Acoust., RWTH Aachen Univ., 52056 Aachen, Germany, gkb@akustik.rwth-aachen.de)

Room-acoustical measurements in general are performed with omnidirectional sound sources. With respect to auralization, such an impulse response may not be ideal since it does not represent the situation playing an instrument in the room. To achieve the directivity of a real source (such as an instrument or human voice) with a technical sound source (a loudspeaker) requires either to copy the body and the surface velocity distribution of that particular source or to reproduce the directional pattern of the radiation using a multiple source configuration like a dodecahedron loudspeaker array with independent excitation of each transducer. The advantage of the latter method is obvious since one single source is able to provide different directivities by changing the excitation profile. To maintain the appropriate excitation of each individual transducer, different approaches can be made. The method described here uses spherical harmonics decomposition of the target radiation pattern and a subsequent calculation of the frequency dependent excitation coefficients for each transducer. The advantage of this method is a flexible and fast calculation delivering filters that can be used either for real time convolution or off-line processing of the measuring signals. To measure the instruments directivity an array with 32 microphones is used.

8:45

2aAAa3. Considering modal aliasing in the implementation of an acoustic echo canceller in the wave domain. Martin Schneider and Walter Kellermann (Multimedia Commun.s and Signal Processing, Univ. Erlangen-Nuremberg, Cauerrstr 7, 91058 Erlangen, Germany, schneider,wk@LNT.de)

Traditional multichannel acoustic echo cancellation applied to wave field synthesis systems is computationally extremely expensive due to the large number of channels to be identified. By using wave domain adaptive filtering (WDAF) one is able to choose an approximation which neglects the interaction (exchange of energy) between different modes. This reduces the number of necessary adaptive filter coefficients drastically. Furthermore, it allows to use computationally relatively inexpensive single-channel filter adaptation algorithms. Then, however, modal aliasing due to the limited resolution of the used microphone array becomes a significant problem since it constitutes an interaction between different modes with respect to the microphone signals. The effects of modal aliasing on the adaptation behavior of a WDAF-based echo cancellation system are analyzed and a modified wave domain representation of the synthesized wave field is proposed which reflects the limited resolution of the microphone array.

9:05

2aAAa4. Spherical harmonic beamforming for room acoustic analysis. Gary W. Elko and Jens Meyer (mh acoustics LLC, 25A Summit Ave., Summit, NJ 07901)

We describe the potential of using a spherical beamforming microphone array to investigate the spatial correlation of sound fields in rooms. We are building spherical microphone arrays consisting of many acoustic pressure sensors mounted appropriately on the surface of a rigid sphere. Our associated spherical eigenbeamformer decomposes the sound-field into spatially orthonormal spherical harmonics up to third-order. We refer to the signals from the eigenbeamformer as eigenbeams. All eigenbeams have phase centers at the physical center of the array. Due to the orthonormal property of the eigenbeamformer, a diffuse field ideally results in zero correlation between the eigenbeams. Therefore, by measuring the cross-correlation between the eigenbeam signals, one can investigate the proximity to the isotropy (or "diffuseness") of the sound-field. Simultaneously, the underlying eigen-beam patterns can be steered without effecting the orthonormality property. How the cross-correlation function changes with general orientation of the eigenbeams is another potential measure for sound field diffuseness in rooms. We will show some real room measurements demonstrating the potential usefulness of this approach.

9:25

2aAAa5. Imaging room acoustics with the audio camera. Adam O'Donovan, Ramani Duraiswami, Nail A. Gumerov, and Dmitry N. Zotkin (Perceptual Interfaces and Reality Lab., Dept. of Comput. Sci. Univ. of Maryland, College Park, MD 20742)

Using a spherical microphone array and real time signal processing using a graphical processing unit (GPU), an audio camera has been developed. This device provides images of the intensity of the sound field arriving at a point from a specified direction to the spherical array. Real-time performance is achieved via use of GPUs. The intensity can be displayed integrated over the whole frequency band of the array, or in false color, with different frequency bands mapped to different color bands. The resulting audio camera may be combined with video cameras to achieve multimodal scene capture and analysis. A theory of registration of audio camera images with video camera images is developed, and joint analysis of audio and video images performed. An interesting application of the audio camera is the imaging of concert hall acoustics. The individual reflections that constitute the impulse response measured at a particular seat may be imaged, and their spatial origin determined. Other applications of the audio camera to people tracking, noise suppression, and camera pointing are also presented. [Work partially supported by NVIDIA and the VA.]

9:45

2aAAa6. Proposed method to measure the diffusion coefficient. Peter D'Antonio (651-C Commerce Dr., Upper Marlboro, MD 20774, pdantonio@rpginc.com)

A method to measure the uniform diffusion coefficient has been published as an AES Information Document [AES-4id-2001, JAES, Vol. **9**, pp. 148–165 (March 2001)]. The method utilizes 37 fixed pressure zone microphones separated by 5 degrees located on a 1 m semicircle and a loudspeaker located on a 2 m concentric semicircle. A sample array sits at the origin. Under computer control 37 impulse responses are collected for the sample, background without sample, and a reference flat panel of similar size. The data reduction procedure will be reviewed to include all developments since the 2001 publication. In addition, experimental data will be presented along with the current presentation format. Currently the method is in the final stages of review for incorporation as Part 2 of ISO 17497-1, which describes the procedure to measure the random incidence scattering coefficient. A review and comparison between the scattering and diffusion coefficients will also be presented. A summary of this research can be found in the reference text [T. J. Cox and P. D'Antonio, Acoustic Absorbers and Diffusers: Theory, Design and Application, Spon Press 2004, second edition in press].

10:05—10:15 Break

10:15

2aAAa7. Analysis of *in situ* acoustic absorption using a spherical microphone array. Jonathan Rathsam and Boaz Rafaely (Dept. of Elec. and Comp. Eng., Ben-Gurion Univ. of the Negev, Beer-Sheva, Israel 84105, jrathsam@gmail.com)

Acoustic absorption of materials typically depends on the characteristics of the incident sound field. Differences in the incident sound field between one laboratory and another, or between the laboratory and *in situ*, may therefore lead to differences in the measured absorption for the same material. To overcome this problem, a new method is proposed to measure acoustical absorption using a spherical microphone array. With this method one measures simultaneously the acoustic absorption as well as the incident sound field. The incident sound field and the reflected sound field are separated by the spherical microphone array using spatial filtering, or beamforming. The acoustic absorption is then determined from the amplitudes of the incident and the reflected fields. The measurement method may also be useful for verifying sound field diffusivity in a reverberation chamber when measuring diffuse-field absorption. Furthermore, absorption coefficients measured under in-situ sound fields may yield more accurate computer-based sound field simulations than diffuse-field absorption coefficients when the in-situ sound field is not diffuse. [Work supported by the National Science Foundation.]

10:35

2aAAa8. Speech intelligibility improvement in rooms using microphone arrays. Michael R. Stinson (Inst. for Microstructural Sci., Natl. Res. Council of Canada, Ottawa, ON K1A 0R6 Canada), Bradford N. Gover (Inst. for Res. in Construction, Natl. Res. Council of Canada, Ottawa, ON K1A 0R6 Canada), and Gilles A. Daigle (Natl. Res. Council of Canada, Ottawa, ON K1A 0R6 Canada)

Microphones arrays reduce the effects of reverberation and background noise as compared to a single microphone. The resulting improvement in speech intelligibility in rooms is investigated here, following the approach discussed by Houtgast *et al.* [Acustica **46**, 60–72 (1980)]. Room characteristics (volume, reverberation time), the background noise spectrum, and the source-receiver separation are used to compute a modulation transfer function. This function is input into the procedure described in IEC standard 60268-16(2003)

to arrive at an objective measure of speech intelligibility, the speech transmission index (STI). Doing this for both omnidirectional and microphone array receivers, the improvement in intelligibility is determined. The signal source has the spectral shape of a human talker, as given in the IEC standard; the background noise spectrum is based on measurements made in a restaurant. The benefit of using microphone arrays is discussed for various conditions.

10:55

2aAAa9. Inter-aural cross correlation in a sound field represented by spherical harmonics. Boaz Rafaely and Amir Avni (Dept. of Elec. and Comput. Eng., Ben-Gurion Univ. of the Negev, Beer Sheva 84105, Israel)

Spaciousness is an important acoustic feature of concert halls. An accepted measure for spaciousness is the inter-aural cross-correlation (IACC), which employs the transfer function from a source in the hall to the two ears of a listener, the latter referred to as head-related transfer functions (HRTF). Recently, spherical microphone arrays have been studied for room acoustics analysis and music recordings. As these arrays typically use a finite number of microphones, they may not be able to capture the spatial information required for complete spatial analysis or for sound reproduction with realistic spaciousness. This study proposes the use of spherical harmonics representations for both the HRTF data and the sound field data, facilitating IACC analysis for sound fields represented by a finite order in the spherical harmonics domain. The effect of limited spherical harmonics order on the spaciousness of various sound fields is finally studied using simulated and measured data.

Contributed Papers

11:15

2aAAa10. A new method for the measurement of directional sound arrivals in rooms. Brian T. Thornock (Acoust. Res. Group, Dept. of Phys., Brigham Young Univ., N-283 ESC, Provo, UT 84602, brianthornock@gmail.com) and Timothy W. Leishman (Brigham Young Univ., Provo, UT 84602)

In room acoustics, directional measurements have the ability to more fully detail room effects than common nondirectional measurements. The extraction of directional information has been a subject of considerable interest for years and has resulted in the development of several interesting approaches to the problem. However, past methods have often suffered from inaccuracies, difficult implementation, lengthy procedures, extensive computational requirements, or the need for large amounts of equipment. A practical new method will be presented that extracts directional information of sound arrivals through a single multichannel measurement and a new cross-correlation technique. A direct comparison of numerical simulations will demonstrate that the method is more accurate than other well-established methods. Advantages and limitations of the new approach will be discussed.

11:30

2aAAa11. Microphone array beamforming with near-field correlated sources. Jonathan L. Odom (Dept. of Elec. and Comput. Eng., Duke Univ., CIEMAS 2410B, Durham, NC 27708, jlo11@duke.edu) and Jeffery Krolik (Duke Univ., Durham, NC 27708)

As the price of omnidirectional microphone arrays has fallen, new applications have emerged for large room audio capture. Further, large room acoustics use loudspeakers, which create correlated sources and severely limit the use of optimum beamformers. Most sources are in the near field due to the large wavelength of speech. Widrow and Kailath's work on correlation in sonar and radar assumed far field, but it cannot be directly applied to near-field acoustics. A new beamforming method has been developed, which incorporates near field and correlation. The source bearings are estimated and an uncorrelated model is formed. A better DOA estimator was developed for the near-field correlated case limited by the width of the mainlobe. The new beamformer is able to null strong, perfectly and nearly perfectly correlated signals using the uncorrelated model and minimum variance distortionless response beamforming.

11:45

2aAAa12. Prediction and measurement of reverberation increase from electroacoustic architecture systems. Roger Schwenke (Meyer Sound Labs., 2832 San Pablo Ave., Berkeley, CA 94702, rogers@meyersound.com), Steve Ellison (Meyer Sound Labs., Sierra Madre, CA 91024), and Mark Poletti (Industrial Res. Ltd., Lower Hutt, New Zealand)

Electroacoustic architecture (EA) systems increase the reverberation time (RT) of rooms by regenerating the physical reverberation of the room, and/or adding electronic reverberation to the direct sound. In regenerative systems, the amount of regeneration is controlled by the loop gain of the system. Increasing loop gain is analogous to reducing the effective absorption in the room. The RT of the electronic reverberator is analogous to the decay time of a physically coupled room, and, therefore, analogous to adding cubic volume to the room. As the electronic RT is increased, there is a point above which the resulting reverberation will begin to be double sloped. This point depends on the gain. The higher the gain, the higher the electronic RT before the resulting reverberation double slopes. In previous work, the gain before feedback of EA systems has been predicted in a statistical approach based on the bulk properties of the room such as RT and cubic volume. This, in turn, can be used to predict the maximum possible power gain and RT increase before double sloping. In this paper, we measure systems in use in the field and compare the achieved performance with predictions.

Session 2aAAb

Architectural Acoustics and the National Council of Acoustical Consultants: Student Design Competition

Robert C. Coffeen, Chair
School of Architecture and Urban Design, Univ. of Kansas, Lawrence KS 66045

The Technical Committee on Architectural Acoustics of the Acoustical Society of America, the National Council of Acoustical Consultants, and the Robert Bradford Newman Student Award Fund are sponsoring the 2009 Student Design Competition that will be professionally judged at this meeting. The purpose of this design competition is to encourage students enrolled in architecture, engineering, physics, and other university curriculums that involve building design and/or acoustics to express their knowledge of architectural acoustics and noise control in the design of a facility in which acoustical considerations are of significant importance.

This competition is open to undergraduate and graduate students from all nations. Submissions will be poster presentations that demonstrate room acoustics, noise control, and acoustic isolation techniques in building planning and room design. The submitted designs will be displayed in this session and they will be judged by the panel of professional architects and acoustical consultants. An award of USD $1250.00 will be made to the entry judged "First Honors." Four awards of USD $700.00 will be made to each of the four entries judged "Commendation."

Session 2aAB

Animal Bioacoustics and Acoustical Oceanography: Autonomous Remote Monitoring Systems for Marine Animals I

Marc O. Lammers, Chair
Hawaii Inst. of Marine Biology, Kailua, HI 96734

Chair's Introduction—8:00

8:05

2aAB1. A survey of remote underwater autonomous acoustic recorders. Whitlow W. L. Au, Marc O. Lammers (Hawaii Inst. of Marine Biology, Univ. of Hawaii, P.O. Box 1106, Kailua, HI 96734), and Michael F. Richlen (Univ. of Hawaii Honolulu, HI 96734)

There has been a proliferation of different types of remote underwater autonomous acoustic recorders in recent years. Many were designed for a specific purpose to measure sounds from specific organisms. Others were designed for general application to encompass a wide variety of sounds. Many have fancy acronyms such as ARP, BPROBE, DTAG, EAR, EARS, HARP, MARU, PALs, RUDAR, and TPOD, to name a few. All have essentially the same subsystems consisting of a hydrophone and amplifier assembly, an analog-to-digital converter, data storage, and a microcontroller to handle the data acquisition and storage operations and to control the overall functioning of the unit. The differences are in the bandwidth of the system, amount of storage available, amount of power required, and duration of deployment possible. Some can be purchased commercially, some can only be leased, while others can only be used in a collaborative research project. The prices also vary considerably. Some have been used for many years while others have come into play within the last few years. The sum total of all these acoustic recorders have contributed tremendously to our understanding of the marine ecosystem in ways that we could not have imagined several years ago.

8:25

2aAB2. Results and insights from operational acoustic monitoring networks. Christopher W. Clark (Bioacoust. Res. Prog., Cornell Univ., 159 Sapsucker Woods Rd., Ithaca, NY 148504), William T. Ellison (Marine Acoust., Inc., Middletown, RI 02842), Brandon L. Southall (Natl. Marine Fisheries Svce., Silver Spring, MD 20910-6233), Adam Frankel (Marine Acoust., Inc., Middletown, RI 02842), Dimitri Ponirakis, Christopher Tremblay, Ann Warde, and Eric Spaulding (Cornell Univ., Ithaca, NY 148504)

Data from two acoustic monitoring networks operating off New England in an area frequented by whales reveal acoustic features of those habitats. These seafloor and moored systems continuously sample the acoustic environment, and resultant data provide mechanisms for mapping, quantifying, and describing the spatio-spectral-temporal variability of the acoustic habitat over ecologically meaningful scales. By focusing on species-specific frequency bands used by fin, humpback, and right whales for long-range communication, we are beginning to measure the acoustic dynamics of their primary communication channels. Results reveal the extent to which different sources of sound in the ocean, both natural and man-made, influence the probability of whale communication. In some habitats with high rates of vessel traffic and high levels of vessel noise, the predicted area over which animals can communicate is reduced to a small proportion of what it would be under quiet conditions. The dynamics of this masking effect are highly variable and vary by species. When considered from a large-scale and behavioral ecological perspective, this reduction in acoustic habitat, as measured in terms of the proportional loss of communication space, likely represents a significant loss for species in which acoustic communication is known to serve critical biological functions.

2aAB3. PAMGUARD: Semiautomated, open source software for real-time acoustic detection and localization of cetaceans. Douglas Gillespie (Sea Mammal Res. Unit, Univ. of St. Andrews, KY16 8lB, Scotland, UK), David K. Mellinger (Oregon State Univ. and NOAA Pacific Marine Environ. Lab., Newport, OR 97365), Jonathan Gordon (Ecologic UK, Newport on Tay, Fife, DD6 8JH, UK), David McLaren, Paul Redmond, Ronald McHugh, Philip Trinder, Xiao-Yan Deng (Heriot-Watt Univ., Edinburgh, Scotland, UK), and Aaron Thode (Univ. of California, San Diego, La Jolla, CA 92093)

PAMGUARD is open-source, platform-independent software to address the needs of developers and users of Passive Acoustic Monitoring (PAM) systems. For the PAM operator—marine mammal biologist, manager, or mitigator—PAMGUARD provides a flexible and easy-to-use suite of detection, localization, data management, and display modules. These provide a standard interface across different platforms with the flexibility to allow multiple detectors to be added, removed, and configured according to the species of interest and the hardware configuration on a particular project. For developers of PAM systems, an Application Programming Interface (API) has been developed which contains standard classes for the efficient handling of many types of data, interfaces to acquisition hardware and to databases, and a GUI framework for data display. PAMGUARD replicates and exceeds the capabilities of earlier real time monitoring programs such as the IFAW Logger Suite and Ishmael. Ongoing developments include improved real-time location and automated species classification. [PAMGUARD funded by the OGP E&P Sound and Marine Life project.]

9:00

2aAB4. Software for bioacoustic analysis of passive acoustic data. David K. Mellinger (Cooperative Inst. for Marine Res. Studies, Oregon State Univ. and NOAA Pacific Marine Environ. Lab., 2030 SE Marine Sci. Dr., Newport, OR 97365), Douglas Gillespie (Univ. of St. Andrews, KY16 8lB, Scotland, UK), Harold Figueroa (Cornell Univ., Ithaca, NY 14850), Kate Stafford (Univ. of Washington, Seattle, WA 98105), and Tina Yack (NOAA Southwest Fisheries Sci. Ctr., La Jolla, CA 92038)

Software analysis systems comprise an important stage in passive acoustic research. Here we compare and evaluate three animal acoustic analysis software systems: Ishmael, PAMGUARD, and XBAT. These packages are compared and evaluated for their capabilities at some of the common tasks in animal sound analysis: recording, display, detection, classification, measurement, localization, and tracking of animal sounds. They are also compared for their extensibility (how easy is it, say, to add a new detection algorithm), their ease of use (how hard is the software to learn to use, how quick to use it once one knows how), their hardware interfacing (what types of sound acquisition hardware can they receive sound from), their sound file interfaces (can they read everyone's sound files), their documentation, and their software interfaces (how well do they share data with other programs, other methodologies, like visual surveys). Special features of each system will also be discussed.

9:20

2aAB5. Passive acoustic monitoring of marine ecosystems in the Pacific Islands Region. Marc O. Lammers (Joint Inst. for Marine and Atmospheric Res., NOAA-CRED, 1125B Ala Moana Blvd., Honolulu, HI 96814, lammers@hawaii.edu), Kevin Wong, Russell E. Brainard (NOAA Fisheries, Honolulu, HI 96814), Whitlow W. L. Au (Univ. of Hawaii, Kailua, HI 96734), and Pollyanna Fisher-Pool (Joint Inst. for Marine and Atmos. Res., Honolulu, HI 96814)

Monitoring the changing state of marine habitats is a challenging task that is exacerbated when the habitats in question are in remote locations. Passive acoustic monitoring is sometimes the best, if not the only, means of gauging levels of biological and anthropogenic activities in such areas. Since 2006, the Pacific Islands Fisheries Science Center, in partnership with the University of Hawaii, has been building a network of long-term acoustic monitoring stations across the Pacific Islands Region using Ecological Acoustic Recorders (EARs). The network is currently composed of 29 long-term monitoring stations and spans the Hawaiian Archipelago, American Samoa, the Line Islands, Johnston Atoll, Wake Atoll, Guam, and the Commonwealth of the Northern Mariana Islands. EARs are diver-deployed and refurbished by local partners and/or during annual or biennial research cruises to deployment locations. A wide range of natural and anthropogenic acoustic signals are monitored, including sounds produced by invertebrates, fish, cetaceans, vessels, and surface weather events. The long-term trends in biological acoustic activity obtained through this network will be used to gauge the relative stability of the ecosystems associated with each location. Detections of vessels are common at many locations and provide a quantitative means of establishing levels of anthropogenic activity.

9:40

2aAB6. Habitat use of beluga whales revealed by acoustic loggers. Manuel Castellote (Res. Dept., L'Oceanografic of Valencia, Spain, mcastellote@oceanografic.org), Nick Tregenza (Chelonia Ltd., United Kingdom), Ruth Leeney (Provincetown Ctr. for Coastal Studies, MA), José Antonio Esteban (Res. Dept., L'Oceanografic of Valencia, Spain), Gregory O'Corry-Crowe (Harbor Branch Oceanograph. Inst., FL), Bill Lucey (Yakutat Salmon Board, AK), Kathleen M. Stafford (Univ. of Washington, Seattle, WA), Kit M. Kovacs, Christian L. Lydersen (Norwegian Polar Inst., Norway), Rauno Lauhakangas (Helsinki Inst. of Phys., Finland), Vera Krasnova, Anton Chernetsky, Alexandr Agafonov, and Vsevolod Bel'kovich (Russian Acad. of Sci., Russia)

The detection of odontocete echolocation signals with acoustic loggers has proved to be a very effective way to monitor their distribution, seasonal patterns and habitat use. However, belugas (*Delphinapterus leucas*) have never been monitored using this methodology. In order to evaluate its viability, echolocation signals of captive belugas were analyzed and the performance of T-POD (Chelonia Ltd., UK) acoustic loggers in captivity and in the Arctic environment was tested. Results from captivity demonstrated the potential of beluga remote monitoring by T-PODs. Field tests were organized in different environmental conditions with different populations of belugas to ensure the validity and detection robustness of this method. T-PODs were deployed in Svalbard (Norway) in Spring 2007, in Yakutat (Alaska) in Spring 2008, and in Solovetsky (Russia) in Summer 2008. Instruments were deployed concurrently with visual observations and hydrophone recordings to compare presence/absence data from the three different methods. Results proved that T-PODs positively detected all the identified periods of beluga presence without false detections and revealed temporal distribution correlations with tide levels, feeding behaviors, and circadian rhythms in the echolocation activity. Results from this project indicate that beluga remote monitoring is feasible in the Arctic environment using acoustic loggers.

10:00—10:20 Break

10:20

2aAB7. Passive acoustical counting of odontocetes using towed and stationed platforms. Tomonari Akamatsu (Natl. Res. Inst. of Fisheries Eng., Fisheries Res. Agency, 7620-7 Hasaki, Kamisu, Ibaraki 314-0408, Japan), Ding Wang, Kexiong Wang, Songhai Li, Shouyue Dong (The Chinese Acad. of Sci., Wuhan, 430072, China), and Satoko Kimura (Kyoto Univ., 606-8501 Kyoto, Japan)

Counting the number of animals is essential for monitoring and management of marine mammals. Autonomous stereo acoustic event recorder (A-tag) to identify each sound source enabled to count phonating odontocetes in the wild. Finless porpoises were surveyed by towed A-tags in 1100 km stretch of Yangtze River from Wuhan to Shanghai. The calculated detection probability using acoustic method was approximately twice that for visual detection. The difference in detection probabilities between the two methods was caused by the large number of single individuals that were missed by visual observers. However, acoustics tended to underestimate group size due to the limited resolution of sound source bearing angles. The detection performance regarding stationary acoustic monitoring of this species was also examined. Three stereo acoustic data loggers were placed at different locations near the confluence of Poyang Lake and the Yangtze River. Acoustic monitoring confirmed the low density bottle neck of the population between the lake and the river that was consistent with visual observations. The passive pulse event monitoring was proved to be a practical and useful alternative to visual observations, especially for long-term and range-wide monitoring.

2aAB8. Acoustic tracking of whistling dolphins offshore of Southern California. Kaitlin E. Frasier, Sean M. Wiggins, and John A. Hildebrand (Scripps Inst. of Oceanogr., Univ. of California San Diego, Ritter Hall 200E, La Jolla, CA 92093-0205)

Dolphin whistles were recorded near San Clemente Island, offshore of Southern California, by four autonomous high-frequency acoustic recording packages (HARPs) deployed in a sea-floor array (dimensions: 2 km $\times$ 2 km) centered around the R/P FLIP. This array layout allowed localization of the calling animals using time difference of arrivals (TDOAs) from the same calls simultaneously recorded on the four instruments. Whistle TDOAs were calculated using cross-correlations of spectrograms. A matched-field least-squares minimization procedure used whistle TDOAs to localize the animals. Successive localizations were combined to track movement over time, revealing local movements of presumably common dolphins (*Delphinus* spp.), typically during elevated nocturnal activity. These tracks, coupled with the animals' acoustic activity, provide insight into their behavior and could potentially be used to study their response to various stimuli including anthropogenic sources such as sonar. [This research is supported by CNO-N45.]

10:55

2aAB9. A real-time detection system for odontocete echolocation clicks in the low-energy processing environment of an acoustic glider. Holger Klinck (Cooperative Inst. for Marine Resour. Stud., and NOAA Pacific Marine Environ. Lab., Oregon State Univ. 2030 SE Marine Sci. Dr., Newport, OR 97365, Holger.Klinck@oregonstate.edu) and David K. Mellinger (Oregon State Univ., Newport, OR 97365)

This presentation will introduce a real-time system, the energy ratio mapping algorithm (ERMA), for detection of odontocete echolocation clicks. The system has been developed to run continuously over extended periods of time in low-energy processing environments such as acoustic gliders. The detector operates in the time domain and takes advantage of the species-specific differences in the power spectra and interclick interval of echolocation clicks to minimize the number of false positive detections. We will demonstrate the operation of ERMA using the clicks of beaked whales, family Ziphiidae, as example target species. To get information on the performance of ERMA, a comparison with more sophisticated and already established detection systems was conducted. Preliminary results indicate that the developed method is a promising tool to reliably detect echolocation clicks emitted by beaked whales in real time. On-going work is focused on implementation of the detector in the acoustic seaglider developed by the Applied Physics Laboratory of the University of Washington (APL-UW) and the use of this platform for autonomous passive acoustic monitoring and mitigation of beaked whales and other odontocete species.

11:10

2aAB10. Autonomous seafloor recorders and autodetection buoys to monitor whale activity for long-term and near-real-time applications. Christopher Tremblay, Tom Calupca, Christopher W. Clark, Matt Robbins, Eric Spaulding, Ann Warde (Bioacoust. Res. Prog., Cornell Univ., 159 Sapsucker Woods Rd., Ithaca, NY 148504, cjt35@cornell.edu), John Kemp, and Kristopher Newhall (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Biologists and engineers from Cornell have installed arrays of autonomous seafloor recorders in multiple ocean habitats. These systems are de-

signed to continuously monitor for the occurrence of endangered whales, particularly right whales; provide critical data on whale seasonal occurrence, distribution and relative numbers; and evaluate potential noise impacts from manmade activities and commercial shipping. Recent studies have been conducted in Massachusetts Bay around commercial LNG ports, the Arctic Ocean at seismic study locations, and in New York waters extending to the shelf edge. In combination with Cornell-developed MATLAB- and JAVA-based software applications, these seafloor recorders have been utilized to evaluate seasonal whale presence, calculate levels of commercial shipping and construction noise, and locate and track the movements and behaviors of individual whales under different acoustic conditions. Cornell and ocean engineers from the Woods Hole Oceanographic Institution have installed an operational network of autodetection buoys off New England to provide near-real-time data on right whale presence to transiting LNG vessels, government agencies, and public entities. When combined, the seafloor and autodetection buoy systems provide a powerful mechanism for understanding whale behavioral ecology and describing their acoustic habitats, while mitigating the risks from ship strike and noise exposure.

11:25

2aAB11. Passive acoustic survey of bowhead whales in the Chukchi Sea. Julien Delarue, Marjo Laurinolli, and Bruce Martin (JASCO Res., Ste. 432, 1496 Lower Water St., Halifax, NS B3J 1R9, Julien.Delarue@jasco.com)

Western Arctic bowhead whales (*Balaena mysticetus*) transit through the Chukchi Sea in spring and fall during their seasonal migration between their winter grounds in the Bering Sea and their summer feeding grounds in the Beaufort Sea, where their presence is well documented. Comparatively little is known about their use of the Chukchi Sea in summer and winter. Here results are presented from a long-term passive acoustic monitoring program using a multi-recorder array deployed from late July 2007 through July 2008 in this area. Bowhead calls were recorded intermittently between August 2007 and January 1, 2008 and again from May 27, 2008 until the end of the study. Of particular interest is the detection of songs in late fall–early winter, which had previously only been recorded during the northward spring migration. They were compared to songs recorded off West Greenland during the previous mating season and found to be different. This is the first evidence of geographic variation of bowhead songs. Overall these detections provide new information on bowheads' spatiotemporal use of the Chukchi Sea. The successes of the study also highlight the effectiveness of autonomous underwater acoustic recorders for marine mammal surveys in remote locations.

11:40

2aAB12. A high-resolution pressure tag for ocean depth measurements. Prajas John, Jaison Peter, Adrine Antony Correya, M. H. Supriya, and P. R. Saseendran Pillai (Dept. of Electron., Cochin Univ. of Sci. and Technol., Cochin- 682022, India)

Data Storage Tags form an important class of electronic tags, used for studying the migratory patterns of highly migratory marine species. In such tags, the parameters to estimate the position of the species are recorded in the tag memory and are retrieved subsequently upon recapturing the tag. The vertical and spatial migration of such marine species can be analyzed in detail using the pressure measurements made by the tags. The migratory behavior of marine species can be attributed to the light intensity variations and temperature profile as well as the search of food and suitable environmental conditions. The depth measurements can be made more accurate, if the resolution of the pressure sensor is significantly high. An absolute pressure measurement with a resolution of 1.2 mbar (approx. 1.2 cm in depth measurements) has been achieved with a pressure tag, capable of recording pressures at preset time intervals. Conversion of the hydrostatic pressure measurements into linear depth variation is carried out using the well-known equations. Pressure measurements were carried out using the pressure tag in the laboratory conditions as well as in the open ocean and the depth variations were computed using a user-friendly interactive software.

2aAO1. Theoretical models for imaging distributed fish groups in an ocean waveguide with wide-area sonar including multiple scattering. Mark Andrews and Purnima Ratilal (Northeastern Univ., 409 Dana Res. Ctr., Boston, MA 02115)

Wide area sonar has been shown to be a useful tool for instantaneously imaging shoals of fish distributed over large areas on the continental shelf. Numerical models are applied to simulate the active imaging system and determine the statistics of the received matched filtered intensity scattered off remote fish groups in the ocean waveguide environment. The model includes multiple scattering of the dense fish groups and uses a range-dependent acoustic model to simulate the ocean environment. The numerical model results are compared to analytic models, which make a single scattering assumption. We find the conditions for when multiple scattering is important and show that it is a function of both the fish density and mean target strength for a given distribution of fish. We use Monte Carlo simulations to explore the effects on the statistics of the received matched filtered intensity for an ocean waveguide randomized by internal waves. The model can be used to infer fish densities and abundances in wide area sonar imagery as well as provide error analysis of these estimates.

8:35

2aAO2. Atlantic herring low frequency target strength estimation from ocean acoustics wageguide remote sensing (OAWRS) data in the Gulf of Maine over 10 days of observation. Duong Duy Tran, Zheng Gong, Nikhila Srikanth, Mark Andrews, Purnima Ratilal (Dept. Elec. and Comput. Eng., Northeastern Univ., 360 Huntington Ave., Boston, MA 02115, tran.duo@neu.edu), and Nicholas Makris (MIT, Cambridge, MA 02139)

During the Gulf of Maine acoustic experiment in the fall of 2006, massive shoals of Atlantic herring were instantaneously imaged over wide areas using an ocean acoustics waveguide remote sensing (OAWRS) system during evening to midnight hours over a period of 10 days from Sept. 26 to Oct. 5. The low frequency target strength (TS) and abundances of the herring

population have been estimated by correlating the OAWRS data with localized measurements from a conventional fish finding sonar (CFFS) for 3 days from Oct. 1–3 [Gong *et al.*, J. Acoust. Soc. Am. **124**, 2586 (2008)]. Here we provide an analysis of the low frequency TS of the herring population in the frequency range from 300 to 1500 Hz and abundances for the remaining 7 days of the experiment. The acoustic scattering from herring populations is highly frequency dependent and is well modeled using a resonant scattering model for swimbladder bearing fish. Here we compare the TS estimates and the neutral buoyancy depth for herring over the observation period of 10 days.

8:50

2aAO3. Midfrequency backscatter imaging of fish schools in a shallow water waveguide. Christopher D. Jones and Darrell R. Jackson (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105, cjones@apl.washington.edu)

In this experimental effort, field data and modeling are used to investigate backscatter imaging of schools of pelagic fish in a shallow water oceanic waveguide. Two-dimensional (2-D) circular images of an oceanic waveguide are created using a monostatic circular receiving array and vertical line array source (12 kHz) deployed from a stationary ship. Horizontal multibeam images of a radial (depth integrated) cross section of the ocean are formed with targets and reverberation structure observed at ranges up to several Km. Examples of waveguide images are presented for data taken in the Puget Sound of Washington state. In some instances, the backscatter from aggregations of fish was observed to be higher than the reverberation; in other cases, fish schools could not be resolved. Fish school locations were independently observed by vertical echo sounding. Preliminary experimental results are shown to illustrate the potential of resolving the 2-D horizontal structure of aggregations of fish using such methods. Modeling is used to interpret the effects of waveguide propagation on imaging. Operational issues related to using waveguide imaging for fisheries' research and signal processing issues related to waveguide imaging will be discussed. [Work funded by NOPP with support from ONR and NOAA-OE.]

9:05

2aAO4. Tracking fish in a school using a broadband split-beam system. Masanori Ito, Ikuo Matsuo (Dept. of Information Sci., Tohoku-Gakuin Univ., 2-1-1 Tenjinsawa, Izumi-ku, Sendai, 981-3193, Japan), Tomohito Imaizumi, Tomonari Akamatsu (Fisheries Res. Agency, Kamisu, Ibaraki, 314-0408, Japan), and Yasushi Nishimori (Furuno Electric Co., Ltd, Nishinomiya, 662-8580, Japan)

Split-beam echo-sounder has been an important tool to understand fish behaviors undersea. In the split-beam system, each position of these fishes in three-dimensional space was estimated from delays of echoes and differences of delays between receive channels. To estimate the positions with high spatial resolution, the split-beam system which can emit and receive the broadband signals was constructed. However, in the case of a school of fish, it is difficult to determine accurately delay times of these fish because the echoes are overlapped with one another. To solve this problem, the new method was proposed to estimate delay times of fish by using the onset information of echoes, that is, extracting the steep temporal changes of the envelope pattern computed from the echo waveform. In a water tank experiment, it is examined that a location of a sphere can be accurately estimated by using the proposed method. In the sea, the echoes from schools of fish were measured with this system. It is examined that each location of fish in the three-dimensional space can be estimated and the numbers of fish can be counted. The tracks of the fish can be computed by changes of the fish locations along pings.

9:20

2aAO5. Broadband acoustic backscattering from live squid: Experiment and analysis. Wu-Jung Lee, Timothy K. Stanton, and Andone C. Lavery (Woods Hole Oceanogr. Inst., Dept. of Appl. Ocean Phys. and Eng., Woods Hole, MA 02543, wjlee@whoi.edu)

Squid are important organisms both ecologically and commercially. Acoustic scattering techniques can provide synoptic data on their distribution and abundance, and have the advantage of being efficient compared with traditional net sampling methods. However, knowledge of the scattering properties of squid is required to accurately convert the acoustic data into meaningful biological information. To better understand the scattering of sound by squid, and to facilitate future model development, a controlled laboratory backscattering experiment was conducted on live squid (*Loligo pealeii*) using broadband linear chirp signals (45–105 kHz) with data collected over the full 360 deg of orientation in the lateral plane, in 1-deg increments. The scattered spectra often showed significant structure over the frequency band available at different angles of orientation, in addition to high levels of ping-to-ping variability. Pulse compression signal processing techniques were also used, revealing the following dominant scattering features: (1) at normal incidence, the front and back interface of the animal were resolved and (2) at off-normal incidence, the anatomical features in the head region were found to dominate the scattering. This information can serve as the basis for an accurate acoustic scattering model for squid.

9:35

2aAO6. Humboldt squid distribution in three-dimensional space as measured by acoustics in the Gulf of California. Robyn S. Matteson, Kelly J. Benoit-Bird (College of Oceanogr. and Atmospheric Sci., 104 COAS Admin. Bldg., Oregon State Univ., Corvallis, OR 97331, rmatteson@coas.oregonstate.edu), and William F. Gilly (Stanford Univ., Pacific Grove, CA 93950)

The Humboldt squid, *Dosidicus gigas*, is a voracious migratory predator, important prey for many species, and the target of an economically important fishery. However, information on the behavior, life history, and biomass of this species is limited. Current knowledge is based almost exclusively on fisheries records, which only contain nighttime observations and provide no information on squid distribution and behavior outside of heavily fished areas. Acoustic measurements have long been used to study fish. Development of this method for application to squid provides a noninvasive technique to assess squid numbers and sizes. This method was applied in March and April of 2007 and November of 2008 in the Gulf of California, with a focus on the Santa Rosalia region. Squid densities were as high as 25 000 per km^3. Larger numbers of squid were observed at shelf breaks relative to other areas. Squid exhibited a marked diel vertical migration, with daytime depths of 300–400 m, bathymetry allowing, and nighttime depths of 0–200 m. In shallower coastal areas, the distribution of squid closely mirrored the shape of the bottom topography. This new technique is providing previously unattainable insights into the behavior and biology of this commercially and ecologically important squid species.

9:50

2aAO7. Acoustical and optical measurements provide evidence of ecological interactions in planktonic thin layers. Kelly J. Benoit-Bird and Timothy J. Cowles (College of Oceanic and Atmos. Sci., Oregon State Univ., 104 COAS Admin. Bldg., Corvallis, OR 97331, kbenoit@coas.oregonstate.edu)

Coincident physical, optical, and acoustical data were obtained in Monterey Bay, CA during an extensive study of planktonic layers. These concurrent data describing the distributions of phytoplankton, zooplankton, and small fish as well as gradients in the physical habitat were used to examine the interactions between vertically compressed plankton structures (thin layers), their consumers, and the local physical forces they experience. The steepness of the vertical gradient on the top versus the bottom of the plankton layer was correlated to the difference in the relative abundance of consumers above and below the layer. Phytoplankton layer gradients were steeper when more zooplankton were present on one side of the layer versus the other while zooplankton layers were more diffuse with a greater number of fish adjacent to one side of the layer than the other. Both layer types showed nearly symmetrical gradients when predators were in low abundance or absent. Differences in phytoplankton and zooplankton layer "shape" were not correlated with vertical gradients in shear or mixing potential surrounding layers. The consequences of trophic interactions within aggregations can be detected and assessed, and in the absence of strong physical gradients, grazers can play an important role in structuring plankton thin layers.

10:05—10:20 Break

10:20

2aAO8. Long-term broadband acoustic observations of zooplankton scattering layers in Saanich Inlet, British Columbia. Tetjana Ross (Dept. of Oceanogr., Dalhousie Univ., Halifax NS B3H 4J1, Canada; tetjana@dal.ca) and Gareth Lawson (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

The application of broadband techniques to fish and zooplankton bioacoustics is showing potential to transform the field into one that is much more quantitative. This is because broadband techniques allow the use of the known spectra of organisms or nonbiological sources of scattering to distinguish between scatterers, allowing discrimination without the need for extensive groundtruthing. This makes it ideal for remote monitoring of fish or zooplankton assemblages, since continuous net-sampling is often not possible. An upward-looking 85–155 kHz broadband sonar has been collecting data nearly continuously on the Victoria Experimental Network Under the Sea (VENUS) mooring in Saanich Inlet, British Columbia since March 2008. Saanich Inlet is known to have large populations of euphausiids, which create a strong acoustic scattering layer that migrates from depth to the surface and back each day. The thickness, timing, strength and spectral response of this layer is examined throughout the annual cycle and the feasibility of using this type of sonar to elucidate changing zooplankton assemblages (due to growth and changing species composition) is assessed.

10:35

2aAO9. Temporal patterns of fish and mesozooplankton near the Columbia River plume. Amanda M. Kaltenberg (College of Oceanic and Atmospheric Sci., Oregon State Univ., 104 COAS Admin. Bldg., Corvallis, OR 97331, akaltenb@coas.oregonstate.edu), Kelly J. Benoit-Bird (Oregon State Univ., Corvallis, OR 97331), and Robert L. Emmett (NOAA Northwest Fisheries Sci. Ctr., Newport, OR 97365)

The distribution of the dominant fish species in the California Current System is seasonal, with the timing and variability of these distributions having significant ecological consequences. The objective of this study was to observe the seasonal timing of fish school presence and to characterize the temporal patterns their abundance. Fish and mesozooplankton were observed near the Columbia River plume using 200-kHz bioacoustic moorings deployed throughout the transition period from winter conditions to summer upwelling conditions in 2008. Sea surface temperature, sea surface salinity, and ocean current data were used to characterize the oceanographic habitat. Acoustic mooring data revealed that the seasonal timing of schools of Pacific sardine and northern anchovy were linked with temperature and persisted after a rapid increase in temperature occurred near the end of May. The abundance of fish schools and mesozooplankton at two mooring stations was highly variable with dramatic fluctuations occurring over a period of hours to days that were linked with ocean conditions. The use of stationary acoustic moorings in this study provided an effective tool to monitor fish abundance at high temporal resolution and provides insight into the timing and variability of fish populations that will improve ecosystem-based management decisions.

10:50

2aAO10. Pilot work using a codend video camera for improved acoustic interpretation of backscatter observed during fisheries acoustic surveys. Lisa A. Bonacci and W. Waldo Wakefield (NOAA, Fisheries, NWFSC, 2032 SE OSU Dr., Newport, OR 97365, Lisa.Bonacci@noaa.gov)

One challenging but crucial element of fisheries acoustic surveys is accurate groundtruthing of the echo return. Assignment and proportioning of areas of backscatter to the correct species or mix of species affects fish biomass calculations. Typically, survey groundtruthing is done by midwater trawls targeting a single scattering layer of interest. However, the depth at which each species is caught is unknown. Therefore, this method is problematic when multiple scattering layers are present. Small scatters are also missed, which may be important contributors to the echo intensity. To address these issues, we conducted pilot work using a video camera mounted in the codend of an open midwater trawl, which enabled us to look at several scattering layers during each tow. For comparison, we conducted tows with a closed net and no camera at the same location. We then examined each acoustic echogram and the corresponding tow in order to compare backscatter calculations attributable to our species of interest. We found that there were some differences in these measurements between the two types of tows. We conclude that this method appears to provide improved knowledge of acoustic backscatter observed during fisheries acoustic surveys and plan to integrate this method into future surveys.

11:05

2aAO11. Density and soundspeed measurements of various Bering Sea zooplankton. Joseph D. Warren, Joy N. Smith (School of Marine and Atmospheric Sci., Stony Brook Univ., Southampton, NY 11901, joe.warren@stonybrook.edu), and Patrick H. Ressler (NOAA Fisheries AFSC, Seattle, WA 98115)

Walleye pollock is a commercially and ecologically important species in the Bering Sea. Assessment of pollock stocks is conducted regularly using a combination of trawl net sampling and multiple frequency active acoustic echosounder surveys. In addition to backscatter from the species of interest, other marine life including several types of zooplankton and nekton can contribute substantial amounts of acoustic backscatter energy which can provide information regarding the abundance and distribution of these animals as well. Acoustic scattering models are used to estimate both the amount and frequency response of the acoustic energy scattered by the zooplankton, but these models require knowledge of various properties that describe the acoustically important characteristics of the zooplankton. We collected live zooplankton from the Bering Sea during June and July 2008. The morphology (spatial dimensions) and material properties (density and sound speed) of individual and groups of zooplankton (and some nekton) were measured. The taxa studied included euphausiids (*Thysanoessa raschii, Thysanoessa inermis, Thysanoessa spinifera*), copepods (*Neocalanus sp.*), amphipods (*Themisto sp.*), gastropod (*Clione sp.*), siphonophores, jellyfish, and squid. The results of our measurements with regard to acoustic scattering model development and use will also be discussed.

2aBB1. Radiation force on spheres in helicoidal Bessel beams modeled using finite elements. David B. Thiessen, Likun Zhang, and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA, 99164-2814, thiessen@wsu.edu)

Analysis of the scattering of sound by spheres centered on ordinary and helicoidal (higher-order) Bessel beams [P. L. Marston, J. Acoust. Soc. Am. **124**, 2905–2910 (2008)] makes it possible to evaluate the radiation force on spheres centered on the beam in an ideal inviscid fluid. Potentially surprising results include cases where the radiation force is directed opposite the propagation direction of both types of beams [P. L. Marston (submitted for publication)]. For potential biomedical applications such as drug delivery, it would be necessary to know if a small transverse displacement of the sphere from the beam's axis causes a radiation force that pushes the sphere toward (or away from) the axis of the beam. Three-dimensional finite elements were applied to that problem. To trust FEM calculations of the radiation force with helicoidal beams, it was first necessary to verify that analytical values for the axial force are recovered in the on-axis helicoidal case since only the zero-order beam had been previously studied [D. B. Thiessen and P. L. Marston, J. Acoust. Soc. Am. **122**, 3025 (2007)]. Cases were found where displacement of a sphere from the beam axis causes a transverse restoring force. [Supported by ONR and NASA.]

2aBB2. Radiation torque on a sphere centered on an acoustic helicoidal (vortex) Bessel beam. Likun Zhang and Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, zhanglikun@wsu.edu, marston@wsu.edu)

Circularly polarized electromagnetic waves carry axial angular momentum and analysis shows that the axial radiation torque on an illuminated sphere is proportional to the power absorbed by the sphere [P. L. Marston and J. H. Crichton, Phys. Rev. A. **30**, 2508–2516 (1984)]. Hefner and Marston [J. Acoust. Soc. Am. **106**, 3313–3316 (1999)] proposed that a helicoidal acoustic beam (an acoustic vortex) also carries axial angular momentum and noted that absorption of such a beam should also produce an axial radiation torque. In the present work the acoustic radiation torque on a sphere centered on an acoustic helicoidal Bessel beam is analyzed and the torque is predicted to be proportional to the ratio of the power absorbed as a result of the interaction of sound with the sphere to the acoustic frequency. The torque is also proportional to the topological charge of the beam. Depending on the beam helicity, the torque is parallel or anti-parallel to the beam axis. The analysis uses a relation between the scattering and the partial wave coefficients for a sphere in a helicoidal Bessel beam [P. L. Marston, J. Acoust. Soc. Am. **124**, 2905–2910 (2008)]. [This research was supported in part by ONR and NASA.]

8:35

2aBB3. Acoustic radiation force on a gas bubble in tissue. Yurii A. Ilinskii, Evgenia A. Zabolotskaya, and Mark F. Hamilton (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029)

The motion of a gas bubble subjected to acoustic excitation in a soft elastic medium such as tissue was analyzed previously assuming the radiation force acting on the bubble is the same as in liquid [Ilinskii *et al.*, J. Acoust. Soc. Am. **117**, 2338 (2005)]. In the present work we discuss corrections to the acoustic radiation force for finite values of the shear modulus. The analysis is based on the Piola-Kirchhoff equation in Lagrangian coordinates, in which only the stress tensor is nonlinear, and the equation is solved by perturbation. In the linear approximation an analytical solution is obtained for the scattered acoustic wave. The nonlinear stress and full radiation force is calculated at the next order of approximation. For negligible shear modulus the result for a liquid is recovered. For small but finite shear modulus the resulting force differs from that for a liquid by a factor that depends on $k_t R$, where R is bubble radius, $k_t = \omega/c_t$ the wavenumber, ω the angular frequency, and c_t the shear wave propagation speed. For $k_t R > 10$ the radiation force is practically the same as in liquid, but for $k_t R < 10$ its value can be significantly different. [Work supported by NIH DK070618.]

2aBB4. Optimization of ultrasound radiation force source for shear wave dispersion measurements. Matthew W. Urban and James F. Greenleaf (Dept. of Physio. and Biomedical Eng., Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905, urban.matthew@mayo.edu)

The objective of this study was to analyze and optimize the ultrasound radiation force source for creating shear waves for quantitative elasticity and viscosity measurements. A simulation model based on work by Bercoff *et al.*, [IEEE Trans. Ultrason. Ferroelectr. Freq. Contr. **51**(11), 1523–34 (2004)] was utilized to examine the shear wave propagation from a spatiotemporal impulsive force and the simulated radiation force generated from a linear array transducer. Parameters such as aperture size, F-number of the transducer, and medium shear elasticity and viscosity were varied to analyze how the shear wave amplitude and shape changes. The wave attenuation and group and phase velocities were evaluated. The aperture size and the F-number of the transducer affected the spatial distribution of the propagating shear wave significantly. The influence of the coupling term between the bulk and shear waves was analyzed spatially and temporally by evaluating parameters such as shear wave amplitude, wave attenuation, and the group and phase velocities. This simulation model provides insight for making shear wave propagation measurements from the perspective of optimizing the spatial and temporal characteristics of induced shear wave motion from an applied radiation force. [This work was supported in part by Grant EB002167 from NIH.]

9:05

2aBB5. Comparison of unconfined compression and spatially modulated ultrasound radiation force estimates of shear modulus. Stephen A. McAleavey, Erin Collins, Etana Elegbe, and Johanna Kelly (BME Dept., Univ. of Rochester, 309 Goergen Hall, Rochester, NY 14627, stephenm@bme.rochester.edu)

Spatially modulated ultrasound radiation force (SMURF) [S. McAleavey *et al.*, Ultrason. Imag. **29**, 87–104, (2007)] is a novel method for ultrasonic estimation of the low-frequency shear modulus properties of elastic media. In this approach, radiation force with a known lateral magnitude variation is

applied impulsively within a region of interest using short (~30 μs) bursts of ultrasound. The spatial frequency k of the radiation force intensity variation is selectable and determined through beamforming. Application of the radiation force impulse gives rise to a low-frequency (500–2000 Hz) shear wave. The temporal frequency ω of this wave is measured using Doppler ultrasound methods. The modulus is estimated from the relationship $G=\rho(\omega k)^2$, where ρ is the material density. To validate this method, the moduli of five samples of Zerdine (CIRS, Incorporated), an ultrasonically tissue-equivalent elastic material, were measured using conventional unconfined cyclic compression and SMURF implemented on a Siemens Antares scanner. The samples were cylindrical with diam 54 mm and height 25 mm. The shear modulus of the samples ranged from 2.5–35 kPa. For all samples, the two methods agreed to within the estimated variation. An intrasample variation of 8% was observed for SMURF in the (assumed uniform) samples. [Work supported by NIH/NIBIB.]

2aBB6. Optical tracking of acoustic radiation force impulse-induced dynamics in a tissue-mimicking phantom. Richard Bouchard (Dept. of Biomedical Eng., Duke Univ., Box 90281, Durham, NC 27708, rrb@duke.edu), Jason Streeter (UNC-CH and NCSU, Chapel Hill, NC 27599), Mark Palmeri, Gregg Trahey (Duke Univ., Durham, NC 27708), and Paul Dayton (UNC-CH and NCSU, Chapel Hill, NC 27599)

Optical tracking was utilized to investigate the acoustic radiation force impulse (ARFI)-induced response in a translucent, tissue-mimicking phantom. Suspended 10-μm microspheres were tracked axially and laterally at multiple locations throughout a microscope's field of view with 0.5-μm displacement resolution, in both dimensions, and at frame rates (with an attached video camera) of up to 36 kHz. Induced dynamics was successfully captured before, during, and after the ARFI excitation at depths of up to 4.8 mm from the phantom's proximal boundary. Results are presented for tracked axial and lateral displacements resulting from on-axis and off-axis (i.e., shear wave) acquisitions; these results are compared to matched finite element method modeling and independent, ultrasonically based empirical results. A shear wave reflection, generated by the proximal boundary, consistently produced an artifact in tracked displacement data later in time (i.e., after the initial ARFI-induced displacement peak). This new tracking method provides high-frame-rate, two-dimensional tracking data and thus could prove useful in the investigation of complex ARFI-induced dynamics in controlled experimental settings. [This work was supported in part by a National Science Foundation Graduate Research Fellowship.]

2aBB7. Acousto-magnetometry: A new vibrometery based on acoustic radiation force and magnetic measurement. Antonio Adilton O. Carneiro, Oswaldo Baffa (Departamento de Fisica e Matematica, Universidade de São Paulo, Ribeirao Preto, SP 14040-901 Brazil), Glauber T. Silva (Universidade Federal de Alagoas, Maceio, AL, 57072-970 Brazil), and Mostafa Fatemi (Mayo Clinic and College of Medicine, Rochester, MN 55905)

This work introduces a new method based on acoustic radiation force and magnetic measurement for interrogating the mechanical properties of fluid and biological tissues. In this method, ultrasound radiation is used to exert a low-frequency (in kHz range) force on a rigid magnetized target immersed in a viscoelastic medium. In response, the target vibrates in a pattern determined by viscoelastic properties of medium. We report the relation between the magnetic field signal and the incident ultrasonic pressure field in terms of the mechanical parameters of the medium. Simulations were conducted to demonstrate a simple approach based on using amplitude-modulated ultrasound to generate a dynamic acoustic radiation force on a magnetic target. The magnetic field generated by vibration of this target is then obtained and used to estimate the radiation-force-induced displacement as a function of time. It was observed that the intensity of the dynamic component of the magnetic field caused by the acoustic excitation is high enough to be registered by a conventional magnetic sensor. This proposed methodology presents a powerful tool for evaluation of acoustic radiation force as well as the mechanical properties of soft material.

10:20

2aBB8. Shear wave dispersion ultrasound vibrometry of gel dosimetry phantoms. Silvio Vieira (Dept. de Fis. e Mat. da FFCLRP, Univ. de São Paulo, Av. Bandeirantes, 3900-Bairro Monte Alegre-Ribeirão Preto-SP, Ribeirão Preto, SP 14040-901, Brazil, silvio@pg.ffclrp.usp.br), Matthew Urban (Mayo Clinic, Rochester, MN 55901), Andre Baggio (Univ. de São Paulo, Ribeirão Preto, SP 14040-901, Brazil), Antonio Carneiro (Univ. de So Paulo, Ribeirão Preto, SP 14040-901, Brazil), and Mostafa Fatemi (Mayo Clinic, Rochester, MN 55901)

Shear wave dispersion ultrasound vibrometry (SDUV) has been introduced to use the dispersive nature of shear wave speed to locally estimate the material properties or tissue. Shear waves were created using a mechanical shaker and pulsed radiation force. Using the information from the phase one can estimate the shear velocity. A theoretical Voigt model allows us to find, at different frequencies (100–400 Hz), the viscosity and shear elasticity of the polymer gel dosimeter. The aim of this work was to perform the SDUV and mechanical vibrometry techniques to study the viscoelastic properties of absorbed dose phantoms. The experiments were performed using five phantoms of different absorbed doses varying 10 up to 50 Gy, while a nonirradiated phantom was kept as a control. The SDUV technique was performed using a pulsed radiation force to vibrate the gel provide by a confocal transducer with a focal depth of 70 mm, nominal frequency of 3 MHz. For the mechanical vibrometry and SDUV experiments, shear wave motion measurements were made with a commercial ultrasound machine with a research using a 10 MHz linear array transducer. The quantitative elasticity and viscosity results for these two experiments were compared.

10:35

2aBB9. Targeted ultrasound contrast agents—Mediated endothelial permeability. Pavlos Anastasiadis (Dept. of Mech. Eng., Univ. of Hawaii at Manoa, 2540 Dole St., Honolulu, HI 96822, pavlos@hawaii.edu), Chris N. Layman, and John S. Allen (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Endothelial cell dysfunction is considered to play a major role in the early stages of atherosclerosis. Targeted ultrasound contrast agents offer potential for therapeutic treatment though the mechanisms for enhanced ultrasound and microbubble mediated transport across endothelial layers are not well understood. In this study, we evaluate the endothelial cell-to-cell and cell-to-substrate gaps with the electric cell-substrate impedance sensing system (ECIS, Applied BioPhysics, Troy, NY). ECIS can detect the nanometer order changes of cell-to-cell and cell-to-substrate distances separately. Targeted ultrasound contrast agents (UTC) were employed in conjunction with the application of ultrasound, while continuous measurements of electrical resistance across the endothelial monolayers were conducted in real-time for the determination of permeability. The measurements were performed in both, the presence and absence of UCA. Additional complementary, noninvasive acoustic measurements of local changes in the mechanical properties of the endothelial monolayers were conducted at high-frequency (100 MHz) with a time-resolved scanning acoustic microscope. [This work was supported by the National Institutes of Health Grants NIH 2 P20 RR016453-05A1 and NIH 2 G12 RR0030161-21.]

10:50

2aBB10. Targeted ultrasound contrast agents for the imaging of biofilm infections. Pavlos Anastasiadis (Dept. of Mech. Eng., Univ. of Hawaii at Manoa, 2540 Dole St., Honolulu, HI 96822, pavlos@hawaii.edu), Kristina Mojica, Michelle L. Matter, and John S. Allen (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Targeted ultrasound contrast agents (UCA) offer a novel, potential method for diagnostic imaging of biofilm infections. Currently, there is no established method for molecular imaging of *in vitro* biofilm infections with any type of modality. For infective endocarditis, the case of biofilm formation on damaged or diseased heart valves, an early diagnostic method might greatly reduce the associated high mortality rate. Fluorescently labeled lectins were used with targeted ultrasound contrast agents in conjunction with epifluorescence microscopy and time-resolved scanning acoustic microscopy for visualization and characterization of the extracellular polymeric substances (EPS) of two types of infectious biofilms (*Staphylococcus aureus* and *Pseudomonas aeruginosa*). Noninvasive acoustic measurements of the biofilms were conducted at high-frequency (100 MHz) with a time-resolved scanning acoustic microscope. Measurements of the reflection and transmission coefficients, over a broad frequency spectrum for a range of biofilm growth stages in both, the presence and absence of targeted UCA were obtained. The biofilm morphology and structure were also investigated with acoustic microscopy as a function of growth. [This work was supported by the National Institutes of Health Grants NIH 2 P20 RR016453-05A1 and NIH 2 G12 RR0030161-21.]

11:05

2aBB11. Transcutaneous acoustic palpation (TAP) for the localization of peripheral, painful tissue. Pierre D. Mourad (Appl. Phys. Lab., Dept. of Neurosurgery, Box 356470, Univ. of Washington, Seattle, WA 98195, pierre@apl.washington.edu), Michel Kliot, and Jeffrey G. Jarvik (Univ. of Washington, Seattle, WA 98195)

Localizing painful tissue (pain generators) is central to medicine. Here we sought to demonstrate that intense focused ultrasound (iFU) can successfully differentiate normal from painful tissue. Rats were injected with complete Freunds adjuvant in a hind paw to create an inflammatory injury, or underwent a surgical procedure that damaged the nerve enervating the paw, creating a neuropathic injury. Each created a paw sensitive to external stimulation relative to the contralateral paw. iFU was applied individually to each hind paw in increasing doses until the animal withdrew either paw consistently from the iFU stimulus, thereby defining the iFU threshold dose for that animal. This data was correlated with paw withdrawal latencies to a heat lamp (Hargreaves) test. Sensitized paws responded to lower intensities and doses of iFU than control paws greater than 95 percent of the time with sensitivities and specificities generally greater than 90 percent. In general, iFU threshold tests and Hargreaves tests did not affect one another, a functional test of the safety of iFU. This preliminary evidence supports the hypothesis that iFU can safely discriminate between painful and normal tissue. Future work will use image-guided iFU to localize deep rather than superficial pain generators.

11:20

2aBB12. A stabilized forward elasticity finite element formulation yields a stable and convergent inverse elasticity solution. Carlos E. Rivas, Paul E. Barbone (Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, barbone@bu.edu), and Assad A. Oberai (Rensselaer Polytech. Inst., Troy, NY 12180)

"Elastography" refers to the procedure of using ultrasound to image tissue deformation. Images showing tissue deformation are sensitive to distributions of tissue mechanical properties. The mechanical properties themselves may be quantified by solving an inverse elasticity problem. An iterative approach to solving the inverse problem can be formulated by repeated solutions of the forward problem. That is, the shear modulus distribution sought is that which predicts a displacement field most consistent with the measured displacement field. Here we show that given plane displacement measurements for plane stress elasticity, the continuous elastic equilibrium equation uniquely determines the modulus distribution. On the other hand, we shall also demonstrate that the discrete elasticity equations from standard FEM discretization does not, even at the limit of infinite mesh refinement. We diagnose the problem as an underenforcement of the elasticity equations. With this knowledge, we have been able to design new forward elasticity FEM formulations that provide provably convergent forward *and inverse* elasticity solutions.

11:35

2aBB13. Ultrasonic properties of normal and cancerous human breast cell lines. Sang-Mo Shin (School of Medical System Eng., Gwangju Inst. of Sci. and Technol., 1 Oryong-dong, Buk-ku, Gwangju 500-712, Korea, sshin@gist.ac.kr), Koeng-Mo Sung, Hyun-Woo Koh (Seoul Natl. Univ., Seoul 151-600, Korea), and Pavlos Anastasiadis (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Time-resolved scanning acoustic microscopy (SAM) equipped with time-resolved signal analysis offers unique possibilities for studying the mechanical properties of cells *in vitro*. The method is nondestructive and noninvasive on a cellular level, which enables real-time measurements on living cells. The ultrasonic attenuation coefficients and sound speeds of MCF 10A normal breast cells and MCF 7 weakly invasive cancerous cells were measured and compared using a time-resolved SAM operating at 0.86 GHz center frequency and with 5 ns pulse duration. The attenuation coefficients of MCF 10A and MCF 7 cells were found to be 126 ± 67 and 443 ± 129 dB, respectively, while the sound speeds of the same cells were 1583 ± 24 and 1736 ± 61 m/s, respectively. Both the attenuation coefficient and sound speed of MCF 7 cells were higher than those of MCF 10A cells. In particular, the difference in the attenuation coefficients was pronounced. The relative differences in sound speed and attenuation coefficient could be utilized to differentiate normal cells from cancerous cells. [Weiss *et al.* IEEE Trans. Ultrasonics, Ferroeletrics, and Freq. Contrl. **54**, 2257–2271 (2007)] [Work supported by Korean Science and Engineering Foundation.]

Engineering Acoustics and Physical Acoustics: Lasers in Underwater Acoustics

Kenneth M. Walsh, Chair
K M Engineering Ltd., 51 Bayberry Ln., Middletown, RI 02842

Chair's Introduction—7:55

Invited Papers

8:00

2aEA1. Acquiring acoustic data using a scanning laser vibrometer. Walter H. Boober (Naval Undersea Warfare Ctr. Div. Newport, 1176 Howell St., Newport, RI 02841, walter.boober@navy.mil), Kim C. Benjamin, Stephen E. Forsythe (Naval Undersea Warfare Ctr., Newport, RI 02841), and Kenneth M. Walsh (K and M Eng., Middleton, RI 02842)

Scanning laser vibrometers have been in use for many years in acoustic measurements. Unique methods of characterizing both active and passive devices or structures with vibrational modes have been developed by NUWC personnel; these are combinations of signal generation techniques and physics-based data analysis tools. The signal generation techniques reduce the time for potentially lengthy scans at multiple frequencies through the use of a "comb" waveform, [J. Acoust. Soc. Am. **116**(5), (2004)], if the device under test is known to be linear. Scans can be done in either air or water. An analysis technique using the Helmholtz integral (using NUWC's MATLAB-based CHIEF code; Schenck and Benthein, NOSC 1970, 1988) allows analysis from an in-air scan of a transducer face (before encapsulation) to predict the transducer's far-field beam patterns under some conditions. This is especially valuable as a time-saving tool to ensure that the transducer is on track to achieve the final design intent. Examples of the techniques applied to various transducer designs will be presented; for comparison, single-tone results also will be shown.

8:25

2aEA2. On continuous-line acoustic array behavior in a laser Doppler sound pressure measurement system. Michael S. McBeth (Space and Naval Warfare Systems Ctr. Atlantic, 204 Indian Springs Rd., Williamsburg, VA 23185, m.s.mcbeth@ieee.org) and Yongxiang Hu (NASA Langley Res. Ctr., Hampton, VA 23681)

Continuous-line acoustic array behavior in a laser doppler anemometry (LDA) based sound pressure measurement system is considered. Traditional LDA ultrasound measurement systems intentionally minimize the laser beam intersection or interference fringe volume to better achieve point measurements of the sound field. The large laser beam diameters due to beam spreading in remote sensing applications from space or airborne platforms make this approach impractical. Since the sound pressure signal is integrated over the interference fringe volume, continuous-line acoustic array behavior is expected to be observed proportional to the length of the laser light path through the interference fringe volume. This behavior is analyzed from a theoretical perspective and an experimental setup to test for continuous-line acoustic array behavior in a LDA sound pressure measurement system is presented.

8:50

2aEA3. Measurement and imaging of high-frequency sonar fields using acousto-optic tomography. Pete Theobald, Stephen Robinson, Triantafillos Koukoulas, and Gary Hayman (Natl. Physical Lab., Hampton Rd., Teddington, Middlesex TW11 0LW, UK, pdt@npl.co.uk)

The acoustic near-field of a high-frequency sonar array transducer has been measured using a laser scanning acousto-optic method and reconstructed using a tomographic technique similar to that used for x-ray computed tomography. This measurement, using a laser interferometer to scan a plane in front of the transducer for a series of transducer rotations, provides an image of the acoustic field for a plane in front of the transducer array. This method allows measurement of the acoustic field without perturbing the field being measured, which can occur when using the planar hydrophone scanning method, provides high spatial resolution with minimal phase averaging across the measurement aperture and provides potential for significantly decreasing the scan time. Measurements have been performed on two 1–3 composite transducer arrays at frequencies between 330 and 500 kHz. These are compared with planar hydrophone scans obtained using a 1.5-mm probe hydrophone. Both parallel and fan beam tomographic scan geometries have been considered along with the effect of lateral scan resolution versus angular rotation resolution.

2aEA4. Laser light scattering by bubbles in water: Fundamentals and applications to acoustics. Philip L. Marston (Phys. and Astron. Dept., Washington State Univ., Pullman, WA 99164-2814, marston@wsu.edu)

Laser light scattering is sometimes used as an alternative to acoustical methods for monitoring bubbles in seawater. There has also been interest in using lasers to investigate bubbles in wakes. In some cases light scattering by bubbles has been used in conjunction with acoustical measurements to characterize dynamics of bubbles radiating sound [J. S. Stroud and P. L. Marston, J. Acoust. Soc. Am. **94**, 2788–2792 (1993)]. In applications such as these it is important to understand the optical properties of bubbles that differ significantly from drops and particles. Examples include critical angle scattering and the transition to total reflection [D. S. Langley and P. L. Mar-

ston, Appl. Opt. **23**, 1044–1054 (1984)], forward scattering and extinction [D. S. Langley and P. L. Marston, Appl. Opt. **30**, 3452–3458 (1991); J. S. Stroud and P. L. Marston, cited previously], glory back-scattering enhancements and shape effects [W. P. Arnott and P. L. Marston, J. Opt. Soc. Am. **A5**, 496–506 (1988); Appl. Opt. **30**, 3429–3442 (1991)] and Brewster angle scattering. Some optical effects of coatings on bubbles (which can occur naturally) have also been modeled [P. L. Marston, Appl. Opt. **30**, 3479–3484 (1991)]. [Research supported by ONR between 1980 and 1995.]

2aEA5. A laser-based method of detecting underwater sound through an ice layer. Lynn T. Antonelli and Fletcher A. Blackmon (Naval Undersea Warfare Ctr., Code 1512, 1176 Howell St., Newport, RI 02841, lynn.antonelli@navy.mil)

An aerial, remote sensor has been devised to detect underwater sound through an ice layer by optically measuring the resulting vibration velocity on the ice surface, using a laser Doppler vibrometer. The laser was focused on an ice block approximately 8 in. wide by 12 in. long and 3.5 in. thick floating in a tank of water 16 in. deep. A submerged transducer was used to generate underwater acoustic signals to provide ice surface vibrations for the sensor to detect. Although acoustic attenuation through the ice was not an issue for this test, laser alignment was crucial. Since sensor reliability depends on receiving laser reflections from the ice surface, the laser was steered nearly perpendicularly onto the ice surface that had both smooth and rough features. The broadband optical sensor provides a remote sensing capability for measuring ice surface vibrations in response to underwater acoustic signals such as from marine mammals, passive or active sonar, and from underwater acoustic communication systems. The results of this landmark experiment will be presented, which demonstrate the feasibility for detecting underwater sound through an ice layer by probing the ice surface with a laser vibrometer, paving the way for in-air sensing in arctic regions.

2aEA6. Remote, aerial, translayer, nonlinear downlink underwater acoustic communication. Fletcher A. Blackmon (Naval Undersea Warfare Ctr., Code 1512, 1176 Howell St., Newport, RI 02841, fletcher.blackmon@navy.mil) and Lynn T. Antonelli (Naval Undersea Warfare Ctr., Newport, RI 02841)

The nonlinear mechanism for optical to acoustic energy conversion is explored for optoacoustic communication from an in-air platform to a submerged platform. This downlink communication can provide a bell ringer function and transmission of text and data. The nonlinear conversion mechanism, also known as the nonlinear optoacoustic regime where focused laser energy is converted to sound at the air-water interface, involves a phase change of the water medium through evaporation and vaporization leading to plasma production. The nonlinear conversion mechanism provides a more efficient, i.e., higher source level, controllable method for producing underwater acoustic signals. A means of deterministically controlling the spectrum of the underwater acoustic signal has been investigated and demonstrated by varying the laser-pulse repetition rate to provide *M*-ary frequency shift keyed signaling. This physics-based conversion process provides a methodology for providing low probability of intercept signals whose information is embedded in noise-like signals. These laser generated signals can then be used in a frequency hopped spread spectrum technique with the use of the proper receiver structures to take advantage of the frequency diversity and periodicity inherent in this type of signal structure that could also be used to combat frequency selective fading in underwater acoustic channels.

10:45

2aEA7. Intense underwater laser acoustic source for Navy applications. Theodore G. Jones, Melissa K. Hornstein, Antonio C. Ting (U.S. Naval Res. Lab., Plasma Phys. Div., 4555 Overlook Ave. SW, Washington, DC 20375, ted.jones@nrl.navy.mil), and Zachary W. Wilkes (Res. Support Instruments, Inc., Lanham, MD 20706)

An intense remote underwater laser acoustic source is under development at the Naval Research Laboratory. In a novel configuration, a tailored intense laser pulse can be designed to propagate many meters underwater and compress at a predetermined remote location. Controlled compression of these optical pulses is governed by a combination of optical group velocity dispersion and nonlinear Kerr self-focusing. Optical compression can result in laser-induced breakdown, localized heating, and acoustic shock generation. Recent experiments include near-field acoustic source characterization using lens-focused 400 and 800 nm pulses of a Ti:sapphire laser, as well as 532 and 1064 nm pulses of a YAG laser. Sound pressure levels over 210 dB were achieved using a compact laser. Acoustic source characterization includes measurements of photoacoustic energy conversion efficiency, acoustic power spectrum, and directivity. Nonlinear optical studies included the precise measurement of the Kerr index of water at 400 and 800 nm, as well as conditions for optical filament generation, and their effects on acoustic signals. Planned experiments include tests in a bubbly salt water tank. Experimental results will be presented, and laser sources and techniques for underwater acoustic generation will be compared. [This work is supported by the U.S. Office of Naval Research.]

11:10

2aEA8. Transducer characterization by laser Doppler vibrometry. Martin P. Cooling, Victor F. Humphrey (Inst. Sound & Vib. Res., Univ. of Southampton, Southampton, SO17 1BJ, UK, mc@isvr.soton.ac.uk), Pete D. Theobald, and Stephen P. Robinson (Natl. Physical Lab., Teddington, Middlesex, TW11 0LW, UK)

A laser Doppler vibrometer (LDV) can be set up such that its laser beam passes through the glass wall of a water tank to be incident upon the radiating surface of an immersed ultrasonic transducer. Scanning the laser beam across a transducer in this way has the potential to be a fast, noninvasive method for source characterization and, in turn, field prediction. Such measurements are, however, significantly complicated by the acousto-optic interaction—that is, the effect on the measurements of the acoustic field through which the laser beam passes. To increase understanding of the resultant acousto-optic artifact, a detailed simulation of the LDV measurement of a circular, plane-piston transducer emitting a tone-burst has been created. The use of a transient field is important for simulation and experiment, such that measurements can be made over a time window which ends before any acoustic signal reaches the water tank boundaries. The simulation results show a significant acousto-optic artifact contribution to the surface velocity data, but also that for some applications useful field predictions may be made in spite of this. To complement the simulations, experimental measurements have been made using a commercial LDV (Polytec PSV-400) on a 500 kHz circular transducer.

11:25

2aEA9. Measurement of the resonance frequency of a bubble using a laser Doppler vibrometer. Theodore F. Argo, IV and Preston S. Wilson (Mech. Eng. Dept. and Appl. Resource Labs., The Univ. of Texas at Austin, Austin, TX 78712-0292)

Knowledge of the behavior of bubbles that are confined within tubes or channels has a direct impact on the development of various medical applications and industrial processes. In such confined spaces, bubbles are not easily observed by traditional experimental means, such as acoustically with hydrophones, or optically with Mie scattering or stroboscopy. Further, facilitating observation with these methods may significantly perturb the system. A laser Doppler vibrometer (LDV) requires only a narrow (~1 mm diam) line-of-sight access for the beam and illumination of the bubble does not perturb its dynamics. LDV measurements of the resonance frequency and quality factor of an air bubble suspended in a small water tank are presented to demonstrate the utility of this technique. The measurements are compared to a model that includes the acoustic effect of the tank walls. The precision of the technique was found to be similar to the precision of a traditional hydrophone-based acoustic technique.

TUESDAY MORNING, 19 MAY 2009 EXECUTIVE SALON II/III, 10:00 A.M. TO 12:00 NOON

Session 2aED

Education in Acoustics: Hands-On Experiments for High School Students

Uwe J. Hansen, Chair
Indiana State Univ., Dept. of Chemistry and Physics, Terre Haute, IN 47809

Chair's Introduction—10:00

Approximately 20 acoustics experiments will be set up, ranging in complexity from simple resonance on a string to ultrasonic levitation. Around 40 local high school science students will perform the experiments with help from ASA scientists and students. Regular ASA conference participants are welcome to the session as long as they do not interfere with student experimentation.

Session 2aMU

Musical Acoustics: Wind Instruments I

Thomas D. Rossing, Chair
Stanford Univ., CCRMA, Stanford, CA 94305

Invited Papers

8:00

2aMU1. Three decades of wind instrument research at Brigham Young Univ. William Strong (Dept. of Phys. and Astron., Brigham Young Univ., Provo, UT 84602)

Wind instrument research at Brigham Young University during the 1970s, 1980s, and 1990s will be reviewed. In more or less chronological order, the research was as follows: (1) Calculation of input impedances of an oboe; (2) predictor coefficient analysis /synthesis of French horn tones; (3) functional model of a simplified clarinet; (4) calculated and measured modal frequencies of brass instruments; (5) calculation and measurement of flute impedances and standing waves; (6) calculation and measurement of horn impedances; (7) simulation of a player-clarinet system; (8) optimization of clarinet toneholes; (9) simulation of a player-trumpet system; (10) stroboscopic measurement of the lip motions of a trombone player; (11) calculation and measurement of nonlinear effects in loud trombone tones; (12) finite element modeling of the lips of a trombone player. [Work supported by the Institute for Research in Musical Acoustics.]

8:30

2aMU2. Spectral component relationships in wind instrument transients. Peter L. Hoekje (Dept. of Phys. and Astron., Baldwin-Wallace College, 275 Eastland Rd., Berea, OH 44017, phoekje@bw.edu)

Playing characteristics of a wind musical instrument are related to its transient response, the efficiency of its sound production, and the stability of its sustained tones, as determined partly by the acoustical resonances of the instrument, and their nearly harmonic relationships. These can be explored using analysis of instrument attack transients by tracking development of the spectral components. A coupled oscillator model is used to explain the benefits to an instrument's response due to resonances at harmonics of the playing frequency. Furthermore, the slight deviation from harmonic relationships of an instrument's resonances leads to a shift in its tone center during a crescendo. A resonance at a frequency above the tone-hole lattice cutoff can affect the playing behavior of flutes and cornettos. The player's airway in reed woodwinds and brasses is as much a part of the acoustic system as the instrument proper, and its resonances can have a correspondingly important effect.

Contributed Papers

9:00

2aMU3. Impulse response reverb as a tool for voicing organs. Michael Steppat (Erlenweg 17, D-14558 Nuthetal OT Saarmund)

The sound of a flue pipe can be adjusted by voicing. With parameters like the cut-up of the upper lip and their width, the opening in the foot, the height of the languid, and the width of the slit the voicer can influence the promptness of speech and adjust the intensity of the starting transient. The acoustical environment (especially the reverberation time) plays an important role in the reception of the starting transient, therefore the organ builder has to also take the architecture into account. Convolution reverb allows a simulation of the reverb at different positions. Sampled organ sounds with modified starting transients or modeled sounds can be played on a computer and mixed with a convolution reverb using measured impulse responses from different positions of the room. This computer model can be used during the design process to estimate the parameters for the voicing. Results of measurements in a church building and different modeling techniques will be presented

9:15

2aMU4. Measuring the Young's modulus of reeds from American reed organs. Michael B. Wilson (Juniata College, 1700 Moore St., Huntingdon, PA 16652, wilsomb05@juniata.edu), Alexander M. Ramm, and James P. Cottingham (Coe College, Cedar Rapids, IA 52402)

A method of wave coefficients has been used to measure the Young's modulus of brass reeds from American reed organs. Although for some purposes these reeds can be approximated as uniform cantilever beams, their cross sections are sufficiently nonuniform that simple methods such as measuring beam displacement for a known applied force or using resonant frequencies of transverse and torsional modes of vibration are not sufficient to obtain accurate results. In the wave coefficient method [Y. Liao and V. Wells, J. Sound Vibr. **295**, 165–193 (2006)] a wave number is found that forces data at all measurement points to conform to the general forced-vibration solution for a beam, implying that they have the same wave coefficients. This method also assumes a uniform cross section but does not require measurements along the entire length of the beam and was applied only to the most uniform sections of the reeds. Three reeds of the same frequency were selected, with cross sections of varying uniformity. The resulting measurements of the Young's modulus seemed consistent with expected values for brass. For one reed with nearly uniform cross section the wave coefficient method was in good agreement with the simpler methods.

9:30

2aMU5. The influence of curvature on the vibration and tone quality of pipe organ reed tongues. G. R. Plitnik (Dept. of Phys., Frostburg State Univ., Frostburg, MD 21532) and J. Angster (Fraunhofer Inst. fur Bauphysik, Stuttgart, Germany)

Given certain design constraints, such as the type of stop being voiced and the desired tone quality, organ reed voicers must curve each tongue so as to produce the best and most stable tone, as well as maintaining a consistent tone quality across an entire rank of pipes. This study investigated the effects of varying tongue curvatures on two pipes, an F2 Trompette and an

F2 Clarinet. Reed vibration was measured under typical conditions by laser vibrometer; the pressure waves in the boot and shallot were measured by means of one-eighth inch microphones and the emitted sound was recorded at the egress. By integrating the velocity data, the displacement of the reed may be plotted in tandem with the pressure difference across the reed, allowing tongue position to be plotted versus the pressure variation during one steady-state cycle for each reed while vibrating. These graphs can then be compared and correlated to the observed tone quality for each of the differently curved reeds.

9:45

2aMU6. Acoustics of single-reed duck calls. Nicholas P. Goodweiler (College of Eng., Univ. of Iowa, Iowa City, IA 52242, nicholas-goodweiler@uiowa.edu) and James P. Cottingham (Coe College, Cedar Rapids, IA 52402)

A single-reed duck call features a reed of Mylar or similar elastic material mounted above a curved tone channel. The arrangement resembles that of a clarinet, except that the extreme curve of the tone channel (compared to the relatively flat lay of the clarinet) allows for a rather large volume airflow. In addition, the flexibility of the reed results in a low fundamental frequency (typically 100–140 Hz) so that the pitch of the call is close to the natural frequency of the reed, modified only slightly by the short resonating barrel. As the blowing pressure is increased, there is a gradual rise in pitch, punctuated by periodic jumps from one apparent regime of vibration to another. As the blowing pressure is lowered, some hysteresis effects are observed. Several calls built by different makers have been studied, each with a differently proportioned barrel and tone channel. Some of the phenomena observed include reed velocity and displacement, changes in effective reed length as a function of blowing pressure, and effects of barrel design on tone quality. Some observations have also been made of the volume airflow and effects of attaching pipe resonators.

Session 2aPAa

Physical Acoustics: Cavitation: Mechanisms and Physical Effects

Thomas J. Matula, Chair
Applied Physics Lab., Univ. of Washington, Seattle, WA 98105-6698

Contributed Papers

8:00

2aPAa1. Laser-induced dielectric breakdown as a method for noncontact pressure measurement. Jonathan R. Sukovich, Todd W. Murray, and R. Glynn Holt (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Being able to accurately measure pressure fields in acoustic experimentation is of critical importance for understanding and describing observed acoustical phenomena. However, in many experimental situations, it is undesirable or impossible to measure the acoustic field using a transducer in contact with the acoustic host medium. It becomes useful then to have alternative, noncontact, methods for reliably and accurately measuring pressure fields in experiments. One alternative to traditionally invasive means, such as the use of a hydrophone, to measure pressure, is to use focused, short (5–7 ns), high power laser pulses to cause dielectric breakdown. Breakdown events can be detected by looking for the signature, near instantaneous, flash of broadband light generated by the subsequent ionization cascade. This procedure can then be repeated under different known hydrostatic pressures to establish pressure's effect on the breakdown strength of water. Once a relationship is established, the process can be used to map local pressures in acoustic fields of sufficiently long period as to be considered hydrostatic in relation to the laser pulse duration. [Work supported by the US Army Space and Missile Command.]

8:15

2aPAa2. Acoustic measurement of bubble size and position in an ink jet printhead. Arjan van der Bos, Roger Jeurissen, Michel Versluis, Detlef Lohse (Phys. of Fluids, Dept. of Appl. Phys., Univ. of Twente, P.O. Box 217, 7500 AE, Enschede, The Netherlands), Hans Reinten, Herman Wijshoff, Marc van den Berg, and Jos de Jong (Oce Technologies B.V., 5900 MA, Venlo, The Netherlands)

A bubble can be entrained in the ink channel of a piezo-driven ink jet printhead leading to malfunction. Here, an acoustic sizing method for the volume and position of the bubble is presented. The influence of the bubble on the channel acoustics is detected by the piezo-actuator operating in a sensing mode. The acoustic response is also modeled in a linearized bubble dynamics model and it is demonstrated how the size of the bubble and its position within the channel can be inferred from the inverse problem. The validity of the presented method is supported by time-resolved optical observations of the bubble dynamics visualized in a glass connection channel. The combined optical and acoustical recordings are compared to the model, where a very good agreement is found. [This work is part of the research program of the Technology Foundation STW and financially supported by Océ Technologies B.V.]

8:30

2aPAa3. Laser nucleation of bubble clusters in a spherical resonator. Phillip A. Anderson, Todd W. Murray, and R. Glynn Holt (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Due to the strong energy focusing found in sonoluminescence, there is much interest in high-energy bubble collapses. There is evidence in the literature that the collective collapse of a bubble cluster is more violent than a single bubble collapse under similar conditions. Precise control over the spatial and temporal placement of bubbles in an acoustic field would seem critical for achieving the strongest collapses, but nucleating bubbles acoustically is not precise or repeatable and does not allow for the creation of arrays of bubbles. A method is presented for creating two- and three-dimensional bubble arrays in a controllable way. A pulsed Nd:YAG laser is used with custom diffraction gratings and focusing optics to nucleate bubble arrays in a spherical resonator at high static pressure. A specific implementation will be presented, along with results addressing uniformity and repeatability. [Work supported by the US Army Space and Missile Command.]

8:45

2aPAa4. Collapse dynamics of laser-nucleated bubble clusters in a spherical resonator. Phillip A. Anderson, Todd W. Murray, and R. Glynn Holt (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

The collective collapse of bubble clouds or clusters is important to many applications, including underwater sound propagation, shock-wave lithotripsy, and focused ultrasound therapy. Energetic collective cluster collapses appear to happen only when there is sufficient nuclei density. In order to study this phenomenon, we have implemented a laser-based method for creating clusters consisting of planar or cubic arrays of bubbles with controllable interbubble spacing. The growth and collapse of the arrays are observed using ultrahigh-speed photography and other diagnostics. Effects of interbubble spacing and nucleation phase with respect to the acoustic period are studied. [Work supported by the US Army Space and Missile Command.]

9:00

2aPAa5. Detecting cavitation in liquid mercury exposed to a high-energy pulsed proton beam. Nicholas J. Manzi, Robin O. Cleveland, R. Glynn Holt, and Ronald A. Roy (Dept. of Mech. Eng., Boston Univ., Boston, MA 02115)

The Oak Ridge National Laboratory spallation neutron source (SNS) employs a high-energy proton beam incident on a liquid mercury target to generate short bursts of neutrons. Concomitant with neutron production is the rapid heating of the mercury, resulting in the formation of acoustic shock waves and the nucleation of cavitation bubbles. The subsequent collapse of these cavitation bubbles may result in the eventual erosion of the target's steel walls. We report on preliminary measurements using two passive cavitation detectors (megahertz frequency focused and unfocused PZT transducers), installed in a mercury test target to monitor cavitation activity for proton beam energies ranging from 0.041 μC to 4.1 μC. Cavitation was initially detected for a beam "charge" of 0.205 μC by the presence of an acoustic emission approximately 120 μs after arrival of the incident beam, which is characteristic of inertial cavitation collapse. As beam energy was increased, the collapse time increased until the lifetime of the bubbles exceeded the reverberation time of the chamber (~300 μs) at which point complex emissions signatures were detected due to the interaction of the reverberation signal and the cavitation bubbles.

9:15

2aPAa6. Production of cavitation erosion damage by means of an electromagnetic shock wave source. Qi Wang, Nicholas J. Manzi, R. Glynn Holt, Ronald A. Roy, and Robin O. Cleveland (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, robinc@bu.edu)

Central to a spallation neutron source (SNS) is a vessel of liquid mercury. During SNS operation acoustic pulses, with pressures in excess of 10 MPa, are generated in the mercury likely resulting in cavitation, which may erode the walls. We developed an electromagnetic shock wave source to generate similar pressures and cavitation. An electromagnetic source consists of a coil placed close to a metal plate, which is in contact with a fluid. The source is driven by discharging a capacitor through the coil, which results in a repulsive force on the plate launching acoustic waves in the fluid. A 75 mm diameter source coupled to water was fabricated, and the plate motion was measured by laser Doppler vibrometry and the acoustic field by a piezoelectric needle for different capacitance, charging voltage, number of coils, and plate properties. For a 2 μF capacitor charged to 12 kV and discharged through a 28-turn coil with a 0.8 mm thick aluminum plate (spherically focused) the peak pressure measured in water was 20 MPa. Cavitation clouds were produced over a wide range of voltages (imaged with 15 μs exposure) with lifetimes around 300 μs and produced erosion craters on a porous solid. [Work supported by ORNL-SNS, UT-Battelle, US-DOE Contract DE-AC05-00OR22725.]

9:30

2aPAa7. The ultreo: A novel toothbrush that combines sonic and ultrasound physics. Pierre D. Mourad (Appl. Phys. Lab. and Dept. of Neurosurgery, Box 356470, Univ. of Washington, Seattle, WA 98195, pierre@apl.washington.edu), Frank Roberts (Dept. of Peridontics, Univ. of Washington, Seattle, WA 98195), and Chris McInnes (Ultreo, Inc.)

Efficacious, daily oral health care represents an important part of maintaining the overall health of individuals. Here we sought to develop and demonstrate the usefulness of a new power toothbrush, one that incorporated both sonic processes (in the form of rapid bristle motion that directly removes plaque as well as generates bubbles) and ultrasound (sourced from the brush head, that activated the bubbles). We adapted a set of existing power toothbrushes to incorporate an ultrasound source with sufficient controls to explore the effects of different ultrasound parameters on plaque removal *in vitro* and *in vivo*. The combination of sonic and ultrasound physics removed plaque *in vitro* in a synergistic manner, likely through the action of cavitation. *In vivo*, the Ultreo toothbrush—a commercial version of this brush—removed comparable amounts of plaque to another commercial brush in half the time, and removed more plaque than manual toothbrushes. A combination of sonic bristle motion and ultrasound-facilitated cavitation appears to produce superior plaque removal compared to existing, sonic only, or manual tooth brushes.

9:45

2aPAa8. Motion of dissolved gas in a cavitating fluid. I. V. Mastikhin, B. Newling, and S. Kristoffersen (Dept. of Phys., Univ. of New Brunswick, 8 Bailey Dr., Fredericton, New Brunswick, E3B 5A3, Canada)

A strong acoustic field in a liquid separates the liquid and dissolved gases by the formation of bubbles (cavitation). Bubble growth and collapse is the result of active exchange of gas and vapor through the bubble walls with the surrounding liquid. This work investigates a new approach to the study of cavitation, not as an evolution of discrete bubbles, but as the dynamics of molecules constituting both the bubbles and the fluid. Direct Magnetic Resonance Imaging measurements of dynamics of the liquid and the dissolved gas show that the motions of dissolved gas (freon-22, CHClF2) and liquid (water) can be very different during acoustic cavitation and are strongly affected by the ultrasonic power, filtration, or previous cavitation of the solvent. The observations suggest that bubbles can completely refresh their content within two acoustic cycles and that long-lived (~minutes) mi-

crobubbles act as nucleation sites for cavitation. The technique is complementary to the traditional optical and acoustical techniques. [V. Mastikhin and B. Newling, Physical Review E (2005, 2008).] [Authors thank the Natural Science and Engineering Research Council of Canada for funding.]

10:00

2aPAa9. Simultaneous, noninvasive determination of fluid viscosity and density from acoustical resonances. Curtis F. Osterhoudt and Dipen N. Sinha (Los Alamos Natl. Lab., MPA-11 MS D429, Los Alamos, NM 87544, sinha@lanl.gov)

U-tube densitometers make fluid density measurements based on eigenfrequency shifts, which depend on the fluids contained within the densitometer. This measurement method is the current standard for density measurements in industrialized settings. However, ruggedized densitometers have several drawbacks. They are expensive, and require diverting fluids into the apparatus to make their measurements. Viscometers, too, are considered invasive, or require diverting fluid into a measurement chamber (the one exception is the "OSCAR" viscometer, which cannot make measurements on flowing systems). In contrast, a simultaneous density/viscosity measurement can be made without diverting fluid from the container or pipe carrying it. The measurement, in which the container (e.g., pipe section) itself becomes the sensor, is based on acoustical frequency resonance shifts and resonance width changes. Such measurements can in principle be made at a standoff from the container, reducing price and requiring no further contact with the fluids. This presentation will address the technique, give the theoretical background for it, and present experimental validation.

TUESDAY MORNING, 19 MAY 2009 BROADWAY III/IV, 10:30 A.M. TO 12:00 NOON

Session 2aPAb

Physical Acoustics: Thermoacoustics

Martin D. Verweij, Chair
Lab. for Electromagnetics Research, Delft Univ. of Technology, 2628 CD Delft, The Netherlands

Contributed Papers

10:30

2aPAb1. Thermoacoustics in irregular media. Carl Jensen and Richard Raspet (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

One approach to acoustics in random porous media is to use fitting parameters to match theoretical models derived from exact parallel pore theory to measured values of the media's acoustic properties such as the complex compressibility and complex density. [Roh *et al.* J. Acoust. Soc. Am., **121**, 1413–1422 (2007)] extended these ideas to the more complicated thermoacoustic case of an applied temperature gradient by using empirical factors to reshape the known solution for thermoacoustics in a regular framework of rigid tubes to RVC and aluminum foam samples. The validity of this model has been investigated by directly simulating the sound propagation through several irregular, 3-D geometries using a thermal fluid solver. The acoustic and thermoacoustic simulation results for several geometries will be presented and compared to the theoretical results.

10:45

2aPAb2. Helmholtz-like resonators for thermoacoustic prime movers. Bonnie J. Andersen (Dept. of Phys., Utah Valley Univ., 500 W. University Pkwy., Orem, UT 84058) and Orest G. Symko (Univ. of Utah, Salt Lake City, UT 84112)

In a thermoacoustic prime mover, high acoustic output power can be achieved with a large diameter stack and with a cavity with a large volume attached at the open end of the resonator containing the stack. The combination of resonator and cavity makes the device Helmholtz-like, with special characteristics of the resonant frequencies and quality factor Q. Analysis of its acoustic behavior based on a model of a closed bottle presents features that are useful for the development of such prime movers for energy conversion from heat to sound. In particular, the arrangement produces in the cavity a high sound level, which is determined by the Q of the system. Comparison with a half-wave resonator type of prime mover, closed at both ends, shows the advantages of the Helmholtz-like device.

11:00

2aPAb3. Ultrasonic thermoacoustic prime movers. Myra Flitcroft and Orest G. Symko (Dept. of Phys., Univ. of Utah, 115 S. 1400 E., Salt Lake City, UT 84112)

Thermoacoustic devices that generate sound with frequencies in the near ultrasonic range (~21 kHz) have been developed. These devices consist of a wave resonator that is 4.1 mm in length, with hot and cold heat exchangers made of copper mesh placed at the resonator's midpoint. Between these is sandwiched a stainless steel stack; the working fluid is air at 1 atmosphere. Heat is injected to the hot heat exchanger, creating a temperature gradient across the stack. When this exceeds a critical temperature gradient, acoustic oscillations ensue with intensities over 140 dB. The performance of a given engine depends drastically on the alignment achieved in the assembly process. Due to this variability, temperature differences at onset ranged from 85°C to 180°C. In order to increase positive feedback in the systems, single engines were coupled to a resonant cavity, the end of which was fitted with a pressure transducer. The use of a cavity also provides an acoustic coupling mechanism in which two ultrasonic engines can be attached to the same cavity, allowing for the investigation of synchronization of these devices in this regime. [Research supported by the U.S. Army Space and Missile Defense Command/U.S. Army Forces Strategic Command.]

11:15

2aPAb4. Miniature traveling wave thermoacoustic engine. Ivan A. Rodriguez and Orest G. Symko (Dept. of Phys., Univ. of Utah, 115 S. 1400 E., Salt Lake City, UT 84112)

Five high frequency annular thermoacoustic traveling wave devices have been developed and characterized. A 1.27 cm bore diam 2 kHz engine was optimized, increasing its maximum acoustic output from 140 to 167 dB. A new 1.60 cm bore diam 2 kHz engine has been assembled with the expectation of even higher acoustical power output because power is proportional to cross-sectional area. In the 3 kHz regime, two geometries were investigated, an oval shape and more square version, which is easier to assemble. These devices were found to have comparable outputs suggesting that the square geometry is a viable alternative, and, thus, all additional devices were constructed this way. A 4 kHz engine was also studied. In order to measure the effects of the heat exchangers and regenerator assembly on the acoustic flow, a resonator tube was constructed. This tube was fitted with the device innards and driven by a speaker. An absorption coefficient of 0.4 was measured. This information along with the 916 T across the regenerator allows for an estimate of the limit on the acoustic gain of the system to be

calculated. [Research supported by the U.S. Army Space and Missile Defense Command/U.S. Army Forces Strategic Command.]

11:30

2aPAb5. Particle image velocimetry study of acoustic field in miniature traveling wave device. Ivan A. Rodriguez and Orest G. Symko (Dept. of Phys., Univ. of Utah, 115 S. 1400 E, Salt Lake City, UT 84112)

Particle imaging velocimetry (PIV) techniques were employed to investigate the flow patterns inside a 2 kHz annular thermoacoustic device. This thermoacoustic device uses air at one atmosphere as its working fluid and smoke for seeding particles. For these measurements, the sound level output of the device was kept to 140 dB to help maintain the suspension of seeding particles. Several types of flow patterns were observed, including Gedeon streaming, start-up noise characterized by instabilities such as vortices, and a traveling wave throughout accompanied by radial standing waves localized near corners. Such measurements are challenging in small high frequency devices. In order to satisfy the Shannon-Nyquist theorem, a 2 kHz engine would need to be sampled at a minimum of 4 kHz; however, a new technique was developed that allows for the measurements to be made using a camera with a maximum frame rate per sec of 300. This new method makes it possible to perform measurements on a flow without the need for more expensive and delicate high speed equipment, thereby, making observation of high speed flows more readily available. [Research supported by the U.S. Army Space and Missile Defense Command/U.S. Army Forces Strategic Command.]

11:45

2aPAb6. Coupling of midaudio frequency thermoacoustic prime movers. Brenna G. McDonald and Orest G. Symko (Dept. of Phys., Univ. of Utah, 115 S. 1400 E., Salt Lake City, UT 84112)

Multiple unit midaudio frequency thermoacoustic engine arrays have been studied in terms of synchronized self-sustaining oscillators. Thermoacoustic engines can be acoustically coupled through shared gas when attached to a common cavity. The coupling between devices was studied by varying the cavity volume, and by varying the separation distance between devices in an array. Frequency and phase measurements for two-engine arrays have suggested that the engines entrain at a common frequency with approximately zero phase difference implying the onset of synchronization. Amplitude measurements of synchronized arrays suggest that the acoustic amplitude is equal to the sum of the amplitudes of each uncoupled engine, and agree with predictions. Synchronization of four or more units in an array implies that the coupling between engines is global and depends on the volume of the cavity and the density of the gas within the cavity. The detuning between two engines was increased until synchronization no longer occurred. The threshold for this was found to be for a frequency difference of between 80 and 98 Hz for the given coupling strength when operating near 2.5 kHz. [Research supported by the U.S. Army Space and Missile Defense Command/U.S. Army Forces Strategic Command.]

2aPP1. Shampooing, skydiving, and the cochlear amplifier. Christopher A. Shera (Eaton-Peabody Lab., 243 Charles St., Boston, MA 02114, shera@epl.meei.harvard.edu)

What is the evidence that the mammalian cochlea amplifies traveling waves? Although mechanical nonlinearity and physiological lability are both widely cited as such, neither constitutes evidence for actual power amplification. In fact, the only real evidence comes from cochlear modeling. In this presentation I describe two modeling strategies, "shampooing" and "skydiving;" discuss the relative strengths and weaknesses of the two approaches (more conventionally dubbed the forward and inverse method, respectively); and illustrate their application to cochlear mechanics. Skydiving with a parachute provides compelling evidence that the mammalian cochlea operates as a biological, hydromechanical analog of a laser amplifier. [Work supported by the NIH/NIDCD.]

2aPP2. Development of a revised loudness model. Brian C. J. Moore (Dept. of Experimental Psychol., Univ. of Cambridge, Downing St., Cambridge CB3 9LG, UK, bcjm@cam.ac.uk)

The loudness model developed in my laboratory was based on models developed by pioneers such as Fletcher and Zwicker. Their models involved calculation of an excitation pattern for the sound of interest, from the long-term average spectrum of the sound, transformation of the excitation pattern to a loudness pattern (specific loudness plotted as a function of frequency on a perceptually based

frequency scale), and calculation of loudness from the area under the loudness pattern. The innovations used in the Cambridge model were: (1) Incorporation of a linear filter as a first stage, to account for the transmission of sound through the outer and middle ear; (2) Calculation of excitation patterns from extensive measurements of auditory filter shapes, using the notched-noise method; (3) Transformation of the frequency scale to the ERB_N-number scale, which is similar conceptually to the Bark scale, but is different numerically, especially at low frequencies; (4) Transformation of excitation to specific loudness using a function such that loudness has a finite value at the absolute threshold, as opposed to zero loudness. More recently, the model has been modified to include the concept of binaural inhibition, to accommodate experimental evidence indicating that loudness does not simply sum across ears.

9:15

2aPP3. Auditory perception through the cortical analysis of spectrotemporal modulations. Shihab Shamma (Dept. of Elect. and Comput. Eng., Inst. for Syst. Res., Univ. of Maryland, College Park, MD 20742)

To understand the functional organization of the primary auditory cortex (A1), a broad array of stimuli have been used over the years ranging from simple tones to species-specific vocalizations. In our experience, broadband stimuli with spectrotemporally modulated spectra have been most effective in evoking vigorous cortical responses and facilitating measurements of spectrotemporal receptive fields (STRFs). Extensive measurements with such stimuli led us to conclude that A1 cells analyze the spectrotemporal modulation content of their input stimulus through a rich assortment of STRFs spanning the dynamically slow to fast, the spectrally narrow to broad, and tuned at all best frequencies. These experimental findings have subsequently been formulated as a "multiresolution cortical model" whose output is postulated to represent the perceptually significant elements of sound. I shall briefly describe how complex cortical responses have been abstracted and interpreted in the context of this model, and how the model has been effective in a wide variety of applications including the assessment of speech intelligibility, representation of phonemes, explaining the perception of monaural phase sensitivity, detecting speech versus nonspeech sounds, quantifying musical timbre, enhancement of noisy speech, and in the analysis and organization of complex auditory scenes.

9:35

2aPP4. Binaural interaction modeling based on physiology. H. Steven Colburn (Dept. of Biomed. Eng., Hearing Res. Ctr., Boston Univ., 44 Cummington St., Boston, MA 02215, colburn@bu.edu)

Since psychophysical performance is based on information encoded by peripheral sensory receptors, this encoding and the resulting internal representation of sensory information impose limitations on psychophysical abilities. When enough knowledge and data are available to characterize the activity of the neurons carrying the relevant information, it is possible to derive implications for performance and constraints on mechanisms of performance. This approach has been applied for many years to multiple sensory modalities including vision and audition [e.g., Siebert, Kybernetik (1965)]. In this presentation, the impact of these ideas on understanding binaural processing will be discussed. As argued in many talks in this session, explicit models with the potential for quantitative predictions are an effective means to represent current understanding to explore hypotheses. [Work supported by NIDCD, grant No. DC-00100.]

9:55—10:10 Break

10:10

2aPP5. Autocorrelation models of pitch perception. William A. Yost (Speech and Hearing Sci. , ASU, P.O. Box 870102, Tempe, AZ 85287-0102, william.yost@asu.edu)

In 1951, Licklider first suggested autocorrelation as a method to model pitch perception in his Duplex and Triplex Theories. It was not until 1991 that a full-fledged autocorrelation model was developed by Meddis and Hewitt. Over the past decades several investigators have refined autocorrelation or autocorrelation-like models to account for pitch perception and processing. While there have been a few arguments against autocorrelation for explaining pitch phenomena, autocorrelationlike models have been very successful in accounting for a wide range of data including those associated with the pitch of iterated ripple noise. This presentation will review the development of autocorrelation models of pitch perception, especially in accounting for the pitch and pitch strength of iterated ripple noise. The presentation will also cover how refining well-established models or theories may offer a good opportunity for developing skills to build additional models and theories. [Work supported by a grant from NIDCD.]

10:30

2aPP6. Theories of hearing. Neal F. Viemeister (Dept. of Psych., Univ. of Minnesota, Minneapolis, MN 55455, nfv@umn.edu)

One of the more compelling and important aspects of auditory science has been the ability to relate perception to physiology and physics. This challenging endeavor has attracted fine minds from various disciplines and has provided theoretical frameworks for rigorously studying and describing at various levels many basic aspects of hearing. An example is the application of "signal detection theory" and its collection of tools for empirical and theoretical investigation of certain aspects of audition. But what of the future? Do we have comparable tools to construct quantitative theories that enable prediction of complex aspects of audition? Do we need new tools? Definitive answers may or may not be provided during this session.

10:50

2aPP7. Relevance of psychoacoustical theory. William Hartmann (Dept. of Phys. and Astron., Michigan State Univ., 1226 BPS Bldg., East Lansing, MI 48824)

Historically, the principles of psychoacoustics have been described in terms of mathematical theories. Are such mathematical theories now obsolete? Have they been replaced by computer algorithms? Do contemporary answers now come from simulations in computational toolboxes? The case for psychoacoustical theory can be made anew: Mathematical psychoacoustical theory has value because

of the transparency of its assumptions and the universality of its language. It has an unparalleled ability to inspire extensions and revisions in order to evolve. It illuminates new conceptual directions through analogies with other sciences subserved by similar mathematical structures. Theory consolidates large amounts of otherwise unrelated data and serves as a guide to future experiments. Mathematical theory is the practical realization of images about the way the auditory world works, images that promote understanding because of their intuitive appeal. Theory is at its best when the ordinary operations of mathematics transform an initial model into logically inescapable new insights unlikely to have arisen by other avenues. [Work supported by the NIDCD, Grant DC-00181.]

11:10—11:45 Panel Discussion

TUESDAY MORNING, 19 MAY 2009 FORUM SUITE, 8:40 TO 11:55 A.M.

Session 2aSA

Structural Acoustics and Vibration: Computational Structural Acoustics

Kuangcheng Wu, Chair
Signatures & Hydrodynamics, Northrop Grumman Newport News, Newport News, VA 23607-2770

Invited Papers

8:40

2aSA1. A three-dimensional Wiener–Hopf technique for general bodies of revolution, Part I: Symmetrization and factorization of the integral equation's kernel. Rudolph Martinez and Carina Ting (CAA-Alion Corp., 84 Sherman St., Cambridge, MA 02140, rmartinez@alionscience.com)

This is the first of a two-part paper on the development of analytic solutions of acoustic scattering and/or radiation from arbitrary bodies of revolution under heavy fluid loading. The approach followed is the construction of a 3-D Wiener–Hopf technique with Fourier transforms that operate on the finite object's arclength variable (the object's practical finiteness comes about, in a Wiener–Hopf sense, by formally bringing to zero the radius of its semi-infinite generator curve for points beyond a prescribed station). Unlike in the classical case of a planar semi-infinite geometry, the kernel of the integral equation is nontranslational and therefore with independent wavenumber spectra for its receiver and source arclengths. The solution procedure applies a symmetrizing spatial operator that reconciles the regions of $(+)$ and $(-)$ analyticity of the kernel's two-wavenumber transform with those of the virtual sources. The spatially symmetrized integral equation is of the Fredholm second kind and thus with a strong unit "diagonal"–a feature that makes possible the Wiener–Hopf factorization of its transcendental doubly transformed kernel via secondary spectral manipulations. The second of this two-part paper describes how the theory addresses departures from axisymmetry through substructuring techniques and demonstrates the analysis for canonical problems of fluid-structure interaction.

9:00

2aSA2. Midfrequency acoustic radiation analysis. Stephen D. O'Regan (Naval Surface Warfare Ctr., Carderock Div. 9500 MacArthur Blvd., West Bethesda, MD 20816, Stephen.ORegan@navy.mil)

Boundary, finite, and infinite element methods have proven useful for solving the 3-D acoustic wave equation at low frequencies. For high frequency, localized formulations such as plane-wave and ray-tracing methods have been applied successfully. These methods are impractical, inaccurate, or both for treating midfrequency problems. Low-frequency methods make very large demands on computer processing while high-frequency methods account only for local effects. Full-spectrum methods have been developed which apply interpolation between the low and high ends of the frequency range to estimate the response in the midfrequency. While these methods have provided some insight to trends as one moves toward the midfrequency range, it is not well established that they can reliably solve problems well away from their established limits. For surfaces with features having dimensions close to midfrequency wavelengths, the physics is distinct from those that govern low and high frequencies, and is not merely a linear combination of the two. This presentation reports on research to develop a midfrequency analysis tool that directly addresses the midfrequency physics. The author will identify the challenges in a physics-based method, discuss an approach to address them, and report on simulations exercising the approach.

9:20

2aSA3. The discontinuous enrichment method for multiscale and higher-frequency wave propagation problems. Charbel Farhat and Radek Tezaur (Dept. of Aeronaut. and Astronaut., 496 Lomita Mall, Stanford Univ., Stanford, CA 94305-4035)

Wave propagation problems pertain to many technologies including sonar, radar, geophysical exploration, medical imaging, nondestructive testing, and structural design. In the medium frequency regime, the analysis of these problems by the standard finite element method is either computationally unfeasible or simply unreliable, because of the well-known pollution effect. In practice, the higher-order (or *p*-type) finite element method alleviates this effect, but only to some extent. Alternative approximation methods based on plane waves have recently emerged to address this issue. The discontinuous enrichment method (DEM) is such an alternative. It distinguishes

itself from similar approaches by its ability to evaluate the important system matrices analytically, thereby bypassing the typical accuracy and cost issues associated with high-order quadrature rules. DEM also provides a unique multiscale approach to computation by employing fine scales that contain solutions of the underlying homogeneous partial differential equation in a discontinuous framework. The theoretical and computational underpinnings of this method will be overviewed. Then, recent applications to underwater acoustic and elastoacoustic scattering as well as automotive structural vibrations in the midfrequency regime will be discussed. Accuracy of 1 to 2 orders of magnitude and/or solution time improvement over the higher-order Galerkin method will be demonstrated in three dimensions.

9:40

2aSA4. Eigenanalysis in structural acoustics. Jeffrey L. Cipolla (Weidlinger Assoc. Inc., 375 Hudson St., New York, NY 10014)

Determination of characteristic frequencies and solutions (mode shapes) for vibrating systems is a staple of linear dynamics in engineering, so it should be no surprise that analysts strive for the same in coupled structural-acoustic systems. Computation of these eigensolutions confers not only physical insight into the behavior of the system, but also a means to reduce the mathematical dimension of frequency-response and other engineering computations. As in other mechanical vibration problems, the eigensolutions of coupled systems form a nearly optimal space for the approximation of the forced-response solutions. However, the coupled structural-acoustic eigenproblem is not trivial, and can be prohibitively expensive if not handled properly; this is particularly true for exterior problems. Notably, identification of a physically pertinent self-adjoint operator for the system of interest is a critical challenge. Here we will discuss the coupled structural-acoustic eigenproblem, various approximations common in practice, as well as alternative approaches to model reduction.

10:00

2aSA5. Recent innovations and current performance of conventional boundary element computations. John B. Fahnline (Water Tunnel Bldg., The Pennsylvania State Univ., University Park, PA 16802)

As long as boundary element methods have existed, research has been ongoing to make the calculations faster and applicable for larger problems. The rapid rise in computing power, both in terms of processor speed and storage capacity, has increased the problem size that can be addressed and has led to many novel strategies for reducing the computational burden. For example, many of the matrices can be stored at coarse frequency spacing over the range of interest and interpolated at much finer resolution, reducing the computation times enormously. Other strategies for speeding the computations that will be discussed include condensed acoustic meshes, optimized math kernel libraries, and multipole expansions. Results will be presented to indicate typical computation times and problem size limitations.
